A hierarchical three-level controller design was implemented on the Natoli tablet press following to the previously proposed systematic framework for process control design and risk analysis in continuous pharmaceutical solid-dosage manufacturing (Su et al., 2017). The framework consists of a series of steps involving system identification, control design and analysis, hierarchical three-level control, risk mapping, accessing and planning, performance evaluation, etc. The Natoli BLP-16 tablet press has a built-in programmable logic control (PLC) system to manipulate the process parameters of fill depth, turret speed, and feeder speed, which are regarded as providing Level 0 control in this context. In light of the above process variation characterization, the system identification step using state-space model and the control design and analysis step using classical control metrics, e.g., Condition number, Relative Gain Array (RGA) analysis, etc., suggested a Level 1 control with decoupled PID control loops for a cascaded control of tablet weight, production rate, and main compression force by manipulating the set points of fill depth and turret speed at the Level 0 control. The identified state-space model was further employed to develop the Level 2 linear model predictive control (MPC) scheme for the tablet press, in which the main compression force was constrained and monitored as it is closely related to the tablet CQAs of hardness, tensile strength, and dissolution rate. The Emerson DeltaV Control Studio and DeltaV Predict toolbox were utilized for Level 1 and 2 control implementations. Details of control loops and operating panels can be found in Figure 2.

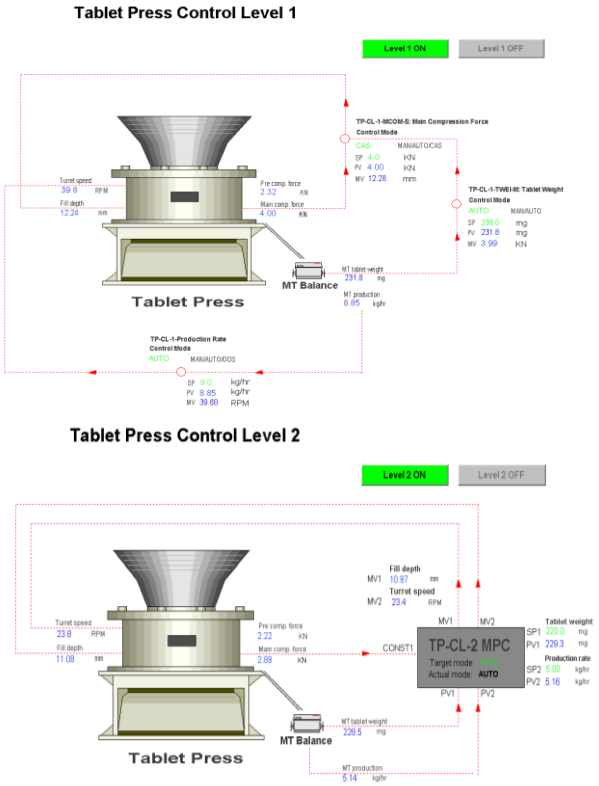

Figure 2. The hierarchical Level 1 (top) and Level 2 (bottom) control for tablet press.

4. Results and discussion

With the Level 0 Natoli built-in control of turret speed and dosing level (feeder speed was set constant and punch displacement was adjusted manually only), step changes in both turret speed and dosing level were conducted, as shown in Figure 3(a). It was observed that the measured tablet weight, as understood in process variation and characterization, strongly depended on dosing level after reaching steady-state. Step changes in turret speed, as highlighted with rectangles, showed only slight changes in tablet weight and main compression force due to changes in die filling time and flow dynamics, as described by Eq. (1). This is also consistent with the research findings of favourable compressibility of the powder formulation investigated (Tye et al., 2005), as described by Eq. (5). This variation was further studied when the tablet press was under closed-loop control operation, as shown in Figure 3(b). The Level 1 PID control for tablet production rate was deliberately set to be open, while a step change in turret speed was introduced. It was demonstrated that the cascaded control loop for tablet weight was capable of bringing the measured tablet weight to the set point of the master loop, as well as the main compression force of the slave loop. The variation of turret speed, viz., the die filling time, was compensated for by relatively minor adjustments of dosing level. Furthermore, this variation contributed insignificantly to the interaction of the decoupled control loops for tablet weight and production rate, as shown in Figure 4(a), when set point changes were made in tablet weight and production rate. It is worth noting that the turret speed was first increased then reduced in response to the first increase in production rate then the following increase in tablet weight, during which both the tablet weight and main compression force reached their set points rapidly and steadily, thus achieving the desired critical quality attributes in relative density, tensile strength, as discussed previously. Due to the moderate nonlinearity and relatively modest interaction of the studied tablet press and specific powder blend, comparable promising performances were achieved for both Level 1 PID control and Level 2 linear MPC control (with sampling time of 1 second) in terms of process set point changes and under the risk of powder bulk density disturbances (see Su et al., 2017, for disturbances due to changes in API mass fraction set point in a feeding and blending system).

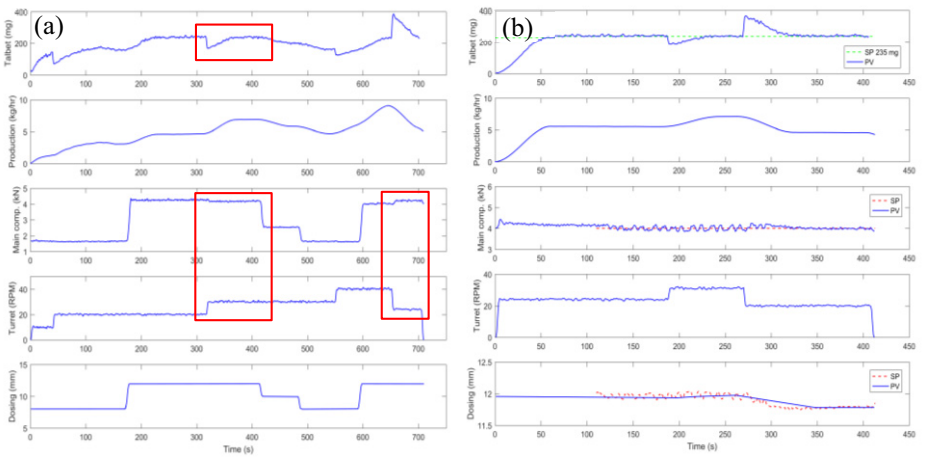

Figure 3. (a) Step changes in turret speed and dosing level under Level 0 control; (b) variation of the turret speed on tablet weight and main compression force control under Level 1 control when production rate control loop was deliberately set to be open.

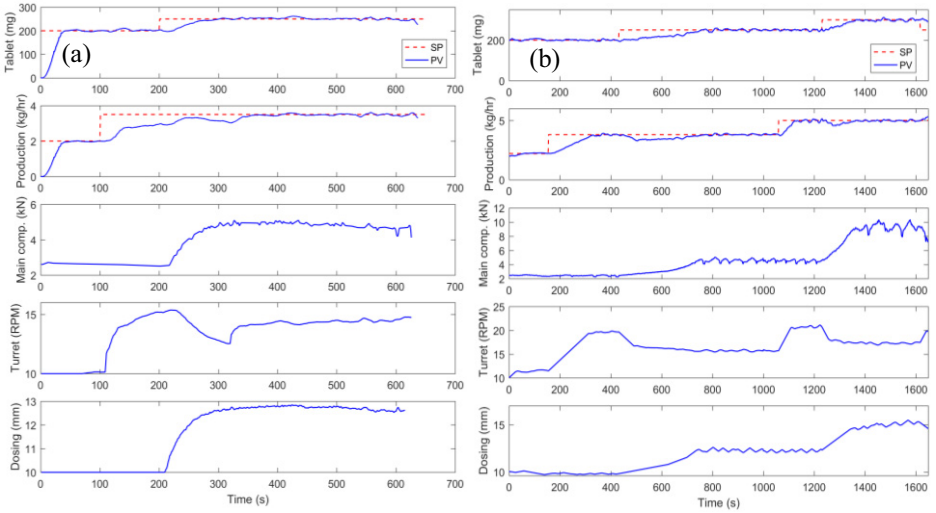

Figure 4. Control performance of Level 1 PID (a) & Level 2 MPC (b) control loop for set point changes.

5. Conclusions and future work

The system variation and its effect on the development of control strategies for a tablet press were investigated. It was found that the monitoring and control of the tablet weight and main compression force, two of the critical-to-quality variables, were important to achieving the consistent product properties under the process variations of turret speed and the risk of uncertainty in powder bulk density. In ongoing work, we are investigating additional powder formulations with different compressibility properties and implementing the control framework on an industrial scale tablet press.

Abstract

The use of natural gas (NG) is increasing worldwide due to its cleaner nature and economic benefits. The distances between its supply and demand centers necessitate long distance transport, which is currently done as liquefied natural gas (LNG). LNG receiving terminals are critical elements of this supply network. They store and regasify the imported LNG and deliver NG at specified rates to the gas distribution network. A regasification terminal usually operates in three modes, unloading mode when LNG is transferred from carrier ship to tank, reloading when carrier ship is loaded from tank and holding or normal operational mode.

In this work, a detailed and rigorous dynamic model of a regasification terminal is developed in Honeywell UNISIM Design and validated against actual operational data of the real terminal. With this detailed and validated dynamic model, boil-off gas (BOG) minimization studies have been done to achieve a reduction of 25% in BOG generation from the base value. Furthermore, we propose an efficient compressor scheduling strategy taking all the modes of terminal operation into account. Equipped with a rigorous dynamic model, we have also included the effects of variable NG demand.

Keywords: LNG, BOG, dynamic model, regasification terminal, compressor scheduling.

1. Introduction

LNG receiving terminals are mainly composed of LNG storage tanks, LNG send out pumps, boil-off-gas (BOG) compressors, cryogenic pipelines, LNG booster pumps, LNG recondensers and LNG vaporizers. Heat leak to tanks and recirculation pipelines from the surroundings is steady influencing factor contributing to BOG generation in the terminal. In addition to this variable influencing factors like changing NG demand, ship unloading and ship reloading can amount for BOG generation several time larger than normal operating mode. During the unloading and reloading of an LNG carrier, a huge volume of BOG is generated due to volume displacement of onboard LNG, heat dissipation from unloading lines, unloading pump and incoming feed flash. BOG generated is handled by compressors which should be operated in a way that tank pressures remains within a safe range. However, excess compressor operation leads to excess BOG generation due to lowering of the tank pressures. Therefore, proper BOG management during all the operating modes is important to ensure effective and reliable terminal operation.

Previous work in BOG management and an effective operational strategy done by Li et al. [2016] and Lee et al. [2012] focuses mainly on unloading mode, assuming constant NG demand. Variable NG demand from terminal, recirculation strategy, unloading and reloading strategy and compressor scheduling together play a key role in framing strategy for the optimal operation of a terminal.

2. Dynamic Simulation

LNG regasification in a receiving terminal is a dynamic process and should be modelled and simulated accurately to study and suggest any improvement in existing operations. A general schematic of LNG receiving terminal as discussed by Park et al. [2010] is depicted in Figure 1. In the present study, UNISIM dynamics is employed to develop a detailed model of the terminal. Modules used to develop dynamic model are listed in Table 1.

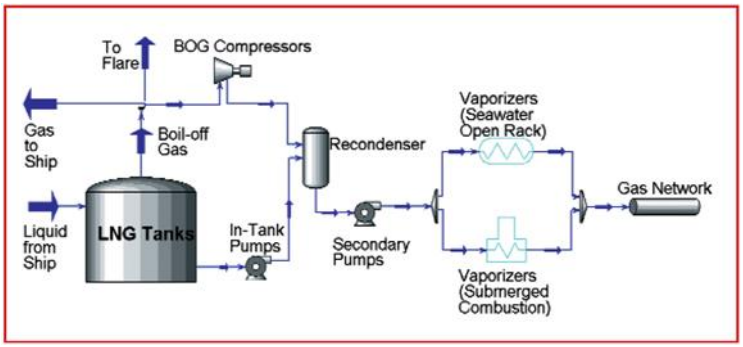

Figure 1. LNG regasification terminal

Table 1.Modules used in UNISIM model

Equipment	Module
Ships	Tank
LNG Tank	Tank
Compressors	Reciprocating Compressor
Recondenser	Separator
Pump	Centrifugal pump
Control Valves	Control Valves
Jetty arms	Valves and pipes
Vaporizers	Heat exchanger
Surge drums	Separator
Headers	Header
Safety Valve	Relief Valve

Developing an accurate dynamic model for the regasification terminal involves capturing all the physics involved in critical equipment like LNG tank, BOG recondenser, vaporizers etc. Accurate predictions of BOG generation during all the modes of operation is important, as BOG handling capability of regasification terminals

is one of the important measure of efficiency of the terminal. LNG tank modelling is critical and challenging, but accurately capturing the non-equilibrium behaviour between liquid and gas within the tank is important. BOG flow and temperature out of LNG tank are important parameters, and have a significant impact on compressor capacity. Similarly, modelling the BOG recondenser in UNISIM is a major challenge. BOG recondenser is a packed bed column for direct contact heat exchange between BOG and LNG. Modelling a packed bed column in UNISIM requires an in-depth understanding of the process as there is no built-in module for the packed column. Packing behaviour should be accurately captured to predict accurate level in the recondenser. Previous work in dynamic modelling of regasification done by Li et al. [2016] involved development of a generic dynamic model of the terminal with basic unit operations and control structure. In the present work, we have developed a much detailed and rigorous dynamic model involving all the plant specifics from ships, jetties, etc. up to the final natural gas metering station. All the equipment are modelled using the design datasheets, accurate pump curves, and all the piping and elevation details for accurate pressure-flow profiles. Piping and instrumentation diagram (P&ID) of the terminal is used to precisely model all the piping layout, mixing headers, valve positions, and controls. In addition to the design details, all the controllers are modelled accurately including the safety interlocks and control loops. This would allow us to perform control studies. This model can also be used to provide hands-on training to the engineers and operators as it includes all the minute details.

3. Validation

Validation of the dynamic model against the real plant data is important as it provides confidence to implement the findings of studies in a real plant operation. Validation of the tank model is done against the plant operational data for the shutdown. Tank pressure profile, tank level and tank bulk liquid temperature are matched against the plant data and shows an excellent agreement which validates the tank model. The data used for this validation cannot be disclosed due to a confidentiality agreement in our project. The validation plots are normalized and expressed as percentages of some base values and shown in Figure 2, 3 and 4.

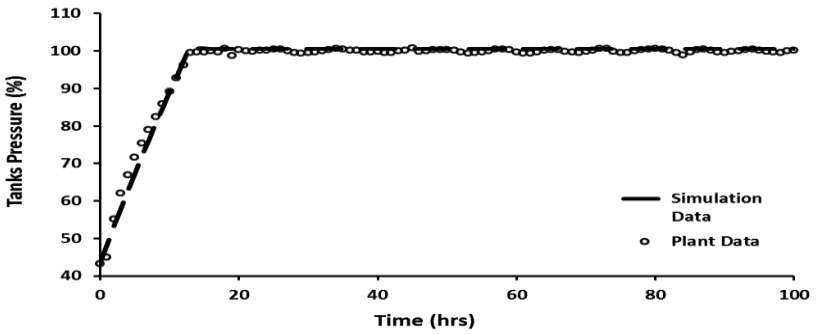

Figure 2. Tank Pressure profile

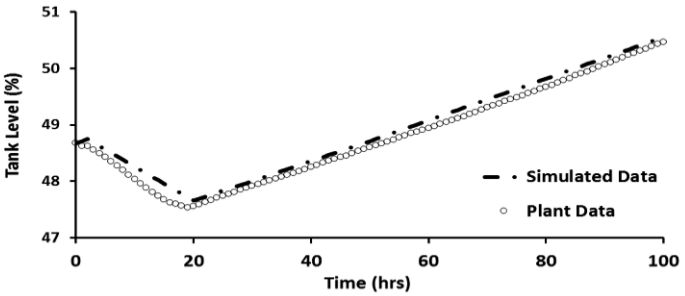

Figure 3. Tank Liquid Level profile

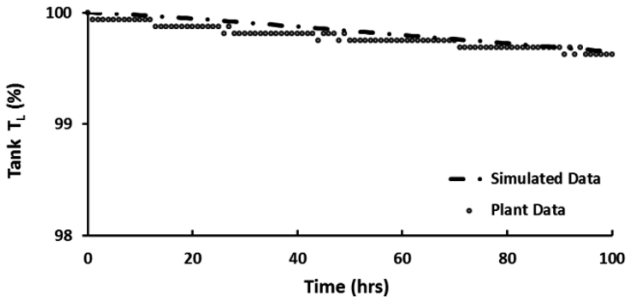

Figure 4. Bulk Liquid temperature profile inside tank

4. Case Study

The validated dynamic model can be used to test various operational and control strategies. We have used the model to perform studies related to BOG management, compressor scheduling, and recondenser operation for the three modes of terminal operation. In this work, we only discuss our study on the holding mode of operation. Our objective was to study various recirculation flow return configurations and their impact on BOG generation and compressor scheduling. These results promises a significant impact on BOG compressor power savings.

4.1. Recirculation flow configuration

Figure 5 below shows the flow scheme for send out and recirculation flow in terminal.

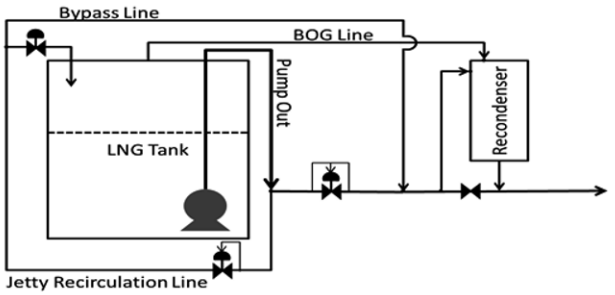

Figure 5. Flow scheme for recirculation and send out flow

A part of total flow from the tank is sent as recirculation flow to keep the unloading lines cool during normal holding mode of operation. This recirculation flow to unloading lines can be controlled using different valve settings. Recirculating LNG receives a lot of heat due to significant temperature gradient between LNG and atmosphere. Recirculation flow
can be completely sent back to LNG tank or a part of the flow can be mixed with send out flow using the bypass line shown in Figure 5 above. In present case study, we have tried different flow strategies by changing valve settings in the flow network and using the hydraulics to distribute the flow between tanks and bypass line. The results for the two configurations are discussed in section below.

4.2. Results and discussion

Figure 6 shows a comparison between complete pressure cycles for LNG tank.

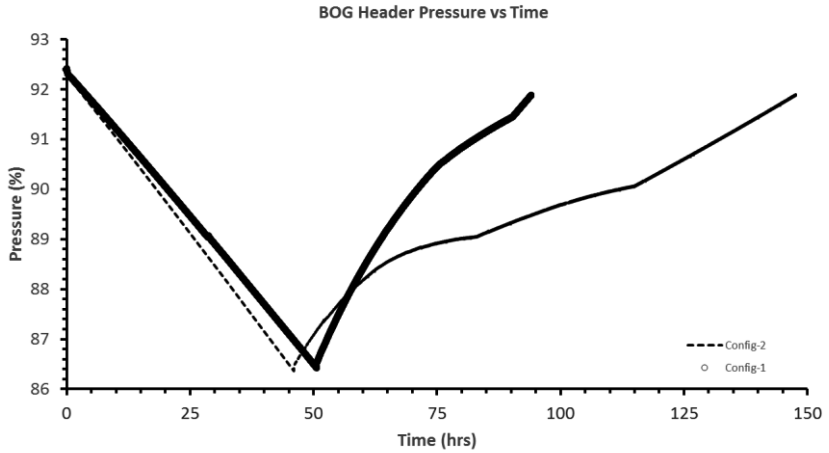

Figure 6. Pressure profile-LNG tank

One compressor is running at 100 % of its capacity for both the strategies. Configuration 1 takes around 52 hr. for compressor to drop pressure from 92.5% of its maximum value to 86.3 %. Configuration 2 takes 6 hours less than configuration 1 to bring down the pressure to the same extent. Once the pressure is lowered, the compressor is switched off and pressure is allowed to increase. Configuration 2 takes 40 hr. more for pressurization when compared to configuration 1, due to less BOG generation. Bypassing the recirculation flow results in lower addition of heat into the tank, and hence less BOG and less compressor running time. Configuration 2 will keep compressor off for 67% of the time and hence can save up to 50% of the compression power. Further study to propose an optimum compressor running capacity based on relative BOG generation rates for both the configurations is investigated and results are summarized in the Figure 7.

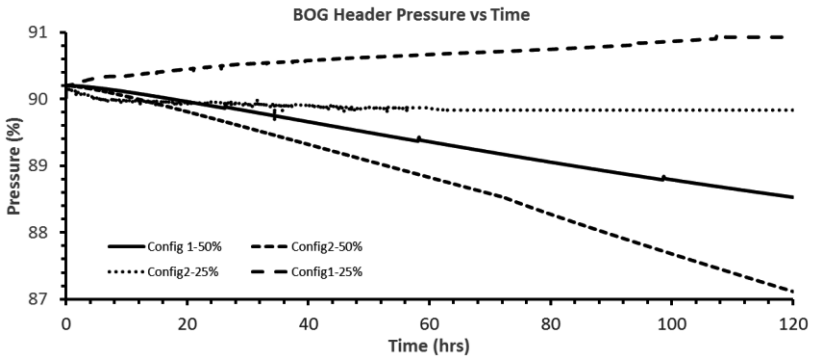

Figure 7. Pressure profile with variable compressor capacity

These results show different pressure profiles for different compressor capacities for both the configurations, and therefore, an optimum strategy for compressor operation can be devised to save maximum power.

5. Conclusion

Considering the dynamics involved in a regasification terminal, a robust and accurate model is necessary to study the process and suggest continuous operational improvements. Implementing any changes to ongoing plant operation is not plausible without foreseeing the risk involved. Having a detail validated dynamic model gives the confidence to apply and test operational changes and evaluate the risks involved. The case study discussed here aims at minimizing the BOG generation during holding mode of terminal operation. We are successful in reducing BOG generation by about 25 % and power consumption by about 36 %. Since there is substantial time gap between two ship unloading in terminal, an effective compressor operation strategy can minimize BOG generation as well as save power. The strategy proposed in this study shows a promising prospect in terms of an added benefit to existing operational practice. Testing controller configuration, response time, what if analysis and HAZOP studies can also be done using this model. Extending this model for expansion studies, testing start up shutdown procedures adds up to the future work.

Modifier Adaptation with Model Adaptation in Iterative Real-Time Optimization

Afaq Ahmad*, Weihua Gao, Sebastian Engell

Process Dynamics and Operations Group, Department of Biochemical and Chemical Engineering, TU Dortmund, Emil-Figge Strasse 70, 44227 Dortmund, Germany. Afaq.Ahmad@tu-dortmund.de

Abstract

This paper deals with the iterative real-time optimization (RTO) of chemical processes under plant-model mismatch. Certain RTO methodologies, called modifier adaptation add bias and gradient correction terms to the underlying model based on measurements of the true values of the objective function and of the constrained function. These affine corrections lead to meeting the first-order necessary-conditions of optimality of the plant in spite of plant-model mismatch. However, accurately computing the gradient corrections is a limiting element here, and to improve the model parameters were possible will speed up convergence. Also, the additional terms do not guarantee satisfaction of the second-order optimality conditions. So modifier adaptation should be combined with model adaptation such that first- and second- order optimality conditions are met at the plant optimum. In this paper, we compare different iterative RTO schemes that perform modifier adaptation and model adaptation. The performance of the approaches is evaluated by means of simulation results for the Williams-Otto reactor benchmark problem.

Keywords: Real-Time Optimization; Modifier Adaptation; Effective Model Adaptation

1. Introduction

Real-time optimization (RTO) can make a significant contribution to profitable and resource efficient operation of processing plants. However, the feasibility and optimality of the proposed operating points relies on the accuracy of the plant model. Due to plant-model mismatch, the optimum of the real plant may differ significantly from the optimum that is computed from the available model and constraints may be violated by the theoretically optimal set-point. Therefore it is necessary to adapt the model or the optimization problem based on the available measurements. In recent years, several RTO methodologies have been developed which differ in how they utilize the information which is provided by the measurements.

In the two-step approach (Chen and Joseph, 1987), the model parameters are estimated at the current operating conditions in order to match the model prediction with the plant outputs. The optimization step is then performed based on the adapted model to update the operating point. This iterative two-step scheme may potentially converge to the process optimum if the plant-model mismatch is mainly of parametric nature, and there is sufficient excitation to estimate the model parameters accurately. However, if there is a structural mismatch, the two-step scheme may not converge to the true plant optimum. Therefore Roberts (1979) proposed a modified two-step scheme, known as *Integrated*

Acknowledgement: The research leading to these results has received funding from the Deutsche Forschungsgemeinschaft (DFG) under grant agreement number EN 152/41-1.

System Optimization and Parameter Estimation (ISOPE) in order to handle structural plant-model mismatch. The ISOPE approach converges iteratively to a Karush-Kuhn-Tucker (KKT) (also known as first-order necessary conditions) point of the plant by adding gradient correction terms to the cost function of the optimization problem.

Tatjewski (2002) realized that the step of the estimation of the model parameters in ISOPE is not required to satisfy the optimality condition of the plant. Based upon this work, Gao and Engell (2005) extended the approach to handle process dependent constraints and applied it to the optimization of a chromatographic separation process. Later, this approach was labelled as modifier-adaptation (MA) in Marchetti et al. (2009). The MA scheme adds bias and gradient modifiers to the cost and to the constraint functions of the model-based optimization so that the first-order necessary conditions of optimality of the adapted model match those of the plant. However, the approach does not ensure convergence if the model adequacy condition is not met as shown by Marchetti et al. (2009) and Gao et al. (2015).

A modification of the two-step approach is to estimate the model parameters such that the updated model predicts the gradient of the plant correctly at the current operating condition as proposed by Mandur and Budman (2015). However, the estimation of model parameters in order to fit the available plant measurements does not necessarily ensure that the model is adequate for optimization purposes (Forbes and Marlin, 1996). Model adequacy can be assured by using modifier adaptation with quadratic approximation (MAWQA) (Gao et al. 2016). However, the rate of the convergence depends on the collected data that is used to construct the quadratic approximation and is of course better when the model quality is high. Recently, Ahmad et al. (2017) proposed an effective model adaptation (EMA) scheme where an *adequate* process model is identified and used in the optimization problem. The key idea is to combine MA with EMA in the sense that the model that is used in the optimization problem is adapted only when the model with the updated parameter values is adequate, meaning that the first- *and* second-order necessary conditions of optimality are satisfied upon convergence.

In this paper, we investigate the reliability and efficiency of different iterative RTO schemes in the presence of plant-model mismatch. A simulation study is performed using the benchmark Williams-Otto reactor as a case study. The RTO schemes are compared based on their ability to converge to the plant optimum and the number of plant evaluations that are required to converge.

2. Iterative RTO schemes

The general model-based optimization problem at the (k)th iteration can be formulated as

$$\begin{aligned} \min_{\mathbf{u}} \quad & J_m(\mathbf{u}, \theta^{(k)}) := J(\mathbf{u}, \mathbf{y}_m(\mathbf{u}, \theta^{(k)})) \\ \text{s.t.} \quad & \mathbf{C}_m(\mathbf{u}, \theta^{(k)}) := \mathbf{C}(\mathbf{u}, \mathbf{y}_m(\mathbf{u}, \theta^{(k)})), \end{aligned} \tag{1}$$

where $\mathbf{y}_m$ is the vector of outputs which is a function of the input variables $\mathbf{u}$ and the set of model parameters $\theta^{(k)}$. $J_m(\mathbf{u}, \theta^{(k)})$ is the objective function that is minimized and $\mathbf{C}_m(\mathbf{u}, \theta^{(k)})$ represents the vector of the constraint functions. In the two-step scheme, the vector of model parameters $\theta^{(k)}$ is obtained as

$$\theta^{(k)} := \arg\min_{\theta} \|\mathbf{y}_p(\mathbf{u}^{(k)}) - \mathbf{y}_m(\mathbf{u}^{(k)}, \theta)\|^2, \tag{2}$$

where $\mathbf{y}_p(\mathbf{u}^{(k)})$ represents the measured variables at the current operating conditions $\mathbf{u}^{(k)}$. Since the conventional model adaptation via least-squares value fitting of the plant measurements does not guarantee the matching of the gradients, Mandur and Budman (2015) introduced an algorithm (called simultaneous model identification and optimization (SMIO)) in which the model is adapted in two steps in order to handle structural plant-model mismatch. In first step the values of the selected model parameters are computed via Eq.(2). The second step is based on gradient fitting, where the model gradients are matched to those of the plant by estimating the change of the model parameters $\Delta\theta^{(k)}$ as

$$\begin{aligned} \Delta\theta^{(k)} \quad &:= \arg\min_{\Delta\theta} \left(w_J \left| \nabla J_p^{(k)} - \nabla J_m^{(k)}(\theta^{(k)} + \Delta\theta) \right| + w_C \left| \nabla \mathbf{C}_p^{(k)} - \nabla \mathbf{C}_m^{(k)}(\theta^{(k)} + \Delta\theta) \right| \right) \\ \text{s.t.} \quad &\mathbf{y}_m(\mathbf{u}^{(k)}, \theta^{(k)} + \Delta\theta) := \mathbf{y}_m(\mathbf{u}^{(k)}, \theta^{(k)} + \Delta\theta) - c_k, \\ &\theta^{(k)} + \Delta\theta \in [\theta_{lb}, \theta_{ub}], \\ &\|\in^T\|_\infty = \in_{max}^T, \end{aligned} \tag{3}$$

where w_J and w_C are the weighting factors for the objective and constraint functions. $\nabla J_p^{(k)} := \nabla J(\mathbf{u}^{(k)}, \mathbf{y}_p(\mathbf{u}^{(k)}))$ and $\nabla \mathbf{C}_p^{(k)} := \nabla \mathbf{C}(\mathbf{u}^{(k)}, \mathbf{y}_p(\mathbf{u}^{(k)}))$ are the plant objective and constraint gradients at $\mathbf{u}^{(k)}$. A correction term $c_k := \nabla y(\theta^{(k)})\Delta\theta$ is introduced to compensate the deviation of the predicted steady-state values of the outputs due to the adjustment of the parameters in the second step, where $\nabla y(\theta^{(k)})$ is the Jacobian matrix of the model output with respect to the model parameters. The accuracy of the correction term can be quantified by using the relative truncation error

$$\in^T \quad = \frac{\mathbf{y}_m(\mathbf{u}^{(k)}, \theta^{(k)} + \Delta\theta^{(k)}) - \nabla y(\theta^{(k)})\Delta\theta^{(k)}}{\mathbf{y}_m(\mathbf{u}^{(k)}, \theta^{(k)})}. \tag{4}$$

In the MA scheme, the model-based optimization problem in Eq.(1) is adapted by the bias and first-order correction terms instead of model parameter adaptation. The updated optimization problem of the MA scheme can be written as follows:

$$\begin{aligned} \min_{\mathbf{u}} \quad & J_{ad}^{(k)}(\mathbf{u}, \theta^{(0)}) := J_m(\mathbf{u}, \theta^{(0)}) + J_p^{(k)} - J_m^{(k)} + \left(\nabla J_p^{(k)} - \nabla J_m^{(k)} \right)^T \left(\mathbf{u} - \mathbf{u}^{(k)} \right) \\ \text{s.t.} \quad & \mathbf{C}_{ad}^{(k)}(\mathbf{u}, \theta^{(0)}) := \mathbf{C}_m(\mathbf{u}, \theta^{(0)}) + \mathbf{C}_p^{(k)} - \mathbf{C}_m^{(k)} + \left(\nabla \mathbf{C}_p^{(k)} - \nabla \mathbf{C}_m^{(k)} \right)^T \left(\mathbf{u} - \mathbf{u}^{(k)} \right) \leq \mathbf{0}, \end{aligned} \tag{5}$$

where $J_{ad}^{(k)}(\mathbf{u}, \theta^{(0)})$ and $\mathbf{C}_{ad}^{(k)}(\mathbf{u}, \theta^{(0)})$ are the adapted objective and constraint functions, $\theta^{(0)}$ represents the fixed model parameter vector, $J_p^{(k)} := J(\mathbf{u}^{(k)}, \mathbf{y}_p(\mathbf{u}^{(k)}))$ is the process objective value and $\mathbf{C}_p^{(k)} := \mathbf{C}(\mathbf{u}^{(k)}, \mathbf{y}_p(\mathbf{u}^{(k)}))$ is the vector of constraint functions. The operating condition at the (k)th iteration is updated as:

$$\mathbf{u}^{(k+1)} = \hat{\mathbf{u}}^{(k+1)} + \mathbf{K}(\mathbf{u}^{(k)} - \hat{\mathbf{u}}^{(k+1)}), \tag{6}$$

where $\hat{\mathbf{u}}^{(k+1)}$ is the solution of Eq.(5) and $\mathbf{K}$ is a diagonal matrix of damping factors with

$0 \leq k_{ii} < 1$. The process gradients are estimated by finite difference approximation via perturbing the system in each iteration as proposed in Gao and Engell (2005).

3. Model adequacy

A criterion of model adequacy has been first discussed in Forbes and Marlin (1996). It states that a process model must produce a fixed point which is a local minimum for an RTO problem at the true process optimum u_p^*.

The model adequacy criterion for MA requires that u_p^* must meet the first- and second-order necessary conditions of optimality for the adapted optimization problem Eq.(5). As the MA scheme relies on the bias- and gradient corrections to ensure satisfaction of the first order KKT conditions of the plant, in addition the second-order necessary conditions of optimality need to be satisfied at u_p^*. This leads to the criterion that the matrix of the reduced Hessian $\nabla^2 \mathcal{L}_{ad,r}\left(\mathbf{u}_p^*, \theta, \mu^*\right)$ of the adapted optimization problem Eq.(5) should be positive definite. The Lagrangian function $\mathcal{L}_{ad}$ of the adapted optimization problem can be written as:

$$\mathcal{L}_{ad}(\mathbf{u}, \theta, \mu) := \quad J_{ad}(\mathbf{u}, \theta) + \mu^T \mathbf{C}_{ad}(\mathbf{u}, \theta), \tag{7}$$

where μ is the vector of Lagrange multipliers.

4. Modifier adaptation with model adaptation

A possible way to handle the issue of model adequacy is to combine the idea of MA with model adaptation. Ahmad et al. (2017) introduced the effective model adaptation (EMA) scheme to identify an adequate process model for the adapted optimization problem Eq.(5) and proposed the modifier-adaptation with EMA (in short MAWEMA) algorithm. EMA ensures and speeds up the rate of convergence to the optimum u_p^*. Let $\theta^{(k+1)}$ be the estimated model parameter vector at $\mathbf{u}^{(k+1)}$, then the updated parameters are accepted by EMA if and only if the following two conditions are satisfied:

- $\nabla^2 J_m(\mathbf{u}^{(k+1)}, \theta^{(k+1)})$ is positive definite
- $\left|J_{ad}^{(k)}(\mathbf{u}^{(k+1)}, \theta^{(k+1)}) - J_p(\mathbf{u}^{(k+1)})\right| < \left|J_{ad}^{(k)}(\mathbf{u}^{(k+1)}, \theta^{(k)}) - J_p(\mathbf{u}^{(k+1)})\right|$.

The first condition ensures the model adequacy criterion of the Lagrangian function $\mathcal{L}_{ad}\left(\mathbf{u}^{(k+1)}, \theta, \mu\right)$. It is sufficient that the Hessian matrix of the adapted objective function is positive definite which is the same as that reduced Hessian is positive definite. To motivate the second condition, we perform a Taylor series expansion of $J_{ad}^{(k)}(\mathbf{u}, \theta) - J_p(\mathbf{u})$ around $\mathbf{u}^{(k)}$, omitting terms of order higher than 2:

$$J_{ad}^{(k)}(\mathbf{u}, \theta) - J_p(\mathbf{u}) \approx \frac{1}{2}\left(\mathbf{u} - \mathbf{u}^{(k)}\right)^T \left(\nabla^2 J_m^{(k)} - \nabla^2 J_p^{(k)}\right)\left(\mathbf{u} - \mathbf{u}^{(k)}\right). \tag{8}$$

The prediction error of the adapted objective function at $\mathbf{u}^{(k+1)}$, that is, $J_{ad}^{(k)}(\mathbf{u}^{(k+1)}, \theta) - J_p(\mathbf{u}^{(k+1)})$, can be used to infer the difference of the Hessian matrices at $\mathbf{u}^{(k)}$. Hence, reducing the difference between $\nabla^2 J_m(\mathbf{u}, \theta)$ and $\nabla^2 J_p(\mathbf{u})$ ensures that the adapted model parameters accelerate the rate of convergence to the process optimum.

5. Simulation study

Different RTO schemes were tested on the Williams-Otto reactor benchmark problem which has been used to evaluate the performance of RTO schemes in many papers, e.g. Marchetti et al. (2010). The plant consists of an ideal CSTR in which three irreversible reactions take place whereas the presence of only two reactions is assumed in the model. The optimization objective is to maximize the profit which is defined as:

$$J(\mathbf{u}, \theta) = 1143.38X_P F + 25.92X_E F - 76.23F_A - 114.34F_B, \tag{9}$$

where $F := F_A + F_B$. The manipulated variables are the feed flow rate F_B and the reactor temperature T_R. The model equations and the description of the variables can be found in Marchetti et al. (2010). The meaning and the values of the model parameters are: $b_1 = -6 \times 10^3$ and $b_2 = -5 \times 10^3$ are the activation energies and $k_{1,0} = 1 \times 10^8$ and $k_{2,0} = 8 \times 10^8$ are the pre-exponential factors of the reactions. The initial model parameters b_1 and b_2 are calculated at the initial conditions of the manipulated variables, $F_B = 6.0$ and $T_R = 70$.

Figure 1 demonstrates the performance of the four RTO approaches presented above. Due to the presence of parametric and structural plant-model mismatch, the two-step approach does not converge to the true plant optimum. The standard MA approach where model parameters are not adapted moves near to the process optimum in the first iteration but then starts to oscillate since the available model is not adequate as it does not meet the second-order necessary condition of optimality. By updating the model at each iteration, the SMIO scheme performs better than the pure MA scheme. However, the SMIO scheme converges to a sub-optimal point after the eighteenth iteration, which is shown in the insert in Figure 1. This is due to the fact that parameter values do not exist which minimize the objective gradient error between the plant and model $\left|\nabla J_p^{(k)} - \nabla J_m^{(k)}(\theta^{(k)} + \Delta\theta^{(k)})\right|$. The best performance was obtained by the modifier adaptation with effective model adaptation (MAWEMA). After the initial iteration, EMA identifies an adequate process model for the modified optimization problem and ensures the convergence to the process optimum. Since the updated model at the first iteration also reduces the difference between the Hessians of the plant and the model, faster convergence to the process optimum is observed as compared to SMIO.

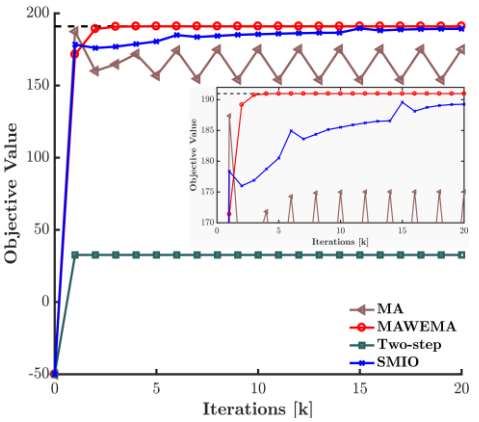

Figure 1: Comparison of the performance of the iterative RTO schemes

To illustrate the benefit of EMA, a simulation study was performed for different values of the initial feed flow rate and the reactor temperature. Figure 2 shows the comparison of the evolutions of the optimization objective over the iterations between SMIO and MAWEMA. Figure 2b shows that all trajectories obtained from the MAWEMA approach converge smoothly to the process optimum and satisfy the first- and second-

order optimality conditions whereas large oscillations can be observed in SMIO for some of the initial operating conditions. The SMIO scheme is not always able to reach the process optimum as the updated parameters cannot adapt the model gradients to the process gradient.

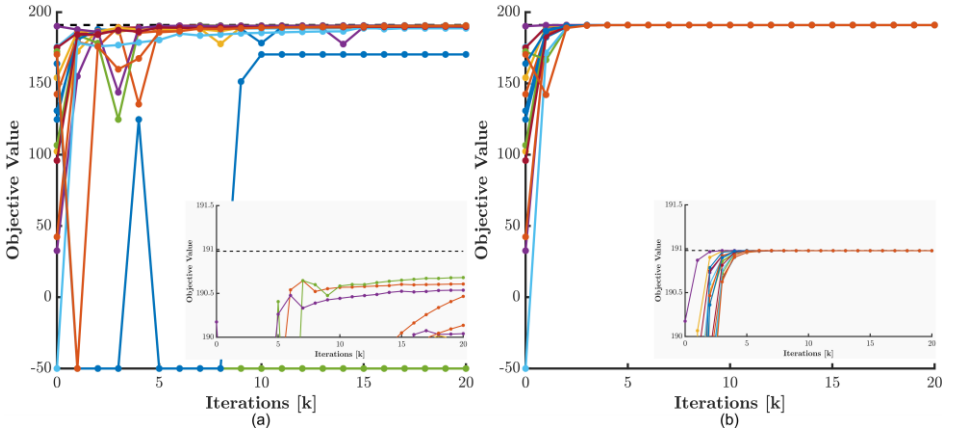

Figure 2: Optimization runs from arbitrary initial operating conditions. (a) SMIO, (b) MAWEMA

6. Conclusions

This paper highlights the importance of model adequacy in model adaptation which further enhances the performance of modifier adaptation. The key feature of MAWEMA is that a modified optimization problem is formulated to meet the first order KKT conditions and the second-order optimality conditions are satisfied via EMA.

Abstract

In this work, we show how scheduling and control problems can be treated within a unified optimization formulation. By transcribing discrete-time scheduling models into state-space form, a single dynamic model encompassing both layers can be optimized online as an instance of economic model predictive control (MPC), which inherits theoretical closed-loop properties from MPC theory. With the addition of suitable terminal constraints, a worst-case bound can be derived for the economic performance of the nominal closed-loop system, which helps to eliminate pathological behavior that can result from rescheduling too infrequently or without regard to recursive feasibility. Via an example system, we illustrate how constant feedback (i.e., reoptimization) and the inclusion of terminal constraints leads to better performance, even in the nominal case when no disturbances are present. With a unified treatment, the system is able to respond optimally and in real time to changing market conditions or process constraints, leading to improved economic performance and stability properties.

1. Introduction

In large-scale industrial environments, production-relevant decisions are typically split into multiple layers, with the most wide-reaching but lowest-resolution decisions at the top (e.g., design and campaign planning), slowly decomposing to more localized but detailed decisions at the bottom (e.g., regulatory control). Somewhere in the middle are layers commonly referred to as "scheduling" and "supervisory control" (Du et al., 2015). The former is primarily concerned with resource allocation, for example when to make a given product and in which unit to make it; the latter encompasses maintaining the process state at its desired operating point by choosing setpoints for localized regulatory controllers. Most decision hierarchies keep these layers completely separate, due to both the nature of the decisions (scheduling requires many discrete, "a or b" choices, while control considers continuous, "how much" process manipulations) as well as timescale separation (scheduling is typically performed over longer timescales than control). Furthermore, optimization of the scheduling layer is typically performed only infrequently, e.g., after some triggering event (Vin and Ierapetritou, 2000; Mendez and Cerdá, 2004), which means a schedule may become "stale" towards the end of its horizon by failing to consider future time points. Thus, reoptimizing more frequently often leads to improved performance but can also result in unexpected closed-loop behavior (Gupta and Maravelias, 2016). A successful technique for the supervisory control layer is model predictive control (MPC), which solves, repeatedly in real time, an optimization problem with an embedded process model to drive the system to its setpoint. Traditionally in industrial practice, MPC has been limited to continuous-valued decision variables. Recent research, however, has shown that discrete inputs can

be treated directly within the MPC formulation with little modification to the resulting stability and performance properties (Rawlings and Risbeck, 2017). An additional generalization is economic MPC, which replaces the artificial tracking objective with a tangible cost metric (Angeli et al., 2012). Thus, the online problem no longer minimizes distance to a static setpoint but rather dynamically optimizes the system's economic performance. These extensions allow the technique to be applied to systems with discrete decisions for which there is no natural steady-state operating point, e.g., cyclic production scheduling. Using ideas from Subramanian et al., (2012), standard scheduling models can be transcribed into the state-space form convenient for MPC, and underlying process dynamics can also be included in the model as necessary. In the remainder of this paper, we briefly discuss the economic MPC formulation and the theoretical cost bound afforded by including terminal constraints. Then, we apply this technique to a simple cyclic scheduling system to illustrate performance.

2. Economic MPC

We assume that the system of interest can be described in terms of internal states x which are affected by inputs u according to a state-space model $x(t+1) = f(x(t), u(t), t)$ with t denoting the discrete time. The goal of the controller is to choose u in a way that minimizes the economic cost function $\ell(x(t), u(t), t)$ while satisfying time-varying constraints $(x(t), u(t)) \in \mathbb{Z}(t)$. We assume further that there exists some feasible infinite reference trajectory $x_r(t)$, $u_r(t)$. Note that $x_r(t)$ could be constant (i.e., a steady state), periodic, or completely time-varying, but it must satisfy the model and constraints. For a given initial state x and initial time t, the following optimization problem is solved:

$$\min_{\hat{\mathbf{x}}, \hat{\mathbf{u}}} \quad \sum_{k=0}^{N-1} \ell\left(\hat{x}(k), \hat{u}(k), t+k\right) \tag{1a}$$

$$\text{s.t.} \quad \hat{x}(k+1) = f(\hat{x}(k), \hat{u}(k), t+k), \;\; k \in \{0, \dots, N-1\} \tag{1b}$$

$$(\hat{x}(k), \hat{u}(k)) \in \mathbb{Z}(t+k), \;\; k \in \{0, \dots, N-1\} \tag{1c}$$

$$\hat{x}(0) = x \tag{1d}$$

$$\hat{x}(N) = x_r(t+N) \tag{1e}$$

in which the decision variables are the (predicted) sequences $\hat{\mathbf{x}} \coloneqq (\hat{x}(0), \dots, \hat{x}(N))$ and $\hat{\mathbf{u}} \coloneqq (\hat{u}(0), \dots, \hat{u}(N-1))$. Letting $\kappa_N(x, t)$ denote an optimal value of $\hat{u}(0)$ in Eq. (1), the true system $x(t)$ evolves using the input $u(t) = \kappa_N(x(t), t)$; that is, the optimization problem is solved repeatedly and only the first input is used, rather than generating a single trajectory $\hat{\mathbf{x}}$, $\hat{\mathbf{u}}$ and following it until exhaustion. This closed-loop implementation imposes the requirement that each optimization problem can be solved within the discrete sample time, but suboptimal solutions are sufficient provided the cost is at least as good as the cost of the shifted solution from the previous timestep. Of particular note in is the terminal constraint Eq. (1e), which requires that the system terminate (in phase) on the reference trajectory $x_r(t)$. The purpose of this constraint is to ensure recursive feasibility of the predicted trajectory $\hat{\mathbf{x}}$. In particular, by joining $\hat{\mathbf{x}}$ and $\mathbf{x}_r$, it is possible to construct an infinite feasible sequence that the system could hypothetically follow. Thus, when the horizon is shifted forward, there is at least one

feasible solution, which then provides an upper bound for the cost of the re-optimized trajectory. More formally, one can show that if the cost function $\ell(\cdot)$ is bounded below, then the nominal closed-loop system satisfies

$$\limsup_{K\to\infty} \frac{1}{K} \sum_{t=0}^{K-1} \left(\ell(x(t), u(t), t) - \ell(x_r(t), u_r(t), t) \right) \leq 0 \tag{2}$$

That is, after an initial transient, the average cost of the real system's trajectory is no worse than the average cost of the reference trajectory. Thus, while the optimal control law $\kappa_N(\cdot)$ may move the system far from the nominal reference, in doing so, it improves the cost function for the system.

3. Example: Cyclic Production Scheduling

To illustrate the ideas from the previous section, we consider a single reactor that can produce multiple products (adapted from Flores-Tlacuahuac and Grossmann, (2006)). Orders of each product are due every 24 h, with excess sales permitted at any time. Product can be stored in inventory at a small inventory cost, while missed orders are heavily penalized and added to backlog that must be met at future times to avoid additional penalty.

3.1. Model Formulation

For each product $i \in \mathbf{I}$ and time $t \in \mathbf{T}$, there are nonnegative state variables S_{it} giving the current inventory and U_{it} tracking the accumulated backlog (both at the end of time period t). Although transition dynamics could be included in the process model alongside the scheduling considerations (possibly in approximate form as in Du et al., (2015)), for illustrative purposes we assume that changes between products can be described by fixed transition times $\tau_{ii'}$. To track product transitions, there are binary state variables X_{int} that are 1 if the reactor is $n \in \mathbf{N} \coloneqq \{0, \ldots, \max_{i,i'} \tau_{ii'}\}$ steps away from producing product i. Note that the X variables have been "lifted" (Subramanian et al., 2012) by the index n so that the values of X_{int} for a single value of t describes the entire state of the reactor. System inputs are how much product to sell V_{it} (nonnegative), how much to backlog H_{it} (continuous), and whether to transition to a new product $W_{ii't}$ (binary; 1 to begin transition and 0 otherwise). The states evolve at each time t according to

$$S_{i(t+1)} = S_{it} + \rho_i \left(X_{i0t} + X_{i1t} + \sum_{i' \in \mathbf{I}_{i0}} W_{i'it} - \sum_{i' \in \mathbf{I}} W_{ii't} \right) - V_{it}, \quad i \in \mathbf{I} \tag{3a}$$

$$U_{i(t+1)} = U_{it} + H_{it}, \quad i \in \mathbf{I} \tag{3b}$$

$$X_{in(t+1)} = X_{i(n+1)t} + \sum_{i' \in \mathbf{I}_{in}} W_{i'it}, \quad i \in \mathbf{I}, n \in \mathbf{N} \backslash \{0\} \tag{3c}$$

$$X_{i0(t+1)} = X_{i0t} + X_{i1t} + \sum_{i' \in \mathbf{I}_{i0}} W_{i'it} - \sum_{i' \in \mathbf{I}} W_{ii't}, \quad i \in \mathbf{I} \tag{3d}$$

with ρ_i giving the production rate of product i at the operating point and the auxiliary set $\mathbf{I}_{in} \coloneqq \{i' \in \mathbf{I} : \tau_{i'i} = n\}$. Constraints for each $t \in \mathbf{T}$ are then given by

$$\sum_{i \in \mathbf{I}} \sum_{n \in \mathbf{N}} X_{int} = 1 \tag{4a}$$

Table 1: Closed-loop profit for nominal system (normalized to $T = 48$ periodic solution).

Terminal Constraint	Rescheduling Period	Horizon		
		$N = 24$	$N = 48$	$N = 72$
None	12 h	−679.74%	−0.32%	−2.53%
None	1 h	−0.51%	−0.00%	+2.06%
$T = 48$	1 h	−0.02%	+0.29%	+0.44%
$T = 72$	1 h	+1.74%	+2.22%	+2.22%

$$\sum_{i' \in \mathbf{I}} W_{ii't} \le X_{i0t}, \quad i \in \mathbf{I} \tag{4b}$$

$$\delta_{it} - V_{it} \le H_{it} \le \delta_{it}, \quad i \in \mathbf{I} \tag{4c}$$

with δ_{it} giving the total orders that must be met or backlogged. Finally, the objective function is

$$\min \sum_{t \in \mathbf{T}} \sum_{i \in \mathbf{I}} (\beta_i U_{it} + \eta_i S_{it} - \pi_i V_{it}) \tag{5}$$

with β_i and η_i the backlog and inventory costs, and π_i the sales price. Note that backlog costs are 100 times inventory costs to discourage missed orders.

In state-space form, the states are $x(t) \coloneqq (S_{it}, U_{it}, X_{int})$ and inputs are $u(t) \coloneqq (V_{it}, H_{it}, W_{ii't})$. The system model $f(\cdot)$ is given by Eq. (3); the constraint sets $\mathbb{Z}(t)$ are Eq. (4) along with the sign and discreteness restrictions on the variables; and, the objective function $\ell(\cdot)$ is given by Eq. (5). The system timestep is 1 h.

3.2. Nominal Performance

To apply economic MPC, we start by determining a reference trajectory. Since orders are due every 24 h, it is natural to look for high-quality periodic solutions with cycle times T that are a multiple of 24 h. Such solutions can be found using Eq. (1) but replacing constraints (1d) and (1e) by the periodicity constraint $\hat{x}(0) = \hat{x}(N)$ and setting the prediction horizon N to the desired period T. Due to the transition times and required orders, there is no feasible $T = 24$ periodic solution, but optimal solutions can be found for $T = 48$, $T = 72$, etc. Note that longer periods generally have lower average cost, but the relationship is non-monotonic. To compare the performance of conventional scheduling with economic MPC, the nominal system is simulated for 30 days using different horizons, terminal constraints, and rescheduling frequencies. Table 1 shows closed-loop profit for each simulation case. In the first row, we see that

the traditional strategy of rescheduling infrequently without any terminal constraints can lead to poor performance. In case of the short $N = 24$ horizon, significant backlog is accumulated (on average, each order is 10.8 h late), which leads to extremely low profit. When the horizon is increased to $N = 48$, significantly less backlog is experienced, but the system still does not perform as well as it could. Interestingly, when the horizon is increased to $N = 72$, profit actually decreases due to the optimizer putting off production of less profitable products.

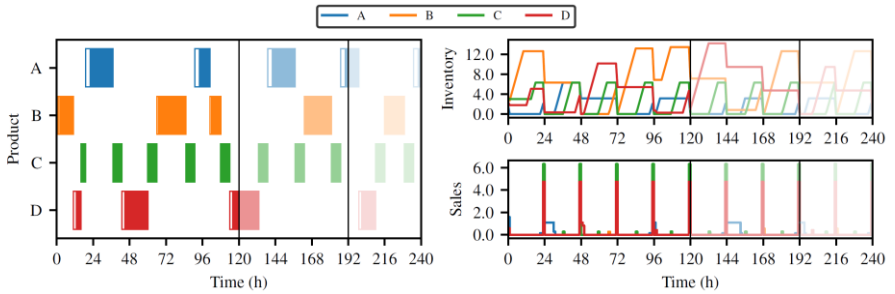

Figure 1: Beginning of closed-loop solution with horizon $N = 72$ and terminal constraint $T = 48$. Plots are split into three sections by vertical lines. First section shows closed-loop solution so far. Second section shows incumbent schedule. Third section shows reference trajectory on which the incumbent schedule terminates.

When the schedule is recomputed every hour, performance is improved. Even without terminal constraints, constant reoptimization is sufficient to prevent backlog in the $N = 24$ case, and profit is increased by almost 5% for the longer $N = 72$ horizon, as the system can react more quickly to new orders. However, without terminal constraints, there is no performance guarantee, and further, there is a lot more variation in schedules from one time period to the next, as new orders that enter the horizon every 24 h are essentially a disturbance not accounted for by the optimizer. By including the terminal constraints as suggested by economic MPC theory, system performance is improved. For the $N = 24$ horizon with the $T = 48$ periodic terminal constraint, Eq. (2) indicates that this value should asymptotically be no less than 0% (as costs were normalized to the $T = 48$ reference trajectory). The small negative value observed in Table 1 is due to aggressive control action in the initial transient required to reach the reference trajectory within 24 h. As the horizon is increased, average profit improves as the system is able to take a less aggressive (and more profitable) path to the reference trajectory. A plot of the system startup is shown in Figure 1. Finally, in all cases with the $T = 72$ terminal constraint, the system converges to the reference trajectory, and closed-loop profit is the highest among all of the simulated cases. Thus, in addition to providing a theoretical closed-loop cost bound, the inclusion of a quality terminal constraint leads to improved closed-loop performance even in the nominal case.

3.3. Effect of Disturbances

In the previous section, all simulations assume that the model is exact. However, real systems are subject to disturbances, either in the form of model mismatch or external forces affecting the system. While the cost bound from Eq. (2) no longer holds with disturbances, including the terminal constraint may still be helpful by keeping the system close to a nearly-feasible periodic solution. To examine this possibility, the reactor is subjected to random yield disturbances. The model prediction assumes that

the reactor production is at some nominal value, but at each timestep, the actual hourly yield can vary from the nominal value by $\pm 15\%$. Using a prediction horizon of $T = 48$ and rescheduling every timestep, the system is simulated 100 times with different yield disturbances both with and without terminal constraints. A kernel density estimate of profit and backlog costs is shown in Figure 2. Note that due to the high cost assigned to backlogs, even a small number of missed orders is sufficient to depress profit. The mean profit with terminal constraints is 4.25% higher than without terminal constraints, indicating that the terminal constraint is still helpful in the presence of disturbances.

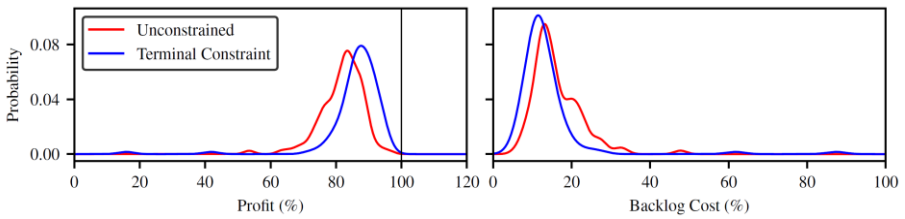

Figure 2: Kernel density estimate for closed-loop profit and backlog cost based on 100 simulations. Values normalized to profit of optimal $T = 48$ periodic solution.

4. Conclusions

In this work, we have demonstrated the formulation of cyclic production scheduling as an economic MPC problem. Even in the nominal case with no disturbances, rescheduling at every time point leads to improved cost over rescheduling only infrequently. In addition, using terminal constraints derived from periodic solutions ensures nominal recursive feasibility, which then gives a bound on the closed-loop cost for the system and leads to improved performance over scheduling without terminal constraints. Finally, when disturbances are present, the theoretical performance guarantees are lost, but as shown in simulation, the inclusion of terminal constraints still leads to higher closed-loop profit. Overall, the treatment of closed-loop scheduling via economic MPC helps to avoid pathological behavior that can result from naive rescheduling and facilitates analysis of closed-loop performance and stability properties.

Abstract
In hydraulic fracturing of shale formations, compared to conventional reservoirs, the fracturing fluid is of low-viscosity, and hence, the proppant settles significantly during the pumping stage, forming a proppant bank. Motivated by this consideration, first, a section-based optimization method is employed to obtain key fracture design parameters for enhanced productivity in shale formations subject to given fracturing resources. Second, a reduced-order model is constructed using high-fidelity simulation data to design a Kalman filter. Lastly, a real-time model-based feedback control system is developed by explicitly taking into account actuator limitations, process safety and economic considerations. A series of closed-loop simulation results demonstrate that the proposed control scheme can regulate the uniformity of proppant bank heights across the fracture at the end of pumping.

Keywords: hydraulic fracturing, optimal pumping schedule, model predictive control.

1. Introduction
Unconventional natural-gas and oil resources are found in rock formations of ultra-low permeability (0.01 to 0.0001 mD or even less). Because of the low permeability of the formation, if a well were to be drilled into such a rock, it would take extremely long time to reach an economically viable amount of production. Horizontal drilling and hydraulic fracturing made the recovery of shale oil and gas economically viable, leading to shale boom in the U.S. (Economides and Nolte, 2000). In practice, while planning for hydraulic fracturing in unconventional reservoirs, very limited information is available. Therefore, the usual combination of sophisticated reservoir simulations and computationally extensive nonlinear optimization algorithms (Wilson and Durlofsky, 2013) might be difficult to justify at the planning stage. Motivated by these considerations, recently, Liu and Valkó (2017) proposed a section-based optimization method to maximize the dimensionless productivity index (PI) assuming constant pressure at the wellbore and infinite conductivity fracture (i.e., zero pressure drop in the fracture during the production stage). This approach converts a fixed amount of proppant into a total length of infinite conductivity fractures that in turn is used as a constraint to find the three decision variables: number of wells, number of fractures per well, and fracture half-length. These optimal design parameters can be used as set-point values to be satisfied during hydraulic fracturing processes. In conventional oil reservoirs, high-viscosity fracturing fluids ensure that most of the proppant remains in suspension during the hydraulic fracturing process. Thus, it is sufficient to regulate the

suspended proppant concentration along the fracture at the end of pumping. Some efforts have been made in this direction by developing model-based pumping schedule design techniques (Yang et al., 2017; Siddhamshetty and Kwon, 2017; Narasingam et al., 2017). In contrast, in unconventional oil reservoirs, predominantly low-viscosity ("slick-water") fluids are used and the proppant settles quickly forming a proppant bank. As a result, the proppant bank will continue to grow until it reaches the equilibrium height; a state when the rate of proppant washout on top of proppant banks due to the shear force is equal to the rate of bank formation via proppant settling. Thereafter, the injected proppant particles will flow over the top of the equilibrium-height proppant bank and travel farther to find a position at which the proppant bank has not reached the equilibrium height yet. This proppant transport behavior has been known for a long time (Kern et al., 1959) but has become dominant only recently, due to the widespread use of slick-water as fracturing fluids. We are not aware of incorporating it into a controller to compute optimal pumping schedules. Motivated by these considerations, we focus on the development of a model-based feedback control system to minimize the spatial variation of proppant bank heights along the fracture at the end of pumping by taking into account (a) actuator limitations that the pumping schedule consists of multiple pumping stages where the flow rate and the proppant concentration can be varied, (b) state constraints to prevent premature termination of the process, and (c) the desired propped fracture geometry obtained using the section-based optimization method.

2. Dynamic modeling of hydraulic fracturing processes

In this work, a hydraulic fracturing process is developed by considering the following three sub-processes: (1) fracture propagation, (2) proppant transport, and (3) proppant bank formation. More details regarding the modeling of hydraulic fracturing processes are given in Siddhamshetty et al. (2017).

3. Computation of optimal fracture configuration in unconventional reservoirs

3.1. Section-based optimization method

We employed a section-based optimization method, developed by Liu and Valkó (2017), to find the optimum number of wells n_c, number of fractures per well n_r, and fracture half-length x_f, that maximize the overall dimensionless PI subject to fixed fracturing resources. The section-based optimization is performed for planning the development of an unconventional reservoir with multi-stage fractured horizontal wells in a large square drainage area that we call a section (refer to Fig. 1). The section is evenly divided into multiple subsections such that there are n_c wells and n_r fractures per well. An individual subsection is considered as the drainage area of a single fracture (refer to Fig. 1), and all the subsections in one column represent a single horizontal well. In this approach, it is assumed that the created fractures will be of infinite conductivity. In addition, it is assumed that the selected total amount of fracturing materials is already enough to ensure that the stimulated volume will cover the whole section in which a uniform enhanced permeability will be established. The optimization problem to maximize the overall dimensionless PI, J_D, using the section-based optimization method is formulated as follows:

$$\max_{n_r, n_c} \quad J_D = n_f J_{D,f}(A_r, I_x) \tag{1a}$$

$$\text{s.t.} \quad J_{D,f} \text{ from the eigenvalue problem} \tag{1b}$$

$$A_r = \frac{n_r}{n_c}, \qquad I_x = \frac{l_{fD}}{n_r}, \qquad l_{fD} = \frac{l_f}{\sqrt{A_s}}, \qquad l_f = \frac{M_{prop}}{\rho_{sd} W_{opt} H_r} \tag{1c}$$

$$0 < x_f \leq x_{f,max} \tag{1d}$$

$$x_e - x_f \geq 0.5 d_{sep,min} \tag{1e}$$

$$x_f = \frac{l_f}{2 n_r n_c}, \qquad x_e = \frac{x_f}{I_x}, \qquad y_e = \frac{x_e}{A_r} \tag{1f}$$

where $n_f = n_c n_r$ is the total number of fractures in the section, l_f is the total fracture length (sum of $2x_f$ over the entire subsections) to be created in the section (injecting the available fracturing resources), and $J_{D,f}$ is the dimensionless PI for each fracture (i.e., a subsection). $J_{D,f}$ is a function of aspect ratio, A_r, and penetration ratio, I_x, of a subsection. x_e and y_e are the half-width and half-length of the subsection, l_{fD} is total fracture length divided by the section side length, A_s is the square drainage area of the section, M_{prop} is the total amount of proppant to be injected, W_{opt} is the average propped fracture width, and H_r is the reservoir thickness. More details regarding how to obtain $J_{D,f}$ can be found in Liu and Valkó (2017). The smallest distance between the tips of two fractures created from neighboring wells is called the separation distance d_{sep}. In this work, we consider $d_{sep,min} = 25$ m via Eq. (1f). The constraint Eq. (1e) imposes the limit $x_{f,max}$ on the fracture half-length. It is a crucial parameter, representing the current level of fracturing technology in the given unconventional formation, meaning that fractures can be routinely and reliably created and propped up to this half-length. In the current problem we use $x_{f,max} = 122$ m.

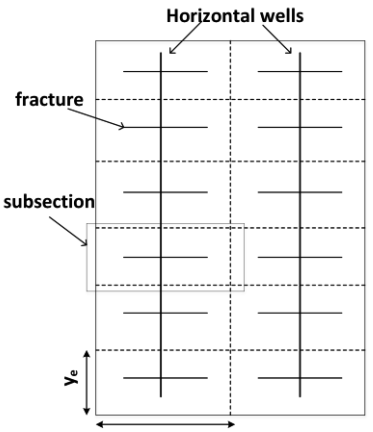

Figure 1. Illustration of a section for the case of two horizontal wells ($n_c = 2$) and six fractures per well ($n_r = 6$).

In the maximization problem, Eq. (1), there are only two decision variables, n_c and n_r. Once M_{prop}, W_{opt}, ρ_{sd} , H_r, and A_s are available, the total fracture length to be created in the section, l_f, is obtained using Eq. (1d). Since we use the concept of infinite conductivity fracture, the W_{opt} average propped fracture width is not the result of the optimization, rather an input, providing the minimum required propped width of a fracture to be considered as a propped fracture at all (often taken as three times the proppant grain diameter). In this work, we assumed the total amount of proppant for the section is $M_{prop} = 3.96 \times 10^7$ kg. Then, we computed the total fracture length in a section, $l_f = 79{,}248$ m, by substituting $W_{avg} = 2.9$ mm and $H_r = 60$ m for Eq. (1d). By solving the optimization problem, Eq. (1), we obtained that $n_c = 6$, $n_r = 55$, and $x_f = 120$ m. In summary, each fracture should be propped with $M_{prop,frac} = 120 \times 10^3$ kg proppant to achieve optimal fracture conductivity (i.e., productivity).

3.2. Treatment targets

As we already discussed, with the low-viscosity fracturing fluid, the proppant settles quickly and forms a proppant bank with an equilibrium height, h_{eq}. By assuming that

the proppant bank will cover the entire optimal fracture half-length, x_f, with the equilibrium height at the end of pumping, we can calculate the desired average fracture width, $W_{avg,target}$, as follows:

$$W_{avg,target} = \frac{M_{prop,frac}}{2\rho_p h_{eq} x_f (1-\phi)} \tag{2}$$

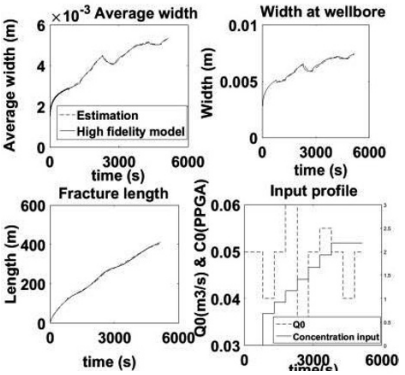

Figure 2. Comparison between the true values and the estimates.

where the equilibrium proppant bank height is $h_{eq} = 54$ m, which was calculated by using a correlation described in (Want el al., 2003). In our case, the calculated target fracture width at the end of pumping is $W_{avg,target} = 5.37$ mm. In the following section, we will focus on the development of a model-based feedback controller that aims to achieve the targeted length and width for developing the proppant bank.

4. Model predictive control for hydraulic fracturing processes

In this section, we first construct a linear time-invariant approximate model from the high-fidelity simulation data using the multi-variable output error state-space (MOESP), which is presented in the following form:

$$x(t_{k+1}) = Ax(t_k) + Bu(t_k) \tag{3a}$$

$$y(t_k) = H(t_k) \tag{3b}$$

where $u(t_k) = [Q_0(t_k), C_0(t_k)]^T$ is the flow rate and proppant concentration of the fracturing fluid at the wellbore (i.e., the manipulated input variables) and $y(t_k) = \left[W_{avg}(t_k), W_0(t_k), L(t_k)\right]^T$ denotes the vector of output variables where $W_{avg}(t_k)$ is the average fracture width, $W_0(t_k)$ is the fracture width at the wellbore, and $L(t_k)$ is the fracture length . In practice, the available real-time measurements are limited to the fracture width near the wellbore and the fracture length. This leaves the average fracture width to be estimated through a Kalman filter, which is presented in the following form:

$$\hat{x}(t_{k+1}) = A\hat{x}(t_k) + Bu(t_k) + M(t_k)(y_m(t_k) - \hat{y}(t_k)) \tag{4a}$$

$$M(t_k) = P(t_k)H^T(R(t_k) + HP(t_k)H^T)^{-1} \tag{4b}$$

$$P(t_{k+1}) = (I - M(t_k)H)P(t_k) \tag{4c}$$

where the notation $(\hat{\cdot})$ denotes the estimated variables, $M(t_k)$ is the Kalman filter gain, $P(t_k)$ denotes the covariance of the state estimation error, and $y_m(t_k) = [W_0(t_k), L(t_k)]^T$ are the available real-time measurements. Fig. 2 shows the comparison between the estimated and the actual average fracture width with time. It is observed that the estimated average fracture width quickly converges to the true value obtained from the high-fidelity process model. Then, a novel model-based feedback control system is designed to minimize the squared deviation of the average fracture width at the end of pumping from its set-point value. The proposed model-based feedback controller is formulated in the following form:

$$\max_{\substack{C_{0,k},\ldots,C_{0,9} \\ Q_{0,k},\ldots,Q_{0,9}}} \left(\widehat{W}_{avg}(t_f) - W_{avg,target}\right)^2 \tag{5a}$$

$$\text{s.t.} \quad \text{Kalman Filter, Eq. (4)} \tag{5b}$$

$$\widehat{W}_0(t_k) = W_0(t_k), \quad \hat{L}(t_k) = L(t_k) \tag{5c}$$

$$C_{0,k-1+m} \leq C_{0,k+m} \leq 2 \text{ ppga} \tag{5d}$$

$$Q_{min} \leq Q_{0,k+m} \leq Q_{max}, \quad m = 1, \ldots, 9-k \tag{5e}$$

$$\Delta\left(\sum_{k=1}^{9} 2Q_{0,k}C_{0,k}\right) = M_{prop,frac} \tag{5f}$$

where $W_{avg,target}$ is the set-point value for the average fracture width at the end of pumping, t_f is the total process operation time, $\widehat{W}_{avg}(t_k)$ is the predicted average fracture width obtained via Kalman filter which is then used in the approximate model (Eq. (3)) to find $\widehat{W}_{avg}(t_f)$, Δ is the sampling time, which is also the duration of each pumping stage, t_k is k^{th} sampling time, $W_0(t_k)$ and $L(t_k)$ are the available measurements, and $C_{0,k}$ and $Q_{0,k}$ are the inlet proppant concentration and the inlet flow rate of k^{th} pumping stage, respectively, which are to be determined by solving Eq. (5) with a shrinking prediction horizon $N_p = t_f - t_k$. The constraint of Eq. (5d) implies that the proppant concentration will be increased monotonically, and the maximum injected proppant concentration is less than 2 ppga, which stands for 1 pound of proppant added to one gallon of fluid and it is a standard concentration unit in petroleum engineering. The constraint of Eq. (5e) imposes the limits on the flow rate of fracturing fluids at the wellbore. The constraint of Eq. (5f) describes the amount of proppant to be injected to a single fracture (i.e., the material constraint).

5. Closed-loop simulation results under model-based feedback controller

In Section 3.2, we computed that to achieve the uniform equilibrium proppant bank height over the optimal fracture half-length, $x_f = 120$ m, the set-point value for the average fracture width that has to be satisfied at the end of pumping is $W_{avg,target} =$ 5.37 mm. For the simulations, the pad time, t_p, was fixed at 800 s in order to avoid

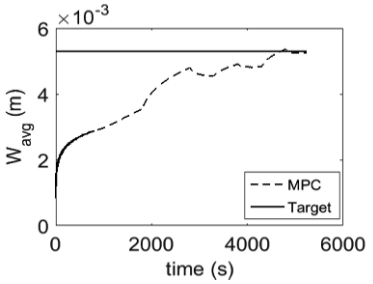

Figure 3. Average fracture width

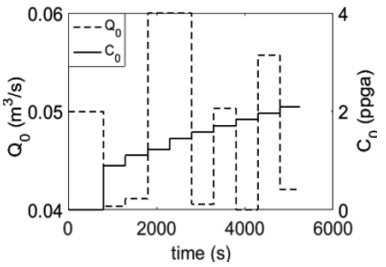

Figure 4. Optimal pumping schedule

premature termination of the hydraulic fracturing process before the fracture tip reaches the desired fracture half-length of $x_f = 120$ m. At $t = t_p$, the feedback control system and the Kalman filter were initialized. In the closed-loop simulations, Δ and t_f were chosen to be 500 s and 5300 s, respectively. The proppant pumping schedule was divided into 9 pumping stages and the duration of each pumping stage was 500 s, which was equal to the sampling time Δ. With this, the proposed model-based feedback controller was applied to the high-fidelity process model of hydraulic fracturing to achieve the desired average fracture width at the end of pumping. Fig. 3 presents that the average fracture width at the end of pumping is very close to the set-point value. Fig. 4 shows the optimal pumping schedule computed by the proposed model-based feedback controller. As we regulated the average fracture width at the end of pumping to the set-point value, for the given amount of proppant to be injected, the proppant

bank height along the fracture with the optimal half-length, x_f, was uniform with the equilibrium value as shown in Fig. 5.

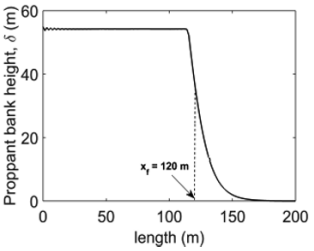

Figure 5. Spatial proppant bank height profile obtained at the end of pumping.

6. Conclusions

In this work, we developed a model-based feedback control system that computes an optimal pumping schedule to achieve the proppant bank with a uniform height over the optimal fracture length at the end of pumping. First, a section-based optimization method was employed to determine the optimal well-fracture configuration, maximizing the overall productivity achievable from a given amount of proppant to be injected. Second, using the high-fidelity simulation data, an approximate model was constructed for a Kalman filter to effectively estimate average fracture width. Third, MPC theory was applied for the design of a real-time model-based feedback control system, which was able to generate an online pumping schedule for a uniform proppant bank height along the targeted length while explicitly taking into account actuator limitations, state constraints for process safety, and economical considerations.

Abstract

The potential of hydrogen, or pH, is an important factor to be controlled in various systems, especially on water treatment, bioprocesses, and sugar processing. However, its control can be a challenging task due to its strong non-linear behaviour and time-varying properties. Therefore, it is important to choose a control strategy that can detect or workaround these changes. Extremum-seeking control (ESC) is a model-free control strategy that has promising results in a range of applications such as increasing the power capture of wind turbines (Ciri et al., 2017) and controlling the position of high-altitude balloons (Vandermeulen et al., 2017), but it not yet very explored in the area of chemical engineering. A Single-Input Single-Output (SISO) and a Multiple-Input Single-Output (MISO) ESC strategies to control the pH of a continuous neutralization pilot-plant reactor are proposed on this paper and were able to successfully control its pH. Special care was taken with the values of the parameters as they greatly influence the rate of convergence of the algorithm.

Keywords: model-free; extremum-seeking control; process control, pH, continuous reactor.

1. Introduction

There are various types of automated control systems, from a simple on/off switch to set the level of a tank to a complex mechanistic model predictive controller to control fluid catalytic cracking. The choice of the right type of control system greatly depends on the system to be controlled.

The potential of hydrogen, or pH, is not only a difficult property to be controlled but also one with great industrial importance owing to the fact that it needs to be controlled in at least one operational unit on most industries. Some examples are wastewater treatment (Cheremisinoff, 2002), sugar processing (Chou, 2000), and for chemical and biochemical processes (Obut and Özgen, 2008).

The control strategies generally used in chemical plants are based on a mathematical model of the system, or mostly based on data that can be collected from them. This paper proposes the use of an extremum-seeking (ES) technique, a data-based strategy with no prior knowledge of the system, to directly control a neutralization reactor. Computational simulation of the system allowed prior performance assessment, while experimental tests showed the potential of ESC techniques in chemical process control.

This paper is organized as follows. Section 2 presents the experimental setup that was used to assess the control performance. Section 3 presents the simulation setup, including its model, software and solving algorithm. Section 4 presents the proposed control structure based on extremum-seeking. Section 5 presents both the results and discussion of the simulation and the experiments. Section 6 presents the conclusions of this work.

2. Experimental setup

A continuous neutralization pilot-plant available at the Laboratory of Automation and Process Control (LCAP) at University of Campinas (UNICAMP) was used to evaluate the strategy, and its instrumentation diagram can be seen on Figure 1, where the construction of the plant is shown along with the name of each unit and controller. Table 1 summarizes the information about all control loops.

The reactor in the plant is a continuous reactor in which a reaction between a solution of nitric acid, a solution of sodium hydroxide, and a solution of sodium bicarbonate take place.

Three liquid streams feeds the reactor, one carries a strong acid, another carries a strong base and a third carries a buffered medium that represents a theoretical effluent to have its pH corrected. The buffered medium is a solution of $NaHCO_3$ at 0.03 M, the acid, a, is a solution of HNO_3 at 0.0034 M, and the base, b, is a solution of NaOH at 0.0057 M. Three barrels are used to store each up to 100 L of each solution.

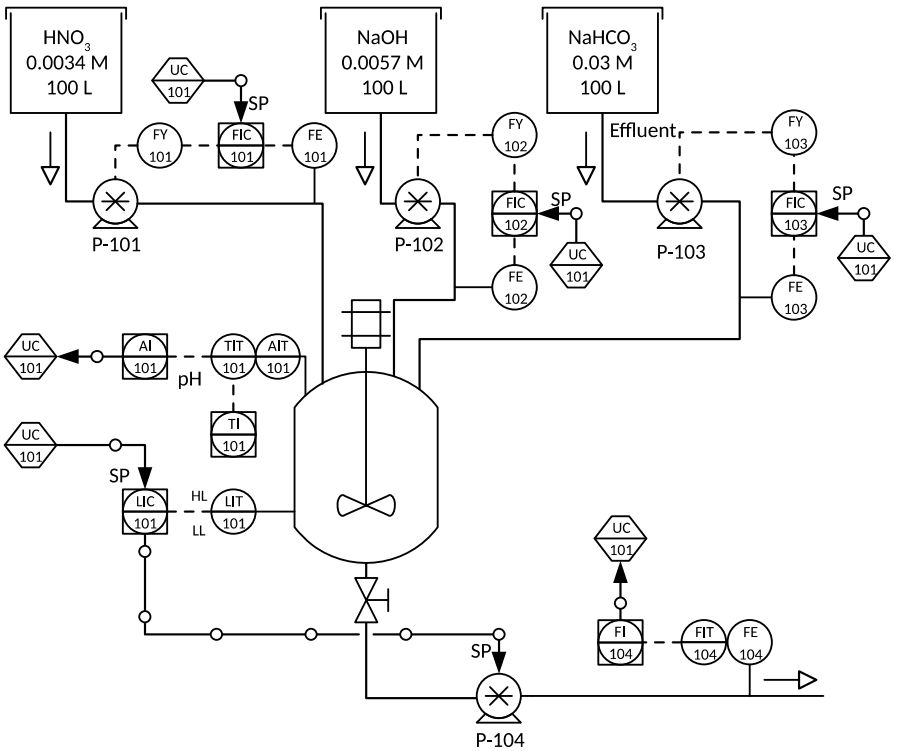

Figure 1 – Instrumentation diagram of the pH neutralization plant.

Table 1 – Summary of all control loops and strategies.

Tag	Controlled variable	Manipulated variable	Type
FIC-101	Acid flow rate	P-101 power	PI
FIC-102	Base flow rate	P-102 power	PI
FIC-103	Buffer flow rate	P-103 power	PI
LIC-101	Liquid level	P-104 power	PI
UC-101	pH	FIC-101 and/or FIC-102 set-points	SISO or MISO ESC

All data collection and management of the PI controllers are done by a PLC installed beside the plant, whose data can then be read and modified through the OPC protocol.

The management of the ESC controller and the monitoring of the plant is done through the computer UC-101, which is also responsible for the extremum-seeking strategy. It operates as an extremum-seeking controller whose slaves are FIC-101, FIC-102, or both at the same time depending if it is operating as a SISO or MISO controller. It can also set the set-point of LIC-101 to the desired level of the reactor. The reactor's height is 30 cm and its base area is 201.06 cm^2.

The free software SciLab and its XCos module along with a custom server software was used to communicate with the PLC and do all the calculations of the control strategy.

3. Process simulation and equations

A simulation of the system being controlled through Extremum-Seeking Control was used to assess the possible performance it can achieve and to have an approximated understanding of its transient response. The model used is based on the Reaction Invariant Model, and its equations are shown on Eq. (1), Eq. (2), Eq. (3), and Eq. (4). The simulations showed promising results, therefore the experimental procedure was designed.

On those equations A_b is the reactor base area, h the liquid level, q_a the flow rate of acid, q_b the flow rate of base, q_{buffer} the flow rate of the buffered medium, and q the flow rate at the reactor outlet.

The invariant $w_{1,a}$ is 0.0034 M, the invariant $w_{1,b}$ is -0.0057 M, the invariant $w_{1,buffer}$ is -0.03 M, the invariants $w_{2,a}$ and $w_{2,b}$ are both 0.00 M, the invariant $w_{2,buffer}$ is 0.03 M. They were calculated using conservation equations and equilibrium relations, similar to the work done by Henson and Seborg (1994). The anti-log of the equilibrium constants K_{a1} and K_{a2} from carbonic acid dissociation are given by pK_{a1}, which is 6.35, and pK_{a2}, which is 10.33, respectively, at 25 °C.

$$A_b h \frac{dw_1}{dt} = q_a(w_{1,a} - w_1) + q_b(w_{1,b} - w_1) + q_{buffer}(w_{1,buffer} - w_1) \quad (1)$$

$$A_b h \frac{dw_2}{dt} = q_a(w_{2,a} - w_2) + q_b(w_{2,b} - w_2) + q_{buffer}(w_{2,buffer} - w_2) \quad (2)$$

$$A_b h \frac{dh}{dt} = q_a + q_b + q_{buffer} - q \tag{3}$$

$$w_1 + 10^{pH-14} - 10^{-pH} + w_2 \frac{1 + 2 \times 10^{pH-pK_{a2}}}{1 + 10^{pK_{a1}-pH} + 10^{pH-pK_{a2}}} = 0 \tag{4}$$

4. Extremum-Seeking Control

Extremum-seeking has diverse literature, and the chosen strategy is based on the discrete variant as proposed by Killingsworth and Krstic (2006) for PI tuning. The cost function can be seen on Eq. (5), where $e(t, q_a, q_b)$ is the error between the set-point and the plant output, the value of the pH. The step size is given by h_D, which is the time in seconds taken between each adjustment of the input variables q_a and q_b.

$$J(q_a, q_b) \triangleq \frac{1}{h_D}[e(t, q_a, q_b)]^2 \tag{5}$$

The control loop can be configured to adjust only one of the input variables, or both at the same time. The parameters that need to be tuned are the integration factors γ_i, the dither amplitudes α_i and frequencies ω_i, and the high pass filter constant h_f.

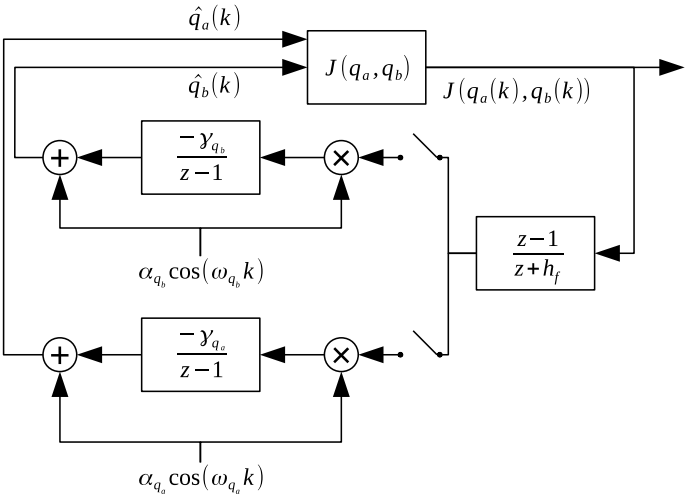

Figure 2 – Proposed Extremum-Seeking Control structure

5. Results and discussion

Prior simulations helped on finding the best parameters for the ESC algorithm on Figure 2, especially the sampling time, which is important for this type of algorithm.

On both experiments the buffered medium flow rate was set to 10 L/h, the reactor level to 60%, and the sampling time, h_D, was set to 15 s as the time-response of the system is slow.

5.1. SISO

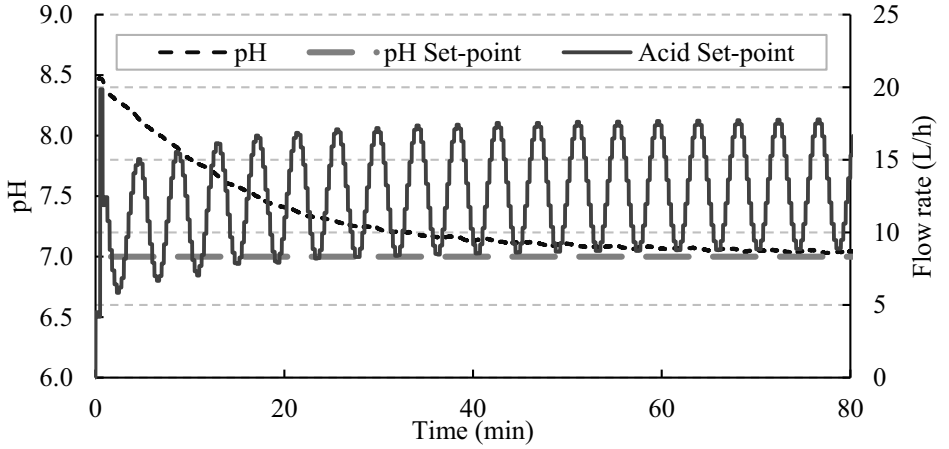

Figure 3 – SISO experimental results. Acid flow rate (FIC-101) as manipulated variable.

The parameters used for the ESC algorithm on this experiment can be seen on Table 2.

Table 2 – Parameters used for the SISO experiment

$h_f(-)$	$\gamma_{q_a}\,(L/h)$	$\alpha_{q_a}\,(-)$	$\omega_{q_a}\,(rad)$
0.5	55	4.5	$0.7^6\pi$

While greater dither amplitude α_{q_a} would increase the rate of convergence, it is also harder on the pump. Thus, the value of the integration factor γ_{q_a} was set high to compensate for the lack of dither. The frequency was set taking in mind the time-scale of both the plant and the pump, higher frequency could increase the convergence rate but the pump could not keep up. All parameters were set through trial and error considering all those factors.

The SISO algorithm managed to control the *pH* and find an optimum point where the cost function is almost zero. While small, the oscillations on the system response caused by the dither can be seen.

5.2. MISO

The parameters used for the ESC algorithm on this experiment can be seen on Table 3.

Table 3 – Parameters used for the MISO experiment

$h_f(-)$	$\gamma_{q_a}(L/h)$	$\gamma_{q_b}(L/h)$	$\alpha_{q_a}(-)$	$\alpha_{q_b}(-)$	$\omega_{q_a}(rad)$	$\omega_{q_b}(rad)$
0.5	55	35	4.0	3.5	$0.7^6\pi$	$0.7^5\pi$

The same observations from the SISO experiment are also valid here. Furthermore, the frequency of both dithers must be different. The integration factor of the base flow rate was set lower than for the acid flow rate as the effect it has on the *pH* is higher due to its higher concentration of base.

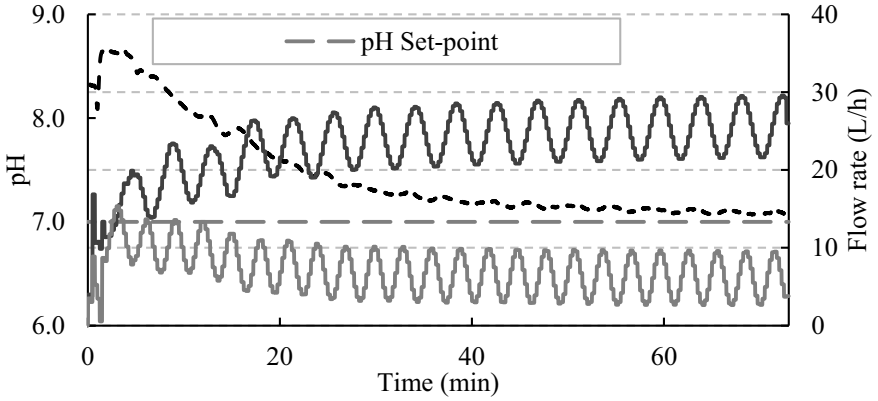

Figure 4 – MISO experimental results. Acid (FIC-101) and base (FIC-102) flow rates as manipulated variables.

The MISO algorithm was able to control the *pH* and find the optimum point where the cost function is almost zero. The oscillations on the system response caused by both dithers can be seen, and upon closer inspection it resembles the sum of both oscillations, as expected.

6. Conclusions

Two ESC algorithms were proposed in this work, a SISO and a MISO algorithms. The control strategy performance was first evaluated through simulations and then confirmed through experiments in a continuous neutralization plant. While the extremum-seeking control technique does not see much use on the chemical engineering area, it was able to properly control the pH of the continuous neutralization reactor, and show promising results for follow up works to increase the rate of convergence and reach the optimum, or set-point, faster. While a standard PI controller is able to control a system well when operating where it was tuned, ESC has the potential to control well on any range.

Integrating Model Identification and Model-Based Control of Networked Process Systems

Amr Zedan, Da Xue, Nael H. El-Farra*

Department of Chemical Engineering, University of California, Davis, CA 95616, USA
nhelfarra@ucdavis.edu

Abstract

In this work, we present a methodology for the integration of model-based control and model identification for networked process systems subject to communication constraints. The methodology aims to enhance the stability and performance properties of the networked closed-loop system in the presence of process parameter variations while simultaneously reducing the overall rate of information transfer between the plant control subsystems. This is accomplished by incorporating within the time-triggered model-based control strategy an event-triggered model parameter update scheme that keeps the plant-model mismatch to a minimum and averts the need for increasing the communication rate in response to the destabilizing influence of process drift. A process monitoring scheme with an instability alarm is devised to trigger model identification whenever a certain instability threshold is breached. The results are demonstrated using a chemical process example.

Keywords: Networked process systems, model-based control, model identification.

1. Introduction

The problem of designing distributed and supervisory control systems for process networks has been the subject of significant research work in process control (e.g., Jillson and Ydstie, 2007; Rawlings and Stewart, 2008; Jogwar et al., 2009; Christofides et al. 2011; Cai et al., 2014). In addition to handling the dynamic interactions between the constituent subsystems, the management and optimization of information flow and communication between the plant subsystems are becoming increasingly important considerations in the control problem formulation (e.g., Sun and El-Farra, 2008; Zheng et al., 2015), especially in view of the growing reliance on networked sensor and control systems in plant operations and the increased emphasis placed on smart plant operations (Christofides et al., 2007). Beyond the economic savings achieved through the deployment and integration of wireless sensor networks in process monitoring and control systems, the increased operational flexibility, the ease of reconfiguration and real-time information coupling between the different plant layers enabled by this technology are appealing goals that promise to significantly enhance process operations.

An approach to address the integration of control and communication in the context of plant-wide control was presented in earlier work (Sun and El-Farra, 2008) where a quasi-decentralized model-based networked control structure that enforces closed-loop stability with minimal cross communication between the distributed control systems was developed. Within each local control system, a set of predictive models were used, in conjunction with local measurements, to generate the local control action at times when communication between the plant subsystems was suspended, and the models' states were updated when communication was permitted at discrete times. The

minimum communication rate required for closed-loop stability was shown to strongly depend on the size of the plant-model mismatch, with a larger mismatch generally requiring a higher rate of information transfer.

While a model-based control strategy generally helps reduce the control system's reliance on the communication medium, and therefore reduces its vulnerability to sensor failures and communication outages, the use of a single model with fixed parameters may limit the achievable savings in network resource utilization, especially when plant operating conditions experience variations and drift over time (e.g., due to catalyst deactivation in reactors and fouling in heat exchangers) causing increased plant-model mismatch. Such variations, if left unaddressed, could cause performance degradation and even instability. While increasing the communication frequency is one way of stabilizing the system (as it provides more frequent feedback that corrects for the increased uncertainty), this approach leads to higher communication costs and bandwidth over-utilization. An alternative approach is to update the model parameters instead, using model identification techniques (e.g., Overschee and Moor, 1996; Huang and Kadali, 2008). This allows keeping the plant-model mismatch to a minimum which ensures stability without the need to increase the communication frequency.

Motivated by this, we present in this work a framework for integrating model identification and model-based control in order to maintain closed-loop stability and reduce network resource utilization, while enhancing controller performance and accounting for plant drift and plant-model mismatch. Initially, a model-based controller with a well-characterized model state update rate is designed and implemented. An error detection scheme with a time-varying alarm threshold is devised to track the state evolution and trigger model parameter updates. When the instability threshold is breached, the communication rate is temporarily increased to avoid instability and, in the meantime, the data collected during this time period are used to identify a new model online based on subspace identification techniques. The networked closed-loop stability region associated with the new model is characterized and used to identify a suitable model state update rate that can restore the communication frequency to its original level. Finally, the results are illustrated using a chemical process example.

2. Preliminaries

We consider a plant comprised of a network of interconnected subsystems with the following state-space representation:

$$\dot{x}_i = A_i x_i + B_i u_i + \sum_{j=1, j\neq i}^{n} A_{ij} x_j \tag{1}$$

where x_i is the state vector, u_i is the manipulated input vector, A_i and B_i are the state and input matrices, respectively, all of the *i*-th subsystem, A_{ij} is the interconnection matrix which captures the coupling between the *i*-th and *j*-th subsystems, and *n* is the total number of subsystems. The various subsystems have local control systems that exchange state measurements over a resource-constrained communication medium. The control objective is to stabilize the overall system at the desired steady state, while simultaneously reducing unnecessary utilization of the communication medium. To simplify the presentation of the main results, we will focus on the state feedback control problem where the states of all the units are assumed to available as measurements.

3. Model-Based Control with Time-Triggered Communication

3.1. Local controller synthesis

To address the control objective, we consider a model-based control strategy similar to the one considered in Sun and El-Farra (2008). The main idea is to embed within the local control system of each unit a set of dynamic models which are used to provide estimates of the states of the neighbouring units in the event when communication between the plant subsystems is suspended. When communication is re-established, the model states are updated using the plant states, at discrete time instances, based on the sensor measured values. The resulting control and update laws are given by:

$$u_i(t) = K_i x_i(t) + \sum_{j=1.j\neq i}^{n} K_{ji}\,\hat{x}_j^i(t),\ t \in (t_k, t_{k+1}),\ \ i \in \{1,2,\cdots,n\} \tag{2}$$

$$\begin{aligned}\dot{\hat{x}}_j^i(t) &= \hat{A}_j\hat{x}_j^i(t) + \hat{B}_j\hat{u}_j^i(t) + \hat{A}_{ji}x_i(t) + \sum_{l=1,l\neq i,l\neq j}^{n} \hat{A}_{jl}\hat{x}_l^i(t)\,,\ t \in (t_k, t_{k+1})\\ \hat{u}_j^i(t) &= K_j\hat{x}_j^i(t) + K_{ji}x_i(t) + \sum_{l=1,l\neq i,l\neq j}^{n} K_{jl}\hat{x}_l^i(t), t \in (t_k, t_{k+1})\end{aligned} \tag{3}$$

$$\hat{x}_j^i(t_k) = x_j(t_k), \qquad k\ \in \{0,1,2,\cdots\} \tag{4}$$

where K_i is the local feedback gain, K_{ij} is the controller gain that compensates for the interactions, $\hat{x}_j^i$ is the state of the model capturing the dynamics of the *j*-th unit embedded in the *i*-th unit, $\hat{A}_j$, $\hat{A}_{ji}$, $\hat{A}_{jl}$ and $\hat{B}_j$ are constant matrices associated the model of the *j*-th unit, and t_k is the update time. Note that, for simplicity, the states of all models are assumed to be updated at the same time.

3.2. Closed-loop stability analysis

An important measure of the extent of network utilization is the update period, *h*, which is defined as the difference between two successive update times, i.e., $h = t_{k+1}$-t_k. To achieve closed-loop stability with minimal communication, it is important to characterize the maximum allowable update period for the control system which dictates the minimum communication frequency required for stability. This characterization can be obtained through a closed-loop stability analysis. Specifically, it can be shown (see Sun and El-Farra (2008) for the details) that the response of the closed-loop system of (1)-(4) in terms of the update period is given by:

$$\xi(t) = e^{\Lambda(t-t_k)}(I_s e^{\Lambda h} I_s)^k \xi_0 = e^{\Lambda(t-t_k)} M^k \xi_0,\ \ t \in (t_k, t_{k+1}) \tag{5}$$

for $k\ \in \{0,1,2,\cdots\}$, where $\xi(t) \coloneqq [\boldsymbol{x^T}(t) \quad \boldsymbol{e^T}(t)]^T$ is an augmented vector of the plant states and model estimation errors between the model and plant states, Λ is the augmented closed-loop matrix which depends on the plant and model matrices as well as the controller gains, I_s is an augmented identity matrix, and $\xi_0 = [\boldsymbol{x^T}(t_0) \quad \boldsymbol{0}]^T$ is the initial condition. By analysing this response, it can be verified that a necessary and sufficient condition for closed-loop stability is to have all eigenvalues of the stability test matrix *M* lie strictly inside the unit circle. This is represented by $\lambda_{max}(M)[A_i, A_{ij}, B_i, \hat{A}_i, \hat{A}_{ij}, \hat{B}_i, K_i, K_{ij}, h] < 1$, where λ_{max} is the maximum eigenvalue magnitude of *M*. This condition can be used to explicitly characterize the maximum allowable update period in terms of the plant-model mismatch and controller gains.

4. Integrating Model Identification and Model-Based Control

In this section, an overview of the proposed methodology is presented first, and is then followed by a discussion of the key implementation issues.

4.1. Overview of the proposed methodology

Fig. 1 summarizes the proposed approach for integrating model identification and model-based control. Initially, the control system is operated at a suitably chosen update period that minimizes communication while ensuring closed-loop stability. The evolution of the closed-loop state is continuously monitored and checked against an instability alarm threshold to determine when the model parameters need to be updated. In the event of a threshold breach, a "safe-parking" protocol is activated to momentarily stabilize the closed-loop system while additional data is collected and a new model is identified. The new model is then checked for stability, and the corresponding communication rate is determined. Finally, the model parameters are updated and the new communication rate is implemented. The algorithm is repeated every time the instability alarm threshold is breached.

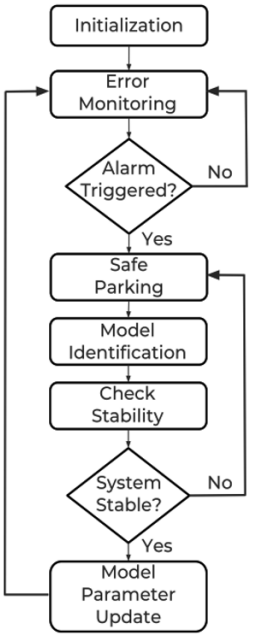

Fig. 1. Flowchart of the algorithm integrating model identification and model-based control.

4.2. Triggering criterion

To determine when a new model needs to be identified, a process monitoring scheme is implemented whereby the closed-loop states are continuously checked to detect potential instabilities caused by the drift in plant parameters. An instability alarm can be designed on the basis of the nominal closed-loop response in (5). Specifically, it can be verified that, in the absence of process parameter variations, the following time-varying bound is satisfied:

$$\|x(t)\| \leq \alpha \cdot e^{-\beta(t-t_0)} \cdot \|x(t_0)\| \tag{6}$$

where $\alpha > 1$ and $\beta > 0$ are tunable constants that depend on the choice of the controller design parameters. Using this bound as a time-varying alarm threshold, instability can be detected once the norm of the state violates the threshold. This acts as a trigger for subsequent steps in the process, culminating in the update of the model parameters. Note that, unlike the model state updates which are time-triggered periodically, the model parameter updates are event-triggered and thus occur less frequently.

4.3. Safe parking and model identification

Once the instability threshold is breached, the plant is switched temporarily to a safe-parking mode of operation where the model state update period is reduced for a certain period of time. The temporary increase in the communication rate serves to maintain closed-loop stability and to collect sufficient data for the model identification step. Model identification is then triggered and new model parameters are obtained. While the choice of the identification method depends on the particular application, subspace techniques are used in this study to identify the new model matrices based on the closed-loop input and state data to keep plant-model mismatch to a minimum. Note that

in the case of time-varying uncertainty where the mismatch continues to deteriorate over time, the safe-parking step may need to be repeated to ensure closed-loop stability.

4.4. Stability check

Once a new model is identified, the closed-loop stability properties are analysed based on the eigenvalues of the new stability test matrix M to determine the range of stabilizing update periods associated with the new model. If either no stabilizing update period exists, or the maximum allowable update period is less than the safe-parking update period, the plant is kept in the safe-parking mode until a stabilizing model with a lower update frequency requirement can be found (possibly using a different identification method); otherwise, the model parameters are updated and the corresponding update period is implemented.

5. Application to a chemical process example

We consider a networked plant comprised of two interconnected non-isothermal continuous stirred tank reactors with a material recycle stream. The control objectives are to stabilize the system at the open-loop unstable steady-state using the heat input rates as the manipulated variables, to minimize the required communication between the two control systems and to account for process parameter variations. The process modelling and controller synthesis details are omitted due to space limitations.

To simulate plant parametric drift, we introduce uncertainty in the plant parameters. We define $\delta = (\Delta H^m - \Delta H)/\Delta H$, where ΔH^m is the nominal values of the heat of reaction used in the plant models. The operating conditions were chosen such that the model states are updated every 4.8 minutes and that there is initially no mismatch between the model and plant states; that is, $h = 0.080$ h and $\delta_1 = 0$. After 1 hour of closed-loop stable operation (see Fig. 2), an uncertainty of $\delta_1 = -0.178$ is introduced in the plant causing a mismatch between the plant and model parameters. It can be seen in Fig. 2 that, starting at approximately the 4th hour of operation, the reactor temperature starts to diverge from the operating steady-state in an oscillatory fashion until the instability alarm threshold is breached and the safe-parking mode is triggered to regain stability.

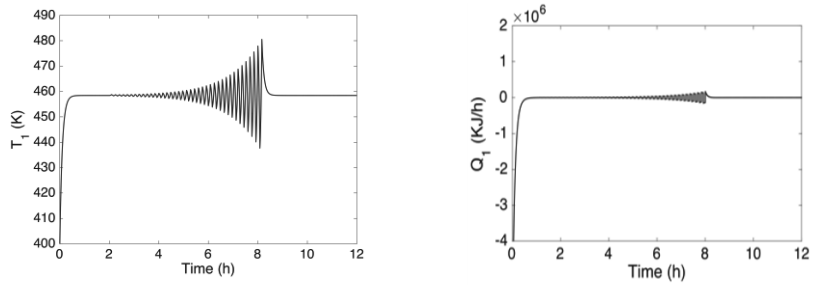

Fig. 2. Closed-loop temperature (left) and heat input rate (right) profiles for the first reactor.

The safe-parking update period is determined from the stability plot in Fig. 3 (see dashed line) which shows that the update period can be reduced to $h = 0.073$ h to stabilize the system. It is noted that it is sufficient to increase the communication frequency to achieve stability; however, the objective here is to maintain stability with low communication frequencies, and model re-identification allows us to continue achieving this balance even after the process drifts. After data has been collected during the safe-parking period, the plant model is re-identified at time = 10 h. At that point, the

stability region of the new model is characterized based on the new stability matrix M and the update period is increased to $h = 0.084$ h to switch the plant out of the safe-parking mode; and, as seen in Fig. 2, maintain stability for the rest of the simulation.

The effect of uncertainty and model re-identification on closed-loop stability can be seen in Fig. 3 which shows the stabilizing ranges for the update period before the uncertainty was introduced, after the error was introduced and the safe-parking mode was invoked, and after the model re-identification took place. Eigenvalues below the critical unit line correspond to stable update periods. It can be seen that when the error is introduced, the stability region shrinks; however, after model re-identification takes place, the stability region increases, thus yielding a larger feasible range of update periods. This translates into stabilization with a lower communication frequency after model uncertainty is introduced.

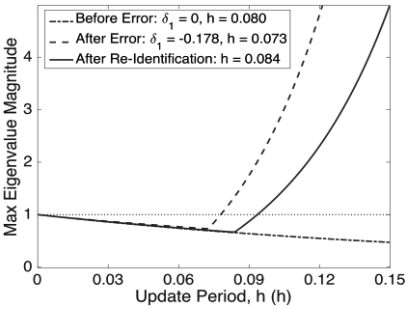

Fig. 3. λ_{max} (M) as a function of the update period under normal operation (dash-dotted), under plant-model mismatch (dashed) and for the identified model (solid).

6. Conclusion

A framework for the integration of time-triggered model-based control and event-triggered model identification for networked process systems subject to process parameter variations and communication constraints was presented in this work. It was shown that by minimizing the plant-model mismatch, model identification techniques can help enhance closed-loop stability with reduced communication requirements. Future work will focus on generalizing this approach to address the output feedback control problem and also explore the effect of the particular choice of the model-identification method on the achievable savings in communication resource utilization.

Abstract

Multiparametric MPC (mp-MPC) is an efficient methodology for computing fast control actions. Control of distributed parameter systems (DPS) remains a challenging task, as the system dynamics are infinite-dimensional. Model reduction of such systems may produce instabilities and thus it is essential that the model reduction methodology used is robust. In this work, a Galerkin-based, efficient model reduction is employed for DPS. The reduced order model is then utilized by the mp-MPC, introducing a novel strategy for computing the critical regions of the approximated multiparametric nonlinear problem. This strategy initializes the solution effectively, reducing the number of the required critical regions and the corresponding computational time. The effectiveness of the proposed algorithm is demonstrated for a tubular reactor where an exothermic reaction takes place.

Keywords: Model reduction, Distributed parameter systems, Nonlinear MPC

1. Introduction

Constrained model predictive control (MPC) is a powerful control strategy, where on-line optimization and a receding horizon are employed to compute the optimum trajectory for the manipulated variables. The use of MPC for DPS, consisting of partial differential equations (PDEs) is computationally expensive (Theodoropoulos 2011, Edgar et al. 1999). The dissipative nature of such systems can be exploited for model order reduction (MOR). Dissipativity can be expressed as the separation of scales in the eigenvalues of the linearized models (Xie et al. 2015). Nevertheless, the computation of the online control action can be problematic even with the use of a reduced model. Mp-MPC has proven to be a powerful control methodology that computes off-line the control actions as functions of the states (Pistikopoulos 2012), overcoming the online computational burden of the classic MPC. Despite the fact that the majority of computations are performed off-line, the large size of the physical system may produce an intractable problem. To tackle this, Rivotti et al. (2012) combine nonlinear mp-MPC (Dominguez and Pistikopoulos 2011) with nonlinear MOR, which is based on balancing of empirical gramians to reduce the size of the system. However, this approach can still be prohibitive for complex large-scale systems, modelled by large sets of PDEs.

In this work, an efficient Galerkin projection-based MOR is applied in order to i) reduce infinite dimensional systems into considerably smaller models and ii) ensure their robustness. The latter is crucial since small open-loop errors may be amplified under the closed-loop conditions, creating spill-over effects (Christofides 2012). Nevertheless, even a reduced system may be computationally expensive, as the number of the critical regions increases steeply with problem size. A novel method is proposed in this work

that can initialize the solution effectively, whilst reducing the number of critical regions and the computational time.

2. Galerkin-based Proper Orthogonal Decomposition

The focus of this work is on feedback control of spatially distributed processes described by dissipative PDEs with the following state-space description, with mixed boundary conditions:

$$\frac{\partial x}{\partial t} = \mathcal{A}\left(\frac{\partial x}{\partial z}, \frac{\partial^2 x}{\partial z^2}, \dots, \frac{\partial^n x}{\partial z^n}\right) + B(z)u + F(x), y = \int_V c(z)xdz \tag{1}$$

where $\mathcal{A}$ is a dissipative, possibly nonlinear, spatial differential operator, $F(x)$ is a nonlinear function, V the spatial domain of the physical system, x the system states, u the manipulated, and y the output variables. The physical system that is represented in Eq. 1 is infinite dimensional and a robust finite dimensional approximation is needed so that spill-over effects are avoided. This is achieved by employing proper orthogonal decomposition (POD) with Galerkin projection. POD is one of the most efficient model reduction techniques, where data compression retains the most 'energy' of the system. The 'energy' of a given mode is related to the magnitude of the eigenvalue corresponding to that mode. The global eigenfunctions (ϕ_i) that efficiently span the system are orthonormal and can be computed with the method of snapshots (Sirovich 1987) after collecting data points using either an experimental set-up or a dynamic simulator. Every basis function is computed as the solution of an integral eigenvalue problem (Xie et al. 2015) and each eigenvalue is associated with a global eigenfunction. Then, the finite dimensional approximation of the infinite dimensional PDE is derived using the Galerkin projection. The infinite dimensional states can be approximated as follows:

$$x(t,z) = \sum_{i=1}^{\infty} a_i(t)\phi_i(z) \simeq \sum_{i=1}^{l} a_i(t)\phi_i(z) + \bar{x} \tag{2}$$

where l is the number of modes that captures the most of the energy, a_i the time coefficients, ϕ_i the orthonormal eigenfunction obtain by POD. Substituting Eq. 2 to Eq.1 and computing the Galerkin projection (taking the $\mathcal{L}_2$ inner product with the eigenfunctions) we get the following for $i = 1 \dots l$:

$$\frac{da_i}{dt} = \int_V \phi_i(z)[\mathcal{A}\left(\sum_j a_j(t)\,\phi_j(z) + \bar{x}\right) + B(z)u + F\left(\sum_j a_j(t)\,\phi_j(z) + \bar{x}\right)]dz \tag{3}$$

The last equation is exploiting the orthonormality of the eigenfunctions in the sense of $\mathcal{L}_2$ inner product. The system now is approximated using a small finite number of modes a_i. The continuous time system in Eq.3 is converted in discrete form using an appropriate integrator (implicit or explicit).

3. Multiparametric Nonlinear MPC

The general mp-MPC case aims to solve the optimization problem for a varying vector of parameters, θ, that are contained in a fixed set, ϑ. The nonlinear continuous multiparametric problem can be stated as:

$$J(\theta) = \min_{\chi} f(\chi, \theta) \tag{4}$$
$$G(\chi, \theta) = 0$$
$$h(\chi, \theta) \leq 0$$

$\theta \in \vartheta$

where χ are the degrees of freedom of the problem, J is the optimum solution, f the nonlinear objective function, G are the equality constraints that usually include the equations describing the physical system, and h the inequality constraints, which include any bounds for the degrees of freedom. MPC for the reduced order system can be written as a nonlinear mp-optimization problem with $\theta = \begin{bmatrix} \alpha^T & u_{-1}^T & y_{ref}^T \end{bmatrix}^T$:

$$J(\theta) = \min_{\alpha,u} h(\alpha, u, \theta) = \min_{\alpha,u} \sum_{i=1}^{N} \left\| y_i - y_{ref} \right\|_Q^2 + \sum_{i=1}^{M} \|\Delta u_i\|_R^2 \quad (5)$$
$$u_i = u_{i-1} + \Delta u_i,\ y_i = C\alpha_i$$
$$G(\alpha, u, \theta) = \alpha_{i+1} - g(\alpha_i, u_i) = 0$$
$$h(\alpha, u, \theta) \leq 0$$
$$A\theta \leq b$$

where $\alpha_i = \alpha(t_i) = [a_1(t_i) \dots a_l(t_i)]^T$, N, M are the prediction and control horizon, respectively, u_{i-1} the manipulated variable at the previous time point, y_{ref} the set-point and g the temporal discretization of Eq. 3.

Mp-nonlinear methodologies, such as the one in (Jahansen 2002), which can be used to solve Eq.5, aim to divide the parameter space in many partitions and approximate Eq. 5 with multiple mp-QP. The state space is partitioned into hyper-rectangles and the main advantage for convex problems is that the approximation error can be a priori computed. In the case of non-convex problems, it is proposed (Johansen 2002) to compare the solution of the implicit NLP and the mp-QP problem at the vertices of each region. This approach appears to approximate the nonlinear problem adequately well, although the computational cost increases steeply with the size of the system. In this work, we develop a number of novel solutions in order to improve the computational efficiency and robustness of nonlinear mp-MPC.

3.1 *The proposed algorithm*

Our proposed algorithm begins with the multiple linearization of the system's dynamics considered to be the main contribution to the nonlinearity of the problem. This means that the approximation of Eq. 5 with multiple QPs can be seen as optimization with a multi-linear model (Bonis et al. 2014) for the corresponding system. To take advantage of this approach, a piecewise affine (PWA) identification problem is considered, where the reduced order system is approximated by a PWA function by employing clustering and piecewise linearization. The collected trajectories (snapshots) for the POD-basis construction can be also used to identify a number of clusters using k-means (Hastie et al. 2009). Cluster centroids can be utilized as linearization points and cluster polyhedral partitions (given by the Voronoi diagram of the clusters' centroids) are used to compute the boundaries of each linear model (multi-category discrimination can be also applied (Breschi et al. 2016)). This step will give a good approximation of the system for different convex regions without separating the phase space in hundreds of partitions as in (Johansen 2002). The solution of mp-multi-linear MPC for the PWA approximation can be then computed. The exact solution of hybrid MPC (Oberdieck and Pistikopoulos 2015) could also be used as an initial approximation but the computational cost would increase. After constructing the initial solution for the critical regions, the approximated solution is compared at the vertices of each critical region with the implicit NLP (Eq. 5). If the result is not satisfactory with respect to ta chosen tolerance, then a refinement step follows.

We, subsequently apply a multiple shooting method to improve numerical stability of the algorithm (side-stepping sequential approaches that are not appropriate for stiff problems) at a point inside each partition (computed through the Chebyshev center). Then, an efficient procedure is built to construct and solve the local mp-QP problem (one for each partition) in the form of Eq. 6.

$$J(\theta) = \min_{U} \frac{1}{2}\Delta U^T H\, \Delta U + (B + F(\theta - \theta_0)^T \Delta U + J^* \tag{6}$$
$$C\Delta U \leq d\Delta\theta + E$$
$$A\theta \leq b$$

$H = \nabla^2_{UU} J|_{\theta_0,U^*}$, $F = \nabla^2_{U\theta} J|_{\theta_0,U^*}$, $B = \nabla_U J|_{\theta_0,U^*}$, $C = -\nabla_U h|_{\theta_0,U^*}$, $d = -\nabla_\theta h|_{\theta_0,U^*}$, $E = -h$ all computed for the optimum set of parameters. The number of the new partitions depends on the size of the critical region but not the size of the parameter space. First and second order derivatives with respect to degrees of freedom and the varying parameters are computed, through numerical perturbations of the equality constraints, and are then substituted in the objective function and in the inequality constraints to produce Eq. 6. If J^* is the optimal solution obtained with the multiple shooting method, for parameters θ_0 and optimal degrees of freedom U^* then, for example, the derivative of the objective function with respect to parameter θ_0 is computed as follows:

$$\frac{\partial h}{\partial \theta_0^i} = \frac{h\left(\alpha_{U^*,\theta_0+\epsilon}, U^*, \theta_0 + \epsilon\right) - h(\alpha_{U^*,\theta_0-\epsilon}, U^*, \theta_0 - \epsilon)}{2\epsilon} \tag{7}$$

where α_{U^*,θ_0} is the solution of $G(\alpha, U^*, \theta_0)$=0 and $\alpha_{U^*,\theta_0+\epsilon}$ the solution of $G(\alpha, U^*, \theta_0 + \epsilon)$=0. This refinement procedure continues until an a priori tolerance is satisfied. If the new mp-approximation creates only one critical region that still does not provide an appropriate solution then the region should be divided according to a geometrical criterion (in this work a triangulation is employed). This approach may produce complex convex geometrical regions; however, the number of regions does not increase as steeply as in (Johansen 2002), and because of the good initial approximation the result doesn't produce many additional critical regions. In the next section, this algorithm is employed to an infinite dimension problem in order to illustrate its computational capabilities.

4. Application

To illustrate the effectiveness of the proposed algorithm, a chemical engineering application is considered, particularly an exothermic tubular reactor. The physical system is described by two partial differential equations with Neumann boundary conditions:

$$\frac{\partial c}{\partial t} = \frac{1}{Pe_1}\frac{\partial^2 c}{\partial z^2} - \frac{\partial c}{\partial z} - Da\, c\, e^{\gamma \frac{T}{1+T}} \tag{8a}$$
$$\frac{\partial T}{\partial t} = \frac{1}{Pe_2}\frac{\partial^2 T}{\partial z^2} - \frac{\partial T}{\partial z} - BDa\, c\, e^{\gamma \frac{T}{1+T}} + b(T_w - T) \tag{8b}$$

Here c and T are the dimensionless concentration and temperature respectively, while T_w is the temperature of the cooling zone. The system's parameters are $Pe_1 = Pe_2 = 7$,$Da = 0.1$, $B = 2.5$, $b = 2$,and $\gamma = 6$. The eigenfunctions are computed employing the method described in section 2, where after the eigenanalysis 2 dominant modes capturing 99.8% of the system's energy are computed. It should be noted that the

number of dominant modes depends on the accuracy required, as well as on the phenomena that dominate the physical system. When diffusion is dominant, a small number of modes is required. When convection dominates, a (slightly) larger number of modes is typically required to capture the system's energy. Then, Eq. 8a, b are projected onto the slow modes using Galerkin projection in order to produce an accurate reduced-order discretized model from the infinite-dimensional one. The reduced model is then used to construct the NLP problem (with Q= Identity matrix (I) and R=0.01I) at each Chebyshev center with $-1 \leq u_i \leq 1$ and $-1 \leq \alpha_i \leq 1$ with control and prediction horizon being 2 time steps. The collected trajectories can then be used to identify the clusters as in section 3.1 and the, mp problem is subsequently solved. The facet in Fig. 1a depicts two reduced variables after the mp-multi-linear MPC solution with 23 critical regions and the final solution is depicted in Fig.1b with tolerance=0.002. Overall 66 critical regions (~1 CPU-hour) are constructed through the refinement process. For demonstration purposes the method of Johansen is also applied here, producing 841 critical regions (over 4 CPU-hour). Then, the controllers are validated for different set-points and the results are depicted in Fig.2. The solution given by the multi-linear MPC has a large offset, but the final solution is adequately close to the actual implicit nonlinear MPC, and as a matter of fact closer to the one provided by Johansen (2002) for the same a priori error bound. This shows the effectiveness of the proposed method. For demonstration purposes, 4 modes were selected for the model reduction and the same algorithm was applied. The algorithm produced 126 critical regions in ~3 CPU-hours.

All the simulations are carried out using a i7 and 16 RAM single threaded machine. All the calculations are implemented in MATLAB, and each mp QP as well as each NLP problem, is solved using the toolbox POP (Pistikopoulos 2012) with NAG Mark 25. It should be noted that global optimization technique will be considered in a future publication.

5. Conclusions

We have developed a reduced order mp MPC suitable for infinite dimensional systems such as ones described by PDEs. POD-Galerkin is employed to produce a reduced order system which is then employed within a new nonlinear mp-MPC algorithm. The effectiveness of the proposed methodology is illustrated through the MPC of an exothermic tubular reactor described by complex nonlinear PDEs. The offline complexity is reduced and the approximated solution is obtained with computational efficiency using a multi-linear solution as an initial partition.

Abstract

A distributed model predictive control (DMPC) strategy brings interesting features of topology, flexibility and maintenance to large-scale nonlinear systems. This work introduces two new cooperative distributed nonlinear model predictive control strategies with automatic partitioning. The first approach is based on oriented graphs of the linearized model of the plant and the second one based on incidence matrices of the nonlinear model of the plant. The proposed strategies were applied to a benchmark plant and compared to other control structures, obtaining promising results.

Keywords: Cooperative Distributed Model Predictive Control, Large-Scale Systems and Partitioning.

1. Introduction

Controlling of large-scale nonlinear systems is still a challenging problem. A distributed model predictive control (DMPC) strategy brings interesting features of topology, flexibility and maintenance to this scenario. The distributed control strategy can be divided into two types: non-cooperative, where each local controller optimizes a local objective function and the cooperative, where each local controller optimizes a global objective function. This paper focuses on the study of the cooperative approach, which may improve performance when compared to the non-cooperative structure by requiring each subsystem to consider the effects of local control actions on all subsystems in the network as presented in the study of Venkat et al., (2008).

The selection of pairs of manipulated input and controlled outputs belonging to each subsystem is still made in most cases based on the physical structure of the plant (Christofides at al., 2013; Jogwar et al., 2009; Kumar & Dautidis, 2002). This is simple for a small-scale system but can become an arduous task in large-scale systems applications. So, the study of a systematic methodology of partitioning presents great applicability in applications of DMPC, mainly in large scale plants.

The objective of this study is to introduce and evaluate two new cooperative distributed nonlinear model predictive control strategies with automatic partitioning. The paper is organized through the following sections: section 2 has the problem formulation, presenting the decomposition methodologies and the cooperative DMPC controller

design. In section 3 a case study is presented along with the results and discussions. Finally, we draw the main conclusions in section 4.

2. Problem Formulation

Let a process be assumed to be described by the following nonlinear ordinary differential equation system: $\dot{\mathbf{x}} = \mathbb{f}(\mathbf{x}, \mathbf{u})$ and $\mathbf{y} = \mathbf{g}(\mathbf{x})$, where $\mathbf{x} \in \mathbb{R}^n$, $\mathbf{u} \in \mathbb{R}^m$ and $\mathbf{y} \in \mathbb{R}^l$ are state variables vector, manipulated variables vector and controlled variables vector, respectively.

This paper proposes two new cooperative distributed nonlinear model predictive control strategies with automatic partitioning. The approached are presented in Figure (1), where the controllers perform the steps presented to calculate their respective control actions. The control methodologies, using the respective partitioning method will be presented in the next section.

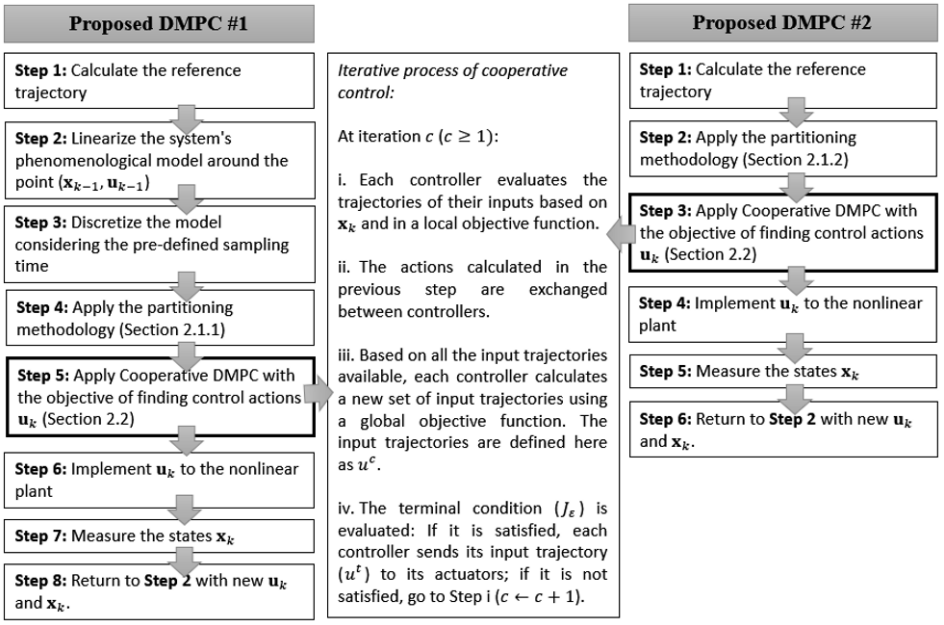

Figure 1: Cooperative DMPC schemes proposed in this work, with emphasis on the iterative process of cooperative control methodology.

2.1. The partitioning methodology

This section presents the partitioning methodologies proposed in this work. The first approach refers to the partitioning from a linear local model of the plant and the second approach from the nonlinear model.

2.1.1 Proposed Cooperative DMPC #1 - Partitioning for linear local model

Partitioning from the linear model of the plant can be applied when the model is linearized around a point of interest. For application in non-linear processes, the non-linear model is linearized around the condition ($\mathbf{x}_{k-1}, \mathbf{u}_{k-1}$) and discretized as a function of the sampling time T_S, obtaining the locally discrete time representation of the process model. The details of the obtained model can be found in Rocha and Oliveira-Lopes

(2016b) and the details of the applied partitioning process are presented in Rocha and Oliveira-Lopes (2016a).

2.1.2 Proposed Cooperative DMPC #2 - Partitioning for non-linear model

In this approach, the partitioning will be applied directly to the non-linear model of the process. In order to perform that consider the following definitions:

Definition 1: Define the incidence matrix of manipulated inputs (**E**), identifying at each $\dot{x}_i = \mathbb{f}(\mathbf{x}, \mathbf{u})$, for $i = 1, \cdots, n$ of the phenomenological model, which input affects $\dot{x}_i$. If there is an effect, the matrix element $e_{ij} = 1$, otherwise $e_{ij} = 0$, where e_{ij} is the *i*-th row and *j*-th column of the incidence matrix of the manipulated inputs, **E**.

Definition 2: Define the incidence matrix of the states (**S**), identifying at each $\dot{x}_i = \mathbb{f}(\mathbf{x}, \mathbf{u})$, for $i = 1, \cdots, n$ of the phenomenological model, which state affects $\dot{x}_i$. If there is an effect, the matrix element $s_{ij} = 1$, otherwise $s_{ij} = 0$, where s_{ij} is the *i*-th row and *j*-th column of the incidence matrix of states, **S**.

Definition 3: Define the incidence matrix of the controlled outputs (**C**), identifying at each $y_k = \mathbf{g}(\mathbf{x})$, for $k = 1, \cdots, l$ of the phenomenological model, which state affects y_k. If there is an effect, the matrix element $c_{kj} = 1$, otherwise $c_{kj} = 0$, where c_{kj} is the *k*-th row and *j*-th column of the incidence matrix of controlled outputs, **C**.

Definition 4: Define a set $\boldsymbol{\varphi}_j = \{\alpha | e_{\alpha j} = 1, \alpha = 1, \cdots, n\}$, in which $e_{\alpha j}$ is the α-th row and *j*-th column element in the **E** matrix. The set $\boldsymbol{\vartheta}_j = \{x_\alpha, \alpha \in \boldsymbol{\varphi}_j\}$ represents the states directly controlled by the input u_j.

Definition 5: Define a set $\boldsymbol{\xi}_j = \{\alpha | s_{\alpha j} = 1, \alpha = 1, \cdots, n\}$, in which $s_{\alpha j}$ is the α-th row and *j*-th column element in the **S** matrix. The set $\boldsymbol{\varrho}_j = \{x_\alpha, \alpha \in \boldsymbol{\varphi}_j\}$ represents the states directly affected by the state x_j.

Definition 6: Define a set $\boldsymbol{\pi}_j$ with the dynamic behaviors of the states ($\dot{x}_i = \mathbb{f}(\mathbf{x}, \mathbf{u})$) that must be included in the submodel $\mathbf{M}\{\boldsymbol{\pi}_j\}$. Each submodel $\mathbf{M}\{\boldsymbol{\pi}_j\}$ will be defined based on the mapping of each state belonging to the set $\boldsymbol{\varphi}_j$ and affecting the output space (from matrix **C** previously defined). If any controlled output is not directly affected by any input, the set $\boldsymbol{\xi}_j$ must be added to the submodel thus including the indirect effects. This setting ensures that the partitioning method is based on the effects of each input on the controlled outputs.

The system partition proposed is based on the Definitions (1-5). A step-by-step algorithm for the introduced decomposition strategy is given as follows:

Step 1: create the set $\boldsymbol{\varphi}_j$ and $\boldsymbol{\xi}_j$, as well as their associated sets $\boldsymbol{\vartheta}_j$ and $\boldsymbol{\varrho}_j$. $\boldsymbol{\vartheta}_j$ is based on the incidence matrix of the manipulated inputs **E**. $\boldsymbol{\varrho}_j$ is based on the incidence matrix of states **S**;

Step 2: create the set $\boldsymbol{\pi}_j$ with the states belonging to the sets $\boldsymbol{\vartheta}_j$ and $\boldsymbol{\varrho}_j$ affecting directing the states that affect the controlled outputs space;

Step 3: compose submodel $\mathbf{M}\{\boldsymbol{\pi}_j\}$ with elements of the set $\boldsymbol{\pi}_j$;

Step 4: merge $\mathbf{M}\{\boldsymbol{\pi}_j\}$ and $\mathbf{M}\{\boldsymbol{\pi}_p\}$ $(j \neq p)$ submodels if $\boldsymbol{\pi}_j$ and $\boldsymbol{\pi}_p$ are identical sets. Create a new set of inputs by merging u_j and u_p inputs.

Step 5: check if the submodel $\mathbf{M}\{\boldsymbol{\pi}_j\}$ is controllable, otherwise additional elements (states) are augmented to $\boldsymbol{\pi}_j$ until that requirement is satisfied.

The described partitioning process will generate submodels $\mathbf{M}\{\boldsymbol{\pi}_j\}$ of the type:

$$\dot{\mathbf{x}}_i = \mathbb{f}_i(\mathbf{x}_i, \mathbf{u}_i) \tag{1}$$

$$\mathbf{y}_i = \mathbf{g}_i(\mathbf{x}_i) \tag{2}$$

where $i = 1, \cdots, M$; $\mathbf{y}_i(k) \in \mathbb{R}^{l_i}$; $\mathbf{x}_i(k) \in \mathbb{R}^{n_i}$; $\mathbf{u}_i(k) \in \mathbb{R}^{m_i}$ are output, state and input vectors of subsystem $\mathbf{M}\{\boldsymbol{\pi}_j\}$.

2.2. Controller Design

The cooperative methodology that occurs in Step 5 (for Proposed DMPC #1) and Step 3 (for Proposed DMPC #2) of the algorithm is shown in detail in Figure (1). At the iteration described in the item *iii*, each controller solves the optimization problem for proposed DMPC #2 shown in Figure (2). The optimization problem performed for the DMPC # 1 approach, as well as the details of the controller design and the iteration structure of cooperative control are presented in Rocha and Oliveira-Lopes (2016b).

$\min_{u_i(k+j\|k),j=0,\cdots,H_{ui}-1} \quad V(k) = \sum_i V_i(k)$ s.t. Eqs. (1) - (2) $\mathbf{y}_i(k+j\|k) \in Y, j > 0, \mathbf{y}_i(k+H_{pi}\|k) \in Y_f$ $\mathbf{u}_i(k+j\|k) \in \Lambda_i, j = 0, \cdots, H_{ui} - 1$ $\mathbf{u}_l(\mathrm{k}+j\|k) = \mathbf{u}_l(k+j\|k)^{c-1}, \forall l \neq i$	with $V_i(k) = \sum_{j=H_{wi}}^{H_{pi}} \left\|\bar{\mathbf{y}}_i(k+j\|k) - \mathbf{r}_{yi}(k+j)\right\|^2_{\mathbf{Q}_i(j)} +$ $+ \sum_{j=0}^{H_{ui}-1} \|\bar{\mathbf{u}}_i(k+j\|k) - \mathbf{r}_{ui}(k+j)\|^2_{\bar{\mathbf{R}}_i(j)} +$ $+ \sum_{j=0}^{H_{ui}-1} \|\Delta\bar{\mathbf{u}}_i(k+j\|k)\|^2_{\mathbf{W}_i(j)}$

Figure 2: Optimization problem solved by each controller in the cooperative structure for proposed DMPC #2 (adapted from Christofides at al., 2013).

where $\mathbf{Q}_i > 0$, $\mathbf{R}_i > 0$ and $\mathbf{W}_i \geq 0$ are the state, input and variation of inputs weighting matrices, respectively. H_{wi} represents the beginning of the considered prediction horizon (useful for delayed systems); H_{pi} is the prediction horizon and H_{ui} is the control horizon. $\mathbf{r}_{yi}$ is the reference trajectory defined for the controlled outputs and $\mathbf{r}_{ui}$ is the reference trajectory defined for the manipulated inputs.

3. Application

Consider a plant present in Stewart et al. (2010). The model was adapted from Stewart et al. (2010) resulting in the equations and parameters shown in Rocha and Oliveira-Lopes (2016b). The controlled outputs and manipulates inputs are denoted, respectively $\mathbf{y} = [H_1 \;\; T_1 \;\; H_2 \;\; T_2 \;\; H_3 \;\; T_3]^{\boldsymbol{T}}$ and $\mathbf{u} = [Ff_1 \;\; Q_1 \;\; Ff_2 \;\; Q_2 \;\; F_R \;\; Q_3]^T$.

The sampling time is $T_s = 0.5$ min. The manipulated input constraints for Q_1, Q_2 and Q_3 are defined in the region (0;500) kJ/min and $|\Delta u| \leq 10$ kJ/min and (0;500) kg/min and $|\Delta u| \leq 10$ kg/min for the inputs Ff_1, Ff_2 and F_R. The simulations presented are performed for a prediction horizon $H_p = H_u = 3$; the weighting matrices for centralized, cooperative DMPC and non-cooperative DMPC are set as $\mathbf{Q} = \mathbf{I}_{l\,x\,l}$, $\mathbf{R} = \mathbf{I}_{m\,x\,m}$ and $\mathbf{W} = \mathbf{I}_{m\,x\,m}$, with adequate dimensions. The terminal condition that stops the process of cooperation between controllers is defined as the successive relative variation

of the objective function at each iteration, which should be less than J_ε, in this work a value of $1 \cdot 10^{-2}$ was used.

The purpose of control is to keep the controlled variables at steady state *ss1* until the instant $k = 10$, from this point take it and keep it at steady state *ss2* until the instant $k = 90$, and then return it to the initial condition up to $k = 160$, when the simulation ends.

Table (1) represents the evolution of the partitions for cooperative DMPC proposed #1 and the intervals of sampling time that each partitioning occurs (I_{St}). The model and partitioning update were done at every sampling time, and the number of distinct partitions found by the proposed methodology was updated as necessary throughout the operating space composed by ten different types of graphs representing the process during this transition.

Table 1 – Evolution of partitions for the case study for cooperative DMPC proposed #1

Graphs	***Partition***	I_{St}
G_1:$\{u_1\} \Rightarrow \{x_1,\ x_4,\ x_5,\ x_8\ and\ x_{12}\}$ G_2:$\{u_2\} \Rightarrow \{x_4\}$ G_3:$\{u_3\} \Rightarrow \{x_4,\ x_5,\ x_8,\ x_9\ and\ x_{12}\}$ G_4:$\{u_4\} \Rightarrow \{x_8\ and\ x_{12}\}$ G_5:$\{u_5\} \Rightarrow \{x_1,\ x_4,\ x_5,\ x_8\ and\ x_9\}$ G_6:$\{u_6\} \Rightarrow \{x_4\ and\ x_{12}\}$ G_7:$\{u_5\} \Rightarrow \{x_1,\ x_4,\ x_5,\ x_8,\ x_9\ and\ x_{12}\}$ G_8:$\{u_5\} \Rightarrow \{x_1,\ x_4,\ x_5,\ x_9\ and\ x_{12}\}$ G_9:$\{u_6\} \Rightarrow \{x_{12}\}$ G_{10}:$\{u_2\} \Rightarrow \{x_4\ and\ x_8\}$	**Partition #1:** $\{G_1,\ G_2,\ G_3,\ G_4,\ G_5$ and $G_6\}$	1-11; 129-130; 142-160
	Partition #2: $\{G_1,\ G_2,\ G_3,\ G_4,\ G_7$ and $G_6\}$	12-13; 131-141
	Partition #3: $\{G_1,\ G_2,\ G_3,\ G_4,\ G_7$ and $G_9\}$	14-18
	Partition #4: $\{G_1,\ G_{10},\ G_3,\ G_4,\ G_7$ and $G_6\}$	19-53; 56-59; 91-128;
	Partition #5: $\{G_1,\ G_{10},\ G_3,\ G_4,\ G_5$ and $G_6\}$	54-55; 60-90;

Figure (3) presents the dynamics of the controlled outputs. They show the responses obtained by centralized control, non-cooperative DMPC, cooperative DMPC proposed #1 and cooperative DMPC proposed #2.

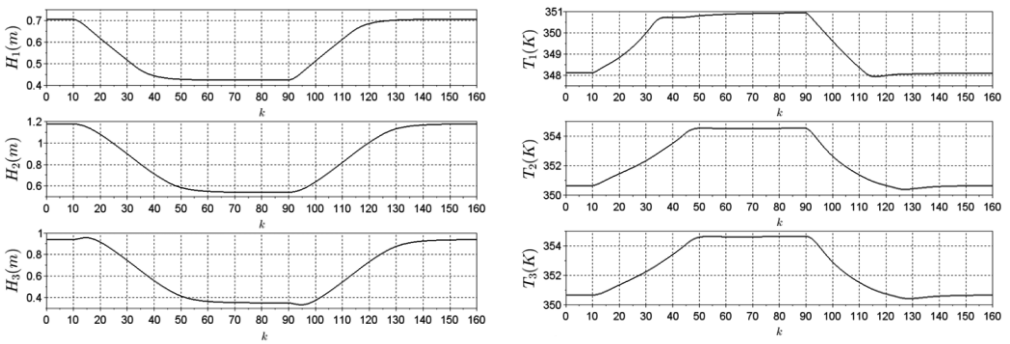

Figure 3: Dynamic evolution of controlled outputs obtained by centralized control and proposed DMPC approaches (overlapping curves).

From the graphical results for the controlled outputs, one can notice that the responses obtained for controlled outputs by the DMPC control structures (non-cooperative, cooperative # 1 and cooperative # 2) are close to those obtained by centralized control (curves overlapping). The performance of each control strategy was evaluated by comparing the absolute error sum of the groups of variables with the same dimension, including the manipulated inputs agreeing with the results Figure (3). The results obtained show the similarity of the performances between the approaches for distributed control and the centralized control. The parameter that will in fact discriminate such

strategies will be the processing time used in the calculation of control actions. The parameter in question is displayed in the Table (2).

No effort for optimizing the computer codes or controller tuning was made. Analyzing Table (2), one can notice that the non-cooperative structures and cooperative DMPC# 2 are the ones with the shortest computer processing time, when compared to centralized control. On the other hand, there was an increase in the processing time for the cooperative control DMPC # 1. This is due to the increase in the number of iterations in the structure in the cooperative process to achieve the same performance.

Table 2 - Comparison of computer processing time

Control Strategy	***Processing Time***
Centralized	$T_C = 57.77$ s
Non-cooperative DMPC	$0.11 \cdot T_C$
Cooperative DMPC #1	$1.52 \cdot T_C$
Cooperative DMPC #2	$0.77 \cdot T_C$

4. Conclusion

This work introduces two new cooperative distributed nonlinear model predictive control strategies with automatic partitioning. The first approach is based on oriented graphs of the linearized local model of the plant and the second one is based on incidence matrices of the nonlinear model of the plant. While the first approach solves a set of linear optimization problem, it requires a larger number of iterations for same performance. The proposed strategies were applied to a benchmark plant and compared to other control structures. The results indicate good performance of the proposed DMPC structures when compared to centralized control. In addition, they presented acceptable computer processing time for the case study evaluated.

Abstract

Accurate characterization of reservoir properties is of central importance to achieve a desired fracture geometry during a hydraulic fracturing process. However, the estimation of spatially varying geological properties in hydraulic fracturing is inherently ill-posed due to a limited number of measurements. In this work, parameterization is performed to reduce the dimensionality of spatially varying Young's modulus profiles via proper orthogonal decomposition (POD), and a data assimilation technique called Ensemble Kalman filter (EnKF) is used to estimate the parameter values in the reduced low-dimensional subspace. Through a series of simulation results, it is demonstrated that the POD-based EnKF technique provides accurate process models with updated spatially varying geological parameters. Next, we use the updated high-fidelity process model in a model predictive control framework to construct a closed-loop system that achieves uniform final proppant concentration in a hydraulic fracturing process.

Keywords: parameter estimation, ensemble Kalman filter, proper orthogonal decomposition, hydraulic fracturing.

1. Introduction

In recent years, the extraction of underground resources such as shale gas and oil, which are trapped in ultra-low permeability formations, has become economically viable due to the advances in well-stimulation techniques such as hydraulic fracturing. In a typical hydraulic fracturing process, water and viscosifying agents such as proppant (e.g., sand or ceramic materials) are introduced to propagate fractures in a rock formation. This process will create a highly-conductive channel through which the oil can be produced from the reservoir (Economides and Nolte 2000). The final fracture conductivity depends on the propped fracture geometry and the proppant distribution throughout the fracture.

Several homogeneous reservoir assumptions have been proposed for the design of optimal control strategies to achieve the desired fracture geometry and uniform proppant concentration at the end of pumping (Gu and Hoo, 2015; Siddhamshetty et al., 2017a). However, field data indicates that even within the same rock formation, the performance of hydraulic fracturing can be notably different. This variability can, in part, be attributed to the spatially varying rock mechanical properties such as the Young's modulus. As a consequence, one of the key tasks, which has to be performed

prior to the controller design, is the characterization of spatially varying rock mechanical properties.

A well-known technique for estimation of states and parameters of a nonlinear system is the ensemble Kalman filter (EnKF) (Evensen, 1994). The EnKF has proven to be very successful in solving large and complex history matching problems within the petroleum industry (Aanonsen et al., 2009). The EnKF assimilates real time data sequentially to provide an updated process model. In a typical hydraulic fracturing process, real time measurements may include downhole pressure and micro-seismic data which will be processed to provide the fracture width at the wellbore and the fracture length, respectively. However, the number of parameters to be estimated far exceeds the measurements owing to the high-resolution required to describe the nonlinear hydraulic fracturing process. To deal with this unidentifiability issue, in this work, we perform parameterization (Afra and Gildin, 2016) using Proper Orthogonal Decomposition (POD) (Holmes et al., 1996) to reduce the number of unknown model parameters, prior to estimation via the EnKF. In particular, POD has been employed to compute the basis functions that retain the dominant spatial trends in the underlying geological properties.

The high-fidelity model of hydraulic fracturing with the updated spatially varying Young's modulus profile is simulated to generate the data required for model order-reduction. The local dynamic mode decomposition with control (LDMDc) methodology, which is developed in our previous work (Narasingam and Kwon, 2017), is then applied to the high-fidelity simulation data to derive reduced-order models. It has been demonstrated that the proposed LDMDc methodology provides accurate approximations to the high-fidelity solutions of nonlinear distributed parameter systems, particularly in the presence of time-dependent spatial domains. These reduced-order models are used in the model predictive controller (MPC) to drive the fracture geometry and the proppant concentration at the end of pumping to their respective set-point values by manipulating the flow rate and inlet proppant concentration at the wellbore.

The rest of the paper is organized as follows. First, we provide a brief description of the the POD-based EnKF methodology for the parameterization and estimation of spatially varying Young's modulus profiles. This is followed by the development of a model-based feedback control system to compute the optimal pumping schedule. Finally, the closed-loop simulation results of hydraulic fracturing process are presented.

2. POD-based EnKF

This section provides a brief description of the POD-based EnKF methodology employed for characterizing the spatially varying Young's modulus profile of the reservoir. Hydraulic fracturing can be modeled as a dynamic process describing the fracture propagation, fluid flow, and proppant transport inside the fracture. For a detailed description of the high-fidelity model, we refer the readers to Siddhamshetty et al. (2017b). While the true values of the spatially varying parameters are unknown, we can assume that we have access to the first two statistical moments (i.e., mean and covariance) of the underlying geological features of the formation, which are often available by analyzing historical data. Using this a priori knowledge, an initial ensemble of R realizations is constructed by adding R different perturbations to the mean of the spatially varying parameter distribution. Now, we apply POD to the ensemble R realizations to approximate its members by a set of basis functions as follows:

$$E(z) \approx \sum_{i=1}^{d} \mu_i \varphi_i(z) \tag{1}$$

Here φ_i denote the orthogonal basis functions that contain the key spatial patterns, μ_i are real-valued coefficients that define the appropriate linear combination of basis functions, and d is the dimension of the reduced parameter subspace. These basis functions induce a parametrization of the spatially varying Young's modulus profile if we allow the coefficients μ_i to be free. Below is the sequence of steps involved in the estimation of spatially varying parameters using the POD-based EnKF scheme.

1. Generate R realizations of the unknown parameter fields, $E = \{E^1, \dots, E^R\}$, using the mean and covariance functions available from the prior knowledge.
2. Parameterize the ensemble of realizations via POD, and compute the spatial basis functions $\mathbf{\Phi} = \{\varphi_i(z), \dots, \varphi_d(z)\}$, leaving the coefficients, $\mathbf{M} = \{\boldsymbol{\mu}_k^1, \dots, \boldsymbol{\mu}_k^R\}$, to be free.
3. Given a vector of true measurements, $\mathbf{d}_k$, available at every sampling time t_k, generate R artificial observations for data assimilation.

$$\mathbf{d}_k^j = \mathbf{d}_k + \epsilon_k^j, j = 1, \dots, R;\ \epsilon_k^j \in N(0, \mathbf{C}_D) \tag{2}$$

which can be stored in the columns of $\mathbf{D}_k = \{\mathbf{d}_k^1, \dots, \mathbf{d}_k^R\}$. Here ϵ is a random perturbation drawn from a normal distribution such that $\epsilon \in N(0, \mathbf{C}_D)$, where $\mathbf{C}_D$ is the covariance matrix of the measurement noise.

4. *Forecast* : At time t_k, for every realization in the set $\mathbf{M}$, the forecast of the ensemble, $\mathbf{X}_k^f = \{\mathbf{X}_k^{1,f}, \dots, \mathbf{X}_k^{R,f}\}$, is generated according to:

$$\mathbf{X}_k^{j,f} = \begin{bmatrix} \boldsymbol{\mu}_k^{j,f} \\ \mathbf{y}_k^{j,f} \end{bmatrix} = \begin{bmatrix} \boldsymbol{\mu}_{k-1}^{j,a} \\ \mathbf{h}(\boldsymbol{\mu}_{k-1}^{j,a}, \mathbf{u}_{k-1}) \end{bmatrix} \tag{3}$$

where $\mathbf{X}_k$ is an augmented state vector that contains unknown model parameters $\boldsymbol{\mu}_k$ and the corresponding outputs $\mathbf{y}_k$ given by a nonlinear operator $\mathbf{y}_k = \mathbf{h}(\boldsymbol{\mu}_k, \mathbf{u}_k)$ described by the high-fidelity model and the superscripts f and a denote the forecast and assimilation steps, respectively. Since the predicted outputs and the model parameters are nonlinearly related, by including them in the augmented state vector as above, the relationship between $\mathbf{y}_k$ and $\mathbf{X}_k$ is given by the following linear expression.

$$\mathbf{y}_k = \mathbf{H}\mathbf{X}_k = [\mathbf{0} \quad \mathbf{I}] \begin{bmatrix} \boldsymbol{\mu}_k \\ \mathbf{h}(\boldsymbol{\mu}_k, \mathbf{u}_k) \end{bmatrix} \tag{4}$$

5. *Assimilation* : The covariance matrix, $\mathbf{C}_k$, associated with the ensemble of augmented states at time t_k is computed as:

$$\mathbf{C}_k = \frac{1}{R-1}\left(\mathbf{X}_k^f - \overline{\mathbf{X}}_k^f \cdot \mathbf{1}_R\right)\left(\mathbf{X}_k^f - \overline{\mathbf{X}}_k^f \cdot \mathbf{1}_R\right)^T, \quad \overline{\mathbf{X}}_k^f = \frac{1}{R}\sum_{j=1}^{R} \mathbf{X}_k^{j,f} \tag{5}$$

where $\overline{\mathbf{X}}_k^f$ denotes the ensemble average of the augmented states and $\mathbf{1}_R$ is a row vector whose elements are all equal to 1. The update to the model parameters and predicted outputs is then computed as:

$$\mathbf{K}_k = \mathbf{C}_k\mathbf{H}^T\left(\mathbf{H}\mathbf{C}_k\mathbf{H}^T + \mathbf{C}_\mathrm{g}\right)^{-1}, \quad \mathbf{X}_k^a = \mathbf{X}_k^f + \mathbf{K}_k\left(\mathbf{D}_k - \mathbf{H}\mathbf{X}_k^f\right) \tag{6}$$

where $\mathbf{K}_k$ is the Kalman gain of the ensemble at time t_k.

6. The sequence of forecast and assimilation steps is repeated until all the available measurements are assimilated. The mean of the final ensemble along with the previously obtained basis functions are used to compute the unknown spatially varying Young's modulus profile, according to Eq. (1).

3. Optimal pumping schedule design

Following the parameter estimation, we focus on the design of a model-based feedback controller for achieving uniform final proppant concentration in the hydraulic fracturing process. However, due to the infinite-dimensional nature of the high-fidelity model, it cannot be directly used for the controller design. Alternatively, we seek computationally efficient reduced-order models generated by employing the LDMDc methodology developed in our previous work. Once the reduced-order models are generated, we formulate the following MPC problem to design an optimal pumping schedule that will allow us to achieve uniform concentration of the proppant across the fracture at the end of pumping.

$$\begin{aligned}
\underset{C_{0,k}}{Min} \quad & \left(\hat{\mathbf{C}}(t_f) - \mathrm{C}_{target}\right)^T \mathbf{Q}_\mathbf{c}\left(\hat{\mathbf{C}}(t_f) - \mathrm{C}_{target}\right) \\
s.t \quad & \text{Reduced} - \text{order models} \\
& \hat{\mathbf{x}}(t_k) = \mathbf{x}(t_k) \\
& \mathbf{C}_{\min} \le \hat{\mathbf{C}}(t_k + j\Delta) \le \mathbf{C}_{max}, \qquad \forall j = 0, \dots, 10-k \\
& C_{0,k-1+m} \le C_{0,k+m} \le C_{0,k-1+m} + 4, \qquad m = 1, \dots, 10-k \\
& 2Q_0\Delta\left(\sum_k C_{0,k}\right) = M_{prop} \\
& L(t_f) = L_{opt}, \qquad W_0(t_f) \ge W_{opt}
\end{aligned} \tag{7}$$

where $\hat{(\cdot)}$ indicates the predicted state trajectory, C_{target} is the desired set-point value for the final proppant concentration, $\mathbf{Q}_\mathbf{c}$ is a positive definite matrix used to compute the weighted norm, t_f denotes the total treatment time, Δ is the sampling time, t_k is the current time, $\hat{\mathbf{C}}$ is the vector of proppant concentrations, and $C_{0,k}$ is the inlet proppant concentration (i.e., manipulated input) corresponding to k^{th} time interval i.e., $t \in [t_k, t_{k+1})$. The constraints in the above optimization problem correspond to optimality, safety, and economical considerations that need to be accounted for in the controller design. Please refer to Narasingam and Kwon (2017) for complete details on the MPC formulation adopted above.

4. Simulation results

For the high-fidelity simulation, we generated a synthetic spatially varying Young's modulus profile, which is shown in Fig. 1 (dashed line), to be the true parameter profile. We first employed the POD-based EnKF methodology to estimate this true parameter profile. The predicted outputs were compared against the true measurements at every 25 s. The total duration of the process was 1000 s, which gives $k = 40$ time steps. In the numerical experiments, measurement errors were modeled as white noise with the covariance $\mathbf{C}_{\mathrm{g}}$, the value of which was taken as $diag(0.005; 0.008)$. The values of the key process parameters used in the numerical experiments in this work can be obtained from Siddhamshetty et al. (2017b). The results of parameter estimation are shown in Figs. 1 and 2. Specifically, Fig. 1 shows the initial ensemble mean and Fig. 2 shows the final ensemble mean. It is evident from the figure that the POD-based EnKF method provided a very good estimate for the true spatially varying Young's modulus profile after assimilating all the available measurement data. The estimated parameters in Fig. 2 retain the major spatial trend of the true Young's modulus profile.

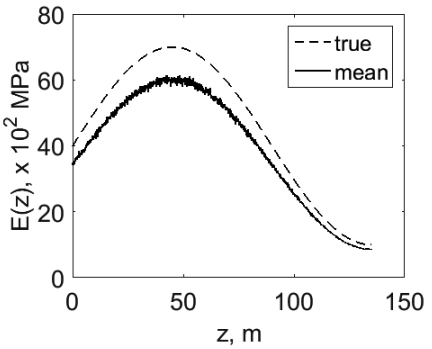

Figure 1. Initial ensemble mean

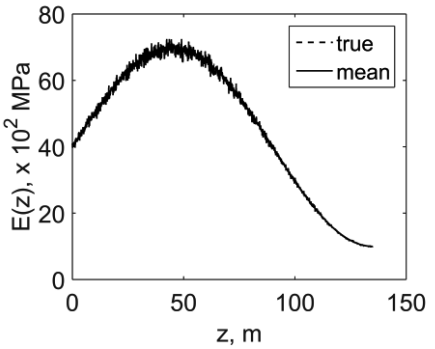

Figure 2. Final ensemble mean

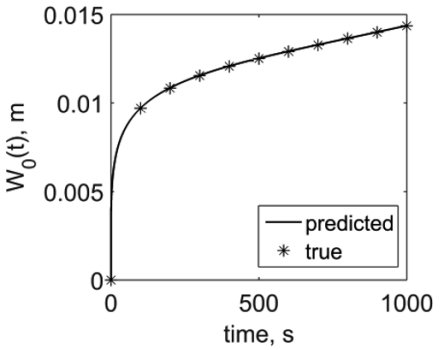

Figure 3. Predicted W_0 and its true measurements

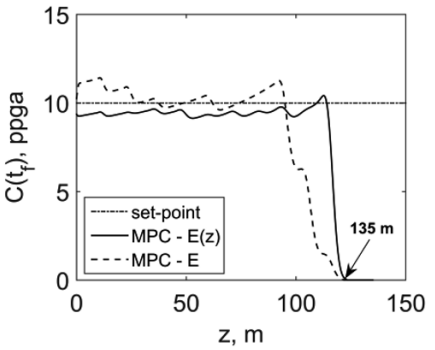

Figure 4. Closed-loop concentration profiles

In addition to finding a good approximation between the true and estimated parameter values, one of the primary objectives of parameter estimation of dynamic models is to accurately predict the process dynamics. This is an important feature in order to design model-based control systems or perform dynamic optimization of the process. The predictive capability of the updated model is evident from Fig. 3, which shows a good match between the true and predicted values of the fracture width at the wellbore, W_0.

With the updated spatially varying Young's modulus profile, reduced-order models were developed via LMDMC, which was then used to design a model-based feedback control system. For the sake of illustrating the effect of not characterizing the spatially varying Young's modulus profile prior to the design of feedback control systems, we have also designed a closed-loop system under MPC based on a constant Young's modulus profile, which was fixed at $E = 50 \times 10^2$ MPa across the fracture. The results are presented in Fig. 4 which shows a comparison of the final concentration profiles achieved by the respective closed-loop systems under MPC. Clearly, the proposed controller with the updated parameter profile drives the final proppant concentration (solid line) towards the target value (dotted line) while propagating the fracture to the desired length (arrow). On the other hand, when the rock properties are not characterized accurately, it can result in a poor controller performance, i.e., non-uniform final concentration profiles (dashed line), thereby diminishing the productivity.

5. Conclusions

In the present work, we have combined POD and the EnKF techniques to successfully estimate the unknown Young's modulus distribution in a hydraulic fracturing process. Parametrizing via POD resulted in a significant increase in the identifiability of the original parameter estimation problem, i.e., the number of variables to be estimated in the data assimilation framework is reduced considerably. We also observed significant predictive capabilities from the updated parameter profile while still retaining the underlying spatial trends in the Young's modulus profile. The update parameter profile is then used in the design of a closed-loop controller to drive the proppant concentration profile at each spatial location to a uniform target value at the end of pumping. Comparison of closed-loop simulation results shows the significance of accurately characterizing the spatial variability in the reservoir parameters on the productivity of hydraulic fracturing.

Abstract

In this contribution, a model-based approach for the control and stable operation of a mini-plant for homogeneously catalysed reactions in microemulsions is presented. Within these systems, the control of the crucial reaction and phase separation steps is hindered by sensitive shifting operation windows and immeasurable concentrations. Combining the optical observation of the separation state and an underlying phase separation model, a soft-sensor is created to identify these relevant concentrations. Together with plant measurements, a moving horizon state estimation is used to calculate a consistent and validated state of the full plant model, which is then used in a dynamic optimization to calculate optimal trajectories for the mini-plant operation. Hereby, a stable separation is achieved for up to 200 h mini-plant campaigns, alongside an efficient reaction performance with up to 38 % yield and a chemoselectivity of 95 %.

Keywords: Soft-sensor, State Estimation, Microemulsion, Mini-plant.

1. Introduction and Motivation

In recent years, tunable solvent systems, which especially enable new synthesis paths for the conversion of usually long-chained bio-based starting materials, have emerged. Substitutionary, a surfactant containing system for the hydroformylation of long-chained alkenes towards the corresponding aldehydes, using aqueous catalyst solutions is regarded within this contribution (see Figure 1). The induced microemulsion provides a large interfacial area for increased reaction rates in a reactor. Subsequently, a gravity settler allows for an efficient separation of the products (oil phase), as well as the catalyst recycling (aqueous phase) using a gravity settler.

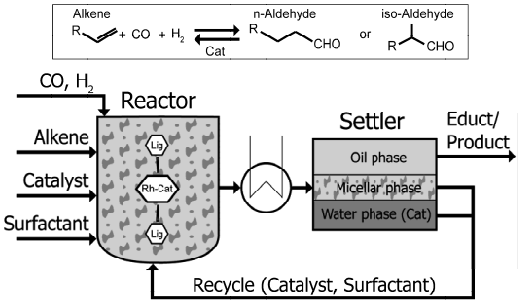

Figure 1: General process concept for the hydroformylation reaction in microemulsions

To test this concept, a mini-plant has been built and operated (Illner et al., 2016). However, the operability of such a system remains critical due to the complexity of the component system and immeasurable states. Since standard automation approaches fail in this case, a stable operation can be achieved with model-based strategies. This comprises a detailed investigation of the phase separation system, from which a soft-sensor is derived to gain relevant information on concentrations in the plant. Subsequently a state estimation can be carried out to calculate initials for the complete plant model. A dynamic real-time optimization is then used to generate optimal trajectories for the set points of the mini-plant's base automation controllers. To prove this concept, long-term min-plant campaigns of up to 200 h were carried out, aiming for a stable operation of especially the crucial phase separation and the reaction step.

2. System Information and Technical Application

Investigations on the afore mentioned process concept are carried out for the exemplarily alkene 1-dodecene, the surfactant Marlipal® 24/70, and a catalyst solution consisting of water, a rhodium precursor (CAS: 14874-82-9) and SulfoXantPhos.

2.1. Mini-plant Set-up

The constructed mini-plant consists of a feed section, holding feed tanks for the used components and corresponding feed pumps, which supply a high-pressure reactor, equipped with a gassing stirrer. The separation is carried out in a self-constructed settler unit augmented with gauge glasses and three drains. Thus, three developed phases can be recycled individually within the process, whereas the oil phase is also conveyed towards a product tank. The plant is fully automatized with SIEMENS PCS 7 and offline gas chromatography is used for the sampling of liquids. Further information on the system, safety layers, and analytics can be found elsewhere (Illner et al., 2016).

2.2. Separation Behaviour of Microemulsion Systems and Operation Window

A ternary mixture of water, oil, and a surfactant, is characterized by the formation of microscopic scale structures, so called micelles. The formation of micelles, their type, and the development of excess phases is influenced by temperature and concentration (Figure 2, left). For the depiction hereof, the Kahlweit's Fish plot in Figure 2 is used.

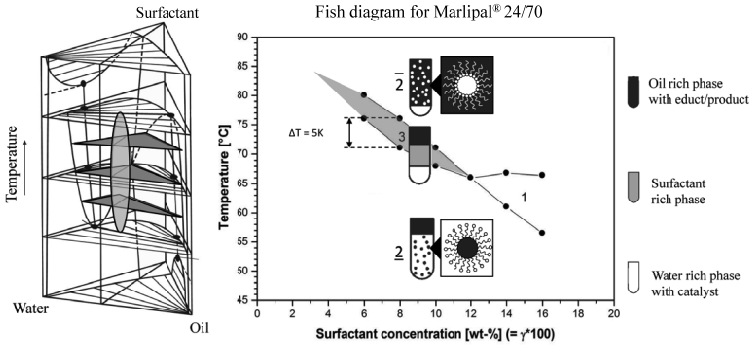

Figure 2: Left: Gibb's phase prism for oil, water, and a nonionic surfactant. Grey areas indicate three phasic miscibility gaps. Taken from (Stubenrauch et al., 2009). Right: Kahlweit's Fish plot with temperature dependent separation regimes for the applied component system. Adapted from (Pogrzeba et al., 2017)

Regarding the process concept, only the three-phase region (3) is feasible, due to the high catalyst loss towards the oil phase in the $\overline{2}$-state and the nonviable slow separation for the $\underline{2}$-state. Thus, an operation region for a successful phase separation is identified.

2.3. Operation Challenges

Controlling the phase separation state for a plant operation requires the identification of relevant influence parameters, their measurability and controllability. Table 1 hereof lists relevant process variables, which directly influence the position of the three-phase region. Besides the separation temperature, which is easily accessible and measured in sufficient accuracy, relevant influence parameters are only available with a large delay (concentration measurements) or are not accessible at all (surfactant concentration). Especially the latter hinders the controllability of the system dramatically, since also the influence on the position and expanse of the phase separation operation window is the largest (see Figure 2). Thus, frequent failures of the separation are to be expected, even with only small perturbations of a steady state operation point. Moreover, Müller (2017) and Illner (2016) reported an affection of the hydroformylation reaction through the separation state, resulting in a reduction of the selectivity towards the target product.

Table 1: Process variables influencing the phase separation, their sensitivity on the separation operation region location, measurability, and controllability. STD: Relative standard deviation of nominal measurement value at standard operation point.

Process variable	Sensitivity on separation	Measurability	STD in %	Sampling frequency	Control element
Temperature T	high	Temperature sensors	0.003	1 s	Heater settler
Oil to water ratio α	moderate	Offline gas chromatography	0.7	1 h	Feed pump
Product concentration X	moderate	Offline gas chromatography	0.7	1 h	Feed pump, residence time
Surfactant concentration γ	very high	Not available	-	-	Feed pump

3. Model Development and Control Strategy

To enable controllability and stable operation a model-based description of the separation behaviour is developed and a soft-sensor for relevant concentrations is derived thereof. To account for the dynamic and non-steady state process behaviour, the development of operation trajectories from a dynamic optimization is employed.

3.1. Phase Separation Model and Surfactant Soft-Sensor

Since no generic thermodynamically driven description of microemulsion systems is available, an empiric model is created based on experimental data. The main idea is to exploit the separation characteristics for the desired three-phase region (3). For constant temperature T and pressure p, the mixture of oil, water, and surfactant, separates into three phases with certain compound concentrations c_i^{Phase}. This corresponds to the corners of the triangle miscibility gap in the ternary diagram (see dark grey area in the Gibb's phase prims in Figure 2). If the mixture concentration is varied, the same individual phases with an equal composition will occur, but the volume fractions will be

shifted. Thus, a correlation between the compound concentrations in the initial mixture $c_i^{Mixture}$, the volume fractions φ^{Phase} and compound concentrations c_i^{Phase} is derived:

$$c_i^{Mixture}(T,p) = f\left(c_i^{Phase}(T,p), \varphi^{Phase}(T,p)\right) \tag{1}$$

A full factorial design of experiments over the relevant influence factors (Table 1) at varying levels (e.g. 4 for α and 10 for T) according to the factor's sensitivity is used to gather results on φ^{Phase}. Using this, Equation 1 is transferred into a smooth polynomial model with the inputs φ^{Phase}, T, and p and a respective maximum order (2, 2, 1), as well as fixed parameters c_i^{Phase} and P_n. The component concentrations c_i^{Phase} are gathered using offline gas chromatography measurements as well as the determination of density and the temperature dependent critical micelle formation concentration, which represents the surfactant concentration in the oily and aqueous excess phase. Subsequently, the surfactant concentration in the settler becomes accessible with a soft-sensor. The combination of the optical observation of the separation performance through gauge glasses via a webcam and an automated image processing results in frequent information on developed phase heights in the settler. Together with the geometric information of this unit, φ^{Phase} is calculated and used together with the settler temperature measurement to identify the settler mixture concentrations $c_i^{Mixture}$.

3.2. Calculation of optimal trajectories

With this approach, the first-time online identification of relevant surfactant concentrations for the microemulsion system at hand is possible and enables further control strategies. Therefore, a discretized dynamic mini-plant model described by Müller et al. (2017) is used. This also includes the transition to a failing separation, resulting in nonlinear, non-smooth (optimization) problems, which is dampened, using sigmoid functions. As a first step, measurement data from the mini-plant, offline gas chromatography sampling and the surfactant soft-sensor is collected and processed in a data conciliation and moving horizon state estimation framework. Extending the work of Hoffman et al. (2016) for dealing with gross errors, the handling of different sampling rates (see Table 1) is incorporated here. This is done by first solving the optimization problem for a reduced plant model containing only component mass balances to estimate stream and level information. Subsequently, when additional deferred concentration measurements are available, the full problem is solved and updated. Gaining validated initials of the full mini-plant model, a dynamic optimization is then carried out. The objective is to maximize the reaction product content in the product stream within the next 4 h. Constraints apply on the reactor and settler surfactant concentration and oil to water ratio in order to maintain an efficient reaction and a stable separation. This results in optimal trajectories for the controller set points of feed streams, recycle streams, and settler temperature (decision variables).

4. Application on Mini-plant Operation

A mini-plant campaign was conducted for a total of 180 h, with several transitions. The startup was realized by feeding the required compounds and initializing a full recycle operation. The reaction was started by the insertion of syngas. In parallel, the optimizer was started and calculated trajectories were applied within the process control system.

4.1. Separation performance

The overall separation performance is evaluated by the amount of oily substances (reaction educts and products) in the settler oil phase, as well as the catalyst leaching. Here, an excellent separation was achieved with a mean oil phase purity of > 99.5 % and a catalyst leaching below 0.1 ppm. Additionally, the effect of the applied optimization and soft-sensor approach is depicted in Figure 3. For a reference time frame of 2 h, the separation performance was observed via a gauge glass. The corresponding evaluation of the soft-sensor implies a reduction of the surfactant concentration, which consequently established with a reduction of the middle emulsion phase fraction. As a control action, the optimizer calculated the addition of surfactant to retain the desired operation point.

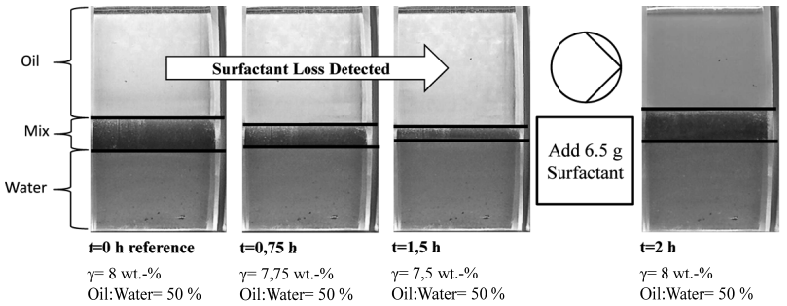

Figure 3: Gauge glass images of the settler over an operation horizon of 2 h and results of the soft-sensor calculations. The right picture shows the separation state after a performed control action derived from the dynamic optimization.

4.2. Reaction

Figure 4 shows the mini-plant reaction performance for the applied reaction residence time of 7 h, whereas a steady state conversion of the applied alkene 1-dodecene of 40 % was achieved. Moreover, a chemoselectivity towards the main product tridecanal of 95 % was observed. This meets results from reference lab scale investigations and shows a successful transfer of the process concept into the mini-plant.

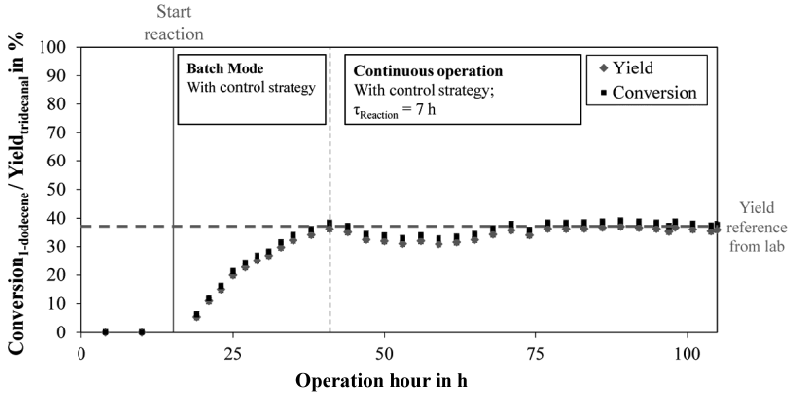

Figure 4: Mini-plant operation results for the conversion of 1-dodecene and the yield of the main product tridecanal for different operation modes.

5. Conclusions and Outlook

Within this contribution, a model-based approach has been presented to cope with the highly dynamic and non-steady state process behaviour of a hydroformylation process in microemulsions. Herein, an empiric model for the separation state and a soft-sensor for the identification of immeasurable surfactant concentrations are used to calculate valid initials for a full mini-plant model. Using calculated trajectories from a dynamic optimization, controller set-point of the process control system a stable mini-plant operation with successful reaction and separation was achieved.

Future works will focus on the online application of the presented framework, using OPC UA to directly interface the process control system. Additionally, the state estimator is to be extended towards a simultaneous handling of multiple sampling rates. Finally, further mini-plant operations will focus on testing the robustness of the used optimization framework regarding multiple or large perturbations.

6. Acknowledgements

This work is part of the Collaborative Research Centre 'Integrated Chemical Processes in Liquid Multiphase Systems' (subproject D2/D4) coordinated by the Technical University of Berlin. Financial support from the German Research Foundation (Deutsche Forschungsgemeinschaft, DFG) is gratefully acknowledged (TRR 63). Furthermore, the authors gratefully acknowledge the support of Umicore N.V. for sponsoring the rhodium catalyst precursor 'Acetylacetonatodicarbonylrhodium(I)' (CAS: 14874-82-9), Sasol Ltd. for the surfactant used in the described experiments, the support of SIEMENS AG for sponsoring the entire process control system, SIMATIC PCS7 for the automation of the mini-plant, and Rhodius GmbH for sponsoring the knitted fabrics.

Abstract

The Organic Rankine Cycle (ORC) is a thermodynamic process capable of utilising low temperature heat sources such as geothermal reservoirs and industrial waste heat. For an ORC system to be effectively controlled and operated, it is important to develop an understanding of the dynamic behaviour of the system and its components. One such aspect is the response of the plant in off-design scenarios that may not occur during normal day-to-day operation. Developing this understanding by performing tests on a real plant can be impractical as plant safety may be compromised. In this paper, dynamic simulation models are used as tools for plant and control design to partially circumvent the need for these potentially unsafe tests. Using a 75 kW waste heat ORC plant as a basis, a dynamic simulation model of an ORC plant was developed using VMGSim, a commercial flowsheet simulator.

A control strategy using conventional PID controllers was designed to maintain safe operation of the plant by regulating the expander inlet pressure and degree of superheat in the working fluid vapour. The response of the plant to a major process disturbance from an up-stream process in the form of a decreased exhaust gas flow rate was studied by performing step tests of varying magnitudes. The dynamic testing revealed that the superheat response exhibited non-linear behavior linked to the vaporizer. Despite this, the proposed PID-based control system was shown to be sufficient in keeping the plant in safe operating conditions under process disturbances that occur during day-to-day operation. Alterations to plant operation are suggested to account for different cooling air temperatures across the year to achieve consistent plant performance. Finally, simulations of a major process disturbance in the form of a decreased exhaust gas flow rate established the limit of operation of the proposed control system.

Keywords: Organic Rankine Cycle, Dynamic modelling, Process Control.

1. Introduction

Between the rapid growth of the world's population, and the advancement of developing countries, the stress placed on conventional energy sources is rising. In response, the amount of research and development of various alternative energy sources has increased. Biomass, solar, geothermal and industrial waste heat are just some of many alternative sources that have shown promise in their ability to alleviate the world's energy demand.

However, conventional power generation methods are unable to efficiently convert the above heat sources into power due to their lower temperatures. For instance, a standard steam Rankine cycle does not allow efficient utilisation of heat below 370 ◦C. One

solution to this problem that has been investigated is the use of the Organic Rankine Cycle (ORC). The ORC applies the same operating principles as the steam Rankine cycle to generate energy, but instead uses an organic working fluid, as opposed to water, that has a lower boiling point than water, allowing for the recovery of usable energy from these lower temperature heat sources.

The control system which regulates the plant is a key component of any ORC system. For an ORC system to be effectively controlled and operated, it is important to develop an understanding of the dynamic behaviour of the system and its components. One such aspect is the response of the plant in off-design scenarios that may not occur during normal day-to-day operation. Developing this understanding by performing tests on a real plant can be impractical as plant safety may be compromised.

In this paper, dynamic simulation models are used as tools for investigating these major process disturbances, circumventing the need to perform potentially unsafe tests. Using a 75 kW waste heat recovery ORC pilot plant as a basis, a dynamic simulation model of an ORC plant is built using VMGSim, a commercial flowsheet simulator. From this model, a control strategy is designed to maintain safe operation of the plant. Finally, the impact of a major process disturbance in the form of a decreased exhaust gas flow rate on the plant's performance is examined using the ORC plant model.

1.1. Simulation of off-design performance

Most studies use dynamic models to explore behaviour of ORC plants under scenarios that might be experienced under normal day-to-day operation. Zhang et al. (2013) utilised a dynamic model to assess the set point tracking ability of their proposed control system while Peralez et al. (2013) used mappings of exhaust gas temperature and flow rates to test the disturbance rejection ability of the proposed control system. However, there is little research on the simulation of an ORC plant outside of normal day-to-day operation, such as start-ups and shut downs, or major process disturbances outside of what can reasonably be anticipated. One example that does is a paper by Antonelli et al. (2015), which models the start-up of an ORC through the ramping of available thermal energy from the heat source, and assessing the time required to reach steady state to compare control systems. More generally, Ramzan and Witt (2007) use dynamic simulation in combination with Hazop to develop an Extended Hazop methodology that provides quantification of the risk posed by operation disturbances in a plant. In a similar vein, a dynamic model of an ORC plant can be used to study its response to major process disturbances, with the results of the simulation then used to provide quantification of risk and consequence in safety analysis.

2. System description

The Above Ground Geothermal and Allied Technologies (AGGAT) programme in New Zealand brings together industry, academic and international partners to deliver new AGGAT products using an established platform of research and development and a functioning innovation pipeline. One aim of the AGGAT programme is to develop an ORC manufacturing industry in New Zealand. A pilot waste heat ORC developed as part of the AGGAT programme is used as the basis of this study. A schematic of this ORC plant is shown in Figure 1.

In this ORC, R245fa is used as the working fluid, being heated by two sources: hot jacket water followed by hot exhaust gas from a set of landfill gas engines. The working fluid is

vaporised at constant pressure to a superheated vapour state before it is passed through the turbine to generate power. The fluid at the turbine outlet is passed through an air cooled condenser to condense it to a liquid. The liquid is then pressurised in a pump before being passed back to the vapouriser. This pilot ORC is designed to produce approximately 75 kW of power, similar to other small-scale waste heat recovery ORCs (Hou et al., 2014).

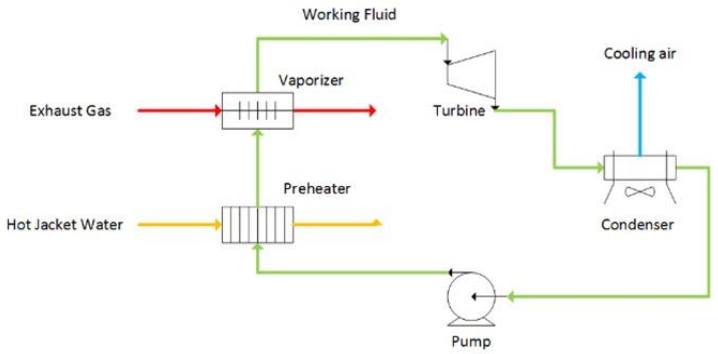

Figure 1: Schematic diagram of the ORC pilot plant

3. Dynamic modelling

The ORC system studied in this paper is modelled using VMGSim, a commercial flowsheet simulator. VMGSim contains a variety of pre-built unit operations and thermodynamic data that has been validated by the software owners and extensive use in different industrial applications. The models within VMGSim are much simpler than their numerically modelled counterparts from literature, allowing for a simpler and more accessible modelling process that requires less computational effort. Although the VMGSim unit operations lack some of the complexity present in numerical models, they have been utilised previously to model a large scale geothermal ORC plant in Proctor *et al*. (2016) with a high level of accuracy when compared with real plant data.

In order to model the ORC plant in VMGSim, the relevant unit operations are chosen and connected together by various material streams, using the plant P&ID as a guide. Equipment and stream specifications are then provided to the model. It should be noted that not all stream specifications are required for the system to be modelled as they will be solved by the relevant thermodynamic calculations performed by VMGSim. The model also includes all bypass lines within the plant.

3.1 Heat exchanger models

The heat exchangers are the most simplified unit operation used in the VMGSim model when compared with models in literature. Whilst the pre-heater, vapouriser and condenser are all different types of heat exchanger, they are all modelled using the same heat exchanger unit operation. This unit operation contains some simplifying assumptions:

- That the heat exchanger is a lumped parameter model;
- That the *UA* value (overall heat transfer coefficient, *U*, multiplied by the heat transfer area, *A*) of the heat exchanger is a constant value; and

- That the pressure drop across any side of the heat exchanger can be computed a '*k*' value, representing flow resistance (defined in Eq.(1))

$$m = \mathrm{k} \times \sqrt{\Delta P \cdot \rho} \tag{1}$$

where m represents the mass flow rate, ΔP is the pressure drop across the heat exchanger, and ρ is the density of the inlet fluid.

Based on these assumptions, each heat exchanger is specified by supplying a constant overall UA value and a 'k' value for each side of the heat exchanger. The UA value is calculated using Eq.(2) and Eq.(3) using values from the plant design point.

$$Q = \mathrm{UA} \cdot \mathrm{LMTD} \tag{2}$$

where, for counter-current heat exchangers,

$$LMTD = \frac{(T_{h,in} - T_{c,out}) - (T_{h,out} - T_{c,in})}{\ln \frac{(T_{h,in} - T_{c,out})}{(T_{h,out} - T_{c,in})}} \tag{3}$$

where the subscripts 'h' and 'c' represent the hot and cold streams of the heat exchanger respectively, and the subscripts 'in' and 'out' represent the inlet and outlet streams respectively. Q represents the amount of heat transferred per unit time. It should be noted that the method used to obtain the constant UA value of each heat exchanger does not rely on knowledge of the heat exchanger geometry, significantly reducing the complexity of heat exchanger modelling.

3.2 Turbine and pump models

The best accuracy in modelling the performance of the turbine and the pump used in the plant can be achieved by using manufacturer data. However, this information was not available at the time of writing and therefore other methods were needed. The performance of the turbine and pump was modelled using a built-in curve in the VMGSim unit operation that can predict off-design behaviour. A design point (including speed, power, flow and efficiency) was then specified for the equipment. This was used alongside a 'Simple Curve' derived from Stepanoff (1957) obeying fan laws. Whilst the curves may be applicable to a wide variety of rotating equipment, it is not specific to any particular turbine or pump and thus may be increasingly inaccurate at conditions far away from the design point.

4. Control system

Typically, the control system in an ORC plant has two main objectives: to regulate power generation, as well as ensure process safety. The power generation of the ORC plant is dictated by the pressure ratio through the turbine, which in turn is largely dictated by the high end pressure.

The papers in literature state the need to protect the turbine from the formation of liquid droplets in the turbine, and furthermore identify the effective control of the degree of superheat of the working fluid at the turbine inlet as a key aspect to ensuring plant safety (Zhang et al., 2012; Peralez et al., 2013).

It should be noted that this is normally achieved by controlling the vapouriser level. However, the vapouriser in this system is a finned-tube heat exchanger, with the working fluid flowing in the tube side to counteract the poor convective heat transfer coefficient of the

exhaust gas. The arrangement of the tubes in the finned-tube heat exchanger makes it difficult to implement level control. Therefore, superheat control is used instead. The working fluid flow rate (manipulated variable (MV)) is used to control the degree of superheat (controlled variable (CV)), whilst the exhaust gas flow rate (MV) is used to control the turbine inlet pressure (CV). Simple PID controllers are used to carry out this proposed control strategy. In addition, an exhaust gas bypass controller was included to keep the exhaust gas line pressure constant.

5. Simulation of a major process disturbance

A major process disturbance here is considered as one which causes the plant to be taken out of the range of operation of the control system, but does not trigger an independent layer of protection. The major process disturbance chosen for investigation in this paper is a decrease in the exhaust gas flow rate. This has the greatest impact on the heat input to the system and can be easily affected by changes in the upstream processes.

In order to examine the effect of a decrease in the exhaust gas flow rate, the flow rate was stepped down from the normal operating point of 6,000 kg/h to 4,500 kg/h and then again to 3,500 kg/h. Figure 2 shows the pressure and superheat response of the plant model to step decreases in exhaust gas flow rate to 4,500 kg/h and 3,500 kg/h.

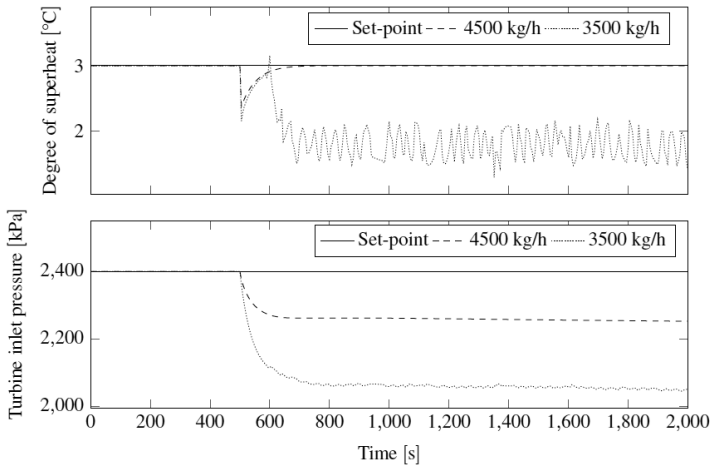

Figure 2: Response of process variables to significant decreases in exhaust gas flow rate

In both cases, there is insufficient heat input to the system for the pressure to return to the set point value, causing the pressure to settle to a value below the set point. Despite this, the working fluid flow rate still adjusts to maintain a constant degree of superheat at the turbine inlet by reducing the valve opening. The stability observed in the change to 4,500 kg/h compared with the instability of the superheat response in the change to 3,500 kg/h indicates that, at some flow rate between 4,500 kg/h and 3,500 kg/h, there is no further decrease in the working fluid valve opening possible, causing the system to become unstable. Interestingly, even though the system is clearly unstable, the degree of superheat remains above 0, indicating that the working fluid is maintained in a superheated vapour state and therefore may not trigger the plant's safety system, such as a turbine bypass.

Further simulations can be performed to more accurately quantify this transition point. Understanding where this point occurs can be useful for quantifying the probability of this situation occurring during real plant operation. By characterising the exhaust gas availability over a long time period, it would be possible to predict the probability that the system would become unstable due to a drop in exhaust gas flow rate, as well as quantify the impact of said disturbance on key plant performance parameters such as power generation. This information can then be used in safety assessments such as layer of protection analysis (LOPA), which in turn would inform decisions on the required layers of protection to ensure an acceptable level of plant safety is achieved. (Center for Chemical Process Safety, 2001). The analysis demonstrated in this paper can be extended to encapsulate other forms of major process disturbances, circumventing the need to perform these tests on a real plant and providing an increased amount of information available in the plant design process.

6. Conclusions

In this paper, a dynamic model for an ORC plant was successfully built using VMGSim and used to analyse the impact of a decrease in exhaust gas flow rate on the system. It was shown the plant was taken out of the range of operation of the control system when the exhaust gas flow rate drops past some value between 4,500 kg/h and 3,500 kg/h. This analysis can be used to quantify the probability of the plant becoming unstable due to this major process disturbance and the impact on the plant's performance, which in turn can be used to inform and improve plant safety and design.

Abstract

A modified two-phase model for gas phase ethylene and propylene copolymerization was used to describe the process in a fluidized bed reactor. The process model considered solid entrainment in the reactor as an improvement to the existing two-phase model assumptions. Conventional controller such as PID is not capable enough to effectively control the process because of its non-linearity. An advanced control strategy (an integration of simple designed fuzzy logic controller (FLC) and generic model control (GMC)) is proposed to control the reactor temperature. This hybrid control system performance was compared to the GMC and PID controller. The simulation results proved that the hybrid Fuzzy-GMC controller performed better than GMC and PID in terms of both set point tracking and disturbance rejection.

Keywords: copolymerization, solid entrainment, modified two-phase model, generic model control, fuzzy logic controller.

1. Introduction

This present work will focus on the copolymerization of propylene and ethylene in fluidized bed reactor (FBR) with two sites Ziegler-Natta catalyst and triethyl aluminium as co-catalyst. The strong interaction between the reactor variables gave additional complexity to the fundamental control problem. Advanced control strategies are needed to cope these problems of which conventional controller are incapable to handle (Ho et al., 2012). Although the studies on the modeling and control of polymerization process in fluidized bed reactor are available in the literature (Akbari et al., 2015, Akbari et al., 2015, Alamolhoda et al., 2015; Ali et al., 2007; Ibrehem et al., 2008; Vahidi et al., 2008) but only a few work has been done especially on the copolymerization of propylene and ethylene, for both modeling and control.

Figure 1 shows the simplified schematic of fluidized bed propylene and ethylene copolymerization reactor. The recirculation of gas will help to remove the heat of polymerization process. The heat removal is crucial since the process is highly exothermic. Hence, it is important to stabilize the reactor temperature above the dew

point in order to achieve not only optimal production rate but also to prevent agglomeration of polymer and reactor thermal runaway.

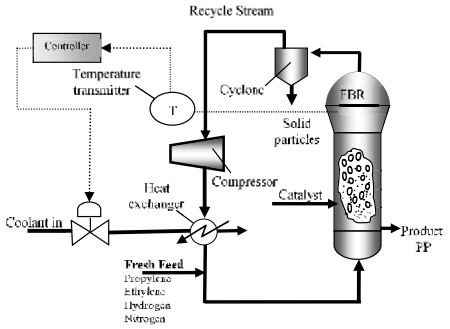

FIGURE 1. Simplified schematic diagram of fluidized bed propylene and ethylene. (from Shamiri et al., 2015)

At the beginning, GMC was chosen to control the temperature of the polymerization reactor since it is easy to implement, as the process model can be applied directly. Fuzzy logic controller was then added to the control strategy since the GMC alone was not sufficient to control the process efficiently. To the best of authors' knowledge, this is the first time that this hybrid Fuzzy-GMC controller is applied to the propylene copolymerization system. A comparative study has been done with the conventional PID controller as well as GMC controller to compare their performance in both servo and regulatory control.

2. Mathematical model

In this study, a modified model developed by Shamiri et al., (2015) is chosen to represent the copolymerization process. It is a modified form of the two-phase model by Shamiri et al., (2011) where in this model, solid entrainment at the top of the reactor has been taken into account.

The energy balance for emulsion phase is as follows:

$$\begin{aligned} &U_e A_e (T_{e,in} - T_{ref}) \sum_{i=1}^{m} [M_i]_e C_{p,i} - U_e A_e (T_e - T_{ref}) \sum_{i=1}^{m} [M_i]_e C_{p,i} - R_v (T_e \\ &\quad - T_{ref}) \left(\sum_{i=1}^{m} \varepsilon_e [M_i]_e C_{p,i} + (1-\varepsilon_b) \rho_{pol} C_{p,pol} \right) + (1-\varepsilon_b) R_{p,e} \Delta H_R \\ &\quad - H_{be} V_e \left(\frac{\delta}{1-\delta} \right) (T_e - T_b) - V_e \varepsilon_e (T_e - T_{ref}) \sum_{i=1}^{m} C_{p,i} \frac{d}{dt} ([M_i]_e) \\ &\quad - \frac{K_e A_e}{W_e (T_e - T_{ref})} \left(\sum_{i=1}^{m} \varepsilon_e [M_i]_e C_{p,i} + (1-\varepsilon_b) \rho_{pol} C_{p,pol} \right) \\ &\quad = V_e \left(\sum_{i=1}^{m} \varepsilon_e [M_i]_e C_{p,i} + (1-\varepsilon_b) \rho_{pol} C_{p,pol} \right) \frac{d}{dt} (T_e - T_{ref}) \end{aligned} \tag{1}$$

3. Control strategy

In this work, generic model control (GMC) controller was used to control the fluidized bed reactor temperature. It is chosen since the process model can be applied directly to formulate the GMC equation, which makes its implementation easier. GMC alone was

observed to be ineffective for the temperature control of the polymerization reactor. Fuzzy logic controller (FLC) is used to solve the oscillation problem in the response by GMC. FLC compensated the outcome from GMC, hence improved the control scheme by manipulating the rate of the cooling water (F_c) to control the reactor temperature.

3.1. Generic Model Control

GMC is highly dependent on the model and is only limited for the systems with linear in control. Implementing the GMC strategy for the propylene copolymerization process, $F(X)$ and $G(X)$ are mass and energy balances of the emulsion phase, U is the coolant flow (F_c), which is the manipulated variable to control the reactor temperature, and $\varepsilon(t)$ is the difference between the emulsion temperature and the desired set point. Based on the energy balance for the emulsion phase from model developed by Shamiri et al., (2015), hence, for the current process, GMC formulation is as follows:

$$F_c = \frac{\propto [K_1\varepsilon(t) + \int_0^{t_f} K_2\varepsilon(t)dt] - F(X)}{G(X)} \tag{2}$$

Where

$$\propto = V_e\left(\sum_{i=1}^{m} \varepsilon_e[M_i]_e C_{p,i} + (1-\varepsilon_b)\rho_{pol}C_{p,pol}\right) \tag{3}$$

$$\begin{aligned} F(X) = {} & (1-\varepsilon_b)R_{p,e}\Delta H_R + H_{be}V_e\left(\frac{\delta}{1-\delta}\right)(T_e - T_b) + U_eA_e(T_e - T_{ref})\sum_{i=1}^{m}[M_i]_e C_{p,i} \\ & + R_v(T_e - T_{ref})\left(\sum_{i=1}^{m} \varepsilon_e[M_i]_e C_{p,i} + (1-\varepsilon_b)\rho_{pol}C_{p,pol}\right) \\ & + V_e\varepsilon_e(T_e - T_{ref})\sum_{i=1}^{m} C_{p,i}\frac{d}{dt}([M_i]_e) \\ & + \frac{K_eA_e}{W_e(T_e - T_{ref})}\left(\sum_{i=1}^{m} \varepsilon_e[M_i]_e C_{p,i} + (1-\varepsilon_b)\rho_{pol}C_{p,pol}\right) + (333.15 \\ & - T_{ref})(U_eA_e\sum_{i=1}^{m}[M_i]_e C_{p,i}) \end{aligned} \tag{4}$$

$$G(X) = \frac{Ke^{-\tau_D s}}{\tau s + 1}U_eA_e\sum_{i=1}^{m}[M_i]_e C_{p,i} \tag{5}$$

GMC performance specifications, K_1 and K_2 is obtained from the generalized GMC profile specification graph by Lee and Sullivan (1988). These values are selected based on the desired response suitable for the process. For the copolymerization process, K_1 = 9 x 10^{-3} and K_2 = 2.25 x 10^{-6}.

3.2. Fuzzy-GMC Hybrid Control

The purpose for the hybrid control scheme is to modify the outcome from GMC, in order to reduce the overshoot problem. A fuzzy-logic controller is used to do the modification then coupled with GMC to control the reactor.

FLC is strongly based on its fuzzy sets, linguistic variables and the approximate reasoning. A set of fuzzy rules are set based on the input and output variables. Its input variables are error, *e* (the difference between set-point and reactor temperature) and $\Delta T_e/F_c$ (quotient of the changes of the reactor temperature and the associated coolant valve rate). The output variable is a factor, f where this value is used to compensate the outcome from GMC ($\Delta F_c = f \times F_c$).

This is a simple designed fuzzy logic controller by using Mamdani method (Mamdani 1976). The membership functions are in triangular form.

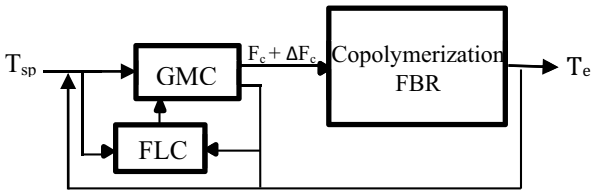

FIGURE 2. Fuzzy-GMC hybrid control scheme

4. Control system analysis

Set point tracking

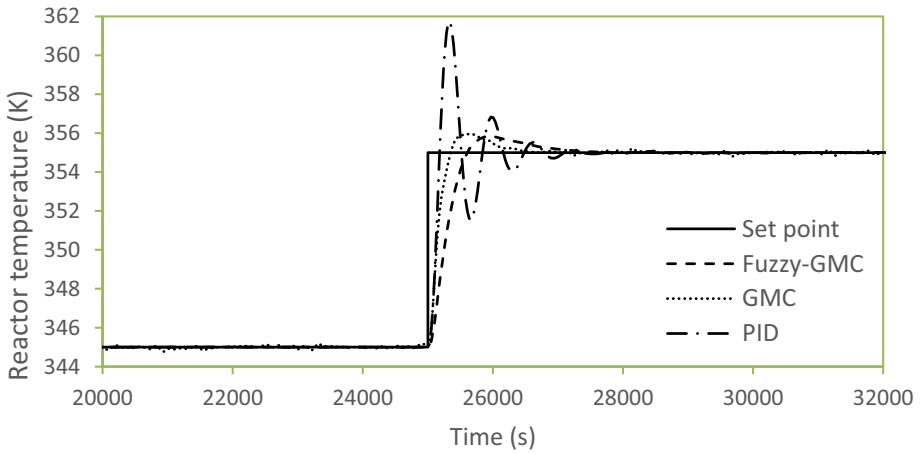

FIGURE 3. Performance comparison of GMC, Fuzzy-GMC Hybrid and PID controller in set point tracking. (PID setting are as follows: $K_c = 24.24$, $\tau_I = 129.5$, $\tau_D = 32.37$)

Figure 3 shows the performances of the controllers tracking the set-point changes. PID controller shows a very high overshoot and low settling time. GMC on the other hand shows lower overshoot and oscillatory response. However, fuzzy-GMC controller manages to track the change in set-point in less than 3000 secs and also slightly reduces the overshoot. Hence, hybrid controller exhibit better performance than GMC and PID controllers (low overshoot and fast and stable response).

Disturbance rejection

A disturbance was introduced to the system to analyse the disturbance rejection capability for each controller. Changes in superficial velocity, U_0 from its nominal value (0.35 m/s) are imposed to the system. At 60000 secs, U_0 is increased to 0.42 m/s.

Based on Figure 4, PID controller is unable to cope with the disturbance since the response did not stop oscillating. Both GMC and fuzzy-GMC hybrid controller exhibit good performance in rejecting the disturbances. The difference is fuzzy-GMC hybrid controller's response has lower overshoot and faster settling time compared to GMC controller.

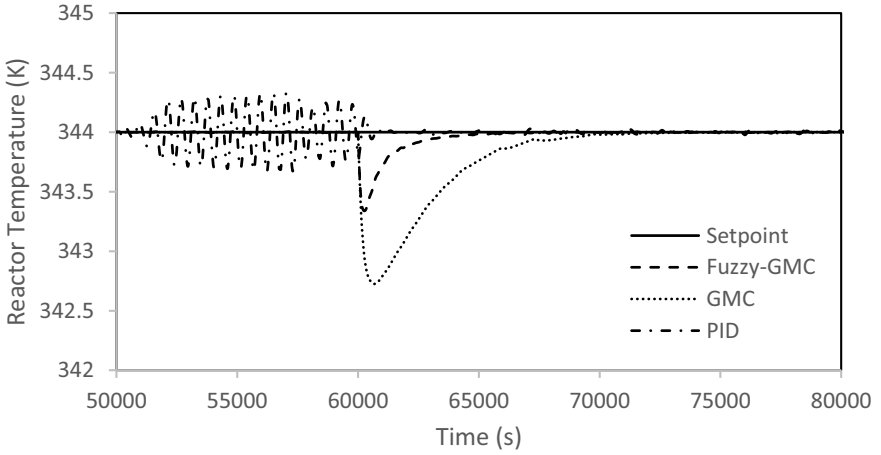

FIGURE 4. Controllers' performance in disturbance rejection.

5. Conclusion

A modified two-phase model that considered solid entrainment in the fluidized bed reactor is utilized in the study to represent the copolymerization process.

A model based controller, GMC is designed to control the temperature of the reactor. GMC gave an unstable and high overshoot response. A hybrid controller is then designed to reduce the instability. Results show that fuzzy-GMC hybrid controller is able to reduce the instability problem and provide the best response in set-point tracking as well as disturbance rejection compared to GMC and PID controller.

Abstract

The work deals with the identification and control of unstable Second Order plus Time Delay (SOPTD) system with positive zero. Presence of positive zero complicates the performance of the control system dynamics. There are many unstable systems which exhibit the second order plus time delay with positive zero such as drum boiler, distillation column. No work has been reported in the literature on identification of unstable SOPTD process with positive zero. In this work, a subspace based method and an optimization method are proposed to identify an unstable SOPTD model with positive zero followed by the PID controller design which can handle set-point changes and disturbance rejection. The subspace-based method uses input-output measurements to estimate the state space model. This method uses projections of block Hankel matrices followed by a singular value decomposition to determine the order of the system. It offers the key advantages on providing low parameter sensitivity with respect to perturbations for higher order systems. The model parameters are also identified using optimization technique by matching the closed loop responses of the process and the model. In any optimization technique, the initial guess plays an important role for proper convergence. A method is suggested to obtain the initial guess values for process gain, poles, zeros and delay. The parameters identified by subspace based method are compared with that obtained using optimization technique. For the models identified by the above two methods, controllers are designed and implemented. Simulation studies on linear and nonlinear systems are demonstrated to evaluate the performance of the proposed methodologies. The closed loop performances comparison can be made in terms of time integral errors and total variation in input variable.

Keywords: Unstable systems, SOPTD with positive zero, subspace identification, optimization method

1. Introduction

Unstable systems are common in chemical industries. Examples include isothermal CSTR (Liou and Chien, 1991), Nonlinear Bioreactor (Agarwal and Lim, 1989), Dimerization reactor (Alio and Al-humaizi, 2000), Fluidized bed reactor (Kendi and Doyle, 1996), polyolefin reactor (Seki et al., 2001). Padma Sree and Chidambaram (2006) have given an excellent review on the control of unstable systems. Unstable SOPTD systems with a zero are difficult to control due to the presence of an overshoot or inverse response. Some of the examples reported in literature include the Klien's unrideable bicycle (Klien, 1989), Jacketed CSTR (Bequette, 2003).The presence of zero

in the unstable transfer function imposes a difficulty in controlling such systems. For the purpose of designing controllers, identification of the model parameters are required which helps in improved tuning of the controllers. Open loop identification cannot be applied to unstable systems. The systems with positive zeros are slow in response because of their undershoot response at the beginning of the response. Presence of this positive zero complicates performance of control system dynamics. One of the prominent problems with this kind of system is internal stability. Ram et al. (2014) have identified unstable SOPTD systems with negative zero using optimization method. In this work, the method is extended to unstable SOPTD systems with positive zero. Recently Sankar Rao and Chidambaram (2017) reported subspace identification for unstable systems. In this work, the unstable system under consideration is stabilized by a PI/PID controller. A second order time delay model with a positive zero is identified from the closed loop response using a step change in the set point. The process model is identified using optimization method and subspace method separately. The identified models by the above two methods are used for designing controllers and the closed loop performance are evaluated for servo and regulatory response.

2. Proposed Methodology

2.1 Identification of Unstable SOPTD systems with positive zero by subspace identification method

Subspace identification is used to get a linear time invariant state space models directly from the input and output measurement data. The various forms of the subspace based identification methods have attracted much of interest. Subspace identification methods use the concepts of systems theory and linear algebra. Subspace identification methods consist of two steps. In first step, it determines the extended observability matrix and state sequences from the row and column spaces of certain matrices, which are formed from the input output data. Second step estimates the state space model using either the knowledge of extended observability matrix or state sequences.

2.2. Identification of Unstable SOPTD systems with positive zero by optimization method

Consider the unstable second order open loop transfer function with a positive zero given by $G_p(s) = \frac{k_p(1-ps)}{a_1 s^2 + a_2 s + 1} e^{-\phi s}$. In order to identify the process parameters (kp, p, a_1, a_2), system is stabilized by a PID controller and the closed loop response is noted. The system is modelled as second order process with a positive zero

$$\frac{y_{cl}(s)}{y_r(s)} = \frac{k_p(1-ps)}{(\tau_e s^2 + 2\zeta\tau s + 1)} e^{-\phi s} \tag{1}$$

For a unit step change in the setpoint the closed loop response is given by (Seborg and Millichamp, 2006)

$$y(t) = k_p\left[\frac{p}{\tau_e\sqrt{(1-\zeta^2}} e^{-\zeta t'/\tau_e} \sin(\sqrt{(1-\zeta^2}\,\frac{t'}{\tau_e})\right] + \left(1 - e^{-\zeta t/\tau_e}\left[\cos(\sqrt{(1-\zeta^2}\,\frac{t'}{\tau_e}) + \frac{\zeta}{\sqrt{(1-\zeta^2}} \sin(\sqrt{(1-\zeta^2}\,\frac{t'}{\tau_e})\right]\right) \tag{2}$$

Where $t'=t-\Phi$. Ananth and Chidambaram (1999) have defined the formulas for obtaining ζ and τ_e

$$v_1 = \frac{y_{inf} - y_{m1}}{y_{p1} - y_{inf}}; v_1 = \frac{y_{p2} - y_{inf}}{y_{p1} - y_{inf}} \tag{3}$$

$$\zeta_1 = \frac{-\ln(v_1)}{\sqrt{\Pi^2 + (\ln(v_1))^2}}; \zeta_2 = \frac{-\ln(v_2)}{\sqrt{4\Pi^2 + (\ln(v_2))^2}} \tag{4}$$

$$\zeta = \zeta_1 + \zeta_2 \tag{5}$$

$$\tau_e = \frac{\Delta T\sqrt{1-\zeta^2}}{\Pi} \tag{6}$$

$$a_1 = \tau_e^{\ 2}; a_2 = -2\zeta\tau_e^{\ 2} \tag{7}$$

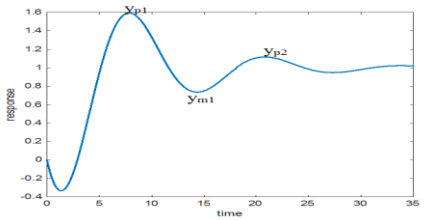

Figure 1: Closed loop response of a system to a step change in setpoint

From the closed loop response the value of y_{p1}, y_{p2}, y_{m1}, y_{inf} are noted. The sign of final steady state value of u (deviation value) is negative and the sign of k_p is positive, then there is one unstable pole and one stable pole present in the system. In order to get the initial guess values for identifying the process parameters from the closed loop response, the method given by Ananth and Chidambaram (1999) is used to obtain the initial guess values of a_1 and a_2. The initial guess value for k_p is taken as the ratio of the final steady state value of the closed loop response to the final steady state value of the manipulated variable u. Equations (3) to (6) are solved to obtain the initial guess values of a_1 and a_2. Equation (2) is solved to obtain the initial condition for the p from undershoot. To evaluate the proposed methodology a known unstable system is taken. The system is stabilized using PID controller and the closed loop response is obtained by giving a unit step change. The model to be identified is also stabilized using the same controller settings. All simulations are carried out on Matlab and Simulink. In order to solve the least square optimization problem, the Matlab routine *lsqnonlin* is used. The objective function is formulated to minimize the sum of the square of the errors between the closed loop response of the model and the process.

Using the methodology explained in Section 2.1 and 2.2, the model identification of the unstable SOPTD system with positive zero is carried out. The identified model parameters by both the methods are stabilised by designing controllers and the results compared.

3. Simulation studies

3.1. Example 1

Consider the transfer function given by $G(s) = \frac{3.5(5 - 0.7s)}{(s^2 - 6.867)}$. The system is stabilized by the PID controller k_c=0.4708; τ_I = 8; τ_D =0.58. The response of the system for unit step change in set point is given in Figure 2. The data obtained are y_{p1}=3.5090; y_{p2}=1.3478; y_{m1}=0.0658; y_{inf} =1; ΔT=12.25; u=-0.3884; ζ=0.0683; τ_e =1.9451. The system has an inverse response which shows the presence of a positive zero in the transfer function. The initial guess values for kp is taken from the closed loop response as the ratio of final steady state value to initial steady state value k_p=1/(-0.3884) = -2.575. To obtain the initial guess values of a_1, a_2 and p the methodology proposed above is applied. The initial guess values are obtained as a_1 =3.7834; a_2=-0.2658; p= -0.9121. To identify the model parameter optimization technique is carried out (Section 2.2). The converged final model parameters identified are k_p=2.5484; p=-0.14; a_1=0.1456; a_2=0. Figure 2 shows that the closed loop response of the identified model matches with the actual response for the same controller settings. Using the identified model parameters the PID controller settings are designed using IMC method. Table 1 shows the controller settings obtained and the ISE, IAE and the TV values. The transfer function model is simulated and the output data is generated. Pseudo Random Binary Signal (PRBS) is used as the exogenous input to excite the process. The order of the system is estimated by inspecting the singular values. The number of dominant singular values will give the information of the order of the system. The model parameters estimated based on subspace based method are K_p = 2.34, p = 0.12, poles are 2.618 and 2.532. From the residual analysis, it is confirmed that the identified model is capable of explaining the dynamic relationship between the cause and effect. Based on the identified model, a PID controller is designed by IMC method and the obtained settings are listed in Table 1. Using the controller settings designed based on the identified model (by optimization and subspace methods), the closed loop performances are evaluated by introducing a unit step change in the set point at time, t = 0 sec and a negative step change in disturbance variable at time, t = 25 sec which is shown in Figure 3. Figure 3 shows the comparison of the closed loop servo and regulatory performance for the identified model by optimization method and subspace identification method.

Table 1: Performance evaluation of the identified models

Examples	Models	Controller settings			Time integral errors		Total Variation in u (TV)
		Kc	τ_I	τ_D	ISE	IAE	
Ex1	Model 1	0.4914	14.6224	0.4141	214.5	42.68	48.3
	Model 2	0.5383	14.3915	0.4143	126.3	38.19	59.2
Ex2	Model 1	0.6493	30.4435	13.2848	220.6	244.3	1170
	Model 2	0.6093	30.3920	13.2903	219.2	258.4	1076

Model 1: Identified by optimization method; Model 2: Identified by subspace method

3.2. Example 2

Consider the isothermal Continuously Stirred Tank Reactor given by Rao and Chidambaram (2006). The transient nonlinear CSTR model is linearized around the

unstable operating point and the resulted transfer function relating concentration of A to to the feed concentration is given by $\frac{\Delta C_A(s)}{\Delta C_f(s)} = \frac{-0.2679(1-41.67s)}{(279.3s^2 - 2.7981s + 11)} e^{-20s}$

The system is stabilised to obtain an underdamped closed loop response of the form as shown in Figure 1 by using the controller settings given by K_c=0.3471;τ_I=-100, τ_D =0.429. From this the value of y_{p1}=1.647; y_{p2}=1.08; y_{m1}=0.7682; y_{inf} =1; ΔT=197.3; u=-3.614 are noted. The values of ζ and τ_e are obtained as ζ =0.0708; τ_e = 31.3224. Using equation (2) and (7) the initial guess values of kp, a_1, a_2 and p are obtained and these are kp=-0.2767.;p=-236.2121;a1=222.3402;a2=-9.3381.Closed loop time constant is assumed as 2-3 times of open loop time constant. The initial guess value for open loop time delay is taken same as the closed loop time delay. Using optimization the process parameters are identified and the converged parameters are obtained as k_p=-0.2679.; p=-41.6667;a_1=279.03;a_2=-2.9781, θ =20. The identified model is used for designing the controllers. In the present work, the controller settings proposed by Sree and Chidambaram (2002) by synthesis method is used. The controller settings given by them are in the form $Gc(s) = K_c(1 + \frac{1}{\tau_I s} + \tau_D s)\left(\frac{1}{\alpha s + 1}\right)$. For the present model parameters obtained by optimization, the controller settings are enlisted in Table 1. Table 1 also shows the IAE, ISE and TV values. Model parameters obtained from the subspace identification method are Kp = -0.285, p = -41.67, a_1 = 279.2, a_2 = -2.953 and θ =20, PID settings are determined by synthesis method and given in Table 1. The time integral error are also calculated and presented in Table 1. Figure 4 shows the closed loop performance for the identified models by the two proposed methodologies.

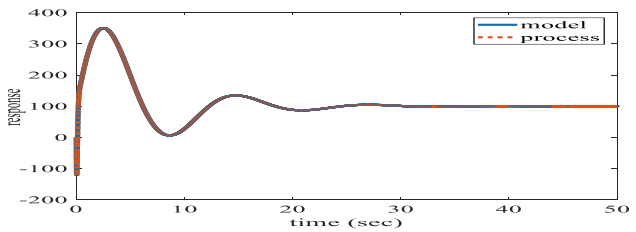

Fig 2: Closed loop servo response of the process and identified model for the same controller settings (optimization method-example 1)

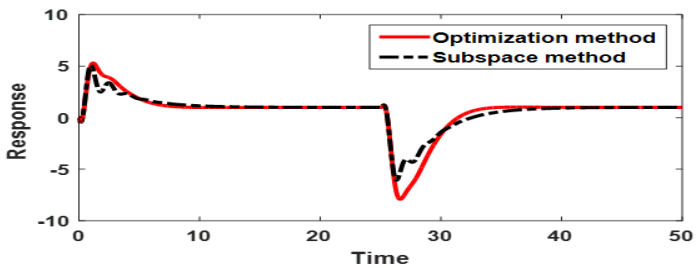

Figure 3: Closed loop response of the controllers designed based on the identified model by optimization method and subspace methods by IMC method for example 1

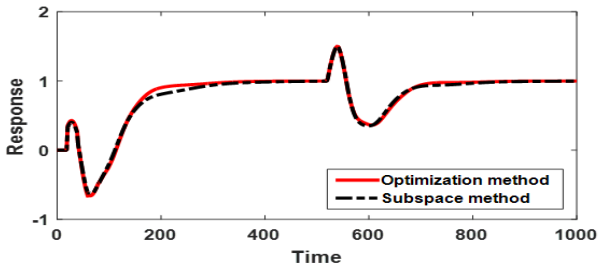

Figure 4: Closed loop response of the controllers designed based on the identified model by optimization method and subspace methods by synthesis method for example 2

4. Conclusions

A closed loop identification method based on optimization and subspace identification for unstable SOPTD systems with zero is proposed. Two case studies were demonstrated in order to evaluate the identification methods. The model parameters obtained by the proposed method were found to match with the actual values. Based on the identified model controllers were designed using methods available in literature. A good set-point tracking and disturbance rejection was obtained. The ISE, IAE and TV values are evaluated. It is found that the closed loop responses obtained by both the identified models are almost similar which emphasis that the proposed methods give good model parameters for designing suitable controller for unstable SOPTD system with zero.

Abstract

The simulation-based multi-objective structural and parameter optimization of continuous chemical production processes is a complex task. To provide a universally applicable optimization tool, the Advanced Process Optimizer was developed and intensively tested in cooperation with different industrial partners over several years. The superstructure can be directly built in a commercial flowsheet simulator. The resulting Generalized Disjunctive Programming formulation of the optimization problem was handled through a combination of newly developed and adapted methods. In order to validate the efficiency of the developed optimization tool the example of a dimethyl ether production process was chosen. The optimization results are compared to a reference solution achieved by conventional approaches and show a significant reduction of both the investment and operating costs.

Keywords: Superstructure, multi-objective optimization, conceptual process design, Generalized Disjunctive Programming

1. Simulation-based multi-objective optimization

Due to growing competition and environmental regulations it is no longer sufficient to fulfill the chemical and technical requirements of a process. Moreover, a holistic view of the process considering different and often opponent objectives is required. The simulation-based process synthesis and design with an overlaid multi-objective optimization is a powerful tool to rise to these challenges. The obtained result is a set of optimal process design trade-offs, illustrated as a Pareto front (PF). On this basis the user is in a position to evaluate the pros and cons of each trade-off considering higher-level qualitative considerations, e.g., the strategic focus of the company, and choose his optimal process in an early stage of process development. To do this, constructive and operative parameters of the process as well as the process structure itself have to be optimized. This is preferably done via a superstructure which is directly implemented in a commercial flowsheet simulator using mostly rigorous models of the apparatuses. Simultaneously, a set of constraints, e.g., the chemical quality of the product streams, have to be satisfied. One systematic formulation of such optimization problems is the Generalized Disjunctive Programming (GDP) representation (Navarro-Amorós et al., 2014). GDP models are known to enclose continuous and Boolean variables, algebraic equations, disjunctions and logical propositions and are often chosen by the Process System Engineering community (Trespalacios and Grossmann, 2014). In order to take advantage of the various available MINLP solvers,

GDP problems are often reformulated as MINLP problems (Trespalacios and Grossmann, 2014). This reformulation has several disadvantages, e.g. the dissimilar responses of different apparatus models in flowsheet simulators (Navarro-Amorós et al., 2014).

In this work, a universally applicable optimization tool for the solution of multi-objective structural and parameter optimization problems that use the GDP formulation is presented. In this regard, the superstructures have been directly drawn in a commercial flowsheet simulator. The developed holistic approach pursues the goal to guide the user through every stage of the optimization project. The developed optimization tool will be shortly presented in the following chapter.

2. Advanced Process Optimizer

Based on former works by Ernst et al. (2017) the Advanced Process Optimizer (Adv:PO) was further developed in order to provide a universally applicable tool for the simulation-based multi-objective structural and parameter optimization of chemical production processes using a GDP representation. The Adv:PO is implemented in Matlab and uses a bidirectional interface to several commercial flowsheet simulators. In the context of this work, the focus lies on the flowsheet simulator Aspen Plus®. A step-by-step user-interface guides the user through the different stages of the optimization project. Figure 1 gives an overview on the implemented system architecture of the Adv:PO focusing on the most important and new components.

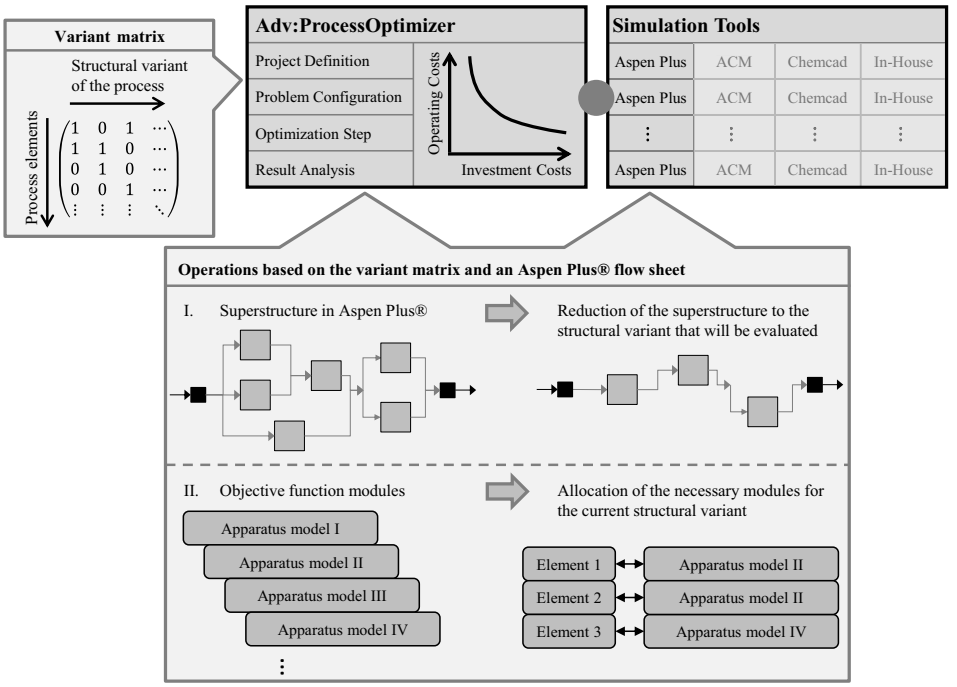

Figure 1: Schematic illustration of the system architecture of the Advanced Process Optimizer for the structural and parameter optimization of chemical production processes, adjusted considering Ernst et al. (2017). Explanatory remarks are given to the most important and new components.

The main stages of an optimization project consist of three blocks: a straightforward concept for the definition of the optimization problem, a robust solution of the multi-objective optimization problem and the provision of appropriate tools for the analysis of the optimization results and a profound decision making support.

In case of the developed Adv:PO, two user inputs are required for the problem definition. The first is the complete superstructure drawn in the flowsheet simulator. And the second is the so-called variant matrix that defines which elements of the flowsheet are part of the process alternative that is currently evaluated. These elements can be apparatus models and connecting material streams but also flowsheeting options of the simulator, like *Design Specs* or *Calculators*, which are needed to formulate special conditions and/or special convergence strategies for the whole process or single apparatuses. The variant matrix is prepared in a provided Microsoft Excel template and automatically imported via the user-interface. For the representation of the disjunctions in the GDP formulation of the problem, a value of 1 in the variant matrix is interpreted as the Boolean variable `true` and a value of 0 as 'false'. Based on this information and as illustrated in Figure 1 the superstructure is automatically cut down to the necessary components reducing the sources of errors in the simulation.

The variant matrix fulfills another important task. On the basis of the objective function modules introduced by Ernst et al. (2017) every apparatus model in the flowsheet is covered by an objective function module. It includes all necessary information about the decision variables, or in other words the apparatus parameters that are varied to find the optimum solutions, and the calculation of the objective functions. Due to this modular concept basically every process can be described. In case of a structural optimization not all apparatuses are part of the evaluation and, as a consequence, the corresponding objective function modules have to be eliminated from the calculations. Analogous to the reduction of the superstructure, this is automatically done by the introduced variant matrix as indicated by Figure 1. The same procedure is employed for the constraints.

The second block of the system architecture contains efficient optimization methods for the robust solution of the optimization problem. The solution method is based on a specially tailored genetic algorithm (GA) introduced by Ernst et al. (2017). GAs are stochastic optimization algorithms that are intensively used in academia and industry. Although GAs do not guarantee to find optimal solutions, they are able to find quasi-optimal solutions in a reasonable timespan. In addition, the adaption of GAs to the optimization problem can significantly improve the convergence velocity and behavior (Chiong, 2009). The developed specially tailored GA is characterized by an innovative elite and diversity preserving strategy (Ernst et al., 2017). Moreover, different operators of the GA have been adjusted for the consideration of the GDP formulation of the optimization problem. In addition, the two-step optimization, introduced by Zimmermann and Fieg (2017), was extended for the use in structural optimization problems. Another important component of the Adv:PO is the implemented parallelization concept for the parallel evaluation of several process design alternatives, as indicated in Figure 1. Due to this concept the hardware of modern computers is used efficiently and the computational time can be reduced significantly.

To complete the holistic view, the third block of the system architecture includes the decision support based on a detailed analysis of the obtained results from a process engineering point of view. One possibility is the export of the results to Microsoft Excel or the export of complete Aspen Plus® flowsheets. In addition, several integrated tools

for the analysis of the results are implemented, e.g. the visualization of the distribution of the process parameters or the convergence of the PF.

3. Exemplary design problem for a dimethyl ether production process

3.1. Dimethyl ether production process

For the evaluation of the developed optimization tool a dimethyl ether process (DME), which was presented in detail by Luyben (2011), was chosen. The example is especially suitable because the optimization results can be directly compared with conventionally achieved reference designs from the author.
In the proposed process, methanol is used as a feed to form DME and water in a gas phase reaction. The basic process consists of a feed preparation for the vaporization of methanol. Subsequently, methanol reacts partially via a catalyst in the reaction section of the process. The products are purified demanding a quality of 99.9 w% for all three components. Unreacted methanol is recycled back to the process. For a more detailed description of the process it is referred to Luyben (2011).

3.2. Definition of the optimization problem

The superstructure drawn in Aspen Plus® is presented in Figure 2. It was developed on the basis of the proposed three alternatives for the reaction section by Luyben (2011) and the original Aspen Plus simulation files, kindly provided by the publisher.

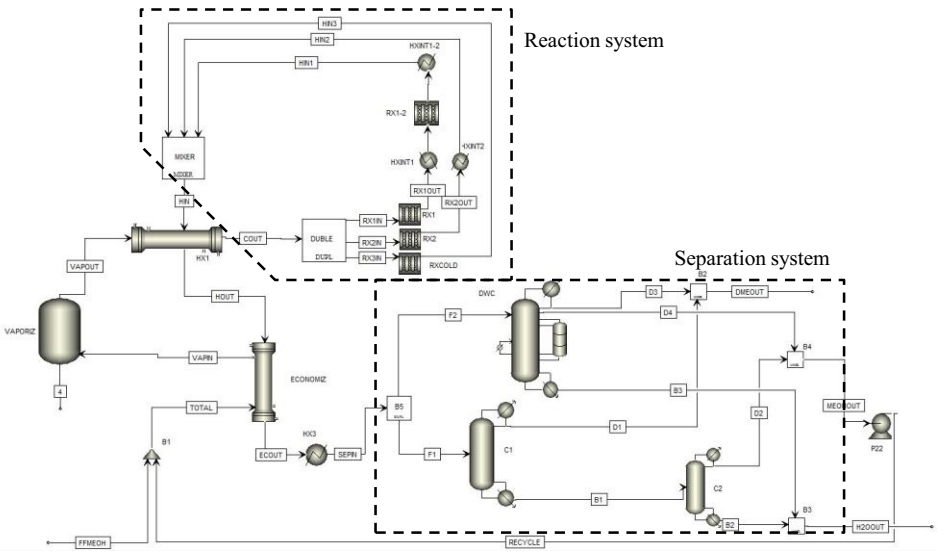

Figure 2: Aspen Plus® flowsheet of the superstructure for the multi-objective optimization of a dimethyl ether production process.

The first alternative is a cooled reactor, the second, one adiabatic reactor with a subsequent heat exchanger (HX), and the third, a series of two adiabatic reactors and HXs. For the separation system a dividing wall column (DWC) was introduced by the authors as an alternative for the direct sequence of two distillation columns proposed by Luyben (2001). In summary, six different process structure alternatives will be regarded for the optimization. For a high comparability of the results the specified objective functions, which are the investment and operating costs of all apparatuses, were

carefully reconstructed (Luyben, 2011). The costs of the newly added DWC are assumed to be similar to the costs of the distillation columns. The constraints demand a high chemical purity of 99.9 w% for all three product streams. In addition, various constraints considering the hydrodynamics of the columns are implemented in the flowsheet. The decision variables with their minimum and maximum values as well as the step size are summarized in Table 1. If an apparatus appears multiple times in the flowsheet a multiple number of the listed decision variables is used due to the modular concept described in the previous section. As the values of the decision variables depend on the process structure altogether 68 decision variables are regarded.

Table 1: Summary of the decision variables for the optimization of a dimethyl ether process.

Type of apparatus	Decision variable	Upper Bound	Lower Bound	Step size	Unit
Vaporizer	Pressure	13.5	15	0.1	atm
Adiabatic reactor	Length	5	12	0.1	m
	Length to diameter ratio	10	15	0.1	-
Heat exchanger	Temperature	550/570	650/670	1	K
Cooled reactor	Number of tubes	150	450	1	-
	Tube length	5	15	0.1	m
	Temperature	600	700	1	K
Distillation column	Number of stages	10	50	1	-
	Feed position	0.1	0.9	0.01	-
	Condenser pressure	1/9	5/10.5	0.1	atm
	Reboiler duty	1	5	0.001	MW
Dividing wall column	Total number of stages	9	65	1	-
	Number of stages for dividing wall	5	25	1	-
	Horizontal position of dividing wall	0.1	0.99	0.1	-
	Reboiler duty	2,5	5	0.001	MW
	Liquid split	0.2	1	0.001	-
	Feed position	0.1	0.9	0.05	-
	Side product position	0.1	0.9	0.05	-
	Condenser pressure	6	10.5	0.1	atm

3.3. Optimization results

For the determination of the optimization results presented in Figure 3, about 48 000 design alternatives have been simulated. The authors do not give information about the computational time intentionally because it highly depends on the independent processing units of the hardware that are used by the previously mentioned specially developed parallelization concept of the Adv:PO. The results presented in Figure 3 are normalized to one reference solution proposed by Luyben (2011) and show a broad PF with 91 process design alternatives. The alternatives consist of three different process structures: two adiabatic reactors plus two distillation columns, two adiabatic reactors plus DWC and cooled reactor plus DWC. Compared to the reference solution a maximum saving of ca. 30 % considering the investment costs is possible. The operating costs can be reduced to a maximum of 11 %. A more detailed analysis of the optimization results goes beyond the scope of this paper.

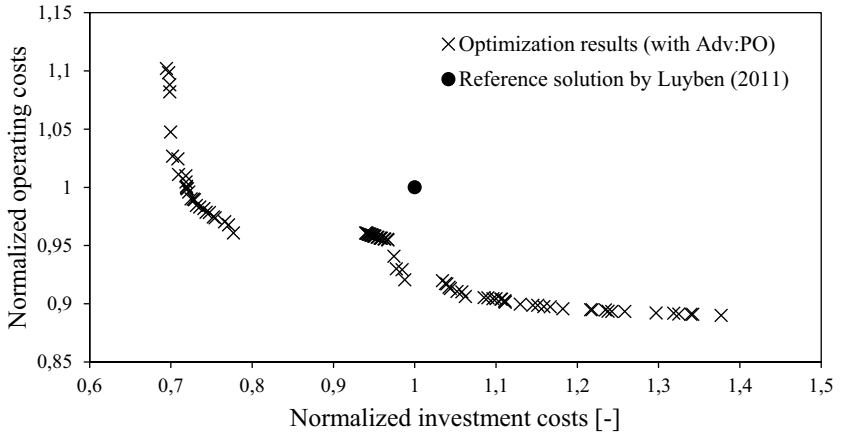

Figure 3: Optimization results determined with the Adv:PO normalized and in comparison to one reference solution calculated by Luyben (2011).

4. Conclusions

For the solution of simulation-based multi-objective structural and parameter optimization problems in a GDP formulation a robust optimization tool, the Adv:PO, was presented. The modular concept for the flexible and automatic consideration of the objective functions and constraints depending on the currently evaluated process structure allows the optimization of basically every process. Moreover, it is possible to draw the superstructure directly in a commercial flowsheet simulator. The developed optimization methods achieved very good results for the exemplary optimization of a DME process in comparison to a reference solution determined by conventional process design methods. The developed methodical approach, the open architecture of the Adv:PO combined with the encouraging results for the exemplary design problem allow the application on more complex design problems. Additionally, not only grass-root design problems can be addressed, but also retrofit problems in an early project phase.

Parsimonious Input Parameterization for Dynamic Optimization Problems

Diogo Rodrigues*, Dominique Bonvin

Laboratoire d'Automatique, EPFL, 1015 Lausanne, Switzerland
diogo.mateusrodrigues@epfl.ch

Abstract

This contribution presents an input parameterization for dynamic optimization problems, which allows reducing the number of decision variables compared to traditional direct methods. Firstly, a finite set of plausible arc sequences is postulated. Then, each arc sequence is described by a small number of parameters that include switching times and initial conditions for the sensitivity-seeking arcs. These arcs are parsimoniously described by cubic splines using only a few parameters. Finally, optimal parameter values are determined for each arc sequence. The reduction in the number of decision variables is such that the problem is often amenable to global optimization. The procedure is illustrated via the optimization of a simulated semi-batch reactor.

Keywords: global dynamic optimization, parsimonious input parameterization, cubic spline.

1. Introduction

Dynamic optimization methods that rely on local numerical optimization are well established (Biegler, 2010). Direct methods reformulate the original infinite-dimensional problem as a finite-dimensional problem by discretizing either the inputs (in sequential methods) or both the inputs and the states (in simultaneous methods). Although these methods typically attain local optimality, they could in principle be extended to global optimality. However, the complexity scales exponentially with the number of decision variables, which is proportional to the number of input parameters in the case of sequential methods (Houska and Chachuat, 2014). Hence, the use of direct methods for global optimization either calls for a rather coarse input parameterization or results in intractable problems.

An apparent way to avoid these difficulties is to use an input parameterization that can approximate the optimal inputs well with a limited number of parameters. This contribution proposes a parsimonious input parameterization, whereby the parameters correspond to (i) switching times between arcs, and (ii) a few parameters used to describe sensitivity-seeking arcs. A similar parameterization was applied to the dynamic optimization of switched systems (Xu and Antsaklis, 2004). However, to the authors' knowledge, it has not been proposed for problems with inequality constraints or in the context of global optimization.

2. Preliminaries

This section presents the formulation of the class of dynamic optimization problems that are considered in this paper and the method used to compute *adjoint-free* optimal control laws.

2.1. Formulation of the dynamic optimization problem

For the sake of clarity, but without loss of generality, this paper will deal with the single-input case. The optimization problem considered in this paper is formulated in Mayer form as

$$\min_{u(\cdot),t_f} \quad \mathscr{J}(u(\cdot),t_f) := \phi(\mathbf{x}(t_f),t_f), \tag{1a}$$

$$\text{s.t.} \quad \mathscr{T}(u(\cdot),t_f) := \boldsymbol{\psi}(\mathbf{x}(t_f),t_f) \leq \mathbf{0}_{n_\psi}, \tag{1b}$$

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}(t),u(t)), \quad \mathbf{x}(t_0) = \mathbf{x}_0, \tag{1c}$$

$$\mathbf{g}(\mathbf{x}(t),u(t)) \leq \mathbf{0}_{n_g}, \tag{1d}$$

$$\mathbf{h}(\mathbf{x}(t)) \leq \mathbf{0}_{n_h}, \tag{1e}$$

where t_f is the finite final time, $u(t)$ is the scalar piecewise-continuous input with trajectory $u(\cdot)$, $\mathbf{x}(t)$ are the piecewise-continuously differentiable states of dimension n_x, and $\phi(\mathbf{x},t)$, $\boldsymbol{\psi}(\mathbf{x},t)$, $\mathbf{f}(\mathbf{x},u)$, $\mathbf{g}(\mathbf{x},u)$, $\mathbf{h}(\mathbf{x},u)$ are smooth functions of dimensions 1, n_ψ, n_x, n_g, n_h, respectively. Moreover, it is assumed that $\mathbf{g}(\mathbf{x},u)$ and $\mathbf{h}^{(1)}(\mathbf{x},u) := \frac{\partial \mathbf{h}}{\partial \mathbf{x}}(\mathbf{x})\mathbf{f}(\mathbf{x},u)$ depend explicitly on u.

2.2. Types of input arcs

Most often, the optimal input consists of a finite number of arcs. For a given arc, the optimal input is determined by either an active path constraint or a single condition that expresses a physical compromise in the system dynamics. Moreover, the resulting optimal control laws (but not necessarily the control values) are independent of the initial conditions and the terminal constraints (Srinivasan et al., 2003).

The control laws express the optimal input or one of its time derivatives in terms of the states and possibly the input and its time derivatives, thus resulting in an *adjoint-free* optimal control law. Each input arc is of one of the following three types (Srinivasan et al., 2003):

1. If the optimal input is determined by the active mixed path constraint $g_k(\mathbf{x},u) \leq 0$ for some $k = 1,\ldots,n_g$, then the control law $u = c(\mathbf{x})$ enforces $g_k(\mathbf{x},u) = 0$.

2. If the optimal input is determined by the active pure-state path constraint $h_k(\mathbf{x}) \leq 0$ for some $k = 1,\ldots,n_h$, then the control law $u = c(\mathbf{x})$ enforces $h_k^{(1)}(\mathbf{x},u) = 0$.

3. If the optimal input is not determined by any active path constraints, then the control law $u^{(\xi)} = c(\mathbf{x},u,\ldots,u^{(\xi-1)})$ enforces $\det(\mathscr{M}) = 0$. Let $\mathbf{x}^u$ be the ρ states that can be reached by manipulating u, with dynamics $\dot{\mathbf{x}}^u = \mathbf{f}^u(\mathbf{x},u)$. Then, we can

construct the $(\rho \leftrightarrow p)$ matrix $\mathcal{M} := \left[\frac{\partial \mathbf{f}^u}{\partial u}(\mathbf{x},u) \vdots \Delta\frac{\partial \mathbf{f}^u}{\partial u}(\mathbf{x},u) \vdots \cdots \vdots \Delta^{\rho-1}\frac{\partial \mathbf{f}^u}{\partial u}(\mathbf{x},u)\right]$ using symbolic computations and the operator $\Delta\mathbf{v} := \frac{\partial \mathbf{v}}{\partial \mathbf{x}}\mathbf{f}(\mathbf{x},u) - \frac{\partial \mathbf{f}^u}{\partial \mathbf{x}^u}(\mathbf{x},u)\mathbf{v} + \sum_{k=0}^{\infty}\frac{\partial \mathbf{v}}{\partial u^{(k)}}u^{(k+1)}$, with $\Delta^l\mathbf{v} := \Delta(\Delta^{l-1}\mathbf{v})$.

The input arcs of types 1 and 2 are labeled *constraint-seeking*, while the input arcs of type 3 are *sensitivity-seeking*. Note that switching between arcs can happen any time, except for the switching to an arc of type 2 that can only occur when the states $\mathbf{x}$ satisfy $h_k(\mathbf{x}) = 0$.

The analytical approach for the computation of adjoint-free optimal control laws shown above is quite useful to get an analytical characterization of the input arcs. However, when the number of reachable states ρ grows beyond 4 or 5, the size and complexity of $\mathcal{M}$ may become intractable. In that case, a more practical approach is needed.

2.3. Approximation of optimal control laws using cubic splines

The idea is to replace the analytical characterization of sensitivity-seeking input arcs by a description using cubic splines (piecewise-cubic functions). Since the optimal profiles in these arcs are smooth functions, they can be approximated by cubic splines with only a few parameters. Piecewise-constant, piecewise-linear or piecewise-quadratic functions could also be used, but these would typically require more parameters for the same quality of approximation.

A cubic spline with π intervals starts at the point (t^0, y^0), passes through the $\pi - 1$ intermediate points $(t^1, y^1),...,(t^{\pi-1}, y^{\pi-1})$ and ends up at the point (t^π, y^π). It is typically parameterized by the $\pi + 1$ coordinates $y^0,..., y^\pi$ and 2 conditions at the endpoints t^0 and t^π (for example, on the second derivatives). Hence, $\pi + 3$ parameters are needed to describe the cubic spline.

In this paper, to enable the computation of sensitivity-seeking input arcs via forward integration of differential equations, a different interpretation is assigned to these $\pi + 3$ parameters. Three parameters correspond to the initial value $u(t^0)$, the initial first derivative $\dot{u}(t^0)$ and the initial second derivative $\ddot{u}(t^0)$, while the remaining π parameters $\mathbf{p}$ correspond to the third derivatives in the π intervals of the cubic spline. Hence, the input u is described by

$$u^{(3)}(t) = p_1, \quad \forall t \in [t^0, t^1); \quad ... \quad ; \quad u^{(3)}(t) = p_\pi, \quad \forall t \in [t^{\pi-1}, t^\pi), \tag{2}$$

with the three initial values $u(t^0)$, $\dot{u}(t^0)$, and $\ddot{u}(t^0)$.

In the remainder, these $\pi + 3$ parameters will be considered as "initial conditions" for the input arc. Note that the locations of the intermediate points are not input parameters since they are fixed at $t^m := (1 - w^m)t^0 + w^m t^\pi$ for all $m \in \{0,1,...,\pi\}$, where w^m is a constant that specifies the relative position of t^m with respect to t^0 and t^π, with $0 = w^0 < w^1 < ... < w^\pi = 1$.

3. Parsimonious input parameterization

3.1. Basic idea

This approach, labeled *parsimonious input parameterization*, was first proposed by Srinivasan et al. (2003). It consists of the following steps:

1. Generate a finite set of arc sequences from all the input arcs that can occur, and choose an initial arc sequence.
2. Use numerical optimization to compute the optimal switching times to arcs of types 1 and 3 and initial conditions for the sensitivity-seeking arcs.
3. Check if the cost for the chosen arc sequence is less than the current optimal cost and, if so, update the current optimal cost and optimal arc sequence.
4. Choose a different arc sequence and repeat Steps 2-4 until all sequences are investigated.

The optimization in Step 2 typically uses algorithms that require the computation of gradients with respect to the decision variables. At each iteration, the states are computed via forward integration of the dynamic equations, since the input can be generated without knowledge of the adjoint variables. The next subsections give more details about this implementation.

Remark. If the optimization in Step 2 can be solved to global optimality for each arc sequence, then the input trajectory with the lowest cost will be globally optimal. To enforce global optimality, one could express the terminal cost and constraints as explicit *polynomial* functions of the decision variables and compute the global solution to this polynomial optimization problem via reformulation as a semidefinite program (Lasserre, 2009). Note that the fact of having fewer decision variables facilitates the whole procedure.

3.2. Model of an arc sequence

Consider a given arc sequence that includes n_s+1 arcs of types 1 and 3, where n_s is the number of switching times to these arcs. These switching times $t_1,...,t_{n_s}$ are considered as decision variables, while the switching times to arcs of type 2 are not decision variables since they depend on the states and cannot occur arbitrarily. We show next that the input $u(t)$ for this sequence is fully defined by the switching times $t_1,...,t_{n_s}$, the final time t_f, and the initial conditions of the sensitivity-seeking arcs, which become the decision variables of the problem.

Note that, in addition to the switching times $t_1,...,t_{n_s}$ considered as decision variables, other switchings between arcs occur when a pure-state path constraint becomes active. In that case, the input $u(t)$ is adjusted such that the path constraint remains active.

Let us describe the input in the time interval $[t_{i-1},t_i)$, for some $i=1,...,n_s+1$, where $t_{n_s+1}=t_f$. There is a degree $\xi_i \geq 0$ for which $u^{(\xi_i)}(t)$ is a function of the states, the input,

the time derivatives of the input, and the vector $\mathbf{p}_i$ of constant third derivatives in the π_i intervals of the cubic spline. This differential relationship requires specifying the initial conditions $u^{(\xi_i-1)}(t_{i-1}),...,u(t_{i-1})$. The element $p_{i,m}$ of the vector $\mathbf{p}_i$ is used only for $t \in [t_i^{m-1}, t_i^m)$, with the instants $t_i^0, t_i^1, ..., t_i^{\pi_i}$ specified by the constants $w_i^0, w_i^1, ..., w_i^{\pi_i}$. Upon defining the $\pi_i + \xi_i$ states $\mathbf{z}_i(t) := [\mathbf{p}_i^{\mathrm{T}} \; u^{(\xi_i-1)}(t) \; \cdots \; u(t)]^{\mathrm{T}}$, one can describe their dynamics for $t \in [t_{i-1}, t_i)$ as

$$\dot{\mathbf{z}}_i(t) = \mathbf{q}_i(\mathbf{x}(t), \mathbf{z}_i(t)), \quad \mathbf{z}_i(t_{i-1}) = \mathbf{z}_{i,0}. \tag{3}$$

Then, for the arc sequence, one defines the extended states $\mathbf{z}(t) := [\mathbf{x}(t)^{\mathrm{T}} \; \mathbf{z}_1(t)^{\mathrm{T}} \; \cdots \; \mathbf{z}_{n_s+1}(t)^{\mathrm{T}}]^{\mathrm{T}}$ and uses the control law $u(t) = \tilde{c}(\mathbf{z}(t))$, which is continuous unless a switching occurs, to eliminate the input dependencies and rewrite the functions in Problem (1) in terms of $\mathbf{z}$, that is, $\tilde{\mathbf{f}}(\mathbf{z}(t))$, $\tilde{\phi}(\mathbf{z}(t_f), t_f)$, $\tilde{\boldsymbol{\psi}}(\mathbf{z}(t_f), t_f)$, $\tilde{\mathbf{g}}(\mathbf{z}(t))$, $\tilde{\mathbf{h}}(\mathbf{z}(t))$, $\tilde{\mathbf{h}}^{(1)}(\mathbf{z}(t))$, with the initial conditions $\mathbf{z}_0 := [\mathbf{x}_0^{\mathrm{T}} \; \mathbf{z}_{1,0}^{\mathrm{T}} \; \cdots \; \mathbf{z}_{n_s+1,0}^{\mathrm{T}}]^{\mathrm{T}}$. The system equations now read:

$$\dot{\mathbf{z}}(t) = \tilde{\mathbf{f}}(\mathbf{z}(t)), \quad \mathbf{z}(t_0) = \mathbf{z}_0. \tag{4}$$

3.3. Numerical optimization for a given arc sequence

To check whether a given arc sequence is a solution to Problem (1), one uses the fact that any input trajectory implementing that arc sequence is given by some switching times and initial conditions for the sensitivity-seeking arcs. Then, the functionals $\mathscr{J}$ and $\mathscr{T}$ reduce to functions $\bar{\phi}$ and $\bar{\boldsymbol{\psi}}$ of the switching times $t_1,...,t_{n_s}$, the final time t_f and the initial conditions $\mathbf{z}_{1,0},...,\mathbf{z}_{n_s+1,0}$, which is more convenient for numerical optimization. This implies that, for any values of the decision variables $\boldsymbol{\tau} := (t_1,...,t_{n_s}, t_f, \mathbf{z}_{1,0},...,\mathbf{z}_{n_s+1,0})$, the terminal cost and constraints $\bar{\boldsymbol{\chi}}(\boldsymbol{\tau}) := [\bar{\phi}(\boldsymbol{\tau}) \; \bar{\boldsymbol{\psi}}(\boldsymbol{\tau})^{\mathrm{T}}]^{\mathrm{T}}$ can be computed via numerical integration of Eq. (4) and evaluation of the functions $\tilde{\boldsymbol{\chi}}(\mathbf{z}(t_f), t_f) := [\tilde{\phi}(\mathbf{z}(t_f), t_f) \; \tilde{\boldsymbol{\psi}}(\mathbf{z}(t_f), t_f)^{\mathrm{T}}]^{\mathrm{T}}$.

However, the gradients of $\bar{\boldsymbol{\chi}}$ with respect to the decision variables $\boldsymbol{\tau}$ also need to be supplied to the optimization algorithm. These gradients can be computed via adjoint sensitivity analysis, which is efficient when the number of functions $\bar{\boldsymbol{\chi}}$ is small. For this, each time Eq. (4) is integrated forward from t_0 to t_f to compute the states $\mathbf{z}(t)$, the adjoint variables $\boldsymbol{\zeta}(t) := [\boldsymbol{\lambda}(t)^{\mathrm{T}} \; \boldsymbol{\zeta}_1(t)^{\mathrm{T}} \; \cdots \; \boldsymbol{\zeta}_{n_s+1}(t)^{\mathrm{T}}]^{\mathrm{T}}$ are computed by integrating backward from t_f to t_0

$$\dot{\boldsymbol{\zeta}}(t) = -\frac{\partial \tilde{\mathbf{f}}}{\partial \mathbf{z}}(\mathbf{z}(t))^{\mathrm{T}} \boldsymbol{\zeta}(t), \quad \boldsymbol{\zeta}(t_f) = \frac{\partial \tilde{\boldsymbol{\chi}}}{\partial \mathbf{z}}(\mathbf{z}(t_f), t_f)^{\mathrm{T}}. \tag{5}$$

Moreover, for each instant θ at which $\tilde{h}_k(\mathbf{z}(\theta^-)) < 0$ and $\tilde{h}_k(\mathbf{z}(\theta)) = 0$ for some $k = 1,...,n_h$, which is equivalent to saying that $\tilde{h}_k(\mathbf{z}(t)) \le 0$ becomes active at $t = \theta$, it holds that:

$$\boldsymbol{\zeta}(\theta^-) = \boldsymbol{\zeta}(\theta) - \frac{\partial \tilde{h}_k}{\partial \mathbf{z}}(\mathbf{z}(\theta^-))^{\mathrm{T}} \frac{[\tilde{\mathbf{f}}(\mathbf{z}(\theta^-)) - \tilde{\mathbf{f}}(\mathbf{z}(\theta^+))]^{\mathrm{T}} \boldsymbol{\zeta}(\theta)}{\tilde{h}_k^{(1)}(\mathbf{z}(\theta^-))}. \tag{6}$$

Finally, the gradients of $\bar{\chi}$ with respect to the decision variables $\boldsymbol{\tau}$ are obtained from the knowledge of the states $\mathbf{z}$ and adjoint variables $\boldsymbol{\zeta}$. It would also be possible to compute higher-order derivatives of $\bar{\chi}$ with respect to the decision variables, which would require the computation of derivatives of the states $\mathbf{z}$ and adjoint variables $\boldsymbol{\zeta}$ with respect to these decision variables. However, this computation is out of the scope of this paper.

4. Simulated example

The example describes the acetoacetylation of pyrrole in a homogeneous semi-batch reactor (Ruppen et al., 1998). The solution with the parsimonious parameterization results in an input trajectory described by 6 parameters. This parameterization outperforms the piecewise-constant parameterization of a direct method using the same number of parameters, which results in a rather coarse input trajectory and a worse cost; about 50 parameters are needed for the piecewise-constant parameterization to obtain an equally smooth input trajectory with similar cost. Details are available from the authors.

5. Conclusions

This paper has presented a parsimonious parameterization that describes the optimal input accurately with fewer parameters than direct methods, which reduces the number of decision variables and makes it a valid candidate for global dynamic optimization.

Future work will consider the multiple-input case, which requires more attention in the definition and selection of arc sequences. Also, it would be useful to express the terminal cost and constraints of dynamic optimization problems as explicit polynomial functions of the decision variables, which is typically required for global optimization.

Abstract

In this paper we use the example of a commercial NGL Plant in Abu Dhabi to explain the practical benefits of Advanced Model-based Optimization. We will describe and show how the key first step in such a study is validation: ensuring that model predictions of key results are matching the actual plant behavior. We will describe how the model is then used to understand the best operational strategies for the facility through model-based optimization. This demonstrates how the approach used overcomes the limitations of the typical workflow and models used, in particular, the ones based on the Sequential Modular approach. The trial-and-error simulations used in this approach are not only time consuming and error prone but often limited in the operating decisions and constraints that can be considered. We will show how using an Equation Oriented environment overcomes these limitations and allows an optimal solution satisfying all operational and safety constraints to be found using mathematical optimization methods. Finally we will show how this leads to the set-up of operating guidelines to allow operators to drive the plant towards optimal operation; giving them the ability to respond to changes in the plant or economic conditions quicker and with more confidence than previously possible.

Keywords: Natural Gas Liquid, Process Simulation, Equation Oriented Approach, Optimization

1. Introduction

Process simulation software has long been used as a key tool to aid in the design and operation of complex plants with the aim to identify optimized designs and operating procedures. Typically, with such tools, a trial and error methodology is adopted to "optimize" the design or operation. Rigorous optimization techniques and tools have been increasingly used, as summarized below, but these either require additional tools compared to the standard ones used in industry or expert users. A body of research on NGL unit optimization has appeared in the literature where various optimization techniques and simulators have been used for such a purpose. Diaz et al. (2002) formulated a MINLP (mixed integer non-linear programming) mathematical model to achieve the optimum operating conditions and flexibility under various feed conditions of various NGL recovery processes. Mehrpooya et al. (2006) used an advanced method known as VPGA (Variable Population size Genetic Algorithm) for parametric optimization of an existing NGL recovery plant. Chebbi et al. (2010) optimized a typical turbo-expander process to various de-methanizer pressures and feeds conditions through process simulations using HYSYS. Yusoff et al. (2011) used the Taguchi parametric

design approach to select the optimization variables for a refrigerated gas plant simulated in HYSYS. Ghorbani et al. (2012) used a combination of pinch and exergy analysis to optimize the energy recovery of the refrigeration cycle in the NGL recovery plant. Park et al. (2015) presented a novel modified form of coordinate descent methodology (MCD) for solving complex NG process optimization problems. Getu et al. (2012) developed a six chance-constrained model using HYSYS and performed the process optimization using the general algebraic modelling system (GAMS). A comprehensive analysis of existing/past technologies and the state of the art in optimization of integrated process systems through the use of process flowsheeting tools was published recently (Pantelides et al. 2013). The main technology adopted by most commercial steady-state flowsheeting tools used is based on the Sequential Modular (SM) approach, where, process units are solved in sequence. Simulation tools based on this approach are easy to use; however, in practice within this environment formal mathematical optimization is very limited due to its problematic handling of non-standard specifications, closing of recycle loops and the unavailability of gradients (which are required by numerical optimization algorithms). To overcome this difficulty, engineers resort to trial-and-error steady state simulations for their optimization studies. This can be time-consuming and error-prone without any guarantee of obtaining an optimal solution or even one that satisfies all important constraints. The need to move away from the Sequential Modular approach in process flowsheeting has long been recognized and there has been increasing development in tools using the Equation Oriented (EO) approach. In this approach, the mathematical model, built up by the representation of each unit operation in a flowsheet, is solved as a single set of equations simultaneously rather than as a unit by unit Sequential Modular approach. This technology can overcome many of the limitations of the Sequential Modular approach. In particular, because the entire system of equations is available it is possible to calculate the partial derivatives required by optimization solvers. In this work we develop a flowsheet model of an NGL plant in gPROMS ProcessBuilder® (Process Systems Enterprise Ltd.), an Equation Oriented process flowsheeting tool and demonstrate the advantages of such technology in terms of performing optimization of a commercial NGL unit.

2. NGL Recovery Process Description

2.1 Overview

The NGL recovery unit produces two main products (NGL and condensates) from the treated natural gas stream. In addition to the two product streams, the majority of the feed material (methane) exits the unit as residue gas which is then sold as sales gas with its value determined through a set of product specifications (e.g. net heating value). Removal of the NGL and condensate components from the feed gas stream results in a reduced revenue for the residue gas stream as the larger hydrocarbon molecules have a higher heating value. Depending on the market conditions a certain level of heavier hydrocarbons may be required in the residue gas to maintain the heating value specification, especially if there are inerts present such as carbon dioxide or nitrogen. Although recovering the maximum amount of liquids in NGL and condensate streams increases the revenues from these streams, a balance is required to ensure the value of the residue gas is maintained and it meets the required specifications for the customer. A simplified schematic of such a process is shown in Figure 1.

2.2 Operation

The key requirements for the operation of these units include:

- Recovery efficiency- (in this case the propane recovery is considered)
- Product purity – the NGL product stream has a maximum acceptable levels for both light (C_2 and lower) and heavy (C_{5+}) components.
- Residue gas specification –a minimum net heating value is required for distribution through the sales gas grid.

Therefore optimizing the operation of such plants is not a simple matter of producing as much NGL liquids as possible given the required product purity. Another complicating factor is variation in the composition of feed gas, which can affect the above operational requirements.

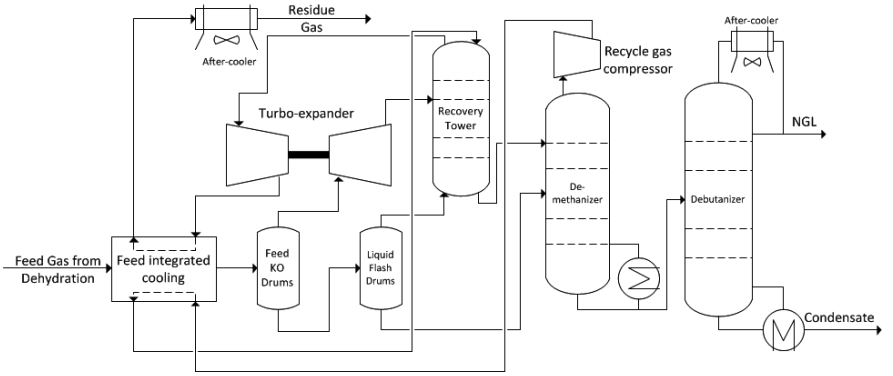

Figure 1: NGL unit simplified schematic

3. Unit Model Validation

The overall topology of the developed model is shown in Figure 2. A model of the propane refrigeration cycle was also developed and integrated with the process section via a hierarchical modeling structure. The topology of the refrigeration cycle is not shown herein. For validation the model was first configured to represent the original design and validated against the design data, with all model predictions within 1% of original design data. Plant data for an entire year was then analysed and used to validate the model at different steady state points during different seasons, using the built in parameter estimation capabilities of the software tool being used to estimate the unknown inputs to the model (not provided by plant measurements). Table 1 shows the deviations of the model predictions in key (product) results for a representative steady state. In total 90 plant measurements are considered with deviations within measurement errors considered.

4. Unit Model Optimization

4.1. Problem formulation

The main objective of the present optimization exercise is to maximize the profitability of the plant (revenue minus cost). The decision variables consist of various operating conditions that can be modified such as pressures, flow splits, steam duties into reboilers, etc. The main constraints include product specifications and equipment limitations and capacities. This optimization problem is formulated in the same Equation Oriented

package used to develop the flowsheet model. The main elements of the optimization problem formulation are listed below:

Table 1: Key result comparison with plant data

Stream	Measurement [unit]	Absolute Deviation
Residue Gas	Compressibility [-]	<0.01
	Heating Value Gross [BTU/ft3]	-2
	Heating Value Net [BTU/ft3]	-2
	Molecular Weight [g/mol]	<0.05
	Specific Gravity (relative to air)	<0.01
	Temperature [degC]	0.5
	Molar flowrate [kNm3/h]	10
NGL	Compressibility [-]	<0.01
	Heating Value Gross [BTU/ft3]	-25
	Heating Value Net [BTU/ft3]	-23
	Molecular Weight [g/mol]	-1.0
	Specific Gravity (relative to air)	-0.1
	Volumetric flowrate [m3/h]	6
Condensate	Mass density [g/mL]	0.02
	Volumetric flowrate [m3/h]	0.3
	Reid vapour pressure [psi]	-0.4
	Temperature [degC]	-5

- Objective function
  - Annualized net revenue, which is the summation of the revenue of the three product streams minus the total utility cost
- Decision variables
  - Main process
    - Reboiler steam duty in de-methanizer and debutanizer
    - Flow splits of feed gas to different heat exchangers
    - Column pressures (all columns)
  - Refrigerant loop
    - Circulating flowrate
- Constraints
  - Product specifications
    - Residue gas – minimum net heating value (BTU)
    - NGL liquid
      - C2 and lighter components maximum composition (5% by mole)
      - C5 and heavier components maximum composition (4% by mole)
    - Condensate – a maximum Reid Vapor Pressure (RVP) specification is required
  - Additional constraints
      - In addition to the product constraints, additional constraints are added to avoid undesirable operating points, such as small temperature differences at heat exchanger boundaries.

The package's built-in optimization capabilities were then used to solve the mathematical optimization problem. In total the optimization problem consists of 10 decision variables, 15 constraints and 80,000 equality constraints (flowsheet model equations).

4.2. Results and Discussion

Table 2 summarizes the results obtained during the optimization and the percentage improvement compared to the original baseline (values normalized to a product revenue of $100million/yr). An increase of 1.51% is seen in the net revenue. The increased revenue requires a higher energy utilization which is reflected in energy cost 5.5% greater than the baseline operating point. On the other hand, the economic improvement is achieved by increasing the production of both liquids, and sacrificing both the production and the residue gas specifications.

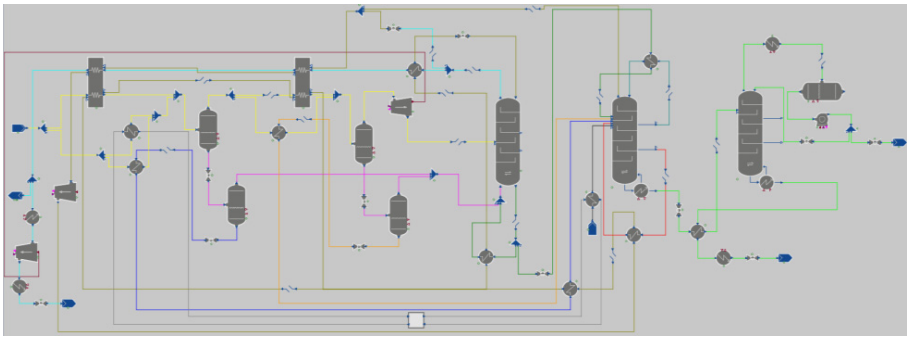

Figure 2: Overall topology of NGL flowsheet model

Table 2: Optimization results

	Baseline ($million/yr normalized)	**Optimized**
Net Revenue	99.611	+1.51%
Revenue	100	+1.53%
Costs	0.389	+5.47%

Table 3 summarizes the changes in the decision variables in the calculated optimal point compared to the original baseline values. It can be seen that the optimal point is a result of a number of factors. The recovery tower pressure is reduced, which gives a greater pressure drop and therefore refrigeration in the turbo expander. In addition flow splits of the feed gas change in a way to increase the amount of refrigeration from the propane loop and recycle heat exchangers. The pressure in the de-methanizer is also reduced compared to the baseline, lowering the steam duty required in the de-methanizer. The pressure in the de-butanizer is higher compared to the baseline, to meet the constraint on the lighter components in the NGL product stream. Due to the higher pressure in the debutanizer, the steam duty in reboiler is increased. To maximize the production of NGL and condensate, both product specifications reach their limits. It is therefore evident that imposing appropriate constraints in an optimization problem is important. The approach taken in this work, solving the optimization problem mathematically, ensures that the optimization algorithm returns a feasible (all the constraints are satisfied) solution.

5. Conclusions

In this paper, we demonstrated how a steady state flowsheet model developed in an Equation Oriented flowsheeting tool can be deployed for an optimization activity in order to improve the economics of a commercial NGL plant by modifying specified operating conditions. In the current work being carried out a series of such optimization

calculations are to be performed, with a wider range of controls, to help improve understanding of how plant operation can be changed in situations that are seen during day to day operation such as feed stock variations. Results from these calculations will be used to determine trends in plant operating conditions and to develop a set of operating guidelines to help operators drive the plant towards optimal operation.

Table 3: Optimized decision variables and product constraints

	Optimized (change from baseline)
Decision variables	
Recovery column pressure	-6.80%
De-methanizer pressure	-9.15%
De-butanizer pressure	12.53%
De-methanizer steam duty	-13.96%
De-butanizer steam duty	17.04%
Flow Split 1	-6.17%
Flow Split 2	-1.34%
Flow Split 3	-15.67%
Constraints	
Residue gas BTU	-0.6%
NGL C2-	57.2%*
NGL C5+	-28.5%
Condensate Reid Vapor Pressure	0.7%*
* these constraints are at their upper limit

Abstract

In equation-oriented process optimization, thermodynamic properties are often challenging to model. Thermodynamic property models tend to be highly nonlinear and must handle complex issues such as root selection and phase identification. In this work, we propose a method for using simple surrogate equations of state (SEOS), fit locally, to derive the thermodynamic state functions of the system. This can be fit to data derived from more complex thermodynamic models or directly from experiments. The SEOS are built to complement the equation-oriented optimization paradigm, while enabling flexibility to model diverse thermodynamic behavior. While still a data-driven model, surrogate equations of state offer better extrapolation potential than general regression of thermodynamic properties. A parameter estimation problem is formulated to determine the parameters of the SEOS, and the resulting model is applied to optimize a flash model encountered in a polymerization process. Finally, we discuss the potential to incorporate SEOS in a trust region framework to adaptively manage the approximation error.

Keywords: Equation of state, Thermodynamic properties, Equation-oriented modelling, Surrogate modelling

1. Introduction

For large scale process optimization, the equation-oriented (EO) paradigm provides attractive performance in terms of computational efficiency and flexibility in problem formulation. While most unit operations are easily modelled in this approach, thermodynamic property evaluations require careful attention. Many equations of state exhibit several volume roots, which need to be either identified with their corresponding phases or ignored as physically irrelevant. Sequential modular approaches attempt to find all roots and use logical conditions to identify the phases, but the equation-oriented approach requires a customized approach for the specific form of an equation of state. For cubic equations of state, Kamath et al. (2010) and Dowling and Biegler (2015) develop phase identification conditions using the sign of the first and second derivatives of the cubic equation. These conditions can then be included in the optimization models as inequality constraints to automatically enforce correct phase identification. However, for many fluids, such as polar or large-chain fluids, cubic equations of state are not always satisfactory. The IUPAC reference (Sengers et al. 2000) reviews these methods in depth. However, when moving to more complex functional forms, the problem of phase identification becomes more serious. For example, the PC-SAFT equation can have up to five real roots for pure components (Privat et al. 2010). Even outside of the equation-oriented context phase identification is non-trivial.

Sometimes, these issues are avoided by using surrogate models of physical properties. These surrogate models may take the form of polynomial or other regressions of thermodynamic state variables as functions of temperature, pressure, and composition, which may then be incorporated in an equation-oriented framework. However, these models are inherently local in nature, and the construction of suitable approximations becomes significantly more difficult as the number of components in a mixture increases. In addition, by independently fitting thermodynamic state variables, the laws of thermodynamics relating these state variables are often ignored, so extrapolation is limited. In this work, we propose instead to use surrogate equations of state (SEOS) fit locally to data from experiment or more complex thermodynamic models. This allows the properties derived from the surrogate equation of state to follow from basic laws of thermodynamics and have better extrapolation potential. We note that the key motivation of surrogate models is not for computational efficiency, but rather to enable EO optimization technology for properties that typically are calculated procedurally.

It is desired to base the surrogate equations of state on well-known simple functional forms for equations of state. The most logical choices for the simple functional form are the virial equation and cubic equations of state. This paper considers cubic equations with the Peng-Robinson form of the attractive term. This functional form will be tuned to match thermodynamic data (either generated from a complex equation of state or experimental data) in a local space, thus providing a surrogate equation of state. Of course, the simple functional form of the SEOS is not able to accurately describe all possible states. Instead, we fit over a local region of temperature, pressure, and concentration, and rely on the trust region approach of Eason and Biegler (2016) to control the error and guarantee accurate solutions.

2. Cubic Equations of State

The basic cubic functional form first proposed by van der Waals has been modified to produce many equation of state models. Valderrama (2003) reviews these variations, showing the great flexibility of cubic equations of state to predict the behavior of many systems. In this work, we will choose the Peng-Robinson equation of state functional form, although it is simple to adjust this to other functional forms.

The Peng-Robinson equation of state for a pure component takes the form:

$$P = \frac{RT}{v-b} - \frac{ma}{v^2 + 2bv - b^2} \quad (1) \tag{1}$$

where $m = \left[1 + (0.37464 + 1.54226\omega - 0.26992\omega^2)\left(1 - \sqrt{T/T_c}\right)\right]^2$ and ω is the Pitzer acentric factor. Eq.(1) can be converted to the standard cubic form in Z by multiplying through by the denominators and rearranging terms.

The parameters a and b in the cubic equation of state can be uniquely determined by imposing criticality conditions. When we require $\left(\frac{dP}{dv}\right)_{T_c} = \left(\frac{d^2P}{dv^2}\right)_{T_c} = 0$, it is determined that $a = 0.45724(R^2\,T_c^2)/P_c$ and $b = 0.07780(RT_c)/P_c$.

From fitting the critical conditions, we can see how the cubic equation of state follows the principle of corresponding states. This principle states that if the reduced conditions T/T_c and P/P_c and the acentric factor ω are the same, then the thermodynamic properties are (nearly) the same, regardless of the fluid. This means that a fluid is parameterized by

its critical temperature, critical pressure, and acentric factor. This principle can be derived from molecular thermodynamics with assumptions including universal pairwise potential functions (see Prausnitz et al. 1999). However, real fluids can vary in behavior depending on quantum effects, polarity etc. To capture these deviations, we propose tuning the critical properties to fit the observed behavior of a fluid locally. For mixtures, it is also necessary to tune binary interaction parameters $\kappa_{i,j}$.

3. Parameter estimation formulation

In this section, we propose a parameter estimation formulation for tuning a cubic equation of state for use in vapor-liquid equilibrium calculations. Because cubic equations of state are parameterized by critical properties, we seek adjusted values for the pure component critical temperatures T_i, pure component critical pressures P_i, and binary interaction parameters $\kappa_{i,j}$ to minimize the squared error in fugacity coefficients ϕ_i for one phase. This requires VLE data as input; in this work we use data generated from the PC-SAFT equation of state. The values associated with each data point k are system temperature $\hat{T}_k$, system pressure $\hat{P}_k$, composition $\hat{x}_{i,k}$, compressibility factor $\hat{Z}_k$, and fugacity coefficient $\hat{\phi}_{i,k}$. Note that the compositions, compressibility factor, and fugacity coefficient are specific to one phase, so the parameter estimation problem is applied separately to both liquid and vapor data. The subscript i represents the components and subscript k represents the data points. All symbols with a hat, for example $\hat{Z}_k$, are parameters associated with a data point. The fitting model is presented as follows:

$$\min \sum_{\mathrm{k}} \sum_{\mathrm{i}} \left(\widehat{\phi}_{i,k} - \phi_{\mathrm{i,k}}\right)^2 + \rho \left(\mathrm{f}\left(\hat{\mathrm{Z}}_k\right)\right)^2$$

$$s.t. \quad \mathrm{a}_{i,k} = 0.45724 \frac{\mathrm{m}_{\mathrm{i,k}}^2 \mathrm{R} \mathrm{T}_{\mathrm{i}}^2}{\mathrm{P_i}}, \quad b_i = 0.07780 \frac{RT_i}{P_i}$$

$$m_{i,k} = \left[1 + (0.37464 + 1.54226\omega_i - 0.26992\omega_i^2)\left(1 - \sqrt{\frac{\hat{T}_k}{T_i}}\right)\right]^2 \tag{2}$$

$$a_k^m = \sum_i \sum_j \hat{x}_{i,k} \hat{x}_{j,k} \sqrt{a_{i,k} a_{j,k}} (1 - \kappa_{i,j}), \quad b_k^m = \sum_i \hat{x}_{i,k}\, b_i$$

$$\alpha_k = \frac{a_k^m \hat{P}}{R^2 \hat{T}^2}, \quad \beta_k = \frac{b_k^m \hat{P}}{R\hat{T}}$$

$$f\left(\hat{Z}_k\right) = \hat{Z}_k^3 + (\beta_k - 1)\hat{Z}_k^2 + (\alpha_k - 2\beta_k - 3\beta_k^2)\hat{Z}_k - \alpha_k\beta_k + \beta_k^2 + \beta_k^3$$

$$\ln\left(\phi_{i,k}\right) = \frac{b_i}{b_k^m}\left(\hat{Z}_k - 1\right) - \ln(\hat{Z}_k - \beta_k) - \frac{\alpha_k}{2\sqrt{2}\beta_k}\left(\frac{2\sqrt{a_{i,k}}}{a_k^m}\left(\sum_j \hat{x}_{j,k}\sqrt{a_{j,k}}\left(1 - \kappa_{i,j}\right)\right) - \frac{b_i}{b_k^m}\right) \times \ln\left(\frac{\hat{Z}_k + (1+\sqrt{2})\beta_k}{\hat{Z}_k + (1-\sqrt{2})\beta_k}\right)$$

The objective function consists of two terms. The first term minimizes the squared relative deviation in fugacity coefficient, while the second term enforces the root of the cubic equation using a penalty parameter ρ. Note that the compressibility factors in the cubic equation are parameters given by data; it is the cubic equation itself that changes during optimization.

An alternative formulation would define a new variable Z_k for each datum k and add constraints to require each Z_k to be a root of the cubic equation at the corresponding temperature and pressure. However, this introduces the issue of root selection and the

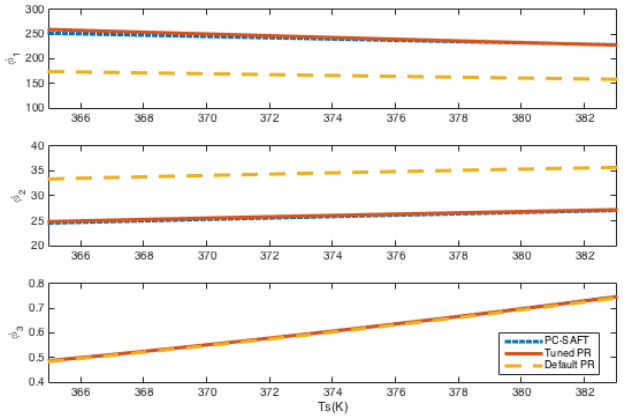

Figure 1: Fugacity coefficients with changing temperature

large number of nonlinear constraints can be difficult to converge. By contrast, the presented formulation can be solved as an unconstrained optimization problem through simple variable elimination and is found to be quite robust. Although the problem is nonconvex and the existence of several local minima has been observed, very good initialization can be derived by using the literature-reported critical temperatures, pressures, and binary interaction parameters. Formulation (2) has been implemented in Pyomo, and the parameter estimation problem is solved using IPOPT.

4. Numerical testing and flash optimization

In this section, the procedure for constructing SEOS is presented and performance is demonstrated on a flash model from a polyethylene production process. This flash model is used to separate unreacted monomer (ethylene) and chain transfer agent (hydrogen) from solvent (hexane) for recycle to the reactor. VLE data were gathered using a PC-SAFT flash model with a 3-level full factorial design on temperature, pressure, and component flowrates. The levels of each variable are shown in Table 1.

Table 1: Full factorial design

Input variable	Values	Explanation
$\hat{T}_k$	[362.15, 372.15, 382.15]	Flash temperature (K)
$\hat{P}_k$	[3.5, 4.0, 4.5]	Flash pressure (bar)
F_1	[0.093, 0.186, 0.373]	Input flowrate hydrogen
F_2	[3.01,6.02,12.05]	Input flowrate ethylene
F_3	[112.8, 141.0, 169.2]	Input flowrate hexane

Out of the 243 points in the full factorial design, two fell outside of the two-phase region and were discarded. The flash model outputs both liquid and vapor phase concentrations, compressibility factors, flowrates, and fugacity coefficients.

Formulation (2) was applied to fit SEOS for both liquid and vapor phases. Both problems were initialized with the literature values for critical properties and binary interaction coefficients. In the liquid phase, there was insufficient information in the data to obtain unique values for hydrogen's critical properties, so these were fixed at their literature values. The resulting parameters are shown in Table 2. Figure 1 compares the fugacity coefficients varying with temperature for PC-SAFT, the SEOS, and untuned Peng-

Robinson when the pressure is fixed at 3.85 bar. The SEOS matches very well over the temperature range, but the untuned PR deviates significantly.

Table 2: Results of fitting SEOS to cubic equation of state

Parameter	Literature	Liquid fit	Vapor fit
T_{H2} (K)	33.0	33.0	76.54
T_{C2H4} (K)	283	347.5	342.3
$T_{n\text{-hexane}}$ (K)	507.5	506.9	649.7
P_{H2} (bar)	13.2	13.2	10.1
P_{C2H4} (bar)	51.2	62.4	84.8
$P_{n\text{-hexane}}$ (bar)	30.1	30.0	61.9
$\kappa_{H2,C2H4}$	0.022	2.8×10^{-6}	0.509
$\kappa_{H2,n\text{-hexane}}$	0.02917	0.513	0.972
$\kappa_{C2H4,n\text{-hexane}}$	0.1144	0.179	0.158

The resulting surrogate equations of state are used in an optimization formulation of a flash drum. The objective is to minimize the amount of monomer in the liquid phase while maintaining a lower bound on mass flow of this stream such that the polymer product (not included in equilibrium calculations) remains a slurry. The model is given as:

$$\begin{aligned} \min_{T,P} \quad & x_{C2H4} L \\ \text{s.t.} \quad & 335 \le \mathrm{T} \le 370, \quad 2.5 \le \mathrm{P} \le 5 \\ & \textstyle\sum_i MW_i x_i \ge c, \quad \sum_i (y_i - x_i) = 0 \\ & F = L + V, \quad F z_i = L x_i + V y_i \\ & y_i = \frac{\phi_{L,i}}{\phi_{V,i}} x_i \end{aligned} \tag{3}$$

where MW_i is the molecular weight of component i, c is a constant specified to keep the product polymer suspended in slurry, and $\phi_{L,i}$ and $\phi_{V,i}$ are functions of T, P, x_i and y_i. Optimization problem (3) was run in three different modes: using PC-SAFT to calculate the fugacity coefficients, using un-tuned Peng-Robinson, and using the tuned SEOS approach. We note however that the PC-SAFT equation of state is difficult to use in equation-oriented optimization due to the presence of multiple volume roots, and the issue of root selection is beyond the scope of this work. Through careful initialization, a result was obtained that was validated against Aspen Plus to have found the correct roots of PC-SAFT.

Table 3: Flash optimization results. Errors are measured relative to PC-SAFT solution.

	PC-SAFT	Peng-Robinson	Error	SEOS	Error	Re-tuned SEOS	Error
x_{H2}	4.62×10^{-5}	6.3×10^{-5}	36%	4.34×10^{-5}	6%	4.62×10^{-5}	0.03%
x_{C2H4}	0.0127	0.0974	23%	0.0125	1.86%	0.0127	0.04%
x_{hexane}	0.9872	0.9902	0.3%	0.9875	0.02%	0.9873	<0.01%
T	351.67	349.68	0.6%	351.38	0.08%	351.64	<0.01%
P	2.5	2.5	0%	2.5	0%	2.5	0%

Table 3 shows that the results of using Peng-Robinson and PC-SAFT can vary by as much as 36 %. Using the SEOS parameters shown in Table 2, the maximum error relative to

PC-SAFT is reduced to 6%. Then, more data were gathered from PC-SAFT, in a full factorial design centered at the solution of the first SEOS optimization problem, with the width of data range cut in half. Then the SEOS is re-tuned using the data in the region of the solution, and the maximum error is reduced to 0.04%. This indicates the potential of using automatic update strategies in a trust region framework to control the optimization error introduced by the SEOS approximation.

5. Conclusions and future work

In this paper, we have demonstrated the potential of using a cubic equation of state to locally represent thermodynamic behavior directly from data. Tuning parameters for the cubic equation are selected based on their interpretation in terms of the principle of corresponding states. Then, an effective and reliable parameter estimation formulation is proposed. The formulation can be naturally converted to an unconstrained optimization problem for ease of initialization and solution. Finally, SEOS models are demonstrated for optimization of a flash unit in a polymerization system, and the SEOS gives accurate results with the potential for refinement by gathering more data.

The SEOS concept is not restricted to cubic functional forms and it may be worthwhile to consider virial-type equations as well. In addition, it is important to consider how to automatically and rigorously manage the error introduced by the SEOS. The use of trust region concepts, in which thermodynamic variables are constrained to lie in the region where data were obtained, is promising. However, the SEOS must be able to sufficiently approximate gradient information if it is to be valid for use in optimization. Future work will focus on verifying these properties and demonstrating the ability to adaptively adjust the surrogate equations of state in large-scale process optimization.

Abstract

New modelling and optimization platforms have enabled the creation of frameworks for solution strategies that are based on solving sequences of dynamic optimization problems. This study demonstrates the application of the Python-based *Pyomo* platform as a basis for formulating and solving Nonlinear Model Predictive Control (NMPC) and Moving Horizon Estimation (MHE) problems, which enables fast on-line computations through large-scale nonlinear optimization and Nonlinear Programming (NLP) sensitivity. We describe these underlying approaches and sensitivity computations, and showcase the implementation of the framework with large DAE case studies including tray-by-tray distillation models and Bubbling Fluidized Bed Reactors (BFB).

Keywords: NMPC, state-estimation, optimal control, sensitivity, pyomo.

1. Introduction

New modelling and optimization tools have created an opportunity for the creation of frameworks for problems in design, control, etc. These recent algebraic modelling languages (AMLs) like Pyomo and JuMP are based on high-level programming languages and are much more flexible than similar tools written in proprietary languages. Combining these platforms with state-of-art solvers makes it easier to deal with more complex problems. Of particular interest are optimal control problems (OCPs) that incorporate first-principles process models as part of a mathematical optimization problem. These models are often systems of differential algebraic equations (DAEs), and can be handled directly by means of direct multiple-shooting or orthogonal collocation, combined with the optimization algorithm.

Several frameworks have been developed for model-based optimal control combining AMLs and NLP solvers, these include ACADO, CasADi and Pyomo. In Pyomo (Hart et al., 2011) the dynamic optimization environment provides a combination of accessible modelling interfaces to solution algorithms. Rather than building a whole new base programming language, Pyomo provides the necessary optimization objects in Python, which escalates the flexibility of applications for optimization-based algorithms for dynamic systems. Previously, (Santamaria and Gomez, 2016) developed NMPC frameworks based on Pyomo and its extension for dynamic optimization Pyomo.DAE. In this work, we develop a new Pyomo-based framework for NMPC and combine it with a framework MHE. Both are implemented to perform close to real time nonlinear control and state estimation by means of NLP sensitivity. We also introduce a simpler sensitivity update based on a reduced set of variables, which decreases the amount of information transfer required for on-line computation.

2. Algorithmic background

Consider a first-principles model with the semi-explicit DAE system.

$$x'(t) = f(x(t), y(t), u(t)), g(x(t), y(t), u(t)) = 0, x(t_0) = x_0 \tag{1}$$

where $x \in \mathbb{R}^{n_x}$ and $y \in \mathbb{R}^{n_y}$ are the differential and algebraic state vectors, $u \in \mathbb{R}^{n_u}$ is the control vector and $t \in \mathbb{R}^1$ is the independent variable (time). The general dynamic optimization problem includes the DAEs (1) among its constraints. One way to deal with the optimization problem is to discretize the variables through orthogonal collocation on finite elements. The resulting problem is then fully algebraic and has a large dimensionality. However, it is also sparse and highly structured, and can be solved with large-scale NLP packages like IPOPT.

Once the modelling and optimization of the dynamic problem has been established, we formulate the respective control and state-estimation problems. The NMPC approach utilizes the model of the plant to make predictions of the optimal input vectors $u_{i|k}$ for a prediction horizon of N steps, given the state vector $x(k)$ (at time step k) from the plant. This leads to the parametric optimization problem $P\big(x(k)\big)$. Without loss of generality, we assume a discretized model of the plant $x_{i+1} = f(x_i, u_i)$ (with algebraic variables and equations eliminated), so that $P(x(k))$ can be written as:

$$\begin{aligned} P\big(x(k)\big): \quad & \min_{u_k} \varphi_N\big(x_{N|k}\big) + \frac{1}{2}\sum_{i=0}^{N-1} u_{i|k}^T R_i^{-1} u_{i|k} + \frac{1}{2}\sum_{i=0}^{N} x_{i|k}^T Q_i^{-1} x_{i|k} \\ \text{s.t.} \quad & x_{l+1|k} = f\big(x_{l|k}, u_{l|k}\big), \quad x_{0|k} = x(k), \\ & x_{l|k} \in \mathbb{X}, \quad l \in \{0,1,\dots,N\}; u_{l|k} \in \mathbb{U}, \quad l \in \{0,1,\dots,N-1\} \end{aligned} \tag{2}$$

where Q and R are positive definite matrices, $x_{i|k}$ denotes the predicted state at stage i given state $x(k)$ (from the plant). Asymptotic stability of problem (2) can be established when $N \to \infty$, although this can also be established through a terminal cost $\varphi_N\big(x_{N|k}\big)$ that approximates the cost of a problem with infinite horizon. However, the NMPC computation requires the knowledge of a full state $x(k)$, which in general is not accessible. Instead, only a limited amount of output data $y(k)$ are usually available.
Reconstruction of $x(k)$ from past data $y(k-i)$ requires the solution of a state estimation problem. In this work, we have considered the Moving Horizon Estimation (MHE) to compute the states. This problem is analogous to the NMPC approach in the sense that the model for the plant is used in conjunction to a set of past data (instead of the future as posed by the NMPC). At step k, the parametric MHE problem $\mathcal{M}\big(\hat{x}_{T-N|k-1}, \Pi_{T-N|k-1}^{-1}, y(k-N), \dots, y(k)\big)$ has a horizon window of length N and depends on the prior state-estimate $\hat{x}_{T-N|k-1}$, inverse prior-covariance $\Pi_{T-N|k-1}^{-1}$, and measurements $y(k-N), \dots, y(k)$. Let $m(k)$ be short notation for all the problem parameters previously described, then the MHE problem can be written as follows:

$$\begin{aligned} \mathcal{M}(m(k)): \quad & \min_{x_{T-N}, w_k} \frac{1}{2}\big(x_{T-N|k} - \hat{x}_{T-N|k-1}\big)^T \Pi_{T-N|k-1}^{-1}\big(x_{T-N|k} - \hat{x}_{T-N|k-1}\big) \\ & + \frac{1}{2}\sum_{i=T-N}^{T} v_{i|k}^T \mathcal{R}_i^{-1} v_{i|k} + \frac{1}{2}\sum_{i=T-N}^{T-1} w_{i|k}^T \mathcal{Q}_i^{-1} w_{i|k} \end{aligned} \tag{3}$$

$$\text{s.t.} \quad x_{l+1|k} = f\left(x_{l|k}\right) + w_{l|k}, l \in \{T-N, \dots, T-1\};$$
$$y(k-l) = h\left(x_{l|k}\right) + v_{l|k},$$
$$x_{l|k} \in \mathbb{X}, \quad l \in \{T-N, \dots, T\}; w_{l|k} \in \mathbb{W}, \ l \in \{T-N, \dots, T-1\}$$

with the process and measurement noise $w_{l|k}$ and $v_{l|k}$ respectively; and positive definite covariance matrices $\mathcal{R}_i$ and $\mathcal{Q}_i$. Note that the solution of $\mathcal{M}(m(k))$ yields the sequence of process noise w_k and most likely state estimates x_k, subsequently, one can set $x(k) = x_{T|k}$ and solve the corresponding control problem. For the next sampling step $k+1$, new data will be available and for a constant horizon window, the problem would require dropping the oldest measurement (i.e. $y(k-N)$) and shift the remaining vectors. Finally, the first term in the objective function is an approximation of the arrival cost, which is analogous to the terminal cost of NMPC and accounts for all the information that is missing from the full information problem.

If the solution of each problem can be computed instantaneously, the controller will achieve stability and robustness properties (Zavala and Biegler, 2009). We denote these as the ideal-NMPC and MHE problems. However, the solution of these problems has a computational overhead, as we are dealing with large NLPs. This situation can be overcome by implementing the Advanced-Step (as-) strategy (Figure 1), in which the NLPs are solved before the sampling time for a predicted state (or measurements). Then the control input (or state-estimate) can be updated and corrected with sensitivity with respect to the state (or measurement) difference. This implies that the NLPs associated with the control and/or state-estimation can be solved in advance, thus avoiding the on-line computational delay. The only computational overhead on-line will correspond to that of the sensitivity update, which is reduced to a matrix-matrix multiplication.

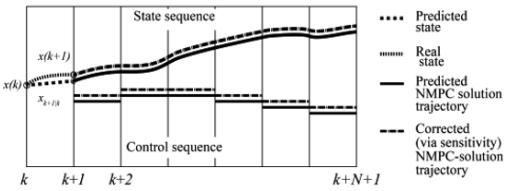

Figure 1 The Advanced-step NMPC strategy

For this framework, rather than performing the full primal-dual sensitivity update, the update is limited to a reduced set of variables of interest (i.e. for NMPC the inputs u_k and for MHE the current state-estimate $\tilde{x}_{T|k}$). This effectively reduces the amount of information that must be taken on-line, to just the sensitivity matrix $\hat{S}$. The sensitivity matrix computation is performed using the implicit function theorem on the optimality conditions of the NLP: $\min_z f(z, p_0), s.t. c(z, p_0) = 0, z \geq 0$, which will yield a linear system of equations (Pirnay et al., 2012) that depends on the parameter p. For this work, the associated linear system has the form:

$$\begin{bmatrix} \nabla_{zz}\mathcal{L}(z^*, p_0) & + Z^{*-1}V^* & \nabla_z c(z^*, p_0) \\ \nabla_z c(z^*, p_0)^T & & 0 \end{bmatrix} \hat{S}(p_0) = E \tag{4}$$

where p_0 is the nominal parameter value (i.e. predicted state for NMPC, predicted measurement vector for MHE), $\nabla_{zz}\mathcal{L}(z^*, p_0)^*$ denotes the Hessian of the Lagrange function of the corresponding NLP at its solution, $\nabla_z c(z^*, p_0)^*$ the gradients of the

constraints, E is a matrix that contains identity matrices at the positions of the variables of interest ($u_{0|k}$ for NMPC and $x_{T|k}$ for MHE) and $\hat{S}(p_0)$ is the corresponding sensitivity matrix. The KKT matrix in (4) is sparse and symmetric; therefore, the factorization can be done with sparse linear solvers like Pardiso or MA57. The subsequent sensitivity update on the parameter change p for the predicted solution $u(p_0)^*$ or $x_k(p_0)^*$ is:

$$\text{NMPC: } p = x(k) \; and \; \tilde{u}(p) = u(p_0)^* - \hat{S}(p_0)^T \begin{bmatrix} \nabla_{zp}\mathcal{L}^{*T} \\ \nabla_p c^{*T} \end{bmatrix} (p - p_0) \tag{5a}$$

$$\text{MHE: } \quad p = y(k) \; and \; \tilde{x}_{T|k}(p) = x_{T|k}(p_0)^* - \hat{S}(p_0)^T \begin{bmatrix} \nabla_{zp}\mathcal{L}^{*T} \\ \nabla_p c^{*T} \end{bmatrix} (p - p_0) \tag{5b}$$

where the term inside the brackets are the corresponding gradients with respect to the parameter. It should be noted that, equations (5a, b) are the only computations that are performed on-line, and will yield the corresponding updated control input vector $\tilde{u}_{0|k}$ (NMPC) or current state-estimate $\tilde{x}_{T|k}$ (MHE).

3. Framework

The Python based framework that formulates and solves these problems is displayed in Figure 2. The underlying idea is that we would like to provide a way to automatically set up the corresponding problems given a dynamic model, and methods that deal with algorithmic issues like initialization, sensitivity computations, etc. This framework is straightforward to extend, though most applications might require tailored algorithmic considerations.

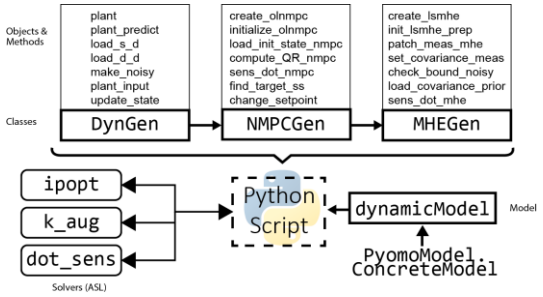

Figure 2 The Python framework for NMPC and MHE

In its current form, the framework requires a dynamic model manually discretized in time using collocation over finite elements, with expressions in place for continuity and initial conditions. Computation of the sensitivity matrices requires the solution of a symmetric sparse linear system of equation (4), that contains first and second order derivatives of the constraints and objective function. These operations are performed by combining Automatic Differentiation, sparse linear solver libraries like Pardiso and a new subprogram (`k_aug`) that performs all these operations separate from the Python framework. This computation is similar to an iteration of Ipopt with a different right-hand-side on the associated linear system. Furthermore, the update of the variables of interest is done in a second program (`dot_sens`) that updates the current solution with information from the sensitivity matrix. Both programs are compatible with Pyomo and use the Ampl Solver Library (ASL) for derivative information. These sensitivity-analysis codes were written in C instead of Python for greater computational speed.

4. Case studies

To demonstrate the application of the framework we consider the control of a Bubbling Fluidized Bed Reactor (BFB) for CO2 capture (Lee and Miller, 2012) as well as the MHE-NMPC coupling for a distillation column (Lopez Negrete et al., 2013). Both case studies were solved using Ipopt 3.12 with MA57, and an Intel(R) Core(TM) i7-6700 CPU @ 3.40 GHz processor.

BFB is a gas-solid reactor that removes CO_2 from a flue gas stream using a solid adsorbent. It can be modelled by using an extended Kunii-Levenspiel fluidized bed model. Due to the space-time discretization, the resulting problem yields 315 states and an NLP problem with 46480 variables and 46470 equations. Background computation for the control input requires solution of $P(x(k))$, which requires about 120 CPU seconds. However, the on-line cost for asNMPC requires *less than a CPU second* for the controller update (5a). Figure 3 shows the results for the NMPC of the BFB with random noise. For a change of CO2 capture set-point, the reactor is controlled by the gas output valve position. Figure 3 shows that asNMPC is not significantly different than ideal-NMPC, and is able to reach the set-point within the same time.

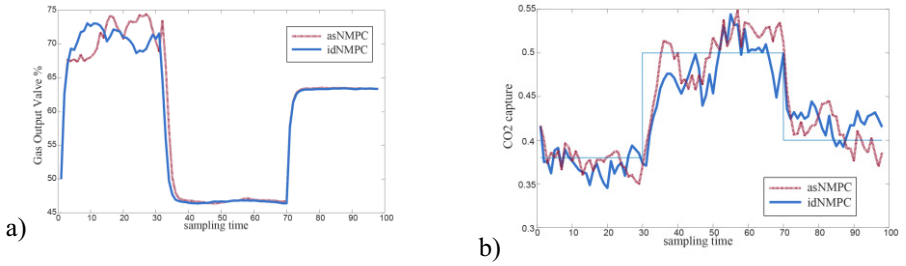

Figure 3 Results for the NMPC of the BFB; a) controller input profile, b) output profile

The full state vector for the distillation column case study is unknown, and it is estimated using MHE. This problem $\mathcal{M}(m(k))$ has 21346 variables and 20486 equations for 84 states. With this estimate, the control input is determined by NMPC. We assume that temperature and liquid molar holdup of each tray are measured, and temperature at tray 14 is the set-point. In Figure 4 both MHE results with the infinity norm of state error ($|error|_\infty$) and NMPC set-point tracking profile of the temperature are shown. Here, noise was introduced to demonstrate the performance of the as-MHE, and both advanced-step and ideal MHE and NMPC strategies reach the set-point with similar solution profiles. Background solution of problem $\mathcal{M}(m(k))$ requires 22 CPU s and the MHE sensitivity update (5b) takes 1 CPU s approximately. Both case studies show that the sensitivity update gives accurate values of control and state-estimates as noted by the values of the Root-Mean-Square Deviation of Table 1, where the deviations are relatively small for the tracked state (Figures 3-4(b)). Hence, the current Pyomo framework can handle nonlinear control effectively, with as-MHE and as-NMPC working together.

5. Conclusions

A new Python-based framework for Non-linear Model Predictive Control and Moving Horizon Estimation has been created in Pyomo. Given a discretized first principles dynamic model of a plant, the framework provides most of the common operations to perform optimal control, and it takes advantage of Pyomo to automatically generate the optimization problems. Fast control and state updates are embedded into the framework by means of NLP sensitivity with the advanced-step strategy. We also present an alternative way to compute sensitivities where the on-line update of the control is reduced to the set of input vectors (control) or state-estimates (state-estimation). The presented framework leverages state-of-art NLP and sparse linear algebra solvers to accelerate the expensive NLP computations. Moreover, capabilities currently under development include the compatibility with new Pyomo.DAE, new algorithmic features like handling active-set changes of the sensitivity updates, and structure exploitation of the underlying DAE models.

Abstract

The synthesis of energy systems is a complex optimization task depending on multiple large time series. Time-coupling constraints, e.g., due to storage systems, complicate computation even further. To still efficiently solve time-coupled synthesis problems, we propose a rigorous synthesis method. In the proposed method, lower and upper bounds are calculated to obtain a feasible solution of the original synthesis problem with known quality. We compute the lower bound by binary relaxation. For the upper bound, we use time-series aggregation to obtain a feasible design for the system. Employing this feasible design, we solve an operational problem, which can be solved efficiently. To tighten the upper bound, we iteratively increase the time resolution of the aggregation. In a case study for an industrial energy system, we show that only few typical periods are required to obtain a solution of the original synthesis problem with excellent quality. The method has fast convergence outperforming a commercial state-of-the-art solver.

Keywords: energy systems, optimal design, typical periods, rigorous optimization, relaxation

1. Introduction

Synthesis of process or energy systems is a complex two-stage optimization task that requires the simultaneous optimization of the first design stage and the second operation stage (Yokoyama et al., 2015). On the design stage, decisions on the type and sizing of components are made. On the operational stage, the on/off status and the load allocation are defined for each energy conversion or storage unit and each time step. Operation usually depends on multiple large time series, e.g., demand profiles, electricity prices and renewable resources. These large time series lead to large-scale optimization problems, which are computationally challenging and often not solvable within reasonable computational time or memory limits. Therefore, the problem size is often reduced by model aggregation (Grossmann, 2012). Time-series aggregation is often applied in synthesis problems for the design of chemical processes (Maravelias and Sung, 2009) and energy systems (Mancarella, 2014). However, the solution of the aggregated synthesis problem is not the solution of the original synthesis problem based on the full time series. Thus, the quality of the aggregated solution is unknown and the resulting design might even be infeasible for the full time series. To obtain a feasible solution with known quality, exact solution strategies are needed. In our previous work, we proposed an exact decomposition method to ensure optimality of the resulting design (Bahl et al., 2018b).

However, the proposed method does not consider the chronology of time steps. The Chronology of time steps is necessary to model storage systems or ramping constraints. Here, we propose a rigorous synthesis method considering the chronology of time steps. We apply our method to the synthesis of an industrial energy supply system.

2. Generic synthesis problem with time-coupling constraints

In Eq. (1), we state the generic synthesis problem of energy systems as a mixed-integer linear program (MILP)

$$\min_{\dot{V}_{n,t},\dot{V}_n^N,\delta_{n,t},\gamma_n,x} TAC = OPEX + CAPEX = \sum_{t\in T}\left(\Delta t_t \sum_{n\in C\setminus C_{stor}} c_{n,t}^o \frac{\dot{V}_{n,t}}{\eta_n}\right) + \sum_{n\in C} c_n^i \dot{V}_n^N$$

$$\begin{aligned}
s.t. \quad & \sum_{n\in C\setminus C_{stor}} \dot{V}_{n,t} + \sum_{n\in C_{stor}} \left(\dot{V}_{n,t}^{out} - \dot{V}_{n,t}^{in}\right) = \dot{E}_t && \forall t \in T, \\
& V_{n,t} + \Delta t_t\left(\dot{V}_{n,t}^{in} - \dot{V}_{n,t}^{out}\right) = V_{n,t+1} && \forall t \in T, \forall n \in C_{stor}, \\
& A_1\dot{V}_{n,t} + \tilde{A}_1\delta_{n,t} \le b_1 && \forall t \in T, \forall n \in C, \\
& A_2\dot{V}_n^N + \tilde{A}_2\gamma_n \le b_2 && \forall n \in C, \\
& A_3\left(\dot{V}_{n,t}, \dot{V}_n^N, \delta_{n,t}, \gamma_n, x\right)^T \le b_3 && \forall t \in T, \forall n \in C, \\
& \gamma_n, \delta_{n,t} \in \{0,1\}; x \in \mathbb{R}^a \times \{0,1\}^{\tilde{a}}; \dot{V}_{n,t} \in \mathbb{R}; \dot{V}_n^N \in \mathbb{R}^+.
\end{aligned} \tag{1}$$

As the objective function, we employ the total annualized costs TAC. The objective function consists of two parts representing the capital and operational expenditures, CAPEX and OPEX. The CAPEX are the nominal capacity of each component $\dot{V}_n^N$ multiplied by the specific investment costs c_n^i summed up for all components C. The OPEX are defined as the sum of the output power $\dot{V}_{n,t}$ of every conversion component $n \in C\setminus C_{stor}$ in every time step t divided by the efficiency η_n and multiplied by the specific operation cost $c_{n,t}^o$ and the duration Δt_t of a time step. In contrast to CAPEX, OPEX directly depend on the set of time steps T. The TAC are minimized subject to several constraints. The sum of the components output power $\dot{V}_{n,t}$ and the net energy output of the storage units $\dot{V}_{n,t}^{out} - \dot{V}_{n,t}^{in}$ have to meet the energy demand $\dot{E}_t$ at every time step t. The future storage level $V_{n,t+1}$ is coupled to the current storage level $V_{n,t}$ by the net energy output of the storage units $\dot{V}_{n,t}^{out} - \dot{V}_{n,t}^{in}$. Further (in)equalities with the coefficient matrices $A_1; \tilde{A}_1; A_2; \tilde{A}_2$ and the vectors $b_1; b_2$ determine the binary on/off status $\delta_{n,t}$, the binary existence γ_n of components and the nominal power $\dot{V}_n^N$. Only equations including the output power $\dot{V}_{n,t}$, the storage variables or the on/off status $\delta_{n,t}$ have to be stated for each time step t and thus depend on the size of the time series T. All other variables are represented by the vector x. Additional constraints are summarized in the surrogate equation A_3. The equation A_3 includes, e.g., sizing constraints $\dot{V}_{n,t} \le \gamma_n\dot{V}_n^N$. The surrogate vector x includes, e.g., additionally variables for the linearization of the bilinear terms $\gamma_n\dot{V}_n^N$. The original synthesis problem (Eq.(1)) is often not solvable in reasonable time for large time series T. In particular, the time coupling constraints due to storage systems enhance the complexity of the synthesis problem (Rong et al., 2008).

3. Rigorous synthesis method using relaxation and time-series aggregation

In this section, we present our rigorous synthesis method for the original large-scale synthesis problem. In Section 3.1, we give a short overview of the method. In Section 3.2, the calculation of the lower bound employing relaxation is explained and in Section 3.3, the calculation of the upper bound via time-series aggregation is presented. In Section 3.4, the evaluation of the optimality gap and the potential increase in time-series resolution are described.

3.1. Method overview

The proposed method consists of six steps (Fig.1):

(i) Relaxation of all binary variables of the original problem to obtain a lower bound of the synthesis problem
(ii) Identification of the length of a typical period
(iii) Time-series aggregation to typical periods and clustering of time steps within each typical period, from our previous work (Bahl et al., 2018a)
(iv) Synthesis optimization with the aggregated time series to obtain a design candidate of the energy supply system
(v) Operational optimization of the candidate design of the energy system with the full time series to provide a feasible solution that serves as an upper bound
(vi) Reiteration of step (iii)-(v) with increasing time resolution until the resulting lower and upper bound satisfy the desired optimality gap ε.

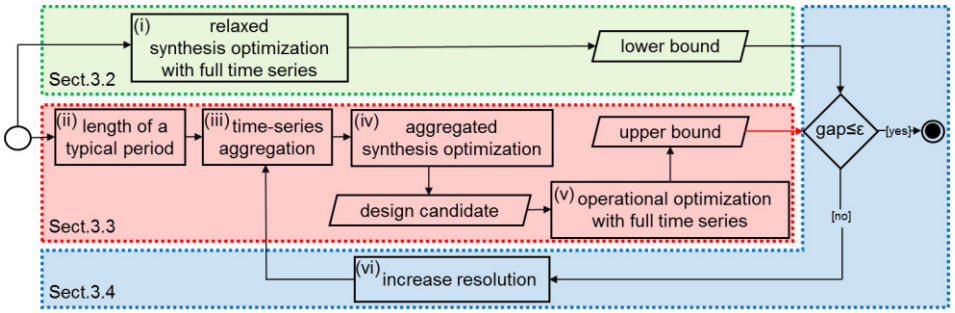

Figure 1: Rigorous synthesis method for energy systems employing time-series aggregation and relaxation to satisfy an optimality gap ε.

3.2. Step (i): Calculation of the lower bound

Step(i): First, we relax all binary variables (δ_{nt}, γ_n, $x \in \{0, 1\}$) of the original problem, thereby converting the complex MILP to an LP, which can be solved efficiently. The solution of the relaxed problem serves as a lower bound of the original synthesis problem. In this work, the lower bound is calculated only once. However, the method could also be extended by an iterative refinement of the lower bound as done in Bahl et al. (2018b) for energy systems without chronology in the time series.

3.3. Step(ii)-(v): Calculation of the upper bound

To calculate upper bounds, we employ time-series aggregation from our previous work (Bahl et al., 2018a).

Step (ii): To identify a suitable period length, we look for periodic patterns by applying autocorrelation to all time series (Box et al., 2015). Autocorrelation correlates each time

series n with itself at different time offsets resulting in a set of n autocorrelated functions ACF_n. For all time series we employ one constant period length in the time-series aggregation. Therefore, we calculate the normalized sum $\overline{ACF}$ of the resulting set:

$$\overline{ACF} = \frac{\sum_n ACF_n}{n}. \quad (2)$$

Splitting the time series into periods is meaningful if periodicity exists. An oscillation pattern in the autocorrelation indicates periodicity in the original time series. Peaks of the $\overline{ACF}$ correspond to suitable period lengths. A short period length can lead to smaller optimization problems using time-series aggregation. However, no chronology between periods is considered, and thus storage in between periods cannot be represented. Therefore, a short period length also implies to a short maximum storage load cycle.

Step (iii): Next, we start to aggregate the original time series to typical periods by first splitting the original time series into periods with the in step (ii) identified length. Typical periods require aggregation in two dimensions: the number of periods and the number of segments per period. We heuristically choose to first aggregate the number of periods and subsequently the number of segments. The aggregation of periods to typical periods is based on the k-medoids algorithm, which does not average as the k-means method does, but selects a period from the time series as a typical period (Kaufman and Rousseeuw, 2008). The k-medoids algorithm requires a mean-value correction, which we apply for each time series separately to obtain the same mean values as for the original time series as in Domínguez-Munõz et al. (2011). To aggregate segments, we iteratively calculate the average of randomly chosen consecutive time steps. The average value is used for the entire aggregated segment with the duration of the sum of the assigned time steps. The aggregated segments of the randomly chosen consecutive time steps with the lowest Euclidean distance to the original segments are used. The employed segment-aggregation method has the advantage that any time step can be used as a starting point for a typical period.

Step (iv): The time-series aggregation reduces the complexity of the synthesis problem by magnitudes. Thus, the aggregated synthesis problem can be solved efficiently. Nevertheless, the solution of the aggregated synthesis optimization cannot serve as an upper bound, as not the full time series is used. However, the optimization of the aggregated problems results in a design candidate of the energy supply system.

Step (v): The design candidate is subsequently used to solve the operational optimization problem with the full time series. For the operational optimization, the design decisions are now given. Thus, the problem can be solved much more efficiently. The feasibility of the design candidate resulting from step (iv) cannot be guaranteed for the full time series. To ensure a feasible design, we add peak demands as single time steps with duration of zero and no chronological order to the typical periods. If the resulting designs is still infeasible, we increase the time resolution in step (iii). The best known solution of the operational optimization with the full time series problem serves as an upper bound for the original synthesis problem.

3.4. Step (vi): Optimality gap ε and increase of time resolution

Step (vi): Last, we compare the resulting lower (step (i)) and upper bound (step (v)) and check if the desired optimality gap is satisfied.

$$gap\ \varepsilon = \frac{upper\ bound - lower\ bound}{upper\ bound}. \quad (3)$$

We iteratively increase the time resolution of either the number of periods or the number of segments until the gap is satisfied, as in Bahl et al. (2018a). The relaxation for the lower bound (step (i)) is not refined in this work. Hence, the method does not converge to a gap ε of 0 %.

4. Case-study

In this section, we apply the proposed method to an MILP industrial synthesis problem based on Voll et al. (2013). We use a superstructure with three units of each energy conversion technology with constant part-load efficiency (boiler, CHP engine, compression chiller, and absorption chiller) and one storage tank for hot and one for cold water. The original time series consists of one year with hourly demand data for process heat, hot and cold water, electricity, and electricity grid prices based on Bahl et. al. (2018a). The original synthesis problem with full time series contains $1.2 \cdot 10^6$ equations and $6 \cdot 10^5$ variables ($2 \cdot 10^5$ binaries) with $3 \cdot 10^6$ nonzero elements. We use a period length of 24 hours derived from step (ii). The period length of 24 hours leads to relatively minor optimization problems, but still enables daily storage cycles. All calculations are performed using 4 Intel- Xeon CPUs with 3.0 GHz and 64GB RAM. All MILP problems are solved using CPLEX 12.6.3.0 with an optimality gap of 2 %. The proposed rigorous synthesis method satisfies the gap ε of 2% in less than 1 hour (2364 s) (Fig. 2). The optimality gap ε of 2 % can be satisfied with only 2 periods and 3 segments resulting in a synthesis problem with only 4231 equations, 3054 variables (418 binaries) and 10,935 non-zero elements, reducing the complexity by about 3 orders of magnitude. Considering more periods and segments increases the accuracy only slightly (Fig. 2). For our calculation with the highest resolution of 8 periods consisting of 8 segments each, an optimality gap ε of less than 1 % is reached. The design candidate obtained from the problem with 2 periods and 3 segments consists of one boiler, 2 CHP engines, one compression and one adsorption chiller and a cold-water storage. The design changes only slightly for the solution with 8 periods and 8 segments; only a hot water storage is added and the capacity of the cold-water storage is doubled. The calculation of the lower bound (step (i)) takes about 800 s. The computational time of the upper bound consists of three parts: time-series aggregation (step (iii)), aggregated synthesis optimization (step (iv)), and operational optimization (step (v)). The computational time for the time-series aggregation and the aggregated synthesis optimization increases with a higher time resolution, but only takes few seconds for small number of time steps. In contrast, the operational optimization is independent of the aggregation of the time series, because the full time series is used. The operational optimization takes up to 5500 s, with a mean value about 1800 s. As a benchmark, we solve the original synthesis problem directly with CPLEX 12.6.3.0. The benchmark provides the first feasible solution after 3 hours (10827 s) and reaches the time limit of 120 hours with a relative gap of 10.07 %. To validate the computational results, we repeat the calculation of the original time series for 10 samples generated by statistical noise. To limit the computational effort, the time limit for each sample was set to 24h. The performance is very similar for all samples of our method (Fig. 2). The performance of the benchmark method differs: seven samples perform in a similar way to the original time series; In one sample no feasible solution is found at all; In two samples the required optimality gap is satisfied in 13h, marked as '+' (Fig. 2). The proposed method outperforms the benchmark in all samples, always satisfying the desired gap in less than an hour.

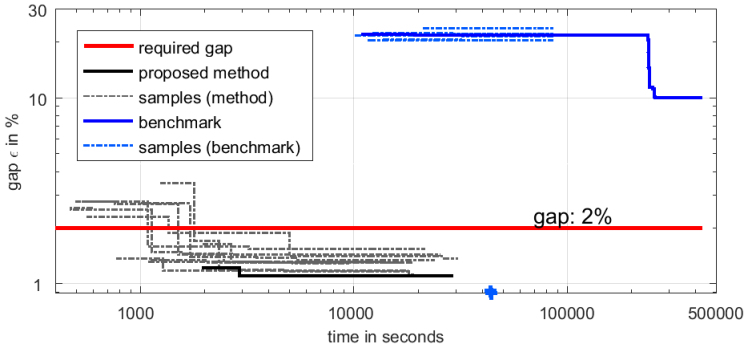

Figure 2: Logarithmic gap ε of the proposed rigorous synthesis method and the benchmark CPLEX as function of the logarithmic solution time. The required optimality gap ε of 2 % is marked in thick red.

5. Conclusions

The synthesis of energy systems results in large-scale optimization problems, which are computationally challenging and often not solvable within reasonable computational time or memory limits. In this paper, we propose a rigorous synthesis method providing feasible solutions via time-series aggregation as well as lower bounds via relaxation. The proposed method is applied to a real-world industrial synthesis problem. The results show that the lower bound provided by the relaxed problem is sufficient to reach an optimality gap of less than 2%. In our case study, only two typical periods with three segments each are required to obtain a solution of the original synthesis problem within the optimality gap. The method provides fast convergence within one hour, outperforming the state-of-the-art solver CPLEX, which does not satisfy the desired gap after 120 hours. The method is generally applicable to two-stage synthesis problems with binary decision variables, in which only the second-stage operational problem depends on the time series.

Abstract

Mixed-integer, partial differential equation (PDE) constrained optimization (MIPDECO) is a flexible modeling framework with many engineering applications, e.g. tidal and wind turbine siting, pharmaceutical business operations, disaster recovery, and solid product creation. But solving MIPDECO is daunting because it combines both integer programming and partial differential equations in a single optimization model. We consider a range of optimization algorithms for addressing MIPDECO from two applications: (i) the Source Inversion and (ii) the Tidal Stream Turbine Optimization problems. We report on the relevant merits of these approaches and make our results available as an open source extension to OpenTidalFarm.

Keywords: Mixed integer optimization, partial-differential equation constraints, tidal stream turbines

1. Introduction

This paper discusses mixed-integer, partial differential equation (PDE) constrained optimization (MIPDECO) through two applications: (i) the Source Inversion problem with applications in well drilling and (ii) the Tidal Stream Turbine Optimization problem with applications in renewable tidal energy (Cay et al. 2016; Funke et al. 2016). To solve these two MIPDECO problem classes, we introduce several novel optimization algorithms including two methods based on branch-and-bound, i.e. relaxation of the PDE constraints, and four methods based on gradient descent, i.e. relaxation of the integer restrictions. We analyze the efficacy of each algorithm with respect to time complexity and performance on our MIPDECO test set.

As an application, we focus on the tidal turbines and tidal stream turbine MIPDECO previously proposed by Funke et al. (2016). We reproduce the Funke et al. (2016) results, i.e. derive results maximizing power from a field of turbines. We also formulate a new objective function incorporating revenue and the time-value of money. We show that our novel MIPDECO algorithms significantly outperform the Funke et al. (2016) approach. Our results are available (https://github.com/cog-imperial/tidal_turbines-source_inversion) as an extended version of the open-source software OpenTidalFarm using FEniCS (Logg et al. 2012), CasADi, dolfin-adjoint (Farrell et al. 2013), and IPOPT (Wächter and Biegler, 2006).

2. Background

2.1. Mixed-integer partial differential equation constrained optimization

The following equations formalize a mixed-integer PDE-constrained optimization (MIPDECO) problem. MIPDECO generalizes mixed-integer optimal control, e.g. as

considered by Mohideen et al. (1997), Allgor & Barton (1999) and Sager et al. (2009). In mathematical terms, it is important to note that the PDE states $\boldsymbol{u}$ and the decision

$$\min_{\boldsymbol{u},\boldsymbol{x}} \; J(\boldsymbol{u},\boldsymbol{x}) \quad s.t. \quad \begin{cases} \mathcal{F}(\boldsymbol{u},\boldsymbol{x}) = 0 \\ \boldsymbol{g}(\boldsymbol{x}) = 0 \\ \boldsymbol{h}(\boldsymbol{x}) \leq 0 \\ x_i \in \mathbb{Z} \quad \forall i \in 1,...,K \\ x_j \in \mathbb{R} \quad \forall j \in K+1,...,N \\ \boldsymbol{x},\boldsymbol{u} \in \mathcal{H}_1, \mathcal{H}_2 \end{cases}$$

variables $\boldsymbol{x}$ exist in a possibly infinite-dimensional Hilbert space, as they represent arbitrary functions varying over the entire domain. The resulting MIPDECO takes the form (where *F* denotes the PDE system, and *K* and *N* are potentially infinite):

2.2. Discretize then optimize versus optimize then discretize

The two primary approaches to solving MIPDECO are illustrated in Figure 1. This paper assumes that the MIPDECO is too big for global optimization, e.g. as in Houska & Chachuat (2017), so the illustrated solutions are local only. Given the initial MIPDECO problem with a continuous PDE constraint, we can either (i) find points satisfying the necessary optimality conditions (NC) and then discretize the PDE, yielding Solution 1 (Sol. 1) or (ii) first discretize the PDE constraint and then solve using nonlinear programming (NLP), yielding Solution 2 (Sol. 2). These two techniques may not yield equivalent answers, i.e. ¬ (Sol.1 = Sol.2).

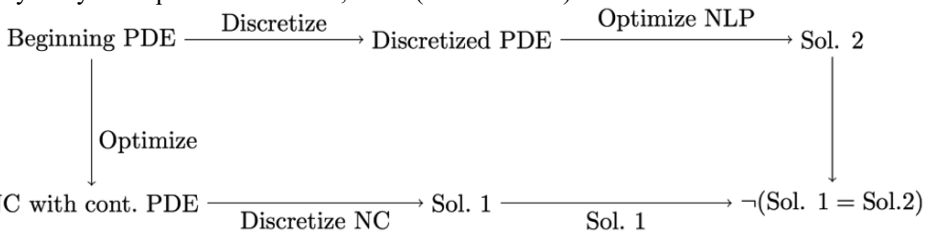

Figure 1 Discretization order matters: discretize then optimize vs. optimize then discretize

Before discretizing/optimizing MIPDECO, observe that MIPDECO can be classified into problems with (i) mesh-independent and (ii) mesh-dependent decision variables. Consider the MIPDECO problem after continuous PDE *F* has been discretized. Denoting the discrete PDE as $\mathbb{F}$, and transforming our infinite dimensional Hilbert spaces into finite vector spaces V_1 and V_2:

$$\min_{\boldsymbol{u},\boldsymbol{x}} \; J(\boldsymbol{u},\boldsymbol{x}) \quad s.t. \quad \begin{cases} \mathbb{F}(\boldsymbol{u},\boldsymbol{x}) = 0 \\ \boldsymbol{g}(\boldsymbol{x}) = 0 \\ \boldsymbol{h}(\boldsymbol{x}) \leq 0 \\ x_i \in \mathbb{Z} \quad \forall i \in 1,...,K \\ x_j \in \mathbb{R} \quad \forall j \in K+1,...,N \\ \boldsymbol{x},\boldsymbol{u} \in \mathcal{V}_1, \mathcal{V}_2 \end{cases}$$

If the problem is mesh-independent, then the decision variables are independent of the PDE discretization, e.g. *O(n)* memory complexity for *n* mesh-independent decision variables. But the number of mesh-dependent decision variables increases as the discretized PDE is refined. Obviously, this distinction has significant ramifications on the scalability of a MIPDECO problem, e.g. with a *m x m* mesh any optimization algorithm will have memory complexity $O(m^2)$ with regards to the decision variables.

3. Test Instances

We consider two optimization problems: (i) the Source Inversion problem with applications in well drilling and (ii) the Tidal Stream Turbine Optimization problem with applications in renewable tidal energy (Cay et al. 2016; Funke et al. 2016).

3.1. Source Inversion Problem

Following Cay et al. (2016), we consider the Source Inversion MIPDECO problem, though with the use of adjoint-based gradient optimization methods (implemented with the FEniCS PDE-solving framework and dolfin-adjoint). The Source Inversion problem is a function-tracking model minimizes the distance between a reference state $\bar{\boldsymbol{u}}$ and the solution to a source PDE $\boldsymbol{u}$ (which is a Poisson equation with the source term equalling the sum of a host of source functions) over the simple box domain Ω, paired with a Dirichlet boundary condition. This minimization problem also requires that the maximum number of activated source functions does not exceed a user-defined integer S, and that each source function at location {k,l} is modelled as a Gaussian function f_{kl} with binary coefficient w_{kl} (which controls the activation/inactivation of each source function). In other words, we want to find the most accurate way to recreate the solution to the reference PDE with a combination of up to S source functions:

$$\min_{\boldsymbol{u},\boldsymbol{w}} \ \mathcal{J}(\boldsymbol{u},\boldsymbol{w}) = \frac{1}{2}\int_{\Omega}(\boldsymbol{u}-\bar{\boldsymbol{u}})^2 d\Omega \quad s.t. \quad \begin{cases} -\Delta \boldsymbol{u} = \sum_{k,l} w_{kl} f_{kl} & \in \Omega \\ \boldsymbol{u} = 0 & \in \delta\Omega \\ \sum_{k,l} w_{kl} \leq S & \\ w_{kl} \in \{0,1\} & \forall k,l \end{cases}$$

The Source Inversion problem has mesh-independent binary variables w_{kl}. We considered 4 methods for solving this problem:

1. **Heuristic Integer Algorithm** This method solves the continuous relaxation of the Source Inversion problem, i.e. $w_{kl} \in [0,1]$, and then rounds each continuous w_{kl} depending on its optimal continuous magnitude and the value of S.
2. **Penalty Algorithm** This method is equivalent to Algorithm 1 except that it penalizes non-binary w_{kl} by adding terms $w_{kl} \times (1 - w_{kl})$ in the objective.
3. **Two-Step Algorithm** This method takes a two-stage approach by beginning with solving a continuous relaxation of the Source Inversion problem and then trying to enforce binary by adding terms $w_{kl} \times (1 - w_{kl})$ to the objective.
4. **Branch & Bound** This method enforces binary w_{kl} using divide and conquer. It converges to the global optimum if all continuous relaxations are convex, but we do not solve each (possibly nonconvex) subproblem to global optimality.

3.2. Tidal Stream Turbine Optimization

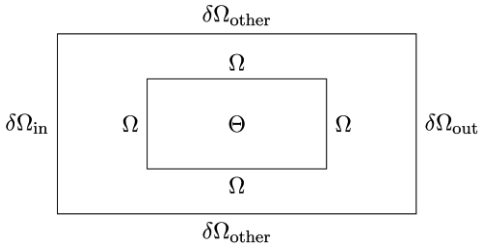

Figure 2 Problem Topology

In tidal stream turbine optimization (TSTO), there is a two- or three-dimensional domain Ω in which the tidal turbines are placed. There is also a sub-domain $\Theta \in \Omega$ such that the tidal turbines are all placed in Θ, with tidal modelling also occurring around the farm area in Ω. In this paper, we consider unidirectional tidal currents in a 2-D rectangular domain. That is, the tidal

velocity enters Ω from boundary $\delta\Omega_{in}$ and leaves from $\delta\Omega_{out}$. We assume no tidal activity on the other two boundaries.

Our model formulation is very similar to the formulation of Funke et al. (2016) and incorporates the following modeling considerations:

- **Constant water velocity.** Alternative approaches may consider a sinusoidal model, e.g. to represent tidal inflow.
- **Shallow water equations.** This approximation of the Navier-Stokes equation models fluid motion around the turbines.
- **Energy captured by the turbine farm.** This will feed into the profit function.
- **Proximity constraints.** Turbines cannot be built too close to one another.

The original optimization formulation of Funke et al. (2016) also required that we specify the number of turbines, but we make this a decision variable. To make the objective function more realistic, we also incorporate the cost of the installed turbines and the revenue from the produced energy into the objective function.

We compute the cost of the turbines using the levelized cost of energy (*LCOE*) to model the lifetime cost of a single turbine with discount rate r = 10%, time period *(0,T)*, value of energy output O_t, and cost C_t at time t as:

$$LCOE = \frac{\sum_{t=0}^{T} C_t/(1+r_t)^t}{\sum_{t=0}^{T} O_t/(1+r_t)^t}$$

From this, given a predefined constant *LCOE*, we can easily calculate:

$$\text{Total Discounted Cost} = \sum_{t=0}^{T} C_t/(1+r_t)^t = LCOE \cdot O_t/(1+r_t)^t$$

Modeling revenue is more difficult because it cannot be modeled per turbine: power extraction (and therefore revenue) depends on the entire turbine field configuration. Consequently, we create a revenue function primarily dependent on: (i) the 10% discount rate, (ii) the power produced by the field at each time step, (iii) a constant k which corrects for efficiency losses, and (iv) the income per unit of energy *I(t)* at time t. To penalize the energy optimism, we set $k = 0.5$, so that only 50% of theoretically extractable energy is actually captured by the farm. Furthermore, the income per energy unit *I(t)*, is based upon the UK government's Electricity Market Reform program which encourages (and subsidies) renewable electricity generation.

$$\text{Total Discounted Revenue} = R(\boldsymbol{u}, d) = k \sum_{t=0}^{T} \frac{IE_t(\boldsymbol{u}, d)}{(1+r_t)^t}$$

Our complete model formulation is available in the MSc thesis of C. Wesselhoeft. We considered several different methods for solving tidal stream turbine optimization:

1. **Continuous**. This method of Funke et al. (2016) calculates the optimal continuous density field, profit, power extraction/cost, and number of turbines.
2. **Two-Step**. This algorithm uses the continuous solution and a method to place N turbines to set up an initial layout for the discrete problem with the number of turbines pre-specified by a continuous relaxation approximation.
3. **MIPDECO**. This algorithm uses the continuous solution and chooses an initial lay-out for a MIPDECO problem without a pre-specified number of turbines.

4. Results

4.1. Case Study 1: Source Inversion Problem

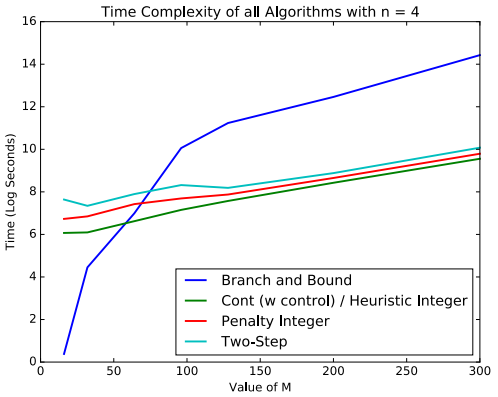

Figure 3 Time complexity versus mesh size

The MIPDECO algorithms for Source Inversion are effectively: (i) solving a relaxed nonlinear optimization problem and then rounding and (ii) solving relaxed nonlinear optimization problems in a branch and bound framework. Branch and bound is fast and accurate when the mesh m is coarse. But the key difference between rounding and branch and bound algorithms lies in their different scaling. Gradient-based algorithms create a control for each source function and only optimize based on these controls; consequently they scale well in mesh size, yet poorly in number of source functions. Branch and bound must explore constraints based on the total set of N + M variables, and thus performs well when $n^2 + m^2$ is small, but performs poorly as the total number of variables increases. In the Source Inversion problem, $n << m$ by construction, and thus mesh refinement will often be the bottleneck whilst scaling.

4.2. Case Study 2: Tidal Stream Turbine Optimization

Table 1 Results for tidal stream turbine maximization (the continuous solution is infeasible). The runtime includes the initialization step. "Initial Two Step" is the first step of the MIPDECO row.

Algorithm	Profit (GBP)	Number of Turbines	Runtime (seconds)
Continuous	9.57e7	122.5	7978
Two-Step Discrete	5.04e7	123	38363
MIPDECO	4.021e7	123	9622
Initial Two-Step	3.11e7	123	7979

Solving the problem posed in Section 3.2 (see Wesselhoeft's MSc https://goo.gl/Srx1Zr and our code, https://github.com/cog-imperial/tidal_turbines-source_inversion), we obtain the results in Table 1 from the optimization algorithms. We chose a mesh size of 4m in the farm area and 100m outside the farm area, i.e. a computational mesh of 90,500 elements. The first three optimization methods are the ones outlined in Section 3.2 and the *Initial Two-Step* method places turbines randomly from a continuous relaxation. Since this is a maximization problem, randomly placing turbines clearly has the weakest performance of the 4 approaches.

The results in Table 1 lie on a spectrum. The continuous formulation automatically yields the optimal number of turbines and supposedly yields the highest profit, though as it does not individually resolve turbines, the profit comparison between the continuous and discrete situations is spurious. Crucially, however, optimizing the continuous case only requires ~133 minutes, despite the large number of elements in the

mesh. After running the continuous example, we placed 123 turbines at random. This initial placement from the two-step algorithm yielded 3.11 x 10^7 GBP profit.

To improve the baseline result, we implemented the second step of the two-step algorithm from Section 3.2 and ran a full discrete optimization randomly-generated layout as a starting position. While the optimization resulted in 5.04 x 10^7 GBP profit, i.e. a large increase over the baseline, the increase in profit came at the cost of a severe increase in time complexity as the second step of the two-step algorithm individually resolves the location of each turbine.

As an intermediate solution, we used the MIPDECO algorithm to fix the possible turbine locations to a subset of the 200 locations, and then optimize binary variables assigned to each fixed turbine. Consequently, the total MIPDECO runtime is roughly one fifth of the Two-Step algorithm's runtime – in this case 2.65 hours instead of 12.87 hours. Additionally, the MIPDECO turbine layout improved profit as compared with the initial random heuristic layout by 33.5%, though still yielded far less profit than the discrete case, which improved upon the initial layout by 62.1%. In short, the two-step discrete method returned a significantly higher profit than the baseline, at the expense of a significant increase in algorithm runtime. The MIPDECO formulation improved moderately upon the baseline, with comparatively little time increase.

5. Conclusions

The methods described in this paper apply to test cases with mesh-dependent (source inversion) and mesh-independent (tidal turbine) optimization problems. We see the trade-off, e.g. with respect to quality of solution or time invested, with respect to a number of approaches. In particular, notice that exact methods for resolving the integer variables are often difficult in these large-scale problems.

Abstract

A hyperheuristics that coordinates the interaction between various metaheuristic techniques is presented. The proposed algorithm, which we called Parallel Optimizer With Hyperheuristics (POWH), includes a Genetic Algorithm, Simulated Annealing, and Ant Colony Optimization. In view of the need to escape from local optima, information exchanges take place between these metaheuristics. In this way, it is possible to take advantage of each metaheuristics' particular strengths during the search process. Testing related to the hyperheuristic approach was carried out by using the following real-life case studies: I. the optimal design of a subsea pipeline network and II. the urban bus-transit optimal planning. In both cases, a satisfactory reduction of the computational time was achieved due to the parallel implementation that allowed several metaheuristics to run simultaneously. Moreover, better results were also obtained thanks to the parallel cooperative combination of metaheuristics compared with serial executions.

Keywords: parallel programming, metaheuristics, pipelines, LRP, hyperheuristics.

1. Introduction

Nowadays, metaheuristic optimization algorithms have turned out to be quite attractive because of their distinct advantages over traditional algorithms (Gupta and Ramteke, 2014). Since metaheuristics can solve multiple-objective multiple-solution and nonlinear formulations, they are employed to find high-quality solutions to an ever-growing number of complex real-world problems, such as the combinatorial ones. Evolutionary techniques, like Genetic Algorithms (GA) and Ant Colony Optimization (ACO), have successfully been employed in solving many general optimal problems, such as the optimization of fed-batch fermentation. Optimization frameworks combining GA and Simulated Annealing (SA) have also been applied for the design and synthesis of heat exchanger networks (Shelokar *et al*., 2014), as well as for model predictive control (Venkateswarlu and Reddy, 2008). In particular, some variants of hybrid-GA techniques have been reported as novel prediction techniques (Sukumar *et al.,* 2014).

In the present study we have proposed a hyperheuristic approach by incorporating GA, SA and ACO. A hyperheuristics (Burke et al., 2013) is a general search method that has a set of solvers (low-level methods) and manages the execution of the most convenient

technique at a given time during the search process. When solving difficult computational search problems, hyperheuristics have proved to be advantageous. In operational research, there are some hyperheuristic-based algorithms that have been developed for single kinds of classical metaheuristics (Koulinas et al, 2014), but the combination of several types of metaheuristics has not been thoroughly analysed. Branke et al. (2016) summarized the state-of-the-art alternatives for hyperheuristic design choices and identified the main issues that future work should focus on. They pinpointed that their high computational requirements constitute a major disadvantage of hyperheuristics. In this context, parallelism emerges as an advanced strategy to reduce computational times significantly.

Both the demand for fast solutions of optimization problems, together with the advent of novel concurrent computing architectures constitute incentives for the development of parallel algorithms (Alba, 2005) in order to solve challenging problems efficiently. Regarding computational efficiency in urban planning strategies, Agrawal and Mathew (2004) have implemented a parallel algorithm based on a GA model for a large-scale problem, reporting satisfactory results in computational time, speedup and efficiency.

In view of the widespread need to solve challenging large-scale PSE problems, a parallel implementation was adopted and the proposed algorithm was called Parallel Optimizer With Hyperheuristics (POWH). The parallelization allows several metaheuristics to run simultaneously in threads, thus achieving a satisfactory decrease of the computational time. POWH design is briefly described in Section 2. Then, in Section 3 both pipelining and bus planning are presented as test problems, whose main features are pointed out before the discussion of some computational results, which are given in Section 4. Finally, some conclusions and hints for future work are summarized in Section 5.

2. Methodology

A cooperative strategy applicable to optimization problems is presented. The proposed algorithm is a hyper-heuristics, which comprises 3 well-known canonical metaheuristics with various strengths. The algorithm for the Parallel Optimizer With Hyperheuristics (POWH) is based on the master–slave paradigm (Fig. 1) and has multiple metaheuristics that cooperate periodically and work concurrently on distributed computing environments. Its organizational framework is an A-team architecture (Talukdar et al., 1998), where the autonomous agents are the following metaheuristics: Simulated Annealing (SA), Genetic Algorithm (GA) and Ant Colony Optimization (ACO).

The partnership is useful because it has been conceived by combining different primary procedures: SA is a trajectory-based technique, GA is a population-based method and ACO is a constructive approach.SA's strategy avoids local minima by allowing with a certain probability to choose a solution whose fitness value is worse than the current solution. Therefore, the SA algorithm converges relatively slowly towards the final solution. This drawback can be remediated by both implementing parallel programming and hybridizing the algorithm with ACO, which is particularly advantageous due to the remarkable ability of artificial ants to construct solutions guided by the pheromone trails. Moreover, SA tends to find local optima, thus delaying convergence. This weakness can also be surpassed thanks to a combination of SA with other metaheuristics that may contribute to diversify the search by enlarging the search space by means of efficient explorations. For this purpose, it was necessary to incorporate another exploratory method, such as GA.

In GA the initial population is chosen randomly, while the best solution designated by the master is always incorporated as an elite solution. In general, the termination criteria are all based on the amount of executions. These limits are: 50 generations for GA, 100 iterations for SA and 50 colonies for ACO.

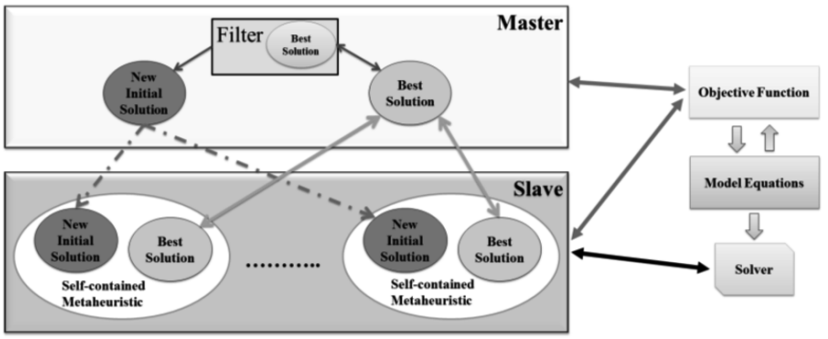

Figure 1. Hyperheuristic Model.

As to the control system, the choice of a suitable metaheuristics is guided by a ranking index (*Ind*) that assesses each metaheuristics' performance through Eq. (1-6), whenever a processor becomes idle. The technique with the highest rank will thus be eligible for the next execution. Besides, the particular problem is not only incorporated in modules for the model equations and the objective function, but also in the filter module because filtering is necessary to detect unfeasible solutions. The filter is a problem-dependent selector that indicates which solutions should be erased.

$$Ind = Fitness + Evaluation + Time + Optimality + Repetition \quad (1)$$

$$Fitness = 1 - \left({BestFitness}/{SumFitness}\right) \quad (2)$$

$$Evaluation = 1 - {Eval}/{SumEval} \quad (3)$$

$$Time = 1 - {BestTime}/{SumTime} \quad (4)$$

$$Optimality = 1 - \left({BestFitness}/{(SA_{bf} + GA_{bf} + ACO_{bf})}\right) \quad (5)$$

$$Repetition = 1 - \left({e^{Rep}}/{Q_{runs}}\right) \quad (6)$$

3. Test Cases

A couple of PSE-representative case studies were solved. Aiming at algorithmic generalization, Case II was chosen since it also serves to create very large challenging instances that may demand long computational times.

CASE I: The optimal design of a subsea pipeline network. It was modelled based on the problem formulation in Oteiza *et al.* (2015). In contrast, the well platforms were represented by concentrating nodes, which are located by the optimizer in the adapted model. Besides, the objective function (Eq. (7)) was adapted in this work so as to comprise offshore pipelining by contemplating specific terms related to installation and operating costs. The Net Present Value (NPV) of the project was calculated from revenue

flows and terms related to the construction and operating costs for each well platform WP_k. In Eq (7), the building costs were taken into account by considering both pipeline construction $CC_{ij,t}$ and the installation costs of every well platform $\delta_{k,t}$. The operating costs include the maintenance cost $MC_{ij,t}$ and the operative labor cost LC_t. The transport tariff P_t is useful to determine whether the project is economically viable. Since fitness values were measured in terms of NPV, this is a maximization problem.

$$NPV = \sum_{t=1}^{o} \frac{P_t \text{ x } Q_t}{(1+r)^{t+d+e}} - \sum_{t=1}^{e} \sum_{i=1}^{f+q} \sum_{j=1}^{q+p} \frac{CC_{ij,t}}{(1+r)^{t-1}} FP_{ij} - \sum_{t=1}^{d} \sum_{k=1}^{q} \frac{\delta_{k,t}}{(1+r)^{t+e-1}} WP_k - \sum_{t=1}^{d} \sum_{k=1}^{q} \frac{MC_{k,t}}{(1+r)^{t+e-1}} WP_k - \sum_{t=1}^{o} \frac{LC_t}{(1+r)^{t+d+e}} \quad (7)$$

CASE II: Bus planning. It was modelled by means of an LRP (Location Routing Problem), which constitutes an NP-complete problem (Wolsey, 2000). The stops and routes were determined in order to meet the demand with minimal cost *Z*. The location and routing model for the urban bus transport was based on the formulation of classical LRPs (Ceder, 2016) with suitable modifications in fitness evaluation, whose function was formulated in terms of network costs Z. It includes three terms to cover the offer, while the fourth one contemplates the demand in more detail through a matrix, whose elements m_{ij} represent walking-distance penalties. As to the offer, the following terms were included: the costs of traversed edges, the fixed costs of opening bus stops and the fixed vehicular costs associated with employed buses. Then, the lower costs become, the better.

4. Performance Results

All the algorithms were implemented in Java and run on a PC with 8 GB of RAM and Intel Core i5-3330. For all instances, each test was repeated independently 30 times. As to the "best average fitness", it was calculated as the average across the 30 runs of the best value identified in each run. In the first place, serial algorithms were programmed to evaluate the behaviour of the individual metaheuristics whose computational times (costs) are employed as the upper bounds for this analysis. An incremental variation of the amount of nodes was considered on Table 1. It shows the best average fitness and the corresponding average time required for each metaheuristics running sequentially for different sample problems. The solution quality (fitness) was always satisfactory, but computational time also increased as problem size grew up. It can be concluded that POWH´s organization (GA-SA-ACO) is effective because the addition of various agents has provided benefits in terms of solution quality (fitness) for large instances.

Table 1 The effect of metaheuristics on the computational time (ms)

Algorithms		**GA**		**SA**		**ACO**		**GA-SA-ACO**	
Case	**Size (Nodes)**	**Fitness (U$S)**	**Time (ms)**	**Fitness (U$S)**	**Time (ms)**	**Fitness (U$S)**	**Time (ms)**	**Fitness (U$S)**	**Time (ms)**
I Small	5	$9.69E^{+07}$	217	$9.69E^{+07}$	328	$8.60E^{+07}$	527	$9.69E^{+07}$	677
I Large	18	$3.19E^{+08}$	3,233	$1.97E^{+08}$	928	$2.00E^{+08}$	923	$1.14E^{+11}$	1,370

Since substantially smaller times are required, a parallel combination of metaheuristics (POWH) was implemented. Parallelization by threading allows several metaheuristics to run simultaneously in threads. On Table 2 the impact of parallelism was corroborated by

comparing serial and parallel times.The average deviation between the best lower bounds (POWH) and the upper bound (SOWH) is around 50% on smaller instances and around 30% on some large instances, whenever solutions of the same quality are reached.

Table 2. Contrasting Parallel (POWH) and Serial (SOWH) algorithms for Case I

Algorithm		**SOWH**		**POWH**	
Case	**Size (Nodes)**	**Fitness (U$S)**	**Time (ms)**	**Fitness (U$S)**	**Time (ms)**
I Small	5	$9.69E^{+07}$	1,458	$9.69E^{+07}$	677
I Large	18	$1.14E^{+11}$	2,097	$1.14E^{+11}$	1,370

As to solution quality and for Case II, Table 3 shows that as the number of processors increases, POWH finds solutions of better quality (i.e., lower Z values) in shorter times.

Table 3. Contrasting Parallel (POWH) and Serial (SOWH) cooperative algorithms.

Algorithm	**# Processes**	**Average Z (U$S)**	**Average Time (ms)**	**Speed-up**	**Efficiency (%)**
SOWH	1	6,354	2,764		
POWH	4	5,804	1,897	1.46	36.5
POWH	7	2,473	1,793	1.54	22.0

5. Conclusions and Future Work

Some real-life PSE optimization problems proved to be benefited from quick solutions that could be achieved with the help of parallel programming by means of the proposed hyperheuristic method (POWH) presented here. The solution method coordinates interactions among metaheuristics to create a fast strategy that is able to escape from local optima, thus performing an effective search of a solution space. Three metaheuristics have been combined: Simulated Annealing, Genetic Algorithm, and Ant Colony Optimization. The solution strategy worked out satisfactorily in practical problems. For different sizes, POWH showed promising performance in the search for solutions since it was able to obtain high-quality results in reasonably shorter computing times. For the continuation of this research work, it is necessary to verify in general terms that POWH is always both rigorous and efficient. Then, further testing that involves a wide choice of sample problems oriented to parallel computing running in threads is vital to complete thoroughly the computational design.

Notation

ACO_{bf}= The best solution yielded by the ACO technique
BestFitness = The best fitness yielded for the best attained solution
BestTime = The shortest time demanded by an execution
$CC_{ij,t}$: construction cost from the *i*-th to the *j*-th point, in the *t*-th period
$\delta_{k,t}$: installation cost of the *k*-th Well Platform in the *t*-th period
d: total number of time periods related to WP construction
e: total number of pipeline construction time periods
Eval = The minimum number of evaluations
f: number of Wells

FP_{ij}: feasible path from the i-th to the j-th point
GA_{bf} = The best solution yielded by the GA technique
Ind = Ranking index
LC_t: operative labor cost in the t-th period
$MC_{k,t}$: maintenance cost of the WP structure
o: project lifetime
p: number of plants onshore
P_t: sale price of gas in the t-th period
q: number of Well Platforms that have been activated
Q_t: amount of gas transported in the t-th period
Q_{runs} = Number of performed executions
r: discount rate
Rep = Counter
SA_{bf} = The best solution yielded by the SA technique
$SumEval$ = The sum of all evaluations
$SumFitness$ = The sum of all BestFitness values
$SumTime$= Runtimes required by the past Ne executions
WP_k: for the k-th Well Platform: WP_k=1 if active, otherwise WP_k=0
Z = Total system cost per trip

Abstract

Molecular weight distribution (MWD) is very important to characterize polymer quality. To reveal non-ideal mixing conditions in a polymerization reactor, computational fluid dynamics (CFD) methods are essential. However, the combination of CFD and MWD calculation is time-consuming. Moreover, it is difficult to obtain gradient information in the CFD simulation. All these challenges make optimization process inefficient. In this project, optimization with embedded polymer MWD for a low-density polyethylene (LDPE) tubular reactor is conducted. To overcome the time-consuming and insufficient gradient information problem in calling a CFD simulation, a surrogate model method is proposed. Instead of building an accurate and global surrogate model with a large number of simulation data, an iterative surrogate model with limited data is preferred to save simulation runs. The result shows that the surrogate method can greatly reduce the time cost and achieve the optimal result.

Keywords: computational fluid dynamics; optimization; molecular weight distribution; surrogate model.

1. Introduction

Molecular weight distribution (MWD) describes the percentage of different-chain-length molecule in a polymer, which reflects more detailed information than macro quality indices, such as average molecular weight and melt index. A number of methods have been reported on MWD computation, e.g., Flory method, discrete Galerkin method Monte Carlo method, et al. But most of these studies focus on ideal reactors, which can be very different from a practical process. To deal with this problem, computational fluid dynamics (CFD) technology has been widely developed in chemical engineering. By adding reactant source terms and reaction heat to transport equations, CFD can extend to non-ideal polymerization reactors. Zhou et al. (2001) applied CFD to model LDPE tubular and autoclave reactors with the method of moments and discussed the influence of initiator concentration and the inlet temperature on the reaction. Roudsari et al. (2013) developed a CFD model to study methyl methacrylate (MMA) solution polymerization and investigated the influence of operating conditions, impeller speed, reaction temperature, residence time and inlet monomer concentration on the conversion and homogeneity of the reaction mixture. However, none of the aforementioned

research considered the MWD in their work. Recently, Zhang et al. (2017) applied the simplex method to solve the optimization of LDPE with MWD constrains. To improve the calculation efficiency, an iterative surrogate model method is proposed in this study to deal with the optimization of CFD models for polymerization reactor.

2. CFD Simulation with MWD for Non-Ideal Reactor

Free radical polymerization involves initiator decomposition, chain initiator, chain propagation, chain transfer to monomer, termination by combination, and termination by disproportionation. The reaction mechanism is shown in Table 1, where *I* denotes the initiator, *A* the initial radical, *M* the monomer, R_n the free radical, P_n the dead polymer. Subscript *n* stands for the chain length, which changes from 1 to a large number. The method of moment is introduced as

$$\lambda_i = \sum_{n=1}^{\infty} n^i [R_n], \mu_i = \sum_{n=1}^{\infty} n^i [P_n], i = 0,1,2 \tag{1}$$

where *i* represents the order of moments.

Denote k_x as the reaction rate coefficient of reaction *x*,

$$k_x = k_{x0} e^{[\frac{-(E_a + V_a p)}{R_g T}]} \tag{2}$$

where k_{x0} is initial reaction rate coefficient, E_a activation energy, and V_a is activation volume. These parameters change with different reaction systems.

The calculation equation of viscosity used in this paper is described as

$$\eta = \eta_{ethy} e^{[2.00+0.017(\frac{\mu_1}{\mu_0})^{0.556} \mu_1 + \frac{E_v}{R_g}(\frac{1}{T} - \frac{1}{423})]} \tag{3}$$

$$E_v = -500 + 560\mu_1 \tag{4}$$

where η_{ethy} is the viscosity of ethylene valued by 0.0016 *kg/(m•s)*.

According to the Flory distribution method (Flory, 1953) with the long chain and quasi-steady assumptions, MWD can be calculated by Eq.(5)-(6).

$$W(n) = (\tau + \beta)[\tau + \frac{\beta}{2}(\tau + \beta)(n-1)]n(\frac{1}{1+\tau+\beta})^{n+1} \tag{5}$$

$$\tau = \frac{k_{td}\lambda_0 + k_{trm}[M]}{k_p[M]}, \beta = \frac{k_{tc}\lambda_0}{k_p[M]} \tag{6}$$

The diameter and length of the tubular reactor are 0.038 m and 10 m, respectively. Gambit 2.4.6 is used to generate the geometry structure and the mesh of the reactor. After deriving the mesh file, Fluent 15.0 is used to establish the CFD model of LDPE based on the reaction mechanism in Table 1 and Eq.(1)-(6). Set the inlet initiator and

monomer mass fractions as 0.00051 and 0.99949, respectively. The inlet temperature is 500 K. Other variable settings are the same as Zhang et al. (2017). The CFD Simulation takes 457.34 s on a desktop with 2.50GHz Intel Core i5-7200U CPU. Fig. 1 shows the conversion distribution. To better illustrate the results, the radial direction is scaled up for 20 times. Fig. 2 shows the distribution of MWD along the centre axial direction.

Table 1. Reaction mechanism of free radical polymerization

Reaction Type	Reaction Mechanism
initiator decomposition	$I \xrightarrow{k_d} 2A$
chain initiator	$A + M \xrightarrow{k_{ini}} R_1$
chain propagation	$R_n + M \xrightarrow{k_p} R_{n+1}$
chain transfer to monomer	$R_n + M \xrightarrow{k_{trm}} P_n + R_1$
termination by combination	$R_n + R_m \xrightarrow{k_{td}} P_n + P_m$
termination by disproportionation	$R_n + R_m \xrightarrow{k_{tc}} P_{n+m}$

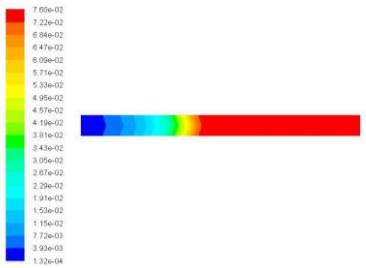

Figure 1. Conversion distribution in the tubular reactor.

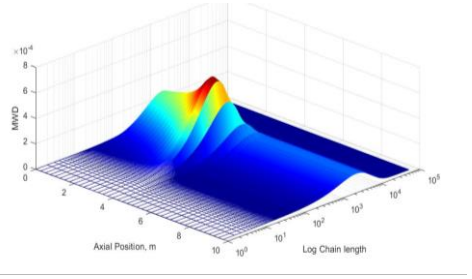

Figure 2. MWD distribution along the axial direction.

3. Optimization with Surrogate Model

The optimization problem studied in this paper is formulated as:

$$\begin{aligned} &\max\ conversion = CFD(M_I, T) \\ &s.t.\ MWD = CFD(M_I, T) \\ &\frac{1}{m}\sum_{i=1}^{m}((MWD_i - MWD_i^*)/MWD_i^*)^2 \le 0.0025 \\ &M_{Il} \le M_I \le M_{Iu} \\ &T_l \le T \le T_u \end{aligned} \tag{7}$$

It is to maximize the monomer conversion subject to an MWD constraint. m denotes the number of points sampled to represent the curve of MWD. MWD_i^* denotes the i^{th} sample point on the target MWD curve. The decision variables include M_I and T, which are the inlet initiator mass fraction and the inlet temperature, respectively. The *CFD* function stands for the CFD simulation presented in section 2. However, as it is time-

consuming and difficult to derive gradient information during the CFD simulation, the *CFD* function is replaced by a surrogate model during the solving process. We propose an iterative surrogate model method, which combines global coarse surrogate model and local accurate surrogate model, to solve the optimization problem (7). Flowchart of the method is shown in Fig. 3.

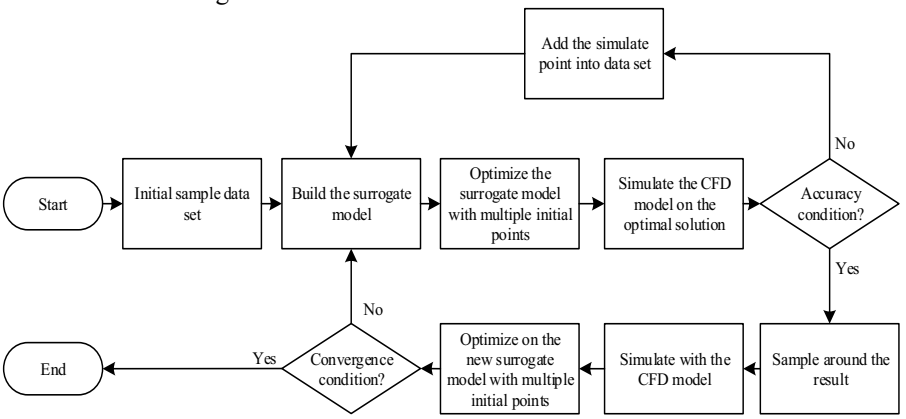

Figure 3. Flowchart of the iterative surrogate model method.

First, this method samples only a few points on the global space to form an initial sample set, S_0. The sampling method is Latin Hypercube Sampling (LHS) method (McKay et al., 1979). Then we establish a coarse global surrogate model M_0 using Kriging method (Lophaven et al., 2002) based on the sample set S_0. Set i=1 and conduct the optimization with the surrogated CFD model (M_{i-1}). To avoid of being trapped into local optimal points, multiple initial points are used for the optimization. The optimal solution is marked as $(x_i, \hat{y}_i)$. Then a CFD simulation is conducted on point x_i, and we obtain the result y_i. The error between y_i and $\hat{y}_i$ reveals the accuracy of M_i. If the accuracy condition is not satisfied, this new point (x_i, y_i) will be added into S_{i-1} to form S_i. Then a new surrogate model M_i will be established based on S_i. Else if the accuracy condition is satisfied, *2*n* (*n* is the dimension of decision variables) sample points will be generated around the point x_i. Each of the sample points is a little bit different from point x_i in one dimension. After conducting simulations on these sample points, a new surrogate model M_i' is built based on the results obtained, followed by another optimization. If the optimal solution x_i' locates in the box formed by the *2*n* sample points, the calculation process stops. As the kriging model based on the *2*n* sample points satisfies κ-fully linear condition in the box region, this convergence condition means that a local optimal point is obtained. Otherwise, this process will go back into the inner loop until the convergence condition is satisfied.

4. Results and Discussion

There are two decision variables in problem (7). Ten points are generated to build the initial sample set. By following the proposed methods shown in the previous section, the optimization process is shown in Table 2.

Table 2 Optimization process of the iterative surrogate model method

16	482.373	5.50000E-4	0.0862758	0.0862758	5.61808E-7	2.51138E-3	2.51044E-3	6.23818E-5
16a	482.368	5.50000E-4	0.0862764	0.0862764	3.75222E-7	2.65615E-3	2.65520E-3	5.98688E-5
16b	482.378	5.50000E-4	0.0862751	0.0862752	9.59119E-7	2.37159E-3	2.37074E-3	5.90140E-5
16c	482.373	5.49995E-4	0.0862751	0.0862756	5.36766E-6	2.53740E-3	2.51351E-3	1.58014E-3
16d	482.373	5.50006E-4	0.0862765	0.0862760	5.66551E-6	2.48031E-3	2.50721E-3	1.80136E-3

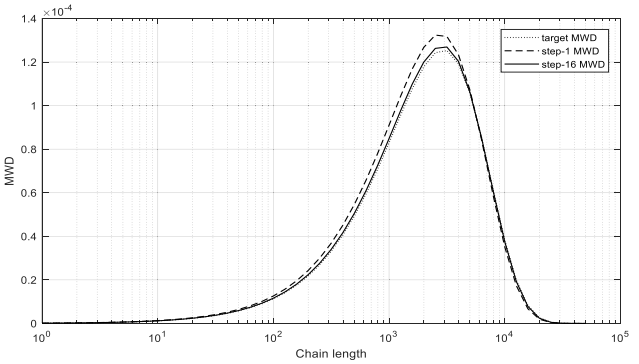

Figure 4. MWD curves of the target, step-1 and step-16 (optimum) points.

From Table 2, the surrogate model satisfies the accuracy condition at the point x_{16}= (482.373,0.00055) after 16 steps, where the absolute errors of τ, β, MWD and conversion are less than 0.001. Then another four points around x_{16} are sampled as listed in Table 2 from 16a to 16d. Each of the four points is slightly different from x_{16}, e.g., x_{16a} = (482.373*(1-1e-5), 5.5e-4). The optimization result of the new surrogate model based on the sample set including the four points is still equal to x_{16} = (482.373,0.00055), indicating that x_{16} is a local optimal point. Together with the initial 10 sample points, the iterative surrogate model method uses only 30 CFD simulations to find the optimal solution. Compared with the results in Zhang et al. (2017), which solved a similar problem using simplex method with 83 simulation runs, this method reduces more than a half calculation burden. As shown in the fifth and eighth columns in Table 2, the conversion is increased from 0.0678933 to 0.0862758, while the MWD error is decreased from 2.89482e-2 to 2.51044e-3. The MWD curves of the first and the last iterations, as well as the target MWD curve, are shown in Fig. 4. The initial MWD (step 1) is quite different from the target MWD, whereas the optimal result (step 16) is very close to the target. According to Wild et al. (2008), surrogate model in the neighbor of x_{16} formed by 4 sample points is satisfied κ-fully linear condition, which ensures local accuracy of function value and derivatives. To further prove the reliability of the

optimization result obtained by the iterative surrogate model method, we sampled another 1000 points and established a global accurate model. Optimization result of the 1000-point surrogate model is (482.327, 0.00055), which is very close to the point x_{16}. The results prove that the propose method, which combines the coarse global model and accurate local surrogate model, is efficient to reduce calculation burden and ensure an optimal solution.

5. Conclusion

The CFD model of LDPE polymerization in the tubular reactor is established to calculate the MWD. Optimization with embedded MWD is proposed for the non-ideal reactor. To overcome the time-consuming and insufficient gradient information problem in calling a CFD simulation, an iterative surrogate model method is proposed to solve the optimization with the CFD model, through which, the optimal solution can be found efficiently and accurately.

Abstract

This study presented computational fluid dynamics (CFD) and experimental validation of hydrodynamic behavior of helical rings random packing. Random packings have been widely used in chemical industries in absorbers, strippers etc. Up till now, development of novel random packing structure has essentially been empirical. Even with the increased computing power, CFD simulations of random packings are hard to find in the literature. The random nature of the packing structures, and the stacked geometry make acceptable grid generation and convergence very difficult because the structure of random packing is complicated when large amounts of it are stacked in a column. In this work, a CFD model was first time developed to simulate countercurrent gas-liquid flow in random packings formed by helical rings. Gravity simulation was used to generate stacking structures. A simple feedback control scheme was applied to control the gas inlet flow rate so that a particular pressure. Multiphase model was employed to compute the gas and liquid interaction in which the surface tension and wall contact angle were found as key factors. The predictions of the CFD model were validated with a lab-scale packed-bed absorber. It was found that the helical structure did increase the interfacial area, liquid hold-up when compared to Raschig rings, and such predictions can be validated by our in-house experiment. The model also showed that helical rings will have lower pressure drop and can sustain a larger liquid-gas ratios compared to Raschig rings . In summary, our study found that CFD simulations can obtain reasonable predictions of hydrodynamic behaviour of packings, and the inclusion of microstructures into a packing element will improve its hydrodynamic properties. These results showed that CFD can be used as a basis for rational packing design.

Keywords: computational fluid dynamics, random packing, helical Rings, Hydrodynamic Behaviour

1. Introduction

Traditional absorbers require huge volume due to the limitation of mass transfer rate. The direct way of intensification process of traditional absorbers is improving the specific surface area utilization of packings. Developing novel packing structures can imporve the mass transfer efficiency to increase gas-liquid contact area. Computational fluid dynamic (CFD) is widely used to investigate hydrodynamic behavior among packings. Klöker et al. presented that using CFD constructed a visual platform of experiment for structured packing.(Klöker et al., 2003; Klöker et al., 2005) The study successfully established the hydraulic and mass transfer correlations of reactive distillation column in

the visual platform. The correlations from the visual platform were validated by real experiments. In order to simplify complicated structure, Petre et al. (2003) and Larachi et al. (2003) presented representative units (REUs) to simulate single phase steam flow for different structure packings, respectively. Raynal et al. (2004) validated that 2D and 3D geometric structure were able to predict liquid holdup and dry pressure. These studies are sufficient to support that using CFD is able to solve complicated issues of flow fields. Generally, traditional absorber columns contain two or more fluids such as gas and liquid fluids. Multiphase model is used to solve the interaction among multi-fluids. (Valluri et al., 2005; CHEN et al., 2009; Haroun et al., 2012) Iliuta and Larachi (2001) developed a one-dimensional two-zone two-fluids mechanistic model for the prediction of structured packing by using multiphase model. The results showed that the multiphase model indeed is able to calculate gas and liquid contact area as well as liquid holdup for structured packing. Haroun et al. (2014) used volume of fluid (VOF) model which is one of multiphase models, to predict the gas and liquid contact area of Mellapak 250X. Simulated results showed that when liquid velocity increased, the gas and liquid contact area increased but liquid holdup decreased. The simulated results had good agreement with experiments. For CFD application for CO_2 capture process, Pham et al. (2015) established a porous media Eulerian CFD model to simplify complicated geometry of structured packing in an absorber as well as to predict mass transfer and pressure drop. The study showed that the model was able to estimate wetted pressure drop, liquid holdup and CO_2 removal efficiency. Based on the aforementioned studies, most studies of CFD focused on regular packing rather than random packing and lacked the investigation of novel structures of packings. The purpose of this study is to present computational fluid dynamics (CFD) simulation and experimental validation of hydrodynamic behavior of helical rings random packing. Using volume of fluid (VOF) method simulates the comprehensive counter-current flow field of randomly stacking of random packing in an absorber. This study evaluates the performance of helical rings random packing by using hydraulic behavior including the gas and liquid contact area liquid holdup, and pressure drop.

2. Methods and Materials

2.1 Process modeling in Fluent®

Fluent®, a commercial CFD simulator, solves the flow field going through the packing. Finite volume element is used for analysing diversity of phenomenon in various flow fields. To solve complicated multiphase fluids, the governing equations include mass conservation equations, momentum conservation equations, and volume of fluid equations. This study is going to compute and investigate gas and liquid contact area and liquid holdup in 3D flow field using VOF for 3 cases of irregular arrangements of random packing. Transient state is used in this study because the multiphase model adopted. To reduce computation time, a supercomputer having 72 cores of Intel ®CPU is used for calculating flow fields. The time step set as 0.0001 s a case took 35 h for integrating 20 sec. of simulation time.

2.2 Volume of Fluid (VOF) Model

This study chooses VOF model to investigate the interface between gas and liquid phases because the gas and liquid are miscible phases. The model going through surface-tracking technique is able to solve out interfaces between two insoluble fluids. Using this model

can clearly define the interface of gas and liquid in the flow field. In a two-phase system as an example, the continuity equations are shown below:

$$\frac{1}{\rho_q}\left[\frac{\partial(\alpha_q\rho_q)}{\partial t} + \nabla\cdot\left(\alpha_q\rho_q\boldsymbol{v}_q\right)\right] = \frac{1}{\rho_q}\left[\dot{S}_q + \dot{m}_{pq} - \dot{m}_{qp}\right] \quad (1)$$

Subscripts p and q indicate two phase indices. α_q is the volume fraction, ρ_q is density, and $\boldsymbol{v}_q$ is velocity vector of phase q. $\dot{S}_q$ is the rate of mass added to phase q. $\dot{m}_{pq}, \dot{m}_{qp}$ are the mass transfer rates to and from phase q to phase p. Continuum surface force (CSF) model was solved to calculation of surface tension force. Wall contact angle of packings represents the material hydrophobic, which set as 70° for plastic packings in this study.

2.3 Helical ring Random Packing Specification and Stacking Method

Helical rings are used to investigate in this case. The height of the ring is around 10 mm, the diameter of rings is 0.6 mm, the interval between the rings is 0.18 mm, and the helical packing diameter is 3.5 mm. To create a structure of irregular arrangement, every Helical ring has to be randomly rotated in 3D space, and then they are randomly stacked in the flow field. In order to prevent making excessively tiny mesh grid, a short distance is required between rings.

2.4 Geometry of Flow Field and Boundary Conditions

A geometry of flow field is created, which is an upright cylinder simplified based on realistic stacking situation of random packing in an absorber, shown in Figure 1. There are 4 circular areas at the top and bottom of the cylinder, respectively. The diameter of the circular areas is 5 mm. The circulars area on the top cylinder is liquid inlet, and the rest area of the top of the cylinder is gas outlet. The circulars area on the bottom is gas inlet and the rest area is liquid outlet. Specifications of the flow field and Helical rings are listed in Table 1. The flow direction of liquid is from top to bottom while the flow direction of gas is from bottom to the top. The inlets and outlets of gas and liquid are set as boundaries. The operating condition for inlet streams is shown in Table 2. The wall boundary is set as "no-slip wall". This study provided three different cases of stacking types in the same flow field.

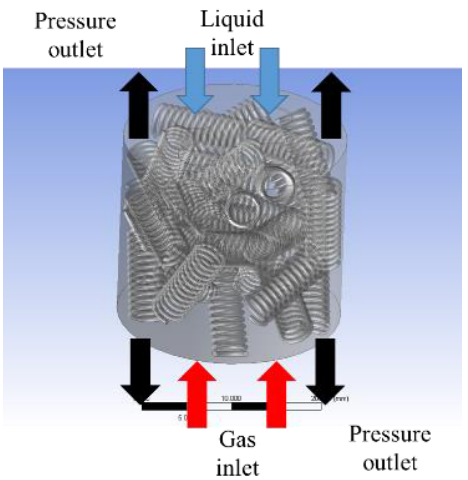

Figure 1 Schematic diagram of helical rings stacking

Table 1 Specifications of flow field and packing

hydraulic diameter (m)	0.005

3. Results and Discussions

3.1 Effect of Liquid Flow Rate for Gas-Liquid Contact Area

Figure 2 showed that the agreements of the interfacial area between helix rings and Raschig rings with the experimental data. The simulated interfacial areas for helix rings and Raschig rings were close to the experimental results. The interfacial area of helix rings had a better performance than the interfacial area of Raschig rings. The helix ring experimental data of the interfacial area was hard to measure at low L/G, leading to the larger deviation so that the model cannot match well, but the model can catch the trend of the interfacial area with L/G increasing.

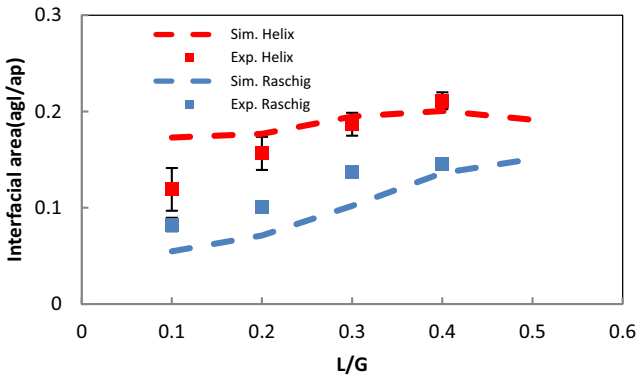

Figure 2 The validation of the interfacial area of helical rings and Raschig rings

3.2 Effect of Liquid Flow Rate for Liquid Hold Up

Figure 3 showed that validations of the liquid holdup between helix rings and Raschig rings with the experimental data. The simulated liquid holdups matched the experimental liquid holdups very well. The liquid hold-up of helix rings was higher than the liquid hold-up of Raschig rings. A slight difference between the helix-simulated result and the helix-experimental data may come from experiment.

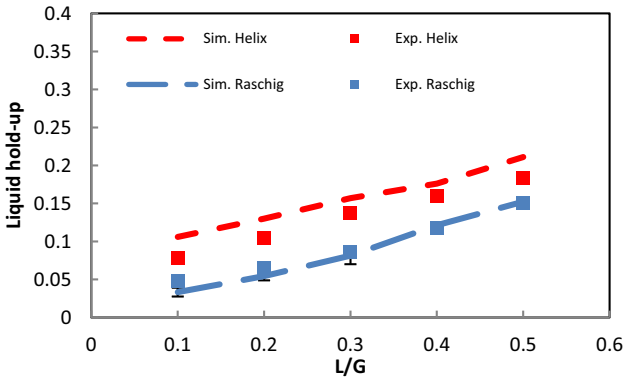

Figure 3 The validation of the liquid holdup of helical rings and Raschig rings

3.3 Effect of Liquid Flow Rate for Pressure Drop

Figure 4 showed that validations of the liquid holdup between helix rings and Raschig rings with the experimental data. The model also was able to predict the pressure drop of helical and Raschig rings. The results showed that the helical rings has a lower pressure drop than the Raschig rings. When the L/G achieved to 0.5, the pressure drop of Raschig rings rapidly increased to flooding but the helical rings still stayed at a lower pressure drop.

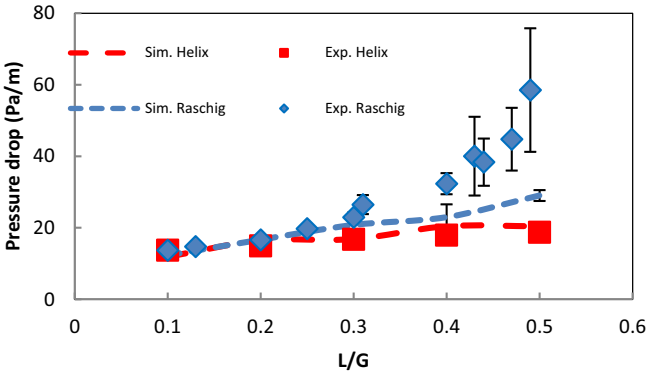

Figure 4 The validation of the pressure drop of helical rings and Raschig rings

4. Conclusions

This study presented CFD simulations and experimental confirmation of the hydrodynamic properties of a helical ring random packing. The results showed that the interfacial area and liquid holdup of helical rings were higher than those of Raschig rings, and the pressure drop of Helical rings is lower than the that of Raschig rings. This study showed that CFD can be implemented to predict hydrodynamics in random packings and serve as a basis for rational packing design and evaluation.

Abstract

The consideration of sustainability is very important for the assessment of life cycle, environmental, health and safety properties of chemicals used in various applications. The screening of wide ranges of molecular structures, prior to the identification of the optimum and most sustainable options, requires the use of efficient and inclusive predictive models. Group contribution (GC) models are popular for the evaluation of numerous molecular options, but they support the calculation of few properties related to sustainability, while their predictive capabilities are often limited by significant data gaps. To address such challenges, we propose the use of a local learning approach as a means of evaluating sustainability properties for a wide range of molecular structures. Supplementing GC methods with data mining ones, such as local lazy learning approaches and exploiting molecular similarities has a potential to improve the predictive capacity of sustainability indices and offers an alternative when GC methods or empirical models are not available for life cycle assessment (LCA) and environmental, health and safety (EHS) hazard assessment indicators. The proposed approach is applied to predict a set of properties (bioaccumulation, persistence and acute aquatic toxicity) of 101 commercial solvents for post-combustion CO_2 capture.

Keywords: Local-lazy learning, Sustainability, Post-combustion CO_2 capture, EHS, data mining

1. Introduction

GC methods have been used very widely for the evaluation and selection of molecular structures with desired properties out of numerous options. Their exploitation in computer-aided molecular design (CAMD) approaches has resulted in numerous prior implementations in the design of solvents, polymers, biofuel additives etc. (Papadopoulos et al., 2016a).

In such implementations, it was realized that it is important to also account for sustainability in the context of environmental, health and safety aspects. Early evaluation of issues such as hazards associated with toxic releases of chemicals could help prevent incidents and minimize harmful impact to human health and environment. One of the main characteristics shared among studies that address the integration of sustainability assessment to automated selection of chemicals is that they focus on only few sustainability indicators. This is because the available GC and/or empirical models only

support few EHS and LCA endpoints. Recent efforts to incorporate sustainability assessment in GC-based CAMD are reported in Ten et. al (2016) who integrates inherent safety and occupational health to the framework. The parameters required for application in CAMD are calculated via property prediction methods available for selected indicators. Another example is the study by Khor et. al (2017) who use a CAMD approach to select sustainable solvents for palm oil extraction. The sustainability indices are obtained by GC and empirical models available for the required parameters. Both studies include safety and health indices, whereas potential impact to the environment is either not assessed or considered to a limited extent. However, a holistic sustainability assessment requires diverse sustainability indicators to achieve a reliable differentiation over a certain, typically large, number of molecules. Data mining methods can be used to analyse, interpret and exploit molecular similarities to supplement GC models to predict sustainability properties, to potentially improve their predictive capabilities and to expand the range of sustainability indicators that can be predicted. Local lazy learning is one such method that was proposed in recent years by Lu et al (2014) to predict the chemical toxicity profile of drug compounds, with encouraging results. To this end, we investigate the implementation of this method in the evaluation of the sustainability performance of numerous, diverse molecular structures used as solvents in CO_2 capture.

2. Methodology

2.1 Motivation and approach

This work is motivated by Papadopoulos et al. (2016b), where CAMD was used for the design of CO_2 capture solvents. The solvent design and selection was based on thermodynamic and reactivity property criteria predicted by GC and empirical models. Sustainability assessment was also performed but only at the post-design stage, where the required information to perform the assessment for few selected solvents was gathered manually from various databases, material data sheets and estimated using available software tools based on Quantitative Structure Activity Relationships. Even though the method provided reliable assessment results, it could not be applied at the design stage hence limiting the evaluated molecular structures.

To estimate safety, health and environmental scores of the metrics, at least one indicator value for dangerous property per aspect should be found for every molecule. An example of dangerous properties and indicators to calculate a score for the environment within EHS is presented in Table 1. To automate the assessment, the dangerous properties should be calculated or estimated by techniques which can be performed computationally and for the desired (wide) range of sustainability indicators. While some of the indicators can be calculated by GC and empirical models, it is troublesome to obtain information for other endpoints which cannot be estimated by such methods. In this work, the local lazy learning (LLL) technique is applied to evaluate its capability in closing data gaps and its potential to be integrated in a CAMD. LLL is a data mining technique which approximates a molecular target function (e.g. a sustainability indicator) locally, based on the known function value of the most similar molecule(s) available in a database (closest neighbours). Closest neighbours can be identified using the Tanimoto coefficient and the extended connectivity fingerprints (ECFPs). ECFPs encode molecular features (e.g. atoms, bonds, stereochemistry) and store them in a bit form. ECFPs are further used to calculate the Tanimoto index to examine similarity between compounds. The most similar compounds have the Tanimoto coefficient close to 1. The aim is to develop LLL

Table 1. Dangerous properties and indicators for Safety score calculation, based on Badr et al. (2017).

Environment	
Dangerous Property	Indicator
Water Mediated Effects	*LC50*aquatic
	Hazard statements
Degradation	Persistency (days)
	Halflife in water (days)
Air Mediated Effects	Chronic toxicity index
Solid waste	Amount of inorganic material
Accumulation	Bioconcentration factor (*BCF*)
	Octanol/water partitioning coefficient (*KOW*)

models and compare their prediction accuracy with GC approaches for three important property indicators mentioned in Table 1 (LC50aquatic, persistence and bioconcentration) using a wide range of molecular structures for which available GC methods can provide predictions.

2.2 Dataset

The comprehensive database of Strempel (2012) was used to create a dataset to generate the models. This data was sorted and only molecules with the existing value for all three indicators of bioaccumulation, persistence and acute toxicity were left in the database. The database was further reduced to a dataset containing compounds consisting of sixteen functional groups relevant to the CO_2 capture case. The selection of the groups was determined by the structure of the molecules identified in the work of Papadopoulos et al. (2016). The influence of functional group selection should be studied further; but it is assumed that such a reduction creates a dataset with more similar compounds that, according to Lu et.al (2014), is needed to enhance the prediction performance of LLL models. This led to a final dataset containing 2106 molecules. Acute toxicity and persistence were converted to logarithmic values.

2.3 LLL Model

For a given compound with an absent indicator value the LLL method identifies *n* nearest neighbours, i.e. most similar molecules in a dataset, and then uses these molecules to predict a property of the compound as follows (Lu et al, 2014):

$$y_{pre} = \sum_{i=1}^{n} \frac{S_i}{\sum_{j=1}^{n} S_j} * y_{i,db} \tag{1}$$

where y_{pre} is the predicted value of the query compound, $y_{i,db}$ is the property value of the *i*-th nearest neighbour from the dataset, S_i is the Tanimoto coefficient indicating the similarity value between the given compound and the *i*-th neighbour, and *n* is the optimized number of nearest neighbours used in the prediction. The Tanimoto coefficient can be calculated as follows:

$$S = \frac{c}{a + b + c} \tag{2}$$

where *c* is the number of atom pairs common for the molecules and *a, b*-the number of molecules' unique atom pairs.

Thus, developing an LLL model consists in finding the optimal value of *n*, over a dataset

and a target property. This optimal value is found by monitoring the LLL model performance over test compounds which are not included in the dataset used to search for the nearest neighbours. In this study this is achieved by leave-one-out cross-validation (LOO-CV). The procedure was applied as follows (Zheng and Tropsha, 2000):
1) One compound (*i*) of the database of *N* compounds was eliminated and the rest of the dataset molecules were used to predict the compound's property (Eq. 3) using *k* (initially set to 1) most similar compounds from the dataset:

$$y_{i,pre,k} = \sum_{i=1}^{k} \frac{S_k}{\sum_{j=1}^{k} S_j} * y_{k,db} \quad (3)$$

where $y_{i,pre,k}$ is the predicted value of the query compound using *k* closest neighbours, $y_{k,db}$ is the property value of the *k*-th nearest neighbour from the database, S_k-the Tanimoto similarity value between the eliminated compound and the *k*-th neighbour, $\sum_{j=1}^{k} S_j$ is the sum of Tanimoto coefficients of the eliminated compound and all its *k* nearest neighbours. The step was repeated for all the compounds in the database (*i*=1 to *N*).
2) Cross-validated Q^2 (Eq.4) was calculated using all the database molecules and their predicted $y_{i,pre}$ and actual values y_i, where y_{avr} is the average property value of all molecules in the dataset.

$$Q^2 = 1 - \frac{\sum(y_i - y_{i,pre})^2}{\sum(y_i - y_{avr})^2} \quad (4)$$

3) Steps 1 and 2 are repeated for *k* in range 1-50. The maximum possible *k* equals to the number of molecules in the dataset, however further increase of the range was unnecessary since the optimal number of neighbours was found to lay in range from 3 to 16 (see Fig. 1). This range remained the same even when the dataset was reduced to 700 and 1400 molecules to analyze the dependence of a dataset size on *k*. The value of *k* which gave the highest Q^2 was set to *n* and used for the final model (Eq. 1).
The optimal *n* number depends on the quality of the database. For instance, a larger database with more similar compounds could possibly result in a lower number of *n*. The obtained *n* number was used to predict properties of solvents for post-combustion CO_2 capture. The assumption here is that a new optimal number of *n* should not be required if this family of molecules has been indirectly included in the initial LLL development (i.e., the initial dataset was obtained by using the same functional groups as those used in the CO_2 capture molecules). Q^2 was calculated in the same way as stated in Eq. (4), and an

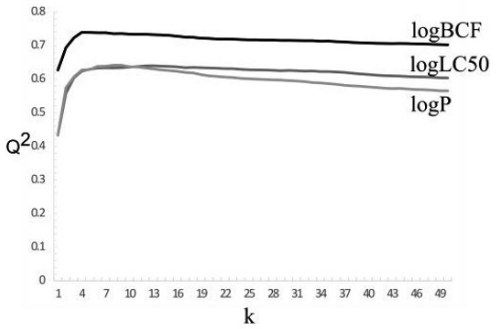

Figure 1. Q^2 vs number of neighbours *k*

average relative prediction error was determined by Eq. (5):

$$RE = \frac{1}{N}\sum_{i}\left|\frac{y_i - y_{i,pre}}{y_i}\right| * 100 \quad (5)$$

3. Results

To demonstrate the performance of the model, the results are presented both for molecules from the dataset of 2106 molecules and for a subset previously identified as potential post-combustion CO_2 capture solvents (Papadopoulos et al., 2016b).

3.1. LLL model performance

The results of LOO-CV showed that the number of closest neighbours required to get the highest Q^2 values are different for every property indicator (Table 2 and Figure 1). After reaching the optimal values, the graphs level up and adding more neighbours into the model does not improve its predictive power. The work carried out by Lu et al. (2014) acquired similar Q^2 values for predicting *LD50* indicator by LLL and their reference library consisting of 2271 compounds. Table 2 also contains Q^2 and *RE* values for the GC+ method as reported by Hukkerikar et al. (2012) for the case of the stepwise approach. It can be seen that published Q^2 numbers for the GC+ method are higher than those obtained by the LLL method for the dataset used.

3.2. Post-combustion CO_2 capture case

The best *n* values found by LOO-CV were used to predict the property indicators for 101 CO_2 capture commercial solvents from Papadopoulos et al. (2016), which all were also present in the dataset of the 2106 molecules. The results were compared to numbers obtained by the GC+ method, as shown in Table 3. The LLL model has a reasonable performance. Higher accuracy might be achieved by adding more molecules that are relevant for CO_2 capture and more structurally similar. Negative Q^2 numbers for the GC+ model show that the model fits the data for CO_2 capture solvents poorly.

Table 2. LLL method results compared to results reported for GC+

	LLL			GC+	
Property indicator	Optimal *n*	Q^2 for the optimal *n* value	Average *RE*	Q^2*	Average *RE**
Log*BCF*	13	0.64	33	0.78	-
Log*LC50*	4	0.74	69	0.82	21
Log *P*	9	0.64	8	-	-

**RE* of Log*BCF* is not given and log *P* is not studied by Hukkerikar, et.al (2012)

Table 3. Results for CO_2 capture solvents obtained by LLL and GC+ methods

	LLL				GC+*			
Property indicator	Q^2 for the optimal n	R^2	Average *RE*	Median *RE*	Q^2	R^2	Average *RE*	Median *RE*
Log*BCF*	0.18	0.55	41	32	-0.71	0.21	71	55
Log*LC50*	0.38	0.75	105	32	-0.17	0.51	150	70
Log *P*	0.68	0.71	9	8	-	-	-	-

4. Discussion and Conclusions

LLL gives different Q^2 values leading to different prediction capacity for particular indicators, which can probably be influenced by the quality of the dataset or character of molecular structure-dangerous property relationship for every indicator. This aspect needs to be studied further to identify which structural fragments are responsible for the highest contribution to further improve the model. An advantage of the LLL method is that it does not require extensive work prior to implementation and can be applied to any set of molecules, whereas GC methods are restricted to molecules that have groups for which contributions have been calculated. Up to now, there is quite a limited data on GC for sustainability assessment indicators which makes it even more difficult to use GC methods for such an analysis. Depending on the number of missing values and the database size, the LLL method can be computationally expensive. This effort can be reduced with a different *n* optimization method.

LLL can be integrated into CAMD to predict information when values are missing, providing an alternative when GC methods or empirical models are not available for some EHS and LCA indices.

Experimental implementation of dynamic real-time optimization in a graft polymerization reactor

Ryad Bousbia-Salah, François Lesage, Guo-Hua Hu, Abderrazak Latifi

Laboratoire Réactions et Génie des Procédés, CNRS-ENSIC, Université de Lorraine, 1 rue Grandville, BP20451, 54001, Nancy Cedex, France

Abstract

This paper deals with experimental implementation of dynamic real-time optimization (D-RTO) in a batch reactor where polymer grafting reactions take place. The objective is to determine the online reactor temperature profile that minimizes the batch period while meeting terminal constraints on the overall conversion rate and grafting efficiency. The optimal temperature profile previously determined in (Bousbia-Salah et al, 2017) was implemented in open loop control and the reactor temperature, the conversion rate and the grafting efficiency were measured. The computed and measured optimal profiles exhibit a quite good agreement and show also that the constraints are satisfied. Moreover, the resulting batch period is reduced by more than 20% with respect to the usual one.

Keywords: Dynamic real-time optimization, Polymer grafting batch reactor, Experimental implementation

1. Introduction

In chemical industry, many plants (especially those that are never in steady-state) deal more and more with uncertainty and changing conditions in their operation. This is due to different factors such as volatile market demands, tougher competition, restrictive environmental standards, changing product specifications, etc.
Their optimal operation is therefore not only a need but also a necessity, and dynamic real-time optimization (D-RTO) is the most suitable technology to succeed (Rawlings et al, 2011; François and Bonvin, 2013; Ellis et al, 2013 and 2014). It makes use of the online available measurements to maximize a process performance index while meeting environmental and operating constraints (e.g. terminal specifications, temperature limits…). The results from the optimization problem can then be sent directly to a control system.
In a previous simulation study (Bousbia-Salah et al, 2017), we considered a batch reactor where polymer grafting reactions take place. The goal was to value the used ground tire rubber (GTR). The latter results from grinding of the rubber part of used tires which retains excellent elasticity. The idea was to take advantage of its elasticity to toughen brittle polymers such as polystyrene upon incorporating GTR into them. D-RTO methodology was applied to the reactor and the objective was to minimize the batch period subjected to some terminal industrial specifications (i.e. conversion rate and grafting efficiency) with the reactor temperature and batch period as decision variables. The simulations showed a good behavior of D-RTO to adapt to parameters mismatch and to generate the optimal temperature trajectory with respect to final constraints and

temperature bounds. A moving horizon observer was successfully implemented to estimate the state of the system.

In the present work, the D-RTO methodology was experimentally implemented within the same batch polymerization reactor. Open-loop and closed-loop D-RTO were implemented and the experimental measurements were compared to the simulation profiles previously computed.

2. Grafting polymerization

When styrene is added to GTR particles, it can be located inside and/or outside them, depending on the styrene/GTR ratio. The latter is kept below 2 so that styrene is completely located inside GTR particles where it polymerizes in two types of polymerization. The first type is the polymerization of styrene itself leading to polystyrene (PS) chains which are not linked to GTR particles. These PS chains are called free PS. The second type is the polymerization of styrene from the rubber chains and the resulting PS chains are attached (grafted) to the rubber ones. These PS chains are designated as GTR-g-PS. The resulting material is GTR particles inside which there are free PS and GTR-g-PS. The main objective is to minimize the amount of free PS in the PS/GTR-g-PS while maximizing the amount of GTR-g-PS in order to allow recycling a maximum of GTR with the best properties, especially the impact strength (Yu, 2015).

This objective is taken into account here through constraints on the grafting efficiency (GE) and the styrene conversion rate (X). GE is defined as the ratio between the amount of grafted PS and that of the total PS (grafted PS + free PS).

3. Formulation of the optimization problem

The dynamic optimization problem of the polymerization reactor considered here may be formulated as

$$\min_{\theta, t_f} J = t_f \tag{1}$$

Subject to

$$\dot{x} = f(x, \theta) \text{ with } x(t_k) = \hat{x}_k \tag{2}$$

$$GE(t_f) \geq GE_f \tag{3}$$

$$X(t_f) \geq X_f \tag{4}$$

$$\theta \leq \theta_{max} \tag{5}$$

where $\theta = \left(T_1, T_2, \dots, T_{n_\theta}\right)^T$ is the vector of time-independent parameters used to approximate the reactor temperature and x the state variables. GE and X are the measured process outputs and GE_f and X_f are their desired final values. $(\theta_{max})_i = T_{max}\,; i = 1,2, \dots, n_\theta$; is the temperature upper bound.
The process model equations (2) consist of 20 ODEs involving 24 unknown kinetic parameters which were previously estimated from experimental measurements (Yu, 2015).

The optimization problem is solved over a shrinking horizon using the control vector parametrization (CVP) method (Goh and Teo, 1988). The latter is based on the approximation of decision variables by means of piece-wise constant functions over the optimization horizon.

The resulting non-linear programming problem is solved by means of a gradient-based method where the gradients are computed through the integration of sensitivities at each iteration of the optimizer. The equations of sensitivities are expressed as

$$\dot{s} = \frac{\partial f}{\partial x} s + \frac{\partial f}{\partial \theta} \text{ with } s(t_k) = 0 \quad (6)$$

where $s(t) = \frac{\partial x(t)}{\partial \theta}$ are the sensitivities of the vector of state variables with respect to the vector of parameters. Note that Eqs.(6) are integrated from t_k to t_f at each iteration of the optimization solver.

The D-RTO proceeds then as follows. Starting from the real process to which the optimal decision variables are applied at a sampling time t_k, the outputs (i.e. GE) as well as the input (i.e. temperature) are used to estimate the state vector $\hat{x}_k$ that will be used as the initial condition for the next optimization at the sampling time t_{k+1}. The corresponding initial condition for the sensitivities is always taken equal to zero. The estimation $\hat{x}$ of x is carried out by means of a moving horizon estimator (MHE) in a closed-loop control (Michalska and Mayne, 1995; Robertson and Lee, 1995) using input and output variables.

4. Experimental rig and measurements

4.1. Experimental rig

The polymerization reactions take place in a stirred batch reactor equipped with a condenser, a temperature control device and a sample collection system. The substances involved in the reactions are GTR particles of 800 μm in diameter, styrene (monomer) and two initiators, i.e. benzoyl peroxide (BPO) and dicumyl peroxide (DCP). Hydroquinone (HQ) and chloroform are used for the measurements of the conversion rate and the grafting efficiency.

4.2. Conversion measurement

The conversion of monomer is measured by a gravimetric method. Samples are taken from the reactor and weighed. A known amount of hydroquinone is added in to stop the polymerization. Then they are put into a Halogen Moisture Analyzer and the temperature is raised to 170°C and kept at this temperature for 10 min. The residual monomer could completely evaporate and the remaining material is composed of free PS, GTR-g-PS and HQ.

4.3. Grafting efficiency measurement

Samples taken from the reactor are put in chloroform to measure the grafting efficiency of the polymerization of styrene inside GTR particles. The free PS and HQ are soluble in chloroform, while GTR and/or GTR-g-PS are not. After at least four days during which the samples are shaken many times, the solvent is removed using filter paper. The free PS and HQ are in the solvent, and the non-soluble portion in the filer paper is GTR or GTR-g-PS.

5. D-RTO implementation

The optimal temperature profiles previously obtained in (Bousbia-Salah et al, 2017) are experimentally implemented in both open loop and closed loop control. However, for the paper length constraint, only open loop control results are presented.

The implementation procedure is as follows. The optimal temperature profile computed for $GE_f = 60\%$ and $X_f = 80\%$ is applied to the reactor using a control temperature device. Since the dynamics of the polymerization reaction is relatively slow, manual temperature control is found to be sufficient to achieve reasonable accuracy. Samples of the reaction medium are taken every 15 minutes and analyzed offline. It is important to note that the conversion rate is measured in 30 minutes whereas the measurement of GE needs much more time and takes about 6 hours.

Figures 1, 2 and 3 show the temperature, monomer conversion and GE profiles, respectively. They compare the computed optimal profiles and the measured ones in the reactor. The temperature profile exhibits a regular increase in order to fulfill the required monomer conversion rate and grafting efficiency. This regular increase is meaningful since at constant temperature, the conversion rate increases with time whereas the grafting efficiency decreases. Therefore the temperature should increase with time in order to achieve the desired conversion rate but not too much in order to guarantee the specified terminal value of grafting efficiency.

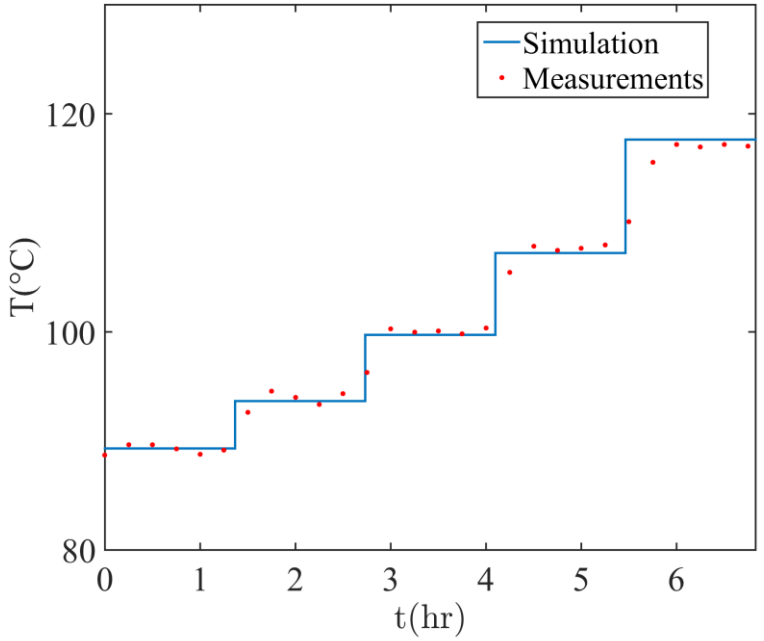

Figure 1: Optimal profiles of reactor temperature for $GE_f = 60\%$ and $X_f = 80\%$.

Figures 2 and 3 show the time-varying process outputs, i.e. conversion rate and grafting efficiency, respectively, with two different profiles. The computed profile given by the integration of the process model equations (Eqs.(2)) using the computed optimal temperature profile, and the measured one. It can be seen that the computed terminal inequality constraints on both process outputs are satisfied and are almost the same as the measured ones. This very good agreement between the computed and measured profiles can be explained by the absence of disturbances and a very good quality of the process model. Furthermore, the resulting batch period is at least 20% less than the usual one

based on two (non-optimized) levels of temperature without terminal constraints on conversion and grafting efficiency (Yu, 2015).

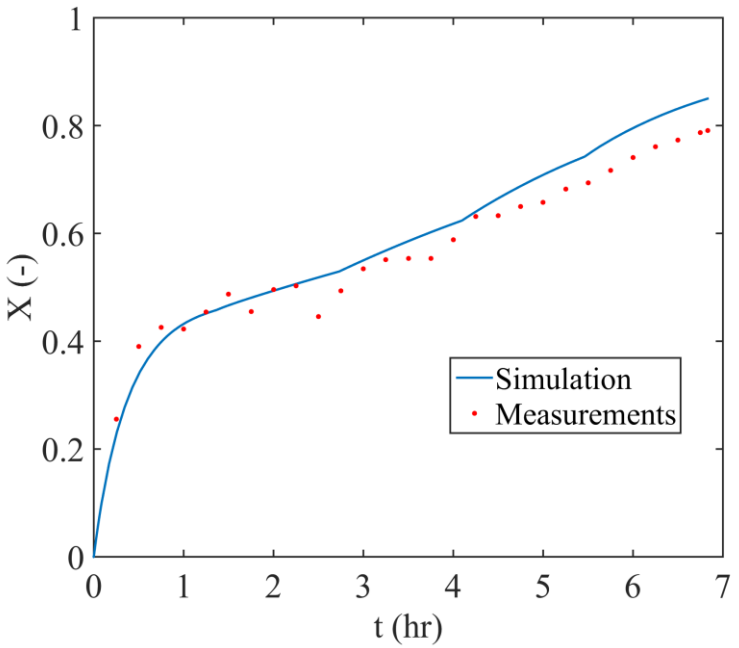

Figure 2: Time-varying profiles of the conversion rate for $GE_f = 60\%$ and X_f =80%.

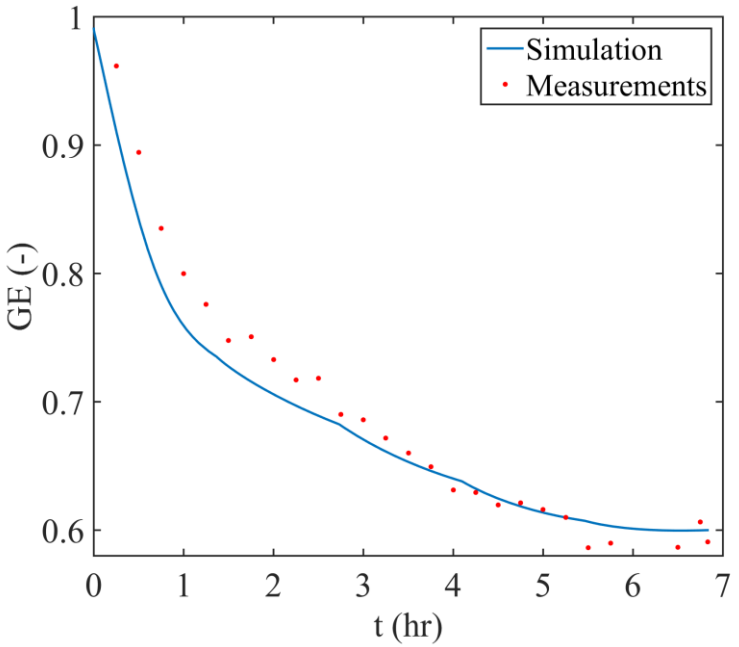

Figure 3: Time-varying profile of the grafting efficiency for $GE_f = 60\%$ and $X_f = 80\%$.

6. Conclusions

The results obtained in this work showed again that real-time optimization is the most suitable technology for online dynamic optimization of the grafting polymerization reactor considered here. It allowed to determine the temperature profile that minimizes the batch period under terminal constraints on monomer conversion and grafting efficiency. The computed profile is then successfully implemented within the reactor in open loop control. The results show very good agreement between the computed and measured profiles of temperature, monomer conversion and grafting efficiency. Moreover, the computed and measured terminal constraints are satisfied and are almost the same. The stability of the computed optimal temperature is guaranteed since the process considered is of the batch type and the shrinking optimization horizon covers the whole operational time. The experimental results obtained in closed loop control will be presented in a paper in preparation.

Abstract

This paper presents a novel data-driven modeling strategy for highly accurate prediction and optimization of complex chemical processes. The material balance, equilibrium, and heat balance equations addressed in a chemical process are nonlinear, thus making it very difficult to optimize. To overcome the above difficulty, a high dimensional model representation (HDMR) method was developed to represent a complex process (Pan et al., 2016), and a novel linear programming (LP) model was then proposed to find the HDMR parameters. Finally, the complexity of a chemical process model can be reduced significantly as its mechanism formulations were replaced with a simple nonlinear HDMR model. The resulting simple nonlinear optimization problem can be solved efficiently by using the iterative linear programming (LP) method proposed in the earlier work (Pan et al., 2013). To validate the proposed approach, a propane dehydrogenation (PDH) process was studied.

Keywords: Complex Chemical Processes; Data-driven Modeling; High Dimensional Model Representation (HDMR); Highly Accurate Prediction; Optimization

1. Introduction

In general, the trade-off between computational efficiency and accuracy must be considered for process modeling, especially for process optimization. Chemical process models can be divided into mechanism-based models and surrogate models. A large number of unit operations and complex physical-chemical reactions are addressed in the mechanism-based models. It is very difficult to optimize such complex nonlinear programming problems by using conventional optimization methods. Compared to the mechanism models, surrogate models can be seen as “black boxes”. The challenge of using surrogate models is to remain high accuracy of the process performance. There is a growing interest in modeling and optimizing process system using complex mathematical models, such as Polynomial (Draper and Smith, 1981), Kriging (Krige, 1951), Artificial Neural Networks (Himmelblau, 2000), and Support Vector Regression (P. Jain et al., 2007). However, some of them need an expensive CPU computation time, or cannot guarantee the model accuracy because of the limit of their approximation algorithms. Recently, high dimensional model representation (HDMR) method has been proposed as an efficient method for chemical process optimization (Pan et al., 2016). It can also be applied to analyze the economic viability of a chemical process under technical and economic uncertainties (Brownbrige et al., 2014) and global sensitivity analysis (Azadi

et al., 2015). Surrogate modeling can be generally classified into two categories: model order reduction and data-driven modeling (Biegler et al., 2014). Model order reduction aims to lower the computational complexity of a high fidelity model, meanwhile, retains most of the structure of the primitive equations. Data-driven modeling only makes use of the data generated with complex models or experiments.

In this work, we study a complex chemical process of propane dehydrogenation (PDH) by date-driven surrogate models based on a novel high dimensional model representation (HDMR) methodology, and then present the highly accurate prediction of the HDMR model and the optimal solutions obtained for the PDH process. A case study is carried out to demonstrate that the proposed HDMR method is computationally efficient and highly accurate.

2. An HDMR model for describing complex chemical process

In practical modeling work, most of chemical process systems are complex to be coded. There are many specialised simulation software packages having been used in the existing studies (e.g., Aspen Plus^{TM}, PRO/II, gPROMS). However, in most situation, these simulation software packages appear to the users as black boxes. To tackle the complexity of building very detailed models based on the explicit knowledge of the physical behaviour of the system, surrogate models are adopted to find the connections between the system state variables (input, internal and output variables). Data generated with applying commercial software packages (e.g., Aspen Plus was applied in this work) or experiments are used to construct simpler but accurate models which include empirical approximations describing the relation between input variables and response values of a process.

In order to build the surrogate models for representing complex chemical processes, HDMR method is used to generate surrogate models which have been demonstrated as the most efficient and actual models in industrial applications (Pan et al., 2016). Moreover, the HDMR method can take into account the inherent uncertainties in input parameters, and also presents the potential nonlinearities and contributions due to the interactions between input parameters. The main feature of HDMR is shown as follows:

$$y = f_0 + \sum_{i=1}^{N} f_i(x_i) + \sum_{i=1}^{N}\sum_{j=i+1}^{N} f_{ij}(x_i, x_j) + \cdots + f_{12\ldots N}(x_1, x_2, \cdots x_N) \tag{1}$$

Where N is the number of input parameters, i and j index the input parameters, and f_0 is the mean value of $f(x)$.

The expansion given in Eq. (1) has a finite number of terms and $f(x)$, however for most practical applications, the functions containing more than two input parameters can often be ignored due to their less contributions compared to the former terms (Rabitz and Als, 1999, Li et al., 2002). Therefore, Eq. (1) can be simplified as (Pan et al., 2016):

$$\begin{aligned} &y = C + \sum_{i=1}^{N}\sum_{k=1}^{K} A_{i,k} \times x_i^k + \sum_{i=1}^{N}\sum_{j=i+1}^{N}\sum_{k=1}^{K}\sum_{n=1}^{K} B_{i,j,k,n} \times x_i^k \times x_j^n \\ &i, j \in \{1, 2, 3, \cdots, N\} \qquad k, n \in \{1, 2, 3, \cdots, K\} \end{aligned} \tag{2}$$

Where C is a constant term, $A_{i,k}$ and $B_{i,j,k,n}$ are the first and second order coefficients, K is the highest degree of input variables , subscript i and j denote the input parameters, and y is function value.

In order to generate accurate surrogate models, the HDMR parameter values of C, $A_{i,k}$ and $B_{i,j,k,n}$ are found by using a novel linear programming (LP) model in GAMS. The objective function of the LP model is shown as follows:

$$\min \sum_{d}^{D} \left| y_d - y_d^* \right|, \quad d \in \{1,2,3,\cdots,D\} \tag{3}$$

In addition, there is a constraint of model maximum allowable error:

$$\left| y_d - y_d^* \right| \le \delta, \quad d \in \{1,2,3,\cdots,D\} \tag{4}$$

D represents the number of data sets, y_d is model calculated value, y_d^* is actual value, δ is the maximum allowable error.

3. Case study

3.1. Process simulation (Aspen Plus™)

To validate the proposed approach, a propane dehydrogenation (PDH) process is simulated by using Aspen Plus software. Figure 1 presents the detailed flowsheet of PDH process developed in Aspen Plus simulation environment. The process feed, LPG, is pre-processed to make propane volume fraction meet the feed requirements for reaction at first, then is reacted with H_2 in a moving bed reactor with four parallel stages and radial flow. The reaction product enters refining section after the rapid cooling, high pressure dehydration and cryogenic dehydrogenation. In the refining section, light end (C1 and C2) are removed from an dethanizer column, and then the propylene and propane are separated via a propylene rectification column. Propylene is sold as a product, while propane enters the reactor as a cyclic feed. To demonstrate the validity of our Aspen Plus models, the Aspen Plus results are compared with the literature data, and the errors of the propane conversion, propylene selectivity, and propylene yield are 0.271%, 0.127% and 0.063%, respectively.

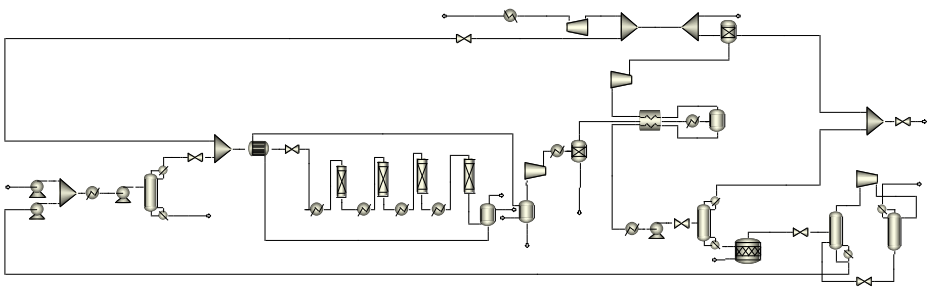

Figure 1. Flowsheet of the PDH process built in Aspen Plus™.

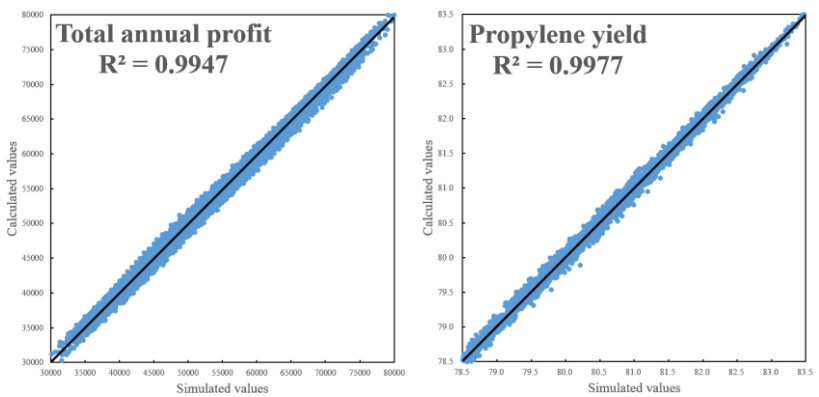
3.2. Process modeling and prediction

The key equipment of PDH process includes pumps, heat exchangers, moving bed reactors, compressors and rectifying columns. For the HDMR modeling of PDH process, the total annual profit and the propylene yield are selected as the outputs, and the five major operating parameters affecting the outputs are set as the inputs, including: the feed flow of LPG, the flow ratio of hydrogen-to-propane, the temperature and the pressure of reactor, and the pressure of propylene rectifier. The simulation data are obtained with varying the five input parameters. The ranges of these parameters are shown in Table 1.

Table 1. Ranges of input parameters for surrogate modeling of the PDH process.

Parameters	Lower bound	Upper bound
x_1: LPG feed flow (kmol/h)	560	840
x_2: Hydrogen to propane ratio	1.60	2.40
x_3: Reactor temperature (℃)	570	610
x_4: Reactor pressure (MPa)	0.18	0.20
x_5: Propylene rectifier pressure (MPa)	0.65	1.00

The HDMR model parameters of the PDH process are obtained by feeding the 8750 groups of simulated results to the proposed LP model, which is performed on a desktop PC with an Intel Core i7 (2.4 GHz) and 16 GB RAM using GAMS 24.4. The CPU time of model training of the total annual profit and propylene yield are 134 and 18 seconds, which are much less than kriging metamodel, in which the time consumption increases exponentially as the data volume picks up. For HDMR model training, the R^2 values of the total annual profit model and propylene yield model are 0.9947 and 0.9977 respectively, which presents a high goodness of fit between the HDMR and Aspen Plus models, and it also can be seen from Figure 2, most of data points of total annual profit or propylene yield are nearby diagonal line.

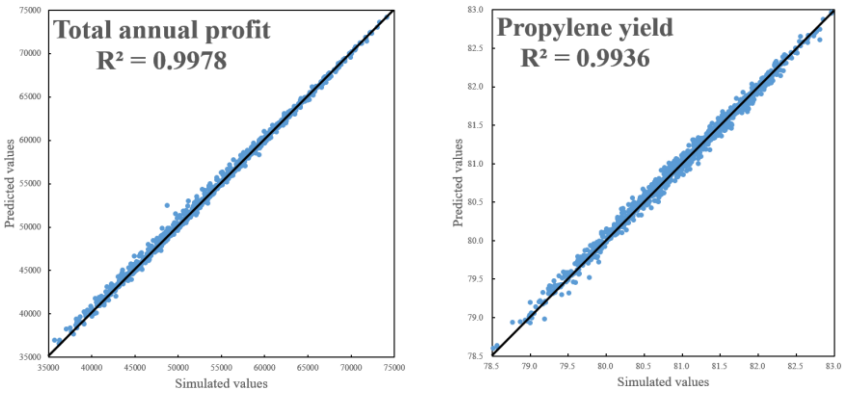


(a) Total annual profit HDMR model (b) Propylene yield HDMR model

Figure 2. Calculated versus simulated total annual profit/propylene yield values

For model prediction, 1024 new groups of simulation data are tested. Highly accurate prediction of the PDH process is shown in Figure 3, and the R^2 values of the HDMR

model prediction of total annual profit and propylene yield are 0.9978 and 0.9936 respectively.



(a) Total annual profit HDMR model (b) Propylene yield HDMR model

Figure 3. Predicted versus simulated total annual profit/propylene yield values

3.3. Process optimization

Regarding the process operation optimization, the resulting simple nonlinear optimization problem can be solved efficiently by using the iterative linear programming based method proposed in the earlier work (Pan et al., 2013). The best operating solutions are obtained (Table 2): (1) the total annual profit reaches the maximum 120.98 million dollars when the feed flow of LPG is 840 kmol/h, the flow ratio of hydrogen-to-propane is 1.6, the reactor's temperature is 610 ℃, the pressure of reactor is 0.18 MPa, and the pressure of propylene rectifier is 0.9727 MPa; (2) the propylene yield reaches the maximum 83.56% when the feed flow of LPG is 840 kmol/h, the flow ratio of hydrogen-to-propane is 1.6, the reactor's temperature is 610 ℃, the pressure of reactor is 0.18 MPa, and the pressure of propylene rectifier is 0.6665 MPa. Our optimal results are identical to the Aspen Plus simulation results under the same input parameters.

Table 2. Optimal solutions in two scenarios (maximisation of total annual profit and propylene yield) based on the obtained surrogate models for PDH process.

	HDMR models						Aspen Plus results	Error (%)
	x_1	x_2	x_3	x_4	x_5	Objective value		
Max total annual profit (M$/year)	840	1.6	610	0.18	0.9727	120.98	120.70	0.16
Max propylene yield (%)	840	1.6	610	0.18	0.6665	83.56	83.54	0.02

x_1: LPG feed flow (kmol/h); x_2: hydrogen to propane ratio; x_3: reactor temperature (℃); x_4: reactor pressure (MPa); x_5: propylene rectifier pressure (MPa).

4. Conclusion

This paper investigates data based modeling of complex nonlinear processes, a novel data-driven modeling strategy based on high dimensional model representation (HDMR) method is proposed to represent a complex chemical process of propane dehydrogenation,

and a novel linear programming model is then used to find the HDMR parameters. Finally, the complexity of a chemical process model can be reduced significantly as its mechanism formulations are replaced with a simple nonlinear HDMR model and the resulting simple nonlinear optimization problem can be solved efficiently by using an iterative linear programming (LP) method. According to the results of case study, the proposed HDMR method can achieve a highly accurate prediction and optimization of the PDH process.

Modeling Ethylene Cracking Process by Learning Convolutional Neural Networks

Feng Hua, Zhou Fang, Tong Qiu*

Department of Chemical Engineering, Tsinghua University, Beijing 100084, China
qiutong@tsinghua.edu.cn

Abstract

Naphtha pyrolysis is the major source of ethylene and other olefin feedstock for petrochemical industry. Due to the complex reaction kinetics and mass transfer process, the traditional kinetic models are often computationally expensive. Neural nets have been used to overcome the difficulty, but the so-called black-box models ignore reaction mechanism in the training process. They typically need a large training set and often perform poorly when the test data is out of the training range. To improve this, the article puts forward a model that uses the topology of the reaction network to guide the construction of the neural network. After undertaking a graph theoretical analysis of the reaction network, we find that similar to images, the architecture of the naphtha pyrolysis network has modular features, which indicates its deep learning might use the convolutional neural networks (CNNs) to extract the features of its topology. Here, a novel model of naphtha pyrolysis is built based on CNN, which reduces the computational cost of previous kinetic models by up to 700 times. Since the CNN architecture learns the network representations, the proposed model generalizes very well and predicts the yields of key products with high accuracy. The outlined framework is not specific to ethylene cracking process and can be applied to other similar chemical reaction network problems.

Keywords: convolutional neural network; chemical reaction network; naphtha pyrolysis

1. Introduction

The modeling of ethylene cracking process is of high importance due to growing interest in olefins as essential feedstock in the petrochemical industry (Zhang et al., 2012). Recently, comprehensive kinetic models are used in the pyrolysis of hydrocarbons to predict the product yields and other information (Green et al., 2007). Researchers have developed a model to simulate the steam cracking process (Van et al., 2002). Its kinetic scheme, having progressed across the years (Ranzi et al.,2005) is based on equations from the standpoint of free radicals, which enables a more detailed description in the heavy feedstock components. To reduce the network scale, it is asumed that in the reaction process, radicals of C5 and above conform to the quasi-steady-state approximate assumption (QSSA) and can be directly removed (Ranzi et al.,2001), thereby greatly reducing the amount of components in the reaction network. As a result, computational complexity of the lumped model is greatly reduced. For the purpose of moving beyond single particles and modeling the entire cracking reactor, the chemical kinetic mechanisms need to be coupled with the simulation of furnace. the three dimensional heat radiation model of the furnace is established, and the corresponding flow patterns is simulated (Detemmerman et al.,2006). The impact of the flue gas flow is further analyzed for the thermal cracking of hydrocarbons. The detailed pyrolysis network is combined

with the heat transfer in furnace simulation (Niaei et al.,2004). The results show good agreement with experimental data in industrial cracking furnaces.

Nevertheless, such models describe the chemical kinetic mechanisms by conservation equations for mass, heat and momentum transport. Numerical solutions to those models, especially in three-dimensions, are computationally expensive.

After undertaking a graph theoretical analysis (Wagner et al., 2001) of the previous reaction network of naphtha pyrolysis, we find that it has evident modular features. The high modularity can be considered as the result of the existence of local communities in the network. In this paper, a framework based on convolutional neural network (CNN) is used to extract the community structure of the naphtha pyrolysis network.

In the last few years, CNNs have been extensively studied and developed by researchers and has led to good performance on a variety of problems, especially in the field of computer vision (Fukushima et al., 1982; LeCun et al., 1998;2015). CNN is a deep learning model inspired by the visual cortex of living creatures. Its architecture usually consists of five parts: an input layer, convolutional layers, pooling layers, fully connected layers and an output layer. For image-based CNNs, the input is the matrix of image pixels. Convolutional layers are the layers where convolutional kernels extract locally connected regions from the input. Each convolutional layer usually contains several kernels, making sure that different patterns can be filtered. Pooling layers aim to the resolution of the feature maps while retaining important information. Fully connected layers perform high-level reasoning, take all data in the previous layer to generate output results.

Currently, CNNs are mainly applied in image-based problems. Distinct from images whose pixels have an implicit spatial order, the connection pattern of the nodes in networks is quite irregular. Furthermore, large-scale chemical reaction networks usually involve large amounts of components and reactions. Thus, chemical networks are more difficult to be described. The major challenge relies in extending the concepts of CNNs to chemical reaction networks. In the paper, a deep-learning model of ethylene cracking is developed by learning from convolutional neural networks.

2. Graph theoretical analysis of the naphtha pyrolysis network

2.1. Graph Construction

Based on publicly available information of naphtha pyrolysis (Zhang et al., 2012), we assemble a list of 4694 reactions with 142 components. Then, a substrate graph (Wagner et al, 2008) is constructed as a representation derived from the stoichiometric equations and is visualized in Fig. 1.

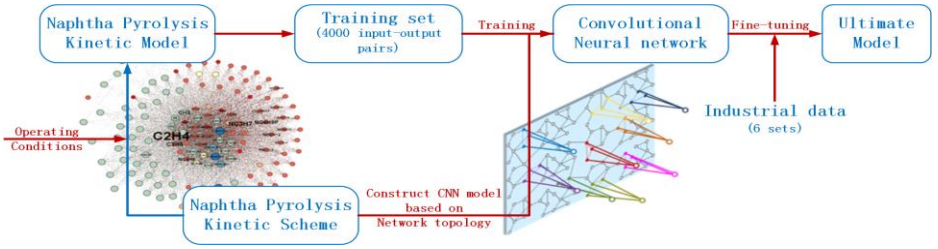

Figure 1: Framework of the modelling process

Figure 1 also gives an overall framework of the modelling process. The substrate graph is then used to guide the construction of the neural net. Its local features are extracted by kernels in the convolutional structure. Each kernel produces 4694 values of output, representing 4694 reactions in the kinetic scheme. The number of outputs is decreased to 142 in the max-pooling layer, representing 142 components. Since the industrial data (8 samples) is not sufficient, the training set (containing about 4000 samples) is generated by the previous naphtha pyrolysis kinetic model. 6 out of 8 of the industrial samples are chosen to fine-tune the model, while the other 2 to test the model.

2.2. Modularity of the network

The modularity of the substrate graph is measured using the community detection method (Blondel et al., 2008). The modularity is defined as a scalar value between -1 and 1 that measures the density of links inside the community compared to links between communities. If the number of inside-community edges is the same as random, we will get Q=0. Q increases with stronger community structure. Through analyse, the modularity of the substrate graph is 0.194. The high modularity can be considered as the result of the similarity of reactions. Reactions of the same mechanism connect the relevant components in the same pattern, resulting in the clustering 'cliques' in this network. The wide existence of communities suggests that the local features of the network topology might be extracted by learning CNN architecture.

3. The neural network architecture

One common type of artificial neural network models is the so-called "black-box" models, where the prior knowledge of the chemical mechanism is completely neglected. This kind of pure data-driven model can simulate much faster than traditional kinetic models and with high predictive accuracy given a large training set. However, even with sufficient training data, the model might still have a poor performance when the input data is out the range of the training set.

In order to improve the ductility of the neural network, we make use of the prior knowledge of the reaction network to guide the design of the neural network architecture. By combining the structural features of naphtha pyrolysis network with the designed neural net, we transform the data-driven model to a hybrid model of both mechanism and data.

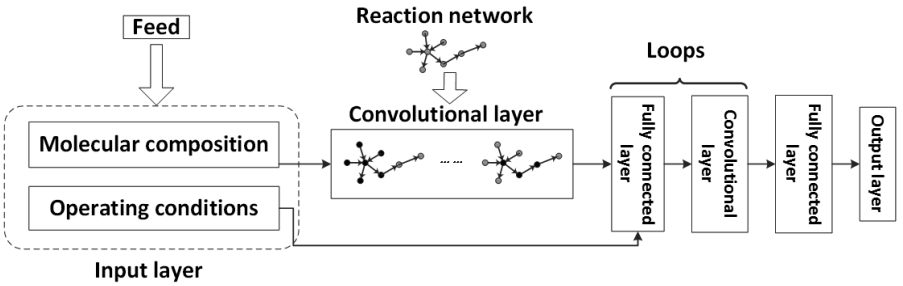

Figure 2: A schematic view of the proposed CNN architecture

Our proposed CNN architecture is shown in Fig.2. The input consists of detailed molecular composition of feedstock and operating conditions. The reaction network is embedded in the convolution layer where the features of the network is learned. The output of the convolutional layer goes into loops. Here, we set 2 loops in the structure.

The output layer exports the yields of 9 key products: H2, CH4, C2H4, C2H6, C3H6, C3H8, C4H6, NC4H8 and IC4H8.

3.1. Convolutional and pooling layer

The design of convolutional layer is presented in Fig3. Each convolutional layer consists of 16 kernels. Each kernel contains 4694 sets of parameters representing 4694 reactions and each set of parameters operates on the relevant feedstock components. After activation function, the convolutional layer gives out a 16*4694 matrix. The max pooling operation is equivalent to summarizing the reaction information by components. The output of the max-pooling layer is 142 values, representing 142 components in the reaction network.

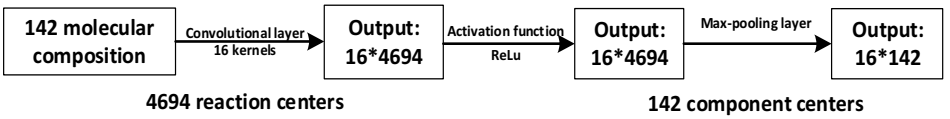

Figure 3: A schematic view of the convolutional and max-pooling layer

3.2. Loop

Each loop consists of a fully connected layer, a convolutional and a pooling layer. Other than the output of the previous layer, the input of the first fully connected layer involves 5 operating conditions including coil inlet temperature (CIT), coil outlet temperature (COT), coil inlet pressure (CIP), federate and water/oil ratio. Thus, the number of input is 16*142+5=2277. We set the number of neurons in the fully-connected layer 142. Each neuron in the fully-connected layer adds the weighted input together plus a certain bias. The result is then transferred by certain activation function and delivered to the next layer. From the mathematic point of view, the operation can be regarded as a row vector (1*2277) multiplied by a matrix of 2277*142 and added to a column vector of 1*142. Thus, the output is decreased to 142, in line with the input of the next layer. A schematic view of the loop is given in Fig4.

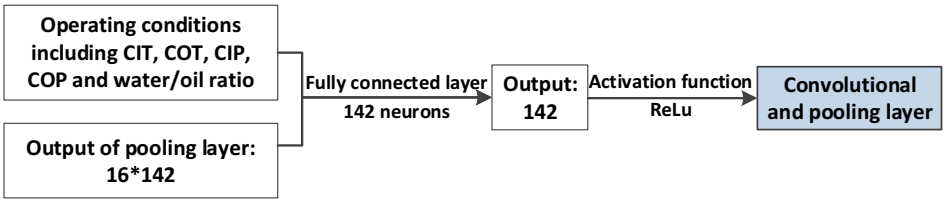

Figure 4: A schematic view of the loop

4. Case study

An industrial case of naphtha pyrolysis is used to testify the proposed CNN model (Fang et al., 2017). Since the experimental data is not enough to form a sufficiently large training set, we train the CNN model by two steps. In the first step, based on the published industrial data of naphtha pyrolysis in the cracking reactor KBR SC-1, we generate 4000 sets of input data by adding a random perturbation and the kinetic model gives out the corresponding output data. The range of input variation is around ±10%. The training set range is thus relatively small because the working conditions don't generally change much for the same furnace in the same factory. In order to apply the neural network to a larger scope, more data will be needed. However, only one cracking reactor is studied

here. The initial network is trained with these input-output pairs. In the second step, we take 6 out of 8 sets of the real industrial data and use them to further fine-tune the neural network.

The ultimate model is used to predict the product yields of three input sets. The operating conditions of the three sets are shown in Table 1. Among them, the first sample is in the training set, while the second and third ones are new to the model.

Table 1: Simulation output of the CNN model

		Sample1 (Trained)		Sample2 (Untrained)		Sample3 (Untrained)	
Feedrate	t/h	6.5686		6.2355		6.2476	
Water/oil ratio	t/t	0.4958		0.5059		0.4837	
CIT	℃	645.68		662.82		617.15	
COT	℃	888.16		868.29		838.83	
CIP	Mpa	0.292		0.294		0.303	
		Industrial	Simulation	Industrial	Simulation	Industrial	Simulation
H2	wt%	1.00	0.96	1.03	0.96	1.06	0.96
CH4	wt%	16.28	16.64	15.88	16.54	17.10	16.80
C2H4	wt%	30.03	30.37	29.66	30.10	30.72	30.26
C2H6	wt%	3.87	3.89	3.79	3.89	3.67	3.89
C3H6	wt%	16.91	16.89	16.27	16.78	16.41	16.84
C3H8	wt%	0.78	0.81	0.72	0.81	0.76	0.81
C4H6	wt%	6.21	6.23	6.14	6.23	5.78	6.23
NC4H8	wt%	1.18	1.16	1.14	1.16	1.03	1.15
IC4H8	wt%	2.78	2.74	2.72	2.74	2.65	2.74
Relative Error Average		1.73%		3.71%		5.55%	

The results show that after the fine-tuning stage, the model can predict the product yields with excellent accuracy. All of the three samples show good consistency with the industrial data. Among them, the trained sample performs better than the untrained ones, with the average relative error of the former equals to 1.73% and that of the latter ones around 5%. Though the phenomenon is quite common for the neural network models and the error is still acceptable for industrial use, it should be mentioned that the application of this model need to be retrained and rebuilt when the input has large differences with the trained ones. To assess the reduction of computational cost compared with the kinetic model, we run 1000 calls of both models and count the average execution time. Each call of the kinetic model takes 31.112s while the CNN model takes 0.044s, which demonstrates the neural set can reduce the computational cost by up to 700 times.

5. Conclusion

In this paper, we build a deep learning model of ethylene cracking process by learning from convolutional neural networks. Different from traditional neural nets that are used as black boxes, the proposed model uses the kinetic scheme to guide the construction of the neural network. Its architecture reads the detailed molecular compositions as well as the operating conditions. The convolutional layers and pooling layers in the network are designed based on the features of the reaction network. As demonstrated above, the CNN model predicts the product yields with excellent agreement with the values in a real industrial case and is about 700 times faster than the previous kinetic model.

In future work, since the performance of neural networks depends largely on the range of training set, industrial data of various furnaces with various working conditions should be added to the training set. Besides, we plan to develop the model to predict the temporal or periodical changes of the product yields. A logical next step is to include time as an additional input of the model. This development will lead to large file size of the training data, which demands the increase of the network depth and width. To overcome this obstacle, various optimization techniques need to be applied to construct deep CNN architectures.

Design of Experiments for Model Discrimination using Gaussian Process Surrogate Models

Simon Olofsson, Marc Peter Deisenroth and Ruth Misener*

Department of Computing, Imperial College London, SW7 2AZ, UK
r.misener@imperial.ac.uk

Abstract

Given rival mathematical models and an initial experimental data set, optimal design of experiments for model discrimination discards inaccurate models. Model discrimination is fundamentally about finding out how systems work. Not knowing how a particular system works, or having several rivalling models to predict the behaviour of the system, makes controlling and optimising the system more difficult. The most common way to perform model discrimination is by maximising the pairwise squared difference between model predictions, weighted by measurement noise and model uncertainty resulting from uncertainty in the fitted model parameters. The model uncertainty for analytical model functions is computed using gradient information. We develop a novel method where we replace the black-box models with Gaussian process surrogate models. Using the surrogate models, we are able to approximately marginalise out the model parameters, yielding the model uncertainty. Results show the surrogate model method working for model discrimination for classical test instances.

Keywords: Design of experiments, model discrimination, Gaussian processes

1. Introduction

Biological engineering deals with noisy and uncertain processes. Modelling these processes is often difficult, and exacerbated by the difficulty of observing mechanisms and reactions on the molecular level. We can hypothesise several different mathematical models to explain a system's behaviour, and run experiments to discriminate between the models. The idea is that there is a real, expensive-to-evaluate system, and M rival models predicting the system behaviour. These models are effectively different hypotheses about some underlying system mechanism. We seek the most accurate model with as few experiments as possible. We will assume the experimental measurement noise is Gaussian distributed with zero mean and a given covariance $\boldsymbol{\Sigma}$.

For analytical models, where the functional relationship can be written down in closed form, extensive literature exists for design of experiments for model discrimination, e.g. Asprey and Macchietto (2000) and Michalik *et al.* (2010). The challenge is that most mathematical models for industrially relevant biological and chemical processes are neither simple nor analytical. They are often, from an optimisation point-of-view, complex black boxes, e.g. legacy codes representing large systems of partial differential equations. For these models, we can simulate the process at discrete locations, but gradient information with respect to model parameters is not readily available.

This paper develops a novel method of using Gaussian process (GP) surrogate models from which model output distributions can be computed and used with existing design criteria from literature, e.g. Box and Hill (1967) and Buzzi-Ferraris *et al*. (1990).

2. Background

2.1. Design Criteria for Model Discrimination

The fundamental principle of experimental design for model discrimination is to select the next experimental point where the model predictions differ the most (Hunter and Reiner, 1965). The measure of how much the models differ is called the *design criterion* and should be maximised. We compare four different design criteria. The first three can be written on the general form $D(\mathbf{x}) = \sum_{i=1}^{M}\sum_{j=1}^{M} D_*(i,j)$, where

- $D_{\mathrm{HR}}(i,j) = \left\|\Delta_{i,j}\right\|_2^2$ (Hunter and Reiner, 1965),
- $D_{\mathrm{BH}}(i,j) = \pi_i\pi_j\left\{\mathrm{tr}\left(\boldsymbol{\Sigma}_i\boldsymbol{\Sigma}_j^{-1} + \boldsymbol{\Sigma}_j\boldsymbol{\Sigma}_i^{-1} - 2\mathbf{I}\right) + \Delta_{i,j}^{\mathrm{T}}\left(\boldsymbol{\Sigma}_j^{-1} + \boldsymbol{\Sigma}_i^{-1}\right)\Delta_{i,j}\right\}$ (Box and Hill, 1967; Prasad and Someswara Rao, 1977),
- $D_{\mathrm{BF}}(i,j) = \mathrm{tr}\left(2\boldsymbol{\Sigma}\left(\boldsymbol{\Sigma}_j + \boldsymbol{\Sigma}_i\right)^{-1} + \Delta_{i,j}^{\mathrm{T}}\left(\boldsymbol{\Sigma}_j + \boldsymbol{\Sigma}_i\right)^{-1}\Delta_{i,j}\right.$ (Buzzi-Ferraris *et al*., 1990},

$\pi_i \in [0,1]$ is the prior likelihood of model i, $\Delta_{i,j} = \boldsymbol{f}_i(\mathbf{x},\boldsymbol{\theta}_i) - \boldsymbol{f}_j(\mathbf{x},\boldsymbol{\theta}_j)$ with $\boldsymbol{f}_i(\mathbf{x},\boldsymbol{\theta}_i)$ the prediction of model i given design $\mathbf{x}$ and model parameters $\boldsymbol{\theta}_i$, and $\boldsymbol{\Sigma}_i = \boldsymbol{\Sigma} + \boldsymbol{\Sigma}_{\mathcal{M},i}(\mathbf{x})$ is the covariance of model i, with $\boldsymbol{\Sigma}_{\mathcal{M},i}(\mathbf{x})$ the model uncertainty due to parameter estimation from noisy observations.

The Michalik *et al.* (2010) design criterion uses Akaike's information criterion: $D_{\mathrm{AW}}(\mathbf{x}) = \sum_{i=1}^{M}\pi_i\left\{\sum_{j=1}^{M}\exp\left(\frac{1}{2}\Delta_{i,j}^{\mathrm{T}}\boldsymbol{\Sigma}_i^{-1}\Delta_{i,j} + D_i - D_j\right)\right\}$, where D_i is the number of model parameters for model i.

We let $\phi_{(e),\ell}(\mathbf{x}) = \partial f_{i,(e)}(\mathbf{x},\boldsymbol{\theta}_i)/\partial\theta_{i,\ell}\big|_{\boldsymbol{\theta}_i=\boldsymbol{\theta}_i^*}$ and use it to define $\left[\boldsymbol{\Phi}_{(e)}\right]_{n,\ell} = \phi_{(e),\ell}(\mathbf{x}_n)$, where $\mathbf{x}_n$ is the location of the n^{th} observation, and $[\boldsymbol{\Phi}(\mathbf{x})]_{(e),\ell} = \phi_{(e),\ell}(\mathbf{x})$. Based on a first-order Taylor expansion of the model functions around $\boldsymbol{\theta}^*$ (Prasad and Someswara Rao, 1977) the model parameters are approximated as Gaussian distributed $\mathcal{N}(\boldsymbol{\theta}^*, \boldsymbol{\Sigma}_\theta)$, with $\boldsymbol{\Sigma}_\theta^{-1} = \sum_{e_1=1}^{E}\sum_{e_2=1}^{E}[\boldsymbol{\Sigma}]_{(e_1),(e_2)}\boldsymbol{\Phi}_{(e_1)}^{\mathrm{T}}\boldsymbol{\Phi}_{(e_2)}$, where E is the number of observable states. The model uncertainty is then approximated by $\boldsymbol{\Sigma}_{\mathcal{M},i}(\mathbf{x}) = \boldsymbol{\Phi}(\mathbf{x})\boldsymbol{\Sigma}_\theta\boldsymbol{\Phi}^{\mathbf{T}}(\mathbf{x})$.

2.2. Gaussian Process Regression

A Gaussian process (GP) is a collection of random variables, any finite subset of which is jointly Gaussian distributed (Rasmussen and Williams, 2006). We can place a GP prior $\mathcal{GP}(m(\mathbf{x}), k(\mathbf{x},\mathbf{x}'))$ on an unknown function f, where m and k are the mean function and covariance function, respectively. Given observations $\mathbf{y} = y_{1:n} \sim \mathcal{N}(f(\mathbf{x_{1:n}}), \sigma_\eta^2)$ at locations $\mathbf{X} = \mathbf{x}_{\mathbf{1}:\boldsymbol{n}}^{\mathrm{T}}$ and a test point $\mathbf{x}_*$, we can compute the posterior predictive distribution $f(\mathbf{x}_*)|\,\mathbf{y},\mathbf{X} \sim \mathcal{N}(\mu(\mathbf{x}_*), \sigma^2(\mathbf{x}_*))$, where $\mu(\mathbf{x}_*) = m(\mathbf{x}_*) + k(\mathbf{x}_*,\mathbf{X})\,\mathbf{K}^{-1}(\mathbf{y}-\mathbf{m})$ and $\sigma^2(\mathbf{x}_*) = k(\mathbf{x}_*,\mathbf{x}_*) - k(\mathbf{x}_*,\mathbf{X})\mathbf{K}^{-1}k(\mathbf{X},\mathbf{x}_*)$, with, in turn, $\mathbf{K} = k(\mathbf{X},\mathbf{X}) + \sigma_\eta^2\mathbf{I}$ the kernel matrix and $\mathbf{m} = m(\mathbf{x_{1:n}})$. The covariance between predictions $f(\mathbf{Z})$ and $f(\mathbf{Z}')$ for the input locations $\mathbf{Z} = \mathbf{z}_{\mathbf{1}:\boldsymbol{H}}^{\mathrm{T}} \in \mathbb{R}^{H\times h}$ and $\mathbf{Z}' = \mathbf{z}'^{\mathrm{T}}_{\mathbf{1}:\boldsymbol{H}'} \in \mathbb{R}^{H'\times h}$ is denoted $k(\mathbf{Z},\mathbf{Z}') \in \mathbb{R}^{H\times H'}$ with elements $[k(\mathbf{Z},\mathbf{Z}')]_{i,j} = k(\mathbf{z}_i,\mathbf{z}_j')$.

A common covariance function is the radial basis function (RBF) kernel $k(\mathbf{x},\mathbf{x}') = \rho^2\exp(-r^2/2)$ with automatic relevance determination (ARD), where ρ^2 is the signal variance, $r^2 = \|\mathbf{x}-\mathbf{x}'\|_{\boldsymbol{\Lambda}^{-1}}^2$, and $\boldsymbol{\Lambda} = \mathrm{diag}(\lambda_{1:D}^2)$, $\mathbf{x} \in \mathbb{R}^D$, are the length scales.

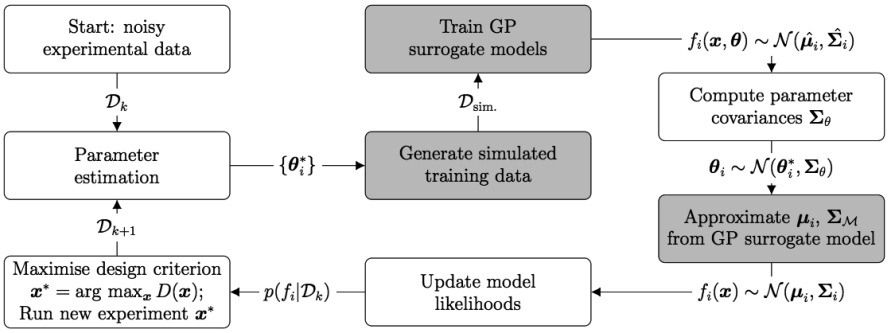

Figure 1: Flowchart description of design of experiments for model discrimination, with novel steps in our method highlighted.

3. Method

We begin by studying the output $\boldsymbol{f}(\mathbf{x}, \boldsymbol{\theta})$ of a single model. We wish to compute the predictive output distribution of the model, taking the uncertainty in the model parameters $\boldsymbol{\theta}$ into account. We place GP priors $\mathcal{GP}(m_{(e)}(\mathbf{x}), k_{x,(e)}(\mathbf{x}, \mathbf{x}')k_{\theta,(e)}(\boldsymbol{\theta}, \boldsymbol{\theta}'))$ on each output $f_{(e)}(\mathbf{x}, \boldsymbol{\theta})$, $e = 1, \dots, E$, of $\boldsymbol{f}$. The noise variance for model output is denoted $\sigma_{\eta,(e)}^2$. The GPs have been trained on the data set $\mathcal{D}_{\text{sim}} = \{\mathbf{X}, \boldsymbol{\Theta}, \mathbf{Y}\} = \{\mathbf{x}_{1:n}, \boldsymbol{\theta}_{1:n}, y_{1:n,1:E}\}$, from n model evaluations.

The predictive distribution $p\big(\boldsymbol{f}(\mathbf{x}, \boldsymbol{\theta})\big) \sim \mathcal{N}\big(\boldsymbol{\mu}(\mathbf{x}, \boldsymbol{\theta}), \boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x}, \boldsymbol{\theta})\big)$ is Gaussian, where $\boldsymbol{\mu}(\mathbf{x}, \boldsymbol{\theta}) = \mu_{1:E}(\mathbf{x}, \boldsymbol{\theta})$ and $\boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x}, \boldsymbol{\theta}) = \text{diag}(\sigma_{\mathcal{M},1:E}^2(\mathbf{x}, \boldsymbol{\theta}))$ with $\mu_{(e)}(\mathbf{x}, \boldsymbol{\theta}) = m_{(e)}(\mathbf{x}) + \mathbf{k}_*^{\mathrm{T}}\mathbf{K}_{(e)}^{-1}(\mathbf{y}_{(e)} - \mathbf{m}_{(e)})$ and $\sigma_{\mathcal{M},(e)}^2(\mathbf{x}, \boldsymbol{\theta}) = k_{x,(e)}(\mathbf{x}, \mathbf{x})k_{\theta,(e)}(\boldsymbol{\theta}, \boldsymbol{\theta}) - \mathbf{k}_*^{\mathrm{T}}\mathbf{K}_{(e)}^{-1}\mathbf{k}_*$. The vector $\mathbf{k}_* = k_{x,(e)}(\mathbf{x}, \mathbf{X}) \circ k_{\theta,(e)}(\boldsymbol{\theta}, \boldsymbol{\Theta})$ and the kernel matrix $\mathbf{K}_{(e)} = k_{x,(e)}(\mathbf{X}, \mathbf{X}) \circ k_{\theta,(e)}(\boldsymbol{\Theta}, \boldsymbol{\Theta}) + \sigma_{\eta,(e)}^2\mathbf{I}$, and $\circ$ denotes element-wise multiplication.

Given a distribution $\boldsymbol{\theta} \mid \mathcal{D} \sim \mathcal{N}(\boldsymbol{\theta}^*, \boldsymbol{\Sigma}_\theta)$ over the model parameters, where $\mathcal{D}$ is the experimental data set, we wish to determine the resulting model uncertainty. The marginalised model output distribution $p(\boldsymbol{f}(\mathbf{x})|\mathcal{D}) = \int p\big(\boldsymbol{f}(\mathbf{x}, \boldsymbol{\theta})\big)p(\boldsymbol{\theta}|\mathcal{D})\mathrm{d}\boldsymbol{\theta}$, which is intractable and has to be approximated. We choose to approximate the marginalised distribution $p(\boldsymbol{f}(\mathbf{x})|\mathcal{D})$ with a Gaussian distribution $\mathcal{N}(\boldsymbol{\mu}(\mathbf{x}), \boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x}))$, where $\boldsymbol{\mu}(\mathbf{x}) \approx \mathbb{E}_{\boldsymbol{\theta}|\mathcal{D}}[\boldsymbol{\mu}(\mathbf{x}, \boldsymbol{\theta})]$ and $\boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x}) \approx \mathbb{E}_{\boldsymbol{\theta}|\mathcal{D}}[\boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x}, \boldsymbol{\theta})] + \mathbb{V}_{\boldsymbol{\theta}|\mathcal{D}}[\boldsymbol{\mu}(\mathbf{x}, \boldsymbol{\theta})]$.

A design of experiments for model discrimination flowchart is shown in Figure 1, with novel steps in our method highlighted. We will compare first- and second-order Taylor approximations of $\boldsymbol{\mu}(\mathbf{x})$ and $\boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x})$. We let $\Delta\boldsymbol{\theta} = \boldsymbol{\theta} - \boldsymbol{\theta}^*$, $\nabla_{\boldsymbol{\theta}}\mu_{(e)} = \nabla_{\boldsymbol{\theta}}\mu_{(e)}(\mathbf{x}, \boldsymbol{\theta})|_{\boldsymbol{\theta}=\boldsymbol{\theta}^*}$ and $\nabla_{\boldsymbol{\theta}}\sigma_{\mathcal{M},(e)}^2 = \nabla_{\boldsymbol{\theta}}\sigma_{\mathcal{M},(e)}^2(\mathbf{x}, \boldsymbol{\theta})|_{\boldsymbol{\theta}=\boldsymbol{\theta}^*}$.

3.1. First-Order Taylor Approximation

The first-order Taylor approximation around a model parameter value $\boldsymbol{\theta}^*$ is given by

$$\mu_{(e)}(\mathbf{x}, \boldsymbol{\theta}) \approx \mu_{(e)}(\mathbf{x}, \boldsymbol{\theta}^*) + \nabla_{\boldsymbol{\theta}}\mu_{(e)}\Delta\boldsymbol{\theta} \tag{1}$$

$$\sigma_{\mathcal{M},(e)}^2(\mathbf{x}, \boldsymbol{\theta}) \approx \sigma_{\mathcal{M},(e)}^2(\mathbf{x}, \boldsymbol{\theta}^*) + \nabla_{\boldsymbol{\theta}}\sigma_{\mathcal{M},(e)}^2\Delta\boldsymbol{\theta} \tag{2}$$

If the model parameter distribution is given by $\boldsymbol{\theta} \mid \mathcal{D} \sim \mathcal{N}(\boldsymbol{\theta}^*, \boldsymbol{\Sigma}_\theta)$, using the first-order Taylor approximations in Eq. (1)-(2), the mean $\boldsymbol{\mu}(\mathbf{x})$ of the approximate marginalised

model output distribution becomes $\boldsymbol{\mu}(\mathbf{x}) \approx \boldsymbol{\mu}(\mathbf{x}, \boldsymbol{\theta}^*)$, and the corresponding covariance matrix has elements $[\boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x})]_{(e_1),(e_2)} \approx [\boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x}, \boldsymbol{\theta}^*)]_{(e_1),(e_2)} + \nabla_{\boldsymbol{\theta}} \mu_{(e_1)} \boldsymbol{\Sigma}_{\theta} \nabla_{\boldsymbol{\theta}} \mu_{(e_2)}^{\mathrm{T}}$.

3.2. Second-Order Taylor Approximation

The second-order Taylor approximation around a model parameter value $\boldsymbol{\theta}^*$ is given by

$$\mu_{(e)}(\mathbf{x}, \boldsymbol{\theta}) \approx \mu_{(e)}(\mathbf{x}, \boldsymbol{\theta}^*) + \nabla_{\boldsymbol{\theta}} \mu_{(e)} \Delta\boldsymbol{\theta} + \frac{1}{2} \Delta\boldsymbol{\theta}^{\mathrm{T}} \nabla_{\boldsymbol{\theta}}^2 \mu_{(e)} \Delta\boldsymbol{\theta} \tag{3}$$

$$\sigma_{\mathcal{M},(e)}^2(\mathbf{x}, \boldsymbol{\theta}) \approx \sigma_{\mathcal{M},(e)}^2(\mathbf{x}, \boldsymbol{\theta}^*) + \nabla_{\boldsymbol{\theta}} \sigma_{\mathcal{M},(e)}^2 \Delta\boldsymbol{\theta} + \frac{1}{2} \Delta\boldsymbol{\theta}^{\mathrm{T}} \nabla_{\boldsymbol{\theta}}^2 \sigma_{\mathcal{M},(e)}^2 \Delta\boldsymbol{\theta} \tag{4}$$

If the model parameter distribution is given by $\boldsymbol{\theta} \mid \mathcal{D} \sim \mathcal{N}(\boldsymbol{\theta}^*, \boldsymbol{\Sigma}_{\theta})$, using the second-order Taylor approximations in Eq. (3)-(4), the mean $\boldsymbol{\mu}(\mathbf{x})$ of the approximate marginalised model output distribution has elements $\mu_{(e)}(\mathbf{x}) \approx \mu_{(e)}(\mathbf{x}, \boldsymbol{\theta}^*) + \frac{1}{2} \mathrm{tr}(\nabla_{\boldsymbol{\theta}}^2 \mu_{(e)} \boldsymbol{\Sigma}_{\theta})$. The corresponding covariance $\boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x})$ has elements

$$\begin{aligned} [\boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x})]_{(e_1),(e_2)} \approx \delta_{(e_1),(e_2)} & \underbrace{\left(\sigma_{\mathcal{M},(e_1)}^2(\mathbf{x}, \boldsymbol{\theta}^*) + \frac{1}{2} \mathrm{tr}\left(\nabla_{\boldsymbol{\theta}}^2 \sigma_{\mathcal{M},(e_1)}^2 \boldsymbol{\Sigma}_{\theta} \right) \right)}_{\mathbb{E}_{\boldsymbol{\theta}|\mathcal{D}}[\boldsymbol{\Sigma}_{\mathcal{M}}(\mathbf{x},\boldsymbol{\theta})]} \\ & + \underbrace{\nabla_{\boldsymbol{\theta}} \mu_{(e_1)} \boldsymbol{\Sigma}_{\theta} \nabla_{\boldsymbol{\theta}} \mu_{(e_2)}^{\mathrm{T}} + \frac{1}{2} \mathrm{tr}\left(\nabla_{\boldsymbol{\theta}}^2 \mu_{(e_1)} \boldsymbol{\Sigma}_{\theta} \nabla_{\boldsymbol{\theta}}^2 \mu_{(e_2)} \boldsymbol{\Sigma}_{\theta} \right)}_{\mathbb{V}_{\boldsymbol{\theta}|\mathcal{D}}[\boldsymbol{\mu}(\mathbf{x},\boldsymbol{\theta})]}, \end{aligned} \tag{5}$$

where $\delta_{i,j}$ is the Kronecker delta.

4. Results

We compare the performance of (i) the first- and second-order Taylor approximations, and (ii) the four different design criteria in Sec. 2.1 as well as random design, for two different case studies. For each experiment we uniformly sample a new set of N_0 initial data points. Each iteration we compute the normalised likelihood $\hat{\pi}_{i,N}$ of model $\boldsymbol{f}_i$ given dataset $\mathcal{D}_N$ of size N as

$$\hat{\pi}_{i,N} = \frac{p(\boldsymbol{f}_i|\mathcal{D}_N)}{\sum_{j=1}^{M} p(\boldsymbol{f}_j|\mathcal{D}_N)}, \qquad p(\boldsymbol{f}_i|\mathcal{D}_N) = \prod_{j=1}^{N} \mathcal{N}\left(\mathbf{y}_j | \boldsymbol{\mu}_i(\mathbf{x}_j), \boldsymbol{\Sigma} + \boldsymbol{\Sigma}_{\mathcal{M},i}(\mathbf{x}_j) \right) \tag{7}$$

The normalised likelihoods $\hat{\pi}_{i,N}$ fluctuate significantly in the experiments due to measurement noise and refitting of model parameters each iteration. Therefore, we choose to update the model likelihoods using a moving average, such that given the $(N+1)^{\text{th}}$ observation the likelihood for model $\boldsymbol{f}_i$ becomes $\pi_{i,N+1} = (\pi_{i,N} + \hat{\pi}_{i,N})/2$, with $\pi_{i,0} = 1/M$.

In each case study, we choose one model to be the true model, from which we generate observations with added noise. We sample all models in a black-box fashion to construct the corresponding GP surrogate models. Performance is measured in the average number (A) of additional experiments $N - N_0$ required for the data-generating model i to reach likelihood threshold $\pi_{i,N} \geq \tau$. (SE) denotes the standard error of (A).

In both case studies, the RBF-ARD covariance function is used for both k_x and k_θ, because we expect the model functions to be smooth.

4.1. Case Study 1

Case study from Buzzi-Ferraris *et al*. (1990) of a reaction with two observables y_1, y_2 and two design variables x_1, x_2. We want to discriminate between four chemical kinetic models $\boldsymbol{f}_i$, each with four model parameters $\theta_{i,j}$. The observed data are generated from model 1 with $N_0 = 5$ initial data points. The results are shown in Table 1.

Table 1. Results after 100 experiments in case study 1, using first- (T_1) and second-order (T_2) Taylor approximation. Averages within one SE of best result in bold font.

4.2. Case Study 2

Case study of the reaction $\mathrm{A} + \mathrm{B} + \mathrm{E} \rightarrow \mathrm{P} + \mathrm{D}$ (Tandogan *et al.*, 2017). There are three different models to describe this process, with intermediary, non-observable reactions. We generate the observed data from model 3, with $N_0 = 3$ initial data points for each experiment. The model parameters $\theta_{i,j}$ are the kinetic coefficients. There are 5, 4 and 7 parameters for model 1, 2 and 3, respectively. The design variables are (1) the ratio $r = V_{\mathrm{A},0}/750$ ml of the initial volume $V_{\mathrm{A},0} + V_{\mathrm{B},0}$ made up by solvent A, (2) the initial amount of $\mathrm{E} \in [10, 200]$ mg added to the solution, and (3) the time point $\mathrm{t} \in [0, 1]$ s at which we measure the concentrations of A, B, E, P and D. We assume that A and B have a molar volume 55 mol/l, and that E has molar weight 440 g/mol. The initial concentrations of all other components are set to 0. The results are shown in Table 2.

Table 2. Results after 100 experiments in case study 2, using first- (T_1) and second-order (T_2) Taylor approximation. Averages within one SE of best result in bold font.

5. Discussion

Tables 1-2 show that replacing the original models with GP surrogate models is outperforming the random strategy. For these test instances, our method performs better using the first-order than the second-order Taylor approximation for marginalising out the model parameters, i.e. fewer additional experiments are required to find the data-generating model. This could be because a first-order Taylor expansion is used for computing the parameter covariance $\boldsymbol{\Sigma}_{\theta}$. Alternatively, the first-order (second-order) approximation might underestimate (overestimate) the model uncertainty, resulting in faster discrimination in these simulated case studies. In future research we will study this more, and explore additional approximation methods.

For case study 1, D_{AW} significantly outperforms the other design criteria. For case study 2, the performances are more similar. The D_{AW} design criterion might have an advantage over the D_{HR} and D_{BF} design criteria because it incorporates the model probabilities used for the subsequent model discrimination.

In Case Study 2, the concentrations can only be measured at a single time point for each experiment. Measurements at multiple time points can be implemented by modelling each output and fixed time point with a separate GP surrogate model, i.e. treat the measurement at each time point as a separate model output.

6. Conclusions

Design of experiments for black-box model discrimination is a difficult but important problem. We have shown that our novel method, hybridising the classical analytical approach with a statistical sampling-based approach using GP surrogate models, can work well. It allows us to be flexible with regards to the software implementations of the underlying models. In future research we will apply our method to more case studies and compare our method to competing black-box design and discrimination methods. We also hope to apply our method in a control setting using a multi-objective approach (Olofsson *et al.,* 2017). The GP surrogate model-based method presented in this paper has been implemented in Python and made available on GitHub (Olofsson, 2017).

Abstract

In this paper, we give a summary of recent advances (K. Meyer et al, 2018) on the use of a nodal discontinuous Galerkin finite element (DG-FE) method for spatial discretization of chromatographic models. Explicit Runge-Kutta (ERK) methods are popular for integrating the semi-discrete systems of equations resulting from DG space discretization. However, ERK methods suffer from stability-based time step restrictions for stiff problems. Therefore, we implement a high order implicit-explicit additive Runge-Kutta (IMEX-ARK) method (Kennedy and Carpenter, 2003, 2007) to overcome system stiffness. The IMEX-RK method advances the non-stiff parts of the model using explicit methods and solve the more expensive stiff parts using an L-stable stiffly-accurate explicit, singly diagonally implicit Runge-Kutta method (ESDIRK). We show that for a multicomponent nonlinear chromatographic system, the IMEX-ARK scheme becomes more efficient than explicit methods for increasingly stiff systems. We recommend integrating the convective term using explicit methods and to integrate both the diffusive and reactive terms using implicit methods.

Keywords: Langmuir isotherm, Nonlinear chromatography, high-order, discontinuous Galerkin finite element method, implicit-explicit.

1. Introduction

Biopharmaceuticals are becoming increasingly important in recent years in treating chronic diseases such as cancer and arthritis. The manufacturing processes are inherently complex due to their non-linear bioprocess dynamics and batch-to-batch variability leading to high production costs of which 50-80 % are attributed to downstream processing (Guiochon and Beaver, 2011). Here, chromatographic separations are essential since they achieve high purity as required for biopharmaceutical drugs. The current trend in the biopharmaceutical industries is the digitalization of the manufacturing processes to switch from a recipe-driven to a data-driven operational approach. This digitalization has an enormous potential to facilitate rapid cost-effective process development for accelerating speed-to-market and near-optimal operation using on-line monitoring strategies to control production costs. This has been successfully used for decades in other industries such as the chemical and petrochemical industries. Biopharmaceutical industries can reap similar benefits from digitalization. Presently, the utility of computers for process design and operation is limited. The current challenges are computational efforts, quality of models, accessibility to experimental data and

component-specific on-line concentration measurements in complex biological feedstocks.

This contribution presents a novel tool for rapid and accurate simulation of chromatographic models to reduce computational efforts and hence, promote the digitalization of the biopharmaceutical industry. The parabolic and convection-dominated transport-dispersive model of chromatography is considered and is discretized using a method-of-lines approach in which the spatial and temporal domains are considered separately. A discontinuous Galerkin finite element (DG-FE) method was presented by Meyer et al. (2018) for spatial discretization resulting in a large system of ordinary differential equations (ODE) in time. Despite the popularity of high-order explicit Runge-Kutta (ERK) methods for time marching of the ODE system resulting from DG space discretization, ERK methods suffer from stability-based time step restrictions for stiff problems. Therefore, we implement a high-order implicit-explicit additive Runge-Kutta (IMEX-ARK) scheme to overcome system stiffness. The IMEX-ARK scheme uses an explicit method to solve non-stiff parts of the model and isolate and solve the more expensive stiff parts using an Explicit, Singly Diagonally Implicit Runge-Kutta method (ESDIRK). In future, we want to consider dynamic optimization problems for optimal closed loop control of chromatographic columns. Therefore, it is especially beneficial to choose an ESDIRK-based method for time integration of the stiff parts over the often applied BDF methods (Schlegel et al., 2004). In general, ESDIRK methods in combination with DG space discretization is superior over BDF methods (Bijl et al., 2002). We show that for increasingly stiff systems, the IMEX-ARK scheme becomes more efficient than explicit Runge-Kutta (ERK) methods. We recommend integrating the convective term with explicit methods and both the diffusive and reactive terms using implicit methods.

2. Transport-dispersive model of chromatography

2.1. Mass transport

The transport-dispersive model of chromatography is used to describe the effects of mass transport (Guiochon et al., 2006). It is for the ith component given, on dimensionless form, by

$$\frac{\partial \boldsymbol{u}}{\partial \tau} + \frac{\partial \boldsymbol{f_c}}{\partial z} - \frac{\partial \boldsymbol{f_d}}{\partial z} = \boldsymbol{p} \tag{1}$$

where

$$\boldsymbol{u} = \begin{bmatrix} c_i + F q_i \\ q_i \end{bmatrix}, \boldsymbol{f_c} = \begin{bmatrix} c_i \\ 0 \end{bmatrix}, \quad \boldsymbol{f_d} = \begin{bmatrix} 1/Pe_i \cdot \partial c_i / \partial z \\ 0 \end{bmatrix}, \quad \boldsymbol{p} = \begin{bmatrix} 0 \\ St_i (q_i^* - q_i) \end{bmatrix} \tag{2}$$

Here, c_i and q_i are the mobile phase and stationary phase concentrations, respectively, $F = (\epsilon_c - 1)/\epsilon_c$ is the column phase ratio, ϵ_c is the column porosity, q_i^* is the equilibrium stationary phase concentration and τ and z are the dimensionless time and axial position, respectively. The Peclet number $Pe_i = vL/D_i$ and the Stanton number $St_i = k_i L/v$ are important dimensionless groups that determine the stiffness of the

system, where v is the interstitial velocity, L is the column length, D_i is the axial dispersion coefficient, k_i is the lumped mass transfer coefficient and L is the column length. As the Peclet number increases, the system stiffness due to diffusion vanishes. For increasingly large Stanton numbers, the reactive term contributes increasingly to system stiffness. Eq.(1) is for the ith component complemented with Danckwerts (1954) boundary conditions and initial conditions corresponding to an initially equilibrated column are used.

2.2. Adsorption

The column adsorption equilibria between bound q_i and unbound c_i states are described by a competitive nonlinear Langmuir isotherm. The model is derived by Guiochon et al. (2006) and is for the ith component given by

$$q_i^* = \frac{a_i c_i}{1 + \sum_{s=1}^{N_c} b_s c_s} \tag{3}$$

where b_s is the ratio of the rate constant of adsorption and desorption and the ratio a_i/b_i is the column saturation capacity.

3. Time integration schemes

The numerical solution of the parabolic and convection dominated system described by Eq.(1) is solved using a methods-of-lines approach. Here, the spatial and temporal discretization's are considered separately. A nodal discontinuous Galerkin finite element (DG-FE) method is presented by Meyer et al. (2018). The resulting semi-discrete equation system is of the form

$$\frac{\partial \boldsymbol{u_h}}{\partial t} = \boldsymbol{F}\big(t, \boldsymbol{u}_h(t)\big) = \sum_{v=1}^{2} \boldsymbol{F}^{[v]}(t, \boldsymbol{u}_h(t)), \quad \boldsymbol{u}_h(t_0) = \boldsymbol{u}_{h,0} \tag{4}$$

where $\boldsymbol{u_h}$ is the numerical approximation to the exact solution $\boldsymbol{u}$, $\boldsymbol{F}^{[1]}(t, \boldsymbol{u_h(t)})$ is the spatial DG approximation to the convective term which we integrate with an explicit method and $\boldsymbol{F}^{[2]}(t, \boldsymbol{u}_h(t))$ is the DG approximation to both the diffusive and reactive terms which we integrate with an implicit method.

3.1. Implicit-Explicit additive Runge-Kutta (IMEX-ARK) method

A 6 stage 4$^{\text{th}}$–order IMEX-ARK$_2$ method (Kennedy and Carpenter, 2003) is used to advance Eq.(2) from time step $t^{(n)}$ until $t^{(n+1)} = t + \Delta t$ by

$$\begin{aligned} \boldsymbol{u}_h^{(i)} &= \boldsymbol{u}_h^{(n)} + \Delta t \sum_{v=1}^{2} \sum_{j=1}^{6} a_{ij}^{[v]} \boldsymbol{F}^{[v]}\left(t^{(n)} + c_j \Delta t, \boldsymbol{u}_h^{(j)}\right), \quad 1 \le i \le 6 \\ \boldsymbol{u}_h^{(n+1)} &= \boldsymbol{u}_h^{(n)} + \Delta t \sum_{v=1}^{2} \sum_{j=1}^{6} b_j^{[v]} \boldsymbol{F}^{[v]}\left(t^{(n)} + c_j \Delta t, \boldsymbol{u}_h^{(j)}\right) \end{aligned} \tag{5}$$

$$\widehat{\boldsymbol{u}}_h^{(n+1)} = \boldsymbol{u}_h^{(n)} + \Delta t \sum_{v=1}^{2} \sum_{j=1}^{6} \hat{b}_j^{[v]} \boldsymbol{F}^{[v]} \left(t^{(n)} + c_j \Delta t, \boldsymbol{u}_h^{(j)} \right)$$

where $a_{ij}^{[v]}$, $b_i^{[v]}$ and $c_i^{[v]}$ are fixed constants. The $\boldsymbol{u}_h^{(n+1)}$-vector is of order 4 and the $\widehat{\boldsymbol{u}}_h^{(n+1)}$-vector associated with the embedded scheme is of order 3. Using the embedded scheme, a local error estimate $\delta = u_h^{n+1} - \hat{u}_h^{n+1}$ of order 3 is obtained. The local error estimate is fed into an I-controller to adaptively change the time step, i.e.

$$(\Delta t)_I^{n+1} = \kappa (\Delta t)^{(n)} \left(\frac{\epsilon}{\| \delta^{(n+1)} \|_2} \right)^{\left(\frac{1}{3}\right)} \tag{6}$$

where $\kappa \approx 0.9$ is a safety factor and ϵ is a user-specified temporal integration tolerance. The ith non-linear stage given by Eq.(5) is solved iteratively using a modified Newton's method, that is

$$\begin{aligned} \boldsymbol{M} \Delta \boldsymbol{u}_h^{(i)} &= -\boldsymbol{R}^{(i)} \left(\boldsymbol{u}_h^{(i,l)} \right) \\ \boldsymbol{u}_h^{(i,l+1)} &= \boldsymbol{u}_h^{(i,l)} + \Delta \boldsymbol{u}_h^{(i)} \end{aligned} \tag{7}$$

where $\boldsymbol{M} = \boldsymbol{I} - \Delta t a_{ii} J$ is the iteration matrix, $\boldsymbol{J} = \partial \boldsymbol{F} / \partial \boldsymbol{u}_h^{(i)}$ is the Jacobian matrix and $\boldsymbol{R}^{(i)}$ is the stage residual. The iteration is termined using a residual test rather than a displacement test for robustness (Houbak, Nørsett, & Thomsen, 1985). Thus, the iteration is terminated when $\boldsymbol{R}^{(i)} \leq c\epsilon$ where $c \approx 0.01$ is chosen such that the temporal integration error dominates. The iteration matrix is factored using Matlab's *lu* function whenever the step size changes. To reduce the number of factorizations, a constant step size is enforced when the step size computed by the I-controller is small compared to the current step size, e.g. if $1 \leq \Delta t^{(n+1)} / \Delta t^n \leq 1.2$, then $\Delta t^{(n+1)} = \Delta t^{(n)}$ (E. Hairer and G. Wanner, 1991). The Jacobian matrix is formed adaptively using similar logic as Shampine (1980). To speed up the Newton iterations and avoid convergence failures a good stage predictor is required. We use stage values from previous time steps to extrapolate into the current step using a dense output formula (Kennedy and Carpenter, 2007; Sand, 1988; Nørsett and Thomsen, 1986). For large time steps, e.g. if $(\Delta t)^{(n+1)} / \Delta t^{(n)} > 3$, we use the trivial guess instead (the most recent stage value).

3.2. Explicit Runge-Kutta (ERK) method

We implement an efficient and accurate 5 stage 4th-order low storage ERK scheme (M.H. Carpenter, and C.A. Kennedy, 1994) which requires storage and overwriting of only 2 vectors $\boldsymbol{k}^{(j)}$ and $\boldsymbol{p}^{(j)}$ by

$$\begin{aligned} &\boldsymbol{p}^{(0)} = \boldsymbol{u}_h^{(n)} \\ &j \in [1, \ldots, 5]: \begin{cases} \boldsymbol{k}^{(j)} = a_j \boldsymbol{k}^{(j-1)} + \Delta t \boldsymbol{F} \left(t^{(n)} + c_j \Delta t, \boldsymbol{p}^{(j-1)} \right) \\ \boldsymbol{p}^{(j)} = \boldsymbol{p}^{(j-1)} + b_j \boldsymbol{k}^{(j)} \end{cases} \\ &\boldsymbol{u}_h^{(n+1)} = \boldsymbol{p}^{(5)} \end{aligned} \tag{8}$$

where a_j, b_j, and c_j are fixed constants. Here, we use a fixed time step size which is restricted by a lower Courant-Friedrichs-Lewy (CFL) condition.

4. Numerical results

The case study considered is concerned with the separation of a two-component mixture under non-linear chromatographic conditions where the two components compete for available sites in the stationary phase. The detailed model parameters are: column length $L = 1$ m, porosity $\epsilon = 0.4$, interstitial velocity $v = 0.1$, isotherm parameters $(a_1, a_2) = (0.5,1)$ and $(b_1, b_2) = (0.05,0.1)$ L/mol. A rectangular pulse is injected at the inlet of the column for 12 s at a feed concentration of $(c_1, c_2) = (10,10)$ mol/L. The spatial domain is discretized using a 5th-order DGFE scheme with 200 elements.

The simulations are performed with varying Peclet numbers at a fixed Stanton number of 10^{-12} to isolate the effect of diffusion with respect to system stiffness. Similarly, the Stanton number is varied at a fixed Peclet number of $Pe = 10^{12}$ to isolate the effect of the reaction term. The results for varying Peclet numbers and varying Stanton numbers are given in Figs. 1A and B, respectively. In Fig. 1A it is seen that decreasing the Peclet number increases the stiffness of the system. Below a certain critical Peclet number, $Pe \approx 2 \cdot 10^4$, the IMEX-RK scheme starts to perform better than the ERK scheme. Under liquid chromatography conditions, Peclet numbers below $Pe = 2 \cdot 10^4$ are common. Therefore, we recommend integrating the diffusive term using an implicit method, although this might be unnecessary under high-performance liquid chromatography conditions where Peclet numbers can be expected to be very high. In Fig. 1B it is seen that increasing the Stanton number increases the stiffness of the system. Above a critical Stanton number of $St \approx 7 \cdot 10^3$ the IMEX-ARK scheme becomes more efficient compared to the ERK scheme. Again, we recommend integrating the reaction term using implicit time integration since Stanton numbers of $St = 7 \cdot 10^3$ are common under liquid chromatography conditions, although lower Stanton numbers can be expected under high-performance liquid chromatography conditions.

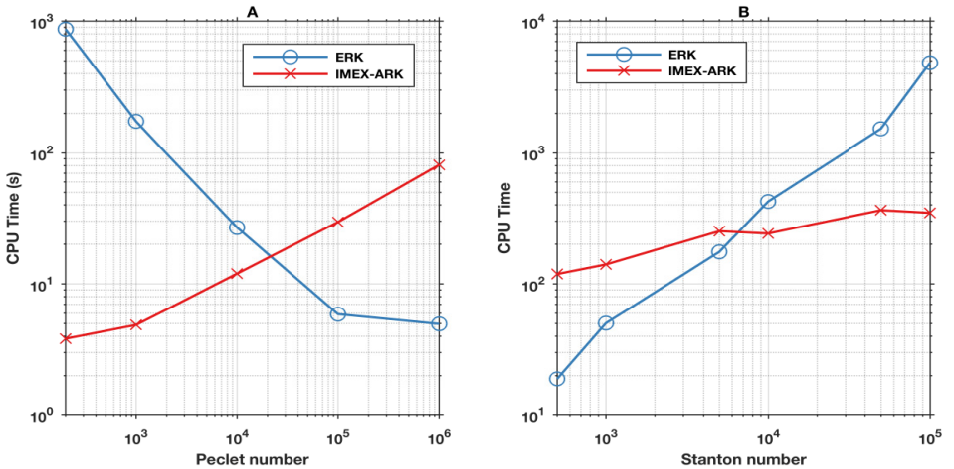

Figure 1. Comparison of IMEX-ARK and ERK results for a two component, non-linear chromatographic system. In A, the Peclet number is varied with a fixed Stanton number of 10^{-12} and in figure B the Stanton number is varied with a fixed Peclet number of 10^{12}.

5. Conclusions

An IMEX-ARK scheme was implemented and compared to an efficient ERK scheme. It was shown that for increasingly stiff systems, characterized by the dimensionless Peclet and Stanton numbers, the IMEX-ARK scheme becomes more efficient than the ERK scheme. In the future, we will improve our IMEX-ARK implementation by introducing a customized linear solver module. For larger systems, we will consider inexact Newton methods with efficient preconditioners. The code will be tested for the most widely used isotherm functions such as the Steric Mass Action isotherm (Brooks and Cramer, 1992) and Mollerup's (2007) isotherms and will be used to study optimal closed loop control of chromatographic systems.

On the efficiency of PT Flash calculations with equations of state

Xiaodong Liang

Center for Energy Resources Engineering, Department of Chemical and Biochemical Engineering, Technical University of Denmark,Kgs. Lyngby, Denmark
xlia@kt.dtu.dk

Abstract

The isobaric-isothermal equilibrium (PT Flash) calculation has been an active research topic in thermodynamics community for decades, of which the conventional framework consists of two subproblems: stability test and phase split calculation. In this work, various aspects on the efficiency of the conventional PT Flash calculation procedures have been investigated, which includes the significances of a few successive substitution steps before starting the second-order method and volume based methods for both PT stability test and PT Flash problems, as well as the use of advanced equations of state.

Keywords: PT Flash, Stability Test, Phase Split, Successive Substitution, Second-order

1. Introduction

The isobaric-isothermal equilibrium (PT Flash) calculation is one of the most important one-stage equilibrium problems. In principle, the PT Flash calculation is a minimization problem, as the objective is to find the number of phases and their compositions that represent the minimum Gibbs free energy of the system. It has been an active research topic for decades. There are different approaches/frameworks for the PT Flash calculation. This work follows the approach proposed by Michelsen (1982a, 1982b, 2007), which consists of two equally important subproblems: stability test, checking if a new phase shall be added, and phase split calculation, determining equilibrium compositions. The PT Flash calculation could start from either of them. In this work, the calculation starts from the stability test, as it is assumed that there is no advanced knowledge available for the equilibrium factors. The output from the stability test is used to generate initial estimates for the phase split calculation, if it indicates that the systems is unstable. The phase split calculation then determines the equilibrium compositions and also take responsible for removing phases if necessary. When the phase split calculation finishes successfully, the stability of the equilibrium system is tested again, and the procedure iterates until the system is stable. It is possible to use either local global minimization methods for stability test, phase split calculation or both. It is generally considered that local minimization methods are more efficient, while the global minimization ones are safer. According to the previous experience, a well-organized PT Flash calculation procedure with a globally convergent local minimization algorithm is very robust, and it is the strategy used in this work. This study focuses on answering (1) if a few successive substitution (*SS*) and/or (2) volume-based methods can improve the efficiency for stability test and/or phase split calculation; (3) how much efficiency cost people need to pay when advanced equations of state (EOS) are used.

2. Methodology

The objective function for stability test, when temperature and pressure are specified, can be formulated (Michelsen, 1982a, 2007)

$$tm(\boldsymbol{n}) = 1 + \sum_i n_i[\ln n_i + \ln\varphi_i(T,P,\boldsymbol{n}) - \ln z_i - \ln\varphi_i(T,P,\boldsymbol{z}) - 1] \tag{1}$$

where n_i and z_i are mole numbers and mole fraction of component *i* of the trial phase and the tested phase, respectively, and $\boldsymbol{n}$ and $\boldsymbol{z}$ are the corresponding vectors. φ_i is the fugacity coefficient of component *i*. Equivalently, it can be written

$$tpd(T,V,\boldsymbol{n}) = \sum_i n_i\left[\frac{\mu_i(T,V,\boldsymbol{n})}{RT} - \frac{\mu_i(T,v_0,\boldsymbol{z})}{RT}\right] - V\left[\frac{P(T,V,\boldsymbol{n})}{RT} - \frac{P_0}{RT}\right] \tag{2}$$

where V is the total volume, μ_i is the chemical potential of component i, v_0 and P_0 are respectively the molar volume and pressure of the tested phase.

The objective function for phase split calculation can be written

$$Q = \sum_{j=1}^{\Pi}\sum_{i=1}^{C} n_{i,j}\ln f_{i,j}\left(T,P,\boldsymbol{n}_j\right) \tag{3}$$

where $f_{i,j}$ is the fugacity of component *i* in phase *j*. Π and C are number of phases and number of components, respectively. The objective function can also be built on the volume-composition space,

$$Q = \sum_{j=1}^{\Pi}\left[\sum_{i=1}^{C} n_{i,j}\frac{\mu_{i,j}\left(T,V_j,\boldsymbol{n}_j\right)}{RT} - \frac{P_j - P_0}{RT}V_j\right] \tag{4}$$

The general ideas of the solution methods for stability test and phase split calculation are from literature as listed in Table 1. There is no volume based (V-based) *SS* method available for stability test and phase split calculation, so whenever V-based and P-based (pressure based) are mentioned hereafter, they refer to the *SO* methods. The two *SO* methods for stability test and the P-based method for phase split calculation are treated as unconstrained minimization problems, solved by the combination of a modified Murry's method for Hessian matrix decomposition and a line search approach developed by Fletcher (2000). The V-based method for phase split calculation is solved by a Newton-Raphson method instead of an optimization method. Whenever the minimum phase volume becomes negative during iteration, the procedure switches to the P-based *SO* method.

Table 1. Solution methods for stability test and phase split calculation

Orders of method	Variable	Stability test	Phase split calculation
First-order (*SS*)	P-based	Michelsen [2007]	Michelsen [2007]
Second-Order (*SO*)	P-based	Michelsen [2007]	Michelsen [2007]
Second-Order (*SO*)	V-based	Nichita [2017]	Paterson [2017]

3. Models and test cases

The Soave-Redlick-Kwong (SRK) (Soave, 1972), the Peng-Robinson (PR) (Peng et al., 1976) and the Perturbed-Chain Statistical Associating Fluid Theory (PC-SAFT) EOS (Gross et al., 2001; von Solms et al., 2003) are the models used in this work. The investigated systems are listed in Table 2.

Table 2. Systems studied in this work

System	Description
S1	Example Ex5 from Nichita (2017)
S2	Example Ex7 from Nichita (2017)
S3	C_1-H_2S-CO_2 with composition [0.5, 0.4, 0.1]. The k_{ij} for PR from Li et al. (2012), while the k_{ij} for SRK and PC-SAFT are from Yan et al. (2015)
S4	An asphaltene fluid (Fluid-2) and the PC-SAFT parameters from Arya et al. (2016) The parameters for SRK from Arya et al. (2017)

4. Results and discussions

In this section, we present the results on various aspects of the computational efficiency. The investigations focus on: V-based versus P-based for stability test alone or the entire PT Flash calculation, number of *SS* steps before the *SO* methods and different EOS models. The core codes are implemented in FORTRAN and compiled by Intel Fortran Compiler X2011 into a DLL. Interfaces to MATLAB are created to manage data input and output, plot and analysis, with possibilities for secondary developments. All the calculations have been conducted in a laptop with Intel Core i5-5300U CPU@2.3GHz. Demonstration cases may be obtained from the author upon request.

4.1. PT Stability test

The average iteration numbers of the V-based and P-based *SO* methods, no *SS* steps conducted, for the stability test for systems S1 and S2 are given in Figure 1 (a) and (b), respectively. The temperature and density ranges for these two systems are taken from Nichita (2017), and the pressure is then calculated from the given temperature and density. The calculations are conducted only if the pressure is larger than 100Pa. Vapour and Liquid in the *x*-axis represent if the feed is considered as a vapour-like or liquid-like fluid. The results of the V-based *SO* method are similar to those presented by Nichita (2017). To a large extent, it can be seen that the P-based *SO* method uses less iterations to converge. As shown in Figure 1 (c) and (d), however, the V-based *SO* method costs less in terms of running time when no *SS* steps are taken. It has to point out that multiple initial estimates are used (Michelsen, 1982a, Castier, 2014) when counting the running time. The running time is an average time for one point (a given temperature and pressure), for which 1000 calculations have been repeated. It can be seen from Figure 1 (c) and (d) that a few *SS* steps can significantly reduce the running cost, while how many number of *SS* steps that shall be taken depends the system of interest. It is recommended 4-7 *SS* steps taken before the *SO* method, in which manner V-based and P-based approaches show comparable performance.

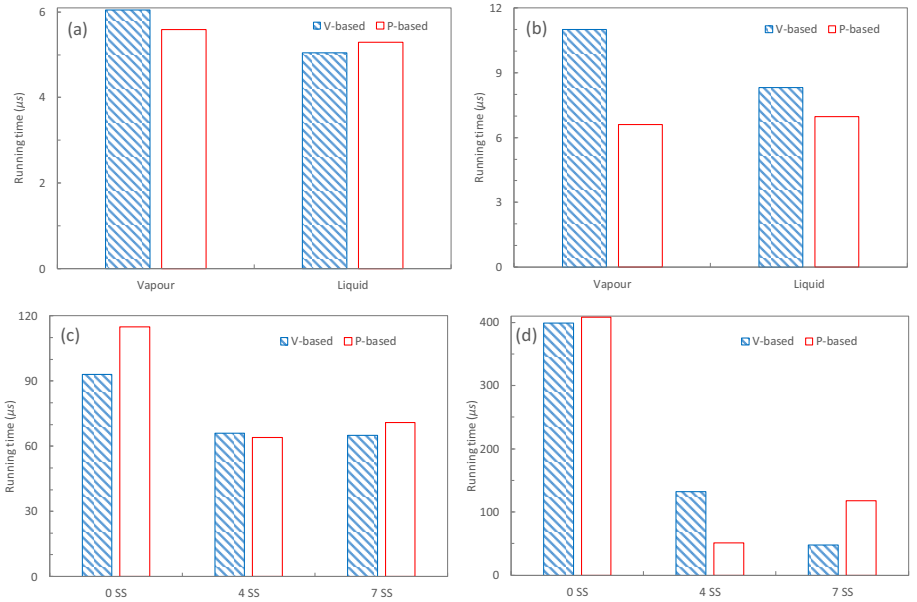

Figure 1. Average iterations for V-based and P-based *SO* methods for PT stability test for systems S1 (a) and S2 (b); The stability test running time of one point by using V-based and P-based *SO* methods following different number of *SS* steps for systems S1 (c) and S2 (d).

4.2. PT Flash (stability test + phase split)

The PT phase envelops of the systems S3 and S4 shown in Figure 2 are constructed by running the PT flash, consisting of stability test and phase split, calculations over wide ranges of temperature and pressure. Three models, PR, SRK and PC-SAFT, are applied for the system S3, while SRK, PC-SAFT (WOA) and PC-SAFT (WA) are used for the system S4. PC-SAFT (WOA) represents the modelling approach without association for asphaltene, and PC-SAFT (WA) is for that with association. More details are referred to Alay et al. (2016, 2017). As shown in Figure 2, PR, SRK and PC-SAFT might given different (Left) or similar (Right) results, which depend on the system and conditions under investigation as well as number of parameters and their tunings.

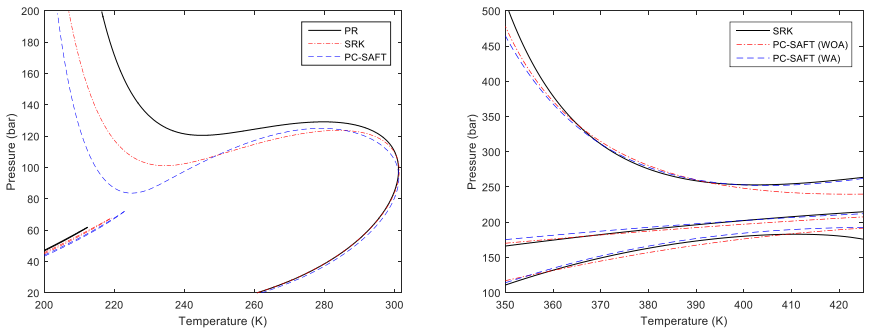

Figure 2. PT phase envelops of the systems S3 (Left) and S4 (Right).

The average PT Flash running times of one point are presented in Figure 3 (a) and (b) for systems S3 and S4, respectively. The ranges of temperature and pressure are: T(S3) = [200 to 300]K and P(S3) = 0.8(T-200) + 20bar, corresponding to a two-phase region shown in Figure 2 (Left); T(S4) = [350 to 425]K and P(S4) = 0.8(T-350)+140bar, corresponding to a three-phase region shown in Figure 2 (Right). As used by Paterson et al. (2017), 2 *SS* steps are taken before entering the *SO* methods in these calculations. The running time is averaged from 1000 repeated calculations. There is no doubt that PC-SAFT in general takes more time (with the same number of compounds), while the efficiency deterioration is acceptable (less than one time). The simplified PC-SAFT (von Solms et al. 2003) is used for the system S3. The efficiency deterioration for highly asymmetric systems may become less even with the original PC-SAFT (Gross et al. 2001) as given in Figure 3 (b). It is surprising that the introduction of association for asphaltene does not deteriorate the efficiency much, which means that association shall not be avoided on purpose because of its superficial complexity. A robust and efficient algorithm (Michelsen, 2006, 2007) is recommended for solving the association term.

It can be seen from Figure 3 that the V-based *SO* method can improve the efficiency by 10-30%, more pronounced with PC-SAFT. The effect of the number of *SS* steps before entering the *SO* methods (both V-based and P-based) on the overall efficiency has been presented for the systems S3 and S4 in Figure 4. It is clear that it is not necessary to take up to 15 *SS* steps, especially for PC-SAFT. The results indicate that 2-7 *SS* steps, preferably 4 *SS* steps, could be recommended in real applications.

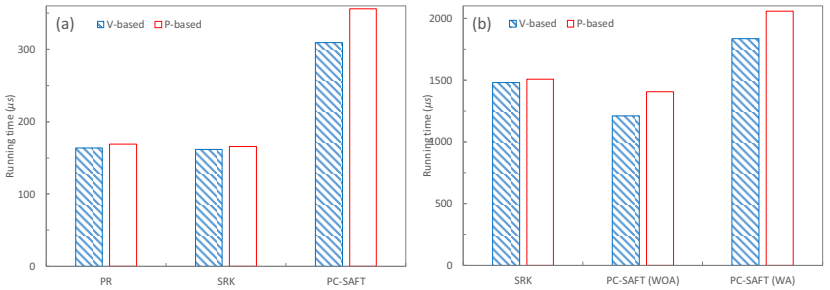

Figure 3. Comparison of the PT Flash running times of the V-based and P-based *SO* methods for phase split calculations and different models: systems S3 (a) and S4 (b).

5. Conclusions

In this work, the various aspects on the efficiency of PT Flash calculations with EOS are investigated. First, in order to study if V-based methods can improve the efficiency, the objective functions of the subproblems of a PT Flash calculation, i.e. stability test and phase split calculation, are formulated in both P-based and V-based methods. The results reveal that V-based and P-based methods perform similarly for a PT stability test in terms of running time after a few *SS* steps, which are necessary. Second, the study on the significance of a few *SS* steps before the *SO* method shows that 4-7 *SS* steps are good choices for stability test and 2-7 *SS* steps, preferably 4 *SS* steps, are recommended for phase split calculations. Third, the efficiency deterioration of using PC-SAFT compared to cubic EOS is acceptable, less than one time, and may become even less as the system becomes more asymmetric. Forth, the association term shall not be avoided on purpose due to a worry of efficiency deterioration.

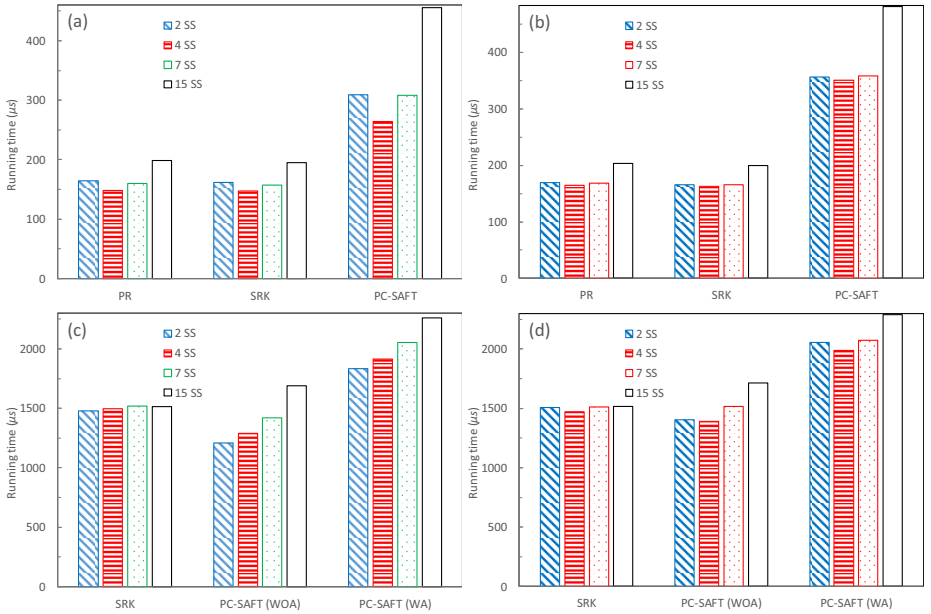

Figure 4. Comparison of the PT Flash running times of one point starting with different number of *SS* steps before using V-based and P-based *SO* methods for phase split calculations and different models. System S3: (a) V-based *SO* method; (b) P-based *SO* method; System S4: (c) V-based *SO* method; (d) P-based *SO* method.

Abstract

In this work, a rigorous tray-by-tray distillation column model is presented based on a new open-source modeling framework built on Pyomo that is designed to specifically support optimization of steady state and dynamic processes. The modeling framework allows for process synthesis and design of conventional tray columns either as an NLP or as a GDP problem. The model was used to simulate a distillation column for a binary mixture using three different property packages (Ideal, NRTL and Peng-Robinson), and the results are compared to results from existing commercial tools. Furthermore, a comparative case study is presented for an optimal column design problem using both frameworks.

Keywords: conceptual design, optimization, modelling framework, distillation

1. Introduction

In the past two decades, the advent of inexpensive computing power and improved numerical algorithms has enabled the increased use of equation oriented (EO) process models in process systems engineering. Though the current commercial equation oriented simulators can be used to model complex unit operations, the platforms do not provide the flexibility required for solving large-scale conceptual design optimization problems. Typically, such design problems are either solved with simplifying assumptions that lead to sub-optimal solutions or with rigorous models that are developed from the ground up, which is both time and labor intensive. The optimal design of a distillation column is an open and extensively researched problem in conceptual design owing to its importance in the process industries. Optimization problems concerning distillation columns can be broadly classified into two categories: (i) minimizing the operating cost subject to purity constraints for a fixed column design and (ii) minimizing the capital and operating cost subject to purity constraints. The former is relatively easy to solve with existing commercial simulation tools, but the latter commonly requires workarounds to overcome challenges such as limited compatibility for deterministic optimization and the lack of initialization routines with existing tools. This is computationally difficult for two reasons: (1) the presence of discrete decision variables for the number of trays and the feed tray location and (2) the non-linearity of the problem when using rigorous models.

Both a Generalized Disjunctive Programming (GDP) and NLP formulations have been proposed to model the discrete decision variables in this problem. The GDP approach

may be solved with a logic-based outer-approximation (LOA) algorithm, where the trays are activated/deactivated using Boolean variables (Yeomans and Grossmann, 2000). In the NLP approach, integer variables are avoided and trays are deactivated using bypass streams (Dowling and Biegler, 2015). The GDP approach simplifies the problem by eliminating the equations associated with deactivated trays. However, the solution to the GDP problem may require several major iterations (Barttfeld et al., 2004).

On the other hand, the NLP approach avoids the combinatorial problem associated with binary variables, but requires solving a larger NLP problem. In general, both approaches provide robust methods that can be solved with existing solvers; however, (i) a comparative study between the two methods is lacking (Dowling and Biegler, 2015) and (ii) distillation models available in existing commercial simulation tools are not compatible with either approach. The objective of the study is to present a comparison of the methodologies, which have been implemented within the IDAES conceptual design framework. A rigorous tray-by-tray unit model that has been developed to optimize the size, feed tray location and operating conditions of the distillation column is also presented.

2. Unit Operations Modelling and Optimization – the IDAES approach

The goal of the Institute for the Design of Advanced Energy Systems (IDAES), a U.S. Department of Energy initiative, is to build an open-source, next generation process systems engineering framework that will help accelerate the development of advanced energy systems. The IDAES modeling framework is based on Pyomo (Hart et al. 2017) – a Python-based algebraic modeling language that leverages the capabilities of a high level programming language to support optimization. One of the major objectives of the IDAES framework is to simplify the formulation and solution of conceptual design problems encountered in process systems engineering, thus addressing limitations with existing commercial tools. To this end, the models that are developed within this framework will be specifically designed for optimization of steady state and dynamic processes.

3. Distillation Tray Column Model

The unit model for the conventional tray-by-tray column in IDAES consists of the standard MESH equations for a distillation column. The model can be used to simulate a tray column with or without a condenser (total or partial) and a reboiler. The trays are numbered from top to bottom where the condenser and reboiler are not included as trays i.e. a distillation column with ten trays has ten trays plus a condenser and reboiler. For every tray there is an option for a feed inlet, outlet side draws for the liquid and vapor streams and heat addition/removal. The IDAES PSE framework is modular such that the user has flexibility to add or remove objects. For example, the property methods are instantiated as separate objects at the flowsheet level keeping them independent of the unit models. This provides the flexibility to easily change property calculations without making any changes to the model equations. At every tray, there is a property block for the feed stream, a property block for the mixer outlet and a property block for the equilibrium separator. The property blocks contain the equations (or constraints) for a flash calculation and also to compute properties like the specific enthalpy, vapor pressure and equilibrium coefficient as a function of the local state variables.

A major limitation for distillation column models that employ the MESH equations is the lack of consistent and robust initialization schemes. The IDAES framework ensures that sufficient flexibility is available to simplify the initialization procedure. For the column model in IDAES, the following three methods have been built to initialize the column:

- **Method 1:** The trays are initialized one by one starting from the top tray.
- **Method 2:** All trays are initialized together by sequentially activating and solving the mass, pressure, and energy balances.
- **Method 3:** Similar to method 1 but the feed stage is solved first followed by the rectification section and then the stripping section.

4. Optimization Framework for Distillation Columns in IDAES

4.1 NLP framework

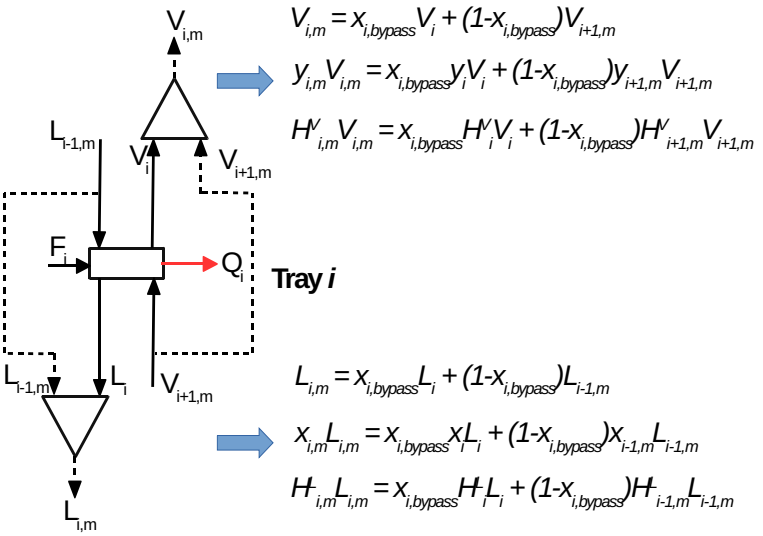

Figure 1: NLP framework with bypass streams

The NLP framework that has been implemented for solving conceptual design problems concerning distillation columns in IDAES is based on Dowling and Biegler (2015). The formulation allows trays to be bypassed using bypass variables ($x_{i,bypass}$) as shown in Figure 1. Typically, these variables should be binary where 1 denotes active and 0 denotes inactive trays. However, in the NLP formulation these variables are continuous variables bounded between 0 and 1, i.e., a relaxed MINLP problem. The general consensus while using bypass variables in distillation columns is to split the tray outlet streams (liquid/vapor) to two streams: a bypassed stream and a stream input to the tray above or below. While this formulation allows trays to be bypassed, using a conventional splitter results in a zero flow if the tray is bypassed which will affect convergence of the flash calculations on the tray. Instead, this framework duplicates the bypass stream and employs an "unconventional mixer" for the vapor and liquid outlets such that zero flows are avoided through bypassed trays. The mass/energy balances for these mixers are shown in Figure 1. When a tray is bypassed, the bypass variable $x_{i,bypass}$

should be 0. Then from the mass and energy balances for the mixer, it can be observed that the inputs to next tray (above/below) are appropriately accounted for depending on whether the tray is active or inactive. Furthermore, engineering knowledge tells us that partial bypass will be avoided as it is inefficient to mix two streams of different purities and separate them again. Another feature with this framework is that it indirectly, concurrently optimizes for the optimal feed tray location. Although the feed tray is fixed, the bypass variables are restricted to trays in the stripping and rectification sections. Thus, the feed tray location is determined depending upon the number of trays eliminated in each section.

4.2 GDP framework

The GDP framework for conceptual design of distillation columns is based upon the formulation given in Barttfeld et al. (2003). Disjunctions at each candidate tray describe the presence or absence of the tray. The general form of the disjunctions is given in Equation 1.

$$\begin{bmatrix} Y_t \\ g_1(x) \leq 0 \end{bmatrix} \vee \begin{bmatrix} \neg Y_t \\ Ax \leq b \end{bmatrix} \tag{1}$$

Y_t is the Boolean variable associated with tray existence. Constraints denoted by g_1 contain the MESH equations for each stage. When the tray does not exist, linear bypass constraints $Ax \leq b$ ensure that flowrates and enthalpies are transmitted unchanged to the next stage. An analogous disjunction governs selection of the feed tray: a tray either is the feed stage and has the relevant inlet material and energy flows OR it is not and the flows are set to zero. A logical proposition enforces that if a tray is selected as the feed, then it implies that the tray is also active. The first and final stages correspond to the condenser and reboiler; the Boolean existence variables associated with these trays are fixed to True.

5. Results and Discussion

The IDAES tray-by-tray column model was used to simulate a distillation column with ten trays (+ condenser + reboiler) to separate an equimolar mixture of benzene and toluene using three different property methods: Ideal, Ideal-NRTL and the Peng-Robinson cubic equation of state. The feed specifications are as follows: Feed = 100 mol/s, T_{feed} = 368 K, P_{feed} = 101 kPa (no pressure drop), feed tray = 5. The molar reflux and reboil ratio were set to 1.4 and 1.3 respectively. The results were compared to a "RadFrac" model in Aspen Plus and are presented in Table 1.

The results using the EO IDAES model show an excellent match with Aspen Plus models solved sequentially. The model was successfully initialized using "Method 2" for all the three simulations and demonstrates robustness even when using a rigorous property method like the cubic equation of state.

5.1 Optimal design problem

The problem for the optimal design of a distillation column has been formulated as follows:

$$\min_{RF,RB,\, feed\ tray, N_{trays}} 10^3 \left(\sum_{i=1}^{N_{trays}} x_{bypass,i}\right) + (Q_R + Q_C)$$

$$s.t.: x_{D,benzene} \geq 0.95\ ;\ x_{B,toluene} \geq 0.95;\ RF \leq 4;\ RB \leq 4 \tag{2}$$

The objective function minimizes the capital cost (number of active trays) and operating cost (reboiler and condenser duty). The number of active trays is multiplied by a cost coefficient of 1000 to scale it to the same range as that of the condenser and reboiler duties in kW so as to ensure equal weights to the capital and operating cost in the objective function. The feed conditions are the same as those used for simulation studies outlined in Table 1 (Ideal case). For the NLP framework, the model was initialized with 35 active trays (feed tray = 10) and initial values for the decision variables were unchanged from the simulation case study. The solver used was IPOPT with MA 27 as the linear solver. The optimal solution using the NLP framework is outlined in Table 2,

Table 1: Comparison of model predictions using IDAES and Aspen Plus models

Variable	Ideal		Ideal – NRTL		Peng-Robinson	
	IDAES	Aspen	IDAES	Aspen	IDAES	Aspen
Distillate (mols/)	47.76	47.71	47.94	47.82	45.31	45.33
$x_{D,benzene}$	0.886	0.887	0.885	0.887	0.900	0.900
$x_{D,toluene}$	0.114	0.113	0.115	0.113	0.100	0.100
Bottoms (mol/s)	52.24	52.29	52.06	52.18	54.69	54.67
$x_{B,benzene}$	0.147	0.147	0.145	0.145	0.168	0.168
$x_{B,toluene}$	0.853	0.853	0.855	0.855	0.832	0.832
$Q_{condenser}$ (kW)	-3626.4	-3594.5	-3639.9	-3591	-3375.2	-3378.7
$Q_{reboiler}$ (kW)	2307.9	2272.2	2300.6	2245.7	2366.8	2366.4

and it can be seen that the total number of trays is an integer value (11 in this case) even though the bypass variables were declared as continuous variables. Also, the optimal feed location is tray 6. The same solution was obtained when the model was initialized with 15/20/50/60 active trays or when the feed location was changed to 10/15/25/30 in the superstructure respectively. The GDP model was solved using the GDPopt solver in Pyomo, which implements LOA and uses both Gurobi and IPOPT as sub-solvers. The GDP model was initialized using the column profile results from a 10-stage square problem; to accommodate additional conditional trays, a linear interpolation of the profile was used. Even though the formulation with the bypass framework consists of a larger NLP model, it required 597 function evaluations to determine the optimal solution. In comparison, the GDPopt terminated after 20 master iterations requiring 2057 NLP function evaluations in total, mainly due to weak linear approximations. However, this may be avoided with better reformulation techniques.

Table 2: Optimal solutions from NLP and GDP frameworks

Optimal solution	NLP framework	GDP framework
Objective	19430	19450
No. of trays	11	10
Feed tray	6	5
Reflux ratio	2.07	2.45
Reboil ratio	2.13	2.39
$x_{D,benzene}$/ $x_{B,toluene}$	0.95/0.95	0.95/0.95

Both the NLP and GDP frameworks yield similar solutions. The NLP framework solution includes one extra tray to reduce column duties, making a slightly different capital vs. operating cost trade-off compared to the GDP framework.

6. Conclusions

This work presents a tray-by-tray distillation column model using MESH equations within the IDAES modeling framework that is suitable for both simulation and deterministic optimization. For the conceptual design of distillation columns, both NLP and GDP frameworks are available, and a comparative case study was presented in this work. In the case study, the NLP and GDP frameworks yield similar solutions; however, the NLP framework using bypass streams requires fewer nonlinear function evaluations compared to the GDP solution, but a robust initialization scheme was necessary. On the other hand, the main limitation of the GDP framework was the quality of the linear approximation, leading to slower convergence. This may be addressed by adding support for stronger GDP to MILP reformulation techniques in GDPopt, improving the bounds via automatic bound-strengthening tools and adding logical propositions to screen out structurally redundant configurations. At the same time, the impact of the reduced space sub-problems in LOA can be seen, as only a few function evaluations are required for each sub-problem, even without a complex initialization scheme. A thorough comparison between the two frameworks will be considered in the future and will incorporate more rigorous property models such as the cubic equation of state.

Abstract

This work introduces a novel flash formulation to calculate vapor-liquid equilibria (VLE) based on a general cubic equation of state (cEOS). The approach leverages smooth max operators to implement complementarity conditions leading to a model with an equal number of variables and constraints (i.e., a square problem). The model correctly calculates equilibrium phase fractions and compositions over a broad range of temperatures and pressures by ensuring that the VLE calculation is only enforced below the critical pressure and between the bubble point and dew point temperatures. We demonstrate the robustness of the flash model by embedding it directly into optimization problems that require moving from initial temperatures and pressures across phase transition boundaries as well as between subcritical and supercritical regions. The flash model is implemented in the open source, Python-based, algebraic modeling language, Pyomo. The roots of the cEOS are calculated analytically using an external function call that returns exact 1st and 2nd derivatives and is embedded directly via the AMPL Solver Library. The model will be publicly available as part of the Institute for the Design of Advanced Energy Systems (IDAES) process systems engineering framework.

Keywords: vapor-liquid equilibrium, equation-oriented flowsheet optimization, cubic equation of state, mathematical programs with complementarity constraints

1. Introduction

Flash calculations that require non-ideal vapor-liquid equilibrium (VLE) relationships are notoriously challenging to implement in an equation-oriented (EO) flowsheet optimization environment. Traditional solution algorithms are susceptible to failure in regions where only one phase exists since VLE relationships are only valid in the two-phase region between the bubble point and dew point conditions. Robust EO implementations have been achieved by formulating flash calculations as mathematical programs with complementarity constraints. For example, complementarities that relax the VLE when either the vapor or liquid phase is absent can be transferred to the objective function of an optimization problem via penalty terms (Kamath et al., 2010; Dowling and Biegler, 2015; Dowling et al., 2015). Choosing the correct weightings for the penalty terms, however, may require extensive trial-and-error to ensure that the VLE conditions are properly enforced but do not dominate the optimization leading to suboptimal solutions.

The square flash model presented here can be solved without optimization or adding penalty terms to an objective function. It greatly facilitates a modular approach to EO flowsheet construction as unit operations involving flash calculations do not have to be initialized by solving sets of optimization problems or by implementing complex solution algorithms. The following sections describe the methodology and demonstrate the robustness of the formulation when implemented in its square form (i.e., zero degrees of freedom) or as part of optimization problems (i.e., ≥ 1 degree of freedom) that require moving across phase boundaries and between subcritical and supercritical regions.

2. Problem Formulation

2.1. General Flash Formulation

The standard form for calculating the liquid and vapor phase flow rates and compositions for a mixture of *i* components is:

$$F = L + V \quad , \quad Fz_i = Lx_i + Vy_i \;\; \forall \;\; i \quad , \; 0 = \sum_i y_i - \sum_i x_i \tag{1-3}$$

$$y_i = K_i(x, Z^L(x,T,P), y, Z^V(y,T,P), T, P)x_i \;\; \forall \;\; i \tag{4}$$

$$Fh_F = Lh_L(x, Z^L(x,T,P), T, P) + Vh_V(y, Z^V(y,T,P), T, P) - Q \tag{5}$$

where F, L and V are the flow rates of the inlet, outlet liquid, and outlet vapor, respectively, while z, x, and y are their mole fractions. The equilibrium ratios, K_i, are defined by an equation of state and are a function of the temperature, pressure, and the liquid and vapor phase compositions. h_F, h_L, and h_V are the specific enthalpies of the inlet, outlet liquid, and outlet vapor streams, while Q is the heat duty. The general flash formulation is necessary but not sufficient to predict the proper number of phases. Thus, it must be supplemented with additional constraints to ensure thermodynamic stability. In this work, we implement the Peng-Robinson Equation of State described in Dowling et al. (2015), though the framework described herein is general enough to handle essentially any cEOS.

2.2. Calculation of Z^L and Z^V

The liquid and vapor phase compressibility factors, Z^L and Z^V, correspond to roots of the cubic equation where A and B are functions of the temperature, pressure and composition, while u and w are equal to 2 and -1, respectively, for the Peng-Robinson EOS.

$$Z^3 - (1 + B - uB)Z^2 + (A + wB^2 - uB - uB^2)Z - AB - wB^2 - wB^3 = 0 \tag{6}$$

One particularly effective method to embed Eq. (6) into EO flowsheet optimizations entailed using inequality constraints on its first and second derivatives to properly assign the smallest root as Z^L and the largest root as Z^V (Kamath et al., 2010; Dowling and Biegler, 2015). Slack variables were employed to relax the constraints for conditions where the liquid or vapor root disappears. More recent approaches have proposed modifying the classical inside-out algorithms using non-smooth equations to relax equilibrium conditions when appropriate (Watson, et al., 2017) or applying a modified root discrimination procedure based on Cardano's method (Glass and Mitsos, 2017). In this work, rather than adding Eq. (6) directly, Z^L and Z^V are calculated analytically using an AMPL Solver Library user-defined function that takes A and B as arguments, and returns the exact solution, using the cubic formula, along with exact 1st and 2nd derivatives. When the cubic equation has more than one root, it is assumed the smallest root is Z^L and the largest is Z^V. If only one real root exists, the root calculating function provides two options. The first option, employed for Eq. (5) only, returns the same root for both the liquid and vapor. This is a discontinuous function with respect to A and B. Also, the derivatives are unde-

fined where there is a double or triple root. Nevertheless, because Z^L and Z^V are not variables in the model, their discontinuity is essentially smoothed by the continuous nature of Eq. (5). For example, the vapor root disappears in the liquid region. Thus in Eq. (5), h_V will be multiplied by zero since V=0. This option becomes necessary in the supercritical region where it is not possible to classify a root as vapor or liquid. The second option returns a fictitious, though continuous, solution for the non-existing root (Z^L or Z^V) while providing the exact solution for the one root that exists. The fictitious solution is found by generating two distinct curves: one for the liquid and one for the vapor. When the cubic function $f(Z)$ (left-hand side of Eq. 6) has two points where the $f'(Z) = 0$, the curves are extended symmetrically from those points to create monotonic functions. When there are no points where $f'(Z) = 0$, the liquid and vapor curve are the same and match the original cubic. Thus, the same Z is returned for both liquid and vapor. This option is employed in all equilibrium equations since our approach ensures that they are applied only between the bubble point and dew point temperatures. Thus, the true solution will always be in the two-phase region where the fictitious root does not exist. The benefits of calculating Z^L and Z^V using an external function are that it reduces the number of variables and constraints per flash calculation, eliminates the need to initialize Z^L and Z^V since they are not variables, keeps the problem square by avoiding inequality constraints, and provides continuous values for Z^L and Z^V for equilibrium equations even when one of the roots disappears. One potential disadvantage is that the algebraic modeling language must support the ability to embed user-defined function calls.

2.3. Flash Model for Subcritical Pressures

A major challenge with applying cEOS thermodynamic models in large-scale flowsheet optimizations is that the problem can be nonconvex and attain nonglobal solutions that represent nonphysical equilibria. In particular, convergence to solutions where $Z^V = Z^L$, $K = 1$, and $x = y$ is a known problem (Gunderson, 1982) that can lead to arbitrary phase assignments when the mixture is not at the critical point or in the supercritical region. When solving square flash models, careful initialization can often avoid convergence to these unwanted "trivial" flash solutions; however, during optimization with ≥ 1 degree(s) of freedom, the modeler has less control over the search path chosen by the optimizer motivating the active elimination of trivial solutions via additional constraints. This is accomplished by calculating the bubble point and dew point temperatures for the mixture Eqs. (7-10) and constraining the temperature at which Eq. (4) is evaluated to be between these two temperatures Eq. (11-12). This differs from the approach proposed by Watson, et al. (2017) which relaxes the equilibrium relationship outside of the two-phase region.

$$y_i^s = K_i(y^s, Z^V(y^s, T_{Bub}, P), z, Z^L(z, T_{Bub}, P), T_{Bub}, P)z_i \;\forall\; i \tag{7}$$

$$z_i = K_i(z, Z^V(z, T_{Dew}, P), x^s, Z^L(x^s, T_{Dew}, P), T_{Dew}, P)x_i^s \;\forall\; i \tag{8}$$

$$0 = \sum_i y_i^s - \sum_i z_i \;\;,\;\; 0 = \sum_i z_i - \sum_i x_i^s \;,\; T_{Eq} = \min(\max(\mathrm{T}, T_{Bub}), T_{Dew}) \tag{9-11}$$

$$y_i = K_i\big(y, Z^V(y, T_{Eq}, P), x, Z^L(x, T_{Eq}, P), T_{Eq}, P\big)x_i \;\forall\; i \tag{12}$$

Here y_i^s and x_i^s are the vapor and liquid mole fractions, respectively, for "shadow" streams used to calculate the bubble and dew point temperatures of the incoming mixture at the flash pressure, P. In this work, the non-smooth Eq. (11) is replaced by Eqs. (13-14) which ensure that T_{Eq} is smooth and continuous for all values of T.

$$T_1 = 0.5 \cdot \left(T + T_{Bub} + \sqrt{(T - T_{Bub})^2 + \varepsilon_1^2}\right) \cong \max(T, T_{Bub}) \tag{13}$$

$$T_{Eq} = 0.5 \cdot \left(T_1 + T_{Dew} - \sqrt{(T_1 - T_{Dew})^2 + \varepsilon_2^2}\right) \cong \min(T_1, T_{Dew}) \tag{14}$$

In general, ε_1 must be greater than ε_2. We chose $\varepsilon_1 = 0.01$ and $\varepsilon_2 = 0.0005$. Eqs. (1-3, 5, 7-10, and 12-14) thus comprise a smooth square flash model with $7 + 4n$ equations (where n is the number of components) that avoids convergence to trivial flash solutions, requires initialization of only physically intuitive variables, and is applicable for all $P < P_c$.

2.4. Flash Model Extension for Supercritical Conditions

The flash model can be extended to handle cases for which the modeler does not know *a priori* if a given stream will be below or above its critical point. To this end, we propose partitioning the phase diagram into two halves and assigning phases as follows: $P > P_c$ (Liquid only), $P < P_c$ (Liquid and/or Vapor). The rationale is that fluid densities above the critical pressure will be liquid-like and more suited to pumps than compressors. We note that this approach will lead to inaccuracies within the small range of pressures between the critical pressure, P_c, and the cricondenbar, P_{cc} (i.e., the maximum pressure at which vapor can exist for a mixture), when $P_{cc} > P_c$. Nevertheless, since few processes are designed to operate in this range, the approach proposed here can be applied with confidence to large-scale flowsheet optimization problems assuming post-solution checks are made to ensure that pressures are either below P_c or above P_{cc}. The supercritical extension first entails adding Eqs. (15-16) to enable calculation of the mixture's critical temperature and pressure using the Peng-Robinson EOS.

$$0.45724 = a^m(z)P_c/(T_c^2R^2)\ ,\ 0.077796 = b^m(z)P_c/(T_cR) \tag{15-16}$$

Both a^m and b^m are functions of the inlet composition as described by Dowling et al. (2015). Next, the variables P_m and P_{mr}, are introduced and assigned such that they can be used to determine whether the flash pressure, P, is above or below P_c.

$$P_c \cdot P_m = 0.5 \cdot \left(P - P_c + \sqrt{(P - P_c)^2 + \varepsilon_3^2}\right) \cong \max(0, P - P_c) \tag{17}$$

$$P_c \cdot P_{mr} = 0.5 \cdot \left(P_c - \mathrm{P} + \sqrt{(P_c - \mathrm{P})^2 + \varepsilon_4^2}\right) \cong \max(0, P_c - P) \tag{18}$$

In this work, ε_3 and ε_4 were chosen to be 0.0005. We then replace P in the VLE equations 7, 8, and 12 with $P - P_cP_m - \varepsilon_4/4 \cong \min(P, P_c)$. This ensures that the VLE equations are never evaluated at pressures above the P_c. It also prevents T_{Eq}, T_{Bub}, and T_{Dew} from assuming arbitrary values when $P > P_c$. Finally, Eq. (14) is replaced by Eq. (19) while Eq. (20) ensures that $T_{Eq} = T_2$ when $P < P_c$ (i.e., $P_m = 0$ and $P_{mr} > 0$) thus enforcing the VLE equations only at subcritical pressures. Eq. (20) also forces the vapor flow rate, V, to be equal to zero when $P > P_c$ (i.e., $P_{mr} = 0$ and $P_m > 0$).

$$T_2 = 0.5 \cdot \left(T_1 + T_{Dew} - \sqrt{(T_1 - T_{Dew})^2 + \varepsilon_2^2}\right) \cong \min(T_1, T_{Dew}) \tag{19}$$

$$\left(T_2 - T_{Eq}\right) \cdot P_{mr} + V \cdot P_m = 0 \tag{20}$$

These modifications lead to a final smooth square flash formulation comprising (Eqs. 1-3, 5, 7-10, 12-13, and 15-20) that contains $12 + 4n$ variables and equations. When applied towards optimization problems, it is sometimes beneficial to replace the right-hand side of Eq. (20) with a small value (e.g., 10^{-7}) to avoid converging to locally optimal solutions where $P = P_c$ and thus both P_m and P_{mr} are near zero. We, however, recommend replacing Eq. (20) with the inequalities below during optimization as this approach has proven most effective at avoiding $P = P_c$ local solutions.

$$V \cdot P_m \leq \left(T_2 - T_{Eq}\right) \cdot P_{mr} \leq V \cdot P_m \tag{21}$$

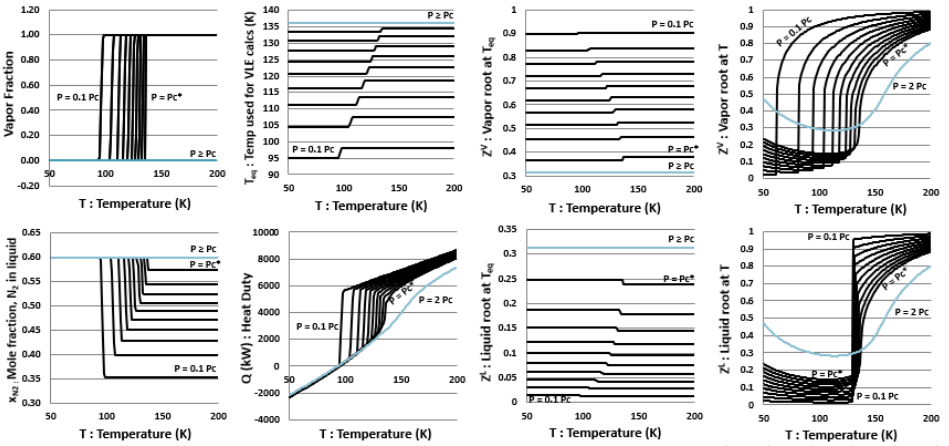

Figure 1: Flash results for the N_2, O_2, and Ar mixture. $P_c^* = 0.99998\ P_c$.

3. Results

3.1. Flash Model Implementation

The flash formulation comprising (Eqs. 1-3, 5, 7-10, 12-13, and 15-20) was applied to an inlet liquid mixture at 95 K and 7 bar containing 60 % N_2, 35 % O_2, and 5 % Ar. The thermodynamics of the two phases were modeled using the Peng-Robinson EOS. Parameters for this study can be found in Dowling and Biegler (2015). The critical temperature and pressure for the mixture were found to be 136.5 K and 3,947,426 Pa, respectively. The equilibrium was calculated at 1 K increments from 50 to 200 K at several pressures: 0.1 P_c, 0.2 P_c, 0.3 P_c, 0.4 P_c, 0.5 P_c, 0.6 P_c, 0.7 P_c, 0.8 P_c, 0.9 P_c, 0.99998 P_c, and 2 P_c. Results are shown in Figure 1. All calculations were performed using IPOPT with the following settings: linear_system_scaling = mc19, linear_scaling_on_demand = no, recalc_y = yes. Notably, correct phase transitions and heat duties were obtained at all temperatures and pressures. The outlet is classified as all liquid for all $P > P_c$. VLE calculations were performed at $T = T_{Eq}$ and P = "smooth" min (P, P_c) resulting in continuous and smooth Z^L and Z^V values regardless of the flash temperature or pressure. Only the energy balance given by Eq. (5), which is inherently smooth, requires the non-smooth Z^L and Z^V values evaluated at the actual flash temperature, T.

3.2. Model Performance within Optimizations requiring PT or PQ Flashes

To demonstrate robustness of the flash model during optimization, the model (Eqs. 1-3, 5, 7-10, 12-13, and 15-19, 21) was first initialized at 4 different starting points: 1) 50 K, 0.1 Pc; 2) 200 K, 0.1 Pc; 3) 50 K, 2 Pc; and 4) 200 K, 2 Pc. Next, P and T were unfixed and calculated by solving several optimization problems employing the objective function below where T_{target} and P_{target} correspond to T's and P's explored in section 3.1.

$$\text{Minimize} \qquad \left(T - T_{Target}\right)^2 / T_{Target} + (P - P_{Target})^2 / P_{Target} \qquad (22)$$

In all cases, an objective function of zero and identical results to Figure 1 were obtained. This clearly demonstrates the ability of the model to move across phase transition boundaries and through both sub and supercritical regions to obtain an optimal solution. Identical results were also obtained using the same strategy when P and Q were unfixed.

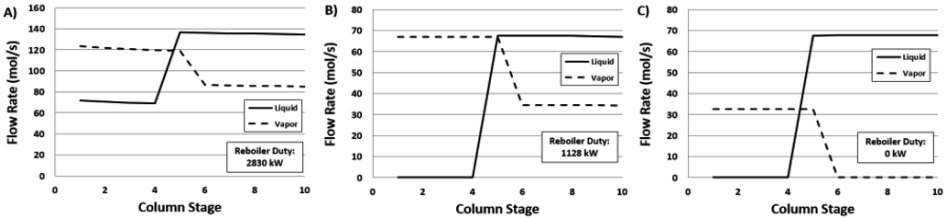

Figure 2: Distillation optimization results for A) $x_{benzene,top}$, $x_{toluene,bottom} \geq 0.90$, B) $x_{toluene,bottom} \geq 0.80$, and C) $x_{toluene,bottom} \geq 0.57$.

Lastly, the model was tested as part of a distillation optimization for a 50% benzene/50% toluene mixture. A 10-stage column at a uniform pressure of 1 bar was used to separate a 100 mol/s inlet stream entering at stage 5. Reboiler duty was minimized subject to three sets of purity constraints. Figure 2 shows results for cases with non-zero flows on each stage (case A) and vanishing phases when the purity constraints are relaxed (cases B, C).

4. Conclusions

The flash model enables reliable VLE calculations over a broad range of operation that spans both subcritical and supercritical conditions. All variables are state variables greatly simplifying the initialization procedure compared to previous work (e.g., Kamath et al. (2010), Dowling et al. (2015)) that required reliable initial guesses and bounds on several intermediate thermodynamic quantities and non-physical slack variables. This model requires no slack variables to relax the VLE constraints outside of the two-phase region and no non-physical terms must be added to the objective function of optimizations. The model moves reliably from initial starting points to distant optimal solutions suggesting that the formulation itself does not introduce non-convexities that might cause optimization solvers to get trapped in local optima. It is thus well-suited for EO flowsheet optimization and will be released as part of the IDAES process systems engineering framework.

Abstract

Many industrial processes are coupled via multiple networks of energy and materials to achieve a resource and energy efficient production. In many cases however, setting up an integrated optimization problem for all units or plants that are directly connected to the networks is not possible, especially when not all information can be shared. In such cases, dual decomposition or price-based coordination can be used, where optimal transfer prices are iteratively determined at which the networks are balanced and the resources are allocated optimally between the participants.

In this contribution, price-based coordination is extended to include the situation where limited resources can be bought or sold at predefined prices from external markets (e.g. via pipelines) and the resulting algorithms are demonstrated for a realistic example.

Keywords: Distributed optimization, Price-based coordination, Dual decomposition, External resources, Shared-resource allocation.

1. Introduction

Many industrial production sites consist of individual plants or units, which are tightly coupled by streams of energy and material. Especially in the chemical industry, these streams, e.g., energy in the forms of steam and electricity as well as raw materials and intermediate products, are exchanged via networks that link consuming and producing systems, where the holdups usually are very small. In order to optimize the overall economic performance as well as the resource efficiency of the site, it is not sufficient to optimize each plant or unit individually, but rather a joint optimization of the production plants or site is necessary taking the balancing of the resource networks into account.

However, finding the solution to the overall optimization problem in a centralized manner may not be realizable. Due to various reasons, such as robustness and local autonomy or confidentiality, when systems belong to different business units or companies, optimizing each plant independently is preferred. One method to coordinate the individual optimization problems is dual decomposition, which uses transfer prices to balance the interconnecting streams, instead of solving the whole problem at once. An optimal solution is determined by iterating between setting the transfer prices (dual variables) and each system optimizing its response, until equilibrium transfer prices are found (Everett III, 1963). This method has various applications and can be used, for instance, to manage the energy flow in electrical micro grids (Zhang et al., 2013) or to optimally allocate resources in chemical production sites (Wenzel et al., 2016, 2017).

Considering all the networks of such a production process as closed systems is not realistic, since usually at least some of the networks are connected to external sources or

sinks, where, on the spot market or according to contracts, limited amounts can be purchased or sold. The topic of optimal procurement for chemical process networks was already discussed by Calfa and Grossmann (2015) for a centralized optimization. In this contribution, the distributed optimization framework of dual decomposition is extended such that it solves this type of problem in a distributed manner by a modified update of the dual variables. We derive this update mechanism and provide a graphical interpretation. Furthermore, we demonstrate the proposed update scheme using an example.

The following syntax is used: Italic lower case letters represent scalar functions or values. Bold lower case letters represent column vectors or vector-valued functions and bold upper case letters represent matrices. The transpose of vector $\mathbf{a}$ is denoted by $\mathbf{a}^T$. We use [k] to identify the k-th row of vectors and matrices. Absolute values and norms are denoted by $|a|$ and $\|\mathbf{a}\|$. To ease the notation, we here assume that all systems have the same number of variables and constraints, which however is not required in general.

2. Problem formulation

The joint optimization of N systems with $n_{Networks}$ network constraints can be written as Eqs.(1a) – (1d):

$$\min_{\mathbf{x}_i\,\forall i} \quad \sum_{i=1}^{N} f_i(\mathbf{x}_i), \tag{1a}$$

$$\text{s.t.:} \quad \mathbf{g}_i(\mathbf{x}_i) \le \mathbf{0}, \tag{1b}$$

$$\mathbf{x}_{LB,i} \le \mathbf{x}_i \le \mathbf{x}_{UB,i}, \tag{1c}$$

$$\sum_{i=1}^{N} \mathbf{A}_i \mathbf{x}_i = \mathbf{0}. \tag{1d}$$

$$\min_{\mathbf{x}_i\,\forall i,\,\mathbf{r}_j\,\forall j} \quad \sum_{i=1}^{N} f_i(\mathbf{x}_i) + \sum_{j=1}^{M} \mathbf{p}_j^T \mathbf{r}_j, \tag{2a}$$

$$\text{s.t.:} \quad \mathbf{g}_i(\mathbf{x}_i) \le \mathbf{0}, \tag{2b}$$

$$\mathbf{x}_{LB,i} \le \mathbf{x}_i \le \mathbf{x}_{UB,i}, \tag{2c}$$

$$\sum_{i=1}^{N} \mathbf{A}_i \mathbf{x}_i - \sum_{j=1}^{M} \mathbf{r}_j = \mathbf{0}, \tag{2d}$$

$$\mathbf{r}_{LB,j} \le \mathbf{r}_j \le \mathbf{r}_{UB,j}. \tag{2e}$$

Each sub-problem i has an objective f_i, is constrained by g_i, and the states $\mathbf{x}_i$ are bounded via Eq.(1c). Additionally, the systems interact with the different networks via their contribution $\mathbf{A}_i\mathbf{x}_i$ and overall, the network constraint Eq.(1d) has to be satisfied for each network l.

In Eqs.(2a) – (2e), the network constraint is extended to include access to M external resources or sinks j, where the amounts $\mathbf{r}_j$, limited by $\mathbf{r}_{LB,j}$ and $\mathbf{r}_{UB,j}$, can be bought or sold at predefined prices $\mathbf{p}_j$.

3. Distributed solution

The problem shown in Eqs.(1a) – (1d) can be solved using dual decomposition, splitting the problem into N independent sub-problems and an overarching coordination problem by relaxation of the network constraint Eq.(1d). The local contributions to the network constraint are multiplied by the corresponding dual variable $\boldsymbol{\lambda}$ and added to the objective of the sub-problem. Locally, Eq.(3) is solved for a given value of $\boldsymbol{\lambda}$:

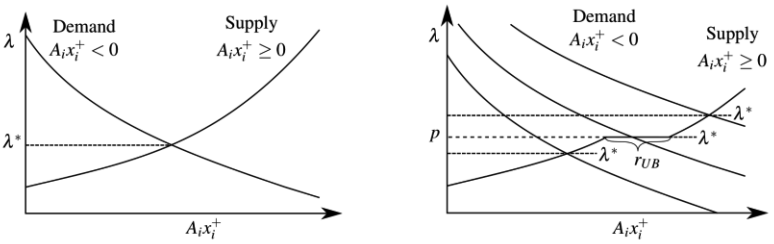
$$\mathbf{A}_i\mathbf{x}_i^+ = \mathbf{A}_i \arg\min_{\mathbf{x}_i} \quad f_i(\mathbf{x}_i) + \boldsymbol{\lambda}^T \mathbf{A}_i \mathbf{x}_i, \tag{3a}$$

$$\text{s.t.:} \quad \mathbf{g}_i(\mathbf{x}_i) = \mathbf{0}, \tag{3b}$$

$$\mathbf{x}_{LB,i} \le \mathbf{x}_i \le \mathbf{x}_{UB,i}. \tag{3c}$$

It is assumed that the subsystems do not share their objectives or constraints due to confidentiality reasons, only the responses to transfer prices $\mathbf{A}_i\mathbf{x}_i^+$, are communicated.

In Figure 1a, a one-dimensional example of aggregated supply, which is defined as the sum of all positive contributions to the network constraint, i.e., $\sum_i\{A_i x_i^+ | A_i x_i^+ \geq 0\}$, and aggregated demand, defined as $\sum_i\{A_i x_i^+ | A_i x_i^+ < 0\}$, depending on the value of λ are shown.



(a) No external resources and outlets corresponding to Eqs.(1a) – (1d).

(b) Possibility to buy external resources at price p for three different demand scenarios corresponding to Eqs.(2a) – (2e).

Figure 1: Optimal response of the systems to the transfer prices in one dimension.

Feasibility, i.e., satisfaction of the network constraint Eq.(1d), is achieved by adjusting the dual variables $\boldsymbol{\lambda}$ in an iterative procedure. Since only the responses to the transfer prices are known on the coordinator level, this cannot be done explicitly. Instead the sub-gradient method is used, where transfer prices $\boldsymbol{\lambda}$ are adjusted proportionally to the difference between supply and demand

$$\boldsymbol{\lambda}^+ = \boldsymbol{\lambda} + \alpha \sum_{i=1}^{N} \mathbf{A}_i \mathbf{x}_i^+. \tag{4}$$

Iterating between the sub-problems Eq.(3) and this update of the transfer prices is done until a stopping criterion is met, e.g., that the residua $\boldsymbol{\rho} = \sum_i^N \mathbf{A}_i\mathbf{x}_i^+$ are all less than a predefined tolerance ϵ. Economically, this can be interpreted as finding the intersection between supply and demand, cf. Figure 1a. The update of the transfer prices is done using the step size parameter $\alpha \in (0, 1]$, which has to be chosen carefully in order to ensure convergence, especially when local constraints $\mathbf{g}_i(\mathbf{x}_i)$ are active. If all objectives and constraints are convex, the solution found upon convergence is the global optimum.

The augmented problem from Eqs.(2a) – (2e) can also be solved using dual decomposition. On the coordination layer, additionally to finding the optimal transfer prices, the cost for interaction with external markets, $\sum_{j=1}^{M} \mathbf{p}_j^T \mathbf{r}_j$, has to be minimized. Finding the optimal values for $\mathbf{r}_j$ can either be done separately from the price adjustment or in a combined step. In Eqs.(5) and (6), the new transfer prices $\boldsymbol{\lambda}$ and the amounts to be bought or sold $\mathbf{r}_j$ are calculated separately using the sub-gradient method:

$$\boldsymbol{\lambda}^+ = \boldsymbol{\lambda} + \alpha \left[\sum_{i=1}^{N} \mathbf{A}_i \mathbf{x}_i^+ - \sum_{j=1}^{M} \mathbf{r}_j \right], \tag{5}$$

$$\mathbf{r}_j^+ = \min\left(\max\left(\mathbf{r}_{LB,j}, \mathbf{r}_j + \operatorname{diag}(\mathbf{p}_j)^{-1} \operatorname{diag}(\mathbf{p}_j - \boldsymbol{\lambda}^+)(\mathbf{r}_{UB,j} - \mathbf{r}_{LB,j})\right)\mathbf{r}_{UB,j}\right). \tag{6}$$

The other approach is to update both variables at the same time, where the coordinator update is shown in Algorithm 1.

Algorithm 1 Coordinator level update step to determine $\boldsymbol{\lambda}^+$ and $\mathbf{r}_j^+$

$\mathbf{r}_j^+ \leftarrow \mathbf{r}_{LB,j}\ \forall j$
for all $\boldsymbol{\lambda}[k]$ in $\boldsymbol{\lambda}$ **do**
  $\boldsymbol{\pi} \leftarrow [-\infty, \mathbf{p}_1[k], \mathbf{p}_2[k], \ldots, \mathbf{p}_M[k], \infty]^T$
  $\underline{\Lambda} \leftarrow \boldsymbol{\lambda}[k] + \alpha \left(\sum_{i=1}^{N} \mathbf{A}_i[k]\mathbf{x}_i - \sum_{j=1}^{M} \mathbf{r}_{LB,j}[k] \right)$
  for $l = 1$ **to** $M+1$ **do**
    $\overline{\Lambda} \leftarrow \boldsymbol{\lambda}[k] + \alpha \left(\sum_{i=1}^{N} \mathbf{A}_i[k]\mathbf{x}_i - \sum_{j=1}^{l} \mathbf{r}_{UB,j}[k] - \sum_{j=l+1}^{M} \mathbf{r}_{LB,j}[k] \right)$
    if $\boldsymbol{\pi}[l] \leq \underline{\Lambda} < \boldsymbol{\pi}[l+1]$ **then**
      $\boldsymbol{\lambda}^+[k],\ \mathbf{r}_j^+[k] \leftarrow \underline{\Lambda},\ \mathbf{r}_{UB,j}^+[k]$ Case 1
      Break
    else if $\overline{\Lambda} \leq \boldsymbol{\pi}[l+1] < \underline{\Lambda}$ **then**
      if $\sum_{j=1}^{l-1} \mathbf{r}_{j,max}[k] \leq \sum_{i=1}^{N} \mathbf{A}_i[k]\mathbf{x}_i < \sum_{j=1}^{l} \mathbf{r}_{j,max}[k]$ **then**
        $\boldsymbol{\lambda}^+[k],\ \mathbf{r}_j^+[k] \leftarrow \boldsymbol{\pi}[l+1],\ \left(\sum_{i=1}^{N} \mathbf{A}_i[k]\mathbf{x}_i - \sum_{j=1, j\neq l}^{M} \mathbf{r}_j^+[k] \right)$ Case 2
      else
        $\boldsymbol{\lambda}^+[k],\ \mathbf{r}_j^+[k] \leftarrow \underline{\Lambda},\ \mathbf{r}_{UB,j}^+[k]$ Case 3
      end if
      Break
    end if
    $\underline{\Lambda} \leftarrow \overline{\Lambda}$
  end for
end for

In the example in Figure 1b, this corresponds to evaluating different realizations for λ^+ using Eq.(5), based on the minimum and maximum values for r. If the price range given by $\underline{\Lambda}$ and $\overline{\Lambda}$ is below the price for the external resource p, then r will be at the lower bound, and the maximum value for λ^+ is used in the next iteration, cf. Case 1 in Algorithm 1. If the price range includes p, Case 2, the difference between supply and demand can be covered by the external resources and therefore $\lambda^+ = p$. If the price range is above the price for the external resources, Case 1 also applies and the external resource r is at the upper bound. Case 3 is only required, if the step size α is too large. The residuals $\boldsymbol{\rho} = \sum_{i=1}^{N} \mathbf{A}_i\mathbf{x}_i^+ - \sum_{j=1}^{M} \mathbf{r}_j^+$ are used for the evaluation of the stopping criterion in both approaches.

4. Example

In the following, an example is used to demonstrate the proposed extension of the dual decomposition approach. Quadratic objective functions with positive diagonal scaling matrices and affine constraints of the following form are assumed:

$$f_i(\mathbf{x}_i) = \left(\mathbf{x}_i - \mathbf{x}_{i,Target}\right)^T \mathbf{B}_i \left(\mathbf{x}_i - \mathbf{x}_{i,Target}\right), \tag{7a}$$

$$\mathbf{g}_i(\mathbf{x}_i) = \mathbf{C}_i\mathbf{x}_i - \mathbf{d}_i = \mathbf{0}, \tag{7b}$$

Five subsystems ($N = 5$) are connected via three shared resources ($n_{Networks} = 3$). For each resource, there are three different sources from which it can be bought ($M = 3$). Each subsystem has four independent variables $\mathbf{x}_i \in \mathbb{R}^4$ and is subject to two local con-

straints, i.e., $\mathbf{g}_i : \mathbb{R}^4 \rightarrow \mathbb{R}^2$. The transfer prices $\boldsymbol{\lambda} \in \mathbb{R}^3$ are initialized with $\mathbf{0}$, the step size is chosen as $\alpha = 0.03$, and the tolerance is set to $\epsilon = 10^{-6}$. The matrices and vectors $\mathbf{x}_{i,Target}$, $\mathbf{B}_i$, $\mathbf{C}_i$, $\mathbf{d}_i$, $\mathbf{A}_i$, $\mathbf{p}_j$, and $\mathbf{r}_{UB,j}$ are generated from a random seed and the lower bound for flows of external resources is $\mathbf{r}_{LB,j} = \mathbf{0}$.

$$\mathbf{x}_{Target,i} = \begin{bmatrix} -2 & -7 & 4 & 6 \end{bmatrix}; \begin{bmatrix} -3 & 9 & -10 & 5 \end{bmatrix}; \begin{bmatrix} -7 & 2 & 8 & -7 \end{bmatrix}; \begin{bmatrix} -8 & 1 & 4 & 9 \end{bmatrix}; \begin{bmatrix} 1 & 2 & -7 & -6 \end{bmatrix},$$

$$\mathbf{B}_i = diag\left(\begin{bmatrix} 3 & 5 & 7 & 8 \end{bmatrix}\right); diag\left(\begin{bmatrix} 6 & 4 & 8 & 9 \end{bmatrix}\right); diag\left(\begin{bmatrix} 1 & 3 & 4 & 5 \end{bmatrix}\right); diag\left(\begin{bmatrix} 4 & 7 & 5 & 9 \end{bmatrix}\right); diag\left(\begin{bmatrix} 3 & 4 & 7 & 7 \end{bmatrix}\right),$$

$$\mathbf{C}_i = \begin{bmatrix} 9 & 7 & 9 & 7 \\ 0 & 5 & 4 & 4 \end{bmatrix}; \begin{bmatrix} 4 & 1 & 8 & 5 \\ 0 & 0 & 5 & 4 \end{bmatrix}; \begin{bmatrix} 8 & 7 & 2 & 3 \\ 0 & 0 & 8 & 1 \end{bmatrix}; \begin{bmatrix} 0 & 2 & 1 & 8 \\ 1 & 6 & 2 & 8 \end{bmatrix}; \begin{bmatrix} 5 & 7 & 6 & 6 \\ 9 & 3 & 9 & 9 \end{bmatrix},$$

$$\mathbf{d}_i = \begin{bmatrix} 9 & 6 \end{bmatrix}^T; \begin{bmatrix} 1 & 3 \end{bmatrix}^T; \begin{bmatrix} 6 & 1 \end{bmatrix}^T; \begin{bmatrix} 3 & 6 \end{bmatrix}^T; \begin{bmatrix} 5 & 6 \end{bmatrix}^T,$$

$$\mathbf{A}_i = \begin{bmatrix} -8 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 6 & 0 \end{bmatrix}; \begin{bmatrix} 2 & 0 & 0 & 0 \\ 0 & 3 & 0 & 0 \\ 0 & 0 & -9 & 0 \end{bmatrix}; \begin{bmatrix} -9 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \end{bmatrix}; \begin{bmatrix} 9 & 0 & 0 & 0 \\ 0 & -5 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}; \begin{bmatrix} 4 & 0 & 0 & 0 \\ 0 & -7 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix},$$

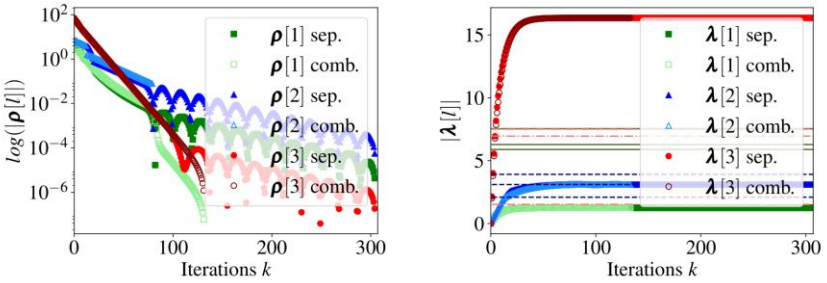
$$\mathbf{p}_j = \begin{bmatrix} 5.89 & 2.09 & 1.52 \end{bmatrix}^T; \begin{bmatrix} 6.28 & 3.1 & 6.95 \end{bmatrix}^T; \begin{bmatrix} 7.54 & 3.91 & 7.5 \end{bmatrix}^T,$$

$$\mathbf{r}_{UB,j} = \begin{bmatrix} 3.1 & 4.5 & 3 \end{bmatrix}^T; \begin{bmatrix} 2.2 & 2.9 & 1.4 \end{bmatrix}^T; \begin{bmatrix} 4.8 & 1.9 & 4 \end{bmatrix}^T,$$

In Figure 2, the evolution of the residuals $\boldsymbol{\rho}$ and of the transfer prices $\boldsymbol{\lambda}$ over the iterations can be seen for both, the separate (filled) and combined (empty), update rules. The distributed solutions converge towards the optimum of the centralized solution. Furthermore, it can be seen that upon convergence $\boldsymbol{\lambda}[1]$ (square) is less than, $\boldsymbol{\lambda}[2]$ (triangle) is equal to, and $\boldsymbol{\lambda}[3]$ (circle) is larger than the prices at which external resources can be bought (indicated by the thin lines), i.e., this example covers all three scenarios from Figure 1b. Comparing the two different methods, it becomes evident that the method with separate steps requires more iterations and oscillates towards the optimum.

5. Discussion and Conclusion

The significantly larger number of iterations in the approach with separate steps is due to $\boldsymbol{\lambda}[2]$ being equal to the external price. Since the variables are set consecutively, an overshoot is necessary because otherwise the sub-gradient for the usage of the external resource does not change. For the combined approach, after 90 iterations the network constraint of resource 2 is balanced by the external market and hence the residuum is 0. The prices can be initialized more efficiently, e.g., at one of the prices for external resources, however the goal was to show convergence regardless of initialization strategy.



(a) Evolution of the residuals.

(b) Evolution of the prices. The lines show $\boldsymbol{p}_j[l]$.

Figure 2: Resulting trajectories of characteristic quantities for the separated (sep.) and the combined (comb.) approach with the iterations.

In general, it can be said that distributed optimization can be used, also when there is access to external markets. What the authors observed running a suite of test cases with 1000 additional randomly generated examples is that the number of iterations of the combined approach is in a similar range as for a price-based optimization without external markets. Additionally, using this method bounds on the transfer prices of resources can be imposed by setting $\mathbf{r}_{LB,j}$ and $\mathbf{r}_{UB,j}$ to low and high values, respectively. The authors found this to be necessary to avoid excessive prices in real applications.

6. Outlook

Future work includes investigating the influence of a dynamic adaptation of the step size parameter α, in order to enable an arbitrary starting value for α and to speed up convergence. From a practical perspective, the distribution of the gains from the usage of external markets needs to be investigated, since here these are only realized at the coordinator level. Another topic of interest is the implementation of other contracts, such as take or pay, minimum required amounts, discounts for large amounts, etc.

Abstract

A well-insulated LNG (Liquefied Natural Gas) tank is a key facility in a regasification terminal. The management of Boil off Gas (BOG) produced from a LNG storage tank due to heat leak from the surrounding is an important issue. Many small-scale experimental studies have been reported on evaporation-condensation of different volatile liquids. However, these studies cannot mimic the behaviour of an industrial process. Computational Fluid Dynamics (CFD) simulation is the preferred alternative to study boiling phenomena at a large scale. However, no such study exists for LNG. A comprehensive dynamic CFD model presented in this study for an onshore full-scale LNG storage tank is a maiden attempt to fill that gap. We carry out a thorough investigation of internal flow dynamics and heat transfer characteristics owing to free convection. Our work provides insights on the boiling phenomena and allows reliable quantification of BOG production.

Keywords: LNG, full-scale tank, BOG, surface evaporation, nucleate boiling.

1. Introduction

Natural gas (NG) use is on the rise due to its lowest CO_2 emission per unit energy among the fossil fuels. After transportation by pipeline, the next preferred mode of NG transport is as Liquefied Natural Gas (LNG). Hence, the demand for LNG is also on the rise. In order to import LNG, a country must have one or more LNG receiving terminals. A LNG terminal consists of several facilities such as unloading, storing, regasification and transmission. A properly insulated LNG storage tank is a key unit in a receiving terminal. No amount of insulation can completely stop heat ingress into the LNG storage tank from the surroundings. Thus, production of boil off gas (BOG) is unavoidable. If not removed, BOG can elevate the tank pressure. Hence, continuous removal of BOG is essential to keep the tank pressure at a safe level. The management of BOG is a key issue for which a good understanding of the mechanism of its generation and at what rate it is generated are important.

LNG storage tank is a multiphase system that encounters liquid-vapor phase change. Many laboratory scale experimental studies have been performed on volatile liquids to understand evaporation and condensation phenomenon. However, laboratory studies are limited by the size and cannot mimic the large static pressure encountered in a full scale industrial system. Furthermore, the variation in surface area to volume ratio during

scaling significantly impacts heat transfer characteristics and flow dynamics of the system. Thus, the alternative to experimental studies for analyzing large scale industrial systems is the use of CFD simulation. In computational phase change studies, governing equations for mass, momentum and energy conservation are solved for entire computational domain (Juric and Tryggvason, 1998). The volume of fluid (VOF) method has been widely used in the literature to track vapor and liquid phases (Banerjee, 2008). CFD tank simulations have been reported to investigate different fuel systems (Hassanvand et al., 2010). However, there are few reported studies on LNG storage. A simplified isobaric and well-mixed 1D model was previously developed by our research group for BOG prediction (Effendy et al., 2017). The CFD model in the present study considers static pressure and hence the associated sensible heat gain. The boiling mechanism inside a properly insulated full-scale LNG storage tank is unknown in the open literature. The rigorous dynamic CFD model presented in this study is the maiden attempt to fill that gap. It examines the validity of the well-mixed assumption of the 1D model and sheds light on the likelihood of nucleate boiling in a typical LNG storage tank in a regasification terminal.

2. Model equations

2.1. VOF model

The volume of fluid (VOF) model is used, which allows tracking of the vapor-liquid interface. It is a multiphase model and employed for two or more phases which are immiscible. The interphase tracking between the two phases is executed by solving the equation of continuity, given by Eq. (1), for one or more phases.

$$\frac{1}{\rho_q}\left[\frac{\partial}{\partial t}\left(\alpha_q \rho_q\right) + \nabla.\left(\alpha_q \rho_q \vec{v}_q\right) = \sum_{p=1}^{n}(\dot{m}_{pq} - \dot{m}_{qp})\right] \quad (1)$$

In the VOF method, a single set of momentum equations in each control volume is solved and volume fraction (α) of each of the comprising phases in each cell is evaluated. Either of three possibilities can exist for a control volume: (a) If the control volume is completely vacant of q^{th} fluid i.e. $\alpha_q = 0$; (b) If control volume is fully filled with q^{th} fluid i.e. $\alpha_q = 1$; and (c) If control volume is partially filled of q^{th} fluid i.e. $0 < \alpha_q < 1$. Inside each computational cell, the summation of volume fractions of all phases must be unity. In the present study, number of phases (n) is two i.e. liquid and vapor.

2.2. Physical properties

If a computational cell contains more than one phase, then the cell properties are evaluated based on volume-average. The volume-average assumption is an integral part of VOF methodology. It provides accurate interface tracking within a cell. Hence, transport properties such as viscosity and density appearing in transport equation are computed based on volume fraction of each phase as indicated by Eq. (2).

$$\rho = \alpha_q \rho_q + (1 - \alpha_q)\rho_q \quad (2)$$

2.3. Lee model

The Lee model is employed to account for evaporation-condensation (Lee, 1980). The mass transfer from liquid to vapor and vapor to liquid during evaporation and

condensation respectively is described by the following Lee model equations i.e. Eq. (3) and Eq. (4).

$$m_{lv} = coeff * \alpha_l \rho_l \frac{(T_l - T_{sat})}{T_{sat}} \quad (3)$$

$$m_{vl} = coeff * \alpha_v \rho_v \frac{(T_{sat} - T_v)}{T_{sat}} \quad (4)$$

The Lee model defines a positive mass transfer from the liquid phase to the vapor phase for the evaporation-condensation problems. The coefficient appearing as first term on right hand side of above equations is called as relaxation time or mass transfer intensity factor. A default value of 0.1 for the intensity factor is used in the present simulation. To account for static pressure effect, a piecewise-polynomial correlation is defined to consider variation of saturation temperature (T_{sat}) with static head of liquid. Thus, Lee model uses Eq. (5) to evaluate the saturation temperature.

$$T_{sat} = 0.3709\, e^{-15}\, P^3 - 3.8013\, e^{-10}\, P^2 + 17.956\, e^{-5}\, P + 96.859 \quad (5)$$

2.4. Boussinesq equation

The Boussinesq approximation given by Eq. (6) treats density as constant in all the terms of solved equations except the buoyancy term in the momentum equation. Thus, a faster convergence is achieved by using this approximation for buoyancy driven flows.

$$(\rho - \rho_o) g = -\rho_o \beta (T - T_o) g \quad (6)$$

In this study, the Boussinesq approximation, valid for small density changes, is used for liquid density.

3. Results and discussion

ANSYS Fluent is used to simulate a tank 80 m in diameter and 40 m high. The axisymmetric CFD model accounts for the effect of gravity or static pressure. Liquid methane fills up to 30 m of the tank height and is initially at a temperature of 111.6 K (-161.5 °C) and pressure of 1 atm. The pressure is maintained constant at the tank top. Using U=0.025 W/m^{2}K, representative of a well-insulated full-scale LNG storage tank, it is seen that evaporation occurs only at the vapor-liquid interface and no nucleate boiling is observed. At the level of heat flux possible in the properly insulated full scale tank, the internal mixing due to natural convection is able to continuously remove heat from the bottom. Hence, the temperature at the tank bottom never reaches the saturation temperature of 122.6 K at the pressure of 2.26 bar (1.26 bar is the static pressure). The well mixed behavior results in a uniform temperature distribution throughout bulk liquid phase.

3.1. BOG profile for a full-scale properly insulated tank

The BOG formed is removed continuously through the vent provided. The BOG flowrate with time is shown in Figure 1. The rate of BOG generation increases with time for about 20 hours before attaining a steady state. Initially, when the heat leaks into tank, a portion of it is used as sensible heat to raise the temperature of subcooled liquid and to superheat the vapor. This explains the transient part until, as explained earlier, the system becomes well mixed due the natural convection current and no further sensible heat gain occurs. Therefore, the steady state BOG generation rate corresponds to entire heat leak supplying the latent heat of vaporization. Since our CFD model

incorporates sensible heat gain in both liquid and vapor phases, thus it accurately captures the initial transient BOG characteristics. The BOG generation rate given by a published isobaric and well-mixed 1D model (Effendy et al., 2017) is also shown in Figure 1. They differ in the transient behaviour but practically converge at steady state.

The initial BOG flowrates were overestimated by the 1D model. In the 1D model, only sensible heat gain is in the vapor phase and steady state is reached in about 4 hours. We also simulated a scenario without static pressure effect by appropriately adjusting the Lee model and the profile is also included in Figure 1. Without the static pressure effect, the CFD and 1D simulation results are nearly identical. This not only confirms the effect of the liquid height in the storage tank on the initial BOG rate, but also shows that its impact on the steady state behaviour is not significant. The CPU time required to simulate 40 hours of BOG production is 118 hours. The computational cost is quite reasonable considering the accuracy by which CFD simulation captures the transient dynamics of BOG production. In addition to validating the adequacy of the 1D model at steady state, this study has investigated the boiling mechanism which would not be possible with the 1D model.

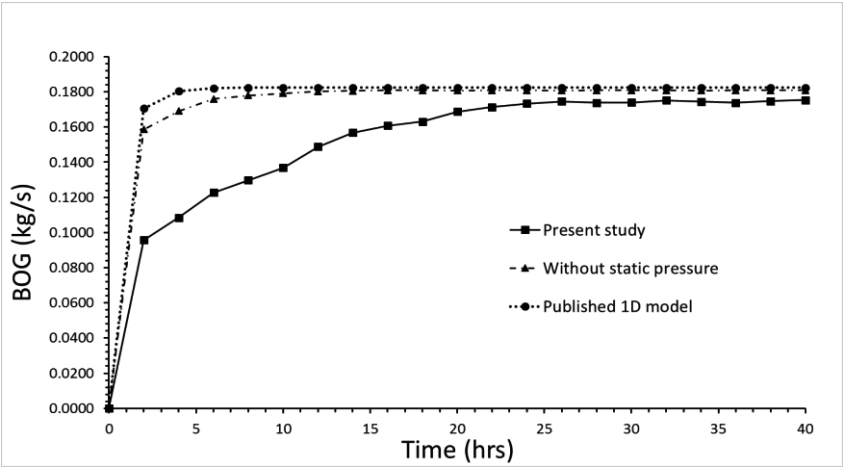

Figure 1. Boil-off-gas (BOG) generation rate in a full-scale LNG storage tank.

3.2. Boiling mechanism in a full-scale tank

To comprehensively understand the boiling mechanism inside a full-scale tank, simulations are performed at U = 0.025, 2.5 and 25 W/m^{2}K. U = 0.025 W/m^{2}K represents a properly insulated tank, whereas U = 25 W/m^{2}K corresponds to a tank which is completely stripped of its insulation. The plot of average bottom wall temperature with time is shown in Figure 2. For U = 0.025 and 2.5 W/m^{2}K, the wall temperature is always less than the saturation temperature at the bottom (122.6 K). This is because at this low heat flux, the heat ingress through the walls is carried to the top by the natural convection before the fluid near the walls can be heated to the local saturation temperature. A steady state is reached well below the local saturation temperature / bubble point. In contrast, at U = 25 W/m^{2}K the rate of heat ingress exceeds the rate at which it is removed to the top by the natural convection current and the wall temperature continuously increases. Eventually, wall temperature reaches the threshold value at which bubble formation occurs. Therefore, it is concluded that surface evaporation is the governing boiling mechanism for a full-scale properly

insulated tank. Thus, advent of nucleate boiling (bubble formation) in a full-size LNG storage tank is unlikely unless the insulation is completely removed.

3.3. Comparison of full-scale and centimetre-scale tanks at U = 2.5 W/m²K

To investigate differences in dynamics of an experimental scale and industrial scale tank, a centimetre-scale tank is simulated and compared with full-scale tank at U = 2.5 W/m²K. In the centimetre scale tank, the numerical values of tank dimensions are kept the same as in the large-scale tank, but the dimension is changed from meter to centimetre. The volume fraction contours for two cases are shown in Figure 3. (Note- white denotes vapor phase and black indicates liquid phase). It is observed that surface evaporation occurs at the vapor-liquid interface for full-scale tank, whereas, bubble formation is witnessed near bottom wall for centimetre-scale tank. The contrasting boiling mechanisms arise due to two factors; (a) static pressure, and (b) surface area to volume ratio. The static pressure for full-scale tank is 1.25 barg at bottom and the corresponding saturation temperature is 122.6 K. In contrast, the static pressure at the bottom of the centimetre-scale tank is almost negligible (0.0125 barg) and the corresponding saturation temperature is 111.6 K.

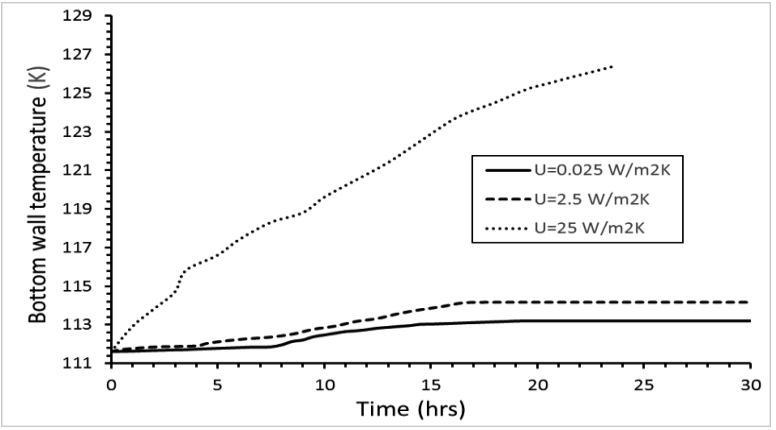

Figure 2. Plot of average bottom wall temperature with time at different values of U.

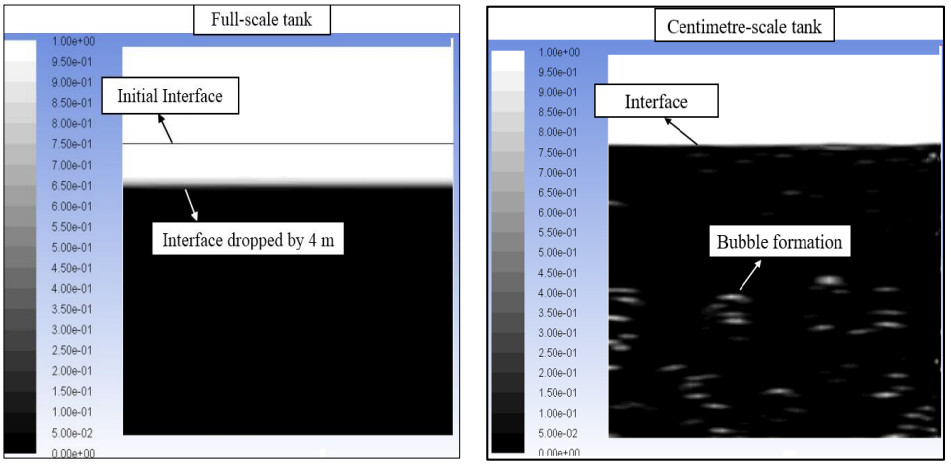

Figure 3. Phase contours for full-scale and centimetre-scale tanks at U = 2.5 W/m²K.

When the scale of the tank is reduced from metre to centimetre, the surface area to volume ratio is increased by 100 times. A higher surface area/volume allows heat to penetrate more aggressively in the bulk liquid phase, which the natural convection current is unable to remove at a comparable rate. Therefore, the temperature near the bottom wall rises to a level that induces bubble formation leading to nucleate boiling.

3.4. Onset of nucleate boiling

In order to investigate the onset of nucleate of boiling in LNG, the heat transfer coefficient is increased by over three orders of magnitude (up to 100 W/m^2K) and the dimensions of the storage tank are also scaled down and the hydrostatic pressure is varied from 1 to 2.26 bar in the scaled down tanks. For liquid methane, nucleate boiling occurs when critical wall superheat (wall temperature above the boiling point near the wall at which the first bubble is seen) is circa 3 degrees, which is unattainable in a well-insulated large scale LNG storage tank.

4. Conclusions

A comprehensive CFD simulation of a well-insulated full-scale LNG storage tank is presented. The BOG generation rate increases with time for about 20 hours before reaching a steady state. The transient is attributed to the static pressure due to the liquid height, which increases the bubble point above the initial temperature and consumes the initial heat ingress to supply the sensible heat. By virtue of the natural convection current, the bulk liquid temperature also becomes nearly uniform except very near the walls. Thus, the 1D model (well-mixed assumption) and CFD simulation results for BOG generation rate deviate in the early part but show good agreement at steady state. The onset of nucleate boiling in LNG requires a critical wall superheat of circa 3 degrees. This is not achieved in a well-insulated full-scale LNG storage tank.

Abstract

In this work, we describe new capabilities for the Pyomo.GDP modeling environment, moving beyond classical reformulation approaches to include non-standard reformulations and a new logic-based solver, GDPopt. Generalized Disjunctive Programs (GDPs) address optimization problems involving both discrete and continuous decision variables. For difficult problems, advanced reformulations such as the disjunctive "basic step" to intersect multiple disjunctions or the use of procedural reformulations may be necessary. Complex nonlinear GDP models may also be tackled using logic-based outer approximation. These expanded capabilities highlight the flexibility that Pyomo.GDP offers modelers in applying novel strategies to solve difficult optimization problems.

Keywords: python, Pyomo, modeling, optimization, disjunctive programming

1. Introduction

Optimization problems involving both discrete and continuous variables are commonplace in Process Systems Engineering (PSE) applications, including process design, planning, scheduling, and operations. Modelers typically formulate these problems as MILPs, or if nonlinear, MINLPs. However, there is no unique model formulation; for the same discrete-continuous problem, some formulations may be tractable while others may not (Grossmann and Trespalacios, 2013).

We claim that most MILP/MINLP formulations arise from attempts to model intuitively disjunctive (logical this-OR-that) problems. Generalized Disjunctive Programming (GDP), proposed by Raman and Grossmann (1994), provides a high-level modeling construct for expressing this application logic intuitively in the form of disjunctions and then applying systematic solution strategies. For example, unit existence in a process network is a disjunction: a candidate unit may exist—and its performance constraints enforced—or it may be absent—and its extensive quantities set to zero (Chen and Grossmann, 2017). Grossmann and Trespalacios (2013) gives the general form of GDP and MILP/MINLP models. Once a GDP model is posed, we can apply reformulations to convert the model structure to a MILP/MINLP and use available mixed-integer solvers, or we can solve the GDP directly using logic-based algorithms. The flexibility of being able to describe a problem using a single GDP model, and then to attempt different solution strategies is invaluable in addressing difficult PSE optimization challenges.

GDP modeling and optimization capability exists in both the open source Pyomo (Hart et al., 2017) and commercial GAMS (GAMS, 2017) algebraic modeling languages (AMLs),

making it accessible to a wide audience of modelers. Both AMLs support the formulation of disjunctions and standard conversions to MILP/MINLP: the big-M (BM) reformulation described in Raman and Grossmann (1994) and the hull reformulation (HR) described in Furman et al. (2016). However, the flexibility to develop and utilize more advanced GDP solution techniques may be necessary to tackle challenging problems.

A key challenge in reformulating GDP models is the generation of MILPs/MINLPs with tight continuous relaxations without growing the problem to an intractable size (Ruiz and Grossmann, 2017). BM leads to smaller formulations, but HR yields tighter relaxations. There has therefore been interest in advanced reformulations to better address this trade-off. Trespalacios and Grossmann (2016) introduced a method for strengthening the BM formulation using cutting planes derived from the HR, leading to a hybrid reformulation tighter than the BM, but smaller than the HR. Another recent development has been the introduction of basic steps for GDP by Ruiz and Grossmann (2012) building on the disjunctive programming concept introduced by Balas (1985). By performing basic steps, the GDP formulation is progressively transformed into disjunctive normal form, tightening the HR of the GDP, and consequently its continuous relaxation. For difficult problems, these advanced reformulations can make a difference in tractability; however, automatic generation of basic steps does not yet exist in a modeling environment, limiting their application.

In some cases, particularly for nonlinear GDP models with higher complexity in the continuous space, it is useful to solve the GDP using direct decomposition algorithms such as logic-based outer approximation (LOA) (Türkay and Grossmann, 1996). However, the LOGMIP 2.0 solver (Vecchietti and Grossmann, 1997) in GAMS 23.7+ no longer supports LOA. A capability gap thus exists for a flexible LOA solver that modelers can tune to fit their needs and adapt to incorporate domain-specific knowledge.

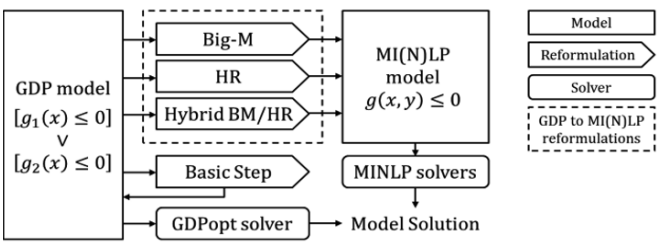

Figure 1. GDP model solution approaches with Pyomo.GDP

In this paper, we present new implementations in Pyomo.GDP enabling use of advanced reformulations such as hybrid BM/HR cutting planes and basic steps, and a flexible LOA implementation in the new direct GDP solver GDPopt. Figure 1 shows how these new capabilities fit in for the solution of a GDP model. In section 2, we discuss the advanced reformulations. In section 3, we present details on GDPopt. We demonstrate hybrid cuts and GDPopt with a case study in section 4, and we conclude in section 5.

2. Advanced GDP reformulations to MILP/MINLP

When reformulating a GDP model to MILP/MINLP, the main challenge is achieving the right compromise between problem size and tightness of the continuous relaxation. We introduce two new automatic tools that modelers can use to find a good trade-off: hybrid big-M cutting planes and GDP basic steps.

2.1. Hybrid BM/HR cutting plane algorithm

The hybrid BM/HR reformulation is based on the idea that cutting planes can be derived from the HR to strengthen the BM relaxation without explicit addition of many new variables and constraints (Trespalacios and Grossmann, 2016). We refer the reader to Section 6 and Figure 13 of Vecchietti et al. (2003) for theoretical background on the BM/HR cutting plane algorithm implemented in Pyomo.GDP.

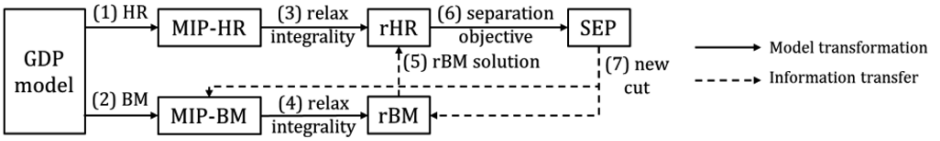

Figure 2. Hybrid BM/HR cutting plane algorithm

The Pyomo.GDP cutting plane implementation relies on pre-existing automatic reformulations for BM and HR. The algorithm is outlined in Figure 2. Note that cuts are generated via a separation problem between the rBM solution and the rHR feasible region. Given a model `m`, the following command will generate a MILP/MINLP representation:

```
TransformationFactory('gdp.cuttingplane').apply_to(m)
```

Following reformulation, the MILP/MINLP may be solved using any standard solver.

2.2. GDP Basic Steps

Basic steps in GDP bring a formulation incrementally from conjunctive normal form to disjunctive normal form by intersecting disjuncts with constraints or other disjuncts. Ruiz and Grossmann (2012) show that by doing so, the HR of the problem is tightened at the expense of a growth in the number of disjuncts. The reformulation that applies a basic step between disjunctions "d" and "e" is implemented with the following command:

```
TransformationFactory('gdp.basic_step').apply_to(m, targets=[m.d, m.e])
```

The result is a reformulation from a GDP model to another GDP model with a basic step applied. The tightened GDP could then be further reformulated to MILP/MINLP or used in the context of the hybrid BM/HR cutting plane algorithm.

3. GDPopt: a flexible logic-based nonlinear GDP solver for Pyomo

We introduce GDPopt, a logic-based solver with a LOA implementation built on top of the Pyomo.GDP framework. GDPopt offers an alternative to reformulation of nonlinear GDPs into MINLPs. For PSE applications with complex nonlinear functions in the continuous space, such as those resulting from mixing, reaction, and equilibrium relations in process networks, LOA allows solution of reduced space NLP sub-problems—including only constraints in selected disjuncts—rather than the full-space representations encountered when solving MINLPs, thereby improving robustness.

Figure 3 illustrates the LOA algorithm. From the original nonlinear GDP model, (1) an initialization procedure is used to generate a linearization, yielding a linear GDP model. (2) An automatic reformulation is then applied to the linear GDP model to yield the MILP master problem. The solution to the MILP master problem provides a lower bound on the overall (minimization) problem as well as (3) a proposed realization of the discrete variables. By (4) fixing the disjunctions and Boolean variables of the nonlinear GDP

model based on the optimal MILP master problem solution, we obtain a reduced space NLP model omitting the constraints in inactive disjuncts. The optimal NLP solution gives an upper bound on the overall (minimization) problem as well as the optimal continuous variable values for (5) generating an outer approximation (OA) cut. GDPopt uses OA/ER cuts described in Viswanathan and Grossmann (1990). The algorithm then loops back through steps 2-6 until a convergence criterion is met. GDPopt also supports the hybrid mixed-integer/GDP models described in Vecchietti and Grossmann (1997).

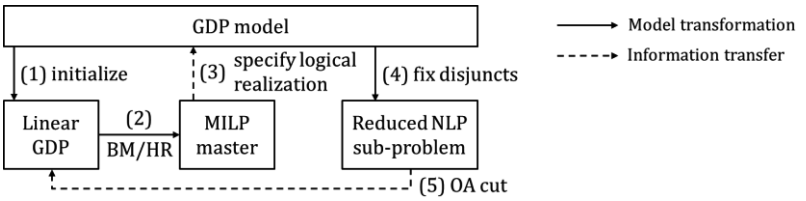

Figure 3. Logic-based outer approximation flow diagram

Two major challenges in applying LOA are the initial linearization of the nonlinear GDP and the solution of the NLP sub-problems. Türkay and Grossmann (1996) introduce a set-covering algorithm to ensure that linearizations are generated for each disjunct. We propose a modification whereby the set cover only needs to include disjuncts that contain nonlinear constraints. Taking advantage of Pyomo model characterization capabilities, GDPopt supports this new set-covering scheme, reducing the number of initialization sub-problems needed for LOA. Furthermore, because GDPopt is written in Python, it offers advanced modelers great flexibility to shape the algorithm according to their needs. GDPopt supports the use of custom initialization schemes for LOA as well as the capability to define callbacks before or after every LOA step outlined above. These callbacks have full access to the underlying Pyomo models used by LOA, and they can even be used to implement custom initialization schemes for the NLP sub-problems, providing warmstart information to the NLP solver that can be important for convergence (Biegler, 2010).

Usage of GDPopt is similar to the invocation of any other Pyomo solver:

```
SolverFactory('gdpopt').solve(m)
```

4. Case study

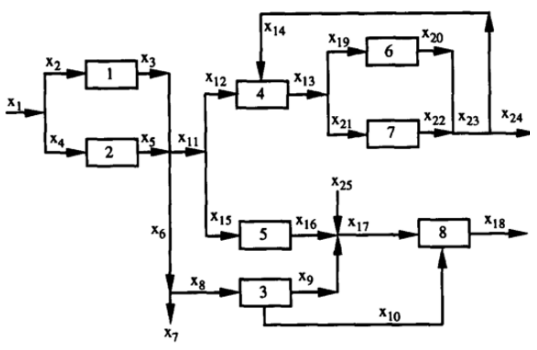

Figure 4. Eight process problem superstructure

We demonstrate the application of advanced reformulations and GDPopt using a disjunctive formulation of a process design problem from Duran and Grossmann (1986). Figure 4 shows the superstructure for the selection among eight process units.

The goal is to minimize annual cost of operation for a process with eight candidate units by determining the optimal flowsheet structure and flowrates. The mathematical formulation for this problem can be found in Appendix A of Türkay and Grossmann

(1996). For brevity, we illustrate below a selection of the model-building and solution steps for the case study in Pyomo.GDP. The complete code is publicly available as a test problem in the Pyomo Github repository.

All models begin with declaration of an empty model object:

```
m = ConcreteModel(name='Eight Process Problem')
```

We can then define model variables, constraints, and disjunctions, such as the one between selection of unit 1 versus unit 2, as shown in Equation 2:

$$\begin{bmatrix} Y_1 \\ \exp(x_3) - 1 = x_2 \\ x_4 = x_5 = 0 \end{bmatrix} \bigvee \begin{bmatrix} Y_2 \\ \exp\left(\frac{x_5}{1.2}\right) - 1 = x_4 \\ x_2 = x_3 = 0 \end{bmatrix} \tag{2}$$

```
m.use_unit1 = Disjunct(); m.use_unit2 = Disjunct()
m.use_unit1.inout1 = Constraint(expr=exp(m.flow[3])-1 == m.flow[2])
m.use_unit1.no_unit2_flow1 = Constraint(expr=m.flow[4] == 0)
m.use_unit1.no_unit2_flow2 = Constraint(expr=m.flow[5] == 0)
m.use_unit2.inout2 = Constraint(expr=exp(m.flow[5]/1.2)-1 == m.flow[4])
m.use_unit2.no_unit1_flow1 = Constraint(expr=m.flow[2] == 0)
m.use_unit2.no_unit1_flow2 = Constraint(expr=m.flow[3] == 0)
m.use1or2 = Disjunction(expr=[m.use_uni1, m.use_uni2])
```

Table 1. MINLP statistics following BM, HR, and Hybrid reformulations

	NLP Relaxation	# vars	# binary	# constraints
HR	67.4	84	12	196
BM	-435.4	37	12	83
Hybrid BM/HR	-140.29	37	12	84

Once defined, the GDP model can be transformed or solved. Table 1 shows the problem size and root node NLP solution for the standard reformulations, demonstrating the trade-off between relaxation quality and problem size. All three examples solve to the optimal solution of 68.0 within 1 CPUs using the DICOPT solver. This example demonstrates the impact of the hybrid BM/HR cutting planes on the relaxation, as the addition of a single constraint improves the BM relaxation by 50%.

Table 2. Iteration results for GDPopt

Iteration	Z_{NLP} (UB)	Z_L (LB)
Set cover #1	68.0	
Set cover #2	100.3	
1		68.0

Another option is to solve the GDP model directly using GDPopt. Table 2 displays the GDPopt iteration results. Compared to Table 5 in Türkay and Grossmann (1996), only two set covering sub-problems are necessary, reducing the number of NLPs that must be solved for initialization. Subsequently, the algorithm converges after the first master iteration.

5. Conclusions

In this work, we introduce new solution capabilities for the Pyomo.GDP ecosystem, including the hybrid BM/HR cutting planes reformulation, GDP basic steps, and the GDPopt logic-based solver. These additions highlight how the Pyomo algebraic modeling language provides a first-class framework for GDP modeling and optimization of discrete-continuous problems in PSE. By modeling in Pyomo.GDP, users can directly express problem logic and leverage a variety of automated solution techniques. Furthermore, as an open tool, advanced modelers are able to modify the reformulations and the GDPopt solution algorithm to incorporate their domain-specific knowledge.

Mixed-Integer Nonlinear Decomposition Toolbox for Pyomo (MindtPy)

David E. Bernal*, Qi Chen, Felicity Gong, and Ignacio E. Grossmann

Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh 15213, PA, USA
bernalde@cmu.edu

Abstract

In this paper, we present a new software framework developed in Pyomo, MindtPy (Mixed-Integer Nonlinear Decomposition Toolbox for Pyomo), which implements several decomposition methods for solving Mixed-Integer Nonlinear Programs (MINLP). These methods decompose the MINLP into a Mixed-integer Linear Program (MILP) and a Nonlinear Program (NLP). The methods implemented in this toolbox are designed to find the global optimal solution of convex MINLP problems. This toolbox allows the user to specify certain algorithmic options for these methods, which were not available in a single solver. Using Process Systems Engineering appications; the computational implementation and performance are discussed.

Keywords: Mixed-integer nonlinear programming, decomposition methods, Pyomo.

1. Introduction

Optimization problems in Process Systems Engineering (PSE) can be expressed with algebraic equations and decision variables, and be solved via mathematical programming. When these problems include nonlinear equations in the objective and/or constraints, and both continuous and discrete variables, they become Mixed-Integer Nonlinear Programs (MINLP).

The nature of the functions involved in optimization in PSE motivated the development of solution methods for both generalized and specialized MINLP models. Convex MINLP models are of special interest since their continuous relaxation gives rise to convex problems with a unique optimum value.

The general form of a MINLP problem is shown in Eq. (1).

$$\begin{aligned} Z = \min_{w,y} \; & f(w,v,y) \\ \text{s.t.}: \; & g(w,v,y) \leq 0 \\ & A_1 w + A_2 v + By \leq b \\ v \in V \subseteq \mathbb{R}^{n_v}, & w \in W \subseteq \mathbb{R}^{n_w}, y \in Y \subseteq \mathbb{Z}^{n_y} \end{aligned} \tag{1}$$

In Eq. (1) we partition the continuous variables as $[w\ v]^T = x \in X = W \times V$ with w being those continuous variables involved in only linear terms in the constraints, and v the variables involved in nonlinear terms.

MINLP problems like the one shown in Eq. (1) can be solved with Branch and Bound (B&B) methods and decomposition methods. In B&B, a systematic enumeration of the

possible combinations of discrete variables is performed, followed by the solution of simpler continuous subproblems obtained by fixing the discrete variables.

Decomposition methods iterate between a relaxation of the original MINLP, using linear approximations of the original feasible region resulting in a Mixed-Integer Linear Programming (MILP), and the solution of a restricted subproblem where the original problem is projected in a certain discrete combination in the form of a Nonlinear Programming (NLP) problem. The relaxation provides a lower bound over the objective function, while the restriction, when feasible, provides an upper bound. The decomposition methods are designed to provide a monotonic improvement on the lower bound while providing new integer combinations to the subproblem to update the upper bound. If the bounds meet, the convex MINLP problem is solved to optimality.

In convex MINLP problems, decomposition methods such as Generalized Benders Decomposition (GBD) (Geoffrion, 1972), Outer-Approximation (OA) (Duran and Grossmann, 1986), and Partial Surrogate Cuts (PSC) (Quesada and Grossmann, 1992) are proven to converge to the global optimum. Another method is the Extended Cutting Plane (ECP) method (Westerlund and Pettersson, 1995), which avoids solving the nonlinear subproblem, which is also proven to converge to the global optimum.

The motivation of this work is that the importance and difficulty of solving MINLP problems require the development of new methods and software. The decomposition methods rely on the solution of the building blocks of MINLP, MILP and NLP; which has improved considerably in recent years (Bonami et al., 2008).

Methods such as OA or ECP have been implemented as part of commercial MINLP solvers as DICOPT, α-ECP, and BONMIN, among others (Bussieck and Vigerske, 2011). In this manuscript, we present an open-source implementation of the OA, ECP, GBD, and PSC methods inside the Python Optimization Modeling Objects (Pyomo) library (Hart et al., 2017) in a single algorithmic framework called MindtPy. MindtPy exploits several advantages of Pyomo, e.g. optimization object-oriented programming, access to commercial NLP and MILP solvers, and third-party Python packages apart from Pyomo.

The main advantage that MindtPy presents in comparison with other MINLP solvers is its flexibility, by offering the possibility to use methods usually available in separate solvers, of which not all are available for Pyomo. This flexibility is similar to the one offered by other open-source solvers like BONMIN, LaGO, and COUENNE, where the user can easily modify the code to specialize it to a certain type of MINLP. Other solvers are non-open-source for all users, limiting the reach that open-source software like Pyomo can provide. Unlike COUENNE, MindtPy is only able to find the global optimum to convex MINLP problems, but by avoiding the solution of a spatial B&B it may find solutions to these problems efficiently.

2. Decomposition methods

A common classification of MINLP regards its continuous relaxation, where if all the constraints and the objective are convex functions, then the MINLP is denoted as a convex MINLP (Lee and Leyffer, 2012) although MINLPs themselves are nonconvex.

The decomposition methods assume that there is a subset of the problem variables that when temporarily fixed, make the remaining optimization problem considerably more tractable. This is the case with MINLP problems, where the complicating variables are

the integer variables, which when fixed, give rise to an NLP problem. The OA, GBD, and PSC methods solve an MILP problem, which provides a lower bound and an integer combination, which when fixed results in an NLP.

The master problem of the GBD method at the iteration k is presented in Eq. (2).

$$\begin{aligned} & Z_{LB,GBD}^{k} = \min_{\eta,y} \eta \\ \text{s.t.:} \quad & \eta \geq f(v^k, w^k, y) + (\mu^k)^T g(v^k, w^k, y) \;\; \forall k \in K_{feas} \\ & (\mu^k)^T g(v^k, w^k, y) \leq 0 \;\; \forall k \in K_{infeas} \\ & A_1 w^k + A_2 v^k + By \leq b \\ & \eta \in \mathbb{R}^1, y \in Y \subseteq \mathbb{Z}^{n_y} \end{aligned} \tag{2}$$

Where μ^k are the Lagrange multipliers of the nonlinear constraints, and K_{feas} and K_{infeas} are the set of iterations where the NLP subproblems were feasible and infeasible, respectively. This problem adds one cut to the master problem per iteration.

In the OA method, the nonlinear constraints are replaced by linear constraints given by the 1st order Taylor approximations. Therefore, we obtain the master problem in Eq. (3) which is a valid relaxation of the MINLP.

$$\begin{aligned} & Z_{LB,OA}^{k} = \min_{\eta,x,y} \eta \\ \text{s.t.:} \quad & \eta \geq f(v^k, w^k, y^k) + \nabla f(v^k, w^k, y^k)^T [v - v^k \quad w - w^k \quad y - y^k]^T \;\; \forall k \in K \\ & g(v^k, w^k, y^k) + \nabla g(v^k, w^k, y^k)^T [v - v^k \quad w - w^k \quad y - y^k]^T \leq 0 \;\; \forall k \in K \\ & A_1 w + A_2 v + By \leq b \\ & \eta \in \mathbb{R}^1, v \in V \subseteq \mathbb{R}^{n_v}, w \in W \subseteq \mathbb{R}^{n_w}, y \in Y \subseteq \mathbb{Z}^{n_y} \end{aligned} \tag{3}$$

This method adds as many cuts as constraints plus the objective cut at each iteration. It can still converge to the optimal solution in finite iterations if only the cuts corresponding to the active constraints for each problem are added, reducing the master problem size.

The PSC method addresses the tradeoff between the master problem size and the strength of the derived cuts. This method can be seen as a combination of the OA and the GBD methods, where the cuts are derived from the gradient-based linearizations of OA, and the KKT conditions as in GBD. The PSC master problem is shown in Eq. (4).

$$\begin{aligned} & Z_{LB,PSC}^{k} = \min_{\eta,v,y} \eta \\ \text{s.t.:} \quad & \eta \geq f(v^k, w, y) + \begin{bmatrix} \lambda^k \\ -\mu^k \end{bmatrix}^T \begin{bmatrix} g(v^k, w, y) & 0 \\ 0 & A_2 \end{bmatrix} \begin{bmatrix} 1 \\ v - v^k \end{bmatrix} \;\; \forall k \in K_{feas} \\ & \begin{bmatrix} \lambda^k \\ -\mu^k \end{bmatrix}^T \begin{bmatrix} g(v^k, w, y) & 0 \\ 0 & A_2 \end{bmatrix} \begin{bmatrix} 1 \\ v - v^k \end{bmatrix} \leq 0 \;\; \forall k \in K_{infeas} \\ & A_1 w^k + A_2 v + By \leq b \\ & \eta \in \mathbb{R}^1, v \in V \subseteq \mathbb{R}^{n_v}, w \in W \subseteq \mathbb{R}^{n_w}, y \in Y \subseteq \mathbb{Z}^{n_y} \end{aligned} \tag{4}$$

An interesting result is that the cuts in the GBD master problem are surrogates of those derived from the PSC methods, which are surrogates of the cuts in OA (Quesada and Grossmann, 1992). This results in the relation between the solutions of each master problem in Eq. (5).

$$Z^k_{LB,GBD} \leq Z^k_{LB,PSC} \leq Z^k_{LB,OA} \tag{5}$$

After solving each master problem, a candidate discrete combination y^{k+1} is found and fixed to solve an NLP subproblem. The NLP solution $(v^{k+1}, w^{k+1}, y^{k+1})$ is used to generate the next cuts in the master problem, and if feasible, it provides an upper bound.

As in OA, the ECP method also relies on the 1st order Taylor approximation cuts to generate a master problem, but instead of solving an NLP subproblem to obtain a new linearization point, it uses the previous master MILP solution. At each iteration, all the nonlinear constraints violated by a ε-tolerance are linearized and added to the master problem, converging to the optimal solution within that ε-tolerance.

Given the tradeoff between the size of the master problem and the strength of the lower bound predicted by it, none of the methods dominates the others and the performance depends on each problem. Another tradeoff is between solving or not solving the NLP subproblems, given that they can be expensive to solve but provide a better linearization point and an upper bound to the problem.

3. Implementation

The decomposition methods for convex MINLP can be seen as meta-algorithms, where the solution of the optimization problem relies on solutions of other subproblems provided by other solvers, namely MILP and NLP.

Given a convex MINLP written in Pyomo, our toolbox solves it using any of the previously discussed decomposition methods. The object-oriented structure of the optimization models in Pyomo allows us to generate a `Block` component for our purposes. Inside the original model, the block `MindtPy_linear_cuts` stores all the data used such as the cuts in the master problem, or intermediate solutions while solving the model.

The first step after receiving the model is to perform an initialization for the decomposition methods. We require an initial integer combination to solve the nonlinear program, or a starting solution to that problem to populate the dual and gradient information required for the initial master problem. Given this, we implement several initialization procedures: 1) solve a continuous relaxation of the MINLP, providing a valid lower bound and a linearization point to generate the master problem; 2) use the user provided initial point as a fixed discrete combination and use this to solve the master problem; 3) maximize the sum of the discrete variables subject to the linear constraints in an assignment problem to obtain this initial discrete combination.

The gradients of the nonlinear constraints are calculated using the `differentiate` function in Pyomo, which performs an exact differentiation of the equations defining the corresponding derivatives. Given that these equations are encoded in expression trees, the differentiation is performed efficiently.

Other options, such as the inclusion of disjunctive cuts generated to ignore the previous solutions, known as integer cuts; the selection of different subsolvers for the MILP and NLP problems; and the convergence tolerances are available for the user to modify. Other algorithmic options include the use of different primal heuristics for finding feasible solutions, namely the Center-cut algorithm and the Feasibility pump, and the

use of regularization for the decomposition methods. The implementation can be found in the public repository of the project (Bernal and Chen, 2017).

4. Numerical example

To illustrate the use of MindtPy with different methods, we solve the problem in Eq. (6). Defining the problem as an optimization model inside Pyomo called `SimpleMINLP`, the command to solve this problem for example with OA and solving the relaxed NLP as an initial strategy we execute within Python, importing Pyomo:

```
opt=SolverFactory('MindtPy')
opt.solve(SimpleMINLP, strategy = 'OA', initi_strategy = 'rNLP')
```

$$
\begin{aligned}
Z = \min_{x,y}\ & y_1 + 1.5y_2 + 0.5y_3 + x1^2 + x2^2 \\
& \text{s.t.}: (x_1 - 2)^2 - 2y_1 \leq 0 \\
& \begin{bmatrix} -1 & 0 \\ 1 & -1 \\ -1 & 0 \\ 0 & 1 \\ -1 & -1 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 2 & 0 & 0 \\ 0 & 4 & 0 \\ -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 3 \\ -1 & -1 & -1 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} \leq \begin{bmatrix} 0 \\ 4 \\ -1 \\ 0 \\ -1 \\ -1 \end{bmatrix} \\
& 0 \leq x \leq 4, x \in \mathbb{R}^2, y \in \{0,1\}^3
\end{aligned} \tag{6}
$$

We solve the problem using the four different methods and an initial point $x^0 = 0$, $y^0 = 1$. The results for each iteration are presented in Table 1. The strength of the lower bound results in a convergence in fewer iterations for OA and PSC, while the ECP method takes more iterations since it does not solve the subproblem, although every iteration is computationally cheaper since it only requires the solution of an MILP.

Table 1. Numerical example: Upper and lower bounds against iteration for each method.

Method	OA		PSC		GBD		ECP
Iteration	LB	UB	LB	UB	LB	UB	LB
1	1	11	1	11	-24	11	0.5
2	1.5	5	1.5	5	-23.5	11	0.5
3	3.5	3.5	3.5	3.5	-3.5	5	1
4					-2.5	5	2.02
5					3.5	3.5	3.5

5. Computational implementation and performance

In this section, we solved several convex MINLP with PSE applications from the MINLPLib2 (Vigerske, 2014). We used Gurobi7.5 and IPOPT3.12 as subsolvers. The tests were performed on a desktop running in Ubuntu16.04, with an Intel Core 2 Duo processor, a CPU of 3.4 GHz and 16 GB of RAM using Pyomo 5.2. We solve every instance with the four methods using the rNLP as initial strategy. The results are presented in Table 2. There we can see that for all the examples, OA managed to converge in fewer or equal iterations than PSC, which also converged in fewer iterations than GBD as mentioned in Eq. (5). We can see that ECP also converged in more

iterations but the computational time per iteration was smaller, showing the trade-offs in performance.

Table 2. Solution details for different test cases using the 4 methods solved to $\varepsilon = 10^{-5}$. Termination without proof of optimality in less than 1000 iterations are marked with *

Method	OA		PSC		GBD		ECP

6. Conclusions

An open source toolbox for MINLP solutions based on decomposition methods implemented in Pyomo was presented in this paper. This toolbox allows the users to modify several algorithmic options for these decomposition methods, allowing him/her to test easily different solution approaches to MINLP problems. MindtPy also provides algorithm designers with a platform to easily test and prototype ideas with access to all the capabilities of Pyomo, such as access to specialized subsolvers. We successfully implemented and tested using PSE related MINLP problems showing the flexibility of the toolbox.

Abstract

Accurate estimation of model parameters is difficult for reactive solvent-based processes due to coupled effects of mass transfer, heat transfer, and reaction kinetics. While commercial process simulators provide capabilities for parameter estimation, it is generally difficult to simultaneously regress parameters of different submodels (e.g. parameters of physical properties and mass transfer models). Morgan et al. (2018) and Chinen et al. (2018) have demonstrated the value of the simultaneous parameter estimation approach in developing highly predictive models. The approach used by Chinen et al. (2018) embedded a simulation of a CO_2 capture process in an external derivative free optimization (DFO) framework. While this approach works well in many cases, it is computationally inefficient, difficult to set up, and limited by the amount of data that can be used. This paper presents an extension to that work where the process model and a generalized parameter estimation tool are developed in the Institute for Design of Advanced Energy Systems (IDAES) process systems engineering (PSE) framework. The IDAES framework allows an entire process model to be implemented in an equation-oriented framework with access to state-of-the-art optimization methods. Improved computational efficiency and ease of implementation are demonstrated.

Keywords: Simultaneous parameter estimation, optimization, CO_2 capture, IDAES

1. Introduction

Accurate estimation of model parameters is important in the development of predictive process models; however, this is difficult for reactive solvent-based processes due to the coupled effects of mass transfer, heat transfer, and reaction kinetics. Experimental data spanning different scales and operating regimes are required to obtain a process model that is predictive for different scales and widely varying operating conditions. Simultaneous parameter estimation for solvent based CO_2 capture systems has been described and a methodology has been presented using chemical process simulators embedded in a DFO framework (Chinen et al. 2018). The focus of this paper is to extend that work by implementing a generic framework that will support the approach within the IDAES PSE framework, which provides a modular process modeling framework on top of the Pyomo algebraic modeling language (AML) (Hart et al., 2011; Hart et al., 2017).

The novelty of the approach is that it facilitates large-scale parameter estimation for hundreds of parameters at multiple scales embedded in complex process models and submodels in a way that is not generally possible with commercial process simulators.

Depending on the complexity and robustness of the process models, over 100 parameters, thousands of experimental data sets, and several hundred thousand equality and inequality constraints can be handled through decomposition methods. The upper limit of this methodology has yet to be identified.

The IDAES framework provides basic modular flowsheeting features and a model library allowing optimization problems to be implemented much more quickly than in a general AML. The benefit of this approach enables the process model and all submodels to be implemented in a common framework where all variables and parameters are easily accessible. In addition, full derivative information is available enabling the use of state-of-the-art optimization solvers and decomposition methods through Pyomo. These features allow the problem to be implemented in a more straightforward way and solved with significantly reduced computation times and superior optimality conditions. The approach presented here can readily solve problems comprising multiple models and submodels while utilizing data from multiple sources and scales.

2. Simultaneous Parameter Estimation

Simultaneous parameter estimation is a technique of regressing parameters of a process model and various interrelated submodels at the same time. This approach allows data from multiple scales and system configurations to be used simultaneously to improve the predictiveness of a model. Features of each coupled sub-model are better identified over a wider domain by this approach. The simultaneous parameter estimation problem formulation used in this work is given by Eq. 1.

$$\min \sum_{i \in R} \sum_{j \in S_i} \frac{\sum_{k \in T_i} \left(\hat{y}_{i,j,k} - y_{i,j,k} \right)^2}{\sigma_{i,j}^2} \tag{1}$$

$$f_{i,k}\left(\theta, x_{i,k}, \hat{y}_{i,k}, z_{i,k}\right) = 0, \quad \forall\, i \in R, k \in T_i$$

Where: R = Data sets (e.g., packed column data and wetted wall column data)
S_i = Set of output measurements for data set i
T_i = Set of experiments in data set i
$\hat{y}_{i,j,k}$ = Predicted output for measurement j for experiment k in set i
$y_{i,j,k}$ = Measured output for measurement j, for experiment k in set i
$f_{i,k}$ = Model equations for experiment k in set i
$x_{i,k}$ = Measured inputs for experiment k in set i
$z_{i,k}$ = Other model variables for experiment k in set i
θ = Model Parameters (same across all experiments)
$\sigma_{i,j}^2$= Variance of measurement j in data set i (for scaling)

Challenges with the simultaneous parameter estimation approach arise due to the size and complex nonlinear nature of the problem. The number of equations to be solved becomes large when considering large data sets, due to the optimization problem containing equations for a full process model for each experiment. This requires the models to be robust over a wide range of conditions.

To overcome these challenges, the IDAES framework was used for this work. The PySP module in Pyomo provides several decomposition techniques for stochastic programming (Watson et al., 2012). The parameter estimation problem is equivalent to a 2-stage stochastic programming problem with no recourse. In the 2-stage stochastic programming problem, a set of scenarios are generated with different parameter values

based on parameter uncertainty distributions, and the weighted sum of scenario objectives is optimized. First-stage variables must be the same for each scenario, while second-stage variables can be adjusted in each scenario to provide recourse against uncertainty. This problem can be decomposed by solving each scenario separately using one of several algorithms to iteratively converge to a solution. In the case of parameter estimation, each experiment corresponds to a scenario, and the inputs to the experiment correspond to the parameter values for a scenario. The parameters being estimated correspond to first-stage variables, and there are no second-stage (recourse) variables.

3. Case study: Amine solvent-based CO_2 absorption

CO_2 capture using aqueous amines is a well-established technology, and a significant amount of bench- and pilot-scale data is available for monoethanolamine (MEA), making it an ideal test case for a parameter estimation framework. This work is applicable to other solvent system as well as other types of process models. Data from two systems are used in this study (Figure 1): (a) a pilot-scale packed column with intercooling (data from the National Carbon Capture Center) and (b) a bench-scale isothermal wetted wall column (WWC) system (Dugas, 2009).

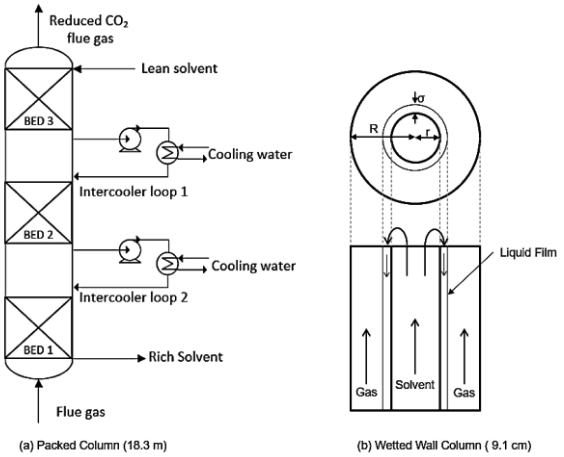

Figure 1: Packed Column and Wetted Wall Column

A 1D rate-based packed absorber column model is implemented. This model is similar to the model of Morgan et al. (2018) with three main differences: (1) an enhancement factor approach is used to characterize the mass transfer resistances through the liquid and gas films as opposed to a rigorous two-film model, (2) the NRTL model is used for calculating the activity coefficients instead of the electrolyte-NRTL (eNRTL) model, and (3) a simplified heat of absorption model is used. A simpler model is used in this work compared to Morgan et al. (2018), and work is ongoing to implement the fully detailed model. The WWC model is developed by considering a column equivalent to the annular space, with appropriate models for the interfacial area and liquid holdup.

Parameters are estimated for the reaction rate constants (A and E in Eq. 2), the vapor phase mass transfer coefficient (C_v, a, and b in Eq. 3), the liquid mass transfer coefficient (C_l in Eq. 4), and the interfacial area (β_1, β_2, and β_3 in Eq. 5) models. The effective interfacial area correlation is applied to the packed-bed model only.

$$k_i = A_i \exp\left(\frac{E_i}{T}\right), \qquad i\epsilon\{\mathrm{H_2O}, \mathrm{MEA}\} \tag{2}$$

$$k_{v,i} = C_v D_{v,i} \left(\frac{a}{\varepsilon_v d_h}\right)^{1/2} \left(\frac{u_v \rho_v}{a \mu_v}\right)^{a} \left(\frac{\mu_v}{\rho_v D_{v,i}}\right)^{b} \tag{3}$$

$$k_{l,CO_2} = 12^{1/6} C_l \left(\frac{u_l}{\varepsilon_l}\right)^{1/2} \left(\frac{D_{l,CO_2}}{d_h}\right)^{1/2} \tag{4}$$

$$\left(\frac{a_e}{\beta_1}\right)^{\beta_2} = {u_l}^{\beta_3} \left(\frac{\rho_l}{\sigma_l}\right) \tag{5}$$

The objective function is given by Eq. 1. The WWC data set is comprised of 35 experiments where CO_2 flux between the vapor and liquid phase is measured. The packed column data set has 17 points where CO_2 capture fraction is measured. The problem is solved using the IPOPT NLP solver (Biegler and Zavala, 2009).

4. Results

The optimization results are presented in Table 1. The initial parameter values were taken from Aboudheir et al. (2003) (Eq. 2) and Morgan et al. (2015) (Eqns. 3-5). The WWC model R^2 was 81.3 % for the initial and 98.3 % for the optimal parameter values. The packed column R^2 was 75.2 % for the initial and 83.3 % for the optimal parameter values. The root mean squared error is 6.4×10^{-5} mol/s/m^2 for the WWC and 1.7 percentage points of CO_2 capture for the packed column models. Some parameters were found to be on their bounds; however, widening the bounds did not yield significant improvement to the fit. Capabilities for parametric uncertainty analysis is currently being developed and will be utilized in future work.

Table 1: Fitted parameters

Model	**Kinetics**				**Mass Transfer**				**Interfacial Area**		
Parameter	A_{H2O}	E_{H2O}	A_{MEA}	E_{MEA}	C_v	a_v	b_v	C_l	β_1	β_2	β_3
Init. value	4.55	3,287	4,610	4,412	0.357	0.750	0.333	0.500	157.0	8.612	1.333
Opt. value*	4.00	4,100	4,800	4,000	0.500	0.495	0.250	0.504	15.0	7.235	-0.50

Figure 2 shows parity plots for the flux in the WWC case and CO_2 capture fraction in the packed column case. The residuals for the packed bed case appear to show a trend suggesting that there are some phenomena not accounted for in the model.

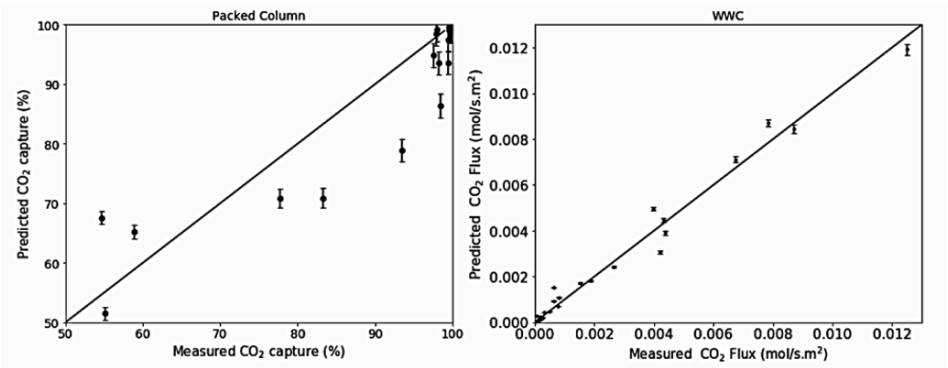

Figure 2: Parity Plots (a) Packed Column, (b) WWC

The packed column temperature profiles in Figure 3 give some insight into this discrepancy among the model used in this work, the Morgan et al. (2018) model, and the plant data. The error bars represent the measurement accuracy based on the type of thermocouples used in the pilot plant. While at low-loading, the temperature profiles agree well, there is a higher discrepancy at high loading. These deviations are within the tolerances given the approximations in the vapor-liquid equilibrium (VLE), mass transfer, and enthalpy models. The e-NRTL model is expected to improve precision by improving the VLE predictions for CO_2 high loading conditions compared with the NRTL model used in this work (Luo et al., 2015; Morgan et al., 2017).

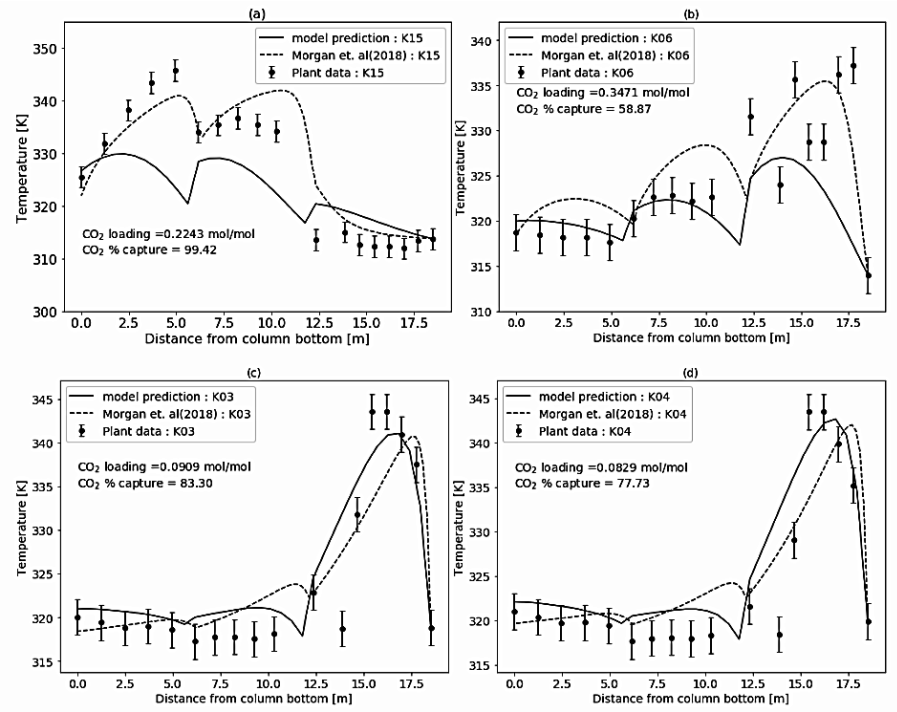

Figure 3: Packed Colum Temperature Profiles, this work, National Carbon Capture Center Data, and Morgan et al. (2018)

The parameter estimation problem in this work consisted of 71,768 constraints, many of which are highly non-linear. The computation time required to solve the optimization problem was 206 seconds on an Intel Xeon E3-1505M CPU, which is a substantial improvement compared with the previous parameter estimation framework (Chinen et al. 2018), which took about 36 hours to run on a similar machine.

5. Conclusions

A new framework for simultaneous parameter estimation has been demonstrated using a system of industrial significance. The novelty of this system is that it facilitates simultaneous parameter estimation for parameters in multiple submodels embedded in complex process models, which is not generally possible with commercial process simulators. The IDAES framework provides basic modular flowsheeting features and a model library allowing optimization problems to be implemented much more quickly than in a general AML. The result showed a significant improvement in computational

efficiency compared with previous methods presented by Chinen et al. (2018), which used a process simulator embedded in a derivative free optimization framework. It is expected that this will lead to the ability to solve larger, multiscale parameter estimation problems with large amounts of data. Future work will provide enhancements to the parameter estimation framework to enable uncertainty both in parameter estimates and measurements to be considered.

Novel MILP-based iteration approach for the equation-oriented simulation and optimization of distillation column

Kunru Yang, Ming Pan, Bingjian Zhang, Qinglin Chen*

School of Chemical Engineering and Technology / Guangdong Engineering Center for Petrochemical Energy Conservation, *Sun Yat-Sen University*, *Guangzhou 510275, China*
chqlin@mail.sysu.edu.cn

Abstract

The material balance, equilibrium, summation and heat balance (MESH) equation describing a distillation column is highly nonlinear, making it very difficult to optimize. A new solution strategy is proposed based on the iterative mixed integer linear programming (MILP) method introduced in the earlier work (Pan et al., 2013). Rigorous phase equilibrium is reformulated by using high dimensional model representation (HDMR), which retains high accuracy (less than 1% of relative deviation) compared with the original thermodynamic models provided by Aspen Plus. Then, the MILP-based iteration approach is utilized to solve the resulting nonlinear programming problems. To validate the proposed approach, a benzene-toluene-o-xylene (BTX) distillation column model is carried out and compared with the results obtained from Aspen Plus. More importantly, the optimization of capital and operating expenses of the system can be achieved based on the iterative MILP-based method which yields an objective of 11.08 with elapsed time of 400 seconds.

Keywords: Simulation, Optimization, Mixed Integer Linear Programming (MILP)–based iteration, Distillation Column

1. Introduction

MESH equation is a system of highly coupled nonlinear equations which is usually solved using Newton or quasi-Newton-type methods. As they are locally convergent, initial guesses that are close enough to the solution are required. Recently, the pseudo-transient continuation (PTC) method was proposed by (Pattison and Baldea, 2014). Through constructing pseudo-transient processes and converting algebraic equations into differential algebraic equations (DAE), the convergence basin of the original model was largely extended.

Traditionally, the design of distillation column is firstly estimated by short-cut method based on simplifying assumptions such as constant molar overflow and constant relative volatility, followed by verification using rigorous tray-by-tray methods. As a result, an optimal synthesis requires a lot of simulations and sensitivity analysis. Another simulation based approach is to combine process simulators with genetic algorithm (GA) reported by (Bravo et al., 2010). The search for optimal synthesis is formulated as a multi-objective problem considering both capital and operating cost.

Besides simulation based approaches, some equation-oriented methods based on mathematical programming were also successfully implemented. (Viswanathan and

Grossmann, 1990) formulated the optimization of the distillation column described by MESH equations as a MINLP problem, which was solved using the outer approximation algorithm. Later, in order to handle the non-existent tray, (Yeomans and Grossmann, 2000) developed generalized disjunctive programming (GDP) model. However, (Dowling and Biegler, 2014) proposed bypass efficiency (ε^j) method, which replaces the stage number by using the summation of continuous variables ε^j. Recently, (Pattison et al., 2016) presented a reformulation of equilibrium tray model as a pseudo-transient DAE system and integrated with previously developed time-relaxed-based optimization algorithm.

The rest of this paper is structured as follows. The reformulation of the thermodynamic model using HDMR method is first introduced in Section 2. In Section 3, the distillation column super structure is illustrated, followed by a detailed MINLP problem statement. Further, an iterative MILP optimization procedure is addressed in Section 4. Finally, Section 5 presents a case study to demonstrate the validity and efficiency of the proposed approach.

2. Thermodynamic model reformulation using HDMR

In MESH equations, the rigorous thermodynamic model describing the phase equilibrium and enthalpy are the most complicated because of the high nonlinearity. Generally, the k value is a function of temperature, pressure, liquid composition and vapor composition, while the enthalpy is a function of temperature and liquid composition or vapor composition. The relations are expressed as follows:

$$k_i = f(T,\ P,\ x_i,\ y_i), \quad H^L = f(T,\ x_i), \quad H^V = f(T,\ y_i) \tag{1-3}$$

To simplify the model while maintain high accuracy, the HDMR method is utilized. In HDMR, the output variable is represented as the summation of a series of functions of input variables. The relation is as follows:

$$y = f_0 + \sum_{i=1}^{N} f_i(x_i) + \sum_{i=1}^{N}\sum_{j=i+1}^{N} f_{ij}(x_i, x_j) + \cdots + f_{12\ldots N}(x_1, x_2, \cdots x_N) \tag{4}$$

N is the number of input variables. Subscript i and j denotes specific variable x. f_0 is the average value of all $f(x)$.

In most of cases, functions containing more than two correlated variables can be omitted. Thus, the simplified form is as follows:

$$y = C + \sum_{i=1}^{N}\sum_{k=1}^{K} A_{i,k} \times x_i^k + \sum_{i=1}^{N}\sum_{j=i+1}^{N}\sum_{k=1}^{K}\sum_{n=1}^{K} B_{i,j,k,n} \times x_i^k \times x_j^n$$
$$i, j \in \{1, 2, 3, \cdots, N\} \qquad k, n \in \{1, 2, 3, \cdots, K\} \tag{5}$$

C is a constant. $A_{i,k}$ and $B_{i,j,k,n}$ are the first and second order coefficients. k and n denote the power of the variables and K is the maximum power.

The parameters of the above model are obtained by feeding the data set to a linear programming model in GAMS, which is formulated to minimized the total deviation. Let y_d denote the calculated values and y_d^* be the real values. D represents the number of the data sets. The objective function is shown as follows:

$$\min \sum_{d}^{D} \left| y_d - y_d^* \right|, \quad d \in \{1, 2, 3, \cdots, D\} \tag{6}$$

Besides, the maximum allowable deviation is added as a constraint:

$$\left| y_d - y_d^* \right| \le \delta, \quad d \in \{1, 2, 3, \cdots, D\} \tag{7}$$

3. Distillation column superstructure and MINLP model

Figure 1 shows the column representation, which is similar to the approach used by (Yeomans and Grossmann, 2000). Three binary variables yf , yr and $mref$ are introduced to determine the feed tray, reflux tray and whether the tray is existent. The trays that are above the reflux tray can be seen as non-existent.

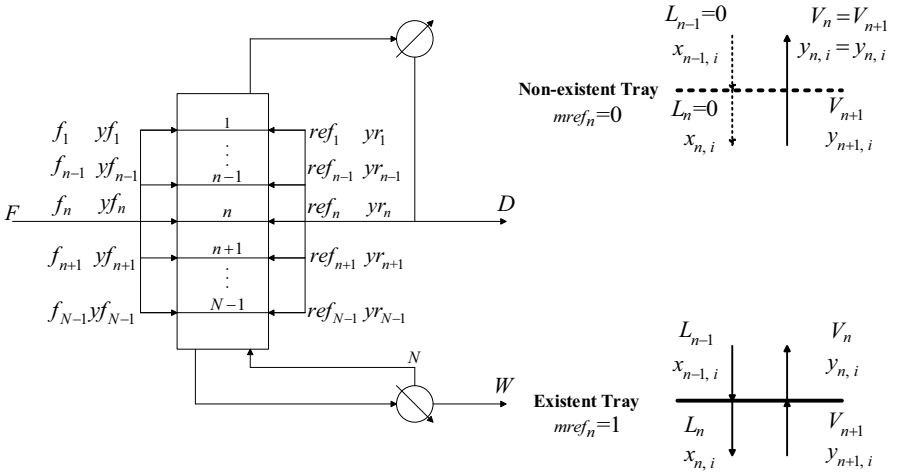

Figure 1: Column superstructure representation

Consider the following set definitions for the model: S is the set of stages n in the column. I represents the set of components i . B is the subset of trays $n \in S$ corresponding to the bottom stage and the reboiler. T is the subset of trays $n \in S$ corresponding to the first tray. As the trays of the column ($n = 1,\ 2,\ \cdots,\ N$) from top to bottom, the top stage is tray 1 and the reboiler is number N .

The objective of the problem is to minimize the capital and operational expenses represented by the summation of the number of stages NT and reflux ratio rr (Viswanathan and Grossmann, 1993), as shown in Eq.(7).

The feed condition, distillate rate and reflux ratio are specified. Eqs.(8)-(14) are representative of mass balance, phase equilibrium, summation and heat balance. Eq.(15) is the mass balance of feed and products. Eqs.(16)-(18) are used to calculate the reflux rate and reflux temperature. Eq.(19) represents the constraint that the reflux tray must be above the feed tray. Eq.(20) is combined with Eq.(21) to determine whether tray n is existent. Eqs.(22)-(25) ensured that the liquid flowrate is set to 0 while the vapor output flowrate and composition are equal to that of input. Eqs.(26)-(31) are the constraints that feed and reflux enter one and only one tray. The modelling equations are as follows:

$$\min \ z = rr + NT \tag{7}$$

$$f_n x_i^{feed} + ref_n x_i^{reflux} + L_{n-1} x_{n-1,\,i} + V_{n+1} y_{n+1,\,i} - L_n x_{n,\,i} - V_n y_{n,\,i} = 0,\ n \in S\ \ i \in I \tag{8}$$

$$k_{n,\,i} = f(T_n,\ P_n,\ x_{n,\,i},\ y_{n,\,i})^{HDMR},\ y_{n,\,i} - k_{n,\,i} x_{n,\,i} = 0,\ n \in S\ \ i \in I \tag{9-10}$$

4. MILP model and iteration algorithm

In the above model, Eqs.(8)-(10), Eq.(12), Eqs.(13)-(14) and Eq.(16) are nonlinear, among which, Eqs.(8)-(10), Eqs.(13)-(14) and Eq.(16) are converted to linear equations using first order Taylor series expansion, while the enthalpy H_n^{L} and H_n^{V} are updated as parameters after solving MILP in each iteration, and thus Eq.(12) is converted to a linear equation. Due to the strong coupled nature of MESH equations, some equations will not hold during iterations. Thus Eqs.(7)-(12), Eq.(16) and Eq.(17) are relaxed by adding slack variables. For non-existent tray, the equilibrium and the summation equations cannot be satisfied together and another couple of slack variables are added to Eq.(9) and take on non-zero value for non-existent tray.

As described in the earlier work (Pan et al., 2013), the objective is formulated to minimize the sum of the infeasibility (the slack variables) in the above equality constraints and the absolute differences between initial and updated variables, subject to a certain capital and operating expenses z'. VS denotes the sum of slack variables and ΔV denotes the absolute difference between initial and updated values of the variables. The equations are shown as follows:

$$\min\ VS + \Delta V,\quad z \leq z' \tag{32-33}$$

The iteration algorithm was successfully implemented in maximizing the retrofit profit of HEN, which was given in details in (Pan et al., 2018). The procedure consists of two

loops: in the first loop, a feasible solution is found under a certain capital and operating expenses z'; in the second iteration loop, an initial z' is first estimated and a feasible solution is obtained within a certain upper bound of z', which will decrease gradually until the optimal value is found.

5. Case study

The base case is presented in Figure 2. The Wilson model is selected for the calculation of liquid activity coefficients. In the system of low pressure, the fugacity coefficient is regarded as 1. As the column pressure is also fixed at 1 bar with no pressure drop, the k value is a function of temperature and liquid compositions. The data sets for HDMR are combinations of different temperatures and compositions that are chosen uniformly within a certain range, which is estimated in advance. In this case, the temperature is ranging from 90 ℃ to 150 ℃ and the molar fractions is set between 0 and 1. With the intervals of temperature (2 ℃) and molar fractions (0.02), over 40,000 groups of data are generated using Aspen Properties Excel Add-in. The HDMR parameters are obtained by feeding the data sets to the proposed LP model (Eqs. (5)-(7)) in GAMS. In this case, the relative deviation is less than 1 %.

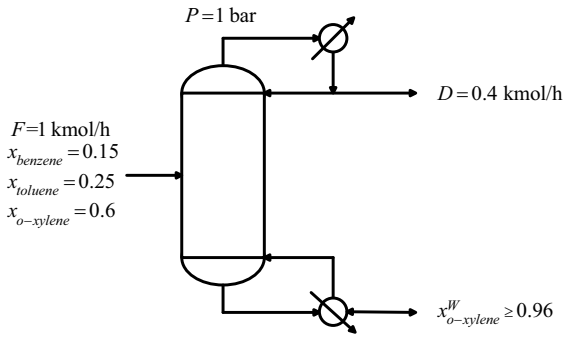

Figure 2: Column Specifications

The aforementioned approaches in Sections 3 and 4 were performed in GMAS 24.4 on an Intel Core i7 processor running at 4.2 GHz. The solvers Antigone, DICOPT and CPLEX are utilized to solve the MINLP and MILP problems.

Table 1: Comparison of Results and Model Statistics

Method	Results	CPU Time(s)	Continuous Variables	Binary Variables	Equations
MILP Iteration	11.08	400	3930	90	3778
MINLP-Antigone	11.08	3600	1639	86	1506
MINLP-DICOPT	11.285	100	1639	86	1506

As shown in Table 1, with the MILP approach, a relatively better objective can be achieved when compared to that obtained by MINLP-DICOPT although the global optimality is not guaranteed. And the time cost is more reasonable than that of MINLP-Antigone approach. At the optimum, the stage number is 8, the feed is at the fourth stage from top and the reflux ratio is 3.08. Finally, the temperature, pressure, flowrate and heat load profiles are compared with Aspen Plus simulation results, and the deviation of major variables are less than 1%, as shown in Table 2. It also can be seen that, the error of toluene (MILP) in bottom product is 11.1 %, which does not affect the accuracy of the MILP results as the key composition in the bottom product is o-xylene with 0.5 % of error compared with the Aspen Plus simulation.

Table 2: Comparison of simulation results of Aspen Plus and MILP approach

	Variables	Values		
Input	Feed composition (benzene, toluene, o-xylene)	0.15/ 0.25/ 0.6		
	Total Stage Number/ Reflux Ratio	8/ 3.08		
	Distillate Rate (kmol/h)	0.4		
	Feed Rate(kmol/h)/ Temperature(℃)	1/ 90		
	Colum Pressure(bar)	1		
Output	Bottom Product Compositions (benzene, toluene, o-xylene)	Aspen Plus: 0.000/ 0.045/ 0.955	MILP approach: 0.000/ 0.040/ 0.960	Error (%): 0/ 11.1/ 0.5
	Top/Bottom Temperature(℃)	96.5/ 141.5	96.4/ 143.1	0.1/ 0.98
	Condenser/Reboiler Duty(kW)	15.3/ 17.4	15.3/ 17.5	0.0/ 0.5

6. Conclusions

The simulation and optimization of distillation column is a challenging task due to the highly coupled nature and high nonlinearity of MESH equations concerning the thermodynamic model. In this work, the equations describing the phase equilibrium and enthalpy model are reformulated using HDMR method and further the nonlinear equations are linearized using first order Taylor series expansion. A MILP-based iterative method has been applied for the equation-oriented simulation and optimization. The case study of BTX separation column has proven that the HDMR reformulation remain high accuracy of the rigorous thermodynamic model, and the proposed approach is more efficient than the original MINLP model.

Abstract

The prominence of biofuel research is growing, as do the global energy policies on renewable energy technologies. Accurate process design and simulation is required when evaluating technological and market capabilities of large scale, novel, fuel production processes. Thermochemical decomposition employed in various biofuel production routes (pyrolysis, liquefaction, etc.) yields complex liquid mixtures (bio-crudes) containing numerous compounds. Process simulation of such processes must accurately represent the physical, thermodynamic and chemical properties of bio-crudes, while reducing complexity to a point where it can be handled by a process simulator in a time effective manner. In this work, a software employing automated modelling of bio-crudes based on raw experimental data, has been developed. The program output is a ready-to-use reduced mixture, including all product phases. The mixture is in mass balance with the Proximate and Ultimate analyses of the feedstock biomass material. As there are many approaches to bio-crude modelling, the novelty of this method lies in the combination of minimization of the number of components needed and the minimization of the level of artificiality introduced in the system. Automation of the method allowed for fast reduction and optimization of seven experimental data sets which were subsequently validated by process simulation.

Keywords: Biocrude modelling, Biofuel, Thermochemical decomposition, Process simulation.

1. Introduction

While fossil fuels still, without precedent, remain the life stream of modern societies, their finite nature is becoming imminent. Coupled with the large greenhouse gas surplus their consumption is producing, it is evident that a new energy carrier will soon have to replace them. These concerns gave rise to utilization of biomass, and in recent years especially, aquatic biomass for biofuel production (i.e., microalgae and macroalgae)[1,2]. Other than the obvious advantage that aquatic biomass does not require land for cultivation and that the available area is far larger, marine biomass can absorb carbon dioxide more effectively (6–8 % photosynthetic efficiency) than any terrestrial biomass (1.8-2.2 % photosynthetic efficiency)[3]. Thermochemical conversion processes of biomass offer the most direct conversion, when compared to biochemical. In them, product phase distribution

and composition are open to modifications with varying process parameters such as temperature, pressure and heating rate[4–6]. Accurate process simulation of thermochemical decomposition of biomass, such as pyrolysis is challenging due to the complex nature of the generated products. Pyrolysis liquid products or bio-crudes are complex organic mixtures containing up to hundreds of compounds[7,8], mostly oxygenated hydrocarbons, organic acids, and other organics[7] with varying molecular masses and boiling points. Process simulators, such as Aspen Plus (Aspen Tech, Cambridge, MA, USA), which was used in this work, are equipped with databases containing compounds with well-defined properties[9]. Often, large number of experimentally identified compounds cannot be found in the databases or if they can be found, their properties cannot be well defined. Another common issue in simulation of bio-crudes is defining a mixture with a minimum number of compounds, which, in all respects (chemical composition, density, heating value, etc.), accurately represents the complex bio-crude mixtures[10–12]. The reduced mixture which is representative of the liquid product, together with products from other phases, must be in atomic mass balance with the feedstock. One approach to these challenges is modelling the pyrolysis kinetics using key biopolymer components[12,13]. Although this approach possesses predictive capabilities, it lacks in-built minimizing strategy of components and does not fully employ experimental data of the product characterization. Another approach is the one of Jones et al.[10], and Bonalumi[14] where a set of pseudo-components is defined from the available components in the database of the process simulator, manually mixing-and-matching to tune the properties of the reduced mixture to the original bio-crude. This could save the user time in constructing the reduced mixture, but results in considerable reduction of accuracy. Similar approach was employed by Cruz et al.[15] where real components and pseudo-components were combined, with the ultimate goal of reproducing the true boiling point (TBP) curve of the bio-crude. Although some real components were used, the total number of components in the reduced mixture was quite large (40 components). Finally, Carrasco et al.[16] manually picked components, which are known to be present in both the bio-crude and the process simulator database. This approach is perhaps the most accurate of and closest to the true bio-crude mixture. However, it does not utilize raw characterization data, and requires a great deal of tedious manual reduction. It also requires extensive a priori knowledge about bio-crude composition making its applicability and accuracy questionable. All the above-mentioned approaches introduce a degree of artificiality and bias to the process simulation.

In this work, we aimed to develop a widely applicable, user-friendly and fully automated reduction method, which directly utilizes raw experimental data. Components which comprise the reduced mixture for bio-crude simulation, are derived from GC-MS data. They are thereby unbiased, and accurately represent the original mixture over key characterization parameters while their number is minimized. As the time required for the manual execution of this method and similar methods is considerable (up to two hours per dataset on average), a software has been developed to automate the procedure. The outputs of the software, in a spreadsheet form, are the reduced mixture representing the liquid pyrolysis product, which is a ready-to-use process simulator input, in which the atomic composition of the biomaterial (feed) is in optimal mass balance with the complete set of products of thermochemical decomposition. This alleviates the need for the time consuming manual reactor balancing.

2. Materials and methods

2.1. Datasets and experimental conditions

The method was tested on seven datasets (Table 1) originating from published works by Choi et al[17–19]. In them, brown macroalgae *Saccharina japonica* was subjected to pyrolysis for investigation in biofuel application. Pyrolysis was performed in fixed- and fluidized-bed reactors under various process conditions (temperature, heating rate, fluidizing velocity, etc.). Proximate and ultimate elemental analyses of the solid feedstock as well as GC-MS analyses of the liquid products were performed for characterization. The higher heating values (HHV) of the feedstock and bio-crudes were calculated using models by Channiwala et al.[20] and Dulong-Bertolet[21], respectively.

2.2. Key concepts of the reduction method

Raw experimental data obtained using GC-MS represent the core of the developed reduction method. GC-MS analysis provided: compound IUPAC names, retention times (min), normalized peak areas (%), and chemical group. BPs and CAS numbers were taken from external literature sources (Chemical Abstracts Service, Columbus, OH, USA). Objective of the reduction method is maximum reduction of the number of components from the original (complex) mixture, while minimizing the difference of key parameters that are points of comparison. Key parameters chosen to compare characteristics and control the level of reduction between original and reduced mixtures were: (i) relative ratios of components in specific chemical groups, (ii) weighted averages of chemical group molecular masses (MM), (iii) weighted averages of chemical group boiling points (BP), and (iv) total atomic amounts of all chemical groups within a single phase. Total amount of atoms (C, H, N, O; kmol) from the entire mixture was calculated from the sum of relative amount contributions from every component in the mixture. Subsequently, components from the same chemical group are identified and classified into subgroups using a threshold retention time value for their discrimination. The threshold retention times for each compound group were optimized using a Genetic Algorithm[22] for a minimum number of compounds within a mixture, with maximum absolute difference in weighted average MM and BP difference as a constraint function. Maximum BP absolute difference of 30°C was taken as a limit beyond which components in the same chemical group are viewed as not similar. Finally, components viewed as structurally similar were reduced. Components with the largest normalized peak area were taken as a representative for a subgroup while others are eliminated. The values of normalized peak areas from eliminated components are then added to the normalized peak area of the remaining component, thus increasing it. Applying this to all chemical groups within the mixture, the total number of components is reduced while the parameters do not considerably change, when compared to raw data (Figure 1).

Table 1. Experimental datasets and their conditions

#	Pyrolysis temperature / reactor type / pre-treatment
1	350 °C / fluidized bed / water-washed
2	375 °C / fluidized bed / water-washed
3	400 °C / fluidized bed / water-washed
4	425 °C / fluidized bed / water-washed
5	450 °C / fluidized bed / water-washed
6	375 °C / fluidized bed / no pre-treatment
7	450 / fixed bed / acid-washed

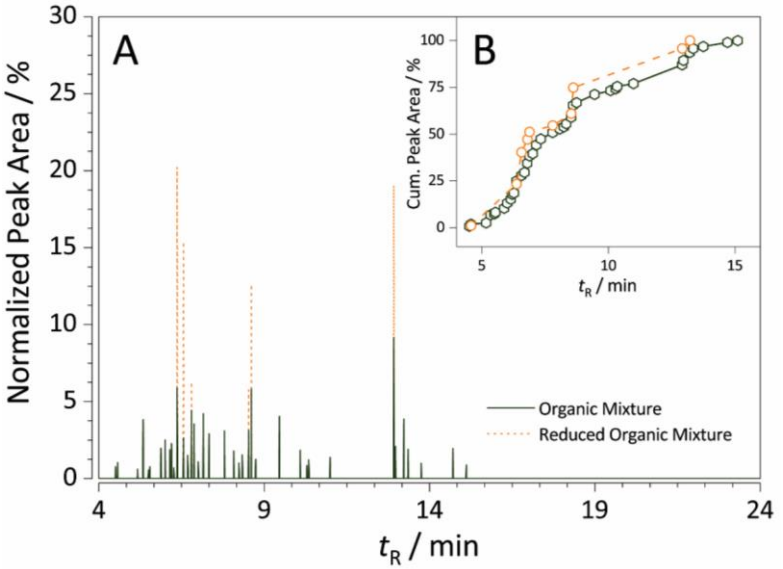

Figure 1. Exemplary depiction of reduction method on the organic phase of dataset 3: A) a normalized GC-MS chromatogram, B) comparison of trends of cumulative peak area over retention time. Experimental organic phase is denoted in full line, while reduced organic phase is denoted in dashed line.

2.3. Automation, performance evaluation and validation of the reduction method

The reduction method and reactor balance calculations were automated in Matlab 2017a (Mathworks, Sherborn, MA, USA). To evaluate the performance of the reduction method, an index, the reduction factor was introduced. It is defined as the ratio of the total number of components in the organic and aqueous phase identified by GC-MS and the total number of components in the reduced mixture. Results of the program (reduced mixtures and reactor balances) were validated by simulation in Aspen Plus 10 (Aspen Tech, Cambridge, MA, USA) at a scale of 100 tonnes per hour of dry seaweed. In order to test the statistical significance of the differences between the experimental and simulated data, two sample *t*-test and one-way analysis of variance (ANOVA) with the Tukey test[23] were used as means of further validation in OriginPro2017. All the statistical hypotheses were tested at a significance level of 95 % ($\alpha = 0.05$).

3. Results and discussion

Table 2. Reduction method performance evaluation

Dataset	1	2	3	4	5	6	7
	Number of compounds						
Experimental*	41	48	64	63	58	55	120
Reduced mixture	15	18	15	16	15	17	22
Reduction factor	2.73	2.67	4.27	3.94	3.87	3.24	5.45
Runtime / min	2.81	3.09	3.5	3.45	3.3	3.19	5.11

3.1. Reduction evaluation parameters

The developed software has reduced seven mixtures by a factor no less than 2.6, while the maximum reduction factor was 5.5 (average 3.7, Table 2). Wall-time was measured, and the lowest wall-time was 2.8, while the highest was 5.1 min. The total number of components is reduced while their normalized peak areas are increased in accordance with the reduction method (Figure 1A). Figure 1B depicts the comparison of trends of cumulative peak area in respect to increasing retention time. The trends are in an excellent agreement and are significantly similar ($t = 0.222$; $p = 0.825 > t$ assuming equal variances; $t = 0.232$; $p = 0.820 > t$ not assuming equal variances).

3.2. Comparison of validation parameters

Reduction method was validated on a simulation of a biofuel production process based on pyrolysis of macroalgae *Saccharrina japonica*. For that purpose, the following validation parameters were used: organic phase mass yield (MY), water content (WC), higher heating value (HHV), and chemical energy recovery (ER). From Figure 2A. It can be observed that the results of the simulation, using the reduced mixture, adhere closely to the experimental values with RMSE values of 2.66 %, 2.32 %, 3.24 MJ kg-1 and 0.65 % for ER, MY, HHV, and WC. Besides that, all the differences between mean values of simulated and experimental validation parameters were found to be insignificant ($p = 0.993 > \alpha$, $p = 0.999 > \alpha$, $p = 0.982 > \alpha$, and $p = 1.000 > \alpha$ for ER, MY, HHV, and WC, respectively).

Figure 2B shows various data points with calculated ER for experimental and simulated organic phases in respect to temperature. Arching lines with represent data sets 1-5 (Table 1) from left to right respectively. Two data points below represent data sets 6-7. Simulated values of ER closely follow experimental ER trend for each data set (representing different reaction conditions). Experimental and simulated water contents are depicted in Figure 2C in respect to simulated density.

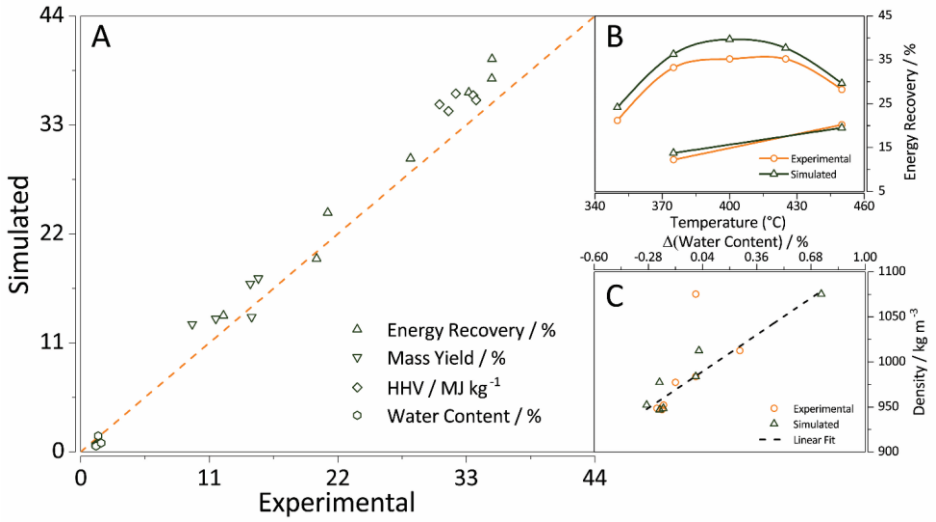

Figure 2. Validation of the automated reduction method. Dependence of A) experimental and simulated validation parameters, B) simulated and experimental energy recovery in respect to pyrolysis temperature, and C) difference in simulated and experimental water content.

4. Conclusions

In conclusion, this is the first time that an automated modelling method for bio-crudes has been developed. It has been tested on seven data sets requiring only 3.5 min wall-time per data set, thereby demonstrating its wide applicability and fast execution. The developed method was validated through process simulation and it has been shown that it produces reduced mixtures, which accurately represent bio-crudes based on statistical inference of parameters commonly valued in biofuel process simulation. Finally, the ease-of-use, wide applicability, execution speed, and accuracy make this methodology a powerful tool in routine biofuel process simulation and design.

Abstract

Continuous manufacturing is an emerging topic in the pharmaceutical industry. To realize continuous manufacturing, quality assurance during processes is essential. To assure the product quality, calibration models are constructed, usually using data that are collected in advance. However, the cost for collection of calibration data is not so small, because model construction is conducted frequently to sustain the model's accuracy. Iterative optimization technology (IOT) is a key technology involving infrared spectroscopy and predicting the concentrations of the pure components in the mixtures. IOT can be a powerful and useful tool, because the concentrations of the pure components in the mixtures, especially active pharmaceutical ingredient, are monitored through the pharmaceutical processes. However, IOT aims, in its original paper, to be applied for the process development step, not for the production step and its accuracy is not reliable enough for monitoring of the manufacturing process. In this work, we propose a method to evaluate quantitatively prediction accuracy for IOT prediction before acquiring the observed mole fractions. Assurance of the prediction accuracy is important as well as construction of accurate models in the actual operation. We estimate the prediction errors of the concentrations using the mixture infrared spectra simulated using Monte Carlo method.

Keywords: Process analytical technology; Applicability domains; Minimal-calibration method; Infrared spectroscopy

1. Introduction

The pharmaceutical industry conducts much research on the continuous processes and online monitoring. The main issue of online monitoring is to assure the product quality at every step in the manufacturing processes. The sensors and quantitative methods for online monitoring are called process analytical technology (PAT). Softsensor is a virtual sensor that enables to monitor variables hard to be observed, such as particle size or the compositions. When predicting active pharmaceutical ingredient (API) content, calibration models that input infrared spectra are employed. However, acquisition of calibration samples usually increases costs of the ingredients and labor for measurements. For instance, API content is measured by high-performance liquid chromatography, which takes hours.

To overcome this problem, iterative optimization technology (IOT), which is based on Beer's law, has been proposed (Muteki *et al.*, 2013). IOT has been shown to predict

concentrations of the pure components in the mixtures from only the pure components' spectra and the mixture spectra with no calibration sample. A wavelength selection method for IOT (WLSEA) (Shibayama, Kaneko and Funatsu, 2016) realizes to predict concentrations stably by IOT. WLSEA requires at least one set of the mixture spectrum and the known composition for the mixture. Therefore, WLSEA-IOT, is a minimal-calibration method in this paper.

Meanwhile, reliability of prediction results can be assessed for predictive models by defining applicability domains (AD) of the models. If the calibration models are constructed, AD is defined as distance from the training samples (Kaneko and Funatsu, 2014). When applying IOT, there is few calibration samples, while the physical model, Beer's law, exists. Therefore, we employed a method like Monte Carlo method, incorporated into Beer's law, for defining AD (Shibayama, Kaneko and Funatsu, 2016). However, it has not been investigated deeply.

The objective of this research is to verify the performance of AD for IOT. We verify whether AD, computed by Monte Carlo method, functions well or not. We apply AD to the binary mixtures that consist of water and acetic acid.

2. Method

2.1. Iterative optimization technology

Iterative optimization technology (IOT) (Muteki *et al.*, 2013) is a calibration-free method based on Beer's law that expresses the linearity between concentrations and absorbances of the pure components in the mixture. Beer's law is incorporated into optimization algorithm in the IOT framework. IOT is carried out by solving the following minimization problem:

$$\min_{r_1,r_2,\ldots,r_c} \sum_{j=1}^{v} \left| x_{\mathrm{mix},j} - \sum_{i=1}^{c} r_i x_{\mathrm{pure},i,j} \right|^2, \quad \text{such that} \quad 0 \le r_i \le 1, \sum_{i=1}^{c} r_i = 1, \tag{1}$$

where i denotes the index of the pure component, c denotes the number of the pure components, j denotes the index of wavelength, v denotes the number of wavelengths, r_i denotes the mole fraction of i, $x_{\mathrm{mix},j}$ denotes the observed absorbance of the mixture at wavelength j, and $x_{\mathrm{pure},i,j}$ denotes the absorbance of i at j.

2.2. Wavelength selection based on excess absorption

Wavelength selection based on excess absorption (WLSEA) is introduced by the authors (Shibayama, Kaneko and Funatsu, 2016). WLSEA eliminates wavelengths where large noises or large spectral changes because of molecular interactions are observed. IOT provides good performance in prediction of mole fractions if the linear relationship between the mole fractions and the spectra of the pure components. To improve prediction accuracy of IOT, WLSEA eliminates wavelengths where the linear relationship does not held.

The prediction method incorporating WLSEA into IOT is called WLSEA-IOT, which is a minimal-calibration method because WLSEA uses at least a set of the mole fractions of the pure components and the mixture spectrum. WLSEA-IOT shows good performance for simple mixtures.

2.3. Estimation of prediction errors of mole fractions

Let the absorbance of the simulated mixture spectrum at wavelength j be $x_{\mathrm{mix,sim},j}$ and the vector of the simulated mixture spectrum be $\boldsymbol{x}_{\mathrm{mix,sim}}=(x_{\mathrm{mix,sim},1},\ x_{\mathrm{mix,sim},2},\ \ldots,x_{\mathrm{mix,sim},v})$. Those are provided through Monte Carlo simulation as follows:

$$\boldsymbol{x}_{\mathrm{mix,sim}} = \sum_{i=1}^{c} r_i \boldsymbol{x}_{\mathrm{pure},i} + k\boldsymbol{e}, \quad \text{such that} \quad e_j \sim N\left(0, s_j^2\right),\ k = 1,2,3,\ldots, \tag{2}$$

where e_j denotes the measurement noise at wavelength j, and s_j denotes the standard deviation, k denotes a factor to scale the measurement noise across wavelengths. k assumes values from 1 to 15 in this paper. The measurement noise e_j follows a normal distribution with mean zero and standard deviation s_j. s_j^2 in Eq.(2) is calculated from the training samples whose mole fractions are known.

Substitute r_i in Eq. (2) for those of training samples. After simulating the observed mixture spectra, WLSEA-IOT is applied for those mixture spectra. The predicted mole fractions have the possible prediction errors of the pure components under the possible measurement noise in $\boldsymbol{x}_{\mathrm{mix,sim}}$.

2.4. Indicator for the assessment of the prediction errors

We employ the prediction errors for the mole fractions and the mixture spectra that are both observed and simulated. The prediction errors of the mole fractions are called mean absolute error (MAE). The indicator to estimate the prediction errors is called root mean square error (RMSE). RMSE is employed for the errors of the mixture spectra because it is the objective function in Eq.(1), which is related to the prediction errors of the mole fractions.

Both indicators are defined as follows:

$$MAE = \frac{1}{c}\sum_{i=1}^{c}\left|r_{obs,i} - r_{pred,i}\right|, \quad RMSE = \sqrt{\frac{1}{v}\sum_{j=1}^{v}\left|x_{mix,j} - x_{mix,pred,j}\right|^2}, \tag{3}$$

where $r_{\mathrm{pred},i}$ and $x_{\mathrm{mix,pred},j}$ denote respectively the predicted mole fractions of the pure component i and the predicted mixture spectrum at the wavelength j, based on Beer's law.

Table 1. Hyper-parameters for SG filter

Polynomial order	Differentiation order	Window size (half)
1	0	20

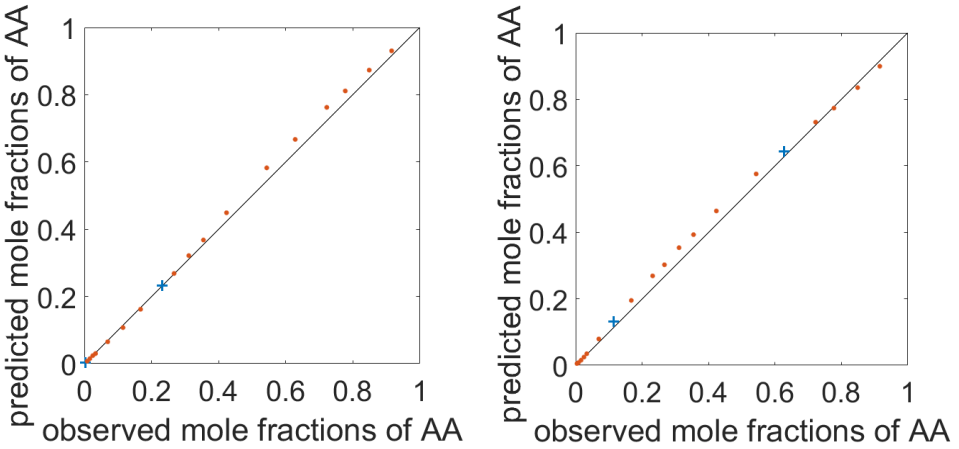
3. Case study

We used the binary liquid mixtures that consist of water (H_2O) and acetic acid (AA). The number of mixtures is nineteen. Our ultimate goal is to predict concentrations of API in the actual process, assuring the model's accuracy. In this study, we started with the simple mixtures to verify that the concept of AD works properly. The spectra of the mixtures showed the strong nonlinear relationship between the absorbances and the mole fractions caused by spectral changes because of water's molecular interactions.

We applied Savitzky-Golay filter (Savitzky and Golay, 1964) (SG filter) with the parameters shown in Table 1 to reduce the effect of noise and baseline shift. The hyper-parameters for SG filter was determined as the prediction errors of the mole fractions of AA was minimized using all samples for WLSEA-IOT training.

Prediction using WLSEA-IOT was carried out with the two sets of training samples whose mole fractions of AA were the 1st and 9th, and the 7th and 15th smallest. The first set of calibration samples would never be selected in the real analysis, because the concentrations of the pure components in the mixtures were not equally divided; however, we employed this set to attempt to verify the performance of the prediction-error estimation method. In the actual case, the calibration samples to be taken were determined by design of experiments.

The prediction results of mole fractions are shown in Figure 1. The blue crosses and orange dots indicate the prediction results for training and test samples. In the first result, in Figure 1(a), the prediction results for the samples between the two calibration samples show good accordance with the observed values. Figure 1(b) shows that the prediction results for the samples whose mole fractions of AA were both from zero to the 7th smallest value, and from the 15th smallest value to one were good. Those figures imply that WLSEA-IOT prediction provided good results for the mixtures in which one component's mole fraction was near one. This implication can be interpreted as follows:



(a) Using the training samples whose mole fractions of AA are the 1st and 9th smallest.

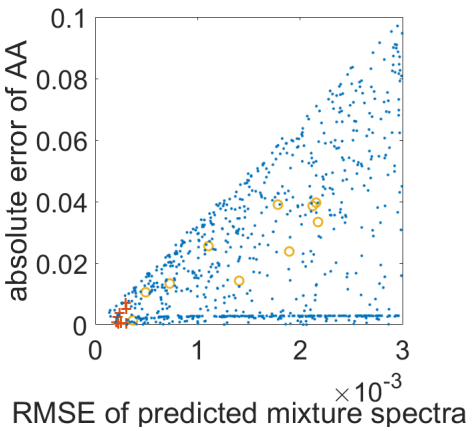
(b) Using the training samples whose mole fractions of AA are the 7th and 15th smallest.

Figure 1. Prediction results of mole fractions for H_2O-AA using WLSEA-IOT. Blue crosses and orange dots denote the calculation results for training samples and the test samples for test samples.

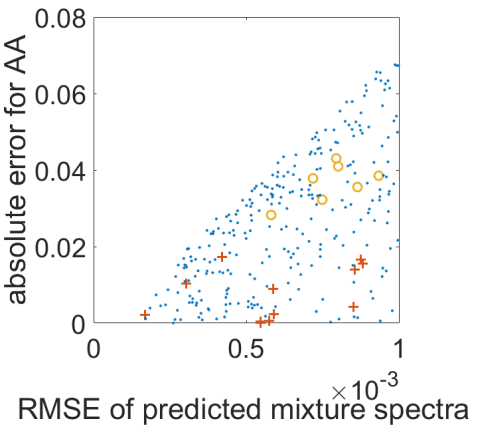
the mixtures in which the mole fraction of a pure component was nearly one accord with Beer's law, because the spectral changes caused by molecular interactions were weak in those mixtures. Thus, we call the samples whose mole fractions varied between those of the training samples and the pure components interpolated samples in the following part.

Next, the relationship between MAE for the mole fractions of AA and RMSE for the mixture spectra is shown in Figure 2. In the figures, the blue dots, orange crosses, and yellow circles denote the results for simulated samples, those for the interpolated samples, and those for the not interpolated samples. The orange crosses and the yellow circles correspond to the results for the observed mixtures; therefore, it can be said that those markers are desirably put in the areas that the blue dots indicate. The scatters of the blue dots in the two figures form the triangles in the different range, because the simulated samples were based on the training samples' mole fraction. In addition, the interpolated samples are predicted well, while not interpolated (or extrapolated) samples were not. The results still follows the assumption that the larger RMSE of the mixture spectra, the smaller the prediction errors are.

As Figure 2 indicates, it can be said that AD worked well as we intended. The prediction errors for the observed mixtures cannot be measured in the actual situation; however, the simulated samples on Figure 2 illustrates how IOT provides the prediction errors for the real mixtures without observed mole fractions. We know the possibly maximum errors of the mole fractions in the IOT prediction from AD. Therefore, we can ensure whether IOT prediction is properly carried out by referring to AD.



(a) When using the mixtures whose the mole fractions of AA are 1st and 9th smallest.



(b) When using the mixtures whose the mole fractions of AA are 7th and 15th smallest.

Figure 2. Estimation of prediction errors of mole fractions from prediction errors of mixture spectra. Markers denote results for a simulated (blue dot), interpolated observed samples (orange cross), and extrapolated observed samples (yellow circle) respectively.

4. Conclusion

We proposed a method to estimate possible prediction errors of mole fractions using a calibration-free method, IOT. The performance of AD for IOT was verified with the binary mixtures. We concluded that AD can estimate the prediction errors of the mole fractions in comparison with the prediction errors for Monte Carlo simulation samples.

However, AD that was applied in this paper did not consider the differences between the absorbances of the pure components at different wavelengths. This would cause the variances in the prediction errors of the mixture spectra. Therefore, we are going to propose a scaling strategy for IOT and corresponding AD in the future.

Abstract

This contribution analyzes different formulations for the constraints in set-membership parameter estimation. For model discrimination and experimental design, parameter estimation and identifiability play a key role. In particular, it is desirable to determine the feasible parameter set, i.e., parameters for which the model outputs remain within defined bounds of available measurements, which are constraints to an optimization problem. The bounds may be defined by an absolute or relative error of single measurement points. As the errors are often unknown a-priori, we present a methodology to estimate them from available experimental data. Alternatively, the bounds can be defined by a statistical analysis of the model deviation from all available measurements. Both methods are applied in a case study of a microgel polymerization reaction involving spectroscopy measurement data. The approximations of the feasible region are compared to confidence ellipsoid predicted with an established method for identifiability based on linearization of the model.

Keywords: parameter, parameter estimation, identifiability, set inversion

1. Introduction

Mathematical process models are used in many tasks of engineering, ranging from model-based experimental design to model-based control. The estimation of unknown model parameters is usually an important step in model development and its results impact the validity and predictivity of the model. Hence, a thorough analysis of the estimation results is important. One state of the art approach for nonlinear models is to determine an ellipsoidal approximation of the parameter confidence region based on linearization (Franceschini and Macchietto, 2008). This method is based on the assumption of a normally distributed measurement error. Should this assumption be violated, the result may become inaccurate (Gottu Mukkula and Paulen, 2017).

Set-membership parameter estimation (Milanese and Vicino, 1991) accounts for the problem of deficient knowledge about the measurement distribution by assuming that the measurement error is random and bounded (Gottu Mukkula and Paulen, 2017). The method aims to determine the set of model parameters for which the respective model outputs remain within defined bounds of the experimental data. In simulation studies, it has been applied in parameter estimation and identifiability (Paulen et al., 2016), and model-based experimental design settings (Gottu Mukkula and Paulen, 2017). In this contribution, we aim to provide a method for the determination of the bounding measurement error based on available experimental data. Additionally, the method is applied to a case study involving real experimental data to show its applicability in practice.

The process under investigation is an isothermal homo-polymerization of Vinylcaprolactam based microgel in a laboratory-scale reactor of 300 ml (Janssen et al., 2017). One measured quantity is the monomer weight fraction in the batch reactor. It is measured via online Raman spectroscopy (Meyer-Kirschner et al., 2016).

In the following, we briefly outline the methodology of set-membership parameter estimation and suggest approximations of the bounding error based on the available experimental data. Additionally, we show that set-membership parameter estimation can be applied with the assumption of normally distributed errors by modification of respective constraints. Then, we consider the case study of the dynamic model in polymerization. Finally, we apply the methodology to estimate the unknown model parameters and compare the respective results to an ellipsoidal approximation of the feasible parameter set based on linearization of the model.

2. Set-Membership Parameter Estimation

The parameters $\boldsymbol{p} \in \mathbb{R}^{n_\mathrm{p}}$ of a given model are mapped to the model outputs $\boldsymbol{y}(t;\boldsymbol{p}) \in \mathbb{R}^{n_\mathrm{y}}$ by $\boldsymbol{y}(t;\boldsymbol{p}) = \boldsymbol{M}(t,\boldsymbol{p})$ with $\boldsymbol{M}\colon \mathbb{R} \times \mathbb{R}^{n_\mathrm{p}} \to \mathbb{R}^{n_\mathrm{y}}$. In the case study presented in Section 4, the model is a system of ordinary differential equations and one algebraic output equation. In set-membership parameter estimation, we aim at determining the feasible parameter set P_e for which model predictions are within defined bounds of the available measurements (Gottu Mukkula and Paulen, 2017).

$$P_\mathrm{e} \coloneqq \{ \quad \boldsymbol{p} \in P\colon \tag{1a}$$

$$B\big(y_\mathrm{i}(t_\mathrm{j};\boldsymbol{p}), \tilde{y}_\mathrm{i}(t_\mathrm{j}), \varepsilon_{\mathrm{i,j}}\big) \leq 0, \tag{1b}$$

$$\boldsymbol{y}(t;\boldsymbol{p}) = \boldsymbol{M}(t,\boldsymbol{p}) \ \}, \tag{1c}$$

where P is an a-priori estimate of the parameter space, $\tilde{y}_\mathrm{i}$ are unperturbed measurements $\mathrm{i} = 1, \ldots, n_\mathrm{y}$ at times $t_\mathrm{j} \in [t_0, t_\mathrm{end}]$ with $\mathrm{j} = 1, \ldots, N$ and B is a function depending on the assumption about the distribution of the measurement error. The errors $\varepsilon_{\mathrm{i,j}}$ are a measure for the acceptable deviation between model outputs and measurements. Herein, only for illustrative purposes, we discretize the a-priori estimate of the parameter space with an equidistant grid. At each grid point, we determine the respective model outputs and check whether their deviation from unperturbed measurements is within the defined bounds. If the deviation is within the bounds, we classify the point as feasible and collect it. The collection of points approximates the feasible region. This brute-force approximation, used herein for illustration purposes, is obviously only applicable in low-dimensional problems.

3. Constraints for Feasible Parameter Set

The bounding deviation of model outputs and experimental data depends on the assumptions made about the measurement error. Here, we consider bounded and normally distributed measurement errors.

3.1. Bounded Measurement Error

For the assumption of bounded measurement errors, a parameter vector $\boldsymbol{p}$ is considered infeasible, if the absolute deviation between any model output $y_\mathrm{i}(t_\mathrm{j};\boldsymbol{p})$ from the respective unperturbed measurement $\tilde{y}_\mathrm{i}(t_\mathrm{j})$ at any time t_j is greater than defined bounds $\varepsilon_{\mathrm{i,j}}$. Hence, the respective constraint formulation is

$$\left|y_{\mathrm{i}}(t_{\mathrm{j}};\boldsymbol{p})-\tilde{y}_{\mathrm{i}}(t_{\mathrm{j}})\right|-\varepsilon_{\mathrm{i,j}}\leq 0, \qquad \forall\,\mathrm{i},\forall\,\mathrm{j}, \tag{2}$$

Hence, the total number of constraints is equal to the number of data points. If a-priori knowledge is available, the bounding error can be chosen based on it. This may be information about the precision of a certain sensor provided by the manufacturers or a defined performance requirement (Hast et al., 2015). However, when dealing with new sensors and unknown systems, the bounding values may be unknown. Here, we suggest to estimate its value based on the variance of the available experimental data. If the measurement error is assumed to be uniformly distributed with zero-mean and an upper and lower bounding error of equal magnitude and invariant with time, the variance can be expressed as

$$\sigma_{\mathrm{i}}=\int_{-\varepsilon_{\mathrm{i}}}^{+\varepsilon_{\mathrm{i}}}\frac{1}{2\varepsilon_{\mathrm{i}}}\zeta^2 d\zeta)=\frac{1}{3}\varepsilon_{\mathrm{i}}^2. \tag{3}$$

By rearrangement we find that for the stated assumptions the bounding error can be estimated based on the variance of the measurement data as $\varepsilon_{\mathrm{i}}=\sqrt{3}\sigma_{\mathrm{i}}$, which we insert in Eq.(2) to define the constraints of the feasible parameter set. We assume that the variance of the available data sample is close to the variance of the population.

3.2. Normally Distributed Measurement Error

If the measurement errors are described by a normal distribution with zero mean and variance σ_{i}^2, a parameter vector $\boldsymbol{p}$ is considered infeasible, if the weighted sum of deviations between model outputs $y_{\mathrm{i}}(t_{\mathrm{j}};\boldsymbol{p})$ and unperturbed measurements $\tilde{y}_{\mathrm{i}}(t_{\mathrm{j}})$ at all measurement time points N is statistically significant (Franceschini and Macchietto, 2008). To analyze the statistical significance, we determine the sum of the deviations of all data points, rather than inspecting the residuals separately. Hence, the respective constraints are

$$\sum_{\mathrm{j}=1}^{N}\left[\left(y_{\mathrm{i}}(t_{\mathrm{j}};\boldsymbol{p})-\tilde{y}_{\mathrm{i}}(t_{\mathrm{j}})\right)^{T}\left(y_{\mathrm{i}}(t_{\mathrm{j}};\boldsymbol{p})-\tilde{y}_{\mathrm{i}}(t_{\mathrm{j}})\right)\right]-\hat{\varepsilon}_{\mathrm{i}}^2\leq 0, \qquad \forall\,\mathrm{i},\forall\,\mathrm{j}, \tag{4}$$

where ε_{i} is the statistically acceptable deviation. It can be determined from the Fisher distribution F_{dist} as (Franceschini and Macchietto, 2008)

$$\hat{\varepsilon}_{\mathrm{i}}^2=\sigma_{\mathrm{i}}^2 n_{\mathrm{p}}F_{\mathrm{dist}}(n_{\mathrm{p}},N-n_{\mathrm{p}},\alpha), \tag{5}$$

where α is the desired confidence level, usually chosen to be 95 % or 99 %. The number of constraints reduces to the number of sensors. A linearization of the respective model in Eq.(4) yields an ellipsoidal approximation of the feasible parameter space (Franceschini and Macchietto, 2008).

4. Case Study: Microgel Polymerization

The radical precipitation polymerization of N-Vinylcaprolactam in solution with water has received considerable attention recently as the product is attractive for a wide range of application including novel biomedical products (Plamper and Richtering, 2017). A number of authors have investigated radical polymerization and respective modeling approaches are well established (Kiparissides, 1996). Here, we make the assumption of a chain initiation reaction at quasi-steady state and a negligible chain transfer reaction.

Additionally, we combine termination by disproportionation and combination to one effective term. The polymerization is carried out in a batch reactor under isothermal conditions at 70 °C. The major reactants are the initiator, the monomer N-Vinylcaprolactam and the active radical polymer chains. Assuming a constant reaction volume, the molar concentration balances of the respective reactants are

$$\dot{c}_{\mathrm{I}}(t;\,\boldsymbol{p}) = -k_{\mathrm{d}} c_{\mathrm{I}}(t;\,\boldsymbol{p}), \qquad c_I(0) = 1.2\ \mathrm{mol\ m^{-3}} \tag{6a}$$

$$\dot{c}_{\mathrm{M}}(t;\,\boldsymbol{p}) = -k_{\mathrm{p}} c_{\mathrm{R}}(t;\,\boldsymbol{p}) c_{\mathrm{M}}(t;\,\boldsymbol{p}), \qquad c_M(0) = 103\ \mathrm{mol\ m^{-3}} \tag{6b}$$

$$\dot{c}_{\mathrm{R}}(t;\,\boldsymbol{p}) = +2 f k_{\mathrm{d}} c_{\mathrm{I}}(t;\,\boldsymbol{p}) - k_{\mathrm{t}} c_{\mathrm{R}}^2(t;\,\boldsymbol{p}), \qquad c_R(0) = 0\ \mathrm{mol\ m^{-3}} \tag{6c}$$

$$w_{\mathrm{M}}(t;\,\boldsymbol{p}) = c_{\mathrm{M}}(t;\,\boldsymbol{p}) M_{\mathrm{M}}/\rho, \tag{6d}$$

where c_{k} is the concentration of species k. The index I represents the initiator, M the monomer, and R the active radical chains. w_{M} is the weight fraction of monomer. The known parameters are the decomposition rate of initiator k_{d}, $1.2 \times 10^{-4}\ \mathrm{s^{-1}}$, the molecular weight of the monomer M_{M}, $1.39 \times 10^{2}\ \mathrm{g\ mol^{-1}}$, and the density of the solution ρ, $0.98 \times 10^{3}\ \mathrm{kg\ m^{-3}}$. The propagation rate constant k_{p}, $1\ \mathrm{m^3 mol^{-1} s^{-1}}$, was determined from quantum chemical calculations (Kröger et al., 2017). The initiator efficiency $f \in [0.1,1]$ and rate constant of termination $k_{\mathrm{t}} \in [0.01,100]\ \mathrm{m^3 mol^{-1} s^{-1}}$ are unknown. The available data for their estimation are monomer weight fraction measurements taken in three repetitions of the same experimental setup using Raman spectroscopy (Janssen et al., 2017). The parameter vector $\boldsymbol{p}_{\mathrm{e}}$ is determined by minimizing the residual of model outputs and experimental data using the enhanced scatter search metaheuristic implemented in the toolbox MEIGO (Egea et al., 2014) in Matlab®. During the estimation the objective function is evaluated approximately 5000 times, while the final parameter values are obtained after only approximately 250 function evaluations. The optimization is constrained by the upper and lower bounds of the parameter values as defined above. Hence, the determined parameter values are assumed to minimize the residual. However, global optimality cannot be guaranteed. It is assumed that model outputs are close to the unperturbed measurements, i.e. $w_{\mathrm{M}}(t_{\mathrm{j}};\,\boldsymbol{p}_{\mathrm{e}}) = \tilde{w}_{\mathrm{M}}(t_{\mathrm{j}})$.

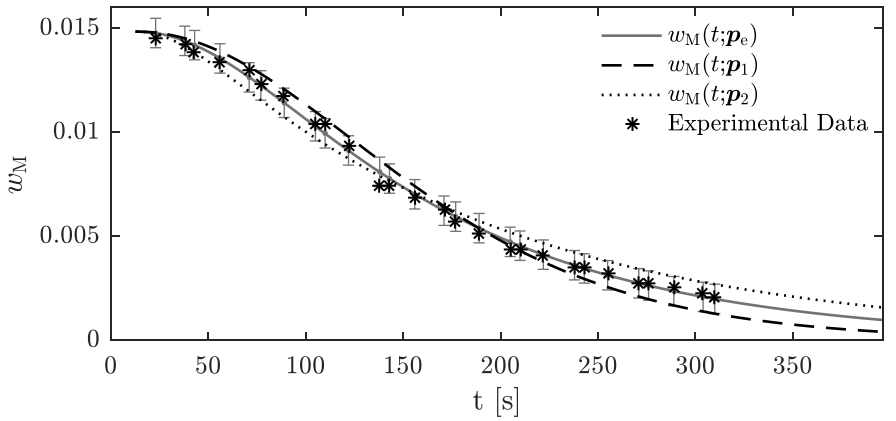

Figure 1: Agreement of model predictions and experimental data with error bounds.

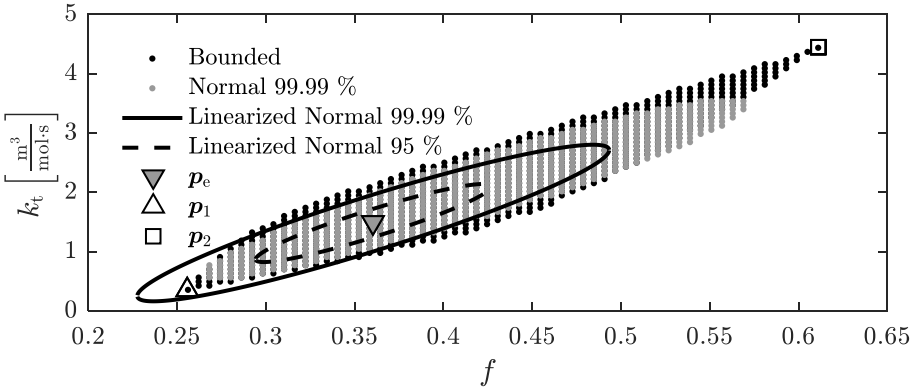

Figure 2: Prediction of the feasible parameter set with $\boldsymbol{p}_e$ based on parameter estimation $\boldsymbol{p}_1$ and $\boldsymbol{p}_2$ and chosen at the edges of the feasible space.

Figure 1 presents the agreement between the experimental data and model predictions for the weight fraction of monomer. The whiskers indicate the error bounds determined based on the methodology presented in Section 2. If the method for the estimation of the bounding error is well suited for this case, we expect (1) that the experimental data is within the determined error bounds and (2) that some measurements are close to the determined bounds. This ensures that error bounds are neither too tight nor too lax, which would cause a too optimistic or too pessimistic approximation of the feasible parameter set respectively. The figure shows that both criteria are fulfilled in the presented case study. All measurements are within the respective bounds, but some are close to them, see measurement at 100 and 140 seconds. Hence, this indicates that the methodology for the determination of the error bounds presented in Section 2 is well suited in this case. Figure 2 presents the approximation of the feasible parameter set for the assumption of a bounded and normally distributed error. Additionally, the figure presents ellipsoidal approximations determined via linearization of the model with the assumption of a normally distributed error (Franceschini and Macchietto, 2008). Respective confidence levels are shown in the legend. The values for the acceptable deviation between measurements and model outputs are $\varepsilon_{w_M} = 7 \times 10^{-4}$, $\hat{\varepsilon}^2_{w_M}(95\,\%) = 0.003$ and $\hat{\varepsilon}^2_{w_M}(99.99\,\%) = 0.01$. The nonlinearities in the model cause a shift between the linearized and non-linearized approximations of the feasible sets based on a normally distributed error. While the differences do not affect conclusions in this study critically, it might be significant in other applications. The approximations of the feasible sets for a bounded and normally distributed error cover a comparable range of parameter values for the unusually high confidence level of 99.99 %. We chose this unusually high value to illustrate at which confidence levels the two approximations become comparable. However, for confidence levels at the commonly selected 95 % the feasible set includes considerably fewer parameter values. To visualize the influence of changes in the parameter values on the predicted outputs, Figure 1 presents the model predictions for the parameter vectors marked in Figure 2.

5. Conclusion

We suggest a method to determine the bounding measurement error based on experimental data and present an application to a case study in polymerization. The results shows that the suggested methodology for the determination of the bounding

measurement error yields reasonable values, as discussed in Section 4. However, while a good agreement with experimental data can be achieved, the unknown parameter values can vary considerably without violating the constraints on the model outputs for the assumption of a bounded measurement error. For the assumption of a normally distributed measurement error similar results are achieved for a confidence level of 99.99 %. However, with the commonly chosen confidence level of 95 % the parameters can be determined within a smaller range. Drawing a conclusion on parameter identifiability from the size of the feasible parameter set is difficult, as the range of feasible parameter values, as expected, depends on the chosen confidence level and the assumption about the distribution of the measurement error.

Abstract

Micro-reactor technology has found increasing usage in the synthesis of several organic compounds and pharmaceutical chemicals in the last decade. The main advantages of micro-reactors are good mixing characteristics, less hold-up volume of reagents and better control as compared to traditional batch reactors. Micro-reactors have recently been used in the laboratory to study the underlying reactions and develop a kinetic models. Further, it is possible to monitor reactions using in-situ spectroscopy in micro-reactors, and collect spectral data at different residence time. In this work, we propose a calibration-free method to analyse spectral data obtained from micro-reactors to identify reaction kinetics. Then, the proposed method can be applied to spectral data directly to identify the parameters of the proposed reaction kinetic model. The method is illustrated using a numerical case study of base catalyzed Knoevenagel condensation reaction system.

Keywords: Reaction kinetics, Model identification, Micro-reactors, Kinetic data, Spectral data.

1. Introduction

Traditional methods for studying the kinetics of reaction systems involves generation of kinetic data, i.e., measurement of concentration of species as a function of time in a batch reactor. The reactions carried out in batch reactor are limited by heat and mass transfer and consumes large amount of reactants. Recently, micro-reactors have been used for kinetic studies as it possess considerable advantages over batch reactors such as better mixing, reduced chemical consumption, better handling of toxic reagents etc [Moore et al (2016)]. Spectroscopy as a non-destructive method of analysis is used extensively in the study of reaction systems. Inline analytical instruments with micro-reactors enable real time monitoring and optimization of reactions.

Mozharov et al (2011) proposed a method for studying the reaction kinetics using flow manipulation technique where a system initially flowing at a steady flow rate is changed to higher flow rate by a step input. Inline Raman spectrometry was used for studying Knoevenagel condensation reaction with steady state measurements and dynamic measurements using flow manipulations. Moore et al (2014) discussed the use of online IR analysis in micro-reactors with flow manipulations for faster generation of kinetic data for the Paal-Knorr reaction. Moore et al (2016) studied the kinetics of aminocarbonylation of aryl halides using inline infrared spectroscopy. In the literature, typically, a calibration model is developed to predict concentrations from the spectral measurements. Then, the predicted concentrations are used to estimate the parameters of kinetic model. Since we have to build a new calibration model for each reaction system, more reagents are used in this approach. Further, building calibration is a time-

consuming exercise. Hence, there is a need for a calibration-free method for identifying reaction systems. In this work, the main objective is to develop a calibration-free methods for identifying reaction systems from spectral data on similar line of the one developed in Armhein (1998).

The paper is organized as follows. Section 2 discusses the model equations for micro-reactors. Then, we propose a calibration-free method to estimate parameters of kinetic models from spectral data collected from micro-reactors. In Section 3, Knoevenagel condensation reaction system is used to demonstrate the proposed method. The results are discussed in Section 4. Section 5 concludes the paper and discusses future extensions. (Note: All vector and matrices are denoted in boldfaced lower and upper case, respectively.)

2. Methodology

In this section, we will discuss the modelling of micro-reactors, and calibration-free method for identification of reaction systems.

2.1 Model equation for Micro-reactors

We consider a homogeneous reaction system with S species and R independent reactions (see Amrhein, 1998 for independent reactions definition). Micro-reactors with low dispersion can be modelled as plug flow reactor (PFR) as mentioned in Nagy et al (2012). For the channel dimension and experimental conditions listed in Section 3 of the paper, the conditions for plug flow behaviour are met, and hence flow behaviour is modelled as plug flow. Further, it is assumed that the reactor is at steady state. Then, the material balance equations for S species in micro-reactors are written as:

$$\frac{d\boldsymbol{f}}{dV_r} = \boldsymbol{N}^{\boldsymbol{T}}\boldsymbol{r}(\boldsymbol{c},\boldsymbol{\theta}),\ \ \boldsymbol{f}(\boldsymbol{0}) = \boldsymbol{f}_{\boldsymbol{0}} \tag{1}$$

where $\boldsymbol{f}$ is an S-dimensional vector of molar flow rates of the species, $\boldsymbol{N}$ is the $R\times S$ stoichiometric matrix, $\boldsymbol{r}$ is the R-dimensional independent reaction rates and V_r is the control volume. $\boldsymbol{f}$ can be expressed in terms of concentrations as follows: $\boldsymbol{f} = q\boldsymbol{c}$, where q is volumetric flow rate. Under the assumption of constant fluid velocity u, and cross section area, Eq. (1) is written in terms of residence time τ and concentrations as follows:

$$\frac{d\boldsymbol{c}}{d\tau} = \boldsymbol{N}^{\boldsymbol{T}}\boldsymbol{r}(\boldsymbol{c},\boldsymbol{\theta}),\ \ \boldsymbol{c}(\boldsymbol{0}) = \boldsymbol{c}_{\boldsymbol{0}} \tag{2}$$

where $\boldsymbol{c}$ is the S-dimensional concentration vector, $\boldsymbol{f_0}$ and $\boldsymbol{c_0}$ are the initial conditions.

2.2 Model for Spectral data

Concentrations of species in micro-reactors are measured using spectroscopy in two manners (i) Spectral data are measured at the end of the micro-reactor at different residence times (τ) at steady-state condition, and (ii) Measurement of spectral data at different locations of micro-reactors after steady-state is established. In both these methods, the spectral data are obtained as a function of residence time. Since the spectral data indirectly measure concentrations, it can be seen that concentrations are measured as different residence times. The spectral measurement model relating

absorbance and concentration according to Beer Lambert's law for a unit path length is written as

$$\boldsymbol{a}^T(i) = \boldsymbol{c}^T(i)\boldsymbol{E} \tag{3}$$

where $\boldsymbol{a}$ is the M-dimensional vector of absorbance's for ith residence time for M wavelengths, $\boldsymbol{E}$ is the $S\times M$-dimensional matrix of pure component spectra for S species, and $\boldsymbol{c}$ is the S dimensional vector corresponding to the ith residence time. The absorbance are measured for L different residence times, Then, Eq. (3) can be written as

$$\boldsymbol{A} = \boldsymbol{CE} \tag{4}$$

where $\boldsymbol{A}$ is the $L\times M$ spectral data matrix, and $\boldsymbol{C}$ is the $L\times S$ concentration matrix at different residence times. For predicting the concentration of the species, a calibration model is required under the assumption that number of absorbing species is equal to S. For reactive systems, the rank of spectral data matrix $\boldsymbol{A}$ can be less than S. This problem is labelled as rank deficiency problem. Hence, the standard calibration methods cannot be applied to the data. The rank deficiency problem of spectral data matrix has been studied by Armhein (1998) and two methods to rectify this issue were proposed. Next, we will formulate a parameter estimation problem to estimate parameters from the spectral data $\boldsymbol{A}$ without using calibration model. Note that $\boldsymbol{C}$ is function of reaction rates and kinetic parameters.

2.3 Calibration-free Approach: Parameter estimation from Spectral data

It is assumed that the minimum number of absorbing species is equal to R. Further, it is assumed that the stoichiometric matrix and the rate expressions are also available. Then, the objective is to estimate the unknown parameters $\boldsymbol{\theta}$ of kinetic model. A constrained objective function J_A can be formulated to minimize the measured spectral data at different residence times with the one obtained by the simulating as follows.

$$\begin{aligned} &\min_{\theta} J_A, \quad J_A = \|\boldsymbol{A} - \boldsymbol{A}(\tau,\boldsymbol{\theta})\| = \|[I_L - \boldsymbol{C}(\tau,\boldsymbol{\theta})\boldsymbol{C}^{+}(\tau,\boldsymbol{\theta})]\boldsymbol{A}\|_F^2 \\ &\text{s.t.} \quad \frac{d\boldsymbol{C}(\boldsymbol{\theta})}{d\tau} = \boldsymbol{N}^T\boldsymbol{r}(\boldsymbol{C},\boldsymbol{\theta}) \\ &\boldsymbol{\theta} \in [\boldsymbol{\theta}^U, \boldsymbol{\theta}^L], \boldsymbol{\theta} \geq 0 \end{aligned} \tag{5}$$

where $\boldsymbol{A(\theta)}$, and $\boldsymbol{C(\theta)}$ are the $L\times M$ and $L\times S$-dimensional matrices computed from the dynamic models with the parameter $\boldsymbol{\theta}$. In Eq. (5), the objective function is the square of the Frobenius norm of the errors between experimental and simulated spectral matrices. Since the pure component spectra are not available, the second expression is minimized to estimate parameters $\boldsymbol{\theta}$. The second expression can be interpreted as projection errors of $\boldsymbol{A}$ on the column space of $\mathbf{C}(\boldsymbol{\theta})$. These projection errors are minimized to find the best estimates of the unknown parameters $\boldsymbol{\theta}$ of the kinetic model. The non-negativity constraints on kinetic parameters with $\boldsymbol{\theta}^U$ and $\boldsymbol{\theta}^L$ as upper and lower limits of parameters are imposed to find the best estimates.

3. Case study: Knoevenagel Condensation Reactions

In this section, the proposed method in Section 2 is illustrated via a simulation study of base catalyzed Knoevenagel condensation reaction in a micro-reactor [Mozharov et al (2011)]. The reactions take place in solution phase where the solution 1 is composed of Benzaldehyde (BZ) and catalyst 1, 4 Diazobicyclo [2,2,2] octane (DABCO) dissolved in methanol and the solution 2 is composed of Ethyl Cyanoacetate (EC) dissolved in

methanol. The reactants are assumed to be pumped into the micro-reactor using an appropriate pump. An Inline Raman spectrometer probe is assumed to be placed at the end of the micro-reactor for measuring spectral data for recording the spectral data continuously with acquisition and delay time of 2 min. The experiment is simulated for different flow rates of reactants (0.2 − 20 μL/min). The simulated steady-state measurements of spectral data are taken after a time period of 1.5 times the residence time for each flow rate. The number of independent reactions in the system is 4, i.e., $R = 4$) and number of species involved in the reaction are equal to 6, i.e., $S = 6$. The reaction scheme and the proposed kinetic model are given in Table 1.

Table 1: Reaction Mechanism and kinetic models

S.No.	Reaction	Kinetic Model
R1		$r_1 = k_1 c_{EC} - k_2 c_{I_1}$
R2		$r_2 = k_3 c_{I_1} c_{BZ}$
R3		$r_3 = k_4 c_{I_2} - k_5 c_{I_3}$
R4		$r_4 = k_6 c_{I_3}$

In the proposed kinetic model, species I_1, I_2 and I_3 are the intermediates of reactions and the number of absorbing species is equal to 4. Under the given experimental conditions catalyst concentration remains constant [Mozharov et al (2011)]. So the catalyst concentration is lumped with kinetic parameters in the rate expressions. The reaction rate vector $\boldsymbol{r}$ is given as: $\boldsymbol{r} = [r_1\ r_2\ r_3\ r_4]^T$ and the stoichiometric matrix **N** is

$$\boldsymbol{N} = \begin{bmatrix} -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & -1 & -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & -1 & 1 \end{bmatrix} \tag{6}$$

The intensity (I_υ) of Raman spectra in terms of concentration of species is given by [J.J. Laserna (1996)]:

$$I_\upsilon = cI_0 V K_\upsilon \tag{7}$$

where I_υ is the Raman intensity of band υ, I_0 is the intensity of the exciting radiation, V is the volume of sample illuminated by the source and viewed by the spectrometer, c is the sample concentration, and K_υ is a constant characteristic for each band. The parameters V, I_0 and K_υ are clubbed together to give the parameter ϕ_υ similar to E in Eq. (3) and Eq. (7) is rewritten as

$$\boldsymbol{I_\upsilon = c\phi_\upsilon} \tag{8}$$

Eq. 8 is the similar to the Eq. 3 with $\boldsymbol{I_\upsilon = a}$ and $\boldsymbol{\phi_\upsilon = E}$. Hence, the method proposed in Section 2 can be applied to the Raman spectra data. The spectral data at different residence times with L = 20 and M = 30 for a selected choice of residence times are shown in Fig. 1. For simulation purpose, the Intensity of Raman spectra $\boldsymbol{I_\upsilon}$ matrix is corrupted with additive zero mean Gaussian noise and the standard deviation σ of each observation is taken as 10 % of maximum intensity from each observation.

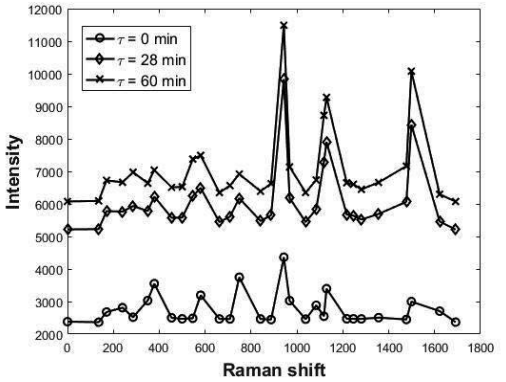

Figure 1: Raman Spectra for reaction mixtures as a function of τ

4. Results and Discussions

The unknown parameters in the model $\boldsymbol{\theta} = [k_1, k_2, k_3, k_4, k_5, k_6]^T$ are estimated from noisy data as mentioned in Section 3 and reported in Table 2. Table 2 also provides the true values and the initial guess values used in the simulation along with the estimated parameter values. The 95% confidence Intervals of parameters are estimated using Bootstrap method and shown in Table 2.

Table 2: True, initial and estimated values of six parameters along with 95 % confidence intervals for the simulation studies.

Parameter	True value	Initial Value	Estimated value	Confidence Interval
k_1 (min^{-1})	0.090	0.050	0.088	[0.081, 0.095]
k_2 (min^{-1})	0.389	0.100	0.385	[0.311, 0.458]
k_3 ($dm^3\ mol^{-1}\ min^{-1}$)	0.308	0.100	0.302	[0.248, 0.356]
k_4 (min^{-1})	15.35	10	15.35	[15.275, 15.426]
k_5 (min^{-1})	512.0	500	512.0	[511.98, 512.02]
k_6 (min^{-1})	294.9	200	294.9	[294.88, 294.91]

The concentration profiles of the species are simulated using the estimated parameters shown in Fig. 2.

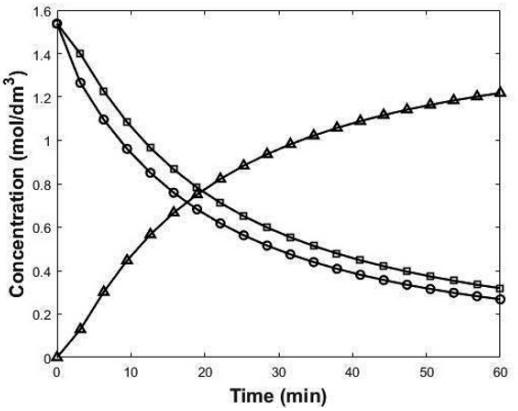

Figure 2: Concentration profiles of the species using the true and estimated values (o – C_{EC}, □ – C_{BZ}, Δ - C_P, solid lines represents the concentrations obtained by the estimated values.)

5. Conclusions

In this paper, it has been shown that spectral data can be collected using two manners in micro-reactors for kinetic studies. A calibration-free approach to identify the kinetic parameters from spectral data obtained in micro-reactors has been proposed. The proposed approach does not require time-consuming calibration and hence, reduces usage of reagents for kinetic modelling using micro-reactors. The proposed approach has been illustrated using a simulated Knoevenagel condensation reaction in micro-reactor. The results show that the proposed approach provides good estimates of kinetic parameters with tight confidence intervals. In future, we will extend the approach to estimate the diffusivities and kinetic parameters from spectral data by relaxing plug flow behaviour assumption.

Abstract

A new framework for optimizing process flowsheets has been developed, which enables a greater degree of flexibility and automation to facilitate the development of hierarchical models suitable for rigorous optimization and control problems under both steady-state and dynamic operating conditions. A library of models for common process unit operations has been developed along with the framework to allow rapid development of flowsheets, with a focus on adaptability and extensibility to allow users to extend and apply these models to novel processes and configurations. This paper presents the development of the framework and model library which support conceptual design, process design/integration, and dynamic optimization/control.

Keywords: Process modeling, simulation, optimization, control, Pyomo.

1. Introduction

Advances in computational power and numerical optimization routines have enabled the possibility of applying rigorous simulation and optimization techniques to large scale problems such as those associated with the design, optimization and control of integrated chemical processes and energy systems. To facilitate the development of process models, a number of simulation packages, such as Aspen Plus®, gPROMS, ProSim, PRO/II®, have been developed which provide robust and easy to use tools, including libraries of common process unit operations, thermo-physical property models, and efficient algorithms to solve large, sparse systems of nonlinear differential algebraic equations. These tools allow engineers to solve very large process flowsheets under both steady-state and dynamic conditions. However, most process simulation packages focus primarily on solving well defined simulation problems, and often have only limited capabilities for advanced optimization, such as conceptual design or optimization under uncertainty. In contrast, there exist several platforms and modeling languages designed specifically for solving large scale optimization problems; however, these platforms lack the specialized infrastructure and model libraries necessary for easily simulating chemical processes and energy systems. In these cases, models must be laboriously assembled for specific systems, often requiring specialized initialization procedures. Developing and applying these models to chemical processes also requires expert knowledge in modeling and optimization not available to the typical process engineer. Thus, there exists a gap in the capabilities of existing software for optimizing process flowsheets.

The U.S. Department of Energy's Institute for the Design of Advanced Energy Systems (IDAES) is addressing this need by developing a next-generation process systems engineering framework (Miller at al., 2018) that is built for optimization from the ground up, enabling the use of modern optimization solvers with a framework for advanced process modeling. The IDAES framework utilizes the Pyomo (Hart et al., 2017) algebraic modeling language (AML), an open source framework for formulating large scale optimization problems based on the Python programming language, which can interface with a wide range of optimization solvers. As part of the IDAES framework, a library of models has been developed, along with a standard modular framework for linking the models in a flowsheet and solving the resulting problem. The goal of these tools and libraries is to reduce the amount of effort required to develop a process model and facilitate rapid development and screening of process configurations.

2. Framework Development

Despite the wide variety of chemical engineering process unit models, they share a number of common features, allowing for a standardized core modeling structure. The process for developing a unit model can be summarized as follows:

1. Specify the operating mode (dynamic or steady state).
2. Define calculations for the thermophysical, transport and reaction kinetic properties of the material(s) of interest.
3. Specify material and energy inlets and outlets, along with the information (state variables) transferred in each (e.g., total flowrate, pressure, temperature, and mole fractions).
4. Define material, energy, and pressure balances.
5. Define additional constraints describing the behavior of the unit (e.g., pressure-flow relations, or heat transfer correlations).

Of these elements, the material, energy and pressure balances are central to the formulation of the model, with the other elements serving mainly to inform aspects of the balance equations. This would suggest that it is possible to write the balance equations in a generic form, and to substitute expressions or variables for the generic terms as needed. Terms which are not needed in a specific model can be excluded by substituting a value of 0 into the balance equations, and the exact form of the expressions can be adapted to the problem at hand to improve tractability. Doing this allows for a completely generic formulation of the balance equations that can be reused between unit models, whilst allowing for formulations which can adapt to the differing needs of each problem. Further, the generic form of the balance equations is inherently unitless, which means that by changing the units of measurement used in the individual terms, the units of the entire model can be changed.

2.1. Material, Energy and Pressure Balances

Mass, energy and pressure balances may contain many terms depending on the operation type including: generation of species via chemical reactions, pressure differentials and heat, work and mass transfer. A framework for modeling these systems needs to accommodate all of the possible terms. At a more fundamental level, there are many ways that material and energy balances can be expressed – whether by mass or moles, by element or component, by component flows or total flow and composition, etc. The preferred formulation of the balance equations is situation dependent, and often one form is more convenient or provides for a more tractable problem formulation.

Despite the variations that may occur, the general form of the balance equations is constant, consisting of terms that may or may not be present in each specific case. These can be summarized as follows:

1. inlet and outlet terms,
2. accumulation terms, which are needed only in models which consider dynamic behavior,
3. generation of species due to kinetic and equilibrium based reactions (including phase equilibria), which are primarily functions of the material state, and,
4. transfer terms which are dependent on the behavior of the unit as well as the material state.

For unit models where consideration of spatial variations are not required (0-dimensional models), this results in the following general forms for the material, energy and pressure balance equations (Eqs. (1)–(3));

$$\frac{\partial M_{p,j}}{\partial t} = F_{p,j,in} - F_{p,j,out} + R_{p,j,kin} + R_{p,j,eq} + K_{p,j} \tag{1}$$

$$\frac{\partial E}{\partial t} = \sum_{p} H_{p,in} - \sum_{p} H_{p,in} + W + Q \tag{2}$$

$$0 = P_{in} - P_{out} + \Delta P \tag{3}$$

Here $\frac{\partial M_{p,j}}{\partial t}$ is the accumulation of species j in phase p within the unit, $F_{p,j,in}$ and $F_{p,j,out}$ are the flows of species j in phase p in and out, $R_{p,j,kin}$ and $R_{p,j,eq}$ are the generation of species j in phase p by kinetic and equilibrium controlled reactions respectively. Similarly $\frac{\partial E}{\partial t}$ is the accumulation of energy in the unit, $H_{p,in}$ and $H_{p,out}$ are the flows in and out of energy in phase p, and P_{in} and P_{out} are the pressure of the material at the inlet and outlet respectively. $K_{p,j}$, W, Q and ΔP represent the mass, work, heat and pressure transfer terms within the unit respectively.

The traditional approach to expressing these equations within an AML would be to either write custom equations for each model which contain only the necessary terms, or to write the balance equations using generic terms and to then provide additional constraints to describe each term. The first alternative results in a more compact problem with fewer variables and constraints, whilst the second alternative allows for greater flexibility and the reuse of code for the balance equations. By exploiting the object oriented nature of Python, it is possible to write the balance equations dynamically, using procedural code to automatically substitute the terms of the balance equations as they are constructed. This can be used to completely automate the construction of the balance equations, using a small set of instructions to inform the code which terms should be constructed for each unit model.

2.2. Property Calculations

Most available software packages and correlations use intensive forms for the property calculations, as these are dependent only on the state variables of the system, and not the flowrates of material. However, there are situations where using extensive forms yields a more tractable formulation for the overall problem (e.g. adjusting when and where bilinear terms appear in the problem structure). Thus, the framework needs to allow for both extensive and intensive formulations in order to provide the flexibility

necessary to achieve the most tractable problem structure. Further, in many cases the developer of a process model is not the developer of thermophysical property models, and may not know the details of the property model formulation. Thus, there needs to be a way for the property calculations to integrate with the unit models without the need for the modeler to be aware of the full details of the property models they are using.

In the IDAES modeling framework, the property module defines the extensive terms in the balance so property models are specific to the application whilst the balance equations are generic. Further, the property calculations become the only part of the model structure where units of measurement are inherently present, which means that the units of measurement for the entire model stem from the property calculations. However, this requires that the units be internally consistent and that property models contain information on the extensive flows of material, which has traditionally been kept separate from the otherwise intensive property calculations.

2.3. Inlets and Outlets

The final consideration when developing a model for a unit operation is what information needs to be passed between units within a flowsheet – i.e. state information for the inlet and outlet streams. The necessary state information and the specific form it takes is dependent on the specific problem at hand. Considering that any two unit models connected together in a flowsheet are by necessity using the same material, and in most cases the same set of property calculations, it follows that the best form for the definition of the inlet and outlet streams of each unit should be the same. Rather than defining a single standard to which inlets and outlets must conform, the IDAES framework allows each property module to define the best set of state variables to pass between units. In cases where the state variables required by two connected units do not match (e.g. a change in property modules between units), a translator block can be used. Connections between two units within a flowsheet are then implemented as equality constraints between the state variables in each connector.

2.4. Models with Spatial Variations

In cases where spatial variations cannot be neglected (e.g. plug flow reactors), it is necessary to include spatial domains and partial differential equations describing these variations within the balance equations. The framework discussed above can be readily extended to include these derivative terms, and Pyomo includes support for partial differential equations through the Pyomo DAE toolbox (Nicholson et al., 2017), which allows for automatic discretization of domains and numerical approximation of the derivatives for an arbitrary number of domains. All that is necessary to extend the framework is to replace the extensive material, energy and pressure terms in the balance equations with differential forms and to use the inlet (and/or outlet) flows as boundary conditions for the differential equations. An example for a 1-dimensional system is shown below, where x is the spatial domain:

$$\frac{\partial M_j}{\partial t} = -\frac{\partial F_j}{\partial x} + R_{j,kin} + R_{j,eq} + K_j \tag{4}$$

$$\frac{\partial E}{\partial t} = -\frac{\partial H}{\partial x} + W + Q \tag{5}$$

$$0 = -\frac{\partial P}{\partial x} + \Delta P \tag{6}$$

2.5. Model Library

Using this framework, a library of models for the most common process unit operations has been developed as part of the IDAES PSE Framework. Models have been developed for operations such as mixers and splitters, compressors, equilibrium separators, and ideal reactors, which support both steady-state and dynamic optimization as well as heterogeneous phases. All of these models have been developed to provide a basic representation for these types of operations that can be easily extended and adapted by users to suit their specific applications. The models in the library have been developed to be the simplest representations of these pieces of equipment possible, with the intent that users will build upon these and add additional correlations as needed to obtain the necessary level of detail and rigor for their particular application.

3. Framework Example

In order to demonstrate the application of the framework, consider the workflow for generating a steady-state model for an isentropic compressor unit. When creating the model, the user must specify a property package containing the necessary property calculations and a set of instructions on how to build the balance equations. For a compressor, it is clear that the pressure drop and work transfer terms will be required, whilst reactions, heat and mass transfer are generally neglected. Each unit model contains a default set of instructions for the terms most commonly used; however, the option is provided for the user to override these if required.

From there, the automatic framework first retrieves the time domain for the problem from the flowsheet. Based on the instructions provided, the framework automatically generates the mass, energy and pressure balances. Taking the mass balances as an example, the framework first eliminates all unneeded terms by substituting a value of zero (such as the accumulation and reaction terms). It then checks with the provided property package to determine the best form to use for the extensive flow terms in the equations. For this example, assuming that the property package uses total flowrate, component mole fractions, temperature and pressure as state variables, the expression $F_p y_{pj}$ would be returned, where F_p is the total flowrate of phase p and $y_{p,j}$ is the mole fraction of component j in phase p. These are then substituted into the mass balance equation, and an equation is automatically written for each component and phase, as shown in Eq. (7).

$$0 = F_{p,in} y_{p,j,in} - F_{p,out} y_{p,j,out} + 0 + 0 + 0 \tag{7}$$

Similarly, the pressure and energy balances are written as shown in Eqs. (8) and (9), where h_p is the specific enthalpy for phase p, as calculated by the property package.

$$0 = \sum_p \left(F_{p,in} h_{p,in}\right) - \sum_p \left(F_{p,out} h_{p,out}\right) + W + 0 \tag{8}$$

$$0 = P_{in} - P_{out} + \Delta P \tag{9}$$

The framework then checks the property package again to determine the state variables to include in the inlet and outlet from the unit (in this case F_p, $y_{p,j}$, P and temperature). The user may then provide the constraints necessary to calculate the remaining terms in the balance equation, notably the isentropic constraints relating ΔP and W. As the entire problem structure is open and accessible to the user, this is as straightforward as adding additional Pyomo constraints to the problem. Users may also easily deactivate existing constraints within the framework if they wish to replace these with more rigorous calculations.

4. Conclusions

A flexible and hierarchical framework for developing and optimizing process flowsheet has been developed which automates much of the development of the mass, energy and pressure balances. The framework has been designed from the ground up to be suitable for advanced optimization and control applications, under both dynamic and steady-state conditions. The framework was developed based on the Pyomo AML and leverages the capabilities of modern optimization solvers by using an equation oriented approach with access to complete first and second derivatives. A library of unit models has been developed as part of the IDAES PSE Framework which includes models for many of the common unit operations used in chemical processes. The models are adaptable and extensible to allow users to customize the models to suit the needs of their specific problem.

Abstract

Optimization is a ubiquitous tool in process systems engineering which is being used on models of ever-increasing size and complexity. Decomposition solution approaches can be powerful tools for solving difficult optimization problems but are dependent on finding a partition of variables and constraints amenable to the solution approach. In this paper, we propose an automated, generic method for decomposing optimization problems using community detection. This method generates subproblems which are tightly interacting amongst themselves but weakly interacting with other subproblems, thus minimizing the amount of coordination required in the solution approach. We demonstrate the ability of our method to find solutions faster than solving the original problem in many cases.

Keywords: optimization, decomposition, community detection

1. Introduction

One of the major goals of process systems engineering is the development of computational tools that aid decision making in the chemical process industry. Optimization is a tool that has become pervasive within the field since it provides guarantees that one is making the best decision for a given situation. Optimization is used for a wide range of tasks, from model predictive control to supply chain optimization. Models used for optimization of systems relevant to chemical engineering can be nonconvex, mixed-integer, multi scale, and uncertain. Optimization problems with these characteristics will innately scale poorly with size. Thus, a major and open challenge in the field is finding ways to solve optimization models that are large-scale and contain nonconvex model equations in a reasonable amount of time. There exist many different ways that one can improve computational tractability of a large optimization problem, but one of the most powerful tools is to apply a decomposition. Doing so requires two steps: first, one must decompose the optimization problem, identifying groups of variables and constraints within an optimization problem to act as subproblems which may share some variables and/or constraints. Once this is done, a decomposition solution approach can be applied to solve the smaller subproblems individually and then coordinate them in some way to find a solution to the original optimization problem. In the simplest case, one simply defines a master problem which updates values of shared primal or dual variables for each iteration of solving subproblems. Various advanced decomposition solution approaches exist which can be broken into two major classes. The first is the case where subproblems share complicating variables. In this case, Bender's decomposition is most commonly used. It was first introduced as an approach for partitioning mixed integer linear programs (Benders, 1962) and has since been generalized to a wider range of optimization problems (Geoffrion, 1972). Conversely, subproblems can be coupled by complicating constraints. These types of problems are commonly solved using a Dantzig-Wolfe, or Lagrangean decomposition. The Dantzig-Wolfe decomposition was introduced

first and solves linear programs using an alternating solution strategy to the subproblems (Dantzig and Wolfe, 1960). Lagrangean decomposition was introduced later and makes use of duality to solve a wider range of problems (Guignard and Kim, 1987). Many examples of other hybrid primal-dual and problem specific decompositions also exist, a few of which are discussed in textbooks (Conejo et al., 2006) and review articles (Grossmann, 2012). All of the aforementioned decomposition solution approaches require that one can find a decomposition of the original optimization problem. Typically this is done using knowledge of the physical problem, such as in our previous work which optimized the design of a plant which produced both renewable energy and biofuels (Allman and Daoutidis, 2017). Ideally, it would not be necessary to rely on intuition to generate decompositions, but to date there does not exist a generic method for generating decompositions. In this work, we propose such a generic method using the network theory method of community detection. The remainder of this paper details this new method and is structured as follows: in section 2, the concept of community detection is introduced in more detail. Then, section 3 describes the method of identifying communities within an optimization problem. Section 4 tests the method in multiple case studies using MINLP test problems. Finally, we conclude and propose avenues for future work in section 5.

2. Community Detection

The concept of community detection has emerged in network science as a method for finding groups within complex systems through represented on a graph. In contrast to more traditional decomposition methods which seek a strict block diagonal or block triangular structure, community detection methods find subnetworks with statistically significantly more links between nodes in the same group than nodes in different groups (Girvan and Newman, 2002). Central to community detection is the notion of modularity, a metric that captures this difference:

$$Q = \frac{1}{2m}\sum_{i,j}\left(A_{ij} - \frac{k_i k_j}{2m}\right)\delta(g_i, g_j) \tag{1}$$

Here, Q is the modularity, A_{ij} is the edge weight between nodes i and j, k_i is the total weight of all edges connecting node i with all other nodes, and m is the total weight of all edges in the graph. The Kronecker delta function $\delta(g_i, g_j)$ will evaluate to one if nodes i and j belong to the same group, and zero otherwise. Modularity is a property of how one decides to partition a network: networks that are not partitioned and those that place every node in its own community will both have modularity equal to zero. The goal of community detection, then, is to find communities that maximize modularity. Although modularity maximization is an NP-hard integer program, many efficient algorithms exist to solve it approximately, including spectral clustering (Newman, 2006) and fast unfolding (Blondel et al., 2008). Figure 1 shows a few networks with increasing maximum modularity; note how the community structure becomes increasingly apparent as this value increases. Previous efforts in our group have applied community detection to chemical plant networks by creating an equation graph of the corresponding dynamic model (Moharir et al., 2017). By doing so, communities of state variables, inputs, and outputs can be obtained which are tightly interacting amongst themselves but weakly interacting with other communities. As such, these communities can form the basis of distributed control architectures (Jogwar and Daoutidis,, 2017) which typically perform better than other distributed control architectures that one may obtain from “intuition” (Pourkargar et al., 2017). For a more comprehensive review of the use of community detection in distributed control, we refer the reader to Daoutidis et al., 2017. An alternative method for finding communities for distributed model predictive control is to apply a decomposition on the optimization problem as a whole (Tang et al., 2017).

However, community structure can exist in all optimization problems, thus it makes sense to extend this method to any generic optimization problem, and this work proposes to do so. The advantage of using community detection to find decompositions is that subproblems generated will have statistically minimal interactions, through complicating variables or constraints, and thus require minimal coordination through the decomposition solution method. The proposed method is generic, applicable to any optimization problem or decomposition solution approach, and scalable, using computationally efficient graph theory algorithms.

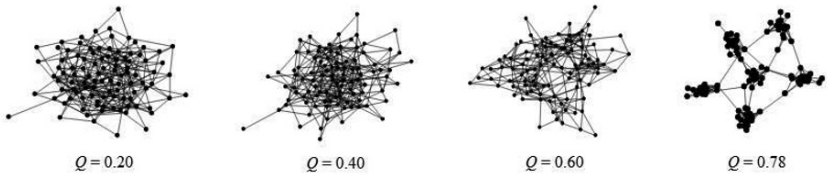

Figure 1. Networks of different maximum modularity.

3. Decomposition Method

To be able to apply community detection algorithms for decomposing an optimization problem, it is first necessary to represent the optimization problem as a graph. To this end, a "variable-constraint bipartite graph" is proposed. To construct such a graph, consider an optimization problem which, without loss of generality, can be written as follows:

$$\begin{aligned} &\text{minimize } \textstyle\sum_{i=1}^{N_v} f_i(x_i) \\ &\text{s.t.} \quad g_j(x) = 0, j = 1, \dots, N_e \\ &\qquad h_k(x) \leq 0, k = 1, \dots, N_i \end{aligned} \tag{2}$$

This formulation only requires that the objective function be a sum of functions of single variables, which can always be satisfied by introducing appropriate auxiliary variables. Then, two sets of nodes are included: a set of N_v variable nodes and a set of $N_e + N_i$ constraint nodes. Edges are then placed between a constraint node and a variable node if the variable appears in the constraint, or, equivalently, if $\frac{\partial g_j}{\partial x_i} \neq 0$ or $\frac{\partial h_k}{\partial x_i} \neq 0$.

Once an equation graph is obtained, community detection can be applied to obtain communities of equations and variables that have maximum modularity. These communities will represent subproblems to be optimized separately by the desired decomposition solution approach. Variables (or constraints) which connect to multiple communities are considered to be shared. This is best illustrated through an example. Consider the following optimization problem:

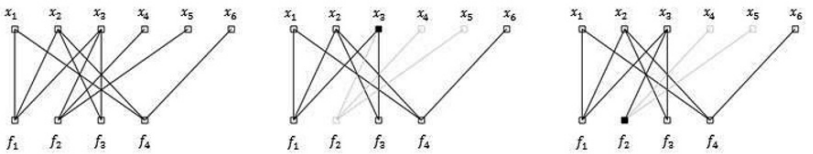

Figure 2.: Graph representation of Eq. (3) (left). Color-coded communities shown with shared variables (center) or constraints (right). Shared nodes are filled in black.

$$\begin{aligned} &\text{minimize } x_1x_2 + 7x_4 + x_5^{0.7} \\ &\text{s.t.} \quad f_1(x) = x_1 + 16x_2 - 9x_3 \leq 0 \\ &\qquad f_2(x) = x_3 \ln x_3 - x_4x_5 = 0 \\ &\qquad f_3(x) = x_2^2 + x_3^2 - 5.8 = 0 \end{aligned} \tag{3}$$

To convert this problem to the form specified by Eq. 2, an auxiliary variable x_6 is introduced and an additional equation $f_4(x) = x_6 - x_1x_2 = 0$ is added. A bipartite graph is constructed with 6 nodes for variables, 4 nodes for equations, and edges added where variables appear within a constraint. The variable constraint graph for this problem is shown in Figure 2. Also shown in Figure 2 are the results of applying community detection to the graph. These communities represent subproblems to be solved; for example, when variables are shared, one subproblem would optimize $x_1, x_2,$ and x_6, a separate subproblem would optimize x_4 and x_5, and a master problem would coordinate these two subproblems by optimizing over x_3.

4. Case Studies

To test the method, problems from the MINLP test library (MINLP World) are used. In particular, feasible problems that did not solve to an optimality gap of 10% or less within an hour using the BARON solver are tested. Some representative results are shown in the following subsections.

4.1. Improving the Upper Bound

"Waterx" is a problem with 68 variables and 52 constraints which, after 1 hour of solving in BARON, had a feasible solution of 984.03 with a lower bound of 240.2, for an optimality gap of 296%. The variable-constraint graph of this problem with communities found in 16.7 s using a fast unfolding algorithm is shown in Figure 3. In this figure, variable nodes are circles, constraint nodes are triangles, shared variables are black asterisks, and nodes in the same community have the same color. This network has a maximum modularity of 0.3937, which gives four separate subproblems. Assigning every constraint to a community gives 18 shared variables, of which 10 can be varied independently while the remaining 8 are coupled to these other variables through equality constraints. To test the performance of the decomposition found by community detection, each community is treated as a subproblem to be repeatedly solved in parallel using BARON. Subproblems are coordinated by a master problem which optimizes shared variables using a derivative-free downhill simplex method. The method is stopped when the objective values of each point on the simplex differ by no more than 10^{-5}.

The results of our method give an upper bound on the solution, and are compared to results from solving the original problem using BARON as shown in Figure 3. In this figure, it is easy to see that after some small initialization time likely due to a poor initial guess, our algorithm is able to find feasible points with objective values less than the best

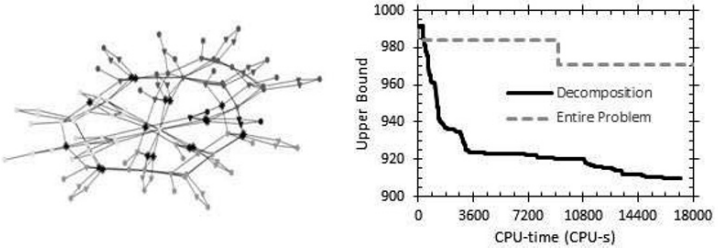

Figure 3. Graph representation of problem "waterx" (left). Performance of decomposition algorithm vs. solving entire problem (right).

value found solving the entire problem with BARON over the same amount of CPU-time. It is important to note that for this problem, the algorithm used does nothing to guarantee that we have found the global optimal, as our algorithm does not find a lower bound to the problem. However, because we were not able to prove global optimality to begin with for this NP-hard problem, we consider the performance of our algorithm satisfactory.

4.2. Improving the Lower Bound

"Feedtray" is a problem with 90 variables and 80 constraints which, after 1 hour of solving in BARON, had a feasible solution of -13.41 with a lower bound of -68.68, for an optimality gap of 81%. The variable-constraint graph of this problem with communities found in 141 s using a fast unfolding algorithm is shown in Figure 4. This network has a maximum modularity of 0.5302, which gives four separate subproblems. Assigning every constraint to a community gives 31 shared variables. However, of the 4 subproblems, only one contains variables which are present in the objective function (the "objective subproblem"); the remaining three subproblems are simply checks of feasibility. It is expected that performing a single feasibility check will be faster than performing three, so the three feasibility checks are combined into a single subproblem. The decompositions are tested using an algorithm which optimizes the objective subproblem using BARON, checks feasibility using the determined values of the shared variables, and generates new cutting plane constraints on the shared variables based on the feasibility check. This process is repeated until a feasible result is obtained.

The results of our method compared to solving the entire problem using BARON are also shown in Figure 4, where the CPU-time neglects time to find communities. Note that unlike the previous case study, intermediate results are not feasible but instead represent a lower bound on the solution. Thus, when the algorithm has converged to a feasible point, this point is a proven global optimal solution. Such a solution can be found in this problem due to its unique decomposition structure of one objective subproblem and one feasibility check subproblem. Figure 4 shows that our algorithm is able to find a better lower bound on the solution than BARON in the same amount of CPU-time and converges on the upper bound determined by BARON. Thus, in this case, the decomposition is used to prove an optimal solution quicker than considering the problem as a whole.

5. Conclusions

In this paper, we have presented a new, generic method for finding decompositions of optimization problems using community detection to find partitions of variables and constraints with high modularity. To implement this method, we developed a novel

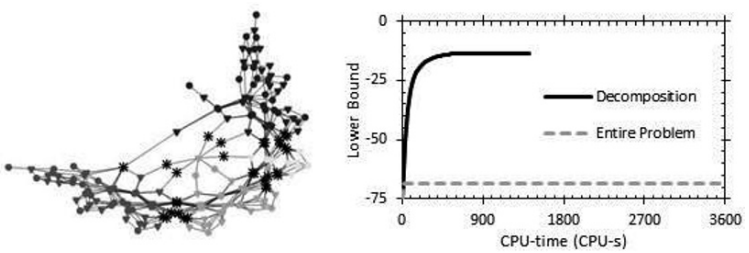

Figure 4. Graph representation of problem "feedtray" (left). Performance of decomposition algorithm vs. solving entire problem (right).

variable-constraint bipartite graph representation of an optimization problem. The algorithm was tested on problems from the MINLP test libraries, and examples were shown where this algorithm can be used to improve both upper and lower bounds of an optimization solution. In the future, we aim to improve our algorithm by considering additional factors which may be important in a decomposition, such as load balancing and constraint convexity.

Abstract

Heat exchanger network (HEN) is one of the major technique of energy saving. We have proposed a HEN design system using pinch technology and multiagent. In this system, the maximum heat recovery is derived from pinch technology. And then, an initial HEN can be obtained according to the AreaTargeting method in order to meet the maximum heat recovery. The initial HEN has complexity and a number of heat exchangers due to the AreaTargeting method. Therefore it is necessary to simplify the HEN without deterioration of the energy saving efficiency. In our system, simplification strategy is defined to prescribe the priority order of procedure and/or the part of HEN. The number and variety of resulted HENs increase along with the number of strategies. It is useful if a large number of HENs with wide variety is obtained because the preferable HEN must be different due to the process objectives or conditions. We implemented several HEN design agents (HENDAs) with different simplification strategies.

In this study, we introduced several improvements in simplification strategy of HENDAs using strategy switching mechanism. Several HENDAs have their own strategy, and then they exchange the HENs on the way—that is “strategy switching” from the standpoint of a HEN. We investigated the effect of improvements in the simplification strategies and strategy switching mechanism.

Keywords: Heat exchanger networks, pinch technology, multiagent framework, simplification, strategy switching.

1. Introduction

The utility consumption in a chemical process can be reduced by heat exchange between the process fluids, which leads to reduction of utility cost and energy consumption. However, it takes too much time and load to manually design the optimal Heat Exchanger Network (HEN). Hence, various methods have been proposed. In our laboratory, we have developed the HEN design support system using Multiagent System. We set a different "strategy" to each Heat Exchanger Network Design Agent (HENDA). And HENDAs simplify HENs according to their own strategy. It brought us various HENs. Using the new mechanism "Strategy Switching Mechanism" in this system, we succeeded in increase of the variation of HENs for a small-scale chemical processes which have two hot streams and two cold streams. In this study, we verified whether Strategy Switching Mechanism is applicable to the larger scale processes.

2. Method

We aim to build a system that can propose alternative plans that meet the users' requirement in various bases of evaluation. The outline of our framework is shown in Figure 1. First, ProjectManager receives PFD from user engineer. Next, the Targeting Agent obtains the maximum amount of the heat recovery by pinch analysis, and designs the initial HEN whose utility usage is minimized by AreaTargeting method. Each HENDA respectively designs a lot of HENs based on the initial HEN. EquipmentCostManager narrows down the designed plans based on the total cost. Furthermore, ProjectManager narrows down the plans based on the maintainability from the plans that EquipmentCostManager narrowed down. Finally, the several selected plans are proposed to user.

2.1. Design of initial heat exchanger network

In this section, we explain about a method to design energy-saving HEN. We decide to use pinch analysis to obtain the maximum amount of the heat recovery. We explain the method using a simple process (4SP1) shown in Table 1. The composite curves are made from the heat demands and the minimum approaching temperature difference of the target process shown in Figure 2. This figure illustrates that the shaded area is the heat recovery area by 5480 kW, the minimum usage of the cold utility is 120 kW and the minimum usage of the hot utility is 960 kW. The place is called a "pinch point" where the heat exchange with the minimum approaching temperature difference is carried out. Unless there is heat exchange crossing the pinch point, the utility usage is kept to the minimum. In order to achieve the HEN with the minimum utility usage, the AreaTargeting method is adopted to design the initial HEN shown in Figure 3. In this initial HEN, the utility usage and the total heat transfer area is the minimum. However, because the number of heat exchangers and splits are very large, the equipment cost is high and the maintainability is low. Therefore, it is necessary to simplify the structures of the initial HEN.

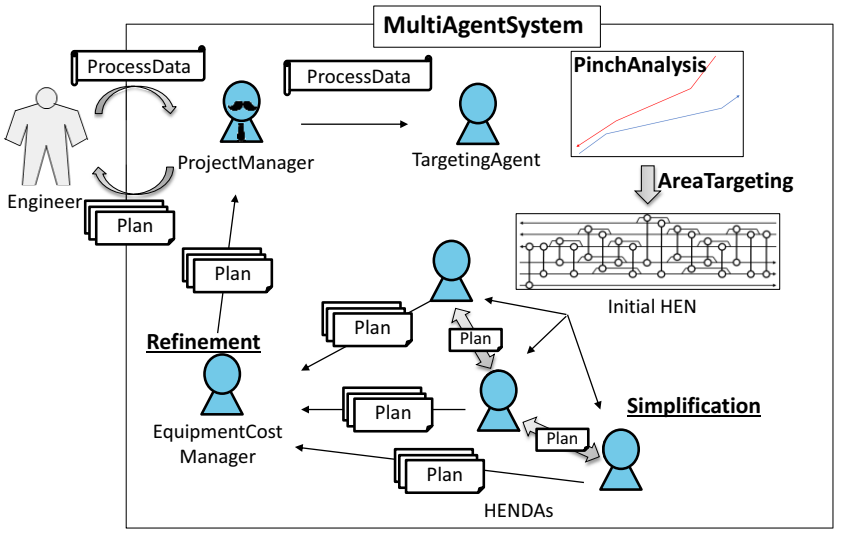

Figure 1: The outline of our framework.

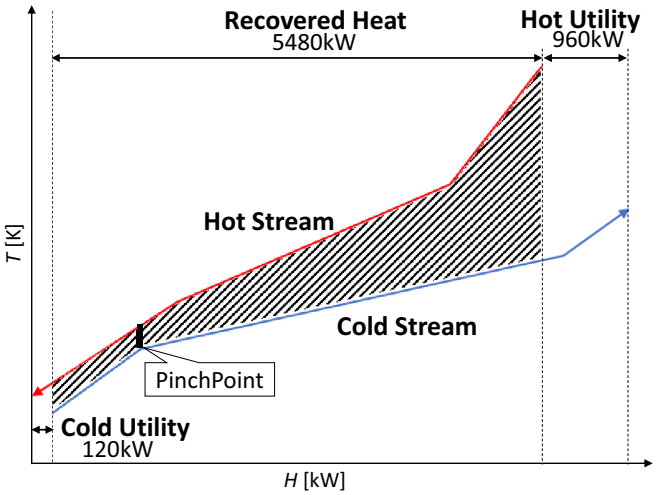

Figure 2: Composite curves of 4SP1.

Table 1: Heat demands of 4SP1.

Stream	T_{in}[K]	T_{out}[K]	CP[kW/K]	ΔH[kW]
Hot1	453	353	20	2000
Hot2	403	313	40	3600
Cold1	333	373	80	3200
Cold2	303	393	36	3240
Steam	378	378	-	
Water	293	298	-	

$\Delta Tmin$ is 10[K].

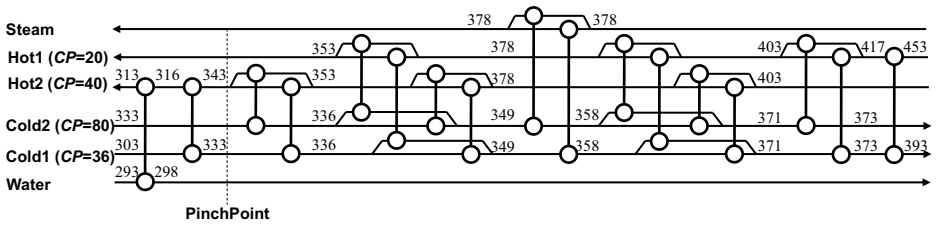

Figure 3: The initial HEN of 4SP1.

2.2. Simplification of HEN

In order to simplify the structures of the initial HEN, several simplification procedures are prepared as shown in Figure 4. We can obtain new alternative plans by every single procedure. In the initial HEN, a lot of partial structures indicated in Figure 4 are found. However the structure of HEN after the application of a procedure differs depends on the order of simplification procedure. Then, we prepared several simplification "strategy" which contains the preference orders of the procedures and the segments to be simplified. For example, we prepared strategies "OutLTDL", "InHTDWSL",

"InHSLTDL". These strategies are intended to design wide variety of HENs. In detail, the strategy "OutLTDL" (Out-Low-Temperature Delete-Loop) focuses on segments in ascending order of exit temperature and preferentially carries out Delete Loop. The details of other strategies are described in our previous study (Kou 2010). We assigned each strategy to each HENDA who is in charge of simplification. HENDAs simplify based on the strategy. After every procedure, it is regarded as the HENs are one of the alternative plans. It means that a HENDA with a single strategy can make a lot of HENs according to the progress of the simplification procedures. However, if the individual HENDA simplifies without "strategy switching," the optimal solutions may not be included, because there are limitations on the number of designed HENs. Furthermore, as shown in Figure 5, each HENDA can hand over partially simplified HEN to another HENDA to continue simplification based on another HENDA's strategy. It is possible to obtain the larger number of HENs. We call this mechanism "strategy switching". In Figure 5, the expression "HEN C2-A3" means that the HEN is simplified twice with strategy C and subsequently simplified once with strategy A.

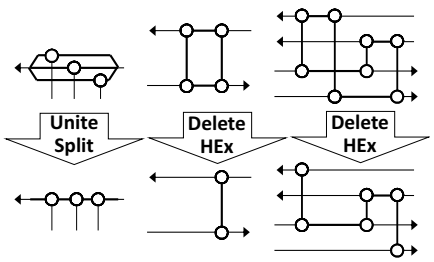

Figure 4: The simplification procedures.

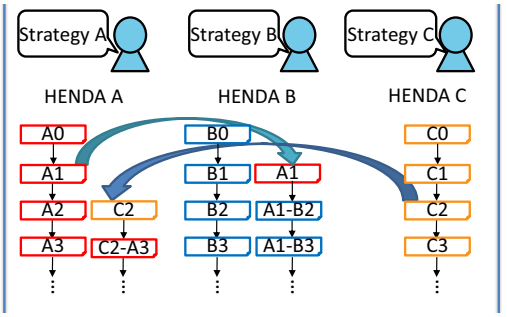

Figure 5: Outline of strategy switching.

3. Simulation

3.1. Application of Strategy Switching Method

In our previous study (Kimura 2016), we verified that the Strategy Switching Mechanism is effective in a small scale processes (4SP1). In this study, we carried out the simulations of several processes (4SP2, 9SP, 10SP). In this paper, we show the result of 4SP2, which is the smallest among the target processes due to the space limitations. The heat demands of 4SP2 are shown in Table 2. In 4SP2, whereas we could only obtain 225 kinds of HENs without switching, we could obtain 498 kinds of HENs with switching. Figure 6 shows the simplest HEN in the simulation with switching. This HEN has the 10 heat exchangers and the 4 splits. However, it is possible to reduce the number of heat exchangers to 6 and splits to 0 theoretically.

3.2. Strategy Improvement

In accordance with the inadequate result mentioned in section 3.1, we tried to improve the strategy.

There is a constraint that the temperature difference of all the heat exchangers must be larger than ΔT_{min}. If a HEN does not satisfy the constraint (that is '*inconsistent HEN*'), the HENDA discarded the HEN. However, we found that there is a possibility that HENDA can obtain consistent HENs by simplifying the inconsistent HEN subsequently. Then, we improved the strategies to make HENDA allowable to

temporarily design an inconsistent HEN. We had expected that consistent HENs are designed from an inconsistent HEN after introducing this mechanism, however, we could not obtain.
In most cases, the inconsistent heat exchangers in the inconsistent HENs are near the pinch point. The heat exchanges near the pinch point must satisfy the following equation:

$$(CP \text{ of stream entering the pinch point}) \leq (\text{the sum of } CP \text{ of stream exiting from the pinch point})$$

Therefore, we improve the strategy to meet this constraint. As a result, HENDAs could design simpler HENs.

Table 2: Heat demands of 4SP2.

Stream	T_{in}[K]	T_{out}[K]	CP[kW/K]	ΔH[kW]
Hot1	443	333	30	3300
Hot2	423	303	15	1800
Cold1	293	408	20	2300
Cold2	353	413	40	2400
Steam	450	450	-	
Water	353	413	-	

$\Delta Tmin$ is 5.6[K].

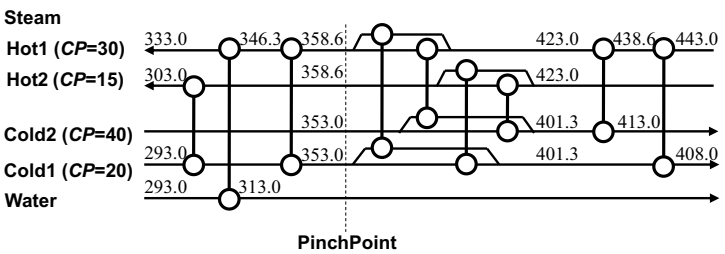

Figure 6: The simplest HEN of 4SP2 before improvement of strategies.

3.3. Result

In the simulation with the improved strategy, whereas we could only obtain 920 kinds of HENs without switching, we could obtain 2,232 kinds of HENs with switching. We show the number of kinds of HEN obtained in each simulation in Table 3, and the simplest HEN in the simulation with switching in Figure 7.
In this study, we compared the results on the total cost [$/year] (the equipment cost plus the utility cost), the numbers of the heat exchangers and splits in the most inexpensive HENs in Table 4. In table 4, the results are by (I) Yerramsetty (2008), (II) Pariyani (2006) and (III) our improved method with strategy switching. Despite implement of the improvement mentioned in section 3.2, the HEN whose cost is lower than the results in other methods could not be obtained.

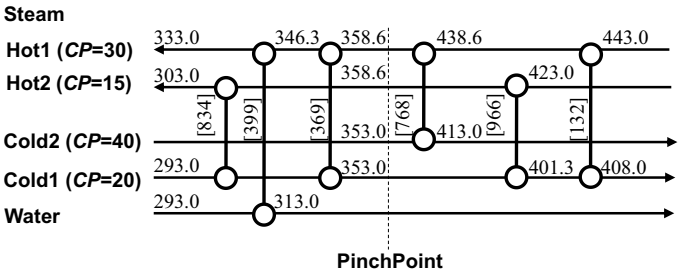

Figure 7: The simplest HEN of 4SP2 after improvement of strategies.

Table 3: The comparison result of the numbers of the HEN in 4SP2.

Supplement		No. of unique HEN
Before improvement	w/o switching	225
	switching	498
After improvement	w/o switching	902
	switching	2,232

Table 4: The comparison result of the costs of the HEN in 4SP2.

Method	Total Cost [$/year]			No. of	
		Equipment	Utility	Heat Exchanger	Split
(I) Differential Evolution (Yerramsetty)	84,222	76,222	8,000	6	1
(II) Randomized Algorithm (Pariyani)	85,307	77,307	8,000	6	1
(III) This study	84,648	76,648	8,000	6	0

4. Conclusion

Strategy switching and simplification of HENs could be proceeded by the improvements of the simplification algorithm. It brought that a large number of HENs with a wide variety can be made for some chemical processes. In our future work, it is necessary to implement a decision-making mechanism to evaluate the huge number of alternatives from various aspects.

Systematic Comparison of Aggregation Methods for Input Data Time Series Aggregation of Energy Systems Optimization Problems

Holger Teichgraeber[a*], Adam R. Brandt[a]

[a]*Department of Energy Resources Engineering, 367 Panama St., Stanford, CA, USA*

hteich@stanford.edu

Abstract

We present a systematic comparison of how aggregation methods represent input data in the operational part of complex energy systems optimization problems. We compare both traditionally used methods such as k-means, k-medoids, and hierarchical clustering, and shape-based clustering methods such as dynamic time warping and k-shape in the domain of the objective function of sample operational optimization problems. Centroid-based approaches show improved performance as the number of clusters increases, whereas medoid-based approaches do not show a clear pattern as to when they best represent the objective function of the optimization problem of the full representation. Furthermore, clustering based on shape-based algorithms can improve performance compared to the traditionally used algorithms.

Keywords: Time-series aggregation, Clustering, Energy systems optimization

1. Introduction

The optimization of energy systems and of design problems of energy-intensive processes is computationally expensive and is often computationally intractable for the full set of input data (e.g. electricity prices, heating and cooling demand, renewable generation).

Clustering for time series aggregation has been used recently to address this challenge. It can reduce computational times for optimization problems by 1-2 orders of magnitude. For example, an energy system can be optimized for a small set of 5-10 representative days instead of a whole model year. Various studies have used different aggregation methods. Brodrick et al. (2015) and Teichgraeber et al. (2017) use k-means clustering for carbon capture applications, Bahl et al. (2017) use k-means clustering for decentralized energy supply systems, and Kotzur et al. (2018) use k-means, k-medoids, and hierarchical with the medoid for various energy supply systems.

All the above mentioned studies jointly investigate the representation in the operational and design domain of these 2-stage problems. In this study, we analyze only the representation of input data in the operational part of the problem in order to decompose the representation of the clustering algorithm by removing the design decisions, which are influenced by extreme values. We compare the previously mentioned aggregation methods as well as clustering methods that are shape-based and have not yet been applied to the optimization of energy systems: k-shape clustering and dynamic time warping barycenter averaging (DBA) clustering.

We formulate two simple operational problems that can be solved for the full set of electricity price time series data, so that the objective function error due to clustering can be exactly computed. These problems capture characteristics of real world energy-intensive industrial applications such as storage, load shifting, and on-site power generation. We then compare the clustering methods in the domain of the objective function of these optimization problems. This paper proceeds as follows: First, we introduce the aggregation methods that we compare, and we then introduce the sample optimization problems and the data. After that, we compare the performance of the aggregation methods on the optimization problems and draw conclusions.

2. Aggregation Methods

In this section, we introduce the aggregation methods that are compared in this paper.

We aggregate a time-series consisting of N daily price vectors $\mathbf{p_1}\ldots\mathbf{p_N}$ into K clusters. We introduce the following sets for notation: N = {1,...,N} is the set of daily indices, T={1,...,T} is the set of hourly time-step indices within each day, K={1,...,K} is the set of cluster indices, and C_k with k∈K are the disjoint sets of daily price vectors belonging to the respective clusters k.

Aggregation typically consists of clustering the days into K clusters and then choosing a representation of the cluster. The cluster center **c** is often, but not always, chosen as the representation.

We compare partitional clustering algorithms (k-means, k-medoids, dynamic time warping, k-shape), and hierarchical clustering algorithms (hierarchical clustering with centroid, hierarchical clustering with medoid).

2.1. Partitional clustering algorithms

All partitional clustering algorithms compared in this work minimize the within-cluster sum of squared distances and result in the assignment of daily price vectors $\boldsymbol{p}_i$ to the sets $C_1^* \ldots C_K^*$:

$$C_1^* \ldots C_K^* = \underset{C_1 \ldots C_K}{\operatorname{argmin}} \sum_{k \in K} \sum_{\boldsymbol{p}_i \in C_k} \operatorname{dist}(\boldsymbol{p}_i, \boldsymbol{c}_k)^2 \tag{1}$$

These algorithms differ in their choice of distance measure and cluster center but can all be solved following the general structure of Lloyd's algorithm (Lloyd, 1982): At the beginning, the cluster representations are initialized randomly. Then, the algorithm iteratively performs two steps until it converges or reaches a maximum number of iterations: In the first step (assignment), each day $\mathbf{p_i}$ is assigned to the closest cluster center, and in the second step (refinement), the cluster centers are updated in order to reflect the changes in cluster assignments.

Cluster centers can be centroid-based or medoid-based. The algorithm yields locally converged solutions based on the random cluster initializations. In this study, we run all

clustering algorithms until convergence and do not consider any non-converged solutions. In the following, we present the partitional clustering algorithms and their respective distance measure and cluster center:

K-means clustering: K-means clustering (Lloyd, 1982) minimizes the Euclidean distance. It uses the centroid for cluster representation, which can be computed with the arithmetic mean.

K-medoids clustering: Similarly to k-means clustering, k-medoids clustering uses the Euclidean distance as distance measure. However, it represents the cluster by its medoid. The medoid is an actual day $\mathbf{p}_i$. Besides being solved with the outlined partitional algorithm, the k-medoids clustering problem can be formulated as a Binary Integer Program (BIP) (Kotzur et al., 2018). The BIP formulation can be solved to global optimality for the number of days considered in this study.

Dynamic Time Warping based clustering: Dynamic Time Warping (DTW) (Petitjean et al., 2011) takes into consideration that the shape of two time-series can be similar but shifted because it is able to align different hours of the day. The optimal non-linear alignment between two days can be calculated using dynamic programming. The algorithm can be constrained to a so-called "warping window", where only hours i and j, $|i - j| \leq b$, can be aligned. DTW allows us to calculate the assignment step in the partitional clustering algorithm. For the refinement step, we use DTW barycenter averaging (DBA), which is an iterative algorithm, to calculate the cluster centroid.

K-shape clustering: K-shape clustering has recently been proposed as an alternative to DTW as a shape-based clustering method (Paparrizos and Gravano, 2015). It uses a shape-based distance SBD. SBD finds the optimal shift w of two time-series vectors **u** and **v** such that the cross correlation between these vectors is maximized. SBD can be calculated efficiently using a Fast Fourier Transform algorithm. Each cluster is represented by its centroid, which can be computed analytically.

2.2. Hierarchical clustering algorithm

Hierarchical clustering starts with k=N clusters and proceed by merging the two closest days into one cluster, obtaining k=N-1 clusters. The process of merging two clusters to obtain k-1 clusters is repeated until we reach the desired number of clusters K. We use the Euclidean distance to find which clusters to merge, using the algorithm proposed by Ward (1963). The final cluster assignments are then represented by either the centroid or the medoid. Hierarchical clustering is deterministic, which means it is reproducible. However, it is also greedy, which means that it yields local solutions.

3. Optimization Problem and Data

We formulate an electricity storage problem and a gas turbine power generation problem. These problems are simple operational problems formulated as linear programs that can be solved directly for 365 days. This gives us the true value of the objective function, to which the value of the objective function with clustered input data is compared. In combined design and operations problems, the optimal decision variables are of primary interest. However, in this study, we consider the operational part of the optimization problem. Because the design decision variables of a potential design and operations problem are strongly influenced by the operational profitability (our objective function), we use the objective function as the measure to compare the performance of the clustering algorithms.

The problem is formulated in a way that maximizes operating profit for one day in hourly time-steps Δt and is carried out for each clustered day. The yearly profit is then calculated as a weighted addition of the individual clustered days' profits.

The electricity storage problem is formulated in Eq.(2):

$$\begin{aligned}
&\max_{\bar{\bar{E}},\bar{E},S} \sum_{k\in K} N_k \sum_{t\in T} (\bar{\bar{E}}_{k,t} - \bar{E}_{k,t}) p_{k,t} \\
&\text{s.t.} \\
&0 \le \bar{\bar{E}}_{k,t} \le P_{max}\Delta t && \forall\, k \in K,\, t \in T \\
&0 \le \bar{E}_{k,t} \le P_{max}\Delta t && \forall\, k \in K,\, t \in T \\
&0 \le S_{k,t} \le E_{max} && \forall\, k \in K,\, t \in T \\
&S_{k,t+1} = S_{k,t} + \eta_{in}\bar{E}_{k,t} - \frac{\bar{\bar{E}}_{k,t}}{\eta_{out}} && \forall\, k \in K,\, t \in T \\
&S_{k,1} = S_{k,T+1} \wedge S_{1,1} = S_{k,1} && \forall k \in K
\end{aligned} \tag{2}$$

Here, $\bar{\bar{E}}_{k,t}$ and $\bar{E}_{k,t}$ are hourly energy that flows out of or into the battery from the market, $p_{k,t}$ is the hourly electricity price, and $N_k = |C_k|$ is the number of days in cluster k. P_{max} is the maximum power, and E_{max} is the maximum storage capacity of the battery. $S_{k,t}$ is the amount of energy stored in the battery, and η_{in} and η_{out} are the charge and discharge efficiencies. We assume maximum power of 100 MW and maximum storage capacity of 400 MWh, with charge and discharge efficiencies at a typical value of 95%.

The gas turbine dispatch problem is formulated in Eq.(3):

$$\begin{aligned}
&\max_{\bar{\bar{E}}} \sum_{k\in K} N_k \sum_{t\in T} \bar{\bar{E}}_{k,t} p_{k,t} - \frac{\bar{\bar{E}}_{k,t}}{\eta_{gt}} p_{gas} \\
&\text{s.t.} \\
&0 \le \bar{\bar{E}}_{k,t} \le P_{max}\Delta t && \forall\, k \in K,\, t \in T
\end{aligned} \tag{3}$$

Here, $\bar{\bar{E}}_{k,t}$ is the hourly electric energy generated from the gas turbine, and p_{gas} is the gas price. We assume a gas price of 6.8 \$/GJ, and assume a combined cycle efficiency η_{gt} of 60% as can be found in modern combined cycle gas turbines.

The different clustering approaches are evaluated on hourly electricity price data from the day-ahead market in Germany from 2015. The mean price is 31.6 EUR/MWh, and the standard deviation is 12.7 EUR/MWh. A visual example of cluster outcomes of k-means on the data can be found in Teichgraeber et al. (2017).

We z-score normalize the data. Z-score normalization is commonly applied in statistics before clustering algorithms are applied, it shifts the mean to zero and the standard deviation to one. We use element-wise z-score normalization, which normalizes each hour of each daily sample by the same mean and standard deviation. Shape-based methods often use sequence-wise z-score normalization, which we suspect to work well in this case as well and will be part of future work.

4. Results

These optimization problems are operational, and the results presented here thus show the representation of the operational problem. We compare the performance of the aggregation method based on the objective function value, and we calculate the objective function value of the respective optimization problem for the full representation (365 days of electricity prices) for comparison. Note that unlike for our simplified problem, it is often computationally intractable for a complex problem involving design and operations to optimize the full representation.

Figure 1 shows the objective function value normalized by the objective function value of the full representation for the battery problem (Figures 1a and 1b) and the gas turbine problem (Figures 1c and 1d). First, we investigate conventionally used clustering methods (Figures 1a and 1c). We observe that k-means clustering and hierarchical clustering with centroid perform similarly on both problems. They generally increase in objective function value with increasing number of clusters (except for two notable decreases from 4 to 5 and 6 to 7 clusters of k-means in the gas turbine problem). Compared to the centroid-based clustering algorithms, the medoid-based algorithms perform less predictably. As the number of clusters increases, the objective function either increases toward or decreases away from the full representation, with no clear pattern emerging. If the full representation is unknown, choosing the number of clusters used in a specific case study is challenging.

The performance of the shape-based clustering methods DTW and k-shape with element-wise normalization is shown in Figures 1b and 1d. We compare DTW with a Sakoe-Chiba warping window of 0 to 3 and k-shape clustering. DTW with a warping window of 0 yields the same results as k-means, which confirms our implementation of the algorithm. A warping window of 1 increases the objective function for both optimization problems. As the warping window increases further, the objective function increases on average, but it also increases toward and decreases away from the full representation with less of a pattern emerging. As we increase the warping window size, the clustering algorithm is able to compare hours further and further away, which at some higher warping window size may lead to clustering peaks and valleys in price that may not belong together physically. Increasing the size of the warping window to a number too large can more generally be seen as overfitting.

K-shape on the other hand overestimates the objective function value for the storage optimization problem, and fluctuates as the number of clusters increases.

5. Conclusions

It is often computationally intractable to solve design and operations optimization problems of energy systems for the full set of input data. In this study, we present a comparison of conventional and shape-based clustering algorithms, and how they affect the operational representation in terms of the objective function value of the full representation. We find that centroid-based clustering algorithms behave more predictably with increasing number of clusters than medoid-based clustering algorithms, and we also find that shape based algorithms can improve performance over k-means. Future work will include comparing shape-based algorithms using sequence-wise instead of element-wise normalization.

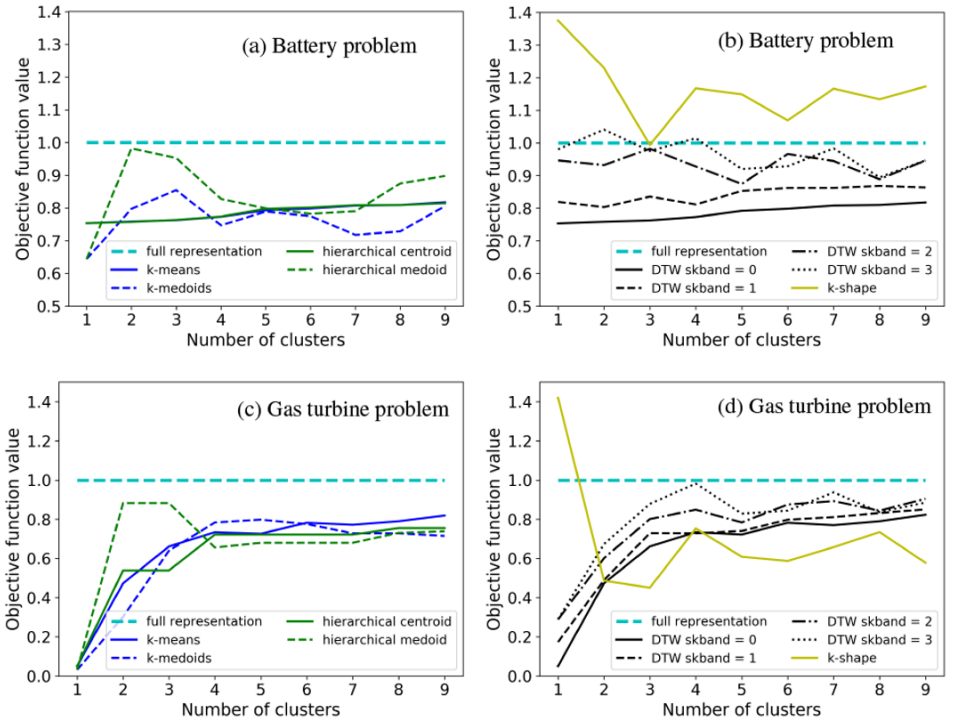

Figure 1: Comparison of normalized objective function values of different clustering methods: (a) conventional clustering algorithms on the storage optimization problem, (b) shape-based clustering algorithms on the storage optimization problem, (c) conventional clustering algorithms on the gas turbine optimization problem, and (d) shape-based clustering algorithms on the gas turbine optimization problem. Abstract

A techno-economic framework is proposed for the optimal exploitation of unconventional shale reservoirs and the delivery of shale gas products within the Marcellus region. A 3-D compositional reservoir model is constructed to simulate realistic drilling, completion, stimulation (DCS) strategies and pad production processes. A feed-forward neural network (FNN) is implemented to understand re-frac well candidature so as to aid development of alternative development strategies throughout a project planning horizon. In addition, optimal well configurations and DCS strategies for well-pad development are developed in line with best petroleum engineering practices. Simulation results are incorporated in a long-term strategic planning model used for determining the optimal shale gas supply chain network and its operations. For this, a mixed-integer non-linear programing (MINLP) formulation is developed to maximize net present value (NPV). Natural gas demand is predicted by running long short-term memory (LSTM) neural networks based on the historical data of critical predictors. Results of this framework depict the influence of reservoir engr., completion engr., and machine learning in predicting project profitability and establishing optimal strategies for shale gas production and distribution.

Keywords: 3-D compositional reservoir model; MINLP model; Feed-forward Neural Network; LSTM neural network.

1. Introduction

The United States has an enormous potential in the energy sector given the abundant presence of natural gas in shale formations. These formations are mainly characterized by low permeability (from 10^{-6} - 10^{-2} md), low porosity, low strength resistance and water sensitivity. In the last decade, the rapid development of technologies including extended-reach directional drilling, hydraulic fracturing, and biodegradable diverter technology have enabled more economic exploitation of shale reservoirs (EIA, 2013).
The development of shale gas resources represents a multidimensional challenge due to the complexities involved in its exploitation. The quality and quantity of shale resources inferred in resource assessments and the exact location of the zones with the highest

productivity ('sweet spots') or richer content in liquids of higher economic value remain uncertain until actual exploratory drilling occurs. Geologists and engineers have to determine pay zones with superior reservoir and geomechanical characteristics to ensure that drilling and completion operations occur within these high-quality intervals. In this context, 3D compositional models that capture the reservoir characterization, the physics of shale gas adsorption and incorporate realistic development strategies can be used as a support tool to analyse multi-shale pad operations. The access to necessary infrastructure is also critical to ensure the optimal allocation of subsequent shale gas products. Once a pad is constructed and wells are producing, the next step is delivery to final consumers. Gathering pipelines, compression stations, water management infrastructure and other support facilities are constructed to ensure the movement of natural gas to in-state distribution pipelines. In the presence of liquid-rich gas, processing is required for separating heavier and more valuable hydrocarbons. These factors have a critical influence on gas developments and encourage gas producers to re-think the short and long-term strategies implemented.

In recent years, large-scale production of shale gas has accompanied the plunge in natural gas prices. Although this slump of gas prices has made the U.S. attractive for developing other industries, it also poses financial difficulties to gas operators and asks significant questions about the future of shale gas production. This factor accompanied by the customary sharp decline of producing shale gas wells has encouraged gas producers to invest more in liquid rich shale plays. For shale oil and gas production, larger expenditures are required for infrastructure, and the economic feasibility of such projects is still a concern in the presence of fluctuating demand. Therefore, a comprehensive approach that combines formation evaluation, reservoir simulation and long-term strategic planning would suffice for predicting the success of these ventures.

2. Problem statement

A techno-economic approach is proposed for the development of shale gas assets. Fig 1 illustrates the workflow for the optimization framework.

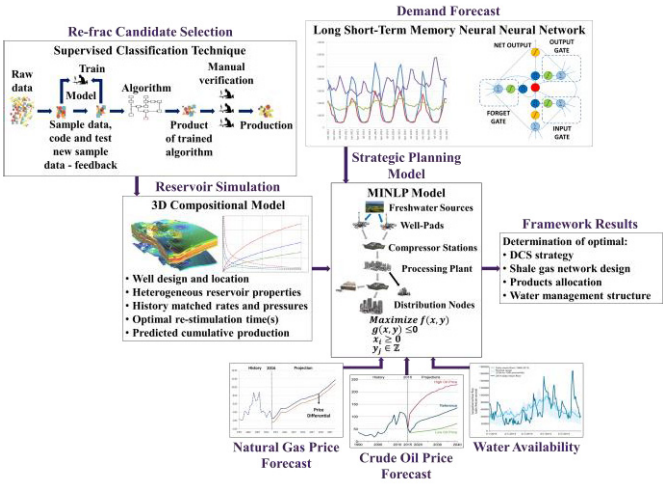

Figure 1: Integrated optimization framework for economic development of shale gas.

In this approach, a supervised classification technique is implemented to determine acceptable candidates for re-stimulation (Hope *et al*., 2017). An FNN with an architecture

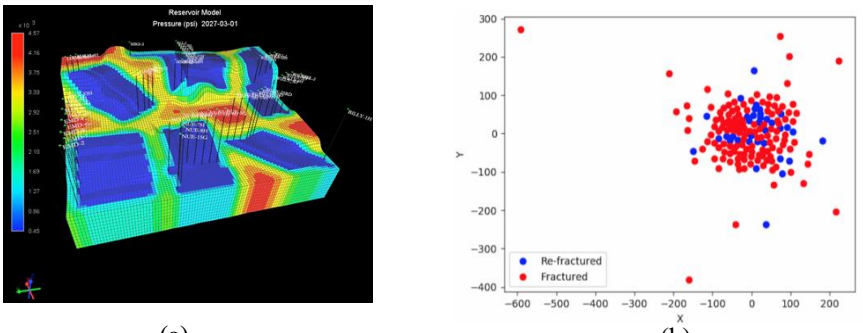
of 23-128-2 was used to determine re-frac candidates from 250 wells. This approach coupled with petroleum engineering practices are used to define potential DCS strategies for the reservoir. Considering geological properties of the formation, these strategies are implemented in a reservoir simulator. After running the simulations, shale gas production, re-fracturing times, and wastewater rates among other parameters are determined for each strategy and utilized as input data to the strategic planning model. This model is described by an MINLP formulation which determines the optimal DCS strategy, infrastructure, operation, and product deliverability, while maximizing enterprise profitability. Natural gas demand trends during the planning horizon are determined by an LSTM neural network and included in the strategic planning model. Other parameters including natural gas and crude oil prices as well as water availability are also inputs to the MINLP model.

3. Reservoir Model, Development Strategy and Candidate Selection

A reservoir model was built for the case study in question in order to simulate alternative field development strategies that will optimize gas recovery and project NPV. The reservoir model was developed using CMG's Builder and run using an adaptive implicit solver (GEM). A single component Langmuir isotherm was used. The near wellbore region of all 54 planned wells employed 7x7x1 local grid refinement (LGR). This aided in capturing important transient effects close to the wellbore and fractures as well as manage the computational effort required to run the compositional model. Fig. 2a illustrates a depletion map for strategy II after 10 years of development.

Three main development strategies (incorporating drilling, stimulation, and re-stimulation) were determined as optimal alternatives for optimizing recovery from the shale reservoir case study. The developed strategies (I, II and III) are the product of reservoir engineering/economic optimization models, current practices in the area, and results of a feedforward neural network algorithm developed for re-frac candidate selection. Details of this approach were discussed by (Hope *et al*., 2017). Six well pads (with variable number of wells) are planned for development having 4000ft - 5000ft laterals, five possible stimulation stage designs and three major well orientations.

A feedforward single layer NN algorithm was developed using well stimulation, completion, reservoir, operational and production data for existing wells in the area of interest. Fig. 2b illustrates mapping of these well datasets. The results of the t-SNE and NN gave insights to the ratio of wells that should be re-fractured among planned wells.



(a) (b)

Figure 2: (a) Illustration of reservoir model showing depletion map at the end of planning horizon, according to strategy II. (b) t-SNE visualization of well data set.

4. Strategic planning model

4.1. MINLP model

For the 10-year planning horizon considered, an MINLP model was developed for shale gas production, transportation and water management, for a venture located in the liquid-rich region of the Marcellus play. The shale gas production in each pad is :

$$SP_{i,t} = \sum_{st \epsilon ST} Y_{st} \cdot spr_{i,st,t} = \sum_{j \epsilon J} FJ_{i,j,t} \quad \forall\, i \epsilon I, t \epsilon T \tag{1}$$

where Y_{st} is a binary variable that equals 1 when a DCS strategy is selected. $spr_{i,st,t}$ is the pad production for each strategy. $SP_{i,t}$ is total shale gas production at each pad. $FJ_{i,j,t}$ represents the shale gas transported from well pads to compression stations.
The variability of total dissolved solids (TDS) in water is considered in this model. This has bilinear terms and introduces non-linearity in our formulation (Yang *et al.*, 2016).
In each compression station, it is possible to establish component balances as follows:

$$FPM_{j,p,t} = mcj_{j,t} \cdot FP_{j,p,t} \quad \forall\, j \epsilon J, p \epsilon P, t \epsilon T \tag{2}$$

where $FPM_{j,p,t}$ is methane transported from compression stations to processing plants. $mcj_{j,t}$ stands for methane composition at each compression station. $FP_{j,p,t}$ is total gas transported from compression station to processing plant. The second term of the equation also includes a bilinear term. This expression can be extended to the other gas constituents. In the case of methane, the flow balance in the processing plat is given by:

$$\sum_{j \epsilon J} FPM_{j,p,t} = \sum_{m \epsilon M} FMM_{p,m,t} + \sum_{u \epsilon U} FMU_{p,u,t} \quad \forall\, p \epsilon P, t \epsilon T \tag{3}$$

where $FMM_{p,m,t}$ is methane transported from processing plant to distribution node. $FMU_{p,u,t}$ is methane transported from processing plant to underground reservoir.
The supply of methane has to satisfy a demand constraint as follows:

$$\sum_{p \epsilon P} FMM_{p,m,t} + \sum_{u \epsilon U} FMUM_{u,m,t} \leq dm_{m,t} \quad \forall\, p \epsilon P, t \epsilon T \tag{4}$$

where $FMUM_{u,m,t}$ is the methane transported from underground reservoirs to distribution nodes. $dm_{m,t}$ stands for gas demand at each distribution node. Similar equations (without storage) can be defined for other shale gas constituents.
The objective function is the maximization of the net present value (NPV), given by:

$$Max\ NPV = \sum_{t \epsilon T} \frac{CFlow_t - CapEx_t}{(1+dr)^{t-1}} - CapExI \tag{5}$$

where NPV is determined as cash flow minus shale wells' investment and capital investment required for gas transportation and processing.

4.2. LSTM neural network for natural gas demand prediction

Time series forecasting, at its heart, is the search for an optimal function that maps historical predictors to forecasted data. Since forecasted data is not available a priori, the algorithm is trained by dividing the historical data into past and future data. Neural network models like LSTM have been shown to outperform traditional time series methods on temporal processing tasks. LSTM's replace the neurons in traditional neural networks with cells that have the ability to retain useful information and overwrite

extraneous data. In this paper, the model is built by stacking an LSTM, sigmoid and linear layer one over the other to maximally increase the accuracy. The number of nodes/layer, epochs and batch size are design parameters that were optimized using exhaustive enumeration. The input to the model comprises of predictors like the price of natural gas, crude oil price, regional population, regional temperature and past natural gas demand. Results of implementing LSTM can be observed in Fig. 3.

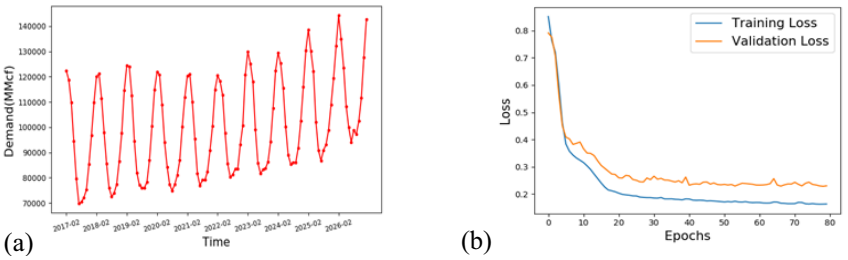


Figure 3. (a) 10-year natural gas demand forecast. (b) Training and validation loss.

5. Results and discussion

The compositional reservoir model was developed with CMG's Builder using an Intel(R) Xeon(R) CPU @ 3.10GHz, 64-bit operating system. Simulation took 10 h of CPU time. Maximum material balance error reported was 2.8113e-5 %. The MINLP model was implemented in an Intel(R) Core(TM) CPU @ 4GHz, 64-bit operating system. The global optimization solver utilized in GAMS was BARON (Tawarmalani and Sahinidis, 2005) with sub-solvers: CONOPT, MINOS and SNOPT. Convergence was achieved in 1.5 h of CPU time with an optimality gap of 2.91%. Python platform was utilized for developing the FNN and LSTM algorithms. The optimal infrastructure is given by Fig. 4.

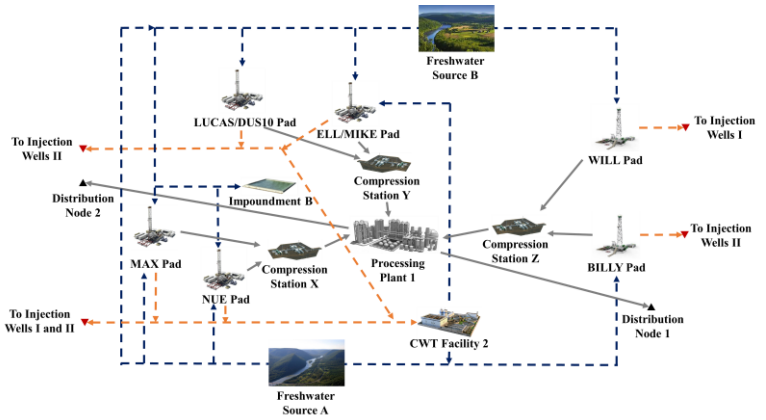

Figure 4: Optimal infrastructure for shale gas production and distribution.

Development strategy II was selected during optimization as it maximizes exploitation of the shale gas reservoir and demand for natural gas, with minimum investment costs. 18 wells were planned for re-fracturing. Fig. 4 shows two distribution nodes are supplied without gas storage. This is necessary to handle when production exceeds demand throughout the planning horizon. Economic results reveal an NPV of 289.83 MMUS$ for

the 54 wells distributed in 6 production pads in the field. The investment required for drilling, stimulation, and completion operations as well as multiple re-stimulation campaigns summed up to 156.626 MMUS$. The costs incurred in drilling and completion far outweighed re-stimulation costs incurred over the planning horizon. This justifies the advantage of re-fracturing selected wells rather than drilling infill wells. Infrastructure costs including pipeline gathering and processing plant summed up to 242.32 MMUS$ (Fig. 5a). Operating and DCS costs are illustrated in Fig. 5b.

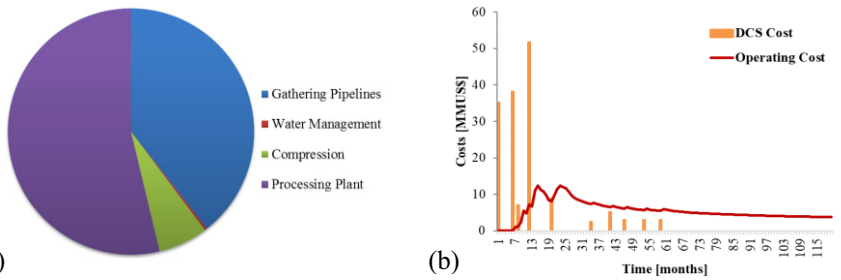

Figure 5: (a) Infrastructure expenditure. (b) Operating and DCS costs.

6. Conclusions

This work demonstrates the importance of an integrated approach for solving the techno-economic problem of shale gas exploitation and supply chain optimization. The simulation of unconventional reservoirs offers a more realistic methodology to define optimal field development strategies which incorporate re-fracturing. Background reservoir engineering optimization should be incorporated in shale gas project planning to support well placement and efficient recovery of natural gas.

Data analytic techniques such as the t-SNE can be analysed with feed-forward algorithms to delineate potentially successful re-frac candidates. This eventually provides a decision support tool for implementing the best initial stimulation and re-stimulation strategies. True NPV optimization was achieved after LSTM demand trends were predicted. Understanding future demand (distribution node dynamics) gave insights to the specific development strategy needed for shale gas exploitation. Future work integrates Machine learning predictions of underground storage, re-frac candidate selection, external/internal demand, and water availability with MINLP optimization.

Abstract

Investments to increase bioenergy generation have been discussed in the sugarcane industry, as public policies opened a broad range of opportunities for bioelectricity in Brazil. The investment decisions are usually based on market conditions, while those projects may implicate relevant changes in product mix decisions and the process conditions in mills. Thus, this study aims to address the nonlinearities associated to process modeling by an optimization framework combining portfolio theory with artificial neural networks, a widely used approach to approximate functions. The results indicate that changes in process conditions impact decision-making for investments. In conclusion, this study evidences the importance of considering process conditions for optimal economic decisions.

Keywords: sugarcane, portfolio optimization, neural networks.

1. Introduction

In industrial processes, the use of residues as a source of revenue has been a practice that enhances the development of strategies to improve energy recovery from waste. In fact, in some sectors, bioelectricity cogeneration already holds a relevant share of the business revenue. This is the case of the Brazilian sugarcane industry, for which there is a large-scale generation of biomass. The bagasse, one of the main residues of the process, represents approximately 27 % of all sugarcane processed. Thus, it is a challenge to find a proper destination for it, which consequently motivates studies for economically feasible applications.

Cogeneration plants were firstly implemented in sugarcane mills as an environmental-friendly destination for the bagasse, applied at the time solely for internal demands of electricity in the process, due to a lack of market for commercialization. Later on, as a consequence of the implementation of public policies to increase renewable energy in Brazil, bioelectricity from bagasse has undergone an expressive growth, now holding a share of approximately 9% of the national matrix of electricity generation.

As a consequence of the increasing opportunities in the energy sector, producers currently face difficulties for decisions with regards of energy recovery projects. Their willingness for investments is usually based on their expectation of profitability, which in turn is highly dependent on market conditions and prices. In the scenario of the Brazilian electricity market, there are two environments of commercialization: the free environment and the regulated environment of commercialization. The first one consists

of bilateral short to mid-term contracts, for which prices are based on the spot market, subject to price volatilities. In the regulated environment, on the other hand, the contracts are usually 20 to 25-years-long, for which there are no variations in electricity prices. Hence, in addition to the investment decisions, sugarcane producers shall also choose a commercialization option for the additional electricity based on their risk-taking profiles.

Price risks have always been an inherent challenge in the sugarcane business, since sugar and ethanol prices have been historically volatile. This way, annual production decisions are usually based on the producer's awareness of price risks. Modern Portfolio Theory, firstly introduced by Markowitz (1952), has been vastly applied as a strategy for such types of risks mitigation. The author provided a method - through an optimization model - to identify how good a given portfolio is, based on the risk and the expected return of assets. Thereupon, the development of risk management theory led to a significant improvement in studies of risk measures. A more recent measure proposed by Rockafellar and Uryasev (2000), the Conditional Value at Risk (CVaR), has been applied in a variety of problems in literature and may be appropriate to deal with this kind of investment decisions, since it is single-tailed. However, the CVaR function is not tractable, resulting in a complex optimization problem to solve and indicating the need for approximation and smoothing techniques (Barrosa et al., 2016).

Moreover, the traditional portfolio optimization approach focuses on economic aspects. Nevertheless, in additional to the high investment costs, the implementation of new bioenergy generation projects implicates extensive process design problems, since they yield changes in process conditions and, consequently, in the availability of surplus electricity. While the process models are nonlinear, and also may considerably change optimal economic decisions, surrogate models emerge as an alternative to make intelligent approximations for complex optimization problems.

Strategies for optimization in process system engineering have been a widely discussed topic in literature, indicating the use of surrogates for modeling as a promising field. In chemical engineering, artificial neural networks (ANN) have been successfully applied to approximate process functions and thus simplify optimization models. Thus, this study aims to propose an optimization framework to solve such types of portfolio decision problems, combining portfolio theory and ANNs. This way, it may contribute to literature in optimization models to support investment decisions on new energy recovery processes, as well as the use of neural networks as surrogate models to portfolio optimization.

This paper is organized as follows: the proposed optimization framework is described in section 2, followed by a case study with an application, in section 3, where results are presented and discussed. Finally, conclusions of this work are in section 4.

2. The proposed framework

In finance, a broadly used measure for risks in a portfolio is the Value at Risk, which states the greatest loss that might occur at a confidence level β, denoted by α. Although popular among portfolio managers, the VaR presents some drawbacks that hinder its use in some applications. Thereupon, the Conditional Value at Risk (CVaR) was proposed by Rockafellar and Uryasev (2000), being a risk measure that accounts for the expected shortfalls at a limited percentile β, as presented in Eq. (1).

$$\mathrm{CVaR} = \mathrm{F}_{\beta}(\mathrm{x},\alpha) = \alpha + \frac{1}{(1-\beta)} \int_{\mathrm{y}\in\mathbb{R}^{\mathrm{m}}} [\mathrm{f}(\mathrm{x},\mathrm{y}) - \alpha]^{+}\mathrm{p}(\mathrm{y})\mathrm{dy} \quad (1)$$

where p(y) is the density function of a random vector *y* that satisfies the cumulative distribution function for the loss associated with the decision vector *x*. Given the relevant volatility in prices for products in the sugarcane sector, the decision-maker has to face a trade-off between expected profitability and risks of significant falls in prices. This way, CVaR may be an adequate measure to deal with such types of product mix and investment decisions in agro-industrial plants.

The portfolio optimization model proposed for this decision problem is presented below. Let $x \in \mathbb{R}^{\mathrm{N}}$ be a decision vector of quantities of each product in a sugarcane mill (sugar, ethanol, free-market electricity, regular-market electricity) and p is the vector of prices for each product in the portfolio. Further, c is the vector of production costs, $\$_{\mathrm{j}}$ is the investment cost of option $j \in \mathrm{J}$, the set of investment options assessed, and $u_j \in \{0,1\}$ is the investment decision. Thus,

$$\begin{aligned} &\min_{x\epsilon X} \mathrm{CVaR}(x,\mathrm{u}) \\ &\text{s. t.} \\ &\textstyle\sum_{i=1}^{N}(\mathrm{E}(\mathrm{p}_i) - c_i)x_i \; - \sum_{j=1}^{J} \$_j u_j \geq r_0\,, \quad x \epsilon \mathbb{R}_{+}^{N}, \;\; u \in \{0,1\} \end{aligned} \quad (2)$$

where X is the set of operational constraints, and r_0 is the lower bound for profit determined by the decision-maker. To build the efficient frontier of risk and expected profit, one should solve the optimization problem for a variety of levels of r_0. Clearly from Eq.(1), the CVaR is not mathematically tractable. Its nonlinearity turns the formulation presented in Eq. (2) into a difficult optimization problem. Thereby, Rockafellar and Uryasev (2000) presented an approximation approach, through the use of historical series or Monte Carlo simulation. However, this method is extremely sensitive to the quantity of simulated scenarios (Barrosa et al, 2016).

In addition, the operational constraints in the model are built from the modeling of processes in the sugarcane mill. Those models also present several nonlinearities that shall be incorporated into the portfolio optimization problem, causing a great increase in the model's complexity. In order to deal with this challenge, it is proposed the use of ANNs, since they have been successfully applied in a variety of chemical engineering problems, including process modeling and optimization. Villarrubia et al (2018) discuss the use of ANNs to approximate the objective function in optimization problems, proposing a framework for which the output function from the ANN is used as an approximation of a nonlinear objective function. Similarly, for the bioenergy investment decisions in the Brazilian sugarcane mills, the portfolio optimization model may be approximated through an ANN. The input variables in the neural network are the amount of sugar (1) and ethanol (2) produced in each product mix, the binary investment decisions (3), and the amount of electricity commercialized to the free (4) and to the regulated market (5). The availability of surplus electricity, which may be destined to either one of the two markets, depends on the process conditions resultant from the first three inputs variables. The simulated process data later used to train and test the ANN is contemplating those inherent variations in process conditions.

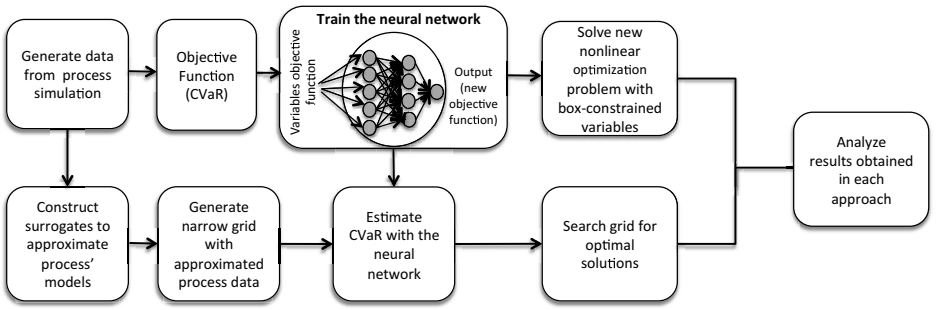

Figure 1 – Optimization framework (Source: Authors)

The optimization framework proposed is presented in Figure 1, summarizing the two possible approaches to use ANN to approximate the solution of this complex problem. The simulated data for decision variables and the CVaR calculated for each product mix, based on the price distributions of all products in the portfolio, are used to fit the neural network, from which the approximated new objective function shall be extracted. The output function obtained from the ANN may be used to find optimal portfolios through grid search or as a new objective function for the optimization problem. In the latter application, the output function is also nonlinear, however, its complexity is reduced, allowing the use of nonlinear optimization software to solve it, while respecting the original box-constraints for the decision variables.

3. Application

In order to illustrate the optimization framework presented in this paper, a simplified case study was performed. Process conditions were simulated from a phenomenological model of a sugarcane mill with processing capacity of 3,000,000 t of sugarcane per year. The original process scenario consists of cogeneration with a Rankine cycle, and the investment decision is to increase electricity generation through the implementation of a backpressure turbine. Opportunity costs associated with other investment options were not considered in the problem. The main production decision is the share of sugarcane's juice that will be diverted to the production of sugar, which implicates changes in ethanol production, as well as in the internal consumption of steam and electricity, changing the amount of surplus electricity available for commercialization.

3.1. Model Calibration

The scenarios were constructed for the two configurations of bioenergy generation, being treated as a binary decision in the optimization problem and implicating investment costs if chosen. For each configuration, the share of juice for sugar was varied from 0 to 100 %, providing annual productions of sugar (t/y), ethanol (m^3/y) and the surplus electricity available for commercialization (MWh/y). Further, scenarios for shares of energy destined to the regulated or the free market were generated randomly, respecting the constraint that all electricity available should be sold. This way, the domain of the variables was created with 440 scenarios generated for combinations of bioenergy configurations (2), shares of juice used for sugar production (11), and shares of energy commercialized in the regulated market (20).

The purpose of this surrogate is to approximate the risk (CVaR) as a function of the decision variables, which in this case are annual production of sugar and ethanol, annual

amount of electricity sold to the free market and the regulated market, and the binary decision on bioenergy investments, accounting also for the important variation in prices associated with variables. Thus, the CVaR was calculated based on a set of historical prices containing 100 monthly observations, from 2005 until 2015. The production costs were assumed to be constant and were based on literature (Grisi et al., 2012), as well as the investment cost, for which the equivalent annual cost (EAC) was obtained from Dantas et al. (2013). All monetary values are in 2010 US dollars. The results obtained are presented in the following subsection.

3.2. Results and Discussion

The neural network that presented the best fit with the training set has one hidden layer with four neurons. Although differentiable, the ANN output function is nonlinear. Thus, its numerical solution is still difficult to determine. The Augmented Lagrangian Method was chosen among the nonlinear optimization packages in R to solve this problem, subject to box-constraints for decision variables, aiming to maintain feasibility of process conditions in the final solution. The optimization problem was solved also for a variety of levels of profits, in order to build the efficient frontier risk-profit.

The use of the ANN as a new objective function for the optimization problem presented some disadvantages, as the algorithm showed a relevant sensitivity to the starting points for search, in some cases resulting in the inability to find solutions within the constrained space. In regards of the results obtained, the portfolios built presented a tendency of increasing sugar production as expected values of profits were incremented, and it also showed a preference for the regulated market. This latter appears to be a manner to reduce CVaR, as this asset is risk-free. However, the choice was done at the expense of feasibility for process conditions, since there was a clear tendency to increase ethanol participation to maintain the profit levels, extrapolating the relation sugar-ethanol production. Thus, to obtain more accurate results, it is necessary to incorporate the nonlinear relations between process variables into the optimization problem, which may potentially increase its complexity.

In order to analyze the potential impacts of those changes in process conditions on the risk-profit results, a second approach of searching within a narrow grid built from the ANN was implemented, which in turn presented more robust results (Figure 2). For the portfolio solutions, quantities of sugar were also increased as expected profit grows. However, instead of increasing ethanol production to unfeasible levels, the portfolios showed an increment in the electricity commercialized to the free market, which increases profits while raises the overall risks. Consequently, levels of risks were higher in the grid search solutions. The changes in the risk levels in relation to the first approach evidence the need of considering process models to obtain more accurate results and assist investor's decisions. Further, in Figure 2, the comparison of frontiers shows that the investment option in bioenergy generation causes a gain in efficiency in the frontier of risk-profit. It is relevant to highlight that, although the second approach was more robust in finding feasible solutions, the grid search method is computationally demanding and may be not viable for large-dimension problems. Thus, an alternative to improve the nonlinear optimization approach for future studies is to combine other surrogate models to perform feasibility analysis within the search-space, as proposed by Ibrahim et al (2017).

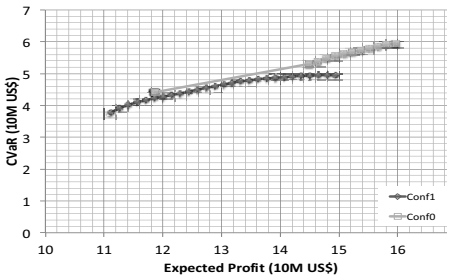

Figure 2 – Efficient Frontiers for Grid Search method (Source: Authors)

4. Conclusions

This paper aimed to discuss the use of artificial neural networks to assist product mix and investment decisions in Brazilian sugarcane mills. The proposed model combined Portfolio Optimization with surrogate models, through the use of ANNs, in order to assess the impact of bioenergy investments in the financial and process conditions. Two approaches were applied showing that nonlinear optimization of the ANN output function was not sufficiently robust to find feasible solutions with regards of process conditions. On the other hand, the grid-search within the results of the ANN presented important insights into the problem, evidencing that the investment in projects to increase energy recovery from waste may present a gain in efficiency in the trade-off risk-profit of bio-refineries. For future studies, a hybrid approach will be developed in order to incorporate feasibility analysis into the optimization framework.

A Projection-based, Data-Driven Method for High-Dimensional Black-Box Optimization

Ishan Bajaj, M.M. Faruque Hasan*

Artie McFerrin Department of Chemical Engineering, Texas A&M University, 3122 TAMU, College Station, TX 77843, USA.
hasan@tamu.edu

Abstract

A derivative-free optimization method based on projection of samples onto a univariate space is proposed to solve multi-dimensional box-constrained black-box problems. This space is defined using sum of the decision variables. When the objective function values are projected onto this space, a multivalued function is generated. It is shown that a univariate function exists on this map that contains the global minima of the original function. A two-step strategy is proposed to identify the function. Sensitivity theorem is employed to predict the values of the function and a trust-region based algorithm is used to correct the predicted point. An algorithm is proposed that identifies the univariate function and then optimizes it such that it corresponds to the actual optima. The proposed algorithm is applied to a test suite of 393 test problems comprising of sets of convex nonsmooth and nonconvex smooth black-box problems and compared with other competitive model-based solvers.

Keywords: Derivative-free Optimization, Univariate Projection, Black-box Optimization, Simulation-based Optimization

1. Introduction

In this paper, we consider the following box-constrained black-box problem:

$$\min\ f(x) \qquad (1)$$

$$s.t.\ x \in [x^L, x^U]$$

where $x \in R^n, f(x) : R^n \to R,$ is a continuous black-box function, whose values are obtained by performing computer simulations. For a variety of reasons, the derivatives are unavailable or unreliable. There are numerous applications of such problems in engineering, physics, medicine, business, and operations research. The methods to solve these problems are referred as derivative-free optimization (DFO). DFO techniques have been applied to many chemical engineering problems including the recent works on process and flowsheet optimization (e.g., Caballero and Grossmann, 2008; Boukouvala and Ierapetritou, 2013). The growing number of potential applications has led to development of several algorithms for solving box-constrained or unconstrained black-box problems. These algorithms can be classified into two major categories, namely direct and model-based (Rios and Sahindis (2013)). Direct algorithms use the function values directly to make progress, and model-based algorithms develop inexpensive surrogate models using simulation data to determine the search direction. Many of the algorithms are currently also available as software packages including ORBIT (Wild et al., 2008), SNOBFIT (Huyer and Neumaier, 2008), BOBYQA (Powell,

2009), IMFIL (Gilmore and Kelley, 1995). Rios and Sahindis (2013) extensively compared the performance of 27 solvers on a set of 502 problems.

In this paper, we propose an algorithm based on projection of samples onto a univariate space defined by a linear combination of the decision variables. This results in a point-to-set map/multivalued function since multiple function values exist corresponding to a single variable value. We identify a univariate function representing the lower envelope of this projection such that its minima is also the minima of the original *n*-dimensional function. We identify the points on this function by applying combination of sensitivity theorem (prediction step) and a trust-region method (correction step). An algorithm is also developed that optimizes the lower envelope such that it converges to the actual optima. We compare the proposed algorithm with BOBYQA, ORBIT, SNOBFIT, IMFIL on 161 convex nonsmooth and 232 nonconvex smooth problems.

2. Main Idea

If an auxiliary variable is added to (1), it is equivalent to projecting the original function in the *t* space. This results in the following optimization problem:

$$\begin{aligned} &\min_{x,t} f(x) \\ &s.t. \frac{\sum_{i=1}^{n} x_i - \sum_{i=1}^{n} x_i^L}{\sum_{i=1}^{n} x_i^U - \sum_{i=1}^{n} x_i^L} = t \\ &\quad x \in [x^L, x^U], t \in [0,1] \end{aligned} \tag{2}$$

While, there are many choices of defining auxiliary variable, the one shown above is a simple choice. The auxiliary variable added is a mathematical artifact and is independent of the objective function. Assuming certain regularity conditions, it can be proved using KKT conditions that the optima of (1) and (2) are the same. Furthermore, we can write problem defined in (2) as follows:

$$\begin{aligned} &\min_{t} G(t) \\ &s.t.\ G(t) = \min_{x} f(x) \\ &\qquad s.t.\ \frac{\sum_{i=1}^{n} x_i - \sum_{i=1}^{n} x_i^L}{\sum_{i=1}^{n} x_i^U - \sum_{i=1}^{n} x_i^L} = t \\ &\qquad\quad x \in [x^L, x^U], t \in [0,1] \end{aligned} \tag{3}$$

Expressing problem as shown in (3) allows us to decompose the problem in two steps. The lower problem defines the problem of identifying the samples on the lower envelope, while the upper problem involves optimizing the lower envelope. Solving the lower problem given in (4) is a linearly constrained black-box problem and needs to be solved for different parameter values, t such as t^p to obtain $G(t^p)$, where t^p is the p^{th} element in the set, $Z_{k'} := \{t^1, \dots, t^Q\}$:

$$\begin{aligned} G(t) = \ &\min_{x} f(x) \\ &s.t.\ g_i^1 := x_i^L - x_i \le 0 && \forall i \in \{1, \dots, n\} \\ &\quad g_i^2 := x_i - x_i^U \le 0 && \forall i \in \{1, \dots, n\} \\ &\quad h_1 := \frac{\sum_{i=1}^{n} x_i - \sum_{i=1}^{n} x_i^L}{\sum_{i=1}^{n} x_i^U - \sum_{i=1}^{n} x_i^L} = t \end{aligned} \tag{4}$$

The conservation of the minima on projection onto a univariate space is illustrated using a 2-dimensional Branin function. Figure 1(a) give the surface plot of the function. It can be observed that the problem has 3 minima, all of which are also global minima. The global minimum value of the function is 0.397887 and is achieved at $\boldsymbol{x}^* = (-\boldsymbol{\pi}, \mathbf{12.275})$, $(\boldsymbol{\pi}, \mathbf{2.275})$, and (9.424, 2.475). Figure 1(b) illustrates the point-to-set map obtained by projecting the samples on the *t* space. It also shows the lower envelope obtained as a result of minimizing $\boldsymbol{f}(\mathbf{x})$ at all *t* values. Figure 1(c) shows that the three minima are conserved after projection.

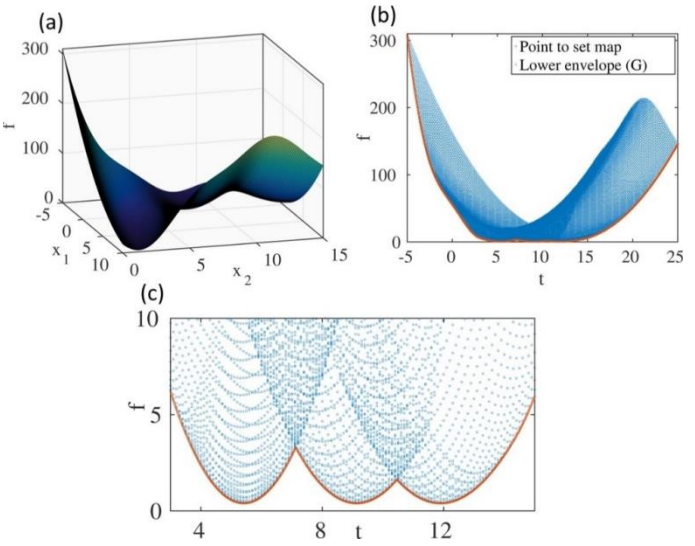

Figure 1. (a) *Branin Function*, (b) *Point-to-set map*, (c) *Lower envelope illustrating the minima.*

3. Properties of *G*(*t*)

It can be observed that (4) is a parametric problem in *t* and therefore, the results about convexity, concavity, continuity, differentiability can be borrowed from sensitivity literature (Fiacco, 1984) to illucidate key properties of $G(\mathrm{t})$.

Property 1. If $f(\mathrm{x})$ is continuous, then $G(\mathrm{t})$ is continuous.

Property 2. Assuming KKT conditions, LICQ hold at the optimal point of (4) at parameter value, t^p ($\bar{x}^p$), then *G*(*t*) is differentiable at t^p.

Property 3. If $f(\mathrm{x})$ is convex (concave), then $G(\mathrm{t})$ is convex (concave).

Property 4. Assume that KKT conditions, SOSC, LICQ and SCS hold true at $\bar{x}^p$ with associated multipliers $\bar{v}$ and $\bar{\lambda}$, then in the neighborhood of t^p, the optimal function *G*(*t*) is twice continuously differentiable.

Property 5. $G(t^L) = f(x^L)$, $G(t^U) = f(x^U)$.

3.1. Prediction of G(t)

Solving (4) from an arbitrary point is challenging. However, a good initial guess can greatly expedite the convergence. If the optima at t^p is known, we desire to obtain the optima at the next parameter value t^{p+1}. Fiacco (1984) proposed a technique to estimate the sensitivity of a local solution of a nonlinear program to small perturbation in the problem parameters. A linear approximation of Fiacco's sensitivity theorem is given as follows:

$$\begin{bmatrix} \Delta\hat{x}_p \\ \Delta\hat{v}_p^1 \\ \Delta\hat{v}_p^2 \\ \Delta\hat{\lambda}_p \end{bmatrix} = -\left(\widehat{M}\left(y(t^p)\right)\right)^{-1} N(t^p)(t^{p+1} - t^p) \tag{5}$$

where $\Delta\hat{x}_p = \hat{x}(t^{p+1}) - \bar{x}^p$, $\Delta\hat{v}_p^1 = \hat{v}^1(t^{p+1}) - \bar{v}^1(t^p)$, $\Delta\hat{v}_p^2 = \hat{v}^2(t^{p+1}) - \bar{v}^2(t^p)$, $\Delta\hat{\lambda}_p = \hat{\lambda}(t^{p+1}) - \bar{\lambda}(t^p)$, and let $\Delta\hat{y}_p = \left[\Delta\hat{x}_p, \Delta\hat{v}_p^1, \Delta\hat{v}_p^2, \Delta\hat{\lambda}_p\right]$.

For definition of $\widehat{M}$ and N, refer Fiacco (1984). $\widehat{M}$ requires the Hessian of the Lagrangian function (L). Since the optimization problem is black-box, the Hessian of the surrogate model is used to approximate the Hessian of the original Lagrangian function. Let the corresponding matrix be defined as $\widetilde{M}$ and the solution given by Fiacco's sensitivity theorem using $\widetilde{M}$ be denoted by $\Delta\tilde{y}_p = \left[\Delta\tilde{x}_p, \Delta\tilde{v}_p^1, \Delta\tilde{v}_p^2, \Delta\tilde{\lambda}_p\right]$. For convenience in notation, $\widehat{M}(y(t^p))$ and $\widetilde{M}(y(t^p))$ will be represented as $\widehat{M}^p$ and $\widetilde{M}^p$ respectively. We derive the bounds on the difference of the solution given by using exact Hessian and the solution obtained if the Hessian of the surrogate model is used.

Theorem 1. Assuming that the surrogate model is fully quadratic, the assumptions of Theorem 1 are satisfied at t^p, then

$$\left\|\Delta\tilde{y}_p\right\| - \left\|\Delta\hat{y}_p\right\| \leq \left((\kappa_{\widetilde{M}^p} - 1) + \frac{\kappa_{\widetilde{M}^p}\kappa_H\Delta}{\left\|\widetilde{M}^p\right\|} \right) \alpha \frac{\kappa_{\widehat{M}^p}\|N\|}{\|\widehat{M}^p\|} \tag{6}$$

Proof. Rewriting first-order sensitivity approximation compactly when the Hessian is known and taking the norm: $\Delta\hat{y}_p = -\left(\widehat{M}^p\right)^{-1} N^p\alpha \;\Rightarrow \|\Delta\hat{y}_p\| \leq \alpha\|\left(\widehat{M}^p\right)^{-1}\|\|N^p\|$. We also know that $\widetilde{M}^p\Delta\tilde{y}_p = \widehat{M}^p\Delta\hat{y}_p$. Taking norm, we get $\frac{\|\Delta\tilde{y}_p\|}{\|\Delta\hat{y}_p\|} \leq \|\left(\widetilde{M}^p\right)^{-1}\|\,\|\widehat{M}^p\|$. We can also show that $\frac{\|\Delta\tilde{y}_p\| - \|\Delta\hat{y}_p\|}{\|\Delta\hat{y}_p\|} \leq \frac{\|\kappa_{\widetilde{M}^p}\widehat{M}^p - \widetilde{M}^p\|}{\|\widetilde{M}^p\|}$, where $\kappa_{\widetilde{M}^p}$ refers to the condition number of $\widetilde{M}^p$. Now, aassuming Frobenius norm is used, the following can be verified:

$$\left\|\kappa_{\widetilde{M}^p}\widehat{M}^p - \widetilde{M}^p\right\|_F = (\kappa_{\widetilde{M}^p} - 1)\left\|\widehat{M}^p\right\|_F + \|\kappa_{\widetilde{M}^p}\nabla^2 L - \nabla^2 L^r\|_F - (\kappa_{\widetilde{M}^p} - 1)\|\nabla^2 L^r\|_F \tag{7}$$

$$\frac{\left\|\Delta\tilde{y}_p\right\| - \left\|\Delta\hat{y}_p\right\|}{\|\Delta\hat{y}_p\|} \leq (\kappa_{\widetilde{M}^p} - 1) + \kappa_{\widetilde{M}^p}\frac{\|\nabla^2 L - \nabla^2 L^r\|}{\|\widetilde{M}^p\|} \tag{8}$$

Assume that the model is fully quadratic, $\|\nabla^2 L - \nabla^2 L^r\| \leq \kappa_H\Delta$ and using Eq. (8), we finally get the bounds given in Eq. (6).

4. Algorithm

The overall algorithm is given in Figure 2. We know the optimal point at $t = t^L$ and therefore, the algorithm is started by setting t^l to t^L and a positive starting step length, α is selected by dividing the t-space into N_p parts. Basic sensitivity theorem (details provided in Section 3.1) acts as a prediction step by estimating the optima at t^{p+1} given the optima at t^p is known. Due to approximations involved, the predicted point, $\tilde{x}^{p+1}$ may not always correspond to the exact optima of (4) and therefore, the predicted points need to be corrected. This mechanism is referred as the correcting algorithm. We adapt the trust-region model-based method of Powell (2009) to handle linearly constrained

problems and use it as the correcting algorithm. The details of the algorithm are not provided here to stay within the page limit. We chose to use trust-region based method since we expect the prediction step to give a good initial guess and trust-region methods are known to converge rapidly if a good initial point is provided. Once an optimal point, $\bar{x}^{p+1}$ is obtained, the objective function value at $\bar{x}^{p+1}$ is compared to that at $\bar{x}^{p}$. If the objective function value at $\bar{x}^{p+1}$ is less than that at $\bar{x}^{p}$, a new step length α is chosen based on the number of evaluations taken by the correcting algorithm to solve (4) at parameter value t^{p+1}. If the number of function evaluations corresponding to the parameter value t^{p+1} is less than that taken at t^{p}, the step length is increased. If the objective function at t^{p+1} is more than that at t^{p}, this implies that $G(\mathrm{t})$ has started to increase and that optima (at least local) lies within $[t^{l}, t^{p+1}]$. A univariate surrogate model to approximate $G(t)$ is then constructed using samples in the interpolation set, Z_{kl}. $G(t)$ is then minimized, and the bounds on t are updated. This procedure is repeated until the bounds on t are smaller than a pre-specified tolerance.

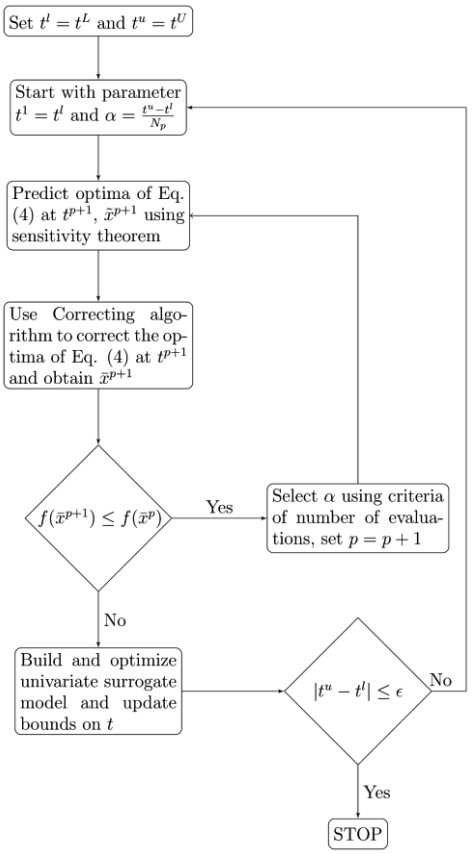

Figure 2. *Optimization framework.*

5. Numerical Results

The algorithm is applied to a test suite of 393 test problems from (Rios and Sahinidis (2013)) consisting of 161 convex nonsmooth and 232 nonconvex smooth problems. The performance of the proposed algorithm is compared to that of BOBYQA, SNOBFIT, IMFIL and ORBIT. All the solvers are allowed to perform 100,000 function evaluations. Each evaluation requires the same computation time for different solvers. Default parameters are used for all the solvers. A solver is said to have solved a problem if a point x^s is obtained such that $f(x^s) \leq \max(1.01 f(x^*), f(x^*) + 0.01)$, where x^* is the minima. The performance is first compared on a set of 232 nonconvex

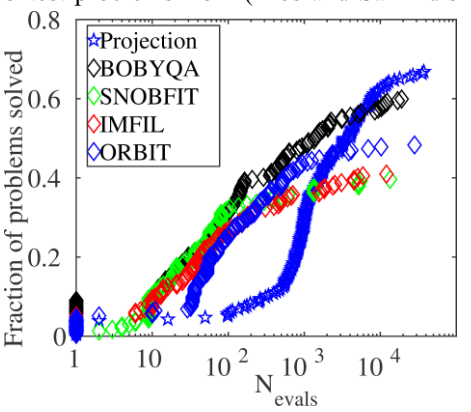

Figure 3. *Data profile illustrating the fraction of problems solved with number of evaluations for 232 nonconvex smooth problems.*

smooth problems. Figure 3 illustrates that the projection based approach is able to obtain solution within 1% of the global minima for 155 of the 232 problems, BOBYQA solves a total of 155 problems. ORBIT, SNOBFIT and IMFIL solves 112, 81 and 81 problems, respectively to global optimality. This illustrates that the proposed approach has a better mechanism to explore the global space more effectively. Figure 4 provides the data profile of different model-based solvers on a test suite of 161 convex nonsmooth problems. The proposed algorithm solves 49 of the 161 problems while ORBIT, BOBYQA, IMFIL and SNOBFIT solves 17, 15, 7 and 2 problems respectively.

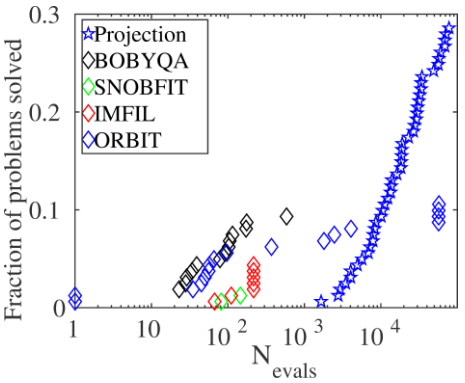

Figure 4. *Data profile illustrating the fraction of problems solved with number of evaluations for 161 convex nonsmooth problems.*

6. Conclusions

We proposed a method for optimizing box constrained black-box problems. The method is based on the concept of projecting multidimensional variables to a univariate space defined by linear combination of the original decision variables. A special function is identified in this space optimizing which is equivalent to optimizing the original problem. An algorithm is developed which identifies the points on the one-dimensional function and optimizes it. A two-step strategy is employed that identifies the function. The first step involves a prediction step based on sensitivity theorem while the second step is a correction step based on trust-region method. It is shown that the difference of the solution given by the sensitivity theorem with the hessian of the surrogate model and the exact Hessian is bounded. The performance of the algorithm is illustrated on 393 problems and compared with BOBYQA, SNOBFIT, ORBIT and IMFIL.

Abstract

This study compares eight surrogate-model construction approaches using computational experiments. The construction approaches considered include: Artificial Neural Networks (ANNs), Automated Learning of Algebraic Models using Optimization (ALAMO), Radial Basis Networks (RBNs), Extreme Learning Machines (ELMs), Gaussian Progress Regression (GPR), Random Forests (RFs), Support Vector Regression (SVR), and Multivariate Adaptive Regression Splines. Each approach is used to construct surrogate models for predicting the outputs of thirty-four test functions. The data used to construct surrogate models were generated using Latin Hypercube Sampling (LHS), Halton and Sobol sampling methods. We studied the impact of sampling method, sample size, and challenge function characteristics on the accuracy of surrogate model predictions. Our results revealed that for smaller sample sizes, on average, surrogate models trained using the data points generated by Sobol sequences provided the best estimation for all surrogate model construction approaches. As the sample size increased, the impact of sampling methods diminished. The comparison of surrogate-modeling construction approaches at large sample sizes revealed that surrogate models trained using ANN, ALAMO, and ELM yielded smaller root mean squared error and higher adjusted R-squared values than the models trained using the rest of the approaches.

Keywords: Surrogate Model, Process Design, Optimization

1. Introduction

Chemical engineering design problems have evolved in recent years from large scale bulk processes to targeted small batch approaches. As a result, computer aided design is reaching beyond the traditional solutions to classical chemical engineering problems. Take for example, the removal of CO_2 from flue gas. The computer aided molecular design framework, CAMD, can be used to identify the ideal ionic liquid for CO_2 removal (Davis et al., 2016). One method that can be used to reduce the computational burden is surrogate modeling. Surrogate models seek to understand input and output relationships that are either unknown or complex via reasonably accurate simpler functions. Many surrogate models have been defined and studied for different applications. Our previous study compared different surrogate modeling approaches in terms of their accuracies using root mean square error (RMSE) and maximum absolute error (MaAE) as the performance metrics. We evaluated the impact of function shape and number of inputs on the accuracies of surrogate model predictions with a sample size of 1,000 data points (Davis et al., 2017). When the results were considered in terms of RMSE, the models developed using Artificial Neural Networks (ANNs) consistently provided the lowest values for all numbers of inputs functions, while the models

developed using Automatic Learning of Algebraic Models for Optimization (ALAMO) were comparable to ANN models for functions with four and 10 inputs. When the performance of surrogate model types based on the shape of the challenge functions were considered, ANN models yielded the smallest RMSE for all function shapes. The current work extends these initial comparisons to understand the relationship between the accuracy of the surrogate model and the following characteristics: (1) sampling method; (2) sample size; (3) block-box model shape; and (4) number of inputs. Eight surrogate modeling approaches were used in the analysis. These approaches are: ANN, ALAMO, Extreme Learning Machines (ELM), Support Vector Regression (SVR), Radial Basis Networks (RBN), Gaussian Process Regression (GPR), Random Forests (RF), and Multivariate Adaptive Regression Splines (MARS). A brief overview of these surrogate modeling approaches is provided in Section 2. Training data was generated using thirty-five challenge functions with various surface shapes and number of inputs for each surrogate model. Some brief introductions of the challenge functions are given in Section 3. Each challenge function-surrogate model combination was trained using data generated using three different sampling methods, Latin Hypercube Sampling (LHS), Sobol Sequence and Halton Sequence. The sample size was varied from 50 to 12800, doubling each time. Section 4 provides the procedure for computational experiments. In addition to the surrogate model training and evaluation times, six performance metrics, MaAE, RMSE, Akaike Information Criteria (AIC), Bayesian Information Criteria (BIC), R-Squared, and R-Squared Adjusted were calculated for each challenge function and surrogate model combination based on the difference between the true values and the surrogate model predictions using a test set of 100,000 data points generated using the Sobol sampling method. The comparison of surrogate model training and evaluation times, and performance metrics for different sampling methods and surrogate model construction approaches are presented in Section 5. Concluding remarks are given in Section 6.

2. Surrogate Models Compared in This Study

ANNs are inspired by the brain. The neurons and the synapses that relay messages use signal strengths in an adaptive feedback loop. ANN was developed by relating the artificial neurons with their biological counterpart and synapses with weights. Weights and biases associated with artificial neurons are optimized by minimizing an error metric (generally mean-squared error) between ANN predictions and training data (Haykin, 2009). An approach which was developed to reduce complexity while maintaining accuracy is ALAMO. This surrogate model takes advantage of many different types of basis functions including: polynomial, multinomial, exponential, logarithmic, and trigonometric. ALAMO decides which basis functions to incorporate in the surrogate model along with the parameters of the basis functions incorporated using global optimization techniques (Cozad et al., 2014). ELMs is based on the same premise as ANN, but differs in the learning scheme. Instead of using a learning algorithm, ELM randomly assigns the weights. This difference allows the training problem to be solved as a linear equation system which provides a significantly faster solution (Huang et al., 2006). Another surrogate model that seeks to transform the data and relationships into a linear system is SVR. This application of support vector machines fits the data onto a linear plane where the data can be analyzed (Jin et al., 2001). RBN, while similar to ANN, differs due to its reliance on the radial spread of each RBF function in each dimension (Jin et al., 2001). GPR is a surrogate model that places all the data on continuous domain, such as time or space, and then uses a linear

combination of the inputs to generate the outputs (Mirbagheri, 2015). The RF model was developed based on the use of decision tress as a prediction method. Input values are processed through a set of decision trees which in turn use probability to estimate the outputs (Breiman, 2001). MARS is the final surrogate model considered. This method overfits the model using a linear summation of spline functions, then removes the additional terms until the model is optimized (Friedman, 1991).

3. Challenge Functions

Thirty-five challenge functions with defined shapes and numbers of inputs were utilized for analysis from the Virtual Library of Simulation Experiments (Surjanovic, 2013). Simon Fraser University created this resource to provide users with functions to evaluate new simulation and optimization methods. The optimization group provides 47 challenge functions divided by shape including: 16 multi-local minima shaped functions, seven bowl shaped functions, five plate shaped functions, four valley shaped functions, three ridges/drops shaped functions and 12 other differently shaped functions. Thirty-five functions with defined shapes were utilized for the analysis. Additionally, the challenge functions were compared based on the number of inputs.

4. Computational Experiments

The sampling methods that were utilized to generate training data from the challenge functions include LHS, Sobol Sequence and Halton Sequence. LHS is a stratified sampling technique, and it splits the range of each input variable into N intervals of equal probability, where N is the number of sample points. Then, each of the N partitions is sampled once, and randomly combined. Sobol and Halton sequences are both quasi-random low-discrepancy sequences, which seek to distribute samples uniformly across the input space. These methods were selected as they are shown to sample input space uniformly with limited sample sizes for functions up to ten dimensions (Dife and Diwekar, 2016). From each challenge function, input-output pairs were generated using the three sampling methods for nine sample sizes. Each surrogate model was trained using these data sets. Then, the performances of all surrogate models were evaluated using a data set of 100,000 input-output pairs that were generated according to the Sobol sampling technique. The error, the difference between the surrogate model prediction and the actual function output, is calculated for each of these 100,000 input-output pairs. The errors and the number of model parameters (when necessary) are then used to calculate performance metrics, which are MaAE, RMSE, Akaike Information Criteria, Bayesian Information Criteria, R-Squared, and R-Squared Adjusted (Mathworks, 2017) Additionally, the training time was recorded during the phase of the program where the model was trained, and evaluation time was recorded during the phase when the final outputs were generated. All computations were carried out on a HP Spectre X360 X64-based PC with 16 GB RAM using MATLAB 2017b.

5. Results and Discussion

5.1. Results Based on Sampling Method and Size

Figure 1 shows the change in average adjusted R-squared values with sample size. The error bars in Figure 1 correspond to standard deviations. At sample sizes of 1,600 or more, the surrogate models trained using any of the three sampling methods performed similarly. However, for smaller sample sizes, surrogate models trained using data generated by Sobol sequence, on average, outperformed models trained using data

generated by Halton sequence and LHS. Similar trends were observed with Akaike Information Criteria, and Bayesian Information Criteria.

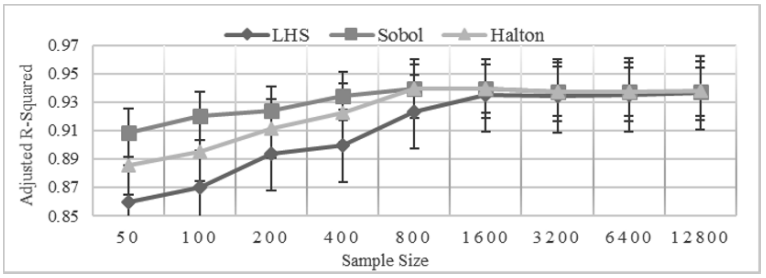

Figure 1: Adjusted R-Squared based on Sample Size

When considering MaAE and RMSE, similar trends were observed, therefore a plot of RMSE is given in Figure 2 to illustrate the trends. As the size of training data points is increased above 400, the RSME of surrogate models trained using any of the sampling methods was about the same. When the sample size was less than 400, all sampling methods error rates increased.

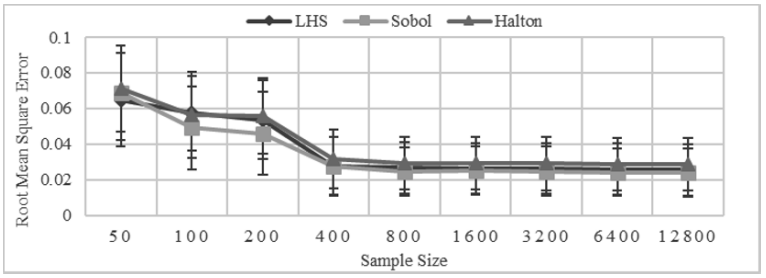

Figure 2: Root Mean Square Error based on Sample Size

Figure 3 shows how the training time changes, as sample size is increased by surrogate model type. In average, surrogate models constructed using ELM were trained the fastest, and ALAMO the slowest.

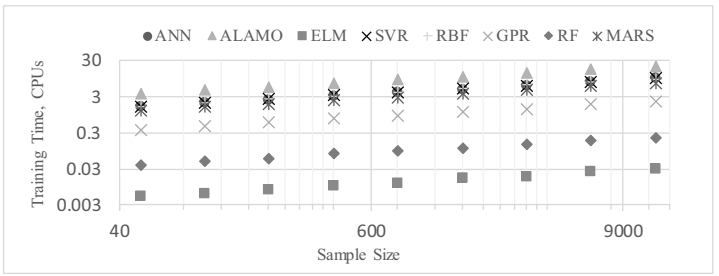

Figure 3: Training times for all Surrogate Models based on Sample Size

All training times increased exponentially with increasing sample sizes. The average surrogate model evaluation times were 0.006953, 0.009465, 0.005953, 0.006648, 0.006656, 0.006652, 0.006642, 0.006652 for surrogate models constructed using ANN, ALAMO, ELM, SVR, RBF, GPR, RF, MARS, respectively. ALAMO was shown to

have the longest evaluation with other models requiring about the same amount of evaluation time.

5.2. Results Based on Challenge Function Shape and Inputs

Two performance measures, MaAE and RMSE, were calculated for each challenge function and surrogate model combination. Both error calculations provide similar inferences, so RMSE was used to illustrate the results. Based on the results previously discussed, the surrogate models were compared using a sample size of 12,800 produced with the Sobol sampling method.

In terms of RMSE (Figure 4) based on the number of input functions for a sample of size of 12,800 using the Sobol Sampling Sequence, the models developed using ANNs consistently provided the lowest values for all functions, where the RMSEs of the models developed using ALAMO were comparable to the RMSEs of ANN models for functions with 2, 3, and 5 inputs. Overall, these comparisons suggest that the models developed using ANNs and ALAMO have comparable accuracy for functions with different dimensions.

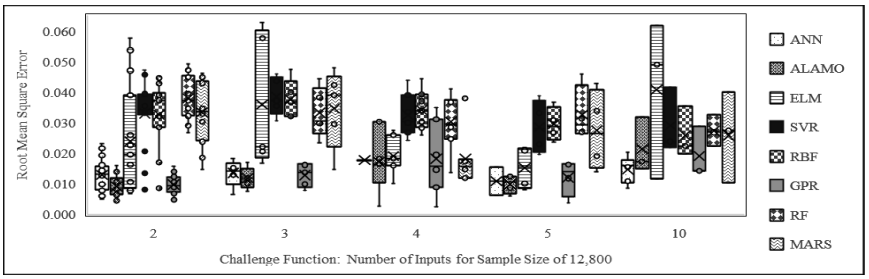

Figure 4: Challenge Function – Number of Inputs for Sample Size of 12,800

When the performance of surrogate model types are compared based on the shape of the challenge functions for a sample of size of 12,800 using the Sobol Sampling Sequence as shown in Figure 5, the error for ALAMO and GPR was almost equal for Multilocal Minima, Plate, Bowl, and Valley Shapes. ANN provided the lowest error for Ridges and Drops, however provided nearly as good results as ALAMO on other shapes.

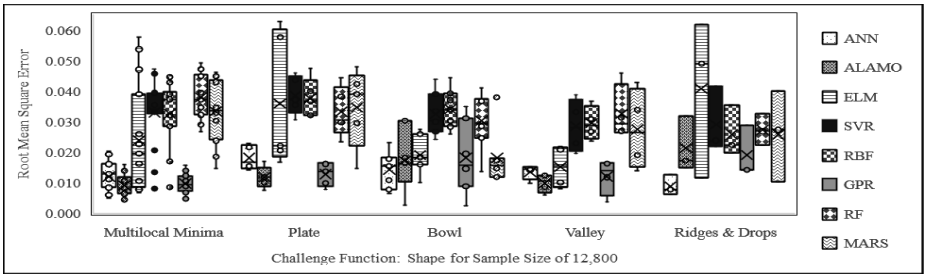

Figure 5: Challenge Function – Shape for Sample Size 12,800

6. Conclusions

This study compared the relationship between the surrogate model and the system variables including: (1) sampling method; (2) sample size; (3) surface shape of the input function; and (4) complexity of the input function. In addition to the training and evaluation time, six performance measures: Maximum Absolute Error (MaAE), Root

Mean Square Error (RMSE), Akaike Information Criteria, Bayesian Information Criteria, R-Squared, and R-Squared Adjusted were analyzed to provide guidance when selecting the optimum surrogate model. All methods and models provided a better fit at larger sample sizes. Sobol provided the best estimation over the full range of sample sizes. Overall, ANN, ALAMO, and ELM models all provided better estimation than the other models tested.

Space mapping based derivative-free optimization framework for supply chain optimization

Atharv Bhosekar, Marianthi Ierapetritou*

Department of Chemical and Biochemical Engineering, Rutgers,The state University of New Jersey, 98 Brett Road, Piscataway 08901, United States,
marianth@soemail.rutgers.edu

Abstract

Derivative-free optimization (DFO) addresses the problem of optimizing over simulations where a closed form of the objective function is not available. Developments in the theory of DFO algorithms have made them useful for many practical applications. However, most of the existing DFO algorithms do not show satisfactory performance on high-dimensional problems. One contributor to this difficulty is the accuracy of the surrogate models used to guide the search for the optimum. Space mapping approach exploits a simplified simulation, which is a physical surrogate of the original problem at hand. As the simplified simulation is computationally efficient, a larger number of samples can be collected for guiding the search. This work aims to assess the potential of space mapping for derivative-free optimization, understand the difficulties and display its performance on a supply chain simulation optimization problem for identifying optimal inventory allocation. Computational results illustrate the potential of this approach.

Keywords: derivative-free optimization, physical surrogate models, multi-fidelity analysis, space mapping, supply chain simulation.

1. Introduction

Simulations are widely used by researchers in various engineering and scientific disciplines due to their ability to capture realistic details of the phenomenon under study. The problem of optimizing over simulations, however, is a non-trivial problem because of high computational requirement and absence of an algebraic model. Derivative-free optimization (DFO) algorithms can be used to address this problem (Conn et al., 2009). There has been a significant research in the area of DFO algorithms in past two decades and these algorithms have achieved significant maturity to be able to solve many problems. A lot of research has been done on strategies to build surrogate models, their accuracy for modelling, and essential considerations for their use in derivative-free optimization (Bhosekar & Ierapetritou, 2018). However, sampling requirement for accurate predictions increases with increase in problem size. Thus, surrogate models fail to provide reliable approximations of the original problem. This poses a difficulty for DFO algorithms (Rios & Sahinidis, 2013).

Another approach for obtaining an approximation of a simulation is to use a simplified but computationally efficient simulation to gather information. These models are referred as physical surrogate models. The idea was introduced and developed under the terminology of space mapping (Bandler et al., 1994) and multi-fidelity analysis (Fernández-Godino et al., 2016). Because of the generality of this idea, it has found

successful applications in various disciplines such as electrical engineering, design simulations, traffic optimization (Osorio & Bierlaire, 2010) and fluid dynamics (Banda, 2011).

Supply chain modelling is one of the areas where simulations have found increasing use. With the help of simulations, one can understand the effects of complex interactions between various supply chain entities on the overall performance of supply chain. Agent based simulations is an efficient way to represent such a complex network of entities (Sahay & Ierapetritou, 2013). Decision making considering such interactions is an interesting but often a non-trivial problem (Sahay & Ierapetritou, 2016).

In this work, an insight into space mapping approaches is provided for their application in optimizing a supply chain simulation. The problem of optimal allocation of inventory for minimizing the total cost of a multi-enterprise supply chain is considered. Simulations are designed to capture the details of the interaction between these enterprises in the form of complex auction mechanisms. Under the influence of complex interactions within a supply chain network, this problem is shown to display a non-convex and non-smooth behavior. Two output mapping strategies are compared for this problem of identifying optimal inventory while minimizing the total cost. Comparisons with existing DFO algorithms show that space mapping shows promising performance. The rest of the article is organized as follows. Section 2 provides an insight into the space mapping methods. In Section 3, specifics of the supply chain simulation under consideration are discussed. Section 4 discusses computational results, potential difficulties and positives of using space mapping. Finally, conclusions and summary are provided in Section 5.

2. Space mapping

Consider the problem of minimizing a simulation output where variable bounds are the only constraints present as shown in the problem (1).

$$\begin{aligned} &\min f(x) \\ &\text{s.t. } \mathrm{LB}_i \le x_i \le \mathrm{UB}_i \; \forall i \in \{1, \dots, n\} \end{aligned} \tag{1}$$

where LB_i and UB_i represent lower and upper bounds on the variable x_i; n is the number of variables; $f: R^n \to R$ is the simulation output which is assumed to be expensive and therefore closed form of f is assumed to be unavailable. Space mapping makes use of an approximation $c: R^n \to R$. This approximation is assumed to be computationally efficient. For the rest of the paper, simulation f is referred to as high-fidelity simulation (HFS) whereas simulation c is low-fidelity simulation (LFS). There are multiple ways in which one can establish a relationship between c and f. One way to do this is by correcting LFS response with the help of additive or multiplicative corrections as given in Equations (2), and (3), respectively.

$$\hat{f}(x) = \rho(x)c(x) \tag{2}$$

$$\hat{f}(x) = c(x) + \delta(x) \tag{3}$$

Corrections $\rho(x)$ and $\delta(x)$ are used to enhance the existing accuracy of the analytical surrogate model with the help of finite HFS evaluations. Another way is to have

comprehensive corrections where multiplicative and additive corrections included together as shown in Eq. (4).

$$\hat{f}(x) = \rho(x)c(x) + \delta(x) \tag{4}$$

In comprehensive corrections, $\rho(x)$ is often considered a constant. Another comprehensive surrogate modelling strategy is co-kriging (Qian et al., 2006). Kriging surrogate can be described as given in Equation (5).

$$\hat{f}(x) = \sum_{i=1}^{m} \beta_j f_j(x) + \epsilon(x) \tag{5}$$

where $f_j(x)$ are m independent basis functions that define the trend of mean prediction at location x; β_j are unknown parameters; $\epsilon(x)$ is a random error at location x that is normally distributed with zero mean. Co-kriging makes use of LFS to build a base Kriging model and relates it to HFS again using a Kriging surrogate as given in Eq. (6).

$$Z_e(x) = \rho Z_c(x) + Z_d(x) \tag{6}$$

where Z_e is the output from HFS and Z_c is the output from LFS; $Z_d(x)$ represents the discrepancy at sample location x. All the above-mentioned mappings consider a relationship between outputs. It is also possible to have a mapping between inputs as given in Eq. (7).

$$x_{LFS} = p(x_{HFS}) \tag{7}$$

where, $p: R^n \rightarrow R^n$ is the input space mapping. This mapping is established iteratively using local secant approximations until mapped HFS and LFS responses align within a certain tolerance limit (Bandler et al., 1995). Since trust-region framework allows any kind of surrogate model to be used, space mapping optimization has been combined with trust-region optimization approach (Osorio & Bierlaire, 2010), (Vicente, 2003). This provides additional properties that help in proving convergence of the optimization approach.

3. Supply chain simulation

In this work, an agent based multi-enterprise supply chain simulation is considered (Sahay & Ierapetritou, 2016). As opposed to centralized supply chains considered in traditional problems, this simulation allows one to handle decentralized decision making by individual entities. Each entity in the supply chain is a separate agent that performs its functions based on a set of policies. These policies determine the behavior of each agent based on its environment. Five different types of agents that are supplier, production site, warehouse, market, and auctioneer are considered. Each entity in this network has its own role. For example, warehouses store products and send shipments to markets according to the demand. Similarly, production sites handle production and ship products to warehouses. Auctioneer agent handles interactions between entities belonging to separate enterprises in the form of auctions. There is a certain cost associated with each agent and the task it performs. Market incurs a backorder cost if the demand is not fulfilled. Warehouses have an inventory holding cost and transport cost to the markets. Production sites have production cost, transport cost as well as holding cost for raw materials and products. Addition of all these costs is the total cost of the supply chain.

There are several differences in the previously proposed simulation (Sahay & Ierapetritou, 2016) and the simulation used in this work. Production sites give preference to the product that is available in the least quantity in the product inventory. Warehouse inventory replenishment is done with continuous review using a policy including reorder level and reorder quantity. The reorder amount of a warehouse depends on the capacity of the warehouse. The demand is considered to be lost with a certain penalty if supply chain fails to satisfy the demand. As production sites and warehouses belong to the same enterprise, production sites aim to satisfy maximum demand from the warehouse. Time delay between an order from warehouse and delivery from production sites is incorporated.

4. Computational results and discussion

4.1. Problem description

A supply chain network consisting of one supplier, three production sites, two warehouses, and two markets is considered in this study. Each market or retailer is considered to belong to a separate enterprise whereas raw material suppliers, production sites, and warehouses are all considered to belong to the same enterprise. The supply chain is considered to produce two products. The problem of optimal allocation of warehouse capacity is considered. Warehouse capacity decides the amount of product inventory maintained at the warehouse. A large amount of inventory may lead to large inventory holding cost. On the other hand, small warehouses make it difficult for the supply chain to satisfy the market demand. This trade-off becomes more complex under the influence of auctions between warehouses and markets. For understanding this, the supply chain simulation is studied over 100 time periods. As the computational cost of the simulation is directly proportional to the number of time periods, a higher number of time periods results in computationally expensive simulations. An LFS for this simulation is obtained by limiting the planning horizon to 10 periods. Demand for each period is approximated as average demand at the corresponding time period if the horizon is divided into 10 subintervals. The aim, in this case, is to minimize the total cost reported by the simulation with respect to warehouse capacity. For the problem under consideration, the total cost can be plotted to study the response. Figure 1 and Figure 2 display the response surface of supply chain total cost with respect to warehouse capacities for both LFS and HFS respectively Close observation of these responses indicates non-smooth behavior.

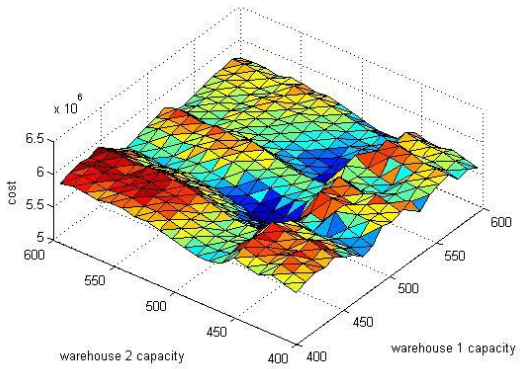

Figure 1:LFS total cost variation with warehouse capacity

4.2. Methods and results

In the computational comparisons, two mappings are considered. First mapping considers a multiplicative correction as given by Equation (2) whereas second mapping considers comprehensive

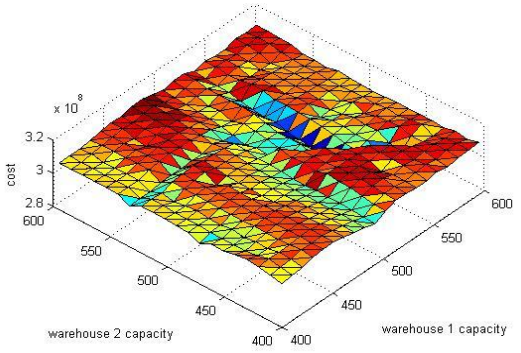

Figure 2:HFS total cost variation with warehouse capacity

correction as given in Equation (4) with a constant $\rho(x)$. These strategies are considered because of their simplicity and because of number of previous applications. Multiplicative correction particularly helps in this case because the total cost of a supply chain can be different by an order of magnitude because the HFS is run for more number of time periods. The ratio and discrepancy of HFS and LFS is approximated using a Kriging model built starting with 50 sample points from the HFS. For optimizing the corrected surrogate model and for optimizing the non-smooth simulation in this work, a discrete gradient method (Bagirov et al., 2008) is used.

Total cost optimization problem is formulated subject to bound constraints on warehouse capacities. Lower and upper bounds are set to be 400 units and 600 units respectively. The best solution found after optimizing the mapping surrogate is 464 units for one warehouse and 466 units for the other warehouse. The same optimum is achieved using both mappings. Total cost at the optimum is \$307110590. Further, HFS is optimized using pattern search and CMA-ES algorithms as these algorithms are not deterministic and make no assumptions on the smoothness of the objective function. These results are tabulated in Table 1.

Table 1: Comparison of space mapping surrogates with existing DFO solvers

Solver name	CMA-ES	Pattern search	Mapping 1	Mapping 2
Total cost	\$306587517	\$304629215	\$307110590	\$307110590

It is clear that pattern search performs better than other algorithms while CMA-ES shows a comparable performance with mapping methodology. Several observations can be made from these results. Relatively worse performance of the mapped surrogates can be attributed to the accuracy of Kriging surrogate used for mapping discrepancy or ratio. As the accuracy of Kriging surrogate depends on the quality of sample set, a model built from a stationary sample set may lead to inaccuracies near optimum. Identical optimal solution achieved indicates that both strategies are equally accurate and lead to a similar response with an identical optimal solution. Finally, as sampling requirements for pattern search and CMA-ES increases steeply with problem size. Therefore, a good simplification with the help of space mapping strategy can be preferred for derivative-free optimization in higher dimensions.

5. Conclusions

In this work, a simplified simulation is used as a surrogate model and its use in optimization of supply chain simulation is studied. Several strategies used by researchers in various disciplines for mapping LFS and HFS are discussed. Two of

these strategies are applied for supply chain simulation optimization. A multi-enterprise supply chain simulation is considered where enterprises interact through multi-attribute auctions. Warehouse capacity allocation problem for minimizing the total cost of the supply chain simulation is considered. This was observed to form a nonconvex as well as non-smooth optimization problem. Results showed that both mapping strategies yielded an identical optimal solution. With the fact that sampling requirements for existing DFO algorithms as well as that for surrogate models grow with problem size, space mapping is a promising approach and needs to be studied for higher dimensional problems.

Abstract

In chemical process optimization, often one type of formulation can be more advantageous due to financial constraints, compatibility issues with modelling software, the availability of optimization solvers and/or the importance of establishing global optimality. Historically, the availability and computational efficiency of linear program (LP) solvers, or even mixed integer linear program (MILP) solvers, were significantly better than some nonlinear program (NLP) solvers, which was a key incentive to reformulate nonlinear optimization problems to LPs or MILPs. However, with the current advanced NLP solvers and the recent improvements in optimization modelling platforms and techniques, it might now be redundant for practitioners to reformulate certain real-world NLP problems into integer/linear programming problem. This paper shows that with the right integration between the NLP formulation and the state-of-the-art solvers, it is possible to achieve significantly better optimization performance for real-world organic Rankine cycle systems.

Keywords: Organic Rankine Cycle, Nonlinear Programming, Mixed Integer Linear Programming, Optimization

1. Introduction

Often practitioners invest a considerable amount of time reformulating their optimization problems into LP and MILP models in order to achieve convergence or better optimization performance, as shown in (Borrelli et al., 2006; Yue et al., 2013). However, with the recent advancement in nonlinear optimization algorithms, we have observed significant performance improvements in NLP solvers in handling complex chemical process optimization problems. This is in addition to the improvement in optimization modelling platforms and computational performance of desktop hardware. Consequently, with the current availability of both advanced modelling platforms and optimization nonlinear solvers, it is debatable if there are sufficient compelling advantages for certain real-world chemical process systems to be reformulated into LPs or MILPs.

In this paper, we test this hypothesis on organic Rankine cycle (ORC) systems, with different topologies consisting of real-world thermodynamic processes. The novelty of this research is to illustrate a systematic equation-oriented modelling approach on a spectrum of ORC systems, namely as NLP and MILP formulations, where exact derivatives can be provided. This differs from the common black-box optimization

approach implemented by Clarke & McLeskey (2015) and Ghasemi et al. (2013). In addition, the paper also aims to compare the computational advantages and disadvantages of both formulations and to indicate if it is advisable to formulate linear models for real-world ORC systems. This way, optimization problems that concern with improving the economics or the performance of the ORC systems, such as those carried out by Astolfi et al. (2014) and Budisulistyo & Krumdieck (2015), can be solved efficiently.

2. Optimization Strategy and Modelling Platform Overview

2.1. Nonlinear Programming Strategies

One of the main difficulties in solving NLP problems is dealing with inequality constraints because they can either act as equality constraints or just strictly satisfies the inequality condition at the optimal solution. Most derivative-based NLP solvers, like FMINCON and IPOPT, are Newton-type algorithms and address this issue using the active-set sequential quadratic programming (SQP) strategy or the interior point (IP) method. Unless optimizing convex problems, these solvers can only assure local optimality and are dependent on a good starting point and accurate derivatives. Whereas, spatial branch-and-bound based global NLP solvers, like SCIP and BARON, can guarantee the "true" global solution but are more computationally expensive as the nonlinear problem are successively divided and solved until it converges to the global solution. Modern NLP solvers are now significantly more reliable and are widely adopted due to the development of the quasi-Newton method and globalization strategies, and the more recent filter method (Biegler & Grossmann, 2004), that helped to overcome the difficulties in dealing with indefinite Hessians and poor starting points.

2.2. Mixed Integer Linear Programming Strategies

MILP methods are derived from the branch and bound algorithm, where the MILP problems are "branched" into subproblems, called nodes, and solved as relaxed LP problems at imposed bounds. The MILP problem will continue to recursively split into nodes until the difference between upper bound (integer solution) and lower bound (LP solution) are within a tolerance. Since the 1990s, there have been significant advancements in MILP methods, such as pre-processing techniques and cutting planes, which have greatly improve the performance of MILP solvers (Balas & Fischetti, 2017).

2.3. Modelling Platforms

Solving process optimization problems with fast and reliable optimization solvers is only one aspect of achieving efficient optimization capabilities. The modelling platform also plays a crucial role in optimization. With a better understanding of the advantages and disadvantages of different optimization algorithms, practitioners can now focus more on formulating well-posed models that are tailored to specific solvers and improve the overall performance. Some simulation packages, such as GAMS, AMPL and AIMMS, have direct interfaces to the solvers and can provide exact derivatives using automatic differentiation strategies that can significantly improve the overall optimization performance (Biegler, 2014).

3. Organic Rankine Cycle Models

For this research, four different ORC configurations were modelled, namely the Basaran ORC (using refrigerant R227ea) (Basaran & Ozgener, 2013), DOE Pilot Plant (DiPippo, 2016, p. 550-561), USGeo Plant (DiPippo, 2016, p.562-571) and Magmamax Binary

Power Plant (DiPippo, 2016, p.516-524). For brevity, the construction of both the NLP and MILP formulations will only be briefly described below for the DOE Pilot Plant.

3.1. Nonlinear Programming Formulation

The DOE plant is a dual-pressure ORC system that consists of a high pressure (HP) and a low pressure (LP) ORC utilizing the same geofluid. The NLP model was formulated in equation-oriented mode, which amounts to deriving a set of deterministic algebraic equations that describes the process of the plant and approximating the output characteristic of the unit operations using regression and thermodynamic analysis. The system was assumed a steady state and a steady-flow process; where changes in kinetic and potential energy were neglected, and losses induced by friction were neglected. The geofluid was treated as pure water and the pressure drops across heat exchangers and pipelines were neglected. A similar procedure is discussed by Am et al. (2017) that results in the following algebraic NLP formulation

$$\min \quad f(\boldsymbol{x}), \quad \text{s.t.} \quad \boldsymbol{h}(\boldsymbol{x}) = 0\,, \boldsymbol{g}(\boldsymbol{x}) \;\leq\; 0, \boldsymbol{x} \;\in\; \mathbb{R} \tag{1}$$

where $f(\boldsymbol{x})$ is the objective function, $\boldsymbol{h}(\boldsymbol{x}) = 0$ is a set of equations that represent the system's performance (mass and energy balances, and operational constraints), and $\boldsymbol{g}(\boldsymbol{x}) \leq\; 0$ describes primarily the operational limits or specifications of the DOE plant. As such, the thermodynamic process of the pump and the turbine, namely the input/output power, were regressed with respect to pressure, P, and/or enthalpy, h, using polynomial functions to allow for the calculation of exact derivatives. As a result, the LP turbine output power can be expressed as

$$\dot{W}_T = -0.286P^2 - 5.33 \times 10^{-5}h^2 + 0.00948Ph + 3.5P + 0.0335h - 41.9 \tag{2}$$

In addition, some of the operational constraints/limits were also regressed if they vary with respect to pressure and/or temperature. For instance, the LP turbine inlet enthalpy must be greater or equal to the saturated vapour enthalpy value can be expressed as

$$h_T^{in} \geq\; 0.014P^3 \;+\; -0.697P^2 \;+\; 15.2P \;+\; 545 \tag{3}$$

The geofluid inlet and outlet properties were kept constant as specified in (DiPippo, 2016), as well as the isentropic efficiencies, mass fraction, and the cooling water and pump inlet/outlet temperatures and pressures. Whereas, the HP and LP turbine inlet pressures and temperatures were allowed to vary between 15 to 26.31 bar and 388.71 to 413.71 K, and 6 to 14 bar and 355.37 to 380.37 K, respectively. Since the focus is on the solver performance and optimization formulations, and not the plant performance, variation of ambient conditions and power output were not considered.

3.2. Mixed Integer Linear Programming Formulation

The MILP model was formulated using piecewise linear approximations on the NLP model described above. For all the nonlinear unit operation approximations and operational constraints, shown in (2) and (3), these were replaced with piecewise linear approximations by changing the order of regression curves and specifying fixed breakpoints. For the isentropic turbine work approximations, the triangle method (D'Ambrosio et al., 2010) was used in order to obtain a better piecewise linear fit. Subsequently, all the mass and energy balance bilinear terms, such as $\dot{m}_i h_i$, can be linearly approximated using the method discussed in Section 7.7 of (Bisschop, 2016). If the objective function is a fractional term, the Charnes & Cooper transformation in conjunction with the Glover's linearization scheme (Yue et al., 2013) can be implemented to acquire the following MILP formulation

$$\min \ \mathbf{c}^{\top}\mathbf{x} + \mathbf{d}^{\top}\mathbf{y}, \quad \text{s.t. } \mathbf{Ax} + \mathbf{Ey} = \mathbf{b}, \mathbf{Fx} + \mathbf{Gy} \leq \mathbf{h}, \mathbf{x} \in \mathbb{R}, \mathbf{y} \in \{0,1\} \qquad (4)$$

where $\mathbf{c}^{\top}\mathbf{x} + \mathbf{d}^{\top}\mathbf{y}$ is the objective function, $\mathbf{Ax} + \mathbf{Ey} = \mathbf{b}$ and $\mathbf{Fx} + \mathbf{Gy} \leq \mathbf{h}$ describe the system's performance, the operational limits or specifications of the ORC system, and the piecewise fit constraints.

4. Model Optimization

The ORC models were constructed using MATLAB R2017a and were optimized using a Windows 3.1 GHz Intel Core i5 laptop. In order to efficiently optimize the ORC models, the OPTI Toolbox v2.27 (J. Currie, 2017) was used due to its compatibility with the nonlinear regression and the piecewise linear approximation functions that were developed in MATLAB. The solvers were selected based on their availability for academic use and their compatibility with OPTI and MATLAB. Derivative-free solvers were not considered as they are not suitable for constrained problems (Biegler, 2014) and do not fully benefit from our algebraic model structure. The optimality tolerance was set to 1×10^{-7} for all solvers and the objective is to maximize the following ratio

$$f(\boldsymbol{x}) = \dot{W}_{\text{net}}/(\dot{m}_{\text{cw}} + \textstyle\sum_{i=1}^{n} \dot{m}_{\text{wf}_i}) \qquad (5)$$

where $\dot{W}_{\text{net}}$ is the total turbine work minus total pump work, $\dot{m}_{\text{wf}}$ is the working fluid mass flow and $\dot{m}_{\text{cw}}$ is the cooling water mass flow. The thermodynamic properties of the fluids were obtained from the REFPROP database (Lemmon et al., 2013).

5. Results and Discussion

Table 1 shows both the comparison between the NLP and the MILP formulations, and the performance between the different solvers. As expected, there are considerably more variables and constraints in the MILP formulations due to the piecewise fit approximations. Interestingly, the results showed that the NLP solvers are significantly faster than their MILP counterparts. All the NLP solvers managed to converge to a feasible solution under 13s. Whereas the MILP solvers took between ~1s and ~2200s to converge and, in a few cases, did not find a feasible solution for some of the ORC plants, namely with CBC and GLPK. The fastest MILP solvers were GUROBI and CPLEX, ranging from 0.79s to 106.72s, but they are still, overall, slower than the NLP solvers.

One factor that could have contributed to the poor performance of the MILP formulations is the number of binary variables. There is a possibility that it can run into time limitation with a large number of binary variables, especially if there is a large difference between the feasible solution and the optimal relaxed LP solution (Biegler & Grossmann, 2004). While the number of binary variables can be reduced by decreasing the number of breakpoints of the piecewise approximation, it might not be sensible as it could render the MILP model infeasible or give an inaccurate representation of the ORC system. In addition, unlike NLP solvers, supplying a good initial guess to MILP solvers does not always improve the performance because all the MILP solvers in this research can automatically handle this internally. This was verified by obtaining similar CPU times as shown in Table 1 for most of the solvers when the optimal solution was substituted back to the problem. Consequently, having a large number of variables would require more effort from the solver to finding a feasible starting point and likely leads longer CPU time. For the NLP solvers, they benefited more from the algebraic model structure; therefore, their short computational time can be attributed to the availability of accurate derivatives

and bypassing the use of finite difference. Furthermore, from analysing the Jacobian matrices of the NLP formulations, they are significantly sparse and have the density values of 47.92% (BAS), 17.93% (DOE), 11.87% (USG), and 17.16% (MMM). Therefore, given that the models are algebraic, the solver can exploit this sparsity information to achieve a faster computational time (J. D. Currie, 2014). Moreover, the inequality constraints present a major difficulty for NLP problems due to the complementarity conditions (Biegler & Grossmann, 2004), and they are much harder to solve than equality constraints. Consequently, given that the number of inequality constraints in the NLP models is relatively small, i.e. 3 for BAS, 7 for DOE, 11 for USG, and 9 for MMM, these NLP models might be inexpensive to optimize.

Table 1: Comparison results between the NLP and the MILP formulations, where ORC Plant BAS, DOE, USG, and MMM are Basaran ORC, DOE Pilot Plant, USGeo Plant and Magmamax Binary Power Plant, respectively. The objective function value (top) and the average CPU time (bottom [seconds]) are given for each solver. Please refer to (J. Currie, 2017) for the solvers' references.

6. Conclusions

This paper compared the NLP and the MILP formulations of various real-world ORC systems and the optimization performance of both formulations. The results showed that the optimization performance of the NLP models, and their respective solvers, performed considerably better than the MILP models. This could be attributable to the availability of exact derivatives, especially with the second derivatives, and utilizing state-of-the-art NLP solvers. In addition, the NLP solvers were able to take advantage of the algebraic

model structure and the sparsity information to efficiently solve the optimization problem. Evidently, with the right integration between the solver and the NLP formulation, such as providing analytical derivatives, can lead to better optimization performance than the MILP formulation. Therefore, for chemical processes that are similar to an ORC system, it is conceivably sensible to initially use the NLP formulation if it is applicable, especially if there is a small number of inequality constraints or no highly nonlinear terms. However, since some MILP solvers do not require any initial values, it is possible to take advantage of the MILP formulation to acquire a good initial guess for the NLP model to further improve the performance or when the initial guess is hard to obtain.

Abstract

One of the biggest challenges today, is the need to feed a growing population. Considering climate change and the effect it may have on agriculture systems, the sustainable intensification of food production is a necessity. The objective of the research presented in this paper is to address the issues related to the large-scale stressors that can present a barrier to the current efforts for sustainable intensification of food production in Qatar. It relies on remote sensing imagery as the primary dataset owing to the ability of the satellite sensors to cheaply gather data with good areal coverage and spatial resolution, and with added benefit of repeated surveys from the satellite overpasses over a given area. The steps of the proposed methodology developed in this research include: (a) image processing for training and prediction using neural networks; (b) extraction of atmospheric and surface features that can directly affect greenhouse operations, e.g. those related to land and water resources, and energy requirements; (c) formulation of a mixed integer non-linear programming (MINLP) framework using surrogate modelling for the maximization of the crop productivity objective; (d) development of GIS database augmented with recommender systems. The results obtained so far are promising, with root mean squared percentage error of 11.93 for the crop water demand prediction, and it is envisaged that the proposed development of a smart geospatial framework with predictive capabilities, EWF optimization, and augmented GIS will facilitate for informed policy development aimed at the success of the food security programs in Qatar.

Keywords: EWF nexus, food security, neural network, MINLP, Optimization

1. Introduction

The global population is expected to increase to 9 billion by 2050 (DESA 2010), thus increasing the demand for energy, water and food (EWF) resources to meet the growing demand for products and services. For instance, food production will need to increase by 50 – 100 % (Royal Society, 2009). In addition, uncertainties with respect to climate change and rapid resource utilization necessitates the need to develop integrated resource models. The complex relationship between climate and agriculture systems requires special attention (Grasty 1999). Temperature changes, shifting of rainfall patterns and increase of the global CO_2 levels are the most obvious consequences of climate change which will inevitably impact global food systems. Perhaps, the most vulnerable regions that may suffer as a result of climate change are those characterised by arid and semi-arid climates. In fact, crop yields vary from season to season in these regions which are dry and lower in latitude primarily due to changes in climate which are difficult to predict (Grasty 1999). As such, the importance of integrated modelling and the utilization of a

EWF nexus approach for assessments on the environment and/or resource utilization is especially important for countries such as the State of Qatar. Considering that, the State of Qatar is embarking on large scale food security initiatives, it is important to manage future resource requirements.

(Ali et al. 2017) used feasible generalized least square (FGLS) and heteroskedasticity and autocorrelation (HAC) error techniques to analyse the impacts of the extreme climate phenomena on the agricultural products of several crops, such as rice wheat, sugarcane and maize in Pakistan. The stressors considered include the maximum and minimum temperature, rainfall, humidity and sunshine. The study concluded that wheat production is significantly affected by the maximum temperature, whereas the effect of the minimum temperature is visible in all crops. (Fraiture et al. 2007) suggested that the wheat production in South Asia will decline by about 50% by 2050 which corresponds to 7% of the global crop production. With current trends of global warming, it is suggested that agricultural production in developing countries can decrease by 10% to 25%.

Considering, the integrated manner in which EWF resources are utilized, it is necessary to understand the system wide affect from climate change and how that may contribute to food insecurity. Al-Ansari et al. (2015; 2016; 2017) developed a EWF nexus, a web of interactions that link the EWF sectors, model which was applied to a hypothetical food security scenario in the State of Qatar. The study evaluated through a nexus approach means to which impacts on the environment can be mitigated when increasing domestic food production. However, the effect of climate change is not considered in their study. In a comprehensive study utilizing the EWF nexus for drought prevention, it was found that climate change is the main driver for reduction in agriculture productivity (Zhang et al. 2017). In their study, the authors used an integrated optimized EWF nexus modelling approach as a basis for the development of an effective agricultural drought management system. This was achieved by combining systematically a real-time irrigation management and drought monitoring by using a geospatial and agricultural data obtained from a remotely measuring satellite, meteorological stations. The study found that the crop yield during a drought year can be reduced by 50% when compared to a wet year.

The objective of this study is to develop a model which is capable of predicting crop water demand for an Alfalfa case study in Qatar when challenged with external stressors. The cultivation of Alfalfa is a fundamental component of Qatar's food security aspirations as it progressively expands its domestic livestock systems. A feedforward neural network is used to predict the effect of large scale stressors on the crop water demand. The application of neural network is very promising in a complex system like agriculture, which constitutes of huge amount of data coming from different components. To incorporate a spatial information of the stressors, a satellite data is used and a non-linear optimization technique is applied to allocate the optimum water required by the production fields. To the best knowledge of the authors, this is the first study done for this region that focuses on the application of machine learning methodologies for monitoring the effect of large scale stressors on crop productivity on a national scale.

2. Data Description

For this study, a predictive model for the water demand of alfalfa crop (m^3/ha) within the State of Qatar is developed. The schematic diagram process is shown in figure 1. The model is challenged by four potential large-scale stressors which include; humidity (%), temperature (C), soil moisture (g/cm^3) and evapotranspiration (mm). Except for soil

moisture, all the other variables are obtained from some meteorological stations in Doha. However, the data for soil moisture was obtained from AMSR-E satellite. The spatial resolution of the soil moisture is 25km by 25km. Furthermore, a monthly timescale is adopted for the analysis and the time range covers from 2002 to 2006. The water used for irrigation is assumed to come from a treated sewage effluent (TSE). The TSE plants found in Doha and which are currently in operation, are shown in GIS map below in figure 2. Moreover, the existing Alfalfa fields, potential areas for growing alfalfa crop and preferable transportation means for the distribution of water are also showed in the map. Previously, both ground water and TSE plants were using for irrigation, but groundwater is neglected from consideration because of depleting ground water reserves and increasing salinity of its water.

3. Methodology

The methodology consists of two parts in which the model development procedure is illustrated on figure 1. The first part involves a forecasting model using a Neural Network to make a prediction of crop water demand. A neural network is a computational model works in an analogous way to the way information is processed in a brain by biological neurons. Once the crop water demand is known, then a Non-linear Programming technique is used to make cost-efficient allocations of water resources. The type of neural network considered in the study is a simple feedforward neural network with three layers i.e. the input, hidden and output layer. A linear transfer function is used for the input layer, and a sigmoidal activation function in the hidden and output layer. The data observed is divided into training and validation groups. The model is first trained using training data and then validated using the portion of the remained data. Back-propagation method is used here, which is the most common technique for training ANN model. Once the parameters of the model are optimized and a least error is obtained in the validation processes, then the model is used for forecasting the crop water demand for one year ahead.

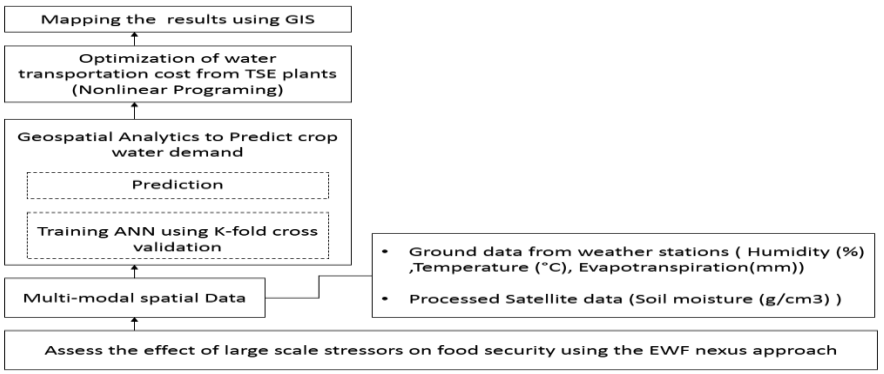

Figure 1. Schematic Diagram of the process

The limitations on the duration of the data available had its own challenge in training the model. To overcome this limitation, a k-fold cross validation was used, where the samples are randomly subdivided into k equal sized parts. The model was trained and analysed using the k-1 subsamples, and a single subsample was left for validation. In this study, k is taken to be 3 due to small data size. The forecasted unit crop water demand (m^3/ha) obtained are used for calculating the amount of water required by the crop production

fields. The areas of the production fields are obtained from the GIS map in figure 2. The irrigation water from the TSE plants are then allocated based on the cost of transportation using Non-Linear Programming. The optimally allocated water demand is finally reported using GIS software. The energy consumption is included in the water utilization and transportation, thereby making the study a holistic approach to the EWF nexus.

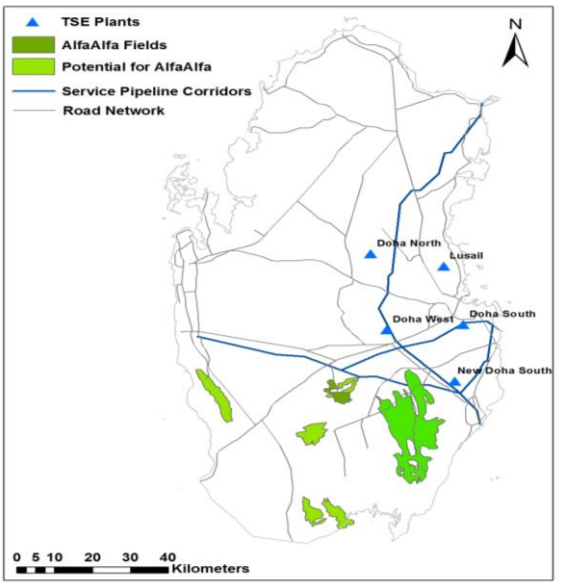

Figure 2. GIS Map of TSE sources and sinks, and transport network options

4. Results and Discussions

In order to demonstrate the objectives of this study two production fields and two nearby TSE plants are considered where the total water demands for field 1 (f1) and field 2 (f2) are 4.25 $x10^6$ m^3 and 5.46$x10^6$ m^3 respectively. The model developed as part of this research is able to capture the variation of the crop water demand during the hot and cold seasons, where the output of the optimized feedforward neural network illustrates agreement with the observed data as illustrated in figure 3(a) below. The accuracy of the output is validated using a correlation coefficient (0.983) and error measurement indices, root mean squared percentage error (11.93). After validation, a scenario is assumed for the one-year forecasting. The temperature observations are multiplied by random numbers generated between 1 and 1.1, by taking the assumption that the temperature will vary up to 10% above the previous observations. Comparison of forecasted year with previous years demonstrates that the crop water demand will increase with the maximum periods from April to August as illustrated in figure 3(b).

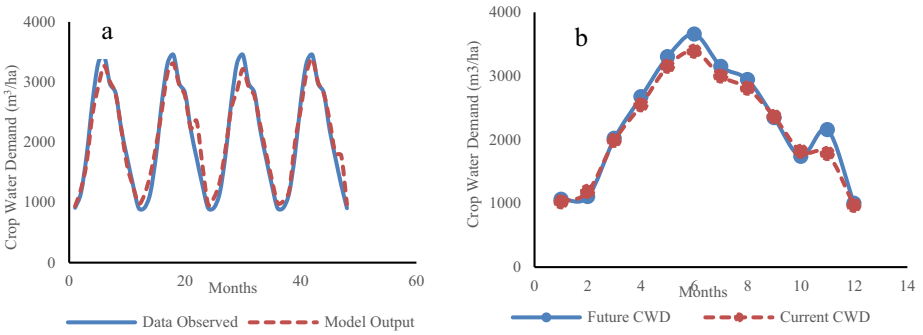

Figure 3: (a) Comparison of Model Output with Observation, (b) Comparison of Future and Current CWD.

The output of the optimization is illustrated in Figure 4. The fraction of water delivered from the TSE plant i to the field j is indicated by qij. It consists of four fractions of water supply distributed from the two sources to f1 and f2, q11, q12, q21 and q22, and optimum location (x,y) for storage water received from TSE plants prior to distribution to f1 and f2.The forecasted unit crop water demand (m^3/ha) is considered uniform throughout all alfalfa fields in Qatar because of the similar regional climatic conditions and the total water demand per production field is calculated using the product of field area and unit crop water demand. The objective of the nonlinear optimization is to minimize the total cost of the network which is a factor of the type of water distribution. The TSE plants which are currently in close proximity to these fields are Doha West and Doha South, with capacities of 7.37×10^6 m^3 and 7.20×10^6 m^3 respectively.

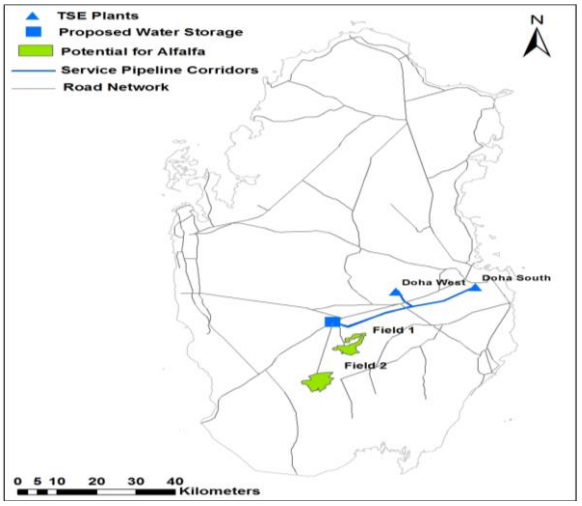

Figure 4. Final output of optimisation.

Water is transported from the TSE plants to the fields through two means: (1) pipeline where the transportation cost is \$0.00061 per m^3.km (Zhou and Tol 2005), (2) and local roads with the price of transportation is assumed to be 10% larger than the cost of pipeline. Based on the analysis, the optimum location of the storage is determined as illustrated on figure 4. Moreover, the results demonstrate that the two TSE plants should distribute 62% of their water capacity to f1, whereas the remaining amount is distributed to f2. The water supplied to f1 is more than the water demand of f1 and thus has an excess of 4.86 $x10^6$ m^3, whereas f2 receives the exact amount of its water demand, therefore remains with no excess water each month. The excess water allocated to f1 can be locally stored and used for next month or through peer to peer water trading system which can be introduced between neighboring fields.

5. Conclusions

In conclusion, ANN is found to be helpful tool in predicting the crop water demand. The non-parametric nature of ANN and its easy adaptation to different data formats give it superiority over traditional modelling tools. In this study, it was found that the impact of drought varies with the growing season of the crop, where the highest impact is observed between Mid- April and Early-June. A number of assumptions is considered in the study, because of coarse resolution of the soil moisture and limited point measurement of temperature available, but the framework is ready enough to work to its capacity when a data with a longer period record and good resolution is obtained. Future work will include: strengthening the model with data to overcome any assumptions considered; model expansion to accommodate other stressors of crop productivity, such as sunshine; and finally, the application of sensitivity analysis to monitor the reaction of the crop productivity for the change of the stressors.

Abstract

The rise in global population and the consumption of energy, water, and food (EWF) resources continues to increase exponentially, placing enormous stresses on the three resource sectors. Therefore, assessing the inter-linkages between EWF resources is a very crucial step to achieve sustainable resource utilization, through increased economic efficiency and enhanced environmental performance. Such integrated assessment is often challenged by the difficulty in presenting a robust formulation which considers the necessary details of embedded systems, the availability of relevant models and data, as well as the representation of their uncertainties, based on which the design and operations of connected supply chains are ideally optimized. The objective of the research presented in this paper is to address the key challenges of the EWF nexus through the development of a techno-economic framework under non-cooperative settings. The methodology developed assumes a bottom-up approach in which the self-interested stakeholders, i.e. the players, are represented based on their own decision variables and objective functions at various levels, i.e. resources and environment systems, engineering systems, and their integration and operations. For this purpose, a combination of optimization models based on linear programming, stochastic programming, and game theoretic approach, represented by a Stackelberg competition, were developed. A case study is set in the State of Qatar with the objective of enhancing food security using hypothetical scenarios. The results obtained demonstrates that interesting interactions between systems, albeit competitive, can potentially result in the achievement of desired objectives under properly regulated markets, and is therefore envisaged as a promising contribution towards sustainable policy development and nexus governance.

Keywords: EWF nexus, food security, stochastic optimization, Stackelberg

1. Introduction

Human activities are driven by a combination of energy, water and food systems. The fact is, water is used in food cultivation and power plants' cooling necessities for electricity generation. Energy is essential for water desalination and treatments as well as for agricultural facilities. In addition, crops produced in agriculture can be converted into energy in the form of biofuels (Garcia and You, 2016). These inherent inter-dependencies between the resources introduces the concept of the energy water food (EWF) nexus. Factors such as exponential population growth, climate change and globalization are considered stressors to EWF systems. As such, to ascertain true resource consumption in

the delivery of products or services, and ensure continuous and sustainable resource utilization, it is necessary to optimize the EWF nexus inter-linkages, enabling the efficient management of trade-offs that will likely exist. Considering environmental issues and the excessive demand for EWF resources, many studies have attempted to utilize a EWF nexus approach to better understand resource utilization and environmental degradation in the delivery of a product or service. For instance, Al Ansari et al. (2015; 2016; 2017) developed a EWF nexus tool that quantifies synergies between EWF systems, in addition to computing environmental impacts in delivering a hypothetical food security scenario. Moreover, the current situation of EWF resources necessitates a holistic analysis that models synergies between the three systems, tackles the inherent competition between their respective supply chains at the decision-making level and optimize the whole performance of the integrated EWF nexus. Yet, this cohesive assessment is usually hindered by modelling complexities, such us multi-scale uncertainties governing the nexus, multi-temporal and spacial structure of supply chains, along with computational limitations associated with optimization (Garcia and You, 2015a).

Process Systems Engineering (PSE) is one of the fields that devoted attention to the modelling and optimization of EWF resources, to enhance their environmental performance and increase their economic efficiency. Karnib (2017) adopted a coupled simulation/optimization framework based on Q-Nexus Model. The latter is based on an input-output theory incorporating water and energy inflows into the production of food, water and energy resources while addressing different interactions amongst the three systems. Garcia and You (2015b) used multi-objective optimization to model water and energy nexus of biofuel products. The study formulated a model that minimizes the water footprint and maximizes economic performance and energy output. Mostly, these studies focused on developing integrated approaches for the evaluation of EWF nexus systems; however, most of them focused mainly on one or two resource systems of the EWF nexus in their optimization models. Thus, investigating the three systems holistically is a very promising research area for PSE community especially with the multiple interactions that exist amongst the EWF subsystems.

The work presented in this research tackles the modelling challenges of the EWF nexus through the implementation of a bottom-up framework aiming to enhance the economic performance of the EWF resource sectors whilst considering the environment. The methodology developed is divided into technology selection and resource allocation. The first problem consists of an integer linear program that determines the best performing combination of technologies under an environmental burden constraint. The second consists of a resource allocation approach which is based on a constraint to resource capacity, natural gas price fluctuations and non-cooperative Stackelberg competition. As part of this study, the developed methodology is applied to the State of Qatar with the target of achieving a hypothetical level of 40% in food self-sufficiency.

2. Technology selection

2.1. Case study

To design resilient and sustainable EWF systems, decision makers, at every level of the nexus, must hedge against negative environmental impacts generated from the interactions between the three sectors. Incidentally, they must do so whilst adhering to economic objectives, including cost minimization and/or profit maximisation. In the context of Qatar and this study, domestic production is assumed to increase to a level which attains a perceived food security self-sufficiency. Al-Ansari et al. (2016;2017) illustrated this target through EWF nexus and a sub-system approach enabling the

evaluation of multiple scenarios. In this paper, a similar design is adopted where the EWF nexus system under consideration is illustrated in Table 1, includes: renewable (i.e. solar energy & biomass) and non-renewable (i.e. natural gas) energy sources representative of the energy sector, a reverse osmosis based seawater desalination system representative of the water sector, and finally the food sector is represented by the production of fertilizers and agricultural activities (i.e. livestock management and application of fertilizers). A carbon capture system is also integrated to the combined cycle driven by both natural gas and gasified biomass, in which the latter is transformed to a negative emission technology (Al-Ansari et al., 2017). The system boundary is limited to a local nexus system where food and energy are produced locally. Thus, import/export relationships are neglected in this model.

Table 1 Technologies by sector

Energy	Water	Food
Combined Cycle Gas Turbine (CCGT)- CCGT with Carbon Capture(CC)-Biomass Integrated Gasification Combined Cycle (BIGCC)/Photovoltaics	Reverse Osmosis (RO)	Agriculture/Fertilizer Production

2.2. Problem formulation

The optimised EWF nexus model proposed in this study is formulated using a linear program where the total cost of the EWF nexus is the objective function to be minimized and the Global Warming Potential (GWP) is considered as the main constraint. This optimization provides an optimum combination of technologies which together will operate at the lowest cost whilst remaining within the assumed value of $5x10^7$ $kgCO_2eq$, being the average of the highest and lowest emissions of the entire nexus. This is represented in equation 1.

$$Min: Total\ Cost = \sum_{i=1}^{n} x_i^e c_i + \sum_{i=1}^{m} x_i^w c_i + \sum_{i=1}^{l} x_i^f c_i \quad (1)$$

The decision variables are x_i^e, x_i^w, x_i^f, the percentages of each technology used in energy, water and food respectively, and c_i (USD)is the capital cost associated with each technology.

Subject to the following set of constraints:

$$\sum_{i=0}^{n} x_i^e = 1 \quad (2)$$

$$\sum_{i=0}^{m} x_i^w = 1 \quad (3)$$

$$\sum_{i=0}^{l} x_i^f = 1 \quad (4)$$

$$\sum_{i=1}^{n} x_i^e t_i + \sum_{i=1}^{m} x_i^w t_i + \sum_{i=1}^{l} x_i^f t_i \leq 5 \times 10^7 \quad (5)$$

Where t_i is the amount of GWP associated with each technology in kg of CO_2eq, while *n* is the number of energy technologies, *m* is the number of water technologies and *l* is the number of food technologies.

As for the capital cost, all technologies are denoted with a value that represents the incurred implementation cost, except for agriculture, it is assumed to be $0 as no leasing costs are associated with agricultural lands in Qatar.

3. Resource allocation

3.1. Baseline scenario

The second step in the bottom-up approach is to find the optimal resource allocation amongst the selected energy and water technologies from the previous step, that will satisfy the additional food self-sufficiency requirement while minimizing the cost (USD).

In this model, it is assumed that only water and energy are the only inflows, since the target is to produce additional food.
The problem is modelled using a LP which is illustrated in equation 6.

$$Total\ Cost = \sum_{i=1}^{m}\sum_{j=1}^{n} s_j^{w-e}\, c_{ij}^{w-e} p_i^{w} + \sum_{i=1}^{m}\sum_{j=1}^{l} s_j^{w-f}\, c_{ij}^{w-f} p_i^{w} + \sum_{i=1}^{n}\sum_{j=1}^{m} s_j^{e-w}\, c_{ij}^{e-w} p_i^{e} + \sum_{i=1}^{n}\sum_{j=1}^{l} s_j^{e-f}\, c_{ij}^{e-f} p_i^{e} \quad (6)$$

The decision variables are $c_{ij}^{w-e}, c_{ij}^{w-f}, c_{ij}^{e-w}, c_{ij}^{e-f}$ denoted as the intersectoral coefficient of allocation (Karnib, 2017). $s_j^{w-e}, s_j^{w-f}, s_j^{e-w}, s_j^{e-f}$ are the inflows from a sector to another. p_i^{w} is the unit price of water and it is equal to US$0.986/m^3 (Al-Karaghouli and Kazmerski, 2012). p_i^{e} is the levelized cost of electricity (LCOE) of energy technologies, which is estimated to be US$ 110/MWh for BECCS and US$ 93/MWh for CCGT (OpenEl, 2015). Subject to the following set of constraints:

$$\sum_{j=1}^{n} c_{ij}^{w-e} = 1 \text{ with } i=1,\ldots,m \quad (7)$$

$$\sum_{j=1}^{l} c_{ij}^{w-f} = 1 \text{ with } i=1,\ldots,m \quad (8)$$

$$\sum_{j=1}^{m} c_{ij}^{e-w} = 1 \text{ with } i=1,\ldots,n \quad (9)$$

$$\sum_{j=1}^{l} c_{ij}^{e-f} = 1 \text{ with } i=1,\ldots,n \quad (10)$$

$$\sum_{i=1}^{m}\sum_{j=1}^{n} s_j^{w-e}\, c_{ij}^{w-e} + \sum_{i=1}^{m}\sum_{j=1}^{l} s_j^{w-f}\, c_{ij}^{w-f} \le Maximum\ water\ capacity \quad (11)$$

$$\sum_{i=1}^{n}\sum_{j=1}^{m} s_j^{e-w}\, c_{ij}^{e-w} + \sum_{i=1}^{n}\sum_{j=1}^{l} s_j^{e-f}\, c_{ij}^{e-f} \le Maximum\ energy\ capacity \quad (12)$$

The constraints represented by Eq.(11) and Eq.(12) restrict the additional amount of water and energy used to the capacity of water and energy. Furthermore, the usage of 99% of water in agriculture compared to fertilizers production is added as a constraint to meet the high irrigation requirement (Al-Ansari et al., 2016).

3.2. Stochastic scenario

In the baseline scenario for resource allocation, the levelized cost of electricity for CCGT is assumed to be fixed. In reality, it is affected by the price of natural gas that knows significant fluctuations. To account for these variations and assess their impact on the overall cost, a new stochastic constraint is added to the baseline model, and it is formulated by the following assumed probabilistic requirement:

$$P(y_1 \le y_2) \ge 95\% \quad (13)$$

where y_1 is the levelized cost of electricity following a normal distribution with a \$93/MWh mean and \$5/MWh standard deviation, which is estimated using a Monte Carlo simulation. y_2 is the LCOE of BECCS equal to \$110/MWh (OpenEl, 2015). The problem is solved using chance constraint programming with a confidence level of 95%.

3.3. Stackelberg duopoly scenario

The EWF nexus system presented in this paper is also part of a competitive milieu, where stakeholders have conflicting interests and each one aims to maximize its profit (Yue and You, 2016). For this reason, a decentralized approach based on a non-cooperative Stackelberg game is modelled. The framework focuses on the energy sector only and assumes that CCGT technology option is the leader, whereas BECCS is the follower. The two technologies compete on resources such as water and food, and their common target is to produce an optimal quantity of energy that will lead to maximization of their profits. This objective is formulated as a constraint and added to the baseline resource allocation scenario. Eq.(11) and Eq.(12) are substituted by the following constraints:

$$z_1 \times c^{CCGT-RO} + z_2 \times c^{CCGT-fert} + z_3 \times c^{CCGT-agr} \ge q_l \quad (14)$$

$$z_1 \times c^{BECCS-RO} + z_2 \times c^{BEECS-fert} + z_3 \times c^{BECCS-agr} \ge q_f \quad (15)$$

where z_1, z_2 and z_3 are the total energy requirement for RO, fertilizers production and agriculture respectively. q_l and q_f are the optimal quantities for the leader and the follower, computed based on backward induction method based on Stackelberg Duopoly.

4. Illustrative example and results

By applying the technology selection to the food security scenario, the model yields a configuration which is composed of the CCGT and the BECCS within the energy sector, RO as the only water source, and the production of fertilizers production as the only technology in the food sector. In this case study, the fertilizers are used for the domestically grown crops and not for crops used to raise of livestock which are assumed to be imported. The crop selection profile considered as part of this study is assumed to meet 40 % food self-sufficiency requirements in which the remainder is assumed to be imported (see Table 2). The capital cost of this configuration is 1.88 Billion USD. This value is the most optimal considering the GWP from the proposed technologies. The highest percentage is given to BECCS, since it has a negative CO_2 emission (Al-Ansari et al., 2016; 2017) and a relatively low cost compared to PV. BIGCC, CCGT+CC and PV are not selected because of their enormous relative capital cost. The CCGT has a major representation as it has the lowest capital cost amongst all technologies. The resource allocation part is based on the configuration found from the technology selection optimization. In fact, all energy technologies with 0% participation are eliminated, while the two other sectors are kept the same. The results for the baseline, stochastic and Stackelberg scenarios are summarized in Figure 1.

Table 2 Results for technology selection

Technology	BECCS	CCGT+CC	CCGT	BIGCC	PV	RO	Agriculture	Fertilizers
Capital cost (Million USD)	1,605	1,175	720	1,150	4,180	650.269	0	37.389
GWP (kgCO2eq)	-11,600,00,000	2,530,000	460,000,000	10,000	45,300	414,892,037	1,260,000,000	45,500,000
Percentage	53.72%	0%	46.27%	0%	0%	100%	0%	100%

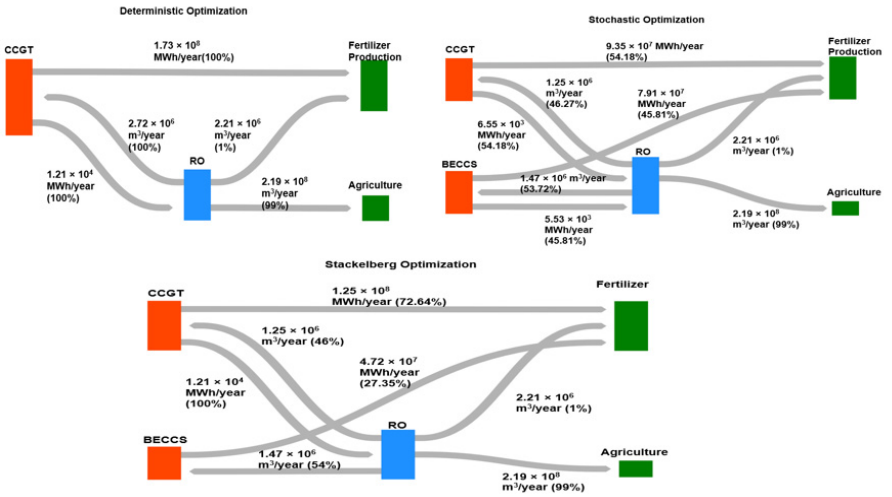

Fig. 1. Summary of the resource allocation results

In comparison to the deterministic optimization, stochastic optimization provides an opportunity for BECCS to contribute to the mix, particularly for both the water and food sectors, as CCGT suffers from an exposure to risk of increasing natural gas prices. Stackelberg duopoly, wherein CCGT is assumed to be the leader and allowed to set the energy prices to reduce its exposure, the contribution of BECCS is reduced in the mix.

5. Conclusions and further improvements

This study presents a techno-economic framework coupled with an optimization methodology for a EWF nexus case study for Qatar. The objective is to achieve a perceived level of food sufficiency at the lowest cost and environmental impact. The bottom-up approach resulted in an optimal configuration of energy technologies. This configuration is then used to come-up with the best resource allocation, considering three scenarios. As a result, the deterministic optimization generated a cost of 1.88 Billion USD with a usage of CCGT only. As for the resource allocation, the cost associated with additional energy and water resources in the baseline scenario 664 Million USD. This amount decreases after adding the natural gas constraint to 227 Million USD. This value decreases further with the game theoretical constraint to 224 Million USD. The extension of this work would include the operating cost of technologies as part of the decision-making process. The Stackelberg competition could be enhanced by considering one of the three sectors of the EWF nexus as the leader whilst the two-remaining act as followers. Moreover, other uncertainties can be considered such as those related to CO_2 prices.

Abstract

Due to fouling in the heat-transfer units, the target temperatures of process streams in a heat exchanger network (HEN) may not always be achievable after a long period of operation. To address this practical issue, the conventional cost-optimal HEN design must be modified to accommodate online cleaning operations via proper allocation of area margins, bypasses, spares and auxiliary heaters/coolers. A solvable MINLP model has been developed in this work to simultaneously generate such design refinements and also the corresponding spare-supported cleaning schedules. The optimization results of one example are presented to demonstrate the feasibility of this approach.

Keywords: heat exchanger network, spare, margin, bypass, cleaning schedule.

1. Introduction

Efficient energy recovery is one of the essential requirements of almost any process design, while a heat exchanger network (HEN) is often utilized to fulfil this need. Since the overall performance of HEN tends to deteriorate over time due to fouling in the embedded heat-transfer units, there are incentives to clean at least some of them when the normal production is still in progress.

The mathematical programming approach was first proposed by Smaïli et al., (1999) to synthesize the optimal cleaning schedules. Since then, this practice has been adopted in numerous realistic applications. For example, Sanaye and Niroomand (2007) produced the optimal HEN cleaning schedule for the urea and ammonia units by minimizing the operating cost. Although these optimal cleaning schedules could indeed be implemented to save energy, the overall heat-exchange rate of a HEN may still gradually decrease over time after cleaning and, furthermore, any defouling operation still calls for temporary removal of online unit(s).

In principle, the aforementioned decrease in total heat recovery level of a HEN may be compensated by (a) introducing a spare unit, (b) adjusting the heat transfer rates of other online units via area margins and bypasses, or (c) raising the hot and cold utility consumption rates in heaters and coolers. Cheng and Chang (2016) developed a MINLP model to create the HEN cleaning schedule and spare replacement schedule simultaneously, while virtually no studies have been performed for systematic implementation of the other options mentioned above. Thus, there are incentives to modify the existing models to optimally allocate spares, margins, bypasses and auxiliary heats/coolers for implementing an effective and energy efficient cleaning schedule.

2. Mathematical representations of network and schedule structures

2.1. HEN networks

It is assumed in this study that, before applying the proposed method, a preliminary HEN design is available. To characterize this given structure, let us first introduce two stream sets, i.e., I and J, to collect and classify the hot and cold process streams respectively. On the other hand, the matches in this given HEN can be characterized mathematically with a function, i.e., the mapping from the set of all heat exchangers (EX) to the set of matches between process steams (MA), i.e., $f: \mathrm{EX} \longrightarrow \mathrm{MA}$. Notice that $f(e) = (i, j)$ is known for every $e \in \mathrm{EX}$. This given structure can be described more clearly by dividing EX into subsets according to hot or cold streams. In particular, $\mathrm{EX}_{i'}$ ($i' \in$ I) and $\mathrm{EX}_{j'}$ ($j' \in$ J) denote respectively the sets of heat exchangers on hot stream i' and cold stream j'. Since the units on each process stream may be placed in series and/or in parallel, they can be further classified into subsets $\mathrm{EX}_{i'}^{m}$ ($i' = 1,2,\cdots, M_{i'}$) and $\mathrm{EX}_{j'}^{n}$ (j$' = 1,2,\cdots N_{j'}$) according to their downstream "mixing points". To clarify this notion, let us consider the bullets (i.e., mixing points) in the fictitious structure in Figure 1. One can identify that

- $M_{i'} = 2$, $\mathrm{EX}_{i'}^{1} = \{1,2\}$ and $\mathrm{EX}_{i'}^{2} = \{3\}$ on hot steam i';
- $N_{j'} = 3$, $\mathrm{EX}_{j'}^{1} = \{4,5\}$, $\mathrm{EX}_{j'}^{2} = \{6,7\}$ and $\mathrm{EX}_{j'}^{3} = \{8\}$ on cold stream j'.

Notice that it is also assumed that a bypass flow may join the output streams from heat exchangers at each mixing point.

2.2. Cleaning and spare replacement schedules

In this work, the time horizon for schedule synthesis (say t_f) is assumed to be given. To simplify calculation, this schedule horizon $[0, t_f]$ is partitioned into n_P different periods and each is further divided into two intervals for performing the cleaning and heat-exchange operations respectively. For computation simplicity, the lengths of aforementioned time periods are fixed, i.e., $t_f = n_P \tau$ and τ is a constant. Also, it is assumed that the durations of all sub-periods required for defouling (f_c) are the same and their values can be determined in advance. Thus, within each partitioned period, four time points can be identified to facilitate accurate presentation of the proposed model, i.e., *bcp* (beginning of cleaning sub-period), *ecp* (end of cleaning sub-period), *bop* (beginning of operation sub-period), and *eop* (end of operation sub-period). Note that time point *ecp* represents the instance just before *bop*. To produce concise model formulation, let us introduce two sets, i.e., P and TP, to characterize the periods and time points respectively.

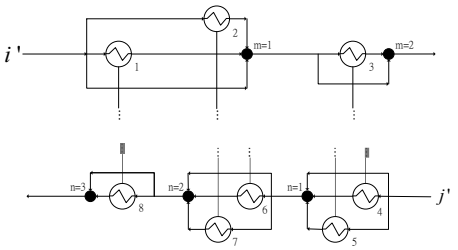

Figure 1. A fictitious stream structure in HEN.

The selections of exchangers to be cleaned in each time period are expressed with binary variables $Y_{e,p} \in \{0,1\}$ (where, $e \in$ EX and $p \in$ P.). Let us also assume that the available spares are given in advance and they are collected in set S. It is clear that the decision to use spare $s \in$ S to replace unit $e \in$ EX in period $p \in$ P can only be made after determining whether this unit should be removed and cleaned in the same period. The corresponding logic constraints can be represented with another set of binary variables $X_{e,p,s} \in \{0,1\}$, i.e., $\left(1 - Y_{e,p}\right) + \sum_{s \in S} X_{e,p,s} \leq 1$

3. Model constraints

3.1. Overall heat-transfer coefficients

As a result of fouling, the overall heat-transfer coefficient of every unit in HEN may decrease with time and this phenomenon can be modelled as follows:

$$U_e(t) = \left[\left(U_e^{cl}\right)^{-1} + r_e(t)\right]^{-1} \tag{1}$$

where, $e \in$ EX; $U_e(t)$ denotes the overall heat-transfer coefficient of exchanger e at time t; U_e^{cl} is the corresponding constant value when the heat-transfer surface is *completely* clean. Notice that the time function $r_e(t)$ is the fouling resistance of unit e at time t, which is expressed with a linear model in this paper, i.e., $r_e(t) = \dot{r}_e t$ and $\dot{r}_e$ is a constant fouling rate. Four scenarios should be considered for determining the overall heat-transfer coefficient of unit e at the aforementioned four time points in period p of a cleaning schedule:

(i) Exchanger e is not cleaned during period p ($p \geq 2$), but in at least one of the prior periods a defouling operation has been performed, i.e., $Y_{e,p} = 0$ and $\prod_{k=1}^{p-1}\left(1 - Y_{e,k}\right) = 0$ for $p = 2,3,\cdots,n_P$.

(ii) Exchanger e is cleaned and replaced with a spare in period p ($p \geq 1$), i.e., $Y_{e,p} = 1$ and $\sum_{s \in S} X_{e,p,s} = 1$ for $p = 1,2,\cdots,n_P$.

(iii) Exchanger e is cleaned but not replaced with a spare in period p ($p \geq 1$), i.e., $Y_{e,p} = 1$ and $\sum_{s \in S} X_{e,p,s} = 0$ for $p = 1,2,\cdots,n_P$.

(iv) Exchanger e has never been cleaned since period 1, i.e., $Y_{e,1} = Y_{e,2} = \cdots = Y_{e,p} = 0$ for $p = 1,2,\cdots,n_P$.

The formulas for computing the overall heat-transfer coefficients in these four scenarios at any time point can be found in Cheng and Chang (2016). It is assumed in this work that the initial and target temperatures of every process stream in a HEN are fixed a priori and these conditions must be kept unchanged throughout the entire horizon. For this operational problem, it is necessary to examine the temperature variations along every process stream in HEN.

3.2. Temperature changes along process streams

Since the temperature of each stream is adjusted with heat exchangers, coolers/heaters and perhaps also mixers according to the structure described in Figure 1, it is important to check if the intermediate temperatures at critical locations satisfy thermodynamic and/or operational constraints. By assuming counter-current flow, let us express the heat transfer rate in unit e at time point tp in period p as $Q_{e,p}^{tp} = \mu_e A_e U_{e,p}^{L,tp} LMTD_{e,p}^{tp}$ and, in this expression, A_e denotes the given heat-transfer area of unit e in the original HEN design; $\mu_e = A_e^M / A_e$ is a dimensionless variable used to represent design margin and A_e^M denotes the enlarged heat-transfer area of unit e; $LMTD_{e,p}^{tp}$ is the log-mean

temperature difference of unit e at time point tp in period p. The corresponding energy balances can be written as

$$Q_{e,p}^{tp} = Fcp_i^H \phi_{e,p}^{H,tp} \left(Ti_{e,p}^{H,tp} - To_{e,p}^{H,tp} \right) = Fcp_j^C \phi_{e,p}^{C,tp} \left(To_{e,p}^{C,tp} - Ti_{e,p}^{C,tp} \right) \tag{2}$$

where, Fcp_i^H and Fcp_j^C respectively denote the heat-capacity flow rates (kW/K) of hot stream i and cold stream j; $Ti_{e,p}^{H,tp}$ and $To_{e,p}^{H,tp}$ respectively denote the inlet and outlet hot stream temperatures of unit e at time point tp; $Ti_{e,p}^{C,tp}$ and $To_{e,p}^{C,tp}$ respectively denote the inlet and outlet cold stream temperatures of unit e at time point tp in period p; $\phi_{e,p}^{H,tp}$ and $\phi_{e,p}^{C,tp}$ denote the flow fractions hot and cold streams, respectively, passing through unit e at time point tp in period p.

Let next consider unit e, its corresponding match (i, j) and its downstream mixing points m and n on hot and cold streams. The mass balances at these mixing points can be written as $\tilde{\phi}_{i,p}^{m,tp} + \sum_{e \in \mathrm{EX}_i^m} \phi_{e,p}^{H,tp} = 1$ and $\tilde{\phi}_{j,p}^{n,tp} + \sum_{e \in \mathrm{EX}_j^n} \phi_{e,p}^{C,tp} = 1$, where $\tilde{\phi}_{i,p}^{m,tp}$ and $\tilde{\phi}_{j,p}^{n,tp}$ denotes the flow fractions of bypasses joining mixing point m on hot stream i and mixing point n on cold stream j at time point tp in period p, respectively. To simplify the final HEN structure, it is assumed that the bypass of each heat exchanger can be placed on its hot or cold stream, but not both.

Notice also that the log-mean temperature difference can also be expressed as a function of inlet and outlet temperatures of the hot and cold streams, i.e.

$$LMTD_{e,p}^{tp} = \frac{\left(Ti_{e,p}^{H,tp} - To_{e,p}^{C,tp} \right) - \left(To_{e,p}^{H,tp} - Ti_{e,p}^{C,tp} \right)}{\ln\left[\left(Ti_{e,p}^{H,tp} - To_{e,p}^{C,tp} \right) \Big/ \left(To_{e,p}^{H,tp} - Ti_{e,p}^{C,tp} \right) \right]} \tag{3}$$

Thus, the outlet temperatures of heat exchanger e can be determined by solving the aforementioned equations simultaneously according to the inlet temperatures. Finally, the mixing point temperatures are calculated in this study with the following formulas:

$$T_{m,i,p}^{H,tp} = \tilde{\phi}_{i,p}^{m,tp} T_{m-1,i,p}^{H,tp} + \sum_{e \in \mathrm{EX}_i^m} \phi_{e,p}^{H,tp} To_{e,p}^{H,tp} \tag{4}$$

$$T_{n,j,p}^{C,tp} = \tilde{\phi}_{j,p}^{n,tp} T_{n-1,j,p}^{C,tp} + \sum_{e \in \mathrm{EX}_j^n} \phi_{e,p}^{C,tp} To_{e,p}^{C,tp} \tag{5}$$

where, $T_{m,i,p}^{H,tp}$ and $T_{n,j,p}^{C,tp}$ respectively denote the temperatures at mixing point m on hot stream i and mixing point n on cold stream j. The last mixing point temperature on a hot stream obviously must be higher than the designated final temperature, while that on a cold stream lower than the given end value. Note that the design targets can always be achieved exactly with cooling and heating utilities.

4. A simple example

The given HEN design in this example can be found in Table 1 (stream data), Table 2 (unit specifications) and Figure 2 (network structure), which is taken from Lavaja and Bagajewicz (2004). For convenience, the overall heat-transfer coefficient of any completely cleaned heat exchanger (U_e^{cl}) is assumed to be constant at $88.1\mathrm{BTU/hr/ft^2/^\circ F}$. Since the linear fouling model is adopted for the present application, the fouling rates ($\dot{r}_e$) of the four units in Table 2 are chosen to be 3.07, 3.27, 3.68 and 3.88 (×

10^7 ft^2°F/BTU), respectively. The unit costs of hot and cold utilities are assumed to be 2.812×10^{-3} and $5{,}624 \times 10^{-4}$ USD/BTU, respectively. The cost of cleaning a heat exchanger is set to be 4000 USD, while that for a spare is 1000 USD. For every unit in HEN, the annualized fixed capital cost is 5500 USD/yr, and the corresponding variable cost coefficient is 15 USD/yr/ft$^{2\alpha}$ ($\alpha = 0.8$). Finally, the time-related model parameters are selected as follows: $t_f = 18$ (mon), $\tau = 1$ (mon) and $f_c = 0.2$ (mon).

By minimizing the total annual cost with only 1 margined unit, one can identify the optimal spare-supported cleaning schedule for the present example. In this schedule, each unit is cleaned in designated periods over the given horizon. Specifically, HE1: 4, 7, 12, 15 (mon); HE2: 9, 12 (mon); HE3: none; HE4: 4, 7, 10, 13, 16 (mon). When HE4 is removed for cleaning, a spare is used to take its place in HEN and the heat-transfer area of this spare unit is 1485 ft^2. Notice also that the optimal design refinements can be found in Figure 3. It can be observed that (1) the margined unit is chosen to be HE3 and its heat-transfer area is enlarged to 1653.9 ft^2 ($\mu_3 = 1.388$), (2) the bypasses are placed at the hot-stream sides of HE2, HE3 and HE4, and (3) one auxiliary heater and three coolers are added and their specifications are given in Figure 3.

It should be noted that, when compared with the scenario in which the given HEN is operated for 18 months without cleaning and without any design refinement, a 27 percent reduction in the total annual cost (TAC) can be achieved with the cleaning schedule suggested by Lavaja and Bagajewicz (2004). On the other hand, a 55 percent saving is realizable by implementing the proposed spare-supported cleaning schedule together with the aforementioned design refinements. This saving can be raised even higher to 84 percent if the number of margined units is increased to 3.

Table 1. Stream data of a given HEN design

Stream	Initial Temp (°F)	Target Temp (°F)	Heat Capacity Flow Rate (BTU/hr/°F)
C1	270	429.67	331862.86
H1	428	374.82	94652.24
H2	513	426.93	51667.7

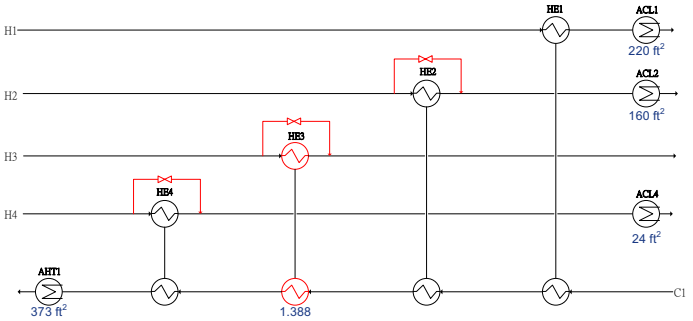

Figure 3. Refined HEN design obtained by introducing area margin to HE3.

5. Conclusions

An improved mathematical programming model has been proposed in this work to synthesize the optimal spare-supported cleaning schedule and the corresponding design refinements for any given HEN design. The effectiveness of this approach has been demonstrated in extensive case studies. It can be observed from the optimization results that spares, margins, bypasses and auxiliary units are viable options for reducing the extra amount of utility consumption due to fouling and/or removing online heat exchangers for cleaning purpose.

songguang@ise.neu.edu.cn

Abstract

To avoid the secondary reactions in steam cracking of hydrocarbon feedstocks, which lead to undesirable products such as coke, the high temperature gas leaving from the cracking furnace need be rapidly quenched in Transfer Line Exchanger (TLE). A severe problem in the process is that coke deposits on the walls of the furnace coil and the TLE tubes, which leads to increasing heat transfer resistances and pressure drops. When the coke deposition reaches an allowable maximum, the TLE must be periodically shut down for decoking. This work developed an optimization model for the operation process of TLE system. The proposed model has been considered an integrated model for TLE to optimize the operation process. Firstly, we built a steady-state heat transfer model and a dynamic coke depositing model, respectively. Then, we integrated two models by using quasi-steady assumption, in which the thickness of the coke deposition is considered as a constant in one time interval. According to the integrated model, we chose the COT as the manipulated variable to optimize the operation period between decoking. At last, the reliability and adaptability of the optimization model was validated by one significant case study. The results showed that the optimization model of TLE system could effectively increase the operation period.

Keywords: TLE, coke deposition, optimization model, operation period.

1. Introduction

Steam cracking of hydrocarbon feedstocks includes two parallel reaction pathways, which are the primary reactions and the secondary reactions. To avoid the secondary reactions, which lead to undesirable products such as coke, the high temperature gas leaving from the cracking furnace need be rapidly quenched in Transfer Line Exchanger (TLE). The TLE can not only quench the cracking gas, but also recover heat from the cracking gas to produce high pressure steam. A severe problem in the process is that coke deposits on the walls of the furnace coil and the TLE tubes, which leads to increasing heat transfer resistances and pressure drops. When the coke deposition reaches an allowable maximum, the TLE must be periodically shut down for decoking. In general, there are three coking mechanisms(Bach et al., 1995): 1) the catalytic mechanism; 2) the free-radical mechanism; 3) the physical condensation mechanism. In recent years, researchers not only developed many kinds of coking-inhibitors that can limit the coke deposition by the catalytic mechanism, but also designed many types of TLE tubes that can reduce the coke deposition by the free-radical mechanism(Geem et al., 2009). Therefore, the coke deposition in TLE tubes is mainly generated by the physical condensation(Kopinke, Bach, & Zimmermann, 1993).

Although the coke deposition in the TLE has important influence on the whole process, the research on this field is few and deficient. Manafzadeh et al develop a comprehensive mathematical model for a TLE system, which can simulate the operation process and predict the coke deposition rate(Manafzadeh, Sadrameli, & Towfighi, 2003). Jin et al propose a parametric model based on theoretical analysis, mathematic reduction and parameters estimation, which can predict the TLE outlet temperature(Jin, Li, Du, Wang, & Qian, 2013). However, the above model lacks optimization for the operation process, which only adopts mathematic model to predict the coke deposition and outlet temperature. Thus, a novel model for the TLE system is proposed in this paper to optimize the operation process.

The paper is organized as follows. In section 2, the details about the TLE system are given. In section 3, we introduce the mathematical formulation, which integrates a steady-state heat transfer model and a dynamic coke depositing model by using quasi-steady assumption. In section 4, we illustrate the use of the optimization model through one significant case study.

2. Transfer Line Exchanger System

Transfer Line Exchanger System includes a set of shell-and-tube heat exchangers. As shown in Figure 1, the cracked gas (CG) /steam mixture from the furnace is quenched in tube pass, and in exchange, the saturated boiler feed water recovers heat to generate high pressure steam in shell-side. The TLE inlet conditions are determined by the furnace outlet operation.

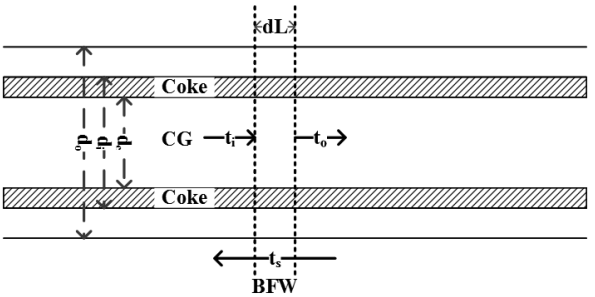

Figure 1. Schematic diagram of TLE tube.

The optimization model is assumed as one dimensional plug flow model which implies the neglect of radial concentration gradients and axial dispersion. The TLE tube is divided into a number of sections, one of which has a length of $\boldsymbol{dL}$. In one section, three assumptions are presented: 1) the thickness of the coke deposition is constant at the same time interval; 2) the temperature of the CG is constant as the inlet temperature; 3) the thermal physical parameters of the CG are constant(Yaws, 1961).

3. Mathematical Model

The optimization model integrates a steady-state heat transfer model and a dynamic coke depositing model by using quasi-steady assumption, in which the thickness of the coke deposition is considered as a constant in one time interval. The mathematical formulation of both models are given below.

3.1. Steady-state Heat Transfer Model.

The steady-state heat transfer model can simulate the temperature distribution in the TLE tubes under the given CG inlet conditions, which include the temperature, the mass flow and the chemical composition.

In one tube section shown in Figure 1, the heat balance is given as equation 1~2, which states that in one tube section the enthalpy change of CG is equal to the heat exchange capacity between CG and BFW.

$$\mathrm{d}Q = m \cdot \mathrm{d}H_i \tag{1}$$

$$\mathrm{d}Q = K \cdot \mathrm{d}A \cdot \Delta t_m \tag{2}$$

Equation 3~4 gives the enthalpy change of CG, in which c_P represents the heat capacity.

$$\mathrm{d}H_i = c_P \cdot \Delta t \tag{3}$$

$$\Delta t = t_i - t_o \tag{4}$$

Equation 5~6 gives the heat transfer area and the logarithmic mean temperature difference.

$$\mathrm{d}A = N \cdot \pi d_o \cdot \mathrm{d}L \tag{5}$$

$$\Delta t_m = \frac{(t_i - t_s) - (t_o - t_s)}{\ln \dfrac{(t_i - t_s)}{(t_o - t_s)}} \tag{6}$$

The overall heat transfer coefficient is given by equation 7, which includes convective heat transfer coefficients inside and outside the tube, the heat conductivity coefficients of the tube wall and coke deposition, and the fouling factors.

$$K = \frac{1}{\dfrac{1}{\alpha_\mathrm{i}} \cdot \dfrac{\mathrm{d_o}}{\mathrm{d_c}} + \dfrac{d_o}{2\lambda_w} \ln \dfrac{\mathrm{d}_o}{\mathrm{d}_i} + \dfrac{d_o}{2\lambda_c} \ln \dfrac{\mathrm{d}_i}{\mathrm{d}_c} + \dfrac{1}{\alpha_\mathrm{o}} + R_o + R_i \dfrac{d_o}{\mathrm{d_c}}} \tag{7}$$

Equation 8 gives the convective heat transfer coefficient inside the tube.

$$\alpha_\mathrm{i} = 0.023 \frac{\lambda_g}{d_c} Re^{0.8} Pr^{1/3} \left(\frac{\mu_g}{\mu_w}\right)^{0.14} \tag{8}$$

Equation 9 gives the convective heat transfer coefficient outside the tube.

$$\begin{aligned} \alpha_o^{4/3} &= h_c^{4/3} + h_r^{4/3} \\ h_c &= 0.62 \left[\frac{gr\rho_v(\rho_l - \rho_v)\lambda_v^3}{\mu_v \, \mathrm{d}_o (t_i - t_s)}\right]^{1/4} \\ h_r &= \frac{\varepsilon\sigma((T_w)^4 - (T_s)^4)}{T_w - T_s} \end{aligned} \tag{9}$$

3.2. Dynamic Coke Depositing Model.

The dynamic coke depositing model can simulate the thickness of coke deposition in the TLE tubes in one operation period under the given temperature distribution.

Equation 10 states that the flow rate of coke deposition is equal to the sum of all the physical condensation components, in which α represents the coke lay-down factor.

$$dm_c = \alpha \cdot dV_c \cdot \sum_i r_i \cdot M_i \tag{10}$$

Table 1 Coking rate and dew points of the physical condensation components

Name	$r_i(\mathrm{mol}/(m^3 \cdot \mathrm{s}))$	Dew Point(℃)	Molar mass(kg/mol)
M-Anthracene	9.624E-04	488	0.1922
Acenaphthalene	2.116E-03	317	0.1521
Anthracene	1.251E-03	381	0.1782
Chrysene	1.677E-03	380	0.2282

Equation 11 gives the rate of the coke thickness.

$$\frac{d\delta_c}{dt} = \frac{dm_c}{\rho_c \cdot dA_C} \tag{11}$$

The tube geometry parameters are given by equation 12.

$$dV_c = \frac{\pi}{4} \cdot {d_c}^2 \cdot dL$$
$$dA_c = \pi \cdot d_c \cdot dL \tag{12}$$

3.3. The integrated model.

We integrated two models by using quasi-steady assumption: 1) one operation period between decoking is divided into a number of time intervals; 2) the thickness of the coke deposition is considered as a constant in one time interval.

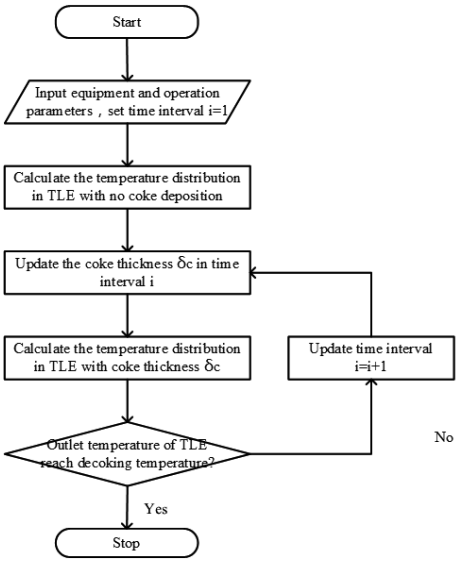

Figure 2. The algorithm diagram of the integrated model.

The algorithm diagram is shown in Figure 2. Firstly, the equipment and operation parameters are input and the time interval i is set to 1. Then, the temperature distribution in TLE with no coke is calculated. According to the temperature distribution, we update the coke thickness δ_c in time interval i. Based on the coke thickness δ_c, the temperature distribution in the time interval $i+1$ is calculated. Then, we check whether the outlet temperature of TLE reaches the decoking temperature. If the answer is "No", the time interval i is updated and the coke thickness δ_c is updated then. If the answer is "Yes", the operation period, coke deposition distribution and the temperature distribution are obtained.

4. Case Study

In this section, a case study of a TLE system is presented to illustrate the use of the proposed optimization model. The TLE configuration and the CG compositions and conditions are given in Table 2.

Table 2 Equipment and operation parameters of a TLE system

Parameters	Values	Component	Mass%
Tube length/m	9.5	H2	0.54
Tube OD/m	0.051	CH4	8.28
Tube ID/m	0.041	C2H4	15.33
Tubes number	50	C2H6	1.90
CG mass flow/(kg/hr)	7500	C3H6	8.07
CG inlet temperature/℃	840~855	C3H8	0.45
CG inlet pressure/MPa	0.072	C4H6	3.01
Steam temperature/℃	325	N-C4H8	0.71
Steam pressure/MPa	13.5	I-C4H8	1.33
Tube inside fouling/(m^2K/W)	0.000688	C5+	10.41
Tube outside fouling/(m^2K/W)	0.000174	H2O	50.00

Based on the data listed in Table 2, the optimal results of the operation period are obtained, which are shown in Figure 3~4. Figure 3 shows that the TLE operation period varies with the CG inlet temperature and the optimal operation period is obtained as 91.03 days with the inlet temperature 843.3℃. Figure 4 gives the TLE temperature distribution of the optimal inlet temperature. At the start of the period, the CG outlet temperature is about 327 ℃ with no coke deposition. As the coke deposition thickness grows, the outlet temperature increases rapidly at first, and increases smoothly then. At the end of the period, the outlet temperature reaches the decoking temperature.

5. Conclusions

This paper proposed an optimization model of the TLE system, which integrated a steady-state heat transfer model and a dynamic coke depositing model. The results of a case study showed that the optimization model could effectively increase the operation period between decoking. In future work, we will add the cracking furnace system into our model, which can optimize the operation period in both systems.

Abstract

Cooperative reuse of water resource across the plants placing in same industrial park would bring significant benefit to each participant plant, the park, and also the realization of resource-saving society. Different from designing water reusing networks merely subjecting to one or several pre-known operation scenarios, this study concentrates on solving the retrofit problem towards the unpredictable scenario which is upcoming yet unrealizable with current water allocation system. A hierarchical procedure is proposed, wherein by introducing series of specific constraints, the mixed integer non-linear programming model formulated for design purpose (Liu et al., 2017) is developed for achieving the optimal retrofit measures respecting to different retrofit specifications of decision-maker requires. At last, an industrial park example containing three retrofit cases at several typical scenarios is illustrated to show the application of the method.

Keywords: industrial park, water network, retrofit, unpredictable scenario

1. Introduction

An industrial park is a cluster of multiple individual plants locating in the same geographical area. This existence creates many extra opportunities for resources saving and sharing beyond plant level. Accordingly, increasing efforts have been contributed to inter-plant water integration due to its remarkable performance on water saving and cleaning for process industries in recent years.

Early work by Olesen and Polley (1996) first addressed water integration across plants based on pinch analysis, where a load table and a capacity diagram were employed. Liao et al. (2007) combined mathematical programming with pinch analysis insights to conduct flexible inter-plant water integration. Then direct and indirect water reusing modes were proposed by Chew et al. (2008) for the same purpose. Lovelady and El-Halwagi (2009) introduced a systematic water integration approach for the design of industrial park based on a source-interception-sink representation, and this work was extended into property-based integration by Rubio-Castro et al. (2013). Chen et al. (2010) developed a novel integration scheme, where water-using units within each plant were interconnected with the use of central and decentralized watermains. Alnouri et al. (2014) included pipe merging purpose into the design of inter-plant water network. Liu et al. (2016) reduced the synthesis complexity by building a plant-based mode for crossing-plant water reusing. In addition to mentioned work, the operation aspect of

inter-plant water integration becomes to gain growing attention in recent years. Faria and Bagajewicz (2011) studied a planning model for time-varying water system, taking the increase in number and mass load of water-using units into account. Burgara-Montero et al. (2013) introduced a multi-period optimization model to involve seasonal variability. Aviso (2014) developed a robust optimization approach for multi-period water integration of direct inter-plant reusing in eco-industrial parks, which satisfied various probable future scenarios. And recently, the same problem was also studied by Liu et al. (2017) by using indirect inter-plant water reusing pattern, accompanying with including in-plant and inter-plant regeneration operations.

Nevertheless, the mentioned study considers a single or several certain operation scenarios only for design purpose. In practice, the variations of many factors like prices of raw material and product, market requirement, government policy etc., will push decision-makers to change production scale so as to gain the maximum profit. In most situations, it is hard to predict these variations in very early advance, for example at the design stage of a process, but requires the plant to timely take retrofit actions on existent water network so as to satisfy the process specifications of coming operation scenario. Concerning this practical necessity, this study undertakes the challenge to handle unpredictable problem of water network retrofit for industrial park. The synthesis method proposed in our former study (Liu et al., 2017)) is extended and developed to catch the optimal network retrofit behaviours against the unanticipated events in future development of the park.

2. Problem statement

The problem addressed in this study is stated as follows: Given is a concerned industrial park with its existing water network, wherein the water reuse and regeneration operations are implemented inside and across individual plants for fresh water saving sake. The network information relating to currently running scenario is known, mainly including the stream connections, flowrates, concentrations and removal ratios of regenerators. However, this management may fail to satisfy a new or unplanned operation scenario so that the appropriate countermeasures are required. For this reason, the purpose of this work is to determine the best fresh water-saving retrofit schemes by re-allocating stream flowrates and re-designing stream connections based on the current network and the retrofit requests that for practical concerns.

3. Method

This retrofit method is developed from the multi-period synthesis model proposed by Liu et al. (2017), which aims at covering all predictable scenarios for network design. The multi-period model is used to build relationships between current network (period 1) and target scenario (period 2). Beyond its design application, we further involve running information of existent network into the model, moreover, new constraints towards the retrofit scope and strategy indicating where and which measures can be taken are also included for optimization. The method can be basically executed in three steps as follows.

Step1. Determine original network. The original network refers to an existent water network in operation. It can be obtained using either single-period water network synthesis method or multi-period synthesis method.

Step2. Determine the scope/part of network where and which retrofit measures are permitted. Production variations commonly occur in one or several plants, rather than the whole industrial park. Therefore, to maintain the stability of other plants, the retrofit measures should be restricted in a certain scope according to process specifications and tolerable fluctuation degree of other plants. With this concern, we can determine which network elements, mainly referring to stream connections and flowrates, are changeable and which are fixed. This information will be used in the mathematical model-based optimization of step 3 for retrofit purpose.

Step3. Optimize retrofit measures. Apply the mathematical model proposed for design purpose to determine the optimal retrofit measures towards a coming park scenario with target of minimum fresh water consumption. The mathematical model used in this study is absorbed from Liu et al., (2017), having a superstructure containing plentiful water allocation schemes formulated. While moreover for retrofit intents, series of specific constraints for stream connections, flowrates and concentrations are also included in the model for retrofit measure optimization according to the scope specified in step 2.

4. Case Study

This study directly takes the active part (in solid lines) of the fifth period in Liu et al. (2017)(Figure 3) as the existent water network, named Case 0, to show the application of the method on solving unpredicted operation problem. The major variation concerned in this work is the significant adjustment of production scale, however other variation scenarios can be also handled in the same way. Assume just the production scale of plant A changes. The six scale adjustment scenarios (process data of original scale in Liu et al., 2017) of +10%, -10%, +20%, -20%, +30%, -30% are investigated and analyzed based on the three retrofit cases set below. To meet these updating water using requirements, new allocations featuring minimum fresh water consumption are desired.

Case 1: *Re-design water network A with holding the rest connections in network, meanwhile adjust all stream flowrates.*

In this case, two parts of retrofit work are simultaneously implemented towards each adjustment scenario: Part 1, re-design the sub-network structure including water stream connections and flowrates for plant A, and Part 2, meanwhile retain stream connections outside plant A in base case Case 0 however assign new flowrates that going through. In such, we extract constraints from Case 0 and act on Case 1, which insure the non-existent connections in the base network section that excludes plant A remain not exist in the new case. Use indicator f_0 (no A) to represent the flowrates of mentioned connection in general, then equation of f_0 (no A) = 0 is included in the model to handle the retrofit problem targeted by Case 1.

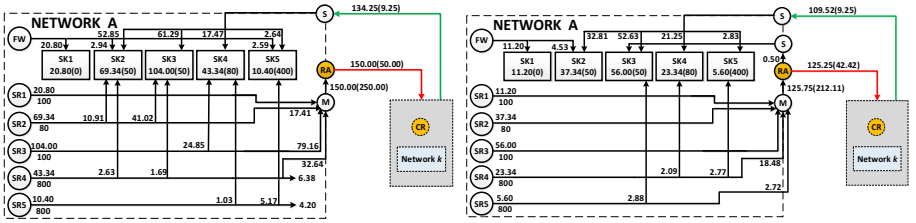
The six scenarios are individually studied, and the new network structures of plant A and new water allocation schemes are achieved accordingly. Optimization results are summarized in Table 1. As indicated, the minimum fresh water consumption alters with production scale. Figure 1 shows the newly designed network of Plant A at production scale of +30% and -30%. With the optimized network retrofit behaviour, the new networks are able to satisfy the new production requirements, meanwhile, conform to the retrofit stipulation of Case 1.

Table 1. Scenario solutions for Case 1

Scale change	0	+10%	-10%	+20%	-20%	+30%	-30%
Fresh water/t·h^{-1}	56	56.02	52.63	59.13	52.81	62.33	51.73

Case 2: *Keep all connections in network unchanged, but adjust stream flowrates, removal ratio and the using of fresh water.*

This case is trying to meet the operation scenario by just altering the water stream flowrates of Case 0, however it may fail because the fixed network structure may cause the flowrate adjustment of no avail. Against this situation, two strategies are proposed to facilitate the retrofit intention.



(a) Increases 30% (+30%) (b) decreases 30% (-30%)

Figure 1. Water network structure of plant A at its production scale changing 30 %

Strategy (1): Enhance removal ratios of regenerators to assist flowrates re-assignment. In this study, the removal ratios are increased in step of 0.01 until to get feasible re-assignment solutions for the new operation scenarios. In such way, Table 2 and 3 have shown the respective removal ratio and fresh water consumption at each scenario. Obviously, not all removal ratios but that of pre-treatment unit in Plant B needs to be intensified. This is because no matter Plant A scale becoming larger or smaller, concentrations of inter-plant streams going forward to centralized regenerator must meet the process constraints, and the flowrates must be sufficient for water sink demands. The base network structure with original removal ratios is not feasible for concerned scenarios, so it has to enhance.

Table 2. Removal ratio of Plant B in Case 2

Scale change	0	+10%	-10%	+20%	-20%	+30%	-30%
RC(B)	0.8	0.81	0.81	0.82	0.82	0.83	0.83

Table 3. Scenario solutions for Case 2

Scale change	0	+10%	-10%	+20%	-20%	+30%	-30%
Fresh water/t·h^{-1}	56	53.6	50.4	55.2	48.8	56.8	47.2

Strategy (2): Re-assign water stream flowrates with involving new fresh water pipelines while fixing network structure and regeneration operations. In such way, Table 4 collects the fresh water quantity added into each scenario and the data show that the more the plant scale is, the more extra fresh water is required for this case. In this study, the newly involved fresh water is added at inlet of centralized regenerator because there are concentration specifications towards streams going into the regenerator, however the fresh water can be also dispersed and directly used into water sinks if the mentioned

concentration limits are ignored. Anyhow, adding fresh water is a choice against the unpredictable scenarios.

Table 4. Added fresh water quantity for each scenario

Scale change	0	+10%	-10%	+20%	-20%	+30%	-30%
Added fresh water / t·h^{-1}	0	1.30	2.40	4.15	4.03	5.80	4.48
Total fresh water /t·h^{-1}	56	54.9	52.8	59.35	52.83	62.6	51.68

Case 3: *Keep all connections in network and operation parameters outside sub-network A unchanged, just adjust the stream flowrates of Plant A and the using of fresh water.*

In this case, the operation adjustment is restricted on the flowrates of connections in plant A and the plant related inter-plant streams, which is to say the elements in other plants including network structure and stream flowrates stay the same with that in base case. Such that according to the inter-plant water allocation diagram presented in Figure 2, the stream flowrates and concentrations should obey the constraints showing on right, meanwhile the inner-plant connections are restricted similarly.

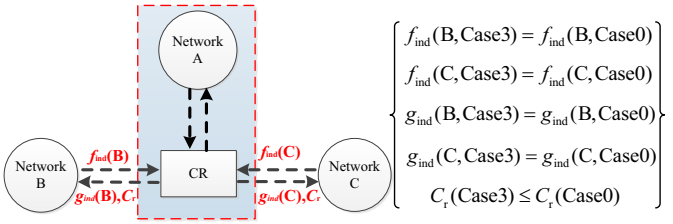


Figure 2. Inter-plant stream allocation diagram

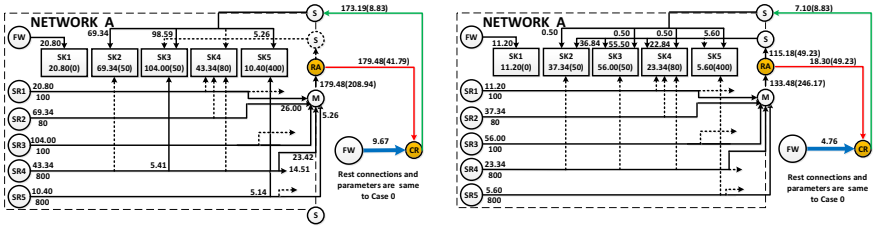
Compared with that of former two cases, the retrofit scope of this case is significantly narrowed, so in order to accommodate the operation scenarios, adding inter-plant fresh water strategy proposed in last case is applied. Through retrofit design, we obtain new allocation solutions for the six unpredictable scenarios. Take +30% and -30% scenarios for example, their required supplementary fresh water quantity are 9.67 t·h^{-1} and 4.76 t·h^{-1}, total fresh water consumption are 66.47 t·h^{-1} and 51.96 t·h^{-1}, respectively. The network information is shown in Figure 3. Anyhow, this case offers the minimal adjustment measures to meet the retrofit purpose.



(a) Increases 30 % (+30 %) (b) decreases 30 % (-30 %)

Figure 3. Water network at production scale of plant A changes 30 %

Observe the three cases some conclusions can be obtained. Firstly, water network structure of a plant changes with its plant scale if the network retrofit is permitted. Secondly, stream flowrates of the same connection in two scale scenarios do not follow the relative ratio of the scales. Thirdly, the allocation details (not only flowrates but also concentrations) of inter-plant streams as well as other in-plant streams are influenced by the variation to a plant if the water using is whole-park considered. Therefore, it is necessary to implement retrofit operation for industrial park in a long-term perspective.

5. Conclusions

This study develops a three-step method for retrofit intentions over water networks of industrial park. The optimal retrofit behaviours are obtained by involving constraints and strategies into the mathematical model having existent network information included.The method is illustrated throguh three retrofit cases with receiving their individual optimal countermeasures against the unpredictable scenario. And the results have shown the ability of this method to provide a variety of feasible retrofit alternatives following decision-makers' intention.

Hybrid Global Optimization Method for the Analysis of Integrated Reaction and Separation Processes

L.-S. Harding[a*], M. Schroeder[a], G. Fieg[a]

[a]*Institute of Process and Plant Engineering, Hamburg University of Technology, Am Schwarzenberg-Campus 4, 21073 Hamburg, Germany*
selin.harding@tuhh.de

Abstract

The reactive distillation and the reactive dividing wall column are examples of integrated reaction and separation processes, which show significant savings in investment as well as operational costs. Due to the high grade of integration the behavior of these processes is strongly nonlinear. This results in several local optima and thus the determination of energy optimal designs is quite challenging. Additionally, it is not trivial to understand and predict how the process performs in detail. Still, a fundamental process understanding is indispensable for a safe and energy efficient design of integrated reaction and separation processes. Therefore, a new hybrid global optimization method is presented, which is based on an evolutionary algorithm. This holistic approach is advantageous for optimization problems where the optimal values of the decision variables depend strongly on a certain decision variable. Dependencies of the process parameters can be deduced easily and a comprehensive process analysis can be carried out.

Keywords: reactive distillation, process integration, energy minimum design, global optimization, evolutionary algorithm

1. Introduction

Process intensification has become an important concept to meet the challenges of an increasing global competition in the chemical industry. A promising possibility of process intensification is the integration of primarily separated process operations into one single shell (Lutze et al. 2010). Examples are the reactive distillation (RD) or the reactive dividing wall column (RDWC) (Figure 1). These apparatuses enable a reaction and a simultaneous separation of the products. In the RD reactive systems with two products can be separated, whereas a separation of reactive systems with three product fractions can be carried out in the RDWC. These fractions can be products of the reaction, non-reacting components or excessive reactants (Müller 2010).

For energy optimal operation the component flows in the column and the resulting realized splits are important parameters. The split in the prefractionator of the RDWC can be characterized by the feedsplit. Latter states the molar fraction of the feed stream that leaves the upper part of the prefractionator (PF). The behavior in the PF of the RDWC equals the one of a reactive distillation, so that the feedsplit is equatable to the distillate/feed-ratio (D/F) in the RD (Schröder et al. 2016; Cici and Fieg 2017).

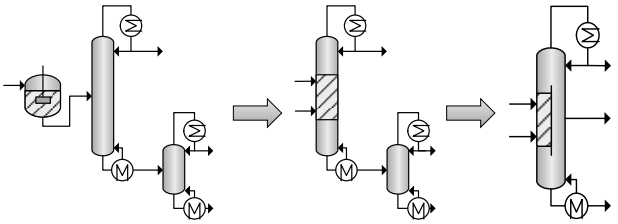

Figure 1: Levels of process integration: reactor and direct distillation column sequence (left), direct reactive distillation sequence (middle) and reactive dividing wall column (right)

Compared to conventional process alternatives integrated reaction and separation processes show significant savings in investment as well as operational costs (Yildirim et al. 2011; Harmsen 2007). These savings increase with the grade of process integration. Though, the complexity of the processes also increases with the grade of process integration. The process behavior of integrated processes is strongly nonlinear. Hence, the design is extremely demanding. A fundamental process understanding as well as reliable design methods are required for a safe and energy efficient design.

Energy minimum designs can be determined by process optimization. The optimization problems for integrated reaction and separation processes belong to the complex type of mixed integer non-linear programming (MINLP). Evolutionary algorithms (EAs) are suitable to solve such problems and are commonly used in science and industry (Chiong 2009). One example of an optimization tool based on EAs is the Advanced Process Optimizer (AdvPO). It is specially tailored for the optimization of chemical processes and is featured with an individual Elite-concept. This consists of an Eliteindex for storing the optimal solutions and an Elitecount for population development. The AdvPO additionally enables the linking of commercial flowsheet simulators and parallel mode calculation (Ernst et al. 2017).

Despite their good performance EAs do not guarantee to find the global optimum. To minimize the risk of convergence to local optima and gain knowledge about the influence of process parameters on the required energy demand at once, a new hybrid global optimization method has been developed. It is based on the algorithm of the AdvPO and is advantageous for optimization problems where the optimal values of the decision variables depend strongly on a certain decision variable. In the following chapter the algorithm will be described with its main characteristics.

2. Methodology

The functional principle of the developed hybrid global optimization method compared to the common method of single objective optimization is shown in Figure 2. In the common optimization method one optimization run yields one process design. Ideally, this result represents the global minimum of the objective. If the influence of a process parameter should be investigated, several optimization runs have to be carried out. Here the parameter of interest is changed manually for each optimization run. In every run the search for the optimum starts at the very beginning. No good genes (values of process parameters) are present from which the individuals (process designs) can profit. This procedure is, especially for fine parameter discretization, computationally intensive and quite time consuming.

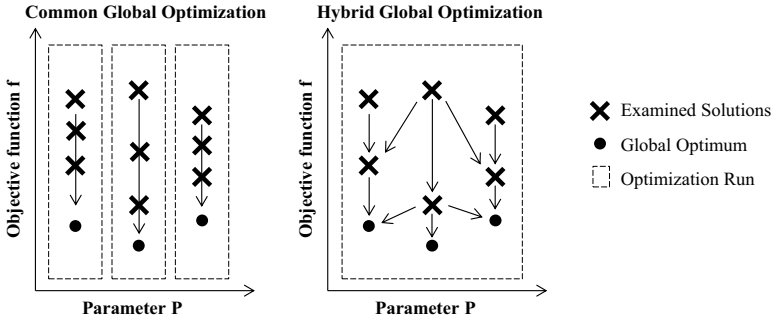

Figure 2: Functional principle of hybrid global optimization method in comparison to common single objective optimization

In comparison the hybrid global optimization method combines the analysis of process parameters and the optimization in one method. The idea behind this innovative concept is that the investigated parameters should only be varied in a practical reasonable interval. The design variables of the resulting optimal designs do not differ in a large range. So, individuals with a specific parameter value can also profit from good genes from individuals with different parameter values. As a result, fast convergence can be achieved for every parameter value.

The algorithm for this new method is based on the EA of the AdvPO, which is described in detail by Ernst et al. (2017). For an equal treatment of all parameter solutions the evaluation and Elite-concept are changed by the implementation of a parameter specific ranking, shown in Figure 3. Initially, the population is sorted by the different parameter values. The individuals of each parameter value are then ranked independently from individuals with different parameter values. For the Eliteindex the ranking is performed for the objective values, whereas for the evaluation the fitness values are ranked. Latter take the objective values as well as the constraints into account. As a result, at least one individual for each parameter value exists with the best rank.

Additionally, a high diversity of the parameter is required in each generation to find the global optimum for each parameter value during the optimization. Therefore, the places in the Elitecount, typically 20 % of the total population, as well as the places for the parents of the next generation are equally distributed to all parameter values. So, for all parameter values the same number of parents is chosen via a tournament selection and the same number of individuals is present in the Elitecount of a generation. Remaining places, which cannot be equally distributed, are randomly assigned to a parameter value. These changes ensure that the diversity of the parameter stays high during the whole optimization without hindering the convergence to optimal process designs. The genetic operations recombination and mutation stay unchanged, so that the genes from one parameter value can profit from good genes of another parameter value.

The progress of the optimization is checked separately for each parameter value. Therefore, the improvement of the objective value over a defined number of generations is analyzed. If no change is measured, the optimization is converged for this parameter value. It is sorted out of the population and the individuals are distributed to the remaining parameter values. The determined optima remains saved in the Eliteindex. The optimization run is terminated as soon as all parameter values are converged.

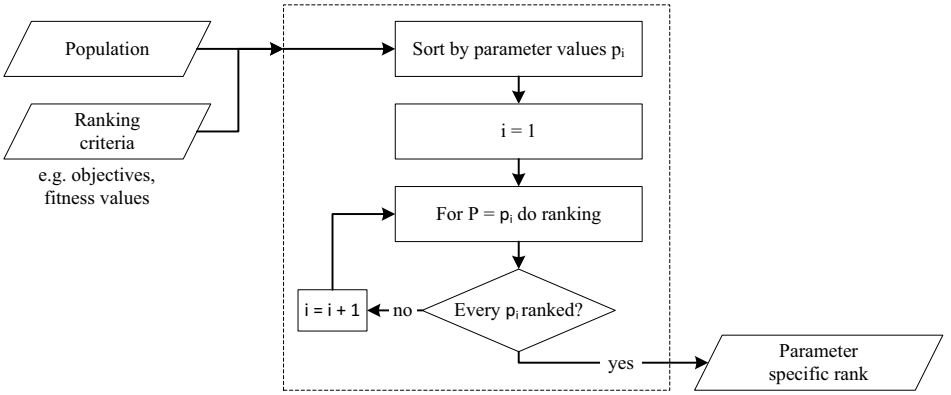

Figure 3: Schematic flow diagram of parameter specific ranking in hybrid global optimization

2.1 Optimization Problem Formulation

The hybrid global optimization method is demonstrated on the example of a reactive distillation. The column model is implemented in Aspen Custom Modeler, which is linked to the optimizer via an DLL-interface. A quinary reactive system given in Eq. (1) is investigated. For a more detailed description of the reaction system the reader is referred to Schröder et al. (2016). The amount of each feed stream into the column is 50 kmol/h with a molar fraction of 10 mol% of inert and a molar fraction of 90 mol% of reactant.

$$A + B + E \rightleftharpoons C + D + E \quad (1)$$

As stated in the introduction, the D/F ratio is an important parameter for energy optimal operation. Thus, the influence of this ratio on the minimum vapor demand of the RD is investigated. So, the objective of the optimization is to minimize the vapor demand of the RD. As a constraint a minimal conversion of 99.5 % of the reactant A is demanded. The decision variables for the optimization with their bounds and step size are presented in Table 1, in which the first decision variable equates the parameter of the D/F ratio.

Table 1: Summary of decision variables with bounds and step size for the optimization of a reactive distillation column

Decision Variable	Lower Bound	Upper Bound	Step Size	Unit
D/F ratio	0.45	0.55	0.01; 0.001	-
Upper feed position	1	1.99	0.01	-
Distance of feed positions	0	20	1	-
Vapor duty	100	400	1	kmol/h
Number of stages top segment	1	50	1	-
Number of reactive stages	60	100	1	-
Number of stages bottom segment	1	50	1	-

3. Results

3.1 Validation

For the validation of the new hybrid global optimization method the obtained results are compared to results of a systematic, complete search of the solution space in Figure 4. As it can be seen for every D/F ratio a minimum vapor demand has been determined by the new method. Nearly all results match the ones from the complete search of the solution space, so that the hybrid global optimization method is validated successfully.

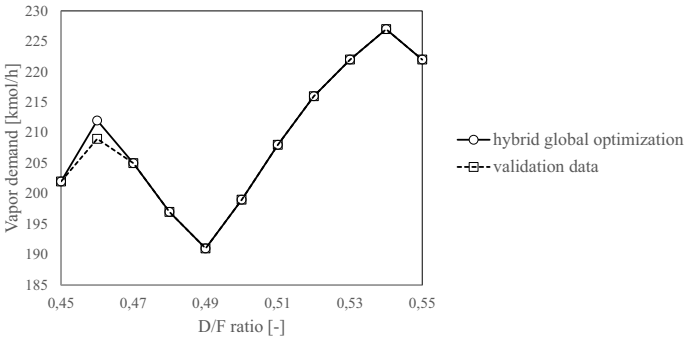

Figure 4: Results of the optimization of the vapor demand of a reactive distillation of the hybrid global optimization method in comparison to validation data

3.2 Analysis of Integrated Reaction and Separation Processes

As a second run the D/F ratio in the region of the global minimum was varied in a smaller step size to get a more detailed distribution. The results are shown in Figure 5. As expected, it can be seen that the vapor demand is highly influenced by the D/F ratio. The correlation of the D/F ratio and the vapor demand shows various saddle points, which hinder the determination of the global optimum with common global optimization methods. The new hybrid global optimization method allows identifying the correlations between the process parameters and thus minimizes the risk of convergence to local optima.

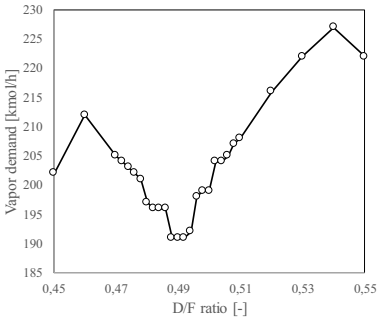

Figure 5: Correlation of minimum vapor demand and D/F ratio in the RD

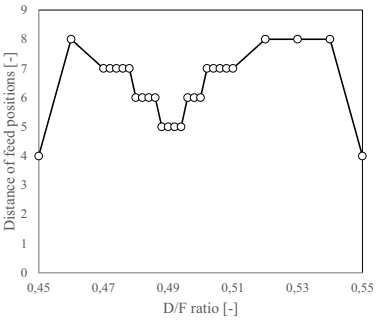

Figure 6: Correlation of distance of feed positions and D/F ratio in the RD

Additionally, further process analysis can be carried out by analyzing the dependencies of other process parameters. In Figure 6 the dependency of the distance of the feed positions and the D/F ratio is presented exemplarily.

4. Conclusions

The proposed hybrid global optimization method is characterized by an EA with a special parameter based ranking and a high diversity of the parameter during the whole optimization. In principle, this method is advantageous for optimization problems where the optimal values of the decision variables depend strongly on a certain decision variable. In these cases, this approach helps to find the optimal solutions more reliably and with less manual effort. An evaluation of this innovative method was carried out on the example of a reactive distillation column. In future work it is planned to investigate this method for further examples. The obtained results showed a good agreement with validation data. Additionally, correlations of the minimum vapor demand, the D/F ratio and the distance of feed positions were identified. So, the hybrid method provides a holistic, time-efficient approach for the design of integrated reaction and separation processes. It enables the determination of the influence of a process parameter and the energy minimum design of apparatuses. Thus, correlations of process parameters can be deduced easily and local optima of the process designs can be identified.

Abstract

To explicitly reveal the interaction mechanism between work and heat integration considering both thermodynamic and economic analysis, an improved superstructure, coupling of work exchange networks (WEN) and heat exchange networks (HEN), is proposed for simultaneous synthesis of work and heat exchange networks (WHEN) in this paper. The formulations based on exergy analysis are developed to determine the cold or hot identity of process streams. Afterwards, economic analysis is performed by formulating a cost-based mixed-integer nonlinear programming (MINLP) model to optimize the sequence of work and heat integration, aiming to minimize the total annual cost (*TAC*). Finally, an example study selected from the open literature is conducted to demonstrate the efficacy of the proposed methodology, where the solutions show a diminution of 40.4% in TAC of HEN prior to WEN, compared with that of WEN prior to HEN.

Keywords: work and heat exchange network; superstructure; exergy analysis; economic analysis; sequence

1. Introduction

Heat-based thermal energy and work-based mechanical energy are two common forms of energy consumed significantly in chemical process industries.(Aida-Rankouhi and Huang, 2017) While heat integration has become a mature technology that is widely used for available thermal energy recovery via heat exchange networks, work integration, however, has not been fully explored. Interestingly, work integration can contribute significantly to mechanical energy recovery through synthesizing work exchange networks (WEN). (Zhuang et al., 2017c)

From the thermodynamics point of view, pressure and temperature are two important thermodynamic parameters for interactive conversion between work and heat. (Fu and Gundersen, 2016) Especially significant at sub-ambient conditions, Wechsung et al. (2011) proposed an optimization formulation allowing for the inter-conversion of work, pressure, and temperature-based exergy to reduce usage of costly cold utility. In addtion, considerable cost savings can be achieved by simultaneous synthesis of work-heat exchanger networks (WHEN) based on the multi-stage superstructure. (Huang and Karimi, 2016) However, the above-mentioned works overemphasize that pressure

manipulation is essential for enhancing heat integration, ignoring the interaction between work integration and heat integration.

In this article, a superstructure for WEN coupled with HEN is proposed to simultaneously synthesize WHEN. Based on exergy analysis, the cold or hot identity of process streams is confirmed prior to WHEN design. Afterwards, economic analysis is performed through a developed cost-based MINLP model to optimize the sequence of work and heat integration, aiming at the minimum *TAC*. Finally, an example study is conducted to demonstrate the efficacy of the proposed methodology.

2. Problem statements

A set of gaseous streams at high pressure (HP) and low pressure (LP) are present in a chemical process, with known flowrates, inlet and outlet pressure, inlet and outlet temperature, heat capacity and heat transfer coefficients etc. The purpose of this paper is to design a network configuration of WEN coupled with HEN to attain the minimized TAC. To simplify the synthesis procedure, the assumptions in our previous work (Zhuang et al., 2017b) are adopted.

3. Model formulation

3.1. Improved superstructure for WEN coupled with HEN

An improved stage-wise superstructure is proposed to achieve simultaneous synthesis of WHEN, consisting of two distinct, but interconnected networks. One (HEN) is for heat integration and the other (WEN) is for work integration, as shown in Figure 1 and Figure 2. From these two figures, it can be found that one concern is the streams should pass through HEN or WEN first, which is optimized in our latter model.

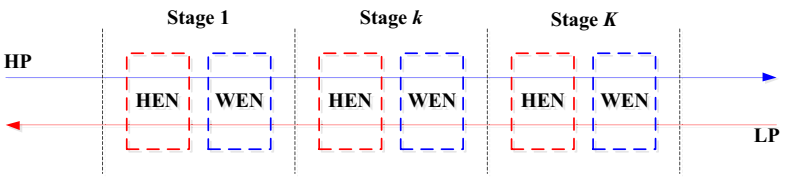

Figure 1 Stage-wise superstructure for synthesizing WHEN

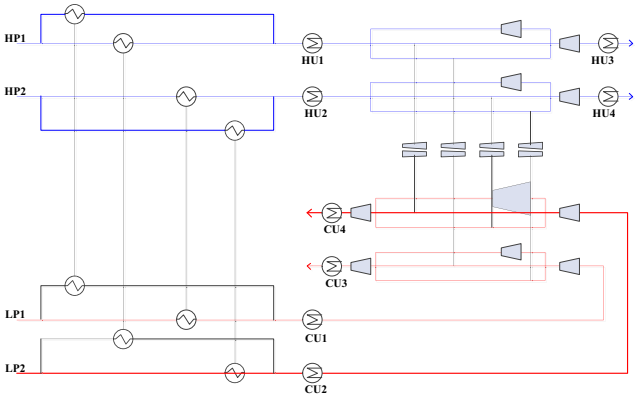

Figure 2 WHEN superstructure in each stage

Another concern is about how to determine the cold or hot identity of HP and LP streams. To settle this problem, an exergy analysis model is established for expanders, compressors and work exchangers, as shown in Figure 3. According to the corresponding exergy balance, the following exergy loss formulations can be obtained.

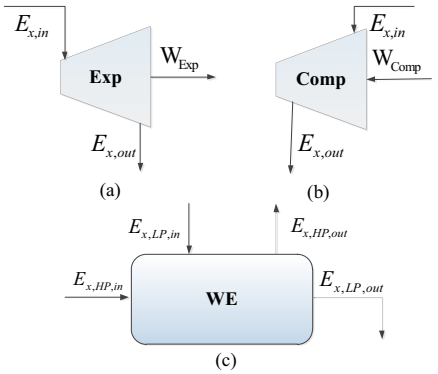

Figure 3 The exergy analysis for expander (a), compressor (b) and work exchanger (c)

$$\Delta E_{X,Exp} = FCpT_0 \ln\{1+\eta\cdot[(\frac{P_{out}}{P_{in}})^{\frac{\gamma-1}{\gamma}}-1]\} + FT_0R\ln(\frac{P_{in}}{P_{out}}) \tag{1}$$

$$\Delta E_{X,Comp} = FCpT_0 \ln\{1+\frac{1}{\eta}\cdot[(\frac{P_{out}}{P_{in}})^{\frac{\gamma-1}{\gamma}}-1]\} + FT_0R\ln(\frac{P_{in}}{P_{out}}) \tag{2}$$

$$\Delta E_{X,WE} = 0 \tag{3}$$

Eqs. (1)-(3) indicate that HEN bears little effect on WEN based on exergy losses analysis. Consequently, since recoverable energy from HP streams increases with inlet temperature while the required energy of LP streams decreases with inlet temperature, thus HP (LP) streams will be treated as cold (hot) streams in HEN.

3.2. Objective function and constraints

In this context, the main objective of the proposed mathematical is to optimize the WHEN synthesis, by minimizing *TAC*, composed of total annual cost of HEN (TAC_{HEN}) and total annual cost of WEN (TAC_{WEN}). Additionally, the TAC for single HEN and WEN both consists of capital investment and operational expenditure, which is based on our previous study presented in Zhuang et al. (2017a) and the famous optimization model for HEN synthesis proposed by Yee and Grossmann (1990).

As for the mathematical formulation, it also refers to the above two open literatures, which includes equipment design equations (such as work exchangers, expanders, compressors, heat exchangers, heaters and coolers), mass and energy balances for heat recovery and pressure manipulation, some logical constraints to ensure feasible solutions and design relationships with physical meaning. The key strategies are to determine the cold or hot identity of streams and optimize the sequence of WEN and HEN synthesis, which facilitates synthesizing WHEN. Since there are more than 40 equality and inequality constraints, thus the detailed representation for each constraint

cannot be shown hereby, due to the limit of six-page manuscript. Despite lack of detailed description, this paper still provides a novel superstructure-based optimization model with thermodynamic and economic factors to simultaneously synthesize WHEN so that the thermal and mechanical energy consumption can be sharply reduced.

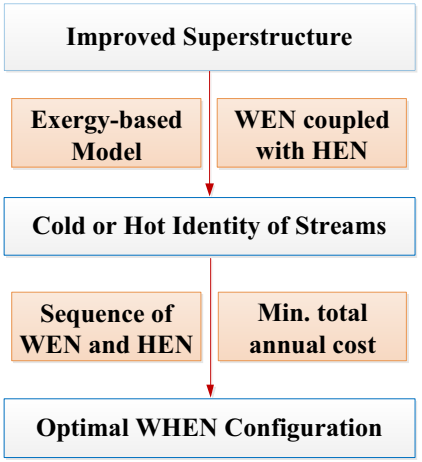

Figure 4 Flow chart of the proposed method.

4. Example study

In this section, the example from Onishi et al. (2014) has two high-pressure streams and two low-pressure streams, where the detailed stream data is shown in Table 1.

Table 1 Process stream data

Stream	*F* (kg/s)	*Cp* (kJ/kg K)	*h* (kW/m^{2}K)	*TIN* (K)	*TOUT* (K)	*PIN* (kPa)	*POUT* (kPa)
HP1	12	2.454	0.1	410	600	900	100
HP2	18	0.982	0.1	355	500	850	150
LP1	15	1.432	0.1	600	350	100	700
LP2	18	2.454	0.1	600	360	100	900

Based on the presented optimization procedure, a two-stage superstructure for WHEN synthesis is introduced to deal with the example. Since the outlet temperature of two high-pressure streams is higher than their respective inlet temperature, each HP stream is treated as cold stream. Similarly, each LP stream is treated as hot stream. Then by targeting the minimized TAC, the formulated MINLP model is solved by BARON solvers in GAMS 24.0.

Interestingly, two cases are studied, one of which considers WEN prior to HEN while the other allows for HEN prior to WEN, represented by Case A and Case B, respectively. In both cases, TAC minimization, composed of capital investment and operational expenditure of both HEN and WEN, is considered to be the objective function. Clearly, the results of these two cases are provided in Table 2 and the corresponding optimal WHEN configurations are shown in Figure 5 and Figure 6.

From Table 2 and Figure 5, 6, it can be seen that our approach adopting Case B yields an optimal configuration with a TAC of 14937 k$/y, a 40.4% decrease to that obtained by Case A. This is because HEN contributes to improving the inlet temperature of HP streams and reducing the inlet temperature of LP streams prior to WEN, which increases the available mechanical energy of HP streams and decreases the demanded energy of LP streams. Thus, the work utility consumption (W_U) with higher cost is considerably decreased despite the increment of heat utility consumption with lower cost.

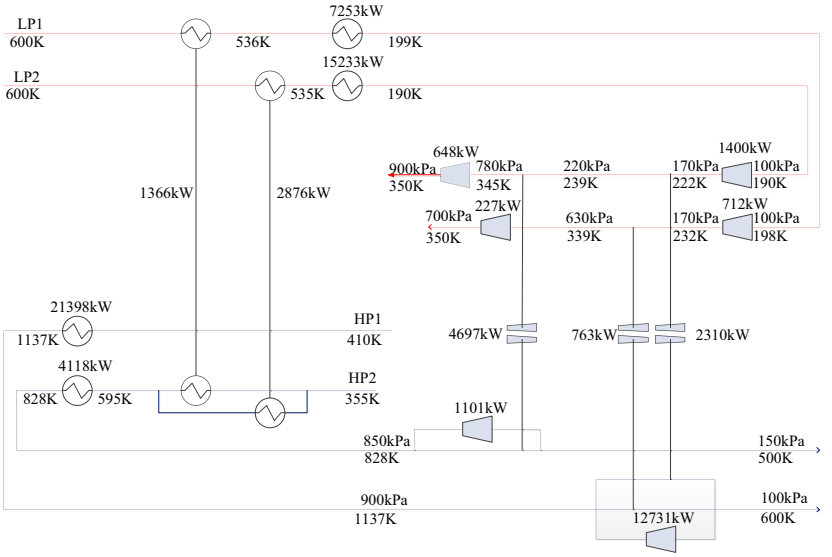

Figure 5 Optimal WHEN configuration for Case A

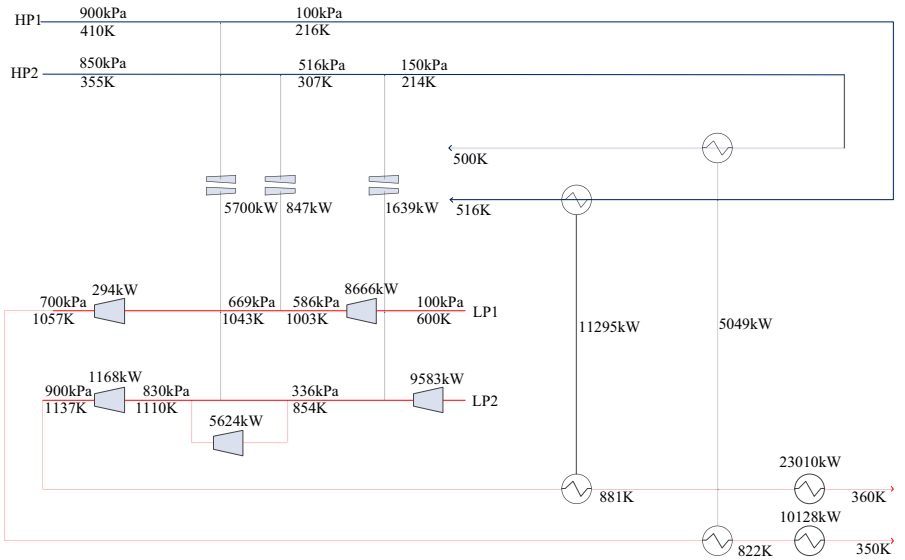

Figure 6 Optimal WHEN configuration for Case B

Table 2 Solution comparison of two different cases

Item	W_U (kW)	Q_U (kW)	TAC_{HEN} (k$/y)	TAC_{WEN} (k$/y)	TAC (k$/y)
Case A	25,335	33,138	279	24,763	25,042
Case B	16,819	48,002	532	14,405	14,937

5. Conclusions

In this paper, a superstructure-based mathematical model for simultaneously synthesizing WHEN is proposed, in order to explicitly reveal the interaction mechanism between work and heat integration considering both thermodynamic and economic analysis. The exergy analysis is conducted to determine the cold or hot identity of process streams. After that, the developed model is formulated as MINLP problem with the objective of minimized TAC. Finally, an example study is carried out to show that our approach yields a HEN-WEN configuration with 40.4% lower TAC than that of WEN-HEN structure.

Abstract

Cooling water system and chilled water system are wildly used in industry to reject waste heat. When cooling water is not capable to cool down the hot stream to target temperature, chilled water is required. So far, cooling water system and chilled water system are designed separately because the two systems use water with different qualities. Desalted water is used in chilled water system but it cannot be used in cooling water system, because water losing is huge in open cooling tower. Meanwhile, fresh water cannot be used in chilled water system because of high concentration of impurities. In this work, closed cooling tower is applied, because there is no lose of recirculating water in closed cooling tower, desalted water can be used in cooling water system. A large amount of water was saved by using closed cooling tower. Cooling water system and chilled water system was integrated into one, cooling duty was redistributed between the two systems. Stage-wise heat exchanger network was employed where water can be reused. For returned hot water, they are firstly sent to closed cooling tower to be cooled down to a certain temperature, and then part of the water is further cooled down by refrigeration cycle. The model is formulated as mixed-integer nonlinear programming (MINLP) problem. The objective is to minimize the cost of integrated cooling and chilled water system, and determine the optimal heat load distribution between closed cooling tower and refrigeration cycle. Results show that optimization model yields significant reduction on total annual cost and energy consumption, in comparison with system where cooling water system and refrigeration cycle are separated.

Keywords: Cooling water, Chilled water, MINLP, Optimization.

1. Introduction

Cooling water system is widely used in industry to reject waste heat. Many works have been done to study the cooling water system and formulate the cost saving and water saving system. Earlier work focus on minimizing water consumption and improving tower efficiency (Kim and Smith. 2001). Later, Ponce-Ortega et al. (2007) used the superstructure approach to optimize cooling water system and formulated cost saving cooling network. It is quite effective to use cooling water as an intermedium to transfer waste heat from industry to environment, owning to the good thermal property of water. However, when the hot streams target temperature is below ambient temperature, the chilled water is needed. Compression refrigeration system produces chilled water that meets the demand of heat exchanging service in industry. Researchers studied the refrigeration system from different perspectives. For example, a recent work conducted

by Yin et al. (2016) formulated cascade vapor compression system that is energy efficiency. Jain et al. (2016) optimized a cascade vapor-absorption refrigeration system and yield a cost saving system with great thermodynamic performance. Both of cooling water and refrigeration system have been studied thoroughly. However, no research has ever integrated two systems into one and explored the interconnections between. This is because different water was used in two systems. Fresh water in cooling water system cannot be used as chilled water. Employing closed cooling tower makes it possible to integrate two systems into one, since the clean recirculating water has no contact with air and the water is qualified to be used as chilled water. Moreover, in cooling water system, because fresh water is replaced by desalted water, the occurrence of scaling in coolers can be prevented and the cost for scaling inhibitor is avoided. In this work, we proposed a method that allows us to optimize two systems simultaneously. Given a set of hot streams, cooling water as well as chilled water is employed to cool down the hot streams to target temperature. For the conventional method, the outlet temperature of cooling tower is specified. The first step is to formulate cooling water network. Since the cooling water cannot cool down some hot streams to target temperature, the chilled water network is formulated. In this study, the proposed method is capable to integrate two systems simultaneously. As shown in figure 1, hot streams were cooled down by cooling and chilled water. Then the cooling water and chilled water mix and enter the closed cooling tower. A partial of outlet water of cooling tower enters heat exchanger network as cooling water, and the rest of water is cooled down by refrigeration cycle as chilled water. The outlet temperature of cooling tower and the flowrate of cooling and chilled water are the optimized variables. Some hot streams are cooled down by cooling and chilled water sequentially, the partition temperature of hot stream is also an optimized variable.

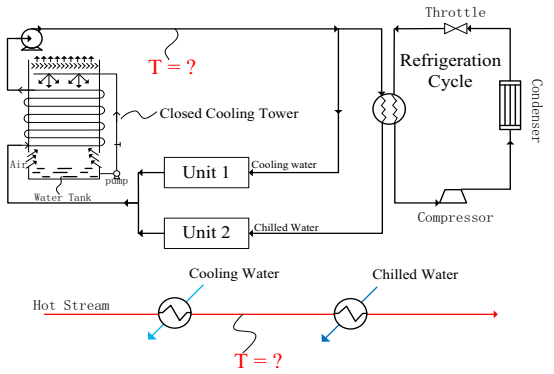

Figure 1. Illustration of two-stage cooling configuration.

2. Model formulation

In this paper, the stage-wise cooler network is employed. The following section describes the equations for the MINLP model. The set HP represents all the hot streams, set CP denotes cold stream which includes cooling and chilled water, set ST represents all the stages in the superstructure. *i*, *j*, *k* represents individual hot, cold streams and stages. In Eq.(1), $th_{i,k}$ is the temperature of hot stream *i* at stage *k*. The hot stream enters at first stage and the temperature of first stage is inlet temperature of hot stream. Target temperature of hot stream is defined as the last stage temperature. In Eq.(2), NOK is the total number of stages, $Thin_i$ and $Thout_i$ are inlet and target temperature of hot stream.

$$th_{i,1} = Thin_i \qquad i \in HP \quad (1)$$

$$th_{i,NOK+1} = Thout_i \qquad i \in HP \quad (2)$$

The cold streams enter at last stage of network and the inlet temperature of cold streams $tc_{j,k}$ equals to the last stage temperature of cold stream i. Similarly, cold streams exit network at first stage and outlet temperature of cold stream i corresponds to the first stage temperature of cold stream i.

$$tc_{j,NOK+1} = Tcin_j \qquad j \in CP \quad (3)$$

$$tc_{j,1} = Tcout_j \qquad j \in CP \quad (4)$$

Eq.(5) and Eq.(6) indicate that the temperature of hot and cold streams decrease constantly through stages of superstructure.

$$th_{i,k} \geq th_{i,k+1} \qquad i \in HP, k \in \mathrm{ST} \quad (5)$$

$$tc_{j,k} \geq tc_{j,k+1} \qquad j \in CP, k \in \mathrm{ST} \quad (6)$$

In Eq.(7), binary variable $Z_{i,j,k}$ is employed to determine the existence of exchanger between hot stream i and cold stream j in stage k. Eh_i is total heat content of hot stream i, $q_{i,j,k}$ is heat load of the exchanger. The heat load of that exchanger is not higher than total heat content of hot stream i.

$$q_{i,j,k} \leq z_{i,j,k} \cdot Eh_i \qquad i \in HP, j \in CP, k \in \mathrm{ST} \quad (7)$$

Energy balance for each match of the superstructure are as Eq.(8) and Eq.(9). Fh_i is heat capacity flowrate of hot stream i, and fc_j is mass flowrate of cold stream j and cp is heat capacity of water.

$$\sum_{i \in HP} q_{i,j,k} = fh_i \cdot \left(th_{i,k} - th_{i,k+1}\right) \qquad i \in HP, j \in CP, k \in \mathrm{ST} \quad (8)$$

$$\sum_{j \in CP} q_{i,j,k} = fc_j \cdot cp \cdot \left(tc_{j,k} - tc_{j,k+1}\right) \qquad i \in HP, j \in CP, k \in \mathrm{ST} \quad (9)$$

In Eq.(10) and Eq.(11), $dt_{i,j,k}$ represent temperature difference for the match between the hot stream i and cold stream j at stage k. $\Omega_{i,j}$ is upper limit for the temperature difference for hot stream i, the value of $\Omega_{i,j}$ is obtained by Eq.(12).

$$dt_{i,j,k} \leq th_{i,k} - tc_{j,k} + \left(1 - z_{i,j,k}\right) \cdot \Omega_{i,j} \qquad i \in HP, j \in CP, k \in \mathrm{ST} \quad (10)$$

$$dt_{i,j,k+1} \leq th_{i,k+1} - tc_{j,k+1} + \left(1 - z_{i,j,k}\right) \cdot \Omega_{i,j} \qquad i \in HP, j \in CP, k \in \mathrm{ST} \quad (11)$$

$$\Omega_{i,j} = max\left\{0, thin_i - tcin_j, thout_i - tcin_j, thin_i - tcout_{\max}, thout_i - tcout_{\max}\right\} \qquad i \in HP, j \in CP \quad (12)$$

The exchanger area between hot stream i and cold stream j at stage k is :

$$Ar_{i,j,k} = q_{i,j,k} \cdot \left(h_w^{-1} + h_i^{-1}\right) \cdot \left[dt_{i,j,k} \cdot dt_{i,j,k+1} \cdot 0.5 \cdot \left(dt_{i,j,k} + dt_{i,j,k+1}\right)\right]^{-1/3} \quad (13)$$

Energy consumption of fan depends on volume flowrate of air V_{air} and pressure drop through the exchanger inside the tower. In Eq.(14), N is the number of bundle, B represents the amount of spraying water and v_{air} is air velocity. The volume flowrate of air depends on velocity of air as well as exchanger frontal area A_{fa}. And power of fan is obtained through Eq.(16).

$$\Delta P = 2.7 \cdot N \cdot B^{0.12} \cdot (v_{air} \cdot \rho_{air})^{1.54} \quad (14)$$

$$V_{air} = v_{air} \cdot A_{fa} \quad (15)$$

$$P_{fan} = \Delta P_{fan} \cdot V_{air} / \eta_{fan} \quad (16)$$

Eq.(17-20) gives the capital cost of components of cooling tower. (Zalewski et al. 2000)

$$CC_{fan} = (21.56 + 20.15 \cdot P_{fan}^{0.5})^2 / 1.16 \quad (17)$$

$$CC_{bath} = (599.9 + 1101.5 \cdot A_{fa}) / 1.16 \quad (18)$$

$$CC_{exchanger} = 310 + 170 \cdot A_{tower} \quad (19)$$

$$CC_{pump} = 2000 + 5 \cdot (B \cdot A_{fa} \cdot \Delta p / \rho)^{0.68} \quad (20)$$

The cooling tower has to provide cooling water for process hot streams as well as the condenser in refrigeration cycle. The heat load of cooling tower is obtained through Eq.(21).*ttin* denotes the inlet water temperature of cooling tower, and $tcin_1$ represents the outlet temperature of cooling tower, it is also the cooling water temperature inlet of the heat exchanger network. fc_1 and fc_2 are the flowrate of cooling water and chilled water. q_{con} is the heat load on condenser.

$$q_{tower} = (ttin - tcin_1) \cdot cp \cdot (fc_1 + fc_2) + q_{con} \quad (21)$$

Eq.(22) is used to calculate the cooling tower inlet temperature *ttin*. $Tcout_1$ and $Tcout_2$ are the return temperature of cooling water and chilled. f_{con} and $tout_{con}$ are the flowrate and outlet temperature of cooling water provided for condenser in refrigeration cycle.

$$ttin = (fc_1 \cdot tcout_1 + fc_2 \cdot tcout_2 + f_{con} \cdot tout_{con}) / (fc_1 + fc_2 + f_{con}) \quad (22)$$

Heat load of evaporator is obtained through Eq.(23)

$$q_{evap} = fc_2 \cdot cp \cdot (tcin_1 - tcin_2) \quad (23)$$

Energy balance around the evaporator gives flowrate of refrigerant. In Eq.(24), ΔH_{evap} is the difference between inlet and outlet enthalpy of evaporator.

$$fm_{ref} = q_{evap} / \Delta H_{evap} \quad (24)$$

The capital cost and power required of compressor are given by Eq.(25) and Eq.(26). COP is coefficient of performance and η_{isen} is isentropic efficiency of compressor. And the heat load of condenser is given by Eq.(27). (Jain et al. 2016)

$$CC_{compressor} = 573 \cdot fm_{ref} \cdot (0.8996 - \eta_{isen})^{-1} \quad (25)$$

$$W_{compressor} = Q_{evap} \cdot COP_{ref}^{-1} \cdot \eta_{isen}^{-1} \quad (26)$$

$$q_{con} = q_{evap} + w_{compressor} \quad (27)$$

Finally, the objective function is expressed as Eq.(28), which includes capital and operation cost of cooling tower and refrigeration cycle, as well as capital cost of coolers in heat exchanger network.

$$TAC = \begin{array}{l} +Af \cdot \{CC_{exchanger} + CC_{fan} + CC_{bath} + +CC_{pump} + CC_{compressor} + CC_{evaporator} + CC_{condenser}\} \\ +P_{fan} \cdot e \cdot h + P_{pump} \cdot e \cdot h + W_{compressor} \cdot e \cdot h + Cost_{makeup-water} \end{array} \quad (28)$$

3. Case Study

A case study is employed to verify the effectiveness of proposed model. MINLP model is implemented in the software GAMS, solvers DICOPT is used to solve the MINLP problem. Table 1 shows the data of hot streams. F_{cp} is heat capacity flowrate, h is film transfer coefficient.

Table 1. Hot stream data

Stream	Tin(°C)	Tout(°C)	Fcp (kW/h)	h (kW/m^2 °C)
1	55	42	200	0.854
2	58	32	150	1.743
3	85	70	60	0.720
4	105	65	100	1.352
5	102	36	80	0.750
6	85	30	120	0.785

In this study, minimum approach temperature difference of exchanger is 10°C, Maximum allowable outlet temperature of cooler is 55 °C. Wet bulb temperature is 26°C. Cooling water specific heat capacity is 4.18 kJ/(kg °C), cooling water film heat transfer coefficient is 2.5 kw/(m^2 K). Annualized factor is 0.298. The Electricity price *e* is 0.1 $/kWh. Annual operation time is 8600 hr. For closed cooling tower, the inlet and outlet temperature of wet air is 27.0°C and 32.0°C. In the base case study, we first formulated cooling water network. The temperature of tower outlet water is specified as 30°C which is 4°C higher than wet bulb temperature. Since the minimum temperature difference of exchanger is 10°C, cooling water could only cool down hot streams to 40°C. Hot stream 2,5,6 are cooled down by cooling water to 40°C and chilled water is required to cool them down to target temperature. With the fixed heat load, the refrigeration cycle was optimized sequentially. Then, we optimized cooling water system and refrigeration cycle simultaneously. The outlet temperature of cooling tower is an optimized variable. The optimal heat load distribution between two systems was obtained. Figure 2 and Figure 3 show two configurations obtained by different methods. Table 2 is the comparison of two configurations.

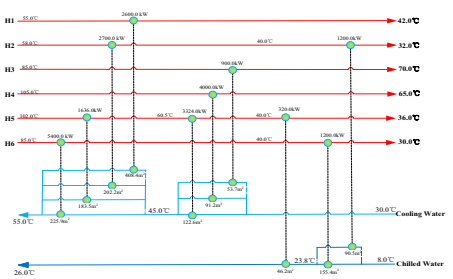

Figure 2. Sequentially optimized.

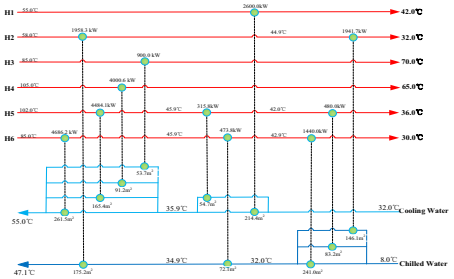

Figure 3. Simultaneously optimized.

Table 2. Comparison of two structures obtained by two different methods

Items	Sequential optimization	Simultaneous optimization
Total flowrate of cooling water	196.1 kg/s	176.1 kg/s
Total flowrate of chilled water	36.0 kg/s	38.3 kg/s
Cooling tower outlet temperature	30.0°C	32.0°C
Refrigeration cycle outlet temperature	8.0°C	8.0°C
Return temperature of cooling water	55.0°C	55.0°C
Return temperature of chilled water	26.0°C	47.1°C
Heat load of cooling tower	(20560+3385)kW	(19419+4805) kW
Heat load of refrigeration cycle (evaporator)	2720 kW	3861 kW
Power required for compressor	665kW	944kW
Heat load of condenser	3385kW	4805kW
Temperature approach of cooling tower	7.3°C	9.7°C
Capital cost of exchangers	$ 332871	$ 328686
Cost of cooling tower	$ 2811618	$ 2122941
Cost of refrigeration cycle	$ 836805	$ 1303482
Total annual cost	$ 3981294	$ 3755109

As shown in table.2, in comparison with sequentially optimized structure, simultaneously optimized structure has lower cooling water flowrate in the system. The minimum temperature difference is 10°C, therefore the return temperature of chilled water in base case cannot be higher than 26°C. However, in the simultaneously optimized structure, the chilled water was integrated with cooling water and return temperature is 47.1°C. This is because the chilled water can be used to cool the hot stream at high temperature. However, in base case, the chilled water can only be used to cool the streams that are under 40°C. In simultaneously optimized structure, the heat load of chilled water is 6295 kW, however, the heat load of evaporator in refrigeration cycle is only 3861kW. This is because in the cascade cooling and refrigeration system, the cooling tower first cools down the chilled water to 32°C, a part of heat load of chilled water is on cooling tower. Different from the structure in base case, the outlet temperature of cooling tower in cascade system is an optimized variable. The temperature increase from 30.0°C to 32.0°C, and the temperature difference inside cooling tower increase from 7.3°C to 9.7°C. Since the heat transfer driving force of cooling tower increase, the corresponding cost of tower reduced. After integrating cooling and refrigeration system into one, the cost of refrigeration system increased. However, the cost of cooling tower reduced significantly owning to the decrease of flowrate of cooling water and increase of heat transfer driving force. Finally, 5.7% reduction on TAC was achieved. This result demonstrated that the proposed method is capable to capture the trade-off between cooling and refrigeration system. The optimal heat load distribution between cooling tower and refrigeration cycle can be obtained by proposed method.

4. Conclusions

This paper presents a model for simultaneously optimizing cooling water and refrigeration system. The optimal distribution of heat load between two systems can be obtained by proposed method. In the simultaneously optimized structure, outlet temperature of cooling water was set as an optimized variable, which gives the cooling tower higher efficiency. In comparison with the method that formulates cooling water and chilled water network separately, simultaneously optimized structure has higher refrigeration cost but much lower cooling tower cost. Since cooling tower cost reduced significantly, the total annual cost of whole system decrease 5.7 %. It identifies that integrating two systems into one is an effective method to save on the cost.

Abstract

In petrochemical and chemical processes, most separations involving mixtures with low relative volatilities as well as CO_2 removal (recovery) are energy intensive. In bio-processes, the downstream separations are difficult because of product recovery from dilute solutions. Ionic liquids (ILs) based separation is emerging as a potentially sustainable and low energy consuming technology because of their non-volatility, good solubility and selectivity properties. That is, the removal of the solute and recovery of the IL-solvent requires very low energy and therefore, has low carbon foot-print. In this work, a method that combines group contribution based property prediction models for computer aided molecular (IL) design (CAMD) with process design is presented. Case studies involving CO_2 capture from natural gas and separation of azeotropic mixtures are highlighted.

Keywords: Ionic liquids, CAMD, Azeotrope separation, CO_2 capture, UNIFAC-IL model.

1. Introduction

The challenges related to energy, water, food and environment is encouraging us develop new sustainable and innovative process designs. Consequently, integration of new technologies into existing process designs, especially those involved within energy intensive processes, is of growing importance to industry. Downstream separations from bioreactors on the other hand, need to operate reliably, efficiently and at low cost due to the relatively small amounts of products in large amounts of reactants and carriers such as water. Separation of close-boiling, azeotropic mixtures, and CO_2 separation are examples of high energy consuming processes. Therefore, it is advantageous to investigate new separation technologies that allow efficient energy intensive operation.

Among many emerging separation technologies, use of ILs as solvents are being considered because of their non-volatility property and therefore low energy consuming solvent recovery operations. Also, unlike organic solvents that may also be classified as volatile organic chemical (VOCs), which would escape into the atmosphere for their high volatilities, ILs pose attractive features such as almost negligible vapor pressure, low-melting point, and high thermal and chemical stability. Moreover, ILs have been found to provide good solubility and selectivity, which are important for separation processes. Therefore, ILs provide promising alternatives for the replacement of VOCs in many separation processes (Roughton et al., 2012).

Works regarding the use of ILs as designer solvents have been in focus, mainly for CO_2 separation and IL-based extraction. Chong et al., (2015) proposed an approach based on

the visualization of high dimensional problems into two or three dimensions for design of ILs for the purpose of CO_2 capture, and then Chong et al., (2016) introduced disjunctive programming to identify optimal operating conditions of the carbon capture process while also solving the IL design problem. For IL-based extraction, Roughton et al., (2012) proposed an UNIFAC based method to simultaneously design IL and the process for separation of azeotropes. Fang et al., (2016) presented a molecular design method using the COSMO-SAC model to select ILs for extractive distillation. A study combing the UNIFAC-IL model and other group contribution (GC) based property models for CAMD and process simulation has been reported by Chao et al., (2017) to identify promising ILs for separation of n-hexane and methylcyclopentane by extractive distillation. An important deficiency with these methods is that the designed ILs have been selected based on their implicit separation task related properties but they are not actually verified through detailed process synthesis-design. Therefore, the actual energy consumption or the equipment design or the capital cost have not been considered.

Also, finding optimal ILs for specific separation tasks by the usual trial-and-error approach can be time consuming and expensive due to numerous ILs that may be considered as potential solvents. On the other hand, techniques such as CAMD is ideally suited as tailor-made ILs can be generated by adjusting the cation, anion, and side chains on the cation (Plechkova and Seddon, 2008). Thus, the "generate and test" approach of generating candidate ILs by tailoring their properties and testing them on the desired separation task is suitable for design of ILs as well as design-verification of their ability to perform specific separation tasks. In this work, such an approach where the CAMD and separation process synthesis design problems are solved simultaneously, is presented. The application of the developed method on two case studies is also highlighted.

2. Methodology

2.1. Framework

The overall framework of the proposed method is illustrated in Figure 1, where two option for problem solution and needed associated tools are shown.

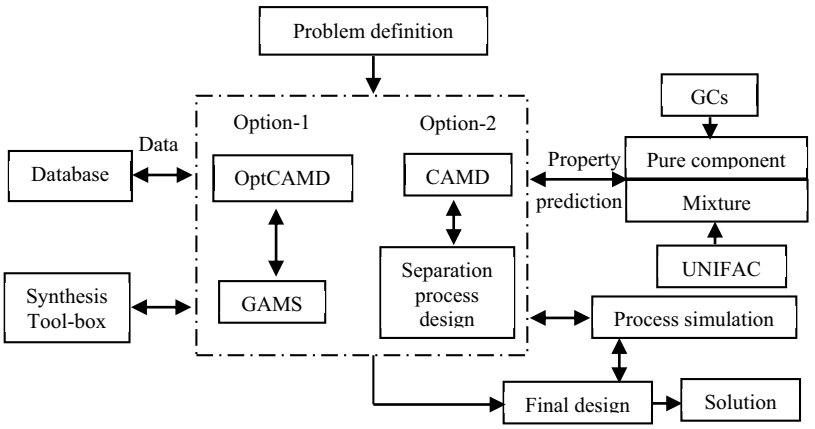

Figure 1: Framework of the integrate IL solvent and process design

2.2. Tools

A comprehensive database has been created by collection of physical properties of ILs from numerous literature sources and also by apriori generation of new ILs. The database has 4960 ILs, out of which around 300 have been reported to exist. There are 7 cations and 16 anions.

In this work, two types of property models: GC-based pure component property (θ_i) models and GC based mixture property (θ_{mix}) models are considered, as given by Eq. (1) and Eq. (2).

$$\theta_i = \sum_{k=1}^{N} n_{k,i}\psi_k \tag{1}$$

$$\theta_{mix} = \sum_{i=1}^{M} x_i\theta_i \tag{2}$$

Where ψ_k is the property contribution of group k for pure component property θ_i. $n_{k,i}$ is the number of group k in component i and N is the total number of groups representing the IL. x_i and M are the mole fraction of component i and the total number of components in mixture, respectively.

The property model library includes IL GC-based models for density, viscosity, melting point, surface tension, heat capacity, heat of vaporization and the Hildebrand solubility. For solubility and phase equilibrium predictions, the UNIFAC-IL model is included due to its high prediction accuracy (Lei et al., 2014). Note that these physical properties of ILs directly or indirectly impact the separation process where the IL is employed as the separation agent.

The integrated IL and process design problem is formulated as a mixed-integer nonlinear programming (MINLP) optimization problem given by Eqs. (3) - (8). In this work, the MINLP problem formulation from Burger et al., (2013) has been adopted.

$$max_{z,y}\, f(z,y) \tag{3}$$

$$s.t. \quad g_p(z,y) = 0 \tag{4}$$

$$g_t(z,y) \leq 0 \tag{5}$$

$$g_m(y) \leq 0 \tag{6}$$

$$z \in R^w \tag{7}$$

$$y \in U^q \tag{8}$$

where the m-dimensional vector z represents continuous variables involving mixture composition, physical properties, operating conditions, equipment sizes and process variables; the q -dimensional vector of integer and binary variables y denoting the molecular (IL) structure; f is the objective function, typically is an economic

performance metric. g_p and g_t are sets of equality constraints and inequality constraints representing the process model and the thermodynamic model, respectively. Molecular (IL) structure feasibility and valency rules are represented by constraints g_m.

3. Case studies

In this work, the four most widely studied cation cores, anions and two organic groups are retrieved from the IL database as the building blocks for IL design (Table 1).

Table 1: Molecular building blocks selected for IL design

Type	k	Groups	Type	k	Groups
Organic groups	1	CH_3	Anions	7	$[BF_4]^-$
	2	CH_2		8	$[Tf_2N]^-$
Cation cores	3	$[Im]^+$		9	$[PF_6]^-$
	4	$[MIm]^+$		10	$[DMP]^-$
	5	$[Py]^+$			
	6	$[MPyr]^+$			

The formulated MINLP problem of both examples are solved using deterministic global optimization solvers (LINDOGLOBAL) in the modeling system GAMS 24.4.6 on an Intel(R) Core(TM) i5-6200U 2.40 GHz PC running Windows 10 system. Information of the formulated MINLP problems is given in Table 2. Detailed results of the case studies can be obtained from the authors.

Table 2: Information of the formulated MINLP problems

	z	y		$g_p(z,y)$	$g_t(z,y)$	$g_m(y)$	Total constraints
		Binary	Integer				
Case 1	270	13	8	154	117	7	277
Case 2	213	12	62	124	71	7	201

3.1. CO_2 capture from natural gas

For this case study, the process flowsheet and cost models used by Pereira et al., (2011) and Burger et al., (2015) are adopted, where the net present value (NPV) of the process in 15 years is the objective function, as given by Eq. (9).

$$NPV = PV_{gas-sales} - TCI - TOC \tag{9}$$

where $PV_{gas-sales}$ is the total revenue from the natural gas sales, TCI and TOC are the total capital investment and the total operating cost of the separation process in 15years, respectively.

The best IL molecular structure and the optimal flowsheet configuration are simultaneously identified by solving the formulated MINLP problem. A selection of the computational results are given in Table 3.

In this case, 1-butyl-2, 3-dimethylimidazolium bis(trifluoromethylsulfonyl)amine ([C_5MIm][Tf_2N]) is found to be the best IL as solvent with an economically attractive NPV of 1764×10^6 US$. Burger et al., (2015) and Pereira et al., (2011) using the same process model reported the use of different organic solvents, including n-alkanes, poly(oxyethylene)dimethylethers and poly(oxymethylene)dimethylethers. For these three organic solvents, optimization yielded NPV values of 871×10^6 US$, 1577×10^6 US$ and 1721×10^6 US$, respectively. Clearly the best IL as solvent for this CO_2 capture process has a higher economic performance than the compared organic solvents.

Table 3: Optimal values of selected variables for CO_2 capture from natural gas

Variable	Optimization value
IL structure	[C_5MIm][Tf_2N]
Solvent flowrate	0.439 kmol/s
Pressure in absorption unit	7.50 Mpa
Temperature in absorption unit	304.9 K
Temperature in flash unit	452.1 K
Volume of the flash unit	82 m^3
Column height	42.6 m
Column cross section	13.0 m^2
NPV	1764×10^6 US$

3.2. Ethanol –water separation

For the case study of ethanol-water separation process, fixed process parameters used in Roughton et al., (2012) and cost models used in Zhou et al., (2015) are adopted, and the minimum of the total annual cost (TAC) of the distillation column is employed as the objective function, as given in Eq. (10).

$$TAC = CI_{column} + CI_{reb} + CI_{cond} + UC_{reb} + UC_{cond} \quad (10)$$

where CI_{column},CI_{reb} and CI_{cond} are the capital investment of the column, the reboiler and the condenser, respectively, while UC_{reb} and UC_{cond} denote the utility cost of the reboiler and the condenser, respectively.

Fixed process parameters (i.e., column operating pressure, composition of distillate, entrainer flow rate….) and the optimization results, including the best IL molecular structure and the optimal distillation column design variables are simultaneously obtained by solving the formulated MINLP problem (given in Table 4).

In this case, 1-methyl-2, 3-bimethylpyridinium hexafluorophosphate ([C_2MPy][PF_6]) is found to be the best IL as solvent with a minimum total annual cost of 423495 US $/year. Two solvents, 1, 3-dimethylimidazolium tetrafluoroborate ([C_1MIm] [BF_4]) and 1, 3-dimethylimidazolium dimethylphosphate ([C_1MIm] [DMP]) investigated by Roughton et al., (2012) are considered for comparison. They gave total costs of 549943 US $/year and 606125 US $/year, respectively. Clearly the optimal IL obtained in this work has a better economic performance than those considered earlier.

Table 4: Parameters and optimization results of the ethanol-water separation process

Fixed parameters	Value		
Column operating pressure	1 atm		
Feed rate and composition	200 kmol/h, (0.7 C_2H_5OH, 0.3 H_2O)		
Distillate flow rate	140 kmol/h		
Composition of distillate	0.998 C_2H_5OH		
Entrainer flow rate	40 kmol/h		
Optimization Variable	This work	Solvent 1	Solvent 2
IL structure	$[C_2MPy][PF_6]$	$[C_1MIm]$ $[BF_4]$	$[C_1MIm]$ [DMP]
Cation	$[Py]^+$	$[Im]^+$	[Im] +
Anion	$[PF_6]^-$	$[BF_4]^-$	$[DMP]^-$
Valence of the cation base	3	2	2
Number of CH_3 in side 1	1	1	1
Number of CH_3 in side 2	1	0	0
Number of CH_3 in side 3	1	1	1
NT (number of trays)	11	16	18
Reflux ratio R	0,307	0,653	0,875
TAC (US $/year)	423495	549943	606125

4. Conclusions

A systematic method combining GC based property models, CAMD and process design-simulation to simultaneously determine the optimal IL as a separating agent and the corresponding optimal flowsheet configuration has been developed. Case studies involving CO_2 capture from natural gas and ethanol-water separation have been presented, highlighting the improvements in the optimization results obtained in this work. Current and future work is extending the model library for IL properties as well as wide range of IL-based separation processes.

Integrated Solvent and Process Optimization Using PC-SAFT for Continuous Crystallization with Energy-intensive Solvent Separation for Recycling

Jiayuan Wang, Richard Lakerveld*

Department of Chemical and Biological Engineering, The Hong Kong University of Science and Technology, Hong Kong, China
kelakerveld@ust.hk

Abstract

Solvents are a major source of waste in the pharmaceutical industry. Anti-solvent crystallization is an important unit operation in many pharmaceutical processes. The trend towards continuous manufacturing in pharmaceutical industry offers better opportunities for anti-solvent recycling. However, the selection of solvents for a continuous process involving crystallization and anti-solvent separation and recycling is nontrivial due to the influence of solvents on the performance of various unit operations and the discrete nature of solvent selection. This work focuses on the simultaneous solvent selection and optimization of a continuous process involving crystallization and an energy-intensive separation for the anti-solvent recycle. A recently developed optimization method for continuous crystallization based on the PC-SAFT equation of state and continuous mapping is extended to include energy balances for the integrated optimization to address processes with energy-intensive separation methods. The extended method is illustrated with a case study that involves continuous crystallization of paracetamol with distillation for anti-solvent recycling.

Keywords: solvent design, crystallization, PC-SAFT

1. Introduction

Crystallization is an important purification and separation technology for pharmaceuticals. The current paradigm shift in pharmaceutical industry towards continuous manufacturing has renewed the interest in continuous crystallization and offers new opportunities to reduce solvent usage via recycling. However, the selection of an optimal solvent system for a continuous anti-solvent crystallization process including anti-solvent separation and recycling is complicated by possible trade-offs between optimal solvent properties for the various unit operations and the discrete nature of solvent selection. Furthermore, optimal process conditions depend on selected solvents. Therefore, there is a need for integrated design approaches that consider solvent selection and process design simultaneously for unit operations in a continuous process.

A systematic approach has recently been developed for the simultaneous optimization of process conditions and solvent selection for continuous crystallization including solvent recycling (Wang and Lakerveld, 2017). A unified PC-SAFT model (Gross and Sadowski, 2001) is used to calculate all thermodynamic properties for mixtures of solvents including solute solubility (Ruether and Sadowski, 2009) for crystallization. The integrated solvent and process optimization inherently leads to a mixed integer nonlinear programming (MINLP) problem due to the discrete nature of solvent selection, which is difficult to

solve. Therefore, the continuous mapping procedure (Stavrou et al., 2014) is applied as the basic solution strategy, which converts the MINLP problem into a NLP problem and provides an approximate solution for the original MINLP problem. The great promise of this approach has recently been demonstrated for cases involving process models based on material balances only (Wang and Lakerveld, 2017). However, the possible recycling of an anti-solvent may rely on an energy-intensive separation method such as distillation. Therefore, to account for realistic operational costs, energy balances should be included in the integrated solvent and process optimization of continuous crystallization involving anti-solvent separation and recycling.

The objective of this work is to develop a simultaneous solvent selection and process optimization approach for continuous anti-solvent crystallization using an energy-intensive separation method for anti-solvent separation and recycling, which considers variables from both the energy and material balances in the objective function. The unified PC-SAFT framework will be used to predict all relevant thermodynamic properties, which will be combined with a process model. The continuous mapping procedure will be used to convert the MINLP problem into an NLP problem. The approach enables the identification of promising solvent candidates for an economically optimized process with minimal experimental efforts, which ultimately can lead to faster process development and reduced solvent waste in the pharmaceutical industry.

2. Approach

2.1. Process model

The studied process configuration is illustrated in Figure 1. A solution that is saturated with an active pharmaceutical ingredient (API) is fed into a continuous crystallizer. Supersaturation is generated by the addition of recycled and fresh antisolvent. After filtration, the antisolvent is partially recovered from the mother liquor by distillation and recycled back to the crystallizer. A distillation column with a single tray, total condenser and partial reboiler is used to demonstrate the approach for a simple yet sufficiently rich case that includes key features of a rigorous distillation. Therefore, the method can be extended in a straightforward manner to, for example, include more trays.

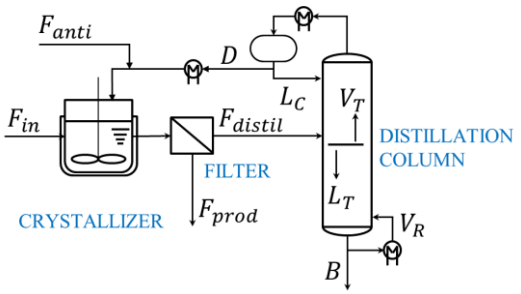

Figure1. Schematic illustration of continuous anti-solvent crystallization process with antisolvent separation and recycling.

The process is described by material balances, equilibrium conditions, summation equations and heat (enthalpy) balances (i.e., MESH equations).

The material balances over the crystallizer and the filter as a single system are given by:

$$F_{in} \cdot x_{i,in} + D \cdot x_{i,C} + F_{anti} \cdot x_{i,anti} = F_{distil} \cdot x_{i,distil} + F_{prod} \cdot x_{i,prod}, \quad (1)$$

and over the condenser, tray and reboiler of the distillation column, respectively by:

$$\left(D + L_C\right) \cdot x_{i,C} = V_T \cdot x_{i,V_T}, \quad (2)$$

$$F_{distil} \cdot x_{i,distil} + V_R \cdot x_{i,R} + L_C \cdot x_{i,C} = L_T \cdot x_{i,L_T} + V_T \cdot x_{i,V_T}, \quad (3)$$

$$L_T \cdot x_{i,L_T} = B \cdot x_{i,B} + V_R \cdot x_{i,R}. \quad (4)$$

F_{in}, F_{anti}, F_{prod}, F_{distil}, V_T, V_R, L_T, L_C, D and B denote the molar flowrate of each stream (see Figure 1). x_i denotes the molar fraction of compound i (i =solvent, antisolvent, API). The following assumptions are made: a) make-up antisolvent is pure; b) the solid product consists of pure API; c) no liquid is entrained with the product d) the API is neglected in the distillation column due to the low concentration and negligible vapor pressure.

Both the API feed and outlet of the crystallizer are assumed to be saturated at different temperatures. The solid-liquid-equilibrium (SLE) is described as follows:

$$x_{API}\gamma_{API} = \exp\left[\frac{\Delta H_m^f}{R}\left(\frac{1}{T_m} - \frac{1}{T}\right) - \frac{\Delta C_p}{R}\left(\ln\frac{T_m}{T} - \frac{T_m}{T} + 1\right)\right], \quad (5)$$

where, γ is the activity coefficient of the API in solution. ΔH_m^f, T_m, ΔC_p are the characteristics of the API, which denote the enthalpy of fusion, melting point and heat capacity difference between the hypothetical super-cooled liquid form and the crystalline form, respectively. Vapor-liquid equilibrium (VLE) is assumed to be present at the feed tray and in the partial reboiler. The VLE criterion is derived from the fugacity of a compound in the vapor and liquid phase:

$$\varphi_{i,V} \cdot x_{i,V} = \varphi_{i,L} \cdot x_{i,L}, \quad (6)$$

where, φ is the fugacity coefficient.

Summation equations (not explicitly listed here) close the material balances. The temperature in the crystallizer is constant, therefore, an energy balances is considered for distillation only:

$$F_{distil} \cdot H_{distil} + V_R \cdot H_R + L_C \cdot H_C = L_T \cdot H_{L_T} + V_T \cdot H_{V_T}, \quad (7)$$

$$V_T \cdot H_{V_T} + Q_C = \left(D + L_C\right) \cdot H_C, \quad (8)$$

$$L_T \cdot H_{L_T} + Q_R = B \cdot H_B + V_R \cdot H_{V_R}, \tag{9}$$

$$D \cdot H_C + Q_D = D \cdot H_{recyc}, \tag{10}$$

where, H denotes the molar enthalpy of each stream; Q_C, Q_R, Q_D denote the heat duty for condenser, reboiler and heat exchanger in the recycle, respectively.

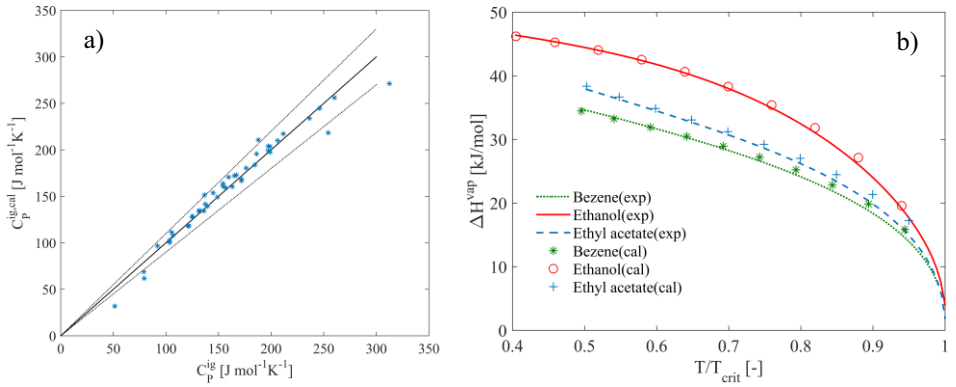

Figure2. a) Parity plot for ideal gas heat capacity at 400 K (dashed lines indicate ±10 % relative error); b) Predicted and experimental values of heat of vaporization for three presentative solvents: benzene representing a non-polar non-associating solvent, ethanol representing an associating solvent and ethyl acetate representing a non-associating polar solvent. All the reference values are taken from the NIST database.

2.2. Thermodynamic model

The PC-SAFT model (Gross and Sadowski, 2001) is used to calculate the reduced Helmholtz free energy $\tilde{a}^{res}$. The PC-SAFT parameterization schemes for APIs and different types of solvents and the solvent database with 48 candidate solvents are adopted from earlier work (Wang and Lakerveld, 2017). The molar enthalpy H consists of an ideal contribution H^{ig} and a residual contribution H^{res}, which can be derived from $\tilde{a}^{res}$ as follows:

$$H = H^{ig} + H^{res} = \left[T \sum_i x_i C_{p,i}^{ig} \right] + \left[(Z-1) - T \left(\frac{\partial \tilde{a}^{res}}{\partial T} \right)_{\rho, x_i} \right]. \tag{11}$$

The required ideal gas heat capacity can be derived from PC-SAFT pure component parameters as follows:

$$C_p^{ig} = -44.66 + 17.29 \left(m \frac{\varepsilon}{kT} \right) + 1.52 \left(m\sigma^3 \right) - 0.57 \left(m\sigma^3 \frac{\varepsilon}{kT} \right). \tag{12}$$

A comparison between predicted and experimentally measured ideal gas heat capacities and a comparison between reference values from the NIST database and calculated values for the heat of vaporization for three different types of solvents show that a satisfied prediction on solvent caloric properties can be obtained for relevant compounds for the considered process using the PC-SAFT model (Figure 2).

2.3. Case study and optimization problem formulation

Paracetamol is selected as the model compound in the case study and the experimental values for calculating the SLE from Eq. (5) are as follows: $\Delta H_m^f = 27.1\ kJ \cdot mol^{-1}$, $\Delta C_p = 99.8\ J \cdot mol^{-1} \cdot K^{-1}$, $\mathrm{T_m} = 443.6\ K$ (Granberg and Rasmuson, 1999). The optimization problem is formulated as:

$$\max_{\bar{p}_i, x_{i,distil}, B, D} \quad \frac{\varphi_1 \cdot F_{prod} - \varphi_2 \cdot F_{anti} - \varphi_3 \cdot B - \varphi_4 \cdot (Q_C + Q_D) - \varphi_5 \cdot Q_R}{F_{in}} \qquad (P1)$$

$$\text{s.t.} \qquad Eq.(1)-(10) \qquad (P1.1)$$

$$P_{process} = 1\,\text{bar} \qquad (P1.2)$$

$$T_{cry} = 298\,\text{K} \qquad (P1.3)$$

$$\frac{1}{x_{sol,distil}} + \frac{\partial \ln \gamma_{sol,distil}}{\partial x_{sol,distil}} \geq 0 \qquad (P1.4)$$

$$A \cdot \bar{p} \leq b \qquad (P1.5)$$

Table 1. Values for cost parameters in the objective function

	Symbol	Price	Source
Paracetamol	φ_1	0.9 US $ / mol	lepro pharma compass opc private limited (www.pharmacompass.com)
Solvent	φ_2	0.4 US $ / mol	icis company (www.icis.com)
Incineration	φ_3	0.2 US $ / mol	-
Cooling water	φ_4	6.5E-7 US $ / kJ	Biegler et al. (1997)
Hot steam	φ_5	3.2E-6 US $ / kJ	Biegler et al. (1997)

The economic objective function is a linear combination of the product revenue ($\varphi_1 \mathrm{F_{prod}}$) with penalties on the use of make-up antisolvent ($\varphi_2 \mathrm{F_{anti}}$), waste solvent incineration ($\varphi_3 \mathrm{B}$), and cooling and heating utilities ($\varphi_4(\mathrm{Q_C} + \mathrm{Q_D})$, $\varphi_5 \mathrm{Q_R}$) normalized by the inlet flowrate ($\mathrm{F_{in}}$). The used values for cost parameters are provided in Table 1. The free variables for the optimization are the solvent and antisolvent PC-SAFT parameters ($\bar{p}_i$), crystallizer outlet solvent composition ($\mathrm{x}_{i,disitl}$), distillate flowrate (D), and distillation bottom flowrate (B). The operating pressure for the integrated system is fixed as 1 bar (P1.2). The crystallizer inlets temperature is fixed as 298 K (P1.3). The solvent and antisolvent should be a miscible pair, which is enforced by constraint P1.4. Finally, the solvent parameter search space is restricted by a convex hull (P1.5). P1 is an NLP problem, which is derived from the original MINLP problem by treating the solvent parameters as continuous. Therefore, the solution provides an upper bound for the objective function value of the original MINLP. After optimization of P1, a Taylor

expansion is used to map the hypothetical PC-SAFT parameters to real solvent parameters from a database and generate a list of optimal solvent pairs. Finally, a process optimization is conducted for the fixed optimal solvent pair to further improve the objective function. The optimization problem is solved using the GAMS/CONOPT solver with multiple initial guesses.

3. Results

The optimal objective function value is 0.015 US $ / mol with the corresponding optimal solvents and process operating conditions as listed in Table 2. The optimal solvent/antisolvent pair enables a drastic reduction in paracetamol solubility from 0.228 to 0.002, which favors a high production rate. Due to the penalty on make-up antisolvent, the optimal F_{anti}/F_{in} remains small and most of the antisolvent is recycled. The antisolvent and solvent can be separated sharply by distillation due to the high relative volatility.

Table 2. Optimization results for the paracetamol case study.

Solvent	Dimethyl sulfoxide	B/F_{in} [-]	0.801
Antisolvent	Isopropyl acetate	D/F_{in} [-]	7.720
F_{prod}/F_{in} [-]	0.210	$(Q_C+Q_D)/F_{in}$ [kJ/mol]	130.74
F_{anti}/F_{in} [-]	0.030	Q_R/F_{in} [kJ/mol]	378.54
$x_{API,in}$ [-]	0.228	$x_{API,distil}$ [-]	0.002
$x_{anti,C}$ [-]	0.984	$x_{anti,B}$ [-]	0.037

4. Conclusions

An approach for the simultaneous optimization of process conditions and solvent selection using continuous mapping and the PC-SAFT model to calculate SLE, VLE, and caloric properties for energy balances is developed for continuous anti-solvent crystallization including recycling. The method allows for process performance criteria related to material balances and energy balances to be combined in a single objective function to minimize waste and energy consumption. A case study based on continuous anti-solvent crystallization of paracetamol demonstrates the effectiveness of the approach.

Optimal Matches with Load Shifting Strategy in Hybrid Power System Considering Varied Price of Outsourced Electricity

Yinghua Jiang, Lixia Kang, Yongzhong Liu*

Department of Chemical Engineering, Xi'an Jiaotong University, Xi'an, Shaanxi, 710049, P.R. China
yzliu@mail.xjtu.edu.cn

Abstract

For hybrid power systems (HPS), an energy management method with load shifting strategy under the varied price of outsourced electricity is presented, where both electricity dispatching and appliance scheduling are involved. In order to minimize the total outsourced electricity (TOE) and total cost of outsourced electricity (TCOE) of HPS, a mixed integer linear programming (MILP) formulation is developed. It features that the optimal load shifting strategy and exact matches between power demands and supplies are determined simultaneously. The application and effectiveness of the proposed model are verified and illustrated through a case study of a photovoltaic-wind-biomass-battery HPS. Results show that the TOE and TCOE of the HPS with load shifting strategies are lower than those without load shifting strategies. The effects of the load shifting strategies on the optimal matches of HPS are further analysed and discussed.

Keywords: hybrid power system; load shifting; varied price of outsourced electricity

1. Introduction

Due to increasing electricity demand, hybrid power systems (HPS) are confronted with high pressure of power supply (Rozali et al., 2016). Load shifting strategy that relocates power demands from peak to off-peak hours in terms of expectations determined by energy utilization and economic judgements is effective to maximize the potential benefits of HPS (Wimmler et al., 2017).

Recently, graphical analysis and mathematical programming methods have been applied to obtain the load shifting strategy for HPS (Theo et al., 2017). For graphical analysis methods, Alwi et al. (2013) presented a graphical tool to visualize and assess the effect of load shifting on the HPS. Mohammad Rozali et al. (2015) formulated a set of strategies to guide load shifting and optimized the electricity cost. For mathematical programming methods, Lujano-Rojas et al. (2012) proposed a load management strategy with load shifting to minimize the electricity supplied by diesel and battery in a wind-battery-diesel HPS. Yang and Xia (2017) developed a power control model of a household photovoltaic-battery HPS with load shifting under the time of use electricity tariff, aiming to minimize the energy cost and consumption. However, these methods cannot simultaneously obtain the optimal load shifting strategy and exact matches between power demands and supplies. In addition, the mutual interactions between the load shifting strategies and the operations of HPS are usually ignored.

To this end, a mixed integer linear programming (MILP) model of HPS with load shifting strategy considering the varied price of outsourced electricity is presented in this work to address these problems.

2. Problem description

Figure 1 shows a schematic diagram of an HPS, where the power demands, including non-flexible and flexible ones, and power supplies are connected to AC and DC buses. The electricity generated by power supplies are used to meet the power demands and/or will be stored in a battery energy storage system (BESS) for later use. The deficit of electricity will be supplied by the grid. The aim of this work is to propose a method so that the optimal matches and load shifting strategy can be determined at the same time.

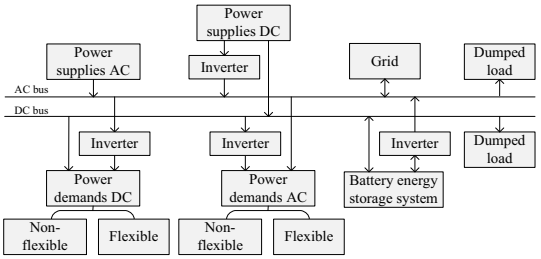

Figure 1 A schematic diagram of an HPS

3. Mathematical programming model of the HPS

3.1. Objective Function

(1) Energy objective. The TOE of the HPS is the electricity consumed by power demands and the BESS from the grid. It can be written as

$$\min \mathrm{TOE} = \sum_{k\in\mathbf{K}}\sum_{j\in\mathbf{J}} E^{\mathrm{D}}_{j,k} + \sum_{k\in\mathbf{K}} E^{\mathrm{B}}_{k} \tag{1}$$

where E^{D} and E^{B} denote the electricity transmitted from the grid to the power demands and BESS, respectively. **K** and **J** are the sets of the time intervals and power demands. The subscripts, k and j denote the time interval k and the power demand j.

(2) Cost objective. The TCOE of the HPS depends on the TOE and electricity price, ρ, which can be expressed as

$$\min \mathrm{TCOE} = \sum_{k\in\mathbf{K}}\sum_{j\in\mathbf{J}} \rho_k E^{\mathrm{D}}_{j,k} + \sum_{k\in\mathbf{K}} \rho_k E^{\mathrm{B}}_{k} \tag{2}$$

3.2. Constraints

(1) Power supply. Electricity generated by each power supply is consumed by the power demands and the BESS. If surplus electricity remains, it will be dumped. The electricity balance of each power supply at the time interval k can be expressed as

$$P_{i,k}\Delta t = \sum_{j\in\mathbf{J}} E_{i,j,k} + E^{\mathrm{SB}}_{i,k} + E^{exp}_{i,k}, i\in\mathbf{I}, k\in\mathbf{K} \tag{3}$$

where P is the power, and Δt denotes the duration of each time interval. E^{SB} and E^{exp} represent the electricity from power supplies to BESS and the electricity being dumped. **I** is the set of the power demands and subscript i denotes the i-th power supply.

(2) Power demand. The electricity required by each power demand can be satisfied by power supplies, the BESS and the grid, which can be written as

$$\begin{cases} P_{j,k}\Delta t = \sum_{i\in\mathbf{I}_\mathrm{A}} E_{i,j,k} + \sum_{i\in\mathbf{I}_\mathrm{D}} \eta^{\mathrm{DC/AC}} E_{i,j,k} + \eta^{\mathrm{DC/AC}} E_{j,k}^{\mathrm{BD}} + E_{j,k}^{\mathrm{D}}, j\in\mathbf{J}_\mathrm{A}, k\in\mathbf{K}\ (\mathrm{AC}) \\ P_{j,k}\Delta t = \sum_{i\in\mathbf{I}_\mathrm{A}} \eta^{\mathrm{AC/DC}} E_{i,j,k} + \sum_{i\in\mathbf{I}_\mathrm{D}} E_{i,j,k} + E_{j,k}^{\mathrm{BD}} + \eta^{\mathrm{AC/DC}} E_{j,k}^{\mathrm{D}}, j\in\mathbf{J}_\mathrm{D}, k\in\mathbf{K}\ (\mathrm{DC}) \end{cases} \tag{4}$$

where E^{BD} is the electricity from BESS to power demands. $\eta^{\mathrm{AC/DC}}$ and $\eta^{\mathrm{DC/AC}}$ denote the conversion efficiencies of AC/DC and DC/AC units. The subscripts A and D denote AC and DC.

Flexible power demands include interrupted and non-interrupted ones. To facilitate the explanation, we define the set of operating time intervals, $\mathbf{K}_j^{oper}$, and that of start time intervals, $\mathbf{K}_j^{star}$, as follows.

$$\begin{cases} \mathbf{K}_j^{oper} = \left\{k \mid k_j^{earl}, ..., k_j^{last}\right\}, j\in\mathbf{J} \\ \mathbf{K}_j^{star} = \left\{k \mid k_j^{earl}, ..., k_j^{last} - d_j\right\}, j\in\mathbf{J}_2 \end{cases} \tag{5}$$

where d_j denotes the elapsed time intervals of the power demand j. k^{oper}, k^{earl} and k^{last} are the operating time interval, the earliest time interval to start the operation and latest time interval to end operation. $\mathbf{J}_2$ is the set of non-interrupted power demands.

The total operating time intervals of each flexible power demand can be expressed as

$$\begin{cases} P_{j,k} = P_j Dz_{j,k}, \sum_{k\in\mathbf{K}_j^{oper}} Dz_{j,k}\Delta t = d_j, j\in\mathbf{J}_1\ (\text{interrupted}) \\ \sum_{k=k_j^{star}}^{k_j^{star}+d_j/\Delta t} P_{j,k} = z_{k_j^{star}} d_j P_j, \sum_{k_j^{star}\in\mathbf{K}_j^{start}} z_{k_j^{star}} = 1, j\in\mathbf{J}_2, k_j^{star}\in\mathbf{K}_j^{start}\ (\text{non-interrupted}) \end{cases} \tag{6}$$

where Dz is binary variable to indicate the states of flexible demand. $Dz_{j,k}$=1 when the flexible demand j operates at the time interval k. $z_{j,k}$ is binary variable to denote whether the non-interrupted demand j starts to operate at the time interval k. $\mathbf{J}_1$ is the set of the interrupted power demands.

(3) BESS. The electricity of the BESS, B, is determined by the remaining electricity of the last time interval, charged electricity, B^c , and discharged electricity, B^d of the current time interval, where B^c is the sum of the electricity supplied by power supplies and grid, and B^d equals to the sum of the electricity consumed by power demands.

$$B_k = (1-\delta)B_{k-1} + \eta^c B_k^c - B_k^d / \eta^d, k\in\mathbf{K} \tag{7}$$

$$\begin{cases} B_k^c = \sum_{i\in\mathbf{I}_\mathrm{A}} \eta^{\mathrm{AC/DC}} E_{i,k}^{\mathrm{SB}} + \sum_{i\in\mathbf{I}_\mathrm{D}} E_{i,k}^{\mathrm{SB}} + \eta^{\mathrm{AC/DC}} E_k^{\mathrm{B}}, k\in\mathbf{K} \\ B_k^d = \sum_{j\in\mathbf{J}} E_{j,k}^{\mathrm{BD}}, k\in\mathbf{K} \end{cases} \tag{8}$$

where δ is the self-discharge rate. η^c and η^d are the efficiencies of charging and discharging of BESS.

The other constraints for BESS are given as follows.

$$\begin{cases} B_k^c \le \Gamma \cdot zc_k, B_k^d \le \Gamma \cdot zd_k, zc_k + zd_k \le 1, k \in \mathbf{K} \text{ (charge and discharge contraints)} \\ C(1-DOD) \le B_k \le C, k \in \mathbf{K} \text{ (electricity contraints)} ; \\ B_0 = B_{NOK} \text{ (periodicity)} \end{cases} \tag{9}$$

where Γ is the maximum charge/discharge power. *C* and *DOD* are capacity and depth of discharge of the BESS. *NOK* is the number of time intervals. *zc* and *zd* are binary variables to indicate the charging and discharging states of the BESS.

4. Case study

4.1. Fundamental data

The fundamental data, taken from the reference (Rozali et al., 2013), is listed in Table 1.

Table 1 Fundamental data of power supplies and demands in HPS

Power supply/demand	Type	Operating time interval			Power (kW)
		From	To	Interval	
P1 (wind)	AC	3	10	8	50
P2 (biomass)	AC	1	24	24	70
P3 (solar)	DC	9	18	10	60
D1 (appliance 1)	DC	1	24	24	30
D2 (appliance 2)	AC	9	18	10	50
D3 (appliance 3)	DC	1	24	24	20
D4 (appliance 4)	AC (flexible)	9	18	10	50
D5 (appliance 5)	DC (flexible)	9	20	12	40

In this case, one day is equally divided into 24 time intervals. The capacity of BESS is assumed to be 500 kWh, and its maximum charge/discharge power takes 20 % of its capacity. The transfer efficiencies between AC and DC are 95 %, and the efficiencies of charge and discharge are 90 %. The self-discharge rate is 0.004 %·h^{-1}, and the DOD is 80 %. The electricity price in the peak hour (at the time intervals 9-11 and 20-21) is 0.16 \$·kWh^{-1}. The flat price is 0.05 \$·kWh^{-1} at time intervals 8, 12-19 and 22-23, and the off-peak price is 0.03 \$·kWh^{-1} at the time intervals 1-7 and 24.

To facilitate the description, three scenarios are assumed. (1) S1: the demands, D4 and D5 are non-flexible. (2) S2: the demands, D4 and D5 are interrupted. (3) S3: the demands, D4 and D5 are non-interrupted. The possible operating time intervals of D4 and D5 are assumed to be 6-18 and 1-24, respectively. Note that the initial electricity of BESS is provided by the grid at the off-peak price, and one day is taken as the time horizon. All calculations are implemented on the GAMS platform, with the CPU of Intel(R) Pentium(R) G630@2.70 GHz. CPLEX is selected to solve the MILP problem.

4.2. Optimal matches and load shifting strategies for TOE and TCOE reduction

The operating parameters of HPS with load shifting strategies are listed in Table 2, when the minimum TOE and TCOE are taken as the optimization objectives, respectively.

In Table 2, the values of the optimization objectives in S2 and S3 are lower than those in S1. For example, the minimum TOE in S2 and S3 are 205 kWh·day^{-1} and 231 kWh·day^{-1}, while that in S1 is 318 kWh·day^{-1}. It indicates that load shifting strategies can effectively reduce the TOE and TCOE of HPS. Taking the results in S2 as an example, the TOE and TCOE are 205 kWh·day^{-1} and 8.2 \$·day^{-1} for the minimum TOE, while 223 kWh·day^{-1} and 6.7 \$·day^{-1} for the minimum TCOE. These differences mainly result from the trade-off between the electricity price and outsourced electricity. In addition, the

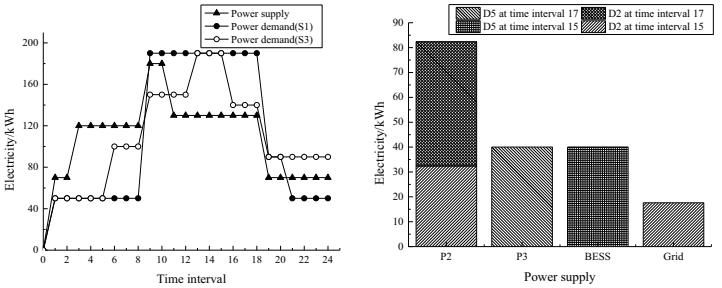
effects of the load shifting strategies on energy and economic efficiencies in S2 are much more remarkable than those in S3. This is because the interrupted power demands (in the scenario S2) are more flexible than the non-interrupted ones (in the scenario S3).

The results in Table 2 also show that the time intervals using outsourced electricity vary with the scenarios and optimization objectives. The outsourced electricity time intervals corresponding to the minimum TOE are at peak and flat hours, while those corresponding to the minimum TCOE are at off-peak and flat hours. It can be inferred that the outsourced electricity time intervals prefer a lower electricity price to a higher one when the electricity prices are considered.

Table 2 The operating parameters of three scenarios with the minimum TOE and TCOE

Operating parameters		Values		
		S1	S2	S3
Minimum TOE	TOE (kWh·day^{-1})	318	205	231
	TCOE ($·day^{-1})	14.1	8.2	11.2
	Outsourced electricity time intervals	11-18	14-18	11-15
	Operating time intervals of D4	9-18	6-10;14-18	6-15
	Operating time intervals of D5	9-20	3-6;9-13;19;22;24	13-24
Minimum TCOE	TOE (kWh·day^{-1})	323	223	260
	TCOE ($·day^{-1})	13.5	6.7	8.1
	Outsourced electricity time intervals	12-18	1-2; 6-7; 24	6-7;15;24
	Operating time intervals of D4	9-18	6-12;14;16;18	6-15
	Operating time intervals of D5	9-20	1-7;9-10;21;23-24	13-24

The optimal load shifting strategies of the HPS corresponding to the minimum TOE and TCOE are listed in Table 2. Taking the results in S3 as an example, the effect of load shifting strategy on the results of HPS is illustrated in Figure 2 (a).



(a) Comparison of electricity curves (b) Matches between supplies and demands

Figure 2 The results of HPS with load shifting corresponding to the minimum TCOE (S3)

Figure 2 (a) is the electricity curves of the supplies and demands. It shows that the differences between the electricity curves of supplies and demands in S3 are smaller than those in S1 when taking TCOE as the optimization objective. This mainly attributes to the utilization of load shifting strategy.

The optimal matches between supplies and demands of the HPS can be determined when the minimum TOE and TOCE are respectively taken as the optimization objectives. In this work, the optimal matches between supplies, and D2 and D5 at the time intervals 15 and 17 in S3 corresponding to the minimum TCOE are used as an example to give the matches in detail, as shown in Figure 2 (b).

It can be seen from Figure 2 (b) that, the required electricity of D2 at time interval 15 is taken from P2 and the grid, while that at time interval 17 is totally taken from P2. The electricity consumed by D5 at time interval 15 is supplied by BESS, while that at time interval 17 is supplied by P3. It implies that, for a given power demand, the electricity providers alter with the time intervals. Likewise, for the same time interval, the matches between the electricity providers and demands are distinct. In addition, the AC power demands prefer the AC power supplies, and the DC power demands prefer the DC power supplies so that the power losses of the electricity transfer between AC and DC are avoided to its minimum.

5. Conclusions

A MILP model is developed to determine the optimal matches between power demands and supplies, aiming to minimize the TOE and TCOE of the HPS. In the proposed method, the load shifting strategies under the varied price of outsourced electricity are considered and the effects of the load shifting strategies on energy and economic efficiencies of HPS are investigated. The application and effectiveness of the proposed model are illustrated through a case study of a photovoltaic-wind-biomass-battery HPS. The results show that the load shifting strategies under varied electricity price can effectively reduce the TOE and TCOE of HPS. The optimal load shifting strategy and exact matches between power demands and supplies can be obtained simultaneously by solving the proposed model. Based on the proposed model, the components capacities of the HPS and environmental impacts can also be evaluated. Of course, it deserves further effort in the future.

Abstract

At present, the shortage of hydrogen resources in refineries is severe and part of the refinery off-gas is used as fuel gas, in which hydrogen and other high value-added components are not fully utilized, resulting in a serious waste of resources. In order to improve the utilization efficiency of resources and minimize the flowrate of hydrogen discharged to the fuel system, we firstly proposed a conceptual approach to design a hydrogen network with near - zero hydrogen emission with the introduction of hybrid separation processes to recover hydrogen and other high value-added components in refinery off-gas streams. The hydrogen emission rate is defined to measure the degree of waste hydrogen discharged to fuel system. The hydrogen emission rate of optimized hydrogen network is only 2.5 % and the near - zero hydrogen emission is achieved conceptually.

Keywords: hydrogen network; multi-contaminant; refinery off-gas; gas separation.

1. Introduction

The quality of crude oil is getting inferior and environmental regulations on clean oil are becoming more stringent. In order to fulfil the environmental regulations on sulphur content (i.e. 10 ppm) for clean fuels, more hydrotreating and hydrocracking processes are needed in refineries. Those processes increase the consumption of hydrogen which is used for desulphurization, aromatics and olefin saturation, as well as the improvement of product quality. At present, most part of the hydrogen - rich refinery off-gas is used as fuel gas. Since the heat value of hydrogen is lower than that of other light hydrocarbon components, excessive hydrogen discharged to the fuel system may cause combustion instability in the furnace. On the other hand, high-valued light hydrocarbons (ethylene, propylene, and LPG) contained in refinery gas can be reused as feedstocks for chemical and plastic products and their demand has been increasing.

The methodologies for the synthesis of hydrogen network include pinch analysis and mathematical programming approaches. Its state-of-the-art can be found in the recent literature review (Marques et al., 2017). Most research on the synthesis of hydrogen network only consider reuse and recycling of hydrogen stream, and few work has been conducted on the recovery of components in the hydrogen stream. Liu et al. (2011)

proposed an evolutionary method for the design of hydrogen networks with multi-impurity which refers to H_2S and other components. Zhou et al. (2012) proposed a mathematical optimization model embedded light hydrocarbon removal module. Jia and Zhang (2011) pointed out the necessity for recovery of other high value-added components of refinery gas. The light hydrocarbon production and integrated flash calculation are incorporated into the hydrogen consumer model. Wu et al. (2014) proposed a model with hydrogen purification units in which C3+ hydrocarbons was regarded as an impurity required to remove.

Hydrogen-rich tail gases are typical by-products of refinery plant, and hydrogen recovery is the key to efficient use of refinery gases. Liu and Zhang (2004) proposed a methodology to select appropriate purifiers for recovering hydrogen from refinery off-gases between the three most common purification, namely, pressure swing adsorption unit (PSA), membrane processes and cryogenic processes. Liu et al. (2014) adopted absorption–hydration hybrid method to separate and recover H_2 from CH_4/H_2 gas mixtures under hydrate formation conditions. In addition, several techniques, such as absorption of intermediate oil, rectification (desulfurization, decarbonization and deoxygenation etc.), can be used to remove and recover other components in the refinery gas and it leads to more efficient utilization of hydrogen.

With the introduction of hybrid separation processes, this paper aims to design the refinery hydrogen network with near - zero hydrogen discharged to the fuel system. Along with gas streams from hydrogenation units, off-gas streams from crude oil distillation unit (CDU), fluidized catalyst cracking unit (FCC), delayed coking (DCU), are taken into consideration. The conceptual design is illustrated via one industrial case.

2. Conventional refinery hydrogen network

A conventional refinery hydrogen network design is shown in Figure 1. High-pressure separator gas (HP gas) from the hydrogenation units can be recycled back into the hydrogenation reactors. Refinery off-gas from CDU, FCC and DCU, low-pressure separator gas (LP gas) and dry gas from hydrocracking diesel and naphtha hydrotreating, as well as the desorption gas from PSAI and PSAII, are purged to the fuel system in conventional design.

Tables 1 and 2 show the extracted data that gas streams are discharged to the fuel system from a conventional industrial refinery plant as shown in Figure 1.

Table 1: Data for dry gas and LP gas streams from hydrogenation units

Purge	Variable and units	Hydrocracking	Diesel hydrotreating	Naphtha hydrotreating
LP Gas	Flowrate (Nm^3/h)	900	900	530
	H_2 Purity (vol %)	80	69	79
	C3+ (vol %)	7	16	5
Dry gas	Flowrate (Nm^3/h)	300	1,700	230
	H_2 Purity (vol %)	45	7	16
	C3+ (vol %)	35	80	72

Table 2: Data for refinery off-gas and desorption gas streams from non-hydrogenation units

	Dry gas from FCC	Dry gas from DCU	Dry gas from CDU	Desorption gas from PSAI	Desorption gas from PSAII
Flowrate (Nm^3/h)	8,000	8,900	690	1,240	6,870
Component (vol %)					
H_2	27	26	49	48	23
C1	26	45	26	18	16
C2	31	26	24	14	0
C3+	0	2	1	20	0
CO_2	4	1	0	0	50

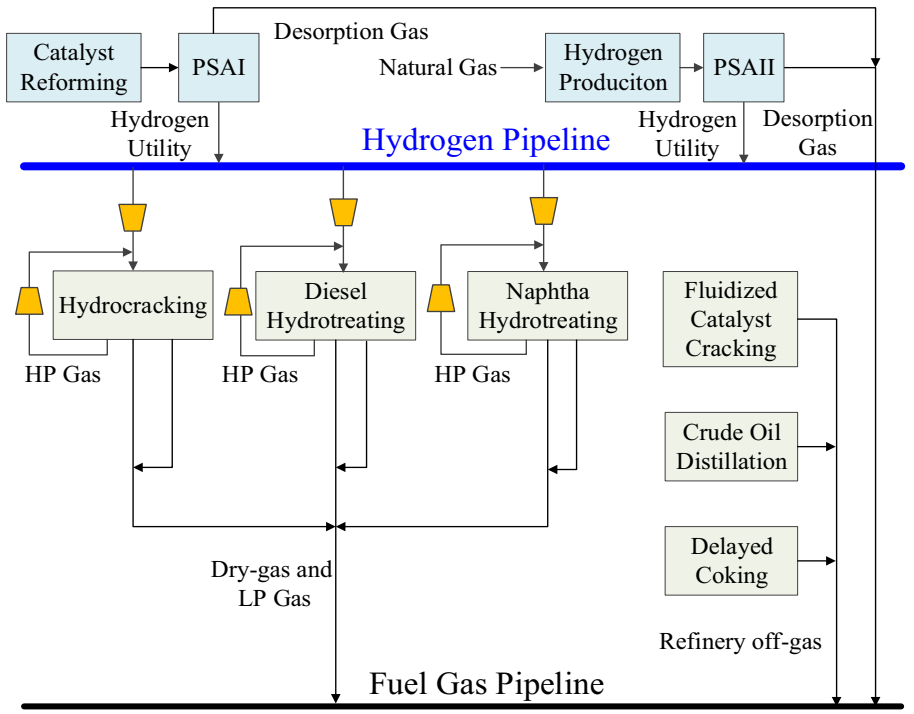

Figure 1: Conventional refinery hydrogen network

In order to quantify the amount of hydrogen released to fuel system, the hydrogen emission rate is defined as Eq. (1).

$$\eta = \frac{\sum_{s} F_{s,f}^{out} y_{s,H_2}^{out}}{F_{HU} y_{HU,H_2}} \times 100\% \quad (1)$$

where η represents the hydrogen emission rate. $F_{s,f}^{out}$ and y_{s,H_2}^{out} denote hydrogen flowrate and hydrogen purity of gas stream discharged to the fuel system, respectively. F_{HU} and y_{HU,H_2} denote the flowrate and hydrogen purity of hydrogen utility. In this case, the flowrate of hydrogen utility (F_{HU}) is 19,100 Nm^3/h with a hydrogen purity (y_{HU,H_2}) of 99.9 % (vol %).

The hydrogen emission rate of conventional refinery hydrogen network can be calculated as 41.4 % via solving Eq. (1) based on the data as shown in Tables 1 and 2.

3. Design of near zero-emission hydrogen network

The components contained in the refinery gas can be recovered by several separation processes, such as distillation, pressure swing adsorption, membrane separation, cryogenic separation, hydrate separation, absorption - adsorption coupling process, etc. The hydrogen contained in refinery off-gas is recovered to the maximum extent. Once the high value-added components such as light hydrocarbons in refinery gas are recovered, hydrogen is enriched and can be allocated to hydrogen consumers.

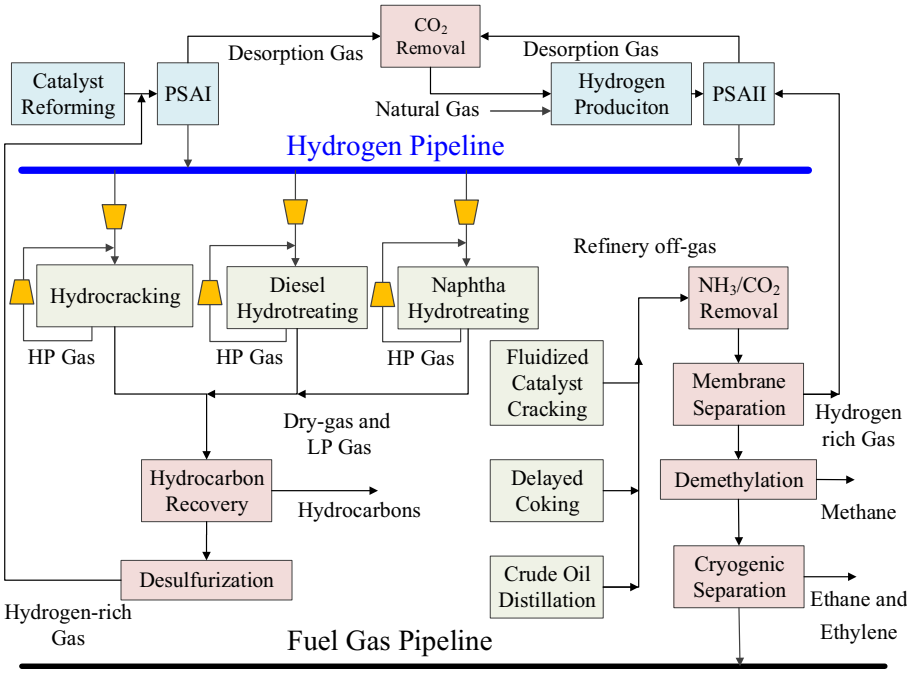

Figure 2: Improved refinery hydrogen network with near - zero hydrogen emission

As shown in Figure 2, LP gas and dry gas with light hydrocarbons (C3+) from hydrogenation units can be delivered to light hydrocarbon recovery unit. We can determine the accurate flowrate of recovered light hydrocarbons. The residual hydrogen rich stream could be sent to a PSA for further purification. The product stream of PSA is fed to hydrogen utility pipeline. With the CO_2 removal for the residual desorption gas,

the components H_2, CO, CH_4 are left in desorption gas and it is suitable raw material for hydrogen production.

The recovery flowrate for each component by different separation treatments can be calculated as Eq. (2).

$$F_{t,c}^{\text{out}} = R_{t,c} \sum_{\text{s}} F_{\text{s}}^{\text{out}} y_{\text{s},c}^{\text{out}} \qquad \forall c \tag{2}$$

where $F_{t,c}^{out}$ represents the total flowrate of recovery component *c*. F_s^{out} denotes the flowrate of the stream being fed in the hybrid separation system and $y_{s,c}^{out}$ denotes the purity for component *c* in this stream. $R_{t,c}$ denotes recovery ratio of the separation treatment for component *c*.

Light hydrocarbons (C3+) recovery is taken as an example to determine the recovery flowrate for C3+. Comparing Figures 1 and 2, LP gas and dry gas originally discharged to the fuel system are delivered to light hydrocarbon recovery. Flowrates and purity of C3+ for LP gas and dry gas can be seen in Table 1. The net flowrate of C3+ contained in the stream can be obtained by the product of the flowrate and purity of C3+ for each stream (i.e. for LP gas from hydrocracking, $F_s^{out} = 900\ \text{Nm}^3/\text{h}$, $y_{s,\text{C3+}}^{out} = 7\ \%$,900 ×7 %=63 Nm^3/h). The net flowrate of C3+ for each LP gas and dry gas stream can be obtained similarly. Then we can get the total flowrate of C3+ fed in the recovery unit by summing up the net flowrate for each stream (1,864.1 Nm^3/h). The recovery ratio of light hydrocarbon recovery is assumed to be 90%. The flowrate of recovered light hydrocarbons (C3+) can be calculated as 1,678 Nm^3/h via solving Eq. (2) ($F_{t,c}^{out} = 1{,}864.1 \times 0.9 = 1{,}678\ \text{Nm}^3/\text{h}$). Next, the hydrogen-rich stream could be sent to PSAI for further hydrogen purification.

As shown in Table 2, off-gas streams from CDU, FCC and DCU contain considerable amount of Methane, Ethane and Ethylene. Since hydrogen purity is much lower in these refinery off-gases, membrane separation is applied to recover hydrogen after the removal of acidic components (NH_3, CO_2). The remaining gas can go through the demethanizer tower to recover high-purity methane. Cryogenic separation technology or hydrate separation technology can be used to recover ethane and ethylene (C2), which are good feed material for ethylene production. Finally, the residual gas is flared or discharged to the fuel system. The recovery ratios of all separation processes are assumed to be 90%. Similar to the light hydrocarbons recovery, we can obtain the flowrates of methane (5,638 Nm^3/h) and C2 (4,464 Nm^3/h) via solving Eq. (2). And the flowrate of fresh hydrogen purified by PSA can be calculated as 6,182 Nm^3/h with the purity of 99.9 %. After recovering hydrogen and high value-added products, the flowrate of residual gas discharged to fuel system is 3,157 Nm^3/h, where the flowrate of pure hydrogen is 481.21 Nm^3/h.

The near zero-hydrogen network is constructed, and the hydrogen emission rate of improved hydrogen network can be calculated as 2.5 % via solving Eq. (1). Since the recovery ratio of separation processes can not reach 100 %, hydrogen cannot be fully recovered. However, the amount of waste hydrogen discharged to the fuel system is already tiny. The hydrogen emission efficiency decreases to be acceptable limit and it can be regarded as a near-zero emission refinery hydrogen network.

4. Conclusions

In this paper, a hydrogen network with zero hydrogen emission is designed by the introduction of hybrid separation processes to recover hydrogen and other valuable components from refinery off-gas streams. Compared with the conventional refinery hydrogen network, the flowrates of recovery hydrogen, methane, ethane and ethylene (C2), light hydrocarbon recovery (C3+) reach 6,182 Nm^3/h, 5,638 Nm^3/h, 1,678 Nm^3/h and 4,464 Nm^3/h, respectively in the improved hydrogen network. In addition, a quantitative index, hydrogen emission rate, is defined to measure the degree of waste hydrogen discharged to fuel system. The hydrogen emission rate of optimized hydrogen network is only 2.5 %, which is much lesser than 41.4 % for the conventional hydrogen network and it can be a near-zero hydrogen emission network. This conceptual approach has been proven to strengthen hydrogen utilization. Detailed simulation and optimization will be followed by the conceptual designed hydrogen network. The recovery processes for refinery gas from FCC, CDU and DCU have been well applied in the refinery. This paper combined with the optimization of refinery hydrogen system with refinery off-gas recovery system

Abstract

Nowadays, the demand for hydrogen in refineries has been increasing rapidly and it is reported that the cost of hydrogen has become the second biggest cost for refineries. As a result, the optimal synthesis of refinery hydrogen network can effectively save hydrogen resources and alleviate the deficit of hydrogen in refinery. In this paper, a superstructure-based mathematical model for the synthesis of refinery hydrogen network with multiple components is constructed. All the possible connections between those units are taken into consideration. Four components, namely H_2, H_2S, C3+ and other components are included, and it leads to a multi-component model. One industrial case is analysed to illustrate the feasibility and applicability of the proposed mathematical model. 9.8 % of reduction on the flowrate of shift gas in optimal hydrogen plant can be achieved.

Keywords: hydrogen network, mathematical programming, multi-component, optimization.

1. Introduction

The processing ratio of inferior crude oil is increasing year by year. At the same time, environmental regulations on the clean fuel are becoming more stringent. In order to meet the standard requirements for sulphur content in the product clean fuel, modern refineries need to improve the ratio of hydrotreating and hydrocracking processes. It leads to the consumption of substantial amounts of hydrogen. Nowadays, synthesis of hydrogen networks is widely accepted as a useful tool to improve hydrogen utilization in refineries. Generally, the methodologies developed for the synthesis and retrofit of refinery hydrogen networks can be classified into pinch analysis and optimization-based mathematical approaches and they are reviewed in the latest article (Marques et al., 2017). Hallale and Liu (2011) firstly proposed a mathematical model incorporated with compressors and pressure swing adsorption for hydrogen network in refineries, which aims to maximize the amount of hydrogen recovered from the whole plant. Jia and Zhang (2011) developed a method of modeling and optimization considering multi-component to overcome the shortcomings of previous work in which light hydrocarbon generation and flash evaporation calculation is included. Liu and Zhang (2004) introduced the shortcut model of PSA and investigated the impacts of design conditions. The optimization of hydrogen network is integrated with hydrogen sulfide removal process (L. Zhou et al., 2012), hydrogen header (C. Deng et al., 2014), flash calculation

model and developed short-cut hydro-treating models (B. Umana et al., 2014), conditioning equipment such as fuel cells (Y. Chiang et al., 2014).

This paper aims to construct a general optimization model of multi-component hydrogen network in refinery, which includes external hydrogen sources (catalytic reforming, hydrogen production units, hydrogen header), purifier (pressure swing adsorption, desulfurization tower, light hydrocarbon recovery units), hydrogenation units, and fuel system. The multiple components consisted of hydrogen streams is assumed as four components, H_2, H_2S, C3+ and other components. One simplified industrial case is utilized to solved and analysed to illustrate the advantages of the optimal synthesis model.

2. Problem statement

The problem of hydrogen network optimization in general refinery can be described as follows. The external hydrogen sources ($u \in U$) of the refinery include catalytic reforming units and hydrogen production units. In general, the catalytic reforming and hydrogen production units are all integrated with a pressure-swing adsorption (PSA) unit. The hydrogen-enriched gas from catalytic reforming should be sent to PSA in the same plant, and shift gas produced by methane steam reforming in hydrogen plant should be sent to its own PSA. The product stream of PSA is fed to hydrogen header pipeline ($h \in H$), and the residual gas is discharged to the fuel system. Hydrogenation units ($k \in K$), mainly include hydrocracking, hydrogenation or hydrotreating units. Each process hydrogen sink is specified by its required flow rate (F_k^{in}), lower bound of hydrogen purity (Y_{k,H_2}^{min}), upper bound of inlet concentration of impurities ($Y_{\mathrm{k,c}}^{\max}, \forall c \neq \mathrm{H}_2$).The outlet of hydrogenation unit mainly includes high-pressure separator gas (HP gas) and low-pressure separator gas (LP gas). The flowrate of HP gas is denoted as F_k^{HP} with the hydrogen purity of Y_{k,H_2}^{HP} and the flowrate of LP gas is denoted as F_k^{LP} with the hydrogen purity of Y_{k,H_2}^{LP} . Most of the HP gas is reused as recycle hydrogen after desulfurization and the residual could be sent to PSA, other hydrogenation units or fuel system. LP gas should be firstly delivered to desulfurization tower to removal acidic gas. Then it could be delivered to PSA, other hydrogenation units or fuel system with or without light hydrocarbon recovery.

The purpose of this paper is to construct a model for hydrogen network optimization in general refinery to reduce the consumption of feed natural gas for hydrogen production.

3. Mathematical Model

Steam-methane reforming (SMR) for hydrogen production includes reforming, shift conversion, and pressure swing adsorption (PSA). The flow rate of shift gas is strongly associated with hydrogen utility and cost of natural gas. Therefore, the objective function can be formulated as Eq. (1).

$$\min fu\_\mathrm{shiftgas} = f_u \qquad \forall u = \mathrm{HPlant} \tag{1}$$

where f_u denotes the flowrate of shift gas produced by methane steam reforming. The flowrate of natural gas can be converted by that of syngas. The conversion coefficient λ

is defined as the amount of natural gas required to produce each unit of shift gas shown as Eq. (2).

$$fu\_ng = \lambda \cdot fu\_\text{shiftgas} \tag{2}$$

where λ denotes 0.2282, which is taken from the case of a petrochemical refinery in northeast China.

The constraints of the objective function include mass balance constraints, capacity constraints and logic constraints. For the compactness of the article, the elaborate constraints do not be listed in this paper.

4. Case study

The case is simplified industrial case from a refinery in northeast China. Current hydrogen network is shown in Figure 1. The current process data for this example is listed in Table 1 to Table 4. As shown in Figure 1, the flowrate of natural gas allocated to the hydrogen plant is 6,067 Nm^3/h. There are two hydrogen consuming processes, namely, hydrocracker unit (HC), and diesel hydrotreater (DHT). The inlets for those hydrogen consumers serve as process hydrogen sinks and their outlets would be considered as process hydrogen sources. In addition to meeting the flow rate requirements, the purity of hydrogen at the inlet of hydrogenation units should be greater than the minimum, and the purity of H_2S should be less than the maximum.

In the current hydrogen network, HP gas of the hydrogenation units is recycled back into the hydrogenation reactors, and LP gas is sent directly to PSA inlet after desulphurization without light hydrocarbon recovery. The purity and flowrate up bound requirements for the sinks are listed in Table 1 and the flowrate, purity and components for the internal sources are listed in Table 2. HP gas and LP gas requires desulfurization before recycling. The ratios of desulfurization tower are both assumed to be 80 %. It is assumed that the light hydrocarbon recovery unit can recover all C3+. Outlet gas stream of the recovery units does not contain C3+. The data of external hydrogen sources, including catalytic reforming (CCR) and hydrogen plant (HPlant), is shown in Table 3. In order to further reduce the consumption of hydrogen utility, the purification unit (PSA) is incorporated into the hydrogen network to upgrade the quality of internal hydrogen sources. The data for two PSAs respectively located in the catalytic reforming and hydrogen plant is listed in Table 4. The recovery ratios of hydrogen for PSAI and PSAII are assumed as 84.38 %. Besides, the fuel system would receive unused process hydrogen sources and other refinery off-gas.

Table 1: Data for inlet requirements of hydrogenation units

Hydrogenation units	Inlet flowrate (Nm^3/h)	Minimum purity for hydrogen (mol %)	Maximum purity for sulfide (mol %)
hydrocracking (HC)	3.681×10^5	94.24	0.1
Diesel hydrogenation (DHT)	7.7568×10^4	91.82	0.1

Table 2: Data for Outlet streams of hydrogenation units

Gas streams	Flowrate (Nm^3/h)	Components (mol %)			
		H_2	H_2S	C3+	others
HP gas from HC	3.281×10^5	93.64	0.1	1.6	4.66
HP gas from DHT	7.435×10^4	91.5	0.1	0.1	8.3
LP gas from HC	7,003	86.61	0.45	5.8	7.14
LP gas from DHT	190	85.67	0.45	0.36	13.52

Table 3: Data of external hydrogen sources

External hydrogen sources	Maximum flowrate (Nm^3/h)	Components (mol %)			
		H_2	H_2S	C3+	others
Hydrogen-rich stream in CCR	28,000	90.83	0	3.92	5.25
Shift gas in HPlant	100,000	74.99	0	0	5.01

Table 4: Data of pressure swing adsorption

PSA	Recovery ratio of hydrogen	Components for product gas (mol %)			
		H_2	H_2S	C3+	others
PSA1	84.38 %	99.98	0	0	0.02
PSA2	84.38 %	99.98	0	0	0.02

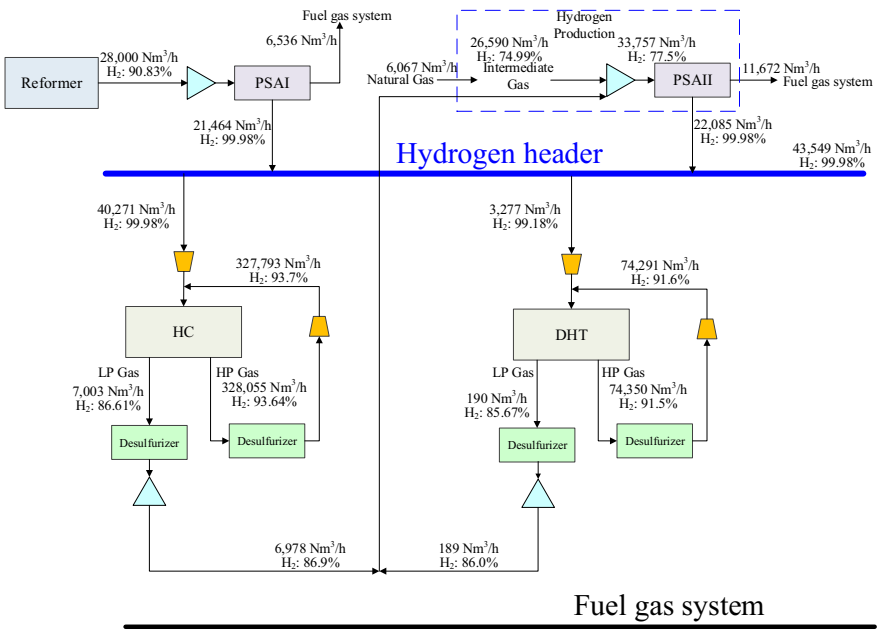

Figure 1: Current hydrogen network

The data from Table 1 to Table 4 were substituted into the optimization model for general refinery hydrogen networks. It is solved in GAMS software (Rosenthal, 2010) using KNITRO for NLP (based on the PC specification: Intel D CPU 3.00 GHz, 4 GB RAM). GAMS software version is 24.2, and the solution time is 1.123 CPUs. By optimization calculation, we can get the minimum flowrate of shift gas (23,986 Nm^3/h), corresponding to flowrate of natural gas (5,473 Nm^3/h). The optimized refinery hydrogen network is shown in Figure 2.

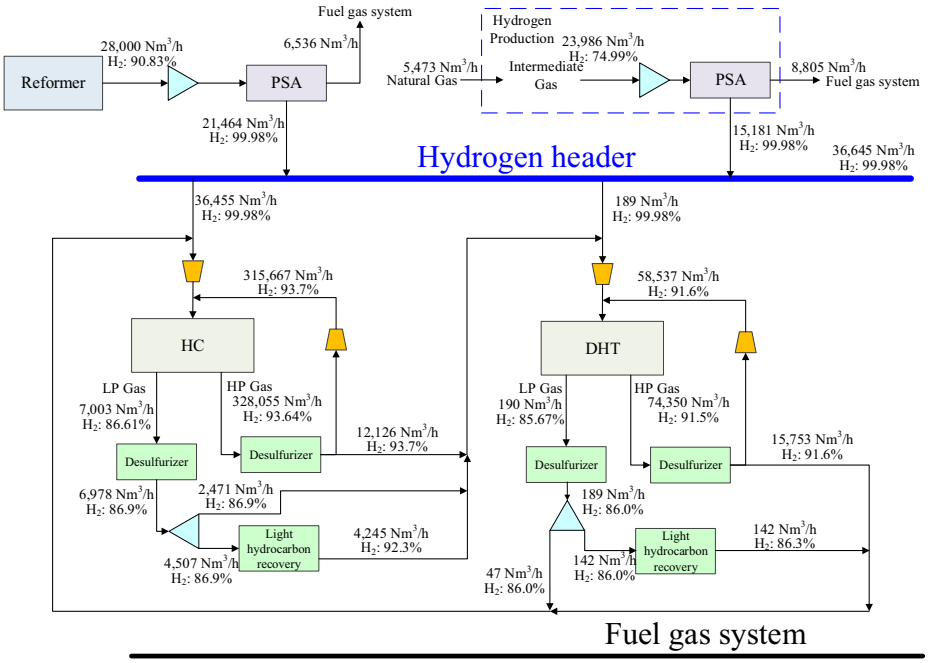

Figure 2: Optimal retrofitted hydrogen network

In the optimized hydrogen network, HP gas of the hydrogenation units is mostly recycled back into the hydrogenation reactors and the small portion is sent to the inlet of the other hydrogenation units directly. The LP gas from hydrogenation units does not be sent to PSA. LP gas is firstly allocated to the desulfurization tower, then one part of them is delivered to the inlet of the other hydrogenation unit and the other part is delivered to light hydrocarbon recovery unit. After recovery of light hydrocarbons, it is allocated to the inlet of the other hydrogenation unit. Compared with the current hydrogen network, the flowrate of shift gas in the hydrogen plant is 23,986 Nm^3/h, with a decrease of 2,604 Nm^3/h, and the consumption of natural gas is 5,473 Nm^3/h, with a decrease of 594 Nm^3/h.

5. Conclusions

In this paper, an optimization model for multi-component hydrogen network model is constructed, which mainly includes four components, namely H_2, H_2S, C3+ and other components. The desulfurization and light hydrocarbon recovery are considered in the optimal model. In addition, referring to the design of actual hydrogen network in refinery, fixed connections between different units are applied as constrains. The high-

pressure separator gas, low-pressure separator gas and dry gas from the hydrogenation units can be sent to PSA, the light hydrocarbon recovery unit, other hydrogenation units or fuel systems. Compared with the current hydrogen network, the flowrate of shift gas in optimal hydrogen plant is 23,986 Nm^3/h and the consumption of natural gas is 5,473 Nm^3/h, with a decrease of 9.8 %. This model can be used for the optimal design of refinery hydrogen network.

Optimal operation of seawater desalination system based on load rolling prediction

Aipeng Jiang*, Haokun Wang, Quannan Zhang, Jian Wang, Shu Jiangzhou

School of Automation, Hangzhou Dianzi University, Hangzhou 310018, China
jiangaipeng@163.com

Abstract

In this work, a real time optimization method integrating freshwater production and supply water load was presented based on hourly water load rolling prediction and sequential solution of the optimization problem. Firstly, based on historical data of supply water, a new load rolling prediction method with better prediction accuracy was proposed. Then, the optimal operation problem was formulated and the real time optimization strategy including water load rolling prediction, discretization of DAEs and rolling update of optimal operation profile was given. Lastly, case study based on history data of water load was carried out as illustration. Computing result shows that the proposed operational optimization method can practically bring more than 25% energy cost saving than the conventional method.

Keywords: operational optimization; seawater desalination; rolling prediction; DAEs

1. Introduction

The seawater reverse osmosis (SWRO) technique is becoming the most attractive seawater desalination technique because of its economy and convenience [1-2]. However, the energy cost for the production process is still quite high because of its high pressure driven character. To reduce the operational cost of the SWRO system, Kim et al. conducted a comprehensive study on the RO process, particularly on the minimization of product costs using the system engineering method[3]. Sassi et al. evaluated the optimal operation of SWRO system through minimizing the specific energy consumption [4]. With the consideration of thermodynamic restriction, Zhu studied the energy cost optimization problem. Among which factors such as stages, energy recovery efficiency and so on was discussed to get the optimal operation condition [5]. Li studied the optimal plant operation of brackish water reverse osmosis (BWRO) desalination to reduce specific energy consumption (*SEC*)[6]. With the consideration of the variable operating and the time-of-use electricity tariff rate schedule, Ghobeity et al. conducted the optimal operation of SWRO system to reduce the electricity charges[7]. The results show the significant electricity and production cost saving potentials with proposed operation method. Kim et al. [8] also discussed the optimization operation of the RO system with the fluctuation of seawater demand and temperature. In his study, storage tank was used as the buffering unit between water production and water supply to add the flexibility of operation. But his result was based on fixed load demand and known temperature profile in the future 24 hours. In fact, large load demand and temperature fluctuations are always unavoidable, which would cause infeasibility of the so call optimal operation. To overcome this problem, in this study an optimal operation framework including rolling prediction of water demand based on history data is presented. With better water demand prediction and correction, and rolling updating of

the optimal control trajectories obtained by solution of the operational optimization problem, more practical energy cost saving was aimed to achieve.

2. Problem modelling and formulation

The RO process model [9-10] is listed in Table 1. From these equations, permeate flowrate Q_p and salt concentration C_p can be obtained.

Table 1 the equations for RO process

Equations	Notes
$Q_p = Q_f - Q_r$	(1)
$Q_f C_f = Q_r C_r + Q_p C_p$	(2)
$Q_p = n_{PV} n_l W \int_0^L Jv dz$	(3)

$Js = B_s (C_m - C_{sp})$	(5)
$P_b = P_f - P_d$	(6)
$\Delta P = (P_b - P_p)$	(7)
$\Delta\pi = RT(C_m - C_p)$	(8)
$\phi = \frac{C_m - C_p}{C_b - C_p} = \exp(\frac{Jv}{k_c})$	(9)
$Sh = k_c d_e / D_{AB} = 0.065 Re^{0.875} Sc^{0.25}$	(10)
$Re = \rho V d_e / \mu$	(11)
$Sc = \mu / (\rho D_{AB})$	(12)
$Js = Jv * C_p$	(13)
$\lambda = 6.23 K_\lambda Re^{-0.3}$	(14)
$\mathrm{d}V / \mathrm{d}z = -2Jv / h_{sp}$ z=0, $V=V_f$; z=L, $V=V_r$	(15)
$\mathrm{d}P_d / \mathrm{d}z = -0.5\lambda\rho V^2 / d_e$ z=0, $P_d = 0$; z=L, $P_d = P_f - P_r$	(16)
$\mathrm{d}C_b / \mathrm{d}z = 2Jv(C_b - C_p) / (h_{sp} V)$ z=0, $C_b = C_f$; z=L, $C_b = C_r$.	(17)
$A_w = A_{w0} \exp(\alpha_1 (T - 273) / 273 - \alpha_2 (P_f - P_d))$	(18)
$B_s = B_{s0} \exp(\beta_1 (T - 273) / 273)$	(19)
$R_{ec} = Q_p / Q_f$	(20)
$SEC = (P_f Q_f / \eta_{HP} - P_r Q_r \eta_{PX}) / Q_p$	(21)
$Sp = C_p / C_f \times 100\%$	(22)
$Ry = (1 - C_p / C_f) \times 100\%$	(23)

The dynamic behaviour of the storage tank can be described as:

$$\mathrm{d}H_t / \mathrm{d}t = (Q_p - Q_{out}) / S_t \tag{24}$$

$$\mathrm{d}C_{p,out} / \mathrm{d}t = Q_p (C_{sp} - C_{p,out}) / S_t H_t \tag{25}$$

Here S_t and H_t denote area and water level of storage tank, respectively. Q_{out} is water load demand, $C_{t,out}$ is salt concentration of supply water to users, and C_{sp} is the average salt concentration from permeate water. The operational optimization problem within 24 hours can be formulated as follow:

$$\underset{Q_f, P_f, H_t}{\mathrm{Min}} \sum_{i=1}^{24} E_p(i) SEC(i)\, Q_p(i) \tag{26}$$

Equality constraints: Eq.(1)-Eq.(25)

Inequality constraints: $\left| H_t(0) - H_t(24) \right| \le \Delta$

Bound constraints: $P_{flo} \le P_f \le P_{fup}$; $Q_{flo} \le Q_f \le Q_{fup}$; $C_{plo} \le C_p \le C_{pup}$

$$T_{lo} \le T \le T_{up}; \qquad H_{t\min} \le H_t \le H_{t\max}; \ \phi \le \phi_{\max}$$

In the inequality constraints, the Δ denotes the allowable deviation of water level to make sure the safety and adjustable margin of storage tank. Solution of the problem leads to optimal trajectories of feed pressure and feed flowrate in the future hours. Prediction of Q_{out} in the future hours is critical to the optimal trajectories, and conventional MPC control method has difficulty in dealing with the terminal inequality constraints in so long time zone.

3. Prediction of water load demand

The moving average method or the auto-regressive moving average method can be used for water demand prediction [11]. But it is difficult to achieve the desired accuracy when the water fluctuation is large, and the cumulative effect of error on water level will cause safe problem. Based on the above considerations, this paper uses the principle of predictive control to reduce the prediction error by rolling prediction and rolling correction. After obtaining the predicted curve for the second day, the hourly water load demand profile is updated and corrected each hour. The characteristics of history data from the 20th hour of the first day to the 5th hour of the second days was used to get and correction the prediction profile in a few hours ahead. The prediction method is as follows:

1) Obtain the hourly water load profile template with history data by moving average method as below:

$$F_{i,m} = \left(x_{i,t} + x_{i,t-1} + \cdots + x_{i,t-n+1} \right) / n \qquad i=1,2,\ldots,24. \tag{27}$$

2) With the hourly water load of the first day, predict hourly water demand of the first several hours by Eq.(28). Then obtain the initial water load prediction profile of the whole second day.

$$\mathrm{Y}_{i+1} - Y_i = \phi_1 (Y_i - Y_{i-1}) + \phi_2 (Y_{i-1} - Y_{i-2}) + \cdots + \phi_n (Y_{i-n+1} - Y_{i-n}) \tag{28}$$

Here $\phi_1 \ldots \phi_n$ denotes the auto-regressive coefficient obtained by nonlinear least square. With Eq.(28) the hourly water load of the first 4-5 hour $Y_{25} \ldots Y_{29}$ is obtained sequentially. Then $Y_{30} \ldots Y_{48}$ is calculated by:

$$Y_j = F_{j-24,m} + G_{ap} \ , j = 30 \ldots 48 \tag{29}$$

$$G_{ap} = \mathrm{Min} \sum_{\bar{j}=25}^{j-1} (Y_{\bar{j}} - F_{\bar{j}-24,m})^2 \tag{30}$$

3) Correct the water load of the i^{th} hour after it is measured, and then update the hourly load from the $(i+1)^{\text{th}}$ hour to the 24^{th} hour by Eq.(29)-Eq.(30).

4. Integrated solution strategy

With known water load prediction, solution of the operational optimization problem leads to optimal control trajectories of feed pressure and feed flowrate in the next 24 hours. Since the water load prediction is hourly updated in to reduce prediction errors, the optimal problem accordingly should be solved sequentially as the prediction profile changes. Since the problem is comprised with a set of differential equations and algebraic equation, it is not easy to be solved in direction way based on necessary optimality conditions. Simultaneous method based on finite element collocation[12] was used to discretize the optimal problem and transfer it into nonlinear program. Then large scale solver IPOPT was used for its efficient solution, and simulation based strategy was used to get reasonable state variable value. With fixed value of control variables and initial state value on the first finite element, the simulation was carried out one by one finite element until all the state variable values obtained. The following monomial basis representation[12] was used for the discretization of the differential equations:

$$w(z) = w_{i-1} + h_i \sum_{q=1}^{K} \Omega_q \left(\frac{z - z_{i-1}}{h_i} \right) \frac{\mathrm{d}w}{\mathrm{d}z_{i,q}} \tag{31}$$

Here, w_{i-1} is the value of the differential variable at the beginning of element i; h_i is the length of element i; $\mathrm{d}w/\mathrm{d}z_{i,q}$ denotes the value of its first derivative in element i at the collocation point q; and Ω_q is a polynomial of order K, satisfying:

$$\Omega_q(0) = 0 \qquad q = 1 \ldots, K \tag{32}$$

$$\Omega_q^{'}(\sigma^r) = \delta_{q,r} \qquad q = 1 \ldots, K \tag{33}$$

The continuity of the differential profile is enforced by:

$$w_i = w_{i-1} + h_i \sum_{q=1}^{K} \Omega_q(1) \frac{\mathrm{d}w}{\mathrm{d}z_{i,q}} \tag{34}$$

5. Case study

A single-stage SWRO system was used for case study. The RO unit consists of 55 parallel pressure vessels with 8 SW30HR-3XX membrane modules in series in each pressure vessel. One storage tank is used to connect the freshwater production and water supply process. Hourly electricity price is shown in Fig.1. Fig.2 shows the comparison of water load demand prediction based on moving average method and the actual value,

from which it can be seen that the conventional prediction method has quite big deviation. Fig.3 shows the rolling prediction of water load demand. Though the first prediction is not good enough, the rolling correction and update reduced the errors along time, just as shown in Fig.4.

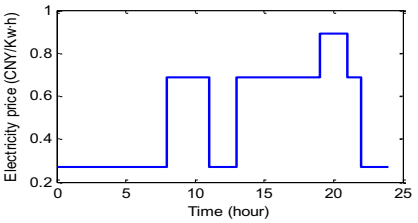

Fig. 1 Curve of hourly electricity price

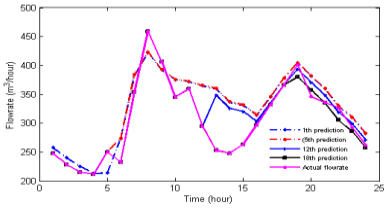

Fig.3 Rolling prediction of hourly load

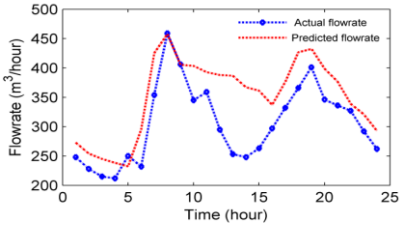

Fig. 2 Prediction of water load demand

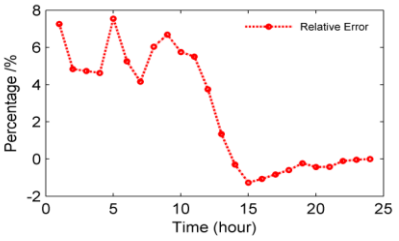

Fig. 4 Total error change along tim

To solve the optimal problem and ensure the discrete accuray, 20 finite elements with 3 Radau collocation points are used to discretize the differential equations of RO. 24 finite elements with 3 collocation points are allocated for the dynamic equation of storage tank. IPOPT under the platform of GAMS24.0 is used as solver. A 3.06GHz computer with Intel Core2 Duo T9900 processor and 5GB of memory is used.

Table 2 Computing results of the cases

No.	Solution time (s)	Objective (10^4CNY/day)	Cost save (%)	Final *Ht* (m)
Case 1	34.375	0.917	0	7
Case 2	285.892	0.671	26.83	6.68

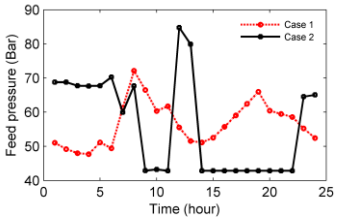

Fig. 5 Optimal feed pressure of the cases

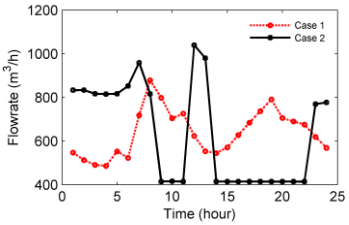

Fig. 6 Optimal feed flowrate of the cases

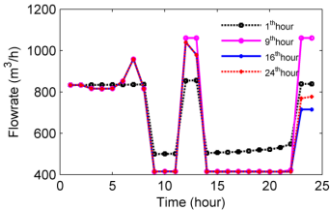

Fig. 7 Rolling update of feed flowrate

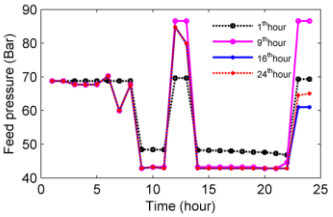

Fig. 8 Rolling update of l feed pressure

Results of our method(Case 2) is compared with conventional method which just optimize the operation at current water load (Case 1). Table2 shows the objective value and computing information. It can be seen that though more computing efforts was used, the energy cost is reduced from 9170 CNY/day to 6710 CNY/day, about 26.83% energy cost saving potential achieved. The computing time 285.892 second is short enough for our rolling optimal operation. Fig.5 and Fig.6 show the final profile of optimal operation in different cases. Since in our method, the profile of optimal operation is rolling updated, we can get 24 optimal control trajectories. Fig.7 and Fig.8 show the rolling change of these optimal control trajectories. Here we must mention that, as the water demand changes, the final terminal constraint in Case 1 can't be satisfied to ensure the safety of water level.

5. Conclusion

Optimal operation of SWRO system has significant potential of cost saving, especially when storage tank and hourly electricity were used as supply water load changes. In this paper, an optimal operation of SWRO system based on water demand rolling prediction was studied. Utilizing the history data, water load characters and rolling update method, better water load prediction accuracy was achieved, and sequentially solution of the operational optimization problem as water load prediction changes lead to better control trajectories. Compared with conventional method, about 26.83% energy cost saving potential can be achieved, and at the same time, terminal constraint of water level can also be guaranteed.

Modelling and Optimisation Approach of an Integrated Oil Refinery and a Petrochemical Plant

Elham Ketabchi*, Evgenia Mechleri, Sai Gu, Harvey Arellano-Garcia

Department of Chemical and Process Enginerring,University of Surrey, Guildford, GU2 7XH, United Kingdom
e.ketabchi@surrey.ac.uk

Abstract

An optimised integration approach connecting a conventional oil refinery with an ethylene production plant is investigated. Using the intermediate materials produced as the connection between the two plants, the use of internally provided feedstocks and blending options removes, at least partially, the reliance on external sourcing. This is also beneficial in terms of increasing profit margins and quality for both production systems. Thus, a mathematical model has been developed and implemented in this work to model the oil refinery and the ethylene production plant while considering their integration as an MINLP problem with the aim of optimising the integrated plants. This work considers the optimisation of each plant individually and later the final integration by modelling the interconnection between the oil refinery and the ethylene production plant. Moreover, a case study using practical data was carried out to verify the feasibility of the integration for an industrial application.

Keywords: Integration, Oil Refinery, Petrochemical Plant, Ethylene Production plant, mixed-integer non-linear programming (MINLP)

1. Introduction

Petroleum refining and refineries play an important role in our lives, mainly because most forms of transportation are powered by the products this industry produces. Accordingly, the price of crude oil has a big impact on this industry as its main feed is crude oil. The rise in this price encourages the industry to develop new ways to increase the profit margin. This requires all resources to be utilised in a highly efficient way that can be done through adequate integration. Other factors, apart from the feedstock price, that need to be considered are the strict environmental regulations that have raised the cost of producing clean fuels (Fahim, Alsahhaf and Elkilan, 2010).

Most of the technological changes in refineries in the last 20 years were due to the environmental concerns that lead to the change and alteration of the existing processes. This “cause and effect” response to environmental mandates have had a negative impact on the refineries’ economic performance, causing increased costs (Leffler, 2008). As mentioned before, an increasing crude oil price has a responsive price increase in all products that are a result of its refining. To mitigate this issue, integrating this plant with other processes can be a more profitable and worthwhile plan.

The idea of this study is to be able to connect complex plants in a way to achieve a beneficial outcome for both integrated plants, in this case, an oil refinery and an ethylene

production plant. This study aims to give the economic benefit in terms of providing an alternate source of feedstock and intermediate material required for both production plants. The integration is conducted in a way to optimise each plant individually while considering the integration. Thus, modelling the interconnection between the oil refinery and the ethylene production plant in such a way that the suitable interaction between the plants is determined by efficient material utilisation. A mathematical model is constructed and presented in this paper to model the oil refinery and the ethylene production plant considering their integration as an MINLP problem. A schematic of the integration can be seen in Figure 1.

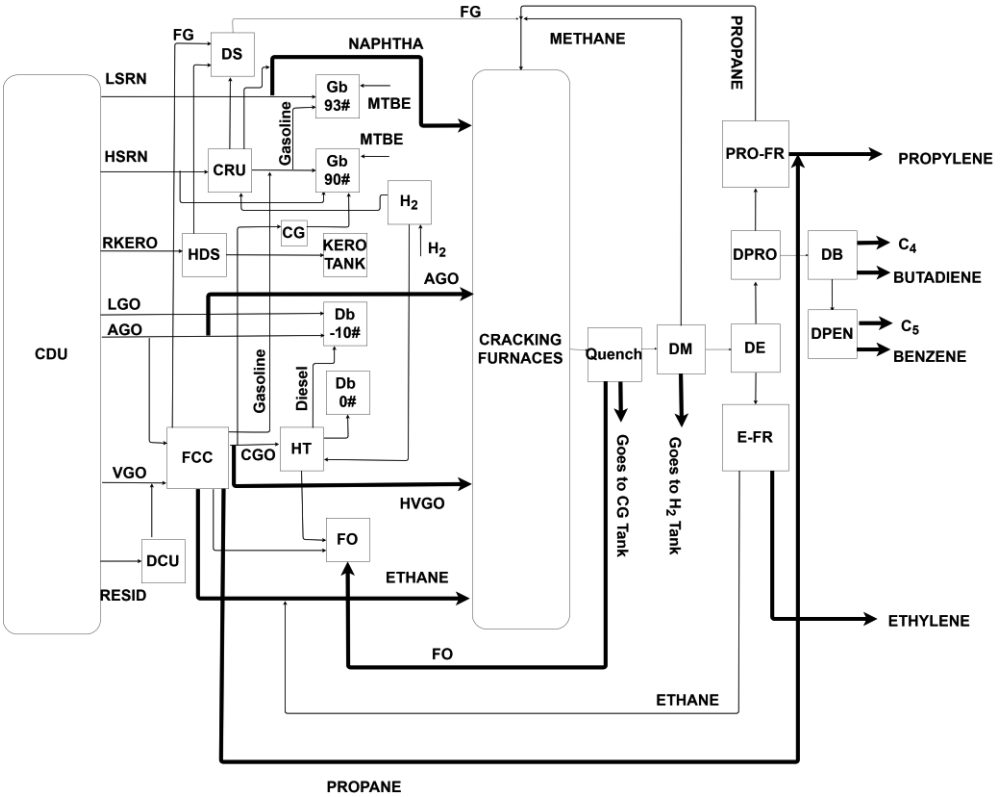

Figure 1. Schematic representation of a possible route of integration between an oil refinery and an ethylene production plant. (DM-Demethaniser, DE-Deethaniser, E-FR-Ethylene Fractionator, DPRO-Depropaniser, PRO-FR-Propylene Fractionator, DB-Debutaniser, DPEN-Dependentaniser)

2. Problem Statement and Mathematical Formulation

In this section, the processes of each plant will be briefly explored and modelled including avenues of potential integration between the two facilities identified and considered as candidates to achieve the final objective of beneficial integration of both the oil refinery and ethylene plant. The process of refining crude oil in an oil refinery consists of converting crude oil to its final products through many processing units. The units chosen for the refinery are: The Crude Distillation Unit (CDU), Fluid Catalytic Cracker (FCC), Delayed Coking Unit (DCU), Catalytic Reforming Unit (CRU), Hydro-Treating unit (HT), Gas Desulfurization unit (DS), and blenders. The distillation process within the

Crude Distillation Unit (CDU) produces, lightest to heaviest: Light Straight-Run Naphtha (LSRN), Heavy Straight-Run Naphtha (HSRN), Raw Kerosene (RKERO), Light Gas Oil (LGO), Atmospheric Gas Oil (AGO), Vacuum Gas Oil (VGO), with heaviest product, residue (RESID), entering the DCU to produce more VGO. This, alongside AGO, is then fed to the FCC producing Cracked Gas Oil (CGO), Cracked Gasoline (CG) and FCC Fuel Oil (FFO) while also generating by-products such as propylene, ethane and Fuel Gas (FG). The ethane finds use in the cracking furnaces of the ethylene production plant, while propylene is stored in a tank as a final product in the aforementioned plant. The Fuel Oil (FO) and FG are used internally to fuel the utility system, though their initially high sulphur content requires these to be desulphurised in the DS prior to use.

The CGO is fed to the HT that produces diesel (DIE) and HT Fuel Oil (HFO) and by-products such as FG. The DIE produced along with portions of LGO and AGO are blended in the diesel blender (DB) producing −10# diesel, while blending DIE with portions of CGO will result in 0# diesel product. RKERO is then consumed in the HDS that produces kerosene (KERO) as a final product that is then stored in a product tank.

The CRU produces Reformer Gasoline (RG), FG and naphtha. RG is blended with LSRN and Methyl tert-butyl ether (MTBE) in the gasoline blender (GB) to produce 90# gasoline. Meanwhile, HSRN and CG are blended with MTBE to produce 93# gasoline. The gasoline and diesel blending processes have requirements in terms of octane number and pour point, for example, the octane number of gasoline 90# and 93# should be higher than 90 and 93, respectively, while diesel −10# and 0# should have a pour point lower than −10◦C and 0◦C, respectively. The most desired products of the refinery plant consist of two kinds of gasoline (90# gasoline and 93# gasoline), two kinds of DIE (-10# diesel and 0# diesel), KERO and FO. One of the main points of this integration is to maintain a balance of material usage. So, the least valuable material in one plant can be utilised in the other, especially in this case as ethylene and ethane that are wasted through heating and boiling in the refinery, could otherwise be utilised in the ethylene production plant. Additionally, the propylene produced by the FCC can be used in the ethylene plant to produce a wide range of chemicals.

The process of ethylene production considered in this study consists of a series of parallel cracking furnaces that utilise ethane, naphtha, AGO and Hydrocracking Vent Gas Oil (HVGO), which are acquired from the oil refinery. Following cracking, quenching and compression occur before entering the separation units that consist of a demethaniser, deethaniser, depropaniser, debutanizer, and dependaniser together with two rectification towers that further separate ethane and propane from ethylene and propylene, respectively. These separations also produce hydrogen, butadiene, benzene, C4 and C5 products. The produced hydrogen is more valuable to the refinery plant than the ethylene plant; a portion of hydrogen can be transferred to the oil refinery, as well as FO and CG from the furnace output.

This optimised integration is beneficial in many ways, implementing changes in requirements for each plant that should lead to mutual improvements, while also increasing production levels using available process technologies. Each plant is mathematically formulated separately as well as specifying their connection to minimise

externally purchased feed material, with the overall model based on the work of Zhao et al.(2017). The simplification of the model involved the removal of the time limits that many variables and parameters considered. Additionally, using literature values instead of a range, assisted in streamlining the problem. Another simplification method was assigning pre-calculated values to some variables that were involved in equations to derive coefficients, temperature, etc. for units such as the furnace. This act makes the model less complex with a lesser amount of equations to be solved. Through these alterations to their model, we developed a simpler, more-straight forward expression of this integration leading to a novel approach.

The integrated models' objective function maximizes the profit by considering the revenue of refinery and ethylene plant sales, raw material cost for both plants, inventory costs, equipment and maintenance costs. This objective function is detailed in Eq. (1).

$$\begin{aligned} Profit = {} & \sum_t \sum_{c \in CP(C)} pri(c) * SC(c,t) + \sum_t \sum_{c \in CE(C)} pri(c) * \\ & SC(c,t) + \sum_t \sum_{c \in CU(C)} pri(c) * SC(c,t) - \sum_{c \in RR(C)} \sum_t pri(c) * \\ & PC(c,t) - \sum_t \sum_{c \in CU(C)} IN(c,t) * INC(c) - \sum_t \sum_{u \in UP(U)} FR(u,t) * OPC(u) - \\ & \sum_{c \in RE(C)} \sum_t pri(c) * SM(c,t) - \sum_t \sum_{c \in RE(C)} PEN(c) * INC(c) - \\ & \sum_t \sum_{u \in US(U)} FU(u,t) * OPC(u) - \sum_t \sum_f Z(u,t) * SEC(f(u)) \end{aligned} \quad (1)$$

The first term in Eq. (1) depicts the revenue of product sales from the oil refinery, $pri(c)$ being the price of material and $SC(c,t)$ the amount of material sold. The second and third terms are the revenue of the ethylene plant products and intermediates, respectively. The fourth, fifth and sixth terms take the costs for raw material, inventory and processing into account with $PC(c,t)$ being the amount of material purchased, $IN(c,t)$ the material inventory, $INC(c,t)$ inventory cost, $FR(u,t)$ the flow rate and $OPC(u)$ the price of unit operation. The last four terms are demonstrating the cost for the supply for the ethylene plant, penalty and material switching costs as well as the cost of operating the separation columns. Additional equations are implemented for this model, which are not presented here due to space limitations, that depict non-linear algebraic constraints for the amount of commodities sold, market demand, unit capacity, flowrates, operation limitations, material balance for each unit, inventory economic penalty, and inventory capacity.

3. Results

The proposed mathematical model, implemented in GAMS, is applied to a typical oil refinery and ethylene production plant in the U.K over a 24 hour period. It requires a number of parameters such as price, capacity, properties, supply, demand, product specifications and process yield, which are not calculated but defined using (BOC, 2017), (Deloitte, 2012) and (Oil and Gas Journal, 2014). The simplified model contained a total of 40 equations with 23 variables while considering the demand of material to be equal to the amount of material sold as well as using only one type of crude oil for the oil refinery section, assuming the maximum capacity of 200,000 bbl/day in the CDU. Furthermore, the physical and chemical properties of the materials and their intermediates from the blending processes were considered, however, the utility costs for both the oil refinery and ethylene plant, were not.

The main units implemented in GAMS for the oil refinery were the CDU, FCC, CRU, DS and blenders having the products and intermediates of gasoline, diesel, kerosene, fuel oil, fuel gas, ethane and propylene. Meanwhile, the main units modelled for the ethylene production plant are the series of furnaces and separation units. These units produce ethylene, propylene, butadiene, benzene, C4 and C5.

The feed required for the ethylene plant is sourced from the refinery products having the values obtained from the optimisation of the oil refinery presented below:

Table 1. Amount of material produced in the oil refinery after optimisation that is sent to the ethylene production plant

Material	Amount (t)
Ethane	10
Naphtha	30
AGO	345
HVGO	380

Table 2.The capacity of units chosen by the solver in order to optimise the plant.

Unit	Capacity (t)
CDU	77,2048
FCC	85,824
HDS	85,824
CRU	80,460
GB	237,551
DB	237,551

All three models were formulated as an MINLP problem solved with the BARON solver (Tawarmalani and Sahinidis, 2005) and using GAMS version 24.8.5 with a compilation time of 0.312 seconds.

The table below represents the profit of each plant individually followed by their integration.

Table 3. Demonstrating the profit of the oil refinery, ethylene production plant, and their integration after implementing the proposed model in GAMS

Plant	Profit (million UK pounds)
Oil Refinery	1.28
Ethylene Production	0.475
Integrated Oil Refinery and Ethylene Production Plant	13.46

4. Conclusions

In this work, a mixed-integer nonlinear programming model has been proposed for the integration of an oil refinery and an ethylene production plant. Each plant was modelled separately and then integrated by adding additional equations followed by their implementation in GAMS. The aim was to use simplified models to solve the problem in a timely manner and thus resulting in a higher revenue for the plants. Using data from a typical oil refinery and ethylene plant in the UK, the models were implemented in GAMS producing the results demonstrated in Table 3.

The challenges encountered for this problem are mainly due to the simplification in certain units resulting in a possibility of less realistic modelling which leaves room for improvement as well as the issue of restraining the model. This has resulted in infeasibilities since less bounds are involved and fixed numbers are presented for simplicity. This has been tackled through implementing different relaxation techniques such as assigning artificial variables as well as using certain options in the GAMS coding to identify the infeasibilities so as to overcome them.

In conclusion, through this integration there is an increase in the profit for both plants, showing the integration to be highly beneficial. The high increase in profit after the integration is due to merging the two plants and using the intermediates from the oil refinery as opposed to purchasing them from an outside source. Not only does the plant benefit from reducing the external feed purchases, it also benefits from upgrading the quality of the final products. Comparing the results, this proposed study aiming to connect the two plants as efficiently as possible, demonstrates the potential of profit increase for both plants compared to the state of operating them individually, which is also depicted in Table 3. This method also gives the opportunity of optimising each plant individually, increasing the profit for each plant, which can be seen in Tables 1 and 2 by choosing the best option of operation regarding the unit capacity, minimising costs. Through this implementation, the best options of materials and units are chosen to have the most beneficial impact on the integration and the end profit. The model proposed is also very versatile as it could be used for further integration regarding similar combinations of production plants.

Integration of Optimal Cleaning Scheduling and Flow Split Control for Crude Oil Fouling Mitigation in the Operation of Refinery Heat Exchanger Networks

Federico Lozano Santamaria[a*], Sandro Macchietto[a]

[a]*Department of Chemical Engineering, Imperial College London, SW7 2AZ, UK*
f.lozano-santamaria16@imperial.ac.uk

Abstract

Fouling in heat exchangers, a slow dynamic process, significantly reduces their thermal and hydraulic performance. For heat exchanger networks (HENs) in particular, mitigation alternatives are needed to restore a profitable and safe operation. Controlling the flow rate distribution in parallel branches of the network is one option, periodically cleaning selected heat exchangers another. These two strategies have been traditionally addressed separately or sequentially, but there is a strong interaction between them. We propose i) a general formulation to model heat exchanger networks under fouling, suitable for ii) the simultaneous optimal control and optimal cleaning scheduling. The resulting large scale dynamic optimization problem with binary variables (MINLP) is reformulated as a mathematical program with complementarity constraints (MPCC) which is solved efficiently for networks of industrially relevant size. The benefit of integrating the two decision layers is demonstrated in a case study for a crude oil preheat train, where the simultaneous solution of the two problems leads to a 25 % savings in operational cost.

Keywords: heat exchanger networks; energy integration; optimisation, MPCC; scheduling and control.

1. Introduction

Improving the energy efficiency of chemical processes is a primary objective in the context of sustainable and profitable operations. Large heat exchanger networks play an important role in energy recovery of chemical processes, where the hot outlet streams of the process are used to heat the cold inlets. Oil fractioning is an energy intensive operation due to the large amount of crude oil processed, and around 65% of the energy necessary for fractioning can be recovered in the pre-heat train (Yeap et al. 2004), with the rest provided by a furnace. However, the efficiency of heat exchangers decreases over time because of the undesired progressive deposition and accumulation of material over the exchange surfaces (fouling). This deposit increases the thermal resistance and reduces the available flow area, which increases pressure drops. The combined effect leads to higher furnace duty and operational cost (Muller-Steinhagen and Zettler 2011).

Fouling mitigation in heat exchanger networks is necessary to maintain the desired operation for long periods, and to satisfy process constraints such as limits on pressure, temperature, and energy consumption at the furnace. Periodical cleaning of a heat exchanger can restore its efficiency (completely or partially, depending on the method), but choosing which exchanger to clean at any specific time, the cleaning sequence, and

the cleaning method is not an easy task. Moreover, when an exchanger is being cleaned, flows, pressure drops, temperatures, deposition and energy recovery in the network will shift significantly. After a clean unit is restored, the flow rate distribution can be changed to enhance heat transfer and recover more energy by preferentially using the clean(er) unit. Thus, the heat exchanger network operates dynamically, and significant changes can be implemented after the cleanings to improve the efficiency of the process.

In principle, solving simultaneously the optimal control and optimal cleaning scheduling problems for HENs should reduce energy consumption by a larger fraction than using only one strategy. However, the integrated problem is very challenging due to its large scale, nonlinearities, large number of binary variables, and different time scales involved. This paper addresses fouling mitigation for the hot end of a refinery pre-heat train using optimal control and optimal cleaning scheduling strategies, with sufficiently detailed models. It further proposes to reformulate the MINLP problem as a mathematical program with complementarity constraints (MPCC) to solve the integrated problem.

2. Problem formulation and case study

The following formulation is general for any HEN undergoing fouling. The HEN is modelled as a directed multigraph network in which each stream type corresponds to a graph, and the connection between two nodes define an arc. The nodes of the network are heat exchangers, sources, sinks, mixers, and splitters, but it is only at the heat exchanger nodes that the streams of two different graphs interact transferring heat. The heat transfer model considered for a heat exchanger is a lumped parameter model subject to fouling based on the definition of P efficiency and number of transfer units (NTU).

To define a consistent mathematical model for the optimal cleaning scheduling of any network of heat exchangers the following sets and indexes are defined:

- $HEX = \{1,2,\dots,n_{HEX}\}$. Set of heat exchangers in the network.
- $Sp = \{1,2,\dots,n_{Sp}\}$. Set of splitters in the network
- $Mx = \{1,2,\dots,n_{Mx}\}$. Set of mixers in the network
- $So = \{1,2,\dots,n_{So}\}$. Set of source nodes
- $Si = \{1,2,\dots,n_{Si}\}$. Set of sink nodes
- $Nodes = HEX \cup Sp \cup Mx \cup So \cup Si$. Set of all the nodes in the network
- $Stream\ types = \{1,2,\dots,n_F\}$. Set of stream types in the network, where each type is a different fluid
- $Arcs = \{(i,j,k) | \exists (i,j,k) \in Nodes \times Nodes \times Stream\ types\}$. Set of arcs that define the connection between nodes for a given stream type.
- $Cleaning\ types = \{1,2,\dots,n_{cl}\}$. Set of distinct types of cleanings that can be used.

The cleanings of the heat exchangers are modelled by introducing bypasses around the shell and the tube sides. The time horizon is discretized in a fix number of periods, but the length of each period is variable. If a heat exchanger state is “being cleaned” at a specific period the length of the period is equal to the cleaning time, while if the exchanger state is “operating” the length of the period is a decision variable with a lower and an upper bound. To increase the accuracy of the integration each period has a fixed number of internal discretization points. Here, orthogonal discretization in finite elements with Radau points is used. This approach of dividing the time horizon in periods, with additional discretization points within the periods allows capturing all the dynamics of the process, from fast ones (e.g. changes of flow rates, valve openings) to slow ones (e.g.

fouling, deposit growth, cleanings). It also guarantees accuracy of the solution in all the time scales involved in the problem.

The following set of equations define the equality constraints in the overall model:

- Mass balances at each node.
- Energy balances at each node.
- Fix inlet temperature at source nodes.
- Assignment of each exchanger state in the network (here, "being cleaned" or "operating").
- Time representation. Non-decreasing starting time of events and events duration.
- Pressure drop equations for the tube side.
- Change in flow diameter of the tubes due to the deposition of material.
- Disjunction for the definition of the length of the period.
- Disjunction between the heat transfer model (P-NTU) for the operating mode and no heat transfer for the cleaning mode.
- Disjunction between the fouling (Ebert-Panchal) and ageing models (first-order kinetics) for the operating mode, and the restoration of the fouling resistance and deposit composition for the cleaning modes. These two models allow predicting the deposit thermal resistance based on its composition (ageing), on the thermal conductivity of the components, and on the deposit thickness. It is assumed that the fresh deposit and the aged deposit do not mix, but form two distinct layers.

The fouling rate and the ageing rate are differential equations with slow dynamics that over long time scales cannot be ignored. In addition, the cleanings introduce discontinuities in the differential equations that have to be handle appropriately. Therefore, changes in operation mode are only allowed between two periods.

The objective function selected, Eq. 1, is the minimization of the total operation cost, which is composed by the loss of throughput, furnace fuel cost, CO2 emission cost, and cleaning cost over the operation horizon, τ_p (Coletti and Macchietto, 2011).

$$\min J = \sum_{p \in Periods} \tau_p \int_0^1 \left[P_{kg} m_{p,l}^{prod} + P_{fuel} \frac{Q_{f,p,l}}{\eta} + P_{CO_2} m_{CO_2} \frac{Q_{f,p,l}}{\eta} \right] d\hat{t} + \sum_{i \in HEX} \sum_{p \in Periods} P_{cl,p,i} \tag{1}$$

There are continuous decisions, related to the flow rate distribution in the network controlled by the inlet flow rates and split fractions, and binary decisions for the assignment and timing of the cleanings. Therefore, the dynamic optimization problem after discretization is defined as a large scale MINLP. To solve the problem the binary variables are relaxed and bounded between zero and one, and complementarity constraints and slack variables are introduced, resulting in a mathematical problem with complementarity constraints, MPCC. Complementarity constraints are a type of constraints between two variables that forces one to be at its bound and the other to be free, thus it is an alternative to model the logical OR operator. Eq. (2) – (4) show the complementarity model for the optimal control and cleaning scheduling problem, where $y_{i,p}$ is a variable used to assign a cleaning to a heat exchanger *i* at a specific period *p*. The

symbol $\perp$ indicates complementarity between the two variables, and in this case the bilinear product is used as complementarity function.

$$0 \leq y_{i,p} \perp s^{b}_{i,p} \geq 0, \qquad \forall i \in HEX, p \in Periods \tag{2}$$

$$0 \leq \left(1 - y_{i,p}\right) \perp s^{a}_{i,p} \geq 0, \qquad \forall i \in HEX, p \in Periods \tag{3}$$

$$0 \leq s^{a}_{i,p}, s^{b}_{i,p} \leq 1, \qquad \forall i \in HEX, p \in Periods \tag{4}$$

The MPCC problem formulation for the optimal control and cleaning scheduling of heat exchanger networks is treated as a NLP. However, the complementarity constraints define an optimization problem which is not well posed because it does not satisfy any constraint qualification criteria (Herty and Steffensen 2012). The complementarity constraints are relaxed by defining an inequality and a ϵ parameter for regularization, $Reg(\epsilon)$. The formulation is illustrated in Eq. (5). The problem is solved in a sequence, decreasing the value of ϵ such that when $\epsilon \to 0$ the solution of the MPCC problem is equivalent to the solution of the original MINLP problem.

$$\begin{aligned} Reg(\epsilon): \min_{x,y,z} & f(x,y,z) \\ s.t. & \; h(x,y,z) = 0 \\ & g(x,y,z) \leq 0 \\ & x_i y_i \leq \epsilon, \;\; i = 1,2,\dots,q \\ & x \geq 0, y \geq 0 \\ & x \in X \subseteq \mathbb{R}^n, z \in Z \subseteq \mathbb{R}^n \\ & 0 \leq y \leq 1 \end{aligned} \tag{5}$$

For a more comprehensive discussion of the detailed dynamic model of heat exchangers, continuous time formulation, time discretization, and MPCC reformulation, the reader is referred to Lozano Santamaria and Macchietto, 2017.

The problem analysed here is a typical refinery network structure in which the crude oil is preheated in heat exchangers in a series configuration, with the flow split in two branches. Figure 1 displays the networks structure and the streams involved. All the exchanger are tube and shell heat exchangers, and the operational conditions and design specifications are taken from previous works that are based on relevant industrial information and plant data (Coletti and Macchietto 2011).

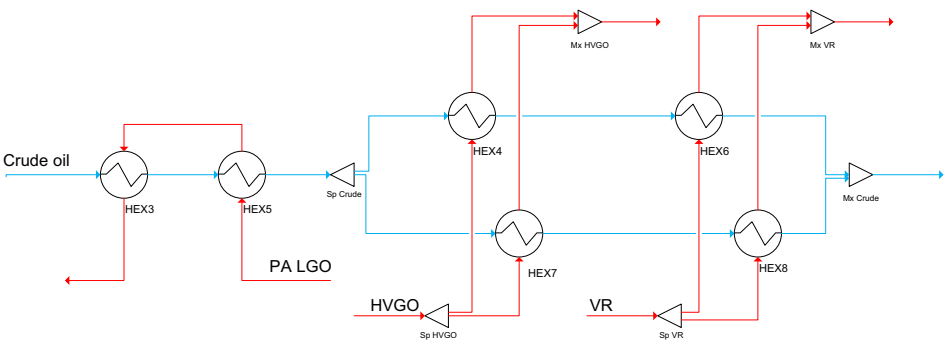

Figure 1. Case study of a refinery preheat train with parallel branches

3. Results and discussion

The regularization parameter, ϵ, is reduced from an initial value of 10 by a factor of 0.1 to a value of 1x10-6 when the optimality and integrity conditions are deemed satisfied. The MPCC problem is modified when the regularization parameter is updated, and solved again. Each modified problem is initialized from the previous solution, Lagrange multipliers and gradients to facilitate the convergence. This way the problem bounds are continuously tightened and the MINLP relaxation gets closer to the original problem.

Four scenarios are analysed: i) no mitigation (NM), with split fractions and flow rates fixed and no cleanings, ii) optimal control (Ctrl), where only the dynamic flow rate distribution in the network is optimized, iii) optimal cleaning scheduling (Sch), where number and timing of cleanings are optimised for fixed flow rates, and iv) simultaneous optimal control and cleaning scheduling (Sch + Ctrl), where both flow distribution and cleanings are optimised. In all cases the starting point is a clean network and horizon 365 days. Figure 2 shows the profiles of two important network performance indicators, the furnace duty (the additional energy required in the furnace to satisfy a fixed distillation column inlet temperature), and the coil inlet temperature (CIT), the temperature before the furnace. In this case, the optimal control solution exhibits almost the same behaviour as the NM (no mitigation) case. Changing the flow distribution alone is not sufficient to mitigate fouling. Scheduling alone with fixed split fractions results in 5 cleanings and a furnace duty well below that of the no mitigation case during almost all the operating window. The combination of scheduling and control results in 6 cleanings and similar profiles. The changes are occasionally more drastic and responses significantly different from the Sch optimal solution, but give an economically significant improvement of about 10 °C in the CIT temperature at the end of the period.

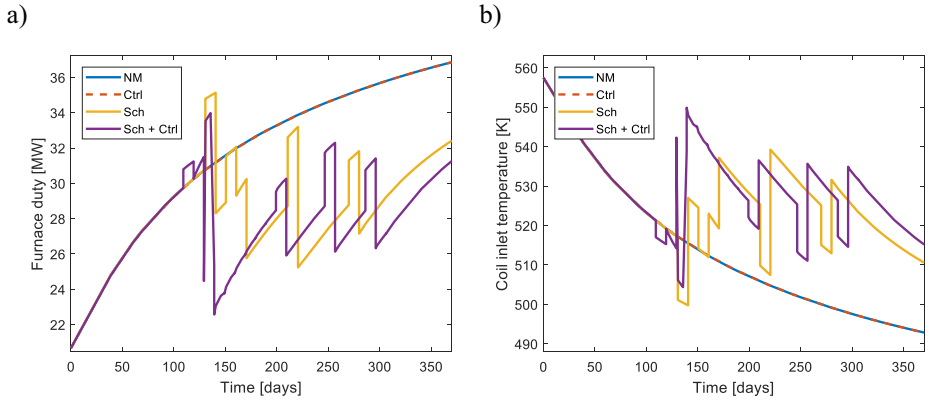

Figure 2. Case study furnace duty (a) and CIT (b) for the optimal cleaning schedule.

Table 1 summarizes the results for the four scenarios analysed in terms of computational time, cleaning schedule, and economic and energy savings relative to the no mitigation case. Introducing flow split control changes the cleaning scheduling significantly: one decision affects the other and vice versa. The simultaneous scheduling and control solution has one additional cleaning compared to case when only the schedule is optimised. When the control variables are available for manipulation over time, the additional cost of an extra cleaning is justified because the changes of flow distribution allow recovering more energy and reducing the operational cost.

Table 1. Computational results and optimal cleaning scheduling for large HEN.

	NM	Optimal control	Optimal scheduling	Simultaneous solution
CPU secs	28.11	197.8	8,407.9	2,466.76
Cleaning schedule (Time of cleaning in days, HEX no.)	X	X	(131, HEX4) (151, HEX7) (161, HEX6) (211, HEX8) (270, HEX7)	(109, HEX7) (119, HEX8) (129, HEX4) (199, HEX6) (247, HEX4) (286, HEX6)
Energy savings [MWd]	0.0	4.70	1,186.0	1,481.7
Savings [MM-USD]	0.0	0.003	0.864	1.080

Savings with optimal control of flow split alone are just $ 0.003 million compared to $ 0.864 million when optimizing the cleaning schedule alone, over 1 year of operation. However, when combined the two approaches have a strong synergistic effect that increases savings by a further 25 % to $ 1.08 million. By optimizing these two decision problems simultaneously, operation of heat exchanger networks under fouling can be improved, the operational cost of the process reduced, and the operational time of the network increased. The operating policies obtained can be practically implemented. Computation times are quite acceptable. All solutions are possibly local optima.

4. Conclusions

Flow distribution control and the cleaning scheduling are two fouling mitigation alternatives that individually can improve the performance of heat exchanger networks. Optimising them simultaneously can significantly reduce the operational cost and the energy consumption of the process. The formulation of the integrated problem presented is general, and its efficient solution strategy based on complementarity constraints allows solving large scale dynamic optimization problem with discrete variables involving different time scales with a high fidelity model, in a reasonable computational time, even for the network of realistic size and complexity considered.

Simultaneous Controllability Analysis and Cyclic Scheduling of Grade Transitions for the Continuous Multi-product Chemical Processes

Yue Li, Jiawen Wei, Zhihong Yuan*

Department of Chemical Engineering, Tsinghua University, 100084 Beijing, China
zhihongyuan@mail.tsinghua.edu.cn

Abstract

The smart production of high-end polymers with agility and flexibility calls for the optimal production sequences and high-efficient control strategy for grade transitions with desirable dynamics. Conducting controllability analysis can not only guarantee the desirable dynamics but also relieve the burden of detailed controller. Therefore, this paper addresses a framework to integrate the controllability analysis and the scheduling of grade transitions for the continuous multi-product chemical process. Zero dynamics is used to evaluate the controllability over the wide design/operating zone. The series of limit points of the bifurcation analysis for zero dynamics divides the whole zone into Non-minimum and Minimum phase ones. The changing trajectories of limit points and the grade transition time are extracted as the function of key design/operating variables according to our proposed machine learning method, respectively. These extracted functions are then introduced to the scheduling framework. By solving the resulted MINLP model, the production time, production sequence, and key design/operating parameters can be optimized to maximize the economic benefit while roughly guaranteeing the desirable dynamic behavior during transitions. A polymerization of methyl methacrylate is studied to demonstrate the availability of the proposed method.

Keywords: Scheduling; Controllability; Data-driven model, MINLP

1. Introduction

The conventional sequential approach for scheduling problem takes economic benefits as the objective function to obtain the optimal production sequence (Sahinidis and Grossmann, 1991). For example, the traditional sequential approach for scheduling and controlling grade transition of polymerization usually generates very long transition time or undesirable transition curve. The basic issue is that the inherent behaviors such as limited cycle, unstable characteristics, and non-minimum phase (NMP) behavior are ignored. To treat such problem, a new approach which integrates scheduling and control has been extensively investigated (Baldea and Harjunkoski, 2014; Dias and Ierapetritou, 2017). Such approach usually formulates a computationally-expensive mixed integer dynamic optimization (MIDO) model. MIDO model can be transferred to a large-scale mixed integer nonlinear programming (MINLP) model. MIDO model therefore might be inapplicable in complex production process such as polymerization. Furthermore, many inherent undesirable behaviors such as input multiplicity cannot be tackled by conventional controller and even nonlinear model predictive controllers.

As known, the control performances are heavily determined by the above inherent behaviors, and these inherent behaviors are basically determined by process design. It

should be pointed out that modifications of a process design itself, such as changing inputs or outputs, operating points, values of design parameters, can sometimes affect the dynamics of the process significantly more than changes in the controllers. Therefore, this paper addresses a framework to integrate the controllability analysis and the scheduling of grade transitions for the continuous multi-product chemical process. The aim of the proposed framework is to determine those key design/operating parameters which would roughly avoid the undesirable inherent characteristic (NMP behavior) while guaranteeing the economic performance through the optimal scheduling.

In our work, zero dynamics is used to evaluate the phase behavior over the wide design/operating zone (unstable zero dynamics denote NMP behavior, while stable zero dynamics mean MP behavior). The series of limit points of the bifurcation analysis for zero dynamics divide the whole zone into NMP and MP ones. The changing trajectories of limit points, the transition time among different grades are then extracted as a function of key design/operating variables, respectively. These obtained functions are added to the scheduling framework as inequality constraints. By solving the resulted MINLP model, the production time, production sequence, and key design/operating parameters are optimized to maximize the economic benefit while roughly guaranteeing the desirable dynamic behavior during transitions. A polymerization of methyl methacrylate is finally studied to demonstrate the availability of the proposed method.

2. Method Description

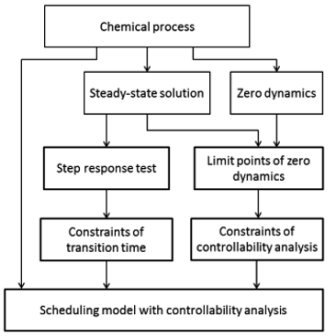

Figure 1. A schematic diagram of integrated scheduling and controllability analysis

2.1. Zero Dynamics and its Bifurcation Points

Controllability is a dynamic characteristic that describes the achievable control performance. Given a chemical process that is described as differential algebraic equations, one can easily extract its zero dynamics (Yuan et al., 2012). Unstable zero dynamics denotes the non-minimum phase behavior implies which means poor controllability. Stable zero dynamics means that the original chemical process exhibits minimum phase behavior. The bifurcation analysis for zero dynamics can divide the whole operating zone into NMP and MP ones. Based on our proposed machine learning method named hybrid symbolic regression and mathematical programming (Wei and Yuan, 2018), the changing trajectories of limit points will be extracted as a function of key design/operating variables.

2.2. Integration of scheduling and controllability analysis

The framework that integrates the scheduling and controllability analysis for a continuous multi-product chemical process is described by Figure 1.

(1) Set-up differential algebraic equations to describe dynamic chemical process.
(2) Solve the differential algebraic equation to obtain the steady-state solutions at different value of operating/design parameters via homotopy continuation.
(3) Extract the zero dynamics of the chemical process and obtain the distribution (changing trajectories) of the limit points of zero dynamics through bifurcation analysis.
(4) Build the function that describes the relationship between changing trajectory of limit points and key design/operating variables.
(5) Set the function that bridges the transition time among different grades and key design/operating variables.
(6) Introduce the functions obtained in steps (4) and (5) into the scheduling framework. Solve the MINLP model to get the optimal schedules and design/operating parameters.

2.3. Mathematical programming model for integrated scheduling and controllability analysis

The major assumptions in the model:

A1. Cyclic production schedule is desired

A2. Demand rate of each kind of product is constant

The following are the parameters of conventional model:

c_i = Production cost of product i per unit mass
d_i = Demand rate of product i
m_i = Unit inventory holding cost for product i
r_i = Production rate of product i
s_{ij} = Transition cost when production is changed from product i to j
τ_{ij} = Transition time when production is changed from product i to product j

The following are the variables:

H = Length of cycle
T_k = Length of time slot k
W_{ik} = Amout of product i produced during time slot k
X_{ik} = Binary variable to denote assignment of product i and slot k

The binary variables defined as follows:

$$X_{ik} = \begin{cases} 1 \text{ if in time slot } k \text{ the product } i \text{ is assigned} \\ 0 \text{ otherwise} \end{cases}$$

$$\min = \sum_i \sum_k c_i r_i \frac{[T_{ik} - \sum_{j \neq i} \tau_{ji} X_{jk-1}] X_{ik}}{H} + \sum_i \sum_j \sum_k s_{ij} \frac{X_{ik-1} X_{jk}}{H} + \sum_j \sum_k m_i W_{ik} \tag{1}$$

$$\sum_i X_{ik} = 1, \quad \forall k, \tag{2}$$

$$H = \sum_k T_k, \tag{3}$$

$$W_{ik} = r_i \left[T_k - \sum_{j \neq i} \tau_{ji} X_{jk-1} \right] X_{ik}, \quad \forall i \, \forall k, \tag{4}$$

$$\sum_k \frac{W_{ik}}{H} = d_i, \tag{5}$$

$$X_{ik} = \{0,1\}, \quad T_{ik} \geq 0, \quad W_{ik} \geq 0, H > 0 \tag{6}$$

$$f_i(u_{i1}, u_{i2} \ldots u_{ir}) = 0, \tag{7}$$

$$c_i = f_{ci}(u_{i1}, u_{i2} \ldots u_{ir}), \tag{8}$$

$$r_i = f_{ri}(u_{i1}, u_{i2} \ldots u_{ir}), \tag{9}$$

$$\tau_{ij} = f_{\tau ij}(u_{i1}, u_{i2} \ldots u_{ir}), \tag{10}$$

$$S_{ij} = f_{sij}(\tau_{ij}), \tag{11}$$

$$g((u_{i1}, u_{i2} \ldots u_{ir}) \geq 0, \tag{12}$$

$$U_{rMin} \leq u_{ir} \leq U_{rMax}, \tag{13}$$

Since the demand at unit time of each product is constant, so the selling revenue is constant at unit time. Thus the objective function as shown in Equation (1) is to minimizing the inventory cost, transition cost and feedstock cost to maximize the profit at unit time. Equations (1) ~ (6) actually describe the conventional scheduling model of multi-product chemical process. Equation (7) is constraint of operating variables on production point to ensure that the chemical process produces product i. Equation (8) denotes the relationship between operating parameters and production cost. Equation (9) is the functional relationship between operating parameters and production rate. Equation (10) is the constraint of transition time. Equation (11) represents the functional relationship between transition cost and transition time. Equation (12) denotes the constraints of controllability analysis.

3. Case Study and Discussion

We take the free-radical polymerization of methyl methacrylate (MMA) (Daoutidis P, 1990) as an example to illustrate the efficiency of our proposed framework. The temperatures of three operating points regarding products 1, 2, 3 are assumed to be 350K, 360K, 370K, respectively. Our previous contribution demonstrated that the open-loop steady-state multiplicity and the stability/controllability of the carried case are heavily depended on the flow rate of initiator F_I and the cooling water flowrate F_{cw}(Yuan Z, 2011). The objective of our novel scheduling is not only to seek the optimal production sequence but also guarantee desirable controllability properties. In addition to the short transition time, the optimal decision through the controllability analysis can enable F_I as the only operating variable to fulfil the desirable transitions. In other words, F_{cw} will keep constant. Through taking the extensive multiplicity analysis around each temperature, the specific relationship between F_I and F_{cw} can be extract as an explicit function $F_I = f(F_{cw})$. So in the present work, F_{cw} will be optimized to meet all of the above requirements.

As shown in Figure 2, the red zone means the undesirable zone with non-minimum phase behaviour, the green zone means the desirable zone with good controllability properties.

Through the hybrid symbolic regression and mathematical programming method, the distribution of bifurcation point can be extracted as the function of F_I and F_{cw} as mentioned in Equation (12). For the conventional scheduling, for each point, F_{cw} is as constant, F_I is also given. Through solving MINLP model shown by Equations (1) ~ (13), the results and the comparisons with conventional scheduling are discussed as follows.

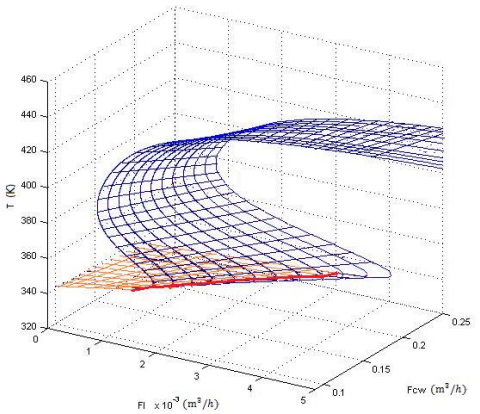

Figure 2. Zone classification of Phase Behavior for space surface of T-F_I-F_{cw}.

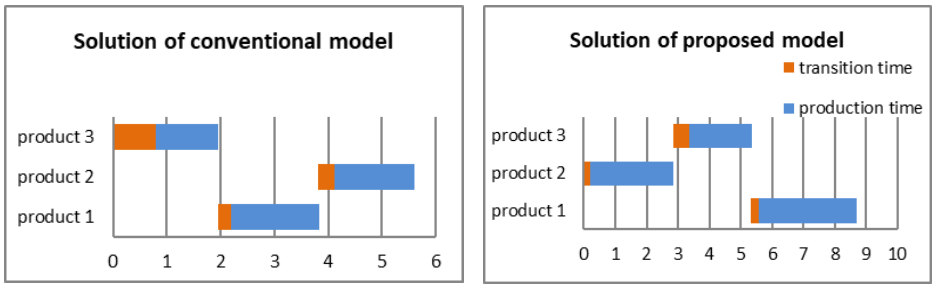

Figure 3. Comparisons on the Gantt chart of Production Sequences.

Figure 3 gives the Gantt Chart of Production Sequences. Table 1 outlines the detailed value of relevant inventory cost, transition cost, and production cost. Clearly, the production sequence from conventional scheduling and our scheduling with controllability is totally different (3-1-2 v. s. 2-3-1). From Table 1, it can be easily found that the optimized F_{cw} is lower than the value given in conventional scheduling. Due to the lower F_{cw} and then the resulted F_I, the production time of each grade is longer than the conventional scheduling. The pair of F_I and the optimized F_{cw} enables the system exhibits good controllability properties such as shorter total transition time. The conventional scheduling enjoys a shorter cyclic time at the cost of the higher inventory cost due to the longer transition times among different grades. The lower F_{cw} can further help the scheduling reduce the production cost. Thus the total cost of conventional scheduling is higher.

It should be mentioned that the uncertainties (accurate of the surrogates) have not been considered in our work. Clearly, the accurate of the surrogates reflects the distribution of the limit points. In the future, the proposed method will be tested by more complex process while also considering the above mentioned uncertainties.

Table 1. Detailed Results of Costs.

	Conventional model	New model
$F_{cw}(m^3/h)$	0.1588	0.117
$F_l(m^3/h)$	0.00175-0.00425-0.00275	0.00200-0.001375-0.002375
Cyclic time (h)	5.597	8.732
Production sequence	3-1-2	2-3-1
Time slot (h)	1.960-1.844-1.793	2.851-2.504-3.377
Production time (h)	1.152-1.615-1.48	2.639-1.992-3.134
Transition time (h)	0.808-0.229-0.313	0.212-0.512-0.243
Total cost ($/h)	152.148	130.665
Inventory cost ($/h)	13.515	21.039
Transition cost ($/h)	38.745	14.528
Production cost ($/h)	99.889	95.099

4. Conclusion

A new method to deal with scheduling problem while considering controllability properties for continuous multi-product chemical processes was proposed. By integrating the constraints which were represented by data-driven surrogate models, the scheduling model was equipped with the relationships between the changing trajectories of limit points. Taking the polymerization of methyl methacrylate as an example, the efficiency of the proposed scheduling model was demonstrated. Also, this work successfully promoted the switch from quantitative controllability analysis to qualitative controllability assessment.

Co-current Partial Condensation of a Multicomponent Vapor Flowing Down Vertical Tubes – Cooling and Purification of a Reactive Mixture

Yihui Tom Xu

DuPont, 200 Powder Mill Road, Wilmington, Delaware 19803, USA
tom.xu@dupont.com

Abstract

Reactive multicomponent vapor condensation inside vertical tubes involves simultaneous transfer of mass and energy between vapor and condensed thin liquid film. Among the modeling tools most popular is the film theory where diffusional interactions, particularly in the vapor phase, are of critical importance for condensable components. In this work, linearization of the Krishna-Standart matrix based manipulations was made by extending the binary models of Colburn and Drew to multicomponent systems using Ackermann's correction factor in the diffusional mass flux calculations. Preliminary results indicate sweeping effect of the light species from the vapor phase bulk to the interface by the heavy component near the tube entrance. The light product compound can condense and react even if its physical driving force for condensation is negative throughout the tube.

Keywords: multicomponent reactive condensations, simultaneous momentum, mass and heat transfer, reactive separations, film theory based non-equilibrium model.

1. Introduction

Many industrially important vapor phase reactions are equilibrium controlled and highly exothermal in nature which leads to low conversions and high reactor exit temperatures. Jiang et al. (1997) developed tools for condensed mode cooling of polyethylene reactor gas in a tubular heat exchanger before it is recycled back to the reactor to shift the reaction forward. Sometimes the product needs to be purified or recovered by condensation of less volatile heavier by-products. Botsch and Stephan (1997) presented dynamic design tools for condensing hydrocarbons from a volatile non-condensable gas. Reactions often occur in the condensed liquid film under reduced temperatures so the end-product purity, yield and final temperature are determined by the relative rates of mass and heat transfer, and of reactions in the liquid film. While studying combined processes of NH_3 recovery from CO_2 containing waste water, Mackowiak et al. (2009) and Weiland and Taylor (1982) concluded that although one can usually simplify diffusional interactions and liquid reactions in absorption and stripping operations, one should not do so for condensations where the fluxes and liquid concentrations of the transferred species are no longer low.

In practice, the vapor mixture could contain non-condensable species, and condensable components which condense in the form of two immiscible liquid phases. This operation's broad importance in industry has brought sustained efforts with theories and tools for its analysis. Ackermann (1937) and Colburn and Drew (1937) developed rate based film model for binary mixtures, followed by the generalization of Fick's Law

applying to film models in the linearized theory of Toor (1964) and Stewart and Prober (1964). A classical general matrix method of implicit solutions to the Maxwell-Stefan equations was developed by Krishna and Standart (1976). This theory was later simplified by Krishna (1981), and Taylor and Smith (1982) to be explicit in computing molar fluxes. This was investigated and summarized in a HTRI document by Sardesai (1994), and in a design manual by Webb (2011). Davis et al. (1979) and Villadsen and Nielsen (1986) studied film reactors of simple first order reactions with rigorous transport models. Higher order and reversible reaction enhancement factors were also studied based on dilute solute assumption for absorption processes (Yue et al. 2013 and Meldon et al. 2007). However, publications on multicomponent condensations in which the condensed species undergo complex reversible reactions in liquid phase are scarce. The situation gets even more complicated when desorption is also involved due to the high volatility of some of the formed reaction intermediate products. This paper presents and solves a rigorous model combining kinetically controlled reversible reactions in the non-dilute liquid condensate film with simultaneous interacting multicomponent condensation and evaporation.

2. Process Description

Figure 1 shows schematics of a vertical shell-and-tube exchanger and falling film in tube for partial condensation of solvents S2, S1, and S3 mixed with product A with increasing volatility, and impurities Imp1 and Imp2 that could condense but do not take part in liquid reactions. For the sake of general applicability, species are not specified but rather, their thermodynamic and transport properties and mutual reactivities are defined. Although very volatile, product A does not have to act as an inert gas in this system. T_V, T_i, T_L, T_W, T_C are temperatures of gas, interface, liquid, wall, and coolant respectively. P, F, Y are system pressure, vapor flow rate and mole fraction respectively. $\delta(z)$ is the film thickness (mm) as function of downflow distance. $U_z(x)$ is the film axial velocity as function of the film thickness (m/s). N_{CV} and N_{VZ} are condensing and downflow gas fluxes respectively.

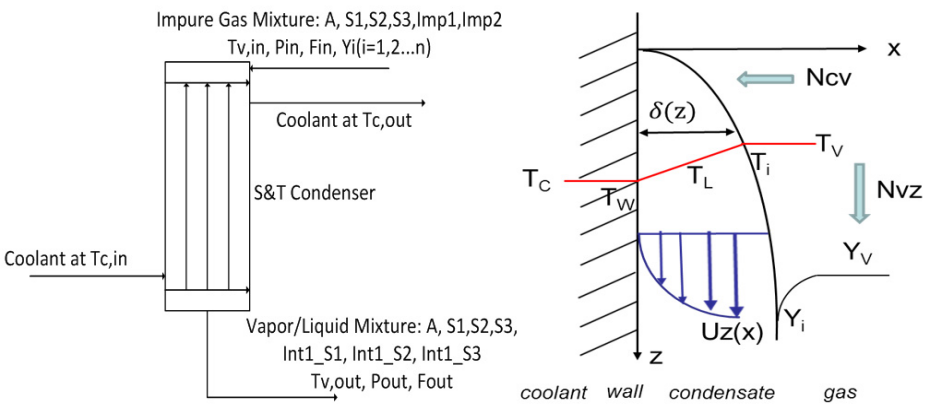

Figure 1. Configurations of a vertical shell-and-tube exchanger and liquid film in tube.

3. Condensate Film Energy and Momentum Balances

Depending on cooling capacity of the tubes the condensate flow can be in the laminar or turbulent regimes. Therefore, uniform or varied temperature and velocity profiles across the film thickness could be generated. Holdup time of a laminar film closest to the tube wall should be longer than that at the gas-liquid interface. If the drag force predominates

over the gravitational force the radial profiles of the axial velocity will be nearly linear with thickness, rather than quadratic. Rates of reactions will be impacted under all these scenarios. Dukler (1959) and Bird et al. (1960) added turbulent transport terms to the standard momentum and energy equations so that transitions from laminar to turbulent flow regimes can be realized in a simple and elegant manner. Charef et al. (2018) also presented rigorous transport equations solving single component tube condensations. The momentum and energy balance equations and their boundary conditions are listed below:

$$\frac{1000}{\delta(z)} * \frac{d\tau_z}{dx} + \rho_{ML} * g = 0 \qquad \text{Motion (g is acceleration due to gravity)} \tag{1}$$

$$\frac{1000}{\delta(z)} * \frac{dq_z}{dx} = 0 \qquad \text{Energy} \tag{2}$$

$$U_z = 0 \qquad @ \text{ x = 0 (no slip at tube wall)} \tag{3}$$

$$\tau_z = \tau_{drag} + P \qquad @ \text{ x = 1 (total stress = drag stress plus momentum)} \tag{4}$$

$$T = T_w \qquad @ \text{ x = 0 (contacting tube wall)} \tag{5}$$

$$T = T_i \qquad @ \text{ x = 1 (gas-liquid interface)} \tag{6}$$

where the terms and variables in the above equations are defined below:

$$\tau_z = 0.001 * \left(\nu_{film} + \nu_{eddy}\right) * \frac{1000}{\delta(z)} * \frac{dU_z}{dx} \qquad \text{Stress} \tag{7}$$

$$q_z = -0.001 * \left(\lambda_L + \nu_{eddy} * c_{pL}\right) * \frac{1000}{\delta(z)} * \frac{dT}{dx} \qquad \text{Heat flux} \tag{8}$$

$$\tau_{drag} = 0.5 * f_{gas} * \rho_{Mv} * (u_{gas} - U_z(@x = 1))^2 \qquad \text{Drag of gas on liquid} \tag{9}$$

$$P = N_{CV} * MW_{cond} * u_{gas} \qquad \text{Momentum transferred by condensing gas} \tag{10}$$

$$\nu_{eddy} = 1000 * \rho_{ML} * n_{Deissler} * U_z * x \left(\frac{\delta(z)}{1000}\right)(1 - exp(-n_{Deissler} * U_z * x * (\frac{\delta(z)}{1000})/(0.001 * \nu_{film})/\rho_{ML})) \qquad \text{Eddy viscosity per Deissler} \tag{11}$$

where $\boldsymbol{n_{Deissler}}$ is a constant. $\boldsymbol{\lambda_L}$, $\boldsymbol{\nu_{film}}$, $\boldsymbol{\rho_{ML}}$ and $\boldsymbol{c_{pL}}$are liquid thermal conductivity, viscosity, density and heat capacity respectively. $\boldsymbol{u_{gas}}$ and $\boldsymbol{\rho_{Mv}}$ are gas axial velocity and density respectively. MW_{cond} is the molecular weight of the condensing vapor.

4. Multicomponent Mass and Heat Transfer

The process being examined here involves large fluxes of the heavy species early in the entrance region which greatly influence the fluxes of the more volatile species and could sweep some of them toward interface. The simplified treatment of gas absorption and reaction into dilute solvent system should not apply here because the condensates are concentrated and the impact of overall flux to individual fluxes could not be ignored. Simplifications of Krishna-Standart method are made in this work by extending the binary models of Colburn and Drew to multicomponent systems using Ackermann's correction

factor in the diffusional flux calculations. Zero-flux vapor mass transfer coefficients are calculated from heat transfer correlations through Colburn-Chilton analogy (1934). All components are condensable and reactions consuming condensed species enhance liquid film mass transfer, so the liquid side mass transfer is not important and the model sets the liquid film resistance to zero. The analysis of Ackermann (1937) is adopted in the bulk vapor sensible heat transfer calculations. All equations for radial and vertical mass and heat balance can be found in the detailed HTRI report authored by Sardesai (1994).

5. Phase & Chemical Equilibrium and Reaction Kinetics

All preferentially condensed solvents react with the more volatile product A to form by-products (intermediates) in the liquid phase. Each individual solvent reacts with A forming first intermediate between A and the respective solvent. Although A could react with the first intermediates to form higher intermediates, only the first reactions have significant rates and only the first intermediates have sizable equilibrium concentrations. These reversible reactions in series can be written as the following:

$$A + S_j \overset{Kx_1}{\Longleftrightarrow} Int_1 - S_j \quad j = 1,\ 2,\ 3\ \textit{(solvents)} \tag{12}$$

$$A + Int_i - S_j \overset{Kx_{i+1}}{\Longleftrightarrow} Int_{i+1} - S_j \quad i = 1,\ 2, \dots, n\ (steps)\ , j = 1, 2, 3 \tag{13}$$

where Kx_{i+1} is the chemical equilibrium constant of the reaction forming respective intermediate, chemical and phase equilibrium equations can be written as the following:

$$K_{x_i - S_j} * a_A * a_{Int_{i-1}-S_j} = a_{Int_i - S_j} \quad i = 2,\ \dots, n+1;\ j = 1, 2, 3 \tag{14}$$

$$y_i P = a_i P_i^{sat} exp(\int_{Psat}^{P} \frac{v_{i,liq}}{RT} dP) \quad i = all\ species\ in\ the\ system \tag{15}$$

note that Poynting pressure correction term in Eq. (15) is not important under moderate pressure, the highest vapor pressure component is product A which is still moderately condensable under the operating pressure. Activity coefficients in $a_i = \boldsymbol{\gamma_i x_i}$ are regressed from experimental total pressure data or estimated from the UNIFAC method. For components showing low concentrations in liquid phase temperature dependent infinite dilution activity model can be used for non-ideal interactions. Reversible reaction rate expressions for reaction step i and solvent j can be written as:

$$R_{x_i - S_j} = k_{i-S_j}(x_A * x_{Int_{i-1}-S_j} - \frac{x_{Int_i - S_j}}{K_{x_i - S_j}}) \quad i = 2,\ \dots, n+1;\ j = 1, 2, 3 \tag{16}$$

$$R_{A-S_j} = -\sum R_{x_i - S_j} \quad i = 1,\ \dots . n \quad \text{for } j = 1, 2, 3 \tag{17}$$

$$R_{S_j} = -R_{x_1 - S_j} \quad \text{for } j = 1, 2, 3 \tag{18}$$

activation energy, equilibrium constants $K_{x_i - S_j}$ and rate constants k_{i-S_j} are all determined from experiments of individual reactions targeting specific solvent S_j.

6. Preliminary Results and Discussions

The combined set of above equations is solved along the incremental length of the tube using Method of Lines. Useful species physical properties are obtained from Aspen Plus® Databank (2015) by working in the environment of Aspen Custom Modeler® version 8.8. Figures 2 and 3 show the mole fractions of species in bulk vapor, the interface and major condensed and formed species in the liquid phase. S2 is the main and heaviest solvent so it condenses first and reacts with condensed A to form Int1_S2. But S1 and S3 are more volatile and react faster with A in liquid and their formed first intermediates show peak

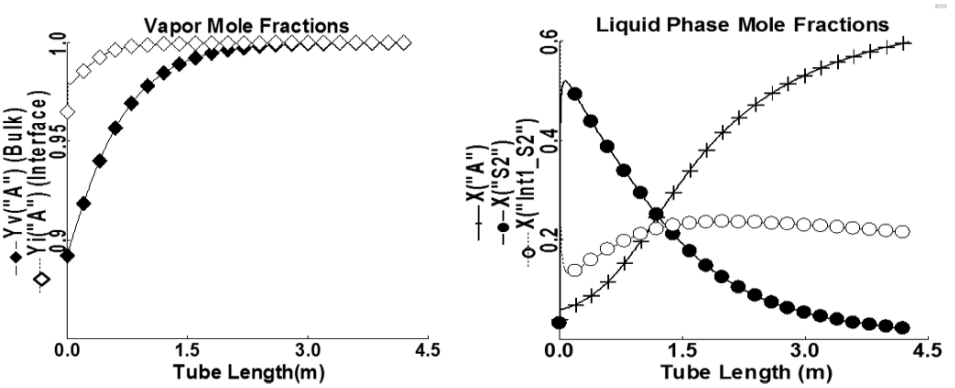

Figure 2. Consistent negative condensing flux of A and liquid profiles of S2 and Int1_S2.

behaviour in the liquid phase, forming higher intermediates by reacting further with A. The initial high S2 flux into liquid film sweeps the lighter species to the interface causing initial higher interface than bulk vapor concentrations for A, S1 and S3. Whereas S1 and S3 fluxes quickly reverse back to positive into liquid due to faster reactions, the physical driving force for A is always negative in the vapor film while it is condensing from the beginning. A's purity increases and the recovery drops as more of it condenses and reacts.

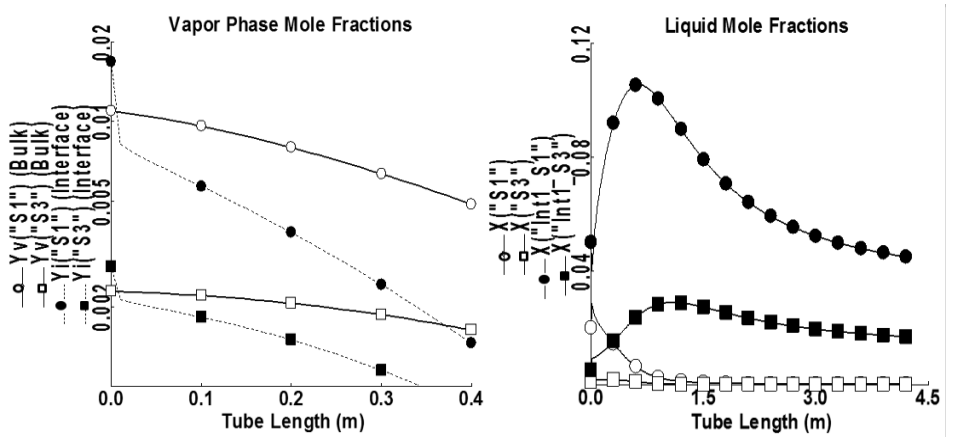

Figure 3. Initial negative condensing fluxes of S1 and S3 (left) and liquid species (right).

7. Conclusions

Rigorous kinetic equations of parallel reversible reactions between several species are introduced into a multicomponent condensation and evaporation system. Preliminary

analysis shows that there are strong interactions between the diffusion fluxes of condensing species, and between mass and heat transfer rates and reaction kinetics. Species could still condense when physical driving force is negative which is the cause of reduced recovery for product A. Strong enhancements on condensation by reactions under the current relative rates of reaction and transport are caused by large concentration driving force and reasonably good solubility of the components in liquid film.

Abstract

LNG is expected to play a major role in global natural gas trade. Implementing a heating value adjustment unit within regasification terminal allows importing LNG from diverse sources around the world, thus increasing the energy security of the importing country. In this study, we investigate the profitability of heavy hydrocarbons removal (HHR) as a strategy to adjust the heating value of LNG to meet desired specifications. In this context, we have developed a superstructure for the HHR process, which incorporates LNG cold utilization, operating and capital costs of the process, and the revenue generated from coproducts produced. The proposed superstructure is then solved within a simulation-based optimization paradigm. The optimal HHR process configuration not only adjusts the heating value of LNG by partially recovering heavy hydrocarbons, but also utilizes LNG's cold energy to reliquefy the methane-rich stream before pumping to send out pressure and produces ethane and LPG as co-products. Our results show that the additional revenue generated by selling these co-products at current market prices yields profit after offsetting the investment for the HHR process.

Keywords: LNG, Heating value adjustment, Hydrocarbons recovery, Simulation-based optimization

1. Introduction

Riding on the shale gas boom, we are witnessing a paradigm shift towards natural gas (NG) as the major energy source. The cleanest among fossil fuels, consumption of NG is projected to increase at a rate of 1.4 – 1.6% per year from 2008 to 2035 (Lim et al., 2013). Like other fossil fuels, NG is also a traded commodity. Countries endowed with surplus NG reserves export it either via pipeline (Piped Natural Gas or PNG), as CNG (Compressed Natural Gas), or as LNG (Liquefied Natural Gas) in specially designed cryogenic tankers. For transportation over a long distance, typically above 3500 km, LNG has been the preferred method for economical, technical, safety-related, and political reasons. The LNG trade is projected to have a higher growth rate than the PNG trade (Lim et al., 2013).

Imported LNG is stored in an insulated cryogenic tank at the receiving terminal and must be re-gasified before it is sent out to the end consumers. The send out gas must meet certain specifications, and one such specification is its heating value. LNG is composed of methane along with other heavy hydrocarbons like ethane, propane, butane, and traces of pentane. The heating value depends on the composition of LNG, which depends on the country of origin. Unless the regasification terminal is equipped with facilities to adjust the heating value of the send out gas, the imported LNG must

match the desired pipeline specification, which may severely restrict the choice of import LNG sources. An LNG importing terminal equipped to adjust the heating value of LNG before regasification and send out will allow LNG import from diverse sources around the world, thus increasing the energy security of the importing country. It would also allow taking advantage of reduced LNG spot prices, when available. The heating value of LNG can be adjusted by adding nitrogen to the LNG stream. This will not only require nitrogen but will also increase the percentage of inert in the send out NG. According to pipeline specifications, the percentage of inert in the send out gas should not exceed 3 mol % (Fahmy et al., 2015). Therefore, the composition range of LNG amenable to heating value adjustment by diluting with nitrogen is also limited. A less restrictive strategy for lowering the heating value of LNG is to partially recover these heavy hydrocarbons from the LNG feed. These hydrocarbons recovered can be further separated to obtain value-added products like ethane and LPG (Liquefied Petroleum Gas) (Gao et al., 2011). Thus, unlike nitrogen dilution, the heavy hydrocarbon removal (HHR) process not only adjusts the heating value of any LNG feed but also produces sellable co-products that will generate additional revenue for the regasification terminal. However, the revenue generated by selling these co-products at current market prices must recover the additional investment required for the HHR process.

Thus, the objective of this study is to analyze the profitability of the HHR process as a strategic measure to adjust the heating value of any given LNG feed. We present a superstructure for the HHR process and solve it using a simulation-based optimization algorithm to obtain a process configuration for a given LNG composition that maximizes the profit for the regasification terminal.

2. HHR process superstructure

The HHR process involves distillation as the separation technique to separate the heavy hydrocarbons from LNG to reduce its heating value. The LNG stream is first pressurized and then fed to a demethanizer column, where methane is completely recovered as the top product, and a hydrocarbon stream rich in ethane, propane, and butane is recovered as the bottom product. The top product is primarily methane vapor. The operating pressure of the demethanizer column is usually lower than the required send out pressure of natural gas. As a result, the methane rich top vapor product from the demethanizer is either compressed using a compressor to the desired send out pressure or the cold energy of LNG is used to reliquefy it so that it can be pumped to the desired send out pressure instead of using the energy intensive compression route. The methane rich vapor product from the demethanizer can be completely or partially liquefied using a multi-stream heat exchanger using the pressurized subcooled LNG stream. If the available cold LNG stream can only partially liquefy the vapor stream, then the liquefied fraction is pumped and the remaining vapor needs to be compressed to the send out gas pressure. The cold LNG stream gains heat in the process and passes through a flash drum. The liquid stream from the flash drum is fed to the demethanizer, and the methane–rich vapor stream is sent back to the multi-stream heat exchanger for liquefaction. The bottom product of the demethanizer is then sent to the deethanizer column to separate ethane from LPG. It is advantageous to store these co-products as liquid at a low pressure. Therefore, the bottom stream from the demethanizer column is depressurized before being fed to the deethanizer. The liquid bottom stream from the demethanizer can either be throttled or it can be expanded using an expander to generate power to partially offset the electricity consumption of the HHR process. However, to

implement an expander the stream must be superheated to avoid any liquid at the exit of the expander. In this study, steam is used for superheating the liquid bottom product from the demethanizer before expansion. The reboilers of the demethanizer and the deethanizer use either steam or sea water as the hot utility depending on the operating pressures of the distillation columns. The cold energy associated with the LNG stream not only liquefies the top product of the demethanizer but also satisfies the condenser duty of the deethanizer. The processed LNG stream at the send out pressure is finally vaporized using sea water to meet the required send out gas temperature.

In this study, we have adopted a comprehensive approach to incorporate these options within our proposed superstructure for the HHR process. The superstructure is then solved within a simulation-based optimization paradigm to obtain process configuration and operating parameters that maximize the profitability of the HHR process for an LNG stream of a given composition. The proposed superstructure for the HHR process is illustrated in Figure 1. The decision variables pertaining to the optimization of the HHR process include: pressures of stream 2 and feed of the deethanizer; pressure differences across pumps 2 and 4; temperature differences across streams 3-2, 6-5A, and 4-3V; number of stages for the demethanizer and the deethanizer columns; feed location for the deethanizer column; split ratios between streams 5A:5B and 10A:10B; minimum temperature approach across the heat exchanger (HEX) and the degree of superheating for stream 11.

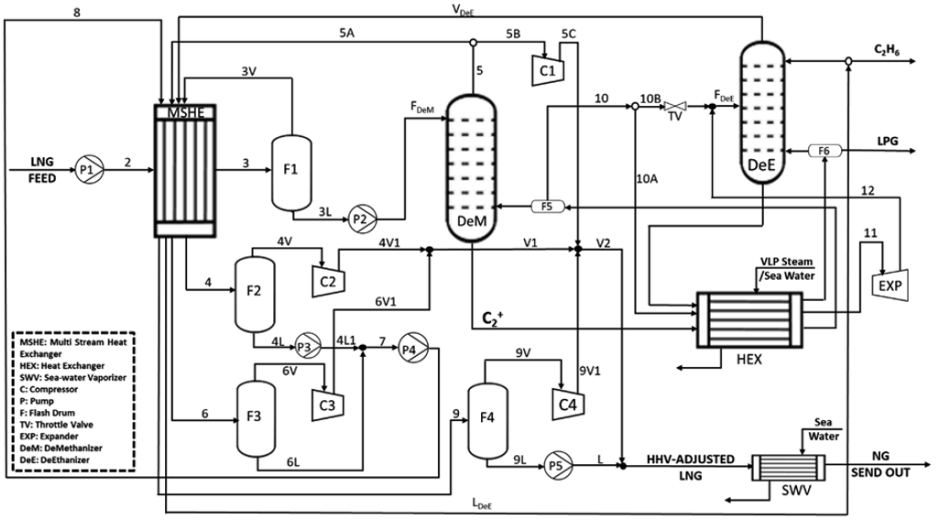

Figure 1: Proposed superstructure for the HHR process.

3. Simulation-based optimization paradigm

Here we adopt a simulation-based optimization paradigm where we combine the benefits of a process simulator to seamlessly perform all thermodynamic calculations and an external platform to perform rigorous optimization. In this study, Aspen HYSYS is used as the process simulator and it is interfaced with MATLAB as the optimization platform. The decision variables obtained at each iteration of the optimization are sent to HYSYS to perform the process simulation and the process data obtained from HYSYS is sent back to MATLAB to update the decision variables for the next iteration.

The superstructure optimization is solved with the following process constraints: the minimum temperature approach for the multi-stream heat exchanger must be at least 3 ^{0}C, the stream exiting the expander (i.e. stream 12 in Figure 1) must be in vapor phase, and the higher heating value (HHV) of the send out natural gas must meet the desired heating value specification used in this study (38.5 MJ/Nm^3). The objective is to maximize the profitability of the HHR process. The objective function is given by equation (1). The capital cost for each equipment is calculated using the relevant cost correlations as given in Turton et al. (2012). The capital investment is annualized using the annualizing factor (AF) given by equation (2). The parameters used for process simulation are highlighted in Table 1.

$$\max_x \ Profit = \left(\sum Revenue_{NG,\ Ethane,\ LPG} - OPEX - AF * CAPEX\right) \quad (1)$$

$$AF = \frac{i(1+i)^n}{(1+i)^n - 1} \quad [i = 10\%, n = 20\ years] \quad (2)$$

Table 1: Summary of process simulation parameters

	Parameters
Fluid package	Peng-Robinson
LNG compositions (mol %):	
Methane	87.83
Ethane	8.30
Propane	2.98
i-Butane	0.40
n-Butane	0.48
Nitrogen	0.01
LNG HHV (MJ/Nm^3)	42.23
NG send out specifications:	
Pressure (kPa)	8000
Temperature (^{0}C)	15
HHV (MJ/Nm^3)	38.50
Flowrate (t/h)	100
Efficiency: Compressor, Pump, Turbine	75 %
Pressure drop per stage in distillation column (kPa)	0.7
Pressure drop on each side of heat exchangers (kPa)	20
Methane recovery	99.99 %
Ethane recovery	99.90 %
Propane recovery	99.90 %
Sea water: Inlet temperature (^{0}C)	25
Outlet temperature (^{0}C)	22
Inlet pressure (kPa)	500
Costs of co-products: Ethane ($/t)	290
LPG ($/t)	580
Utility costs: Electricity ($/kWh)	0.15
Steam ($/t)	21.9

3.1. Optimization algorithm

In this study, Particle Swarm Optimization (PSO) algorithm is coded in MATLAB to optimize the proposed superstructure for the HHR process. The PSO algorithm implemented in this study is based on the gbest type, where every particle is attracted to the best solution obtained by any particle within the population thus, accelerating the rate of convergence. Initialization of PSO particles are done using the Sobol sampling technique. PSO effectively handles exploration and exploitation using three parameters: a cognitive component, a social component, and inertia weight (Eberhart and Kennedy, 1995). In our PSO code, the cognitive component is linearly decreased, and the social component is linearly increased with each iteration of PSO. The inertia weight is adapted based on the total number of particles that improve its solution in each iteration as a feedback parameter. Lower and upper bounds of the decision variables confine the positions of particles within the multi-dimensional search space. The velocities of particles are also restricted by suitable bounds specified in each dimension. When the position or velocity of a particle violates the upper or lower bound in one dimension, it is fixed at the respective bound. If a particle is at its upper bound with a positive velocity or if the particle is at its lower bound with a negative velocity, then the direction of velocity is reversed to impede the movement of the particle in the wrong direction. To handle process constraints, particles are compared according to the following rules: a feasible particle is always preferred over an infeasible particle; among two feasible particles, one having the better objective function value is preferred; among two infeasible particles, one having the smaller constraint violation is preferred. The PSO algorithm is also combined with a mesh adaptive direct search optimization technique (NOMAD) available from the OPTI Toolbox (Currie and Wilson, 2012). Feasible PSO particles are used as initial guesses for NOMAD, and feasible solutions obtained from NOMAD are then used to replace infeasible PSO particles followed by PSO particles with worse objective function values compared to the feasible NOMAD solutions. However, replacement of a PSO particle is allowed only if the feasible NOMAD solution is unique in the decision space w.r.t. all other PSO particles. A distribution-based criterion based on the difference between the best and the worst objective function value for PSO particles is used to terminate our optimization algorithm. The parameters pertaining to the PSO algorithm are given in Table 2.

Table 2: Parameters for the PSO algorithm

No. of particles (N)	Cognitive component (c_{10})	Social component (c_{20})	Inertia weight (w_{Min}, w_{Max})	Maximum iterations (itermax)
60	2.5	1.5	[0, 1]	100

4. Results and discussion

The proposed superstructure for the HHR process is solved using the optimization algorithm within a simulation-based optimization paradigm. The average computational time for solving the optimization problem is about 30 h, which includes repeated evaluations of the HHR process flowsheet within HYSYS during the optimization. The amount of LNG to be processed to maintain a desired send out gas rate depends on the extent of heating value adjustment required. Our results show that the available cold energy of LNG is sufficient to liquefy the various vapor streams in the HHR process, thus avoiding any vapor compression in the optimal HHR process configuration. This not only reduces the power consumption (thus the operating cost) but also the capital

investment of the HHR process. The topology corresponding to the expansion via throttle valve is chosen over the use of an expander, as the power generated using an expander is not adequate to compensate the additional capital investment. As seen from Table 3, the revenue generated from the co-products (ethane and LPG) at their respective current market prices yields a profit of about 9.4 % for the LNG regasification terminal. Thus, the HHR process turns out to be a profitable strategy to adjust the heating value of the imported LNG to meet the desired pipeline specification.

Table 3: Summary of results for the HHR process

LNG Processed (t/h)	Ethane Produced (t/h)	LPG Produced (t/h)	TAC (million$/y)	Profit (million$/y)	Power Consumption (kWh)	Steam Consumption (t/h)
122	10.65	11.31	374.80	35.40	1473	5.25

5. Concluding remarks

In this study, we have demonstrated that in an LNG receiving terminal, heavy hydrocarbons removal prior to regasification and send out is a techno-economically viable option to diversify LNG sources and increase the energy security of the importing country. We have presented a superstructure for the heavy hydrocarbons removal process and solved it within a simulation-based optimization paradigm. The HHR process configuration utilizes the cold energy of LNG thus, resulting in an energetically efficient process that not only adjusts the heating value of the LNG feed but also produces value added co-products i.e. ethane and LPG. The additional revenue generated by selling these co-products yields a net profit of about 9.4 % for the regasification terminal for the representative rich LNG composition as given in Table 1.

The simulation-based optimization framework developed in this study can readily evaluate the techno-economic feasibility of a HHR process to adjust the heating value of any given LNG feed within a regasification terminal.

Abstract

BTXs (benzene, toluene and xylenes), used widely as basic chemical intermediates, are separated generally from petroleum naphtha, coking naphtha, and pyrolysis gasoline. These oil fractions contain aromatic and non-aromatic hydrocarbons between C_5 to C_8 in which certain components have approximate boiling points and form azeotropes. Extractive distillation (ED) is one of the most attractive approaches for separating azeotropic mixtures with approximate boiling points. The aromatic ED technique aided by sulfolane used widely in recent years because of its simple process flowsheet, small equipment investment and high energy efficiency. The solvent and operating parameters are the cores of ED process in the economical design. Some results were published to rapidly screen the solvents as well as process parameter optimization for ED separating process, but few contributions have been reported to optimize an extractive distillation from the view of simultaneous optimization of the solvent composition and operation parameters for process economics. In this work, we propose a systematic optimization approach for energy saving of sulfolane aromatic ED processes based on process simulation and genetic algorithm (GA) optimization. The NRTL property method and rigorous unit models in Aspen Plus are used to simulate the ED processes. In particular, considering multi-variable and their interaction, a coordinating strategy is proposed to optimize the solvent composition and significant operating parameters for the ED processes by combining Aspen Plus with MATLAB. Under given separation specifications, the energy consumption and separation efficiency are investigated and optimized by GA optimization. The results show that the through the above optimization, the minimum heating utility of the ED process is significantly reduced by 29.2%.

Keywords: Extractive distillation; Sulfolane; Process simulation; Optimization; Energy saving.

1. Introduction

BTXs (benzene, toluene and xylene isomers) are extremely important basic chemicals for the oil, gas and petrochemical industries with global productions above 40 million of metric tonnes per year for benzene and xylenes and roughly the half for toluene. BTXs are popularly produced from petroleum naphtha, coking naphtha, and pyrolysis gasoline through hydrotreating and continuous catalytic reforming (CCR) processes and used as starting points of derived downstream

products. CCR processes produce high-quality oil streams that include aliphatic, alicyclic and aromatic hydrocarbons between C_5 to C_8 [1]. Certain components in the oil streams have approximate boiling points and form azeotropes. Hence, it is difficult and energy-intensive to separate aromatics from the oil streams via regular distillation. Some improved distillation processes including extractive distillation (ED) process are adopted to separate the mixture of aromatic and non-aromatic hydrocarbons[2]. The aromatic ED technique has been widely used in recent years because of its simple production process, small equipment investment and high energy efficiency. As an effective method, ED with a separating agent, especially a polar solvent[3-5], has been used to separate the slightly polar aromatics from the reformate, pyrolysis gasoline or coke-oven light oil. Thus, the light components can be drawn out from the top of the column as a product; the heavy components can be drawn out from the bottom of the column as another product. The product containing the entrainer can be further separated through regular distillation. Among these available entrainers, sulfolane is very popular because of the highest selectivity, higher dissolving capacity, higher boiling point and higher thermal stability[6].The sulfolane process licensed by UOP[7] is currently the most popular technology.

ED uses an entrainer to increase the relative volatility of the light and heavy components. Thus, the light components can be drawn out from the top of the column as a product; the heavy components can be drawn out from the bottom of the column as another product. This implicates additional distillation steps to separate the entrainer from both the extract and raffinate phases, and to purify the solvent, with consequently, additional investments and energy consumption. With an increasing awareness of the environmental impacts and practical limitations on energy supply, researchers aim to increase the efficiency of energy utilization. Entrainer optimization and process optimization are the useful approaches to save energy as well as increase the efficiency of the current energy utilization for aromatic ED process. In the research of Pete et al.[8], a preliminary solvent screening tool for two-column extractive distillation flowsheets is described whose results can be used to initialize process simulators. The tool uses shortcut approximations to extractive distillation that accurately predict the relative column performance of alternative solvents with rigorous simulations using the Aspen Plus process simulator. It was found that staging requirements for the flowsheets could be approximated using 4 times the number of stages predicted using the Fenske equation when it was applied over each column section. Using these approximations resulted in a shortcut method for evaluating and comparing alternative solvents and solvent families, predicting the staging requirements and quickly determining the feasibility of completely heat integrating a flowsheet. Ionic liquid, co-solvents are also reported as promising solvents for the separation of this close-boiling point mixture by extractive distillation[9,10]. The operating parameters are the cores of an existing ED process as well as solvent in the economical design. Process simulation and optimization also studied in the aromatic ED process. Choi et al.[11] established a model and optimization system for the sulfolane extraction plant based on process simulation. Optimum recycle rates were found using the sequential quadratic programming (SQP) algorithm. It was found that almost a 10%

increase of the purity of benzene could be achieved by the application of the optimization system.

An effective solution with high selectivity and solubility as well as process operating parameters is crucial to the energy requirement and economic performance for an ED process. As mentioned above, some results were published to rapidly screen the solvents as well as process parameter optimization for ED separating process, but few contributions have been reported to optimize an extractive distillation from the view of simultaneous optimization of the solvent composition and operation parameters for an existing ED process economics aided by co-solvent. In this paper, we propose a systematic optimization approach for energy saving of sulfolane aromatic ED processes based on process simulation and genetic algorithm (GA) optimization. Process simulation and energy analysis were implemented for an existing aromatic ED process aided by the solvent sulfolane. The NRTL property method and rigorous unit models in Aspen Plus are used to simulate the sulfolane ED processes. In particular, considering multi-variable and their interaction, a coordinating strategy is proposed to optimize the solvent composition and significant operating parameters for the ED processes by combining Aspen Plus, EXCEL and MATLAB. Under given separation specifications, the energy consumption and separation efficiency are investigated. And the significant parameters of the process including the temperature, feed location and composition of the lean solution are optimized by GA program.

2. Problem statement

A typical flow sheet for the aromatic ED process is shown in Fig.1, which typically contains an extractive distillation column (EDC), a nonaromatic rectifying column(NRC) and a solvent recovery column (ERC). The EDC uses an entrainer stream (S12, S) to separate the crude feed stream (S1, aromatic and nonaromatic) into a raffinate stream (S3, nonaromatic) and an extract stream (S3, aromatic + solvent, rich solvent). In EDC, the solvent is fed at a location different from the crude feed, resulting in an extra extractive section, as depicted in Fig.1, compare to a conventional column with stripping and rectifying sections. Nonaromatics which have a fainter interaction with the entrainer molecular is recovered from the distillate of EDC and the extract stream is withdrawn from the column bottom. The extract stream is fed into the ERC sequentially to separate aromatics from the rich solvent. The ERC removes aromatics from the top and recycles the entrainer from the bottom. The recycled entrainer is cooled before going back to the EDC. A fresh entrainer compensation (S13, Makeup) is needed to replenish the entrainer lost along with product streams.

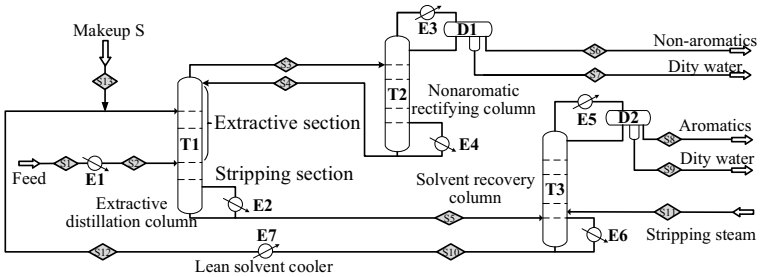

Fig. 1. Flowsheet of the sulfolane extractive distillation process

Solvents used in the ED process is highly important for achieving good process economics and low energy consumption. In other words, optimal process design should also include the optimal design of solvents composition, especially for a co-solvent process. In this work, we propose a systematic optimization approach for energy saving of an existing sulfolane aromatic ED processes based on process simulation and genetic algorithm (GA) optimization. We first conduct a process simulation of an existing sulfolane aromatic ED process in China. Sequentially, a systematic approach for solvent composition and process operation parameters optimization was proposed by taking the minimum hot utility as the objective function based on GA model.

3. Process simulation

The Aspen Plus software (V8.8) is used for the rigorous process simulations carried out in this work. The columns are simulated using the rigorous distillation model RADFRAC. The rigorous and "strongly non-ideal liquid" option is used in the distillation block for columns. The convergence method for tear streams used Wegstein, and the tolerance is set to 1.0×10^{-4}. In particular, the operating pressures of EDC and ERC are 0.07 & -0.05Mpag. The feed location of S12 must be set as 1th when the EDC without condenser. Table 1 lists the real operating data extracted from an existing sulfolane ED plant and the simulation results obtained by Aspen Plus. The relative deviation between the real operating data and simulation results is less than 3%, indicating that the simulation result is reliable.

Table 1. Comparison of plant data and simulation result

	EDC			NRC			ERC		
Item	$T_{top,EDC}$	$T_{bot,EDC}$	D_{EDC}	$T_{top,NRC}$	$T_{bot,NRC}$	D_{NRC}	$T_{top,ERC}$	$T_{bot,ERC}$	D_{ERC}
Unit	°C	°C	kg·h^{-1}	°C	°C	kg·h^{-1}	kg·h^{-1}	°C	kg·h^{-1}
Plant data	114.0	167.0	13120	94.0	140.0	12790	63.0	176.0	42930

AAD%	1.58	2.99	1.32	2.02	0	0.5	2.22	0	0.23

4. Process optimization

4.1. Variable and objective function

Process optimization plays a crucial role in process analysis and evaluation. Generally, lower dissolvability and selectivity resulted in a larger circulation of solution which required greater design sizes of process units and higher energy consumption. Co-solvents are good choices to adjust the dissolvability and selectivity of solvents. In this section, the fraction of sulfolane, hydrocarbons and water in the solvent are analyzed to obtain the minimum circulation volume of solution. In order to obtain the minimum energy requirement of the ED process, the energy consumption and separation efficiency are optimized through adjusting the key operating parameters of the ED process under given separation specifications and an optimal design procedure is proposed by GA program. The adjustable operating variables are summarized as the following four aspects: 1) the operating parameters of column feeding stages, such as feeding location of the crude feed (N_{S2}) and rich solution (N_{S5}), 2) the operating parameters of feeding temperatures, such as the temperature of the crude feed (T_{S2}) and lean solution (T_{S12}), 3) the pressure of columns and 4) the reflux ratio of column T3 (R_{T3}). The solvent composition variables include the hydrocarbon concentration ($x_{HC,S12}$) and water ($x_{H2O,S12}$) in lean solution.

4.2. Aspen plus – MATLAB integrated model

The overall framework of this integrated model is illustrated in Fig. 2. The program use Component Object Model (COM) technologies available in the Microsoft Windows operating system to provide interoperability of COM-aware applications as well as a highly effective approach for process simulation and optimization. The steady-state simulation is implemented in Aspen Plus. A calculation procedure of the minimum heating utility ($Q_{h,min}$) is coded in Excel.

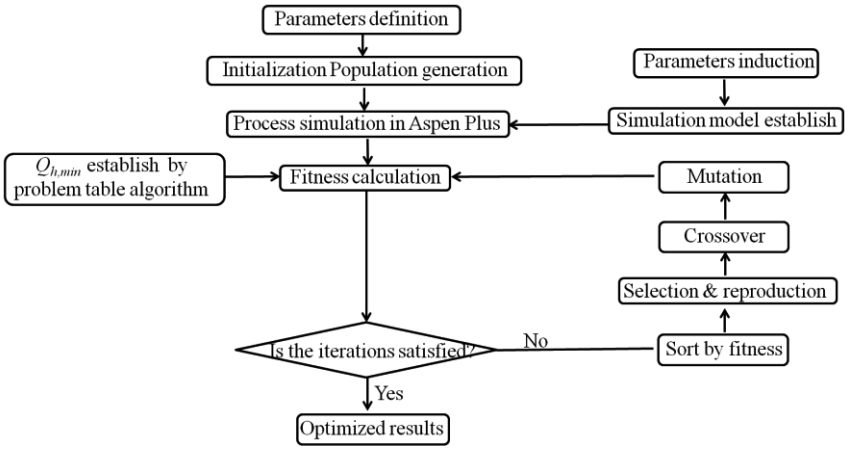

Fig. 2. The overall framework of the integrated program

5. Results and conclusion

A genetic algorithm has been used to optimize both the solvent composition and process operating parameters. As illustrated in Table 2, a set of results was obtained for the ED process when optimized on the basis of minimizing $Q_{h,min}$. Grand composite curves of the existing and optimal process are depicted in Fig.3.

Table 2. Comparison of existing process and optomal process

Plant	EDC			NRC			
Item	$T_{top,EDC}$	$T_{bot,EDC}$	Q_{REDC}	$T_{top,NRC}$	$T_{bot,NRC}$	Q_{RNRC}	Q_{CNRC}
Unit	°C	°C	GJ/h	°C	°C	GJ/h	GJ/h
Orig.	114.8	172.0	49.3	95.9	140.0	10.7	3.0
Opt.	108.8	176.7	29.4	97	145	10.3	3.1

Plant	ERC			
Item	$T_{top,ERC}$	$T_{bot,ERC}$	Q_{RERC}	Q_{CERC}
Unit	kg/h	°C	GJ/h	GJ/h
Orig.	61.6	176.0	60.2	29.81
Opt.	57.7	176	33.2	11.6

The results show that co-solvents have higher adjustability than single solvents. Based on the existing ED process, a compressive simulation model and optimizing strategy of the solvent composition and operating parameters are presented sequentially. Moreover, considering multi-variables and their interaction, a co-ordinative optimization strategy is proposed based on the GA optimization by taking $Q_{h,min}$ as the objective function. Through the above optimization, $Q_{h,min}$ of the ED process is significantly reduced by 29.2%.

Multi-objective Optimization of Membrane-based CO_2 Capture

Miguel A. Zamarripa, John C. Eslick*, Michael S. Matuszewski,
David C. Miller

National Energy Technology Laboratory, 626 Cochran Mills Road, Pittsburgh, PA, USA
John.Eslick@netl.doe.gov

Abstract

This work presents a multi-objective optimization framework that uses a nonlinear programming (NLP) mathematical model for the optimal design and operation of membrane-based post combustion CO_2 capture plants. The proposed approach provides advanced decision-making tools for the power generation industry, involving the simultaneous optimization of alternative process configurations and operating conditions while analyzing different objectives such as cost of electricity and carbon capture target. The proposed approach was demonstrated with a case study from the literature and the mathematical model has been validated against a rigorous simulation model. Results show how the optimal flowsheet changes with different objectives.

Keywords: superstructure optimization, multi-objective optimization, post-combustion capture, membrane systems.

1. Introduction

Post-combustion capture (PCC) is an energy intensive and expensive process that is the subject of considerable research using a variety of technologies, including solvents, sorbents and membranes. Membrane based PCC systems exploit differences in partial pressure across a selective membrane layer to separate CO_2 from other components in the flue gas. The separation is particularly challenging due to the low concentration of CO_2, large volume of flue gas to process, and the high purity requirement of the resulting CO_2 stream. Research efforts include developing new membrane materials as well as new system configurations. Recent work (Budhathoki et al., 2018) reports efforts to simultaneously optimize potential membrane materials and process conditions for a fixed design configuration.

Merkel et al. (2010) demonstrated the importance of the membrane system configuration and integration with the CO_2 generating system by developing a multistage membrane process with multiple recycles, including an air sweep which removes CO_2 from the exit gas and recycles it to the combustor. Ironically, no reported superstructure-based optimization model has enabled the identification of a configuration of that sophistication. Arias et al. (2016) presented superstructure optimization model, which considers multi-stage configurations, including recycles; however, it does not enable recycle streams to be integrated with the CO_2 generating system. Hasan et al. (2012) showed the effect of CO_2 source concentration on overall system cost for simple membrane configurations, and showed how optimal capture technologies are dependent on process requirements. There remains a need for more complex superstructure models to adequately cover the potential optimal configurations that could emerge as new materials are developed,

various CO_2 source concentrations are identified, and different CO_2 capture levels are required.

We present a multi-objective superstructure optimization framework to determine the optimal configuration of membrane-based carbon capture systems under varying CO_2 source concentrations and under various capture levels. The framework is based on rigorous models and incorporates all the innovations proposed by Merkel et al. (2010), including liquefaction and vacuum pumps, multi-stage membranes, a detailed compression train, and a simplified boiler model to capture the effects of recycle streams integrated with the CO_2 source. The multi-objective framework can identify the Pareto front to show the trade-off among objectives such as Cost of Electricity (COE) and capture rate, while also identifying how the optimal process configuration changes.

2. Mathematical model

The proposed framework is formulated as an NLP model that categorizes decisions into two decision types: discrete and continuous. Typically, discrete decisions, such as determining the plant design, are modelled using discrete variables and/or binary variables allowing the model to install or eliminate units (also referred as on-off decisions). However, in this process when selecting the optimal number of stages, a bypass variable (continuous variable) is used instead, avoiding the use of binary variables for this purpose. While formulating a superstructure problem as an NLP is not general, NLP formulations have been used for separation problems, e.g., membrane systems (Hasan et al., 2012) and distillation columns (Dowling, 2015), where a partial bypass would lead to purifying a stream later mixed with an impure stream. Other continuous decisions are flows, temperatures, concentrations, pressure ratios, and sweep feed.

Figure 1 shows a schematic representation of the superstructure framework. We propose a heterogeneous superstructure framework, in which part of the flowsheet is fixed (M1, M2, M3, liquefier column, and compressors with intercooling as these always exist), while the number of membrane stages in series that can be installed is not fixed.

The main objective is to determine the Pareto front showing the optimal tradeoff between COE and CO_2 capture rate. COE is estimated as follows [Eq. (1)]:

$$COE = \frac{(TOC)(CCF) + OC_{fix} + (CF)(OC_{var})}{(CF)(MWH)} \tag{1}$$

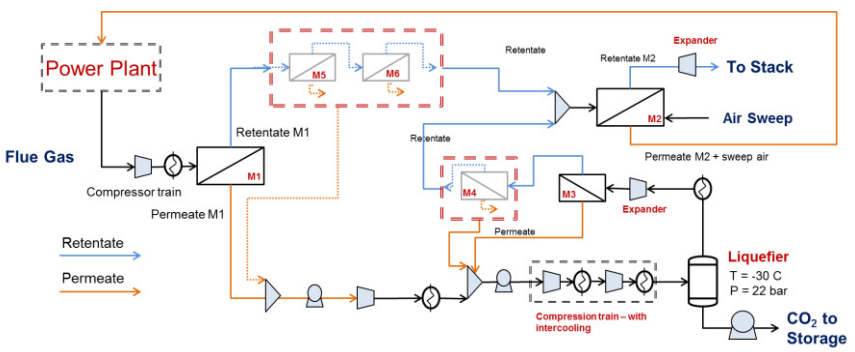

Figure 1. Superstructure optimization framework

where, TOC is the total overnight capital expenses, OC are the operating costs (fixed and variable), net power output is calculated based on the power produced by the plant minus the power used by the PCC process. CF is the plant capacity factor and CCF is the capital charge factor (NETL/DOE, 2011).

2.1. Membrane model

Each membrane stage has been modeled as a counter-current system in which the inlet flow to the membrane is equal to the outlet flow plus/minus the flux change (J_i is the flux moving from the retentate side of the membrane to the permeate side of the membrane). Eq.(2) and Eq.(3) show the material balances for the retentate (component molar flowrate - FR_i) and permeate (component molar flowrate - FP_i) sides of the membrane, respectively.

$$0 = -\frac{\partial FR_i}{\partial x} - J_i \tag{2}$$

$$0 = -\frac{\partial FP_i}{\partial x} - J_i \tag{3}$$

A finite difference method has been applied to Eq. (2) and Eq. (3) (forward and backward, respectively). After the discretization, $J_{i,n}$ represents the flux moving from one side to the other one for component i, at sub-compartment n (a fixed length is discretized over a finite number of elements), and is given by the following equation [Eq. (4)]:

$$J_{i,n} = 2\pi r_{Fo} n_F \frac{Q_{CO_2}}{\alpha_i}\left(PR_n xr_{i,n} - PP_n xp_{i,n}\right) \tag{4}$$

where, Q_{CO_2} is the permeance of the membrane (considered fixed for this study), α_i is the membrane selectivity of component i (relative to CO_2), n_F is the number of fibers/tubes in the membrane, r_{FO} is the external radius of the tube, PR_n is the retentate pressure and PP_n is the permeate pressure in the n^{th} compartment, and $xr_{i,n}$ and $xr_{i,n}$ are the component molar fractions at the retentate and permeate sides, respectively.

The pressure drop at the retentate side behaves linearly, thus, a linear regression has been considered. While, the pressure drop for the permeate side was modeled based on the Hagen-Poiseuille relation along with ideal gas assumptions (dynamic viscosity, ideal gas law, etc.). (Morinelly and Miller, 2011)

2.2. Condenser

The condenser has been modeled as a flash tank; using a mix of surrogate models and material balances, we developed a square formulation of the column. The inlet gas (F, P, T, z_i) and flash temperature are the optimization variables of the problem. A set of surrogate models have been developed for the vapor outlet (F_V, y_i, P, T) and the heat duty of the column, while the material balances estimate the liquid outlet (F_L, x_i).

The Framework for Uncertainty Quantification, Optimization and Surrogates (FOQUS, Miller et al., 2016) was used: (i) to prepare the data set by interfacing with the Aspen process simulation, (ii) to generate the surrogate model using ALAMO (Cozad et al., 2015), and (iii) to validate the surrogate model. The predictions from the surrogate model

showed a good fit when compared to the rigorous flash models from Aspen Plus. All the surrogate models presented have an R^2 value between 97% and 99%.

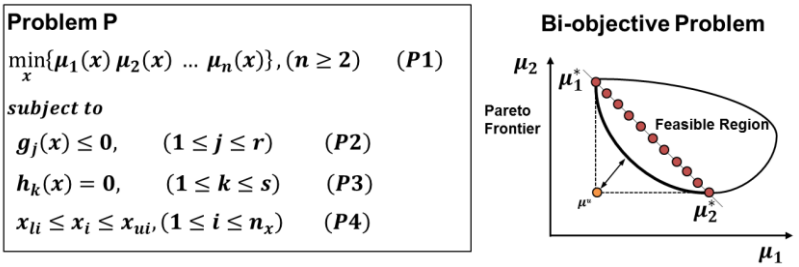

Figure 2. Multi-objective optimization approach.

2.3. Simplified power plant representation

Typically, a simple model for a thermal power plant consists of a boiler, bag house, desulfurization unit and steam cycle. For this work, a representation of the power plant has been developed to account for the potential benefit of recirculating the "sweep" air used in the membrane system, consequently a simplified boiler model was used that considers a stoichiometric balance for the O_2 in the system, while also accounting for recycled CO_2. This model includes a preheater and a desulfurization unit.

2.4. Multi-Objective Optimization (MOO) approach

This work implements the epsilon-constraint method for decision making under multiple objectives (Messac et al., 2003). This method solves a set of single objective optimization problems to determine the Pareto front, from which a solution can be selected based on the Utopia-tracking approach. The Epsilon constraint algorithm for a bi-objective problem consists of the following steps (see Figure 2):

1. Minimize μ_1 (obtaining μ_1*)
2. Minimize μ_2 (obtaining μ_2*)
3. Draw a line between μ_1* and μ_2*
4. Divide the line into m_k points
5. For all m_k
   a. Constraint $\mu_2 \leq \mu_2$ (at m_k)
   b. Minimize μ_1
6. Draw Pareto frontier
7. Select the solution closer to the Utopia point

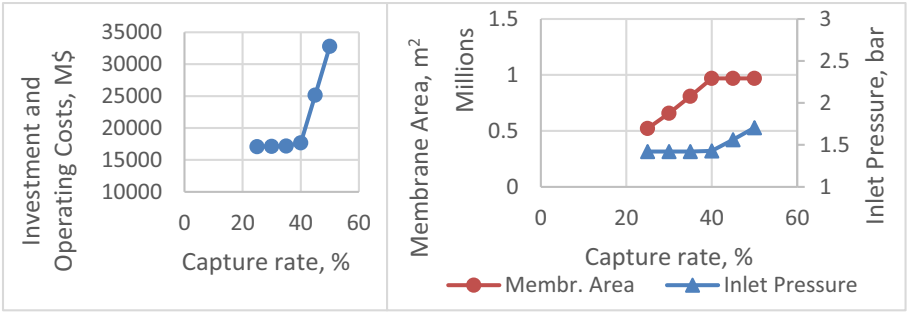

Figure 3. Single unit MOO analysis (M1 – membrane 1), costing method - Hasan et al. (2012).

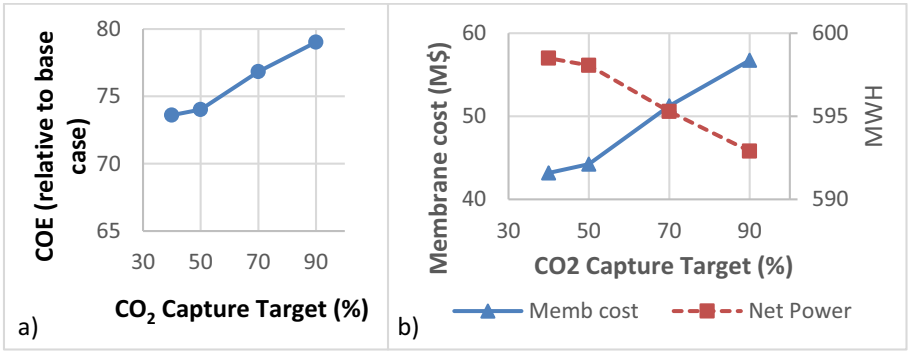

Figure 4. MOO results

3. Results

The membrane system model was tested using a case study from the Carbon Capture Simulation Initiative (CCSI) toolset (Morinelly and Miller, 2011). A 650MW power plant has been used as a basis to analyze the proposed framework. The flue gas from the coal plant is preconditioned to 50°C and 1.013 bar and with a molar fraction of CO_2 12 % (79% N_2, 1.8% H_2O, 5.1% O_2, balance Ar). As discussed above, membrane stage 1, 2, and 3 are installed, while membranes 4 to 6 can be installed or not. The membrane properties are: permeance, Q_{CO2} = 0.12047 kgmol/m2·bar·hr; membrane selectivity, $\alpha_i(CO_2/N_2, CO_2/O_2, CO_2/Ar)=100$; and $\alpha_i(CO_2/H_2O) = 0.5$. The superstructure model has been implemented in GAMS and solved using IPOPT and CONOPT. (IPOPT was used to initialize the problem, and CONOPT was used to solve the optimization problem.) The predictions from the proposed model were compared to the CCSI Aspen model, and the results show similar performance with a 3% of error in the COE and less than 1% of error for the retentate flowrate, permeate flowrate, and permeate pressure.

Regarding the multi-objective analysis, this work focuses on the trade-off between the COE and the CO_2 capture rate (CO_2 out/CO_2 in). At a single unit level, the trade-off is very clear [see Eq. (4)]. A larger membrane area and larger pressure difference are required for a higher capture; however, this also increases the final costs (investment and operating). Figure 3 shows the multi-objective analysis of membrane 1 (M1), in which the trade-off between cost and capture rate for a fixed flue gas is observed. For a higher capture rate (between 40% and 50%), the model increases the inlet pressure instead of the membrane area. At a lower CO_2 capture rate, the model reduces the membrane area maintaining the inlet pressure fixed (25% to 40% capture rate).

Figure 4 shows a few candidate solutions (40%, 50%, 70%, and 90% capture target) from which it can be observed that there is a clear trade-off between these two objectives. A change in the trend is evident from 40% to 70% capture versus 70% to 90% capture. The model predicts the installation of four membrane stages (M1-M3 and M5 see Figure 1) to achieve 70% and 90% capture target, whilst only three stages are installed for 40% and 50% capture target (M1-M3 see Figure 1). In all cases, the optimal membrane area (Memb. Cost = Area ·\$50/m^2) and operating conditions are different.

4. Conclusions

The proposed model has been compared against a rigorous process simulation model predicting a COE with less than 3% error. This work has demonstrated that the optimal process configuration changes at different capture rates, and that advanced PSE tools can help to identify the optimal configurations that result in minimal COE as CO_2 capture rate changes. Additionally, conceptual design and PSE tools should be used to complement the decision-making process, specifically for post-combustion capture. These tools allow the analysis of potential process configuration and the model could be used to analyze alternative membrane technologies/arrangements.

Abstract

As energy consumption in chemical industry is intensive, energy conservation in is of great significance. In refinery hydrogenation operations, hydrogen streams are not only pressurized by compressors which consuming power to increase their pressures, but also cooled down or heated up by other streams, heating or cooling utility before or after compression to adjust their temperatures for hydrogenation reactions. For hydrogen compressor, in addition to inlet pressure, the inlet temperature of hydrogen stream will also affect its power consumption. Meanwhile, for a hydrogen stream, the outlet temperature of compressor also serves as the inlet temperature of heat exchanger and then will simultaneously affect the utility consumption of heat exchange network. Therefore, for each compressor there are optimal inlet and outlet temperatures that can minimize the total energy including compression work, heating and cooling utilities. This paper establishes a nonlinear programming (NLP) model to integrate the hydrogen streams entering and outflowing from the compressors and heat exchangers, optimizing the inlet and outlet temperatures of compressors for simultaneous optimization of compression work and utilities of heat exchange network. Case study shows that this method can further achieve the energy conservation than individual integration of HEN.

Keywords: Heat exchange network; Compression work; Mathematical Programming; simultaneous optimization

1. Introduction

The hydrogenation operation of refinery is of great importance and its products are used in chemical industries. In order to produce qualified products, hydrogenation processes have strict requirements for hydrogen stream properties, such as pressure and temperature, consuming intensive energy to pressurize and heat up or cool down.

As for compression work conservation in refinery hydrogenation processes, Hallale et al. (2001) established a superstructure and set up a mathematical optimization model accounting pressure constraints. Yu et al. (2011) carried out the exergy standard to unify and optimize the consumption of hydrogen and compression work. Wu et al. (2012) developed a mathematical model of hydrogen network to minimize the total exergy consumption including fresh hydrogen and power consumption.

The research for heat exchanger network (HEN) is progressive since it was found. Linnhoff et al. (1978) proposed a thermodynamically oriented pinch analysis for the synthesis of HEN and solved the problem in two stages. First, identify the maximum

heat recovery network and then set the preliminary network as starting point and design the allocation network. Cerda et al. (1983) formulated the minimum utility calculation method for HEN synthesis using a "transportation problem" model by linear programming(LP). Onishi et al. (2015) optimized a liquefied natural gas production process considering the pressure recovery of streams during the HEN design and realized the minimization of the retrofit total annualized cost. Then, an effluent recovery superstructure contains HEN synthesis operator, pressure operator and separation operator was introduced to maximize the total annualized revenue by Liao et al. (2017).

For refinery hydrogenation operation, hydrogen streams are generally flow through heat exchangers and compressors in certain sequence, so the inter-unit temperature of them will influence on both the utility consumption of HEN and compression work demand. Thus, there is energy conservation potential for the two kinds of energy are considered simultaneously when such temperature is optimized. However, those methods stated above are not able to deal with such case. This paper establishes a nonlinear programming(NLP) model to minimize both utilities and power consumption of refinery hydrogenation systems. Case study results show its advantages and application.

2. Theory

The HEN of the refinery hydrogenation system is different from common ones as heat transfer and compression of hydrogen streams are series-wound. Before entering the reactor, hydrogen streams need to be compressed under low temperature and then heated up by heat exchanger. After reaction, they should be cooled down and then recycled to compressors again. The compressor inlet temperature of a hydrogen stream has upper limit and meanwhile the outlet temperature affects the HEN utilities consumption, so for hydrogen stream from each compressor there are optimal inlet and outlet temperatures that can minimize the total consumption of compression work and utilities. Aiming to such goal, a mathematical model is established below.

2.1 Superstructure

Figure 1 shows the superstructure of this method. *HR* and *HS* represent heat source and sink, and the solid lines connecting all sources and sinks represent that heat source and heat sink can transfer heat among all others. Spacer lines indicate the hot streams flowing into compressors after cooling while dotted lines denote cold streams flowing out compressors and then need to be heated up for hydrogenation units. F_{im} and F_{jm} are flow rates of hot and cold streams, respectively, T_{im}^{in} is the inlet temperature of hot stream that cooled down to T_{im}^{out} and then pressurized by compressor. After compression, the stream is cold stream with temperature T_{jm}^{in} and then heated up to T_{jm}^{out} by heat exchanger.

2.2 The mathematical model

Based on the above superstructure, a NLP model aiming at minimizing consumption of compression work and utilities of HEN is established. Meanwhile, the mass balance, heat balance, and temperature requirements for compressors and hydrogenation units are set as the constraints for this model.

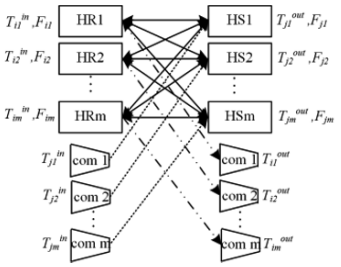

Figure 1 The superstructure of the simultaneous optimization network

$$\begin{aligned} \min \quad & gw = W_{i,j} + Q_c + Q_h \\ \text{s.t.} \quad & m(x) = 0 \\ & h(x) = 0 \\ & t(x) \le const \\ & W = f(t, p, F) \end{aligned}$$

In the NLP model, the objective function *gw* is the sum of compression work, heating and cooling utilities. Restraint *m(x)* is the mass balance of hydrogen streams flowing through the compressors and heat exchangers. Similarly, heat balance for all hydrogen streams is restricted as *h(x)*. Besides, all temperature constraints are simplified as *t(x),* where *const* is a constant, generally taken as 40℃ for inlet temperature of compressor. For the heat exchange process, the minimum heat transfer temperature difference is taken as 10℃ in this model. The compression work W can be calculated using Eq.(1). The cooling and heating utility can be calculated using Eq.(2) and Eq.(3), respectively.

$$W_{i,j} = \frac{C_{pi} \cdot T_i^{out}}{\eta} \cdot \left[\left(\frac{p_j}{p_i} \right)^{\frac{(\gamma-1)}{\gamma}} - 1 \right] \cdot F_{i,j} \tag{1}$$

W is the compressor work needed in the process from stream i to unit j, which is decided by the flow rate $F_{i,j}$, specific heat capacity at constant pressure C_{pi} and the inlet temperature of the compressor T_i^{out} and its efficiency, η . The γ is the ratio of specific heat capacity of gas at constant pressure to that at constant volume, and for hydrogen stream it is generally taken as 1.4. The T_i^{out} is related to compressor and HEN and thus it is an important variable to be optimized in this model.

$$Q_C = \sum_{i=1}^{m} \left(T_i^{out1} - T_i^{out} \right) \cdot Cp_i \tag{2}$$

$$Q_h = \sum_{j=1}^{k} \left(T_j^{out} - T_j^{out1} \right) \cdot Cp_j \tag{3}$$

For a hydrogenation system with m heat exchangers and n compressors. Q_c and Q_h are cooling and heating utilities that hydrogen streams consumed for hydrogenation unit requirements after they heat exchange with process streams. T_j^{out1} and T_i^{out1} are that of cold and hot streams after the heat exchange, and similarly, T_i^{out} and T_j^{out} are outlet temperatures of hot and cold streams after using utilities, respectively.

3. Case study

A practical refinery case in China is employed to demonstrate the application of this method. The schematic diagram is shown in Figure 2 and Table 1 shows the basic data of hydrogen streams in hydrogenation system. There are pressures, flow rates, inlet and outlet temperatures of hydrogen streams, and these are target temperatures of heat exchangers and compressors. Generally, the inlet and outlet temperatures for compressor are taken as 40℃ under the hypothesis that the compressor is in isothermal compression, which is illogical and unrealistic. The case will be optimized by both HEN integration and the proposed model in this paper to demonstrate its advantages and application. The NLP model is coded in GAMS 22.3 and solved by Baron solver. the computational studies are performed on a Dell Vostro 260s with Intel(R) Pentium(R) CPU G630 @ 2.70GHz and 4 GB RAM, using windows 7, 64 bit operating system.

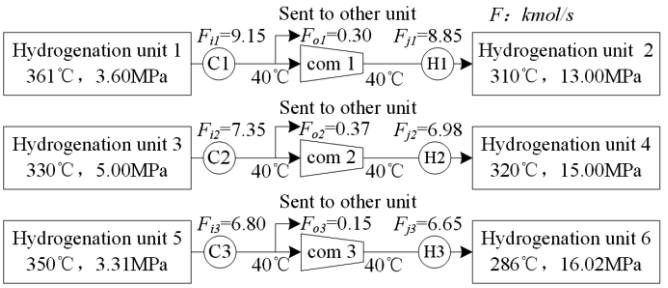

Figure 2 The schematic diagram of case

Table 1 The basic data of the case

Streams	Pressure(MPa)	T^{in}(℃)	T^{out}(℃)	F(kmol/s)
i1	3.60	361	40	9.15
i2	5.00	330	40	7.35
i3	3.31	350	40	6.80
j1	13.00	40	310	8.85
j2	15.00	40	320	6.98
j3	16.02	40	286	6.65

3.1 The optimized network with HEN

Table 2 shows the resulting data after the HEN optimization, where F is flow rate of each stream. For each hot/cold stream, T^{in} represents the inlet temperature of heat exchanger. After interception and heat exchange, all divided streams are mixed back to their original stream, whose temperature is T^{x}. This temperature of i1, i2, i3 are 84.0℃ ,150.8℃,88.7℃ in Figure 3. For hot streams, T^{x} is cooled down to T^{out} using cooling utility while heating utility is used for cold streams. T^{out} is the outlet temperature of heat exchangers and meanwhile the inlet temperature for compressor, such as the T^{out} of stream *i1* is the optimizing variable T_{i1}^{out} in the model. U is the utility consumption and W means the compressor work needed for the whole system. Optimized system with only heat integration is shown in Figure 3, and it can be seen that after HEN optimization, there are 6 heat exchangers, 3 coolers and 1 heaters. The demand for cooling utility is 14534.01kW, 301.76kW for heating utility and 4990.64kW for compression work, respectively.

Table 2 The results after optimization of HEN

Streams	F(kmol/s)	T^{in}(℃)	T^{x}(℃)	T^{out}(℃)	U(kW)	W(kW)
i1	9.15	361.0	84.0	40.0	3779.61	1908.05
i2	7.35	330.0	150.8	40.0	7645.84	1865.14
i3	6.80	350.0	88.7	40.0	3108.56	1167.14
j1	8.85	40.0	310.0	310.0	0.00	0.00
j2	6.98	40.0	315.4	320.0	301.76	0.00
j3	6.65	87.9	286.0	286.0	0.00	0.00
Total:Heating utility: 301.76kW, Cooling utility:14534.01kW, Compression work: 4990.64 kW						

3.2 Simultaneous optimization for compression work and utility of HEN

Different from the results obtained by HEN optimization, the simultaneous optimization achieved the minimization for compression work and heating and cooling utilities simultaneously, and an further optimized network is shown in Figure 4. Table 3 shows the data after simultaneous optimization.

Table 3 The results after simultaneous optimization of heat and compression

Streams	F(kmol/s)	T^{in}(℃)	T^{x}(℃)	T^{out}(℃)	U(kW)	W(kW)
i1	9.15	361.0	74.3	28.0	3976.19	1332.48
i2	7.35	330.0	140.9	31.0	7580.57	985.94
i3	6.80	350.0	76.9	35.0	2675.20	1588.06
j1	8.85	28.0	308.7	310.0	108.24	0.00
j2	6.98	31.0	317.0	320.0	196.59	0.00
j3	6.65	76.9	286.0	286.0	0.00	0.00
Total: Heating utility: 304.83kW, Cooling utility: 14231.96kW, Compression work: 3906.48 kW						
Saved: Utility: 298.98kW, Compression work: 1084.16 kW						

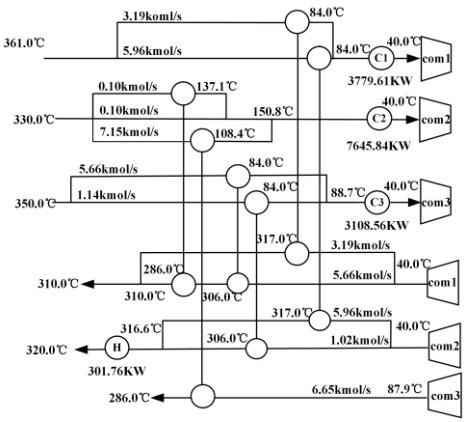

Figure 3 The HEN optimized network

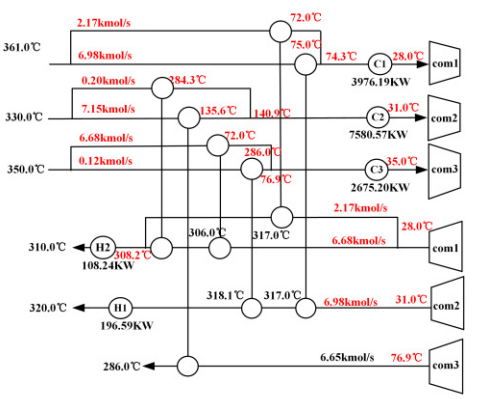

Figure 4 The simultaneous optimized network

The optimal inlet temperature of the compressor for hot streams are 28.0℃, 31.0℃ and 35.0℃, respectively. The minimum cooling utility is 14231.96kW, the heating utility is 304.83kW, and the compression work is 3906.48kW. In summary, the total energy consumption, *gw,* which is the sum of *U* and *W,* was saved about 6.97% of its original consumption, about 1383.14kW.

Compared the two networks, simultaneous optimized network has 6 heat exchangers, 3 coolers and 2 heaters, so only one heat exchanger is added for optimization of T_i^{out}, and T_j^{in}, simultaneously for compressors. In Figure 4, the red numbers are difference to that in Figure 3. This model optimizes the inlet temperatures for compressor, which is also the outlet temperature for hot streams, so that the compression work and HEN utilities can be reduced after optimization to further improve the energy utilization performance. Therefore, this method is contributory on both theory and application aspects.

4. Conclusions

Focused on the holistic energy conservation of refinery hydrogenation system, a method for simultaneous optimization of compression and HEN to minimize total energy consumption is proposed, and then a NLP model is formulated and demonstrated by a practical refinery case. Results show that the simultaneous optimization method can further conserve more energy than that obtained with only heat integration.

Abstract

This study addresses the problem of procurement planning and its integration with production planning of a refinery. Though a complete integration of the optimization models of crude procurement planning and refining process operation is desirable, it is currently computationally problematic due to the very large size of the resulting optimization problem. An alternative to the fully integrated optimization is to determine the optimal crude demand by solving the refinery process optimization problem first, and then to solve the procurement planning problem to minimize the deviation of actual crude supply from the optimized demand. However, such a separation can result in a significant sub-optimality or even an infeasible refinery operation since deviations of same size between supply and demand can bring very different effects on the refining margin and operation depending on the type of deviation and the market situation. Such drawbacks can be alleviated by quantifying the effects of deviations and reflecting them on the weight parameters in the optimization problem of procurement planning. The developed approach is tested on a case study involving an actual industrial refinery. It is shown that the quantified weight factors help reduce feasibility problems and loss from the sub-optimality, compared to the conventional approach without such weight factors.

Keywords: Procurement planning, Oil refining industry, Mixed integer non-linear programming, Process Integration

1. Introduction

A petroleum refinery plant comprises diverse sub-systems with various value chains and time scales, and there exists a significant difference in time scale between the planning stage (usually in months) and the scheduling stage (usually in days). Recently, as the environmental regulation and product specification become tighter and crude price and product demand fluctuate, great economic potentials are there for the refining industry if the gaps between different decision-making stages can be reduced by integrating them more tightly (Grossman, 2012).

Although the importance of integrating planning and scheduling has recently been brought up to attention, few researches have addressed the integration in the context of oil refineries (Erdirik-Dogan et al., 2008). The major difficulty in integrating different

decision-making stages having different time scales is a large size of a completely integrated optimization problem, which must be formulated in the fine timescale not to lose the relevant details. Such problems are computationally challenging despite all the recent advances in computing hardware and numerical methods. To handle the complexity of the problem, Kelly et al. (2017) proposed a solution strategy for a mixed-integer nonlinear programming (MINLP) problem in a petroleum refinery by decomposing it into an MILP and a NLP and reducing the gap between the two problems. Menezes et al. (2015) developed a solution algorithm called phenomenological decomposition heuristic (PDH), which divides the original MINLP problem into 2 sub-models and solve them in an iterative way until the two models converge.

In this research, an alternative to the complete integration approach is proposed, where the integration is achieved by minimizing the gap between the demand and supply profiles of various crude types, which are obtained from production planning and procurement scheduling, respectively. That is, an optimal crude selection profile is first calculated using a refinery optimization model, and then, procurement scheduling is done by a MINLP model aimed at supplying crude oils to the refinery with as small a deviation as possible from the optimal demand for each crude type. However, such a simple approach can result in sub-optimal, or even infeasible operation in the refinery system due to the gap. Note that a gap between supply and demand for different crude types at different times can have different effects on the refining margin and operation, depending on the physical and chemical properties of various crude oils and the market situation.

Motivated by this, this paper explores the possibility of reducing the above-mentioned sub-optimality and infeasibility in the two-step optimization approach by assigning an weight parameter to the difference between demand and supply for each individual crude type. The value of weight parameter is chosen based on the marginal value of deviation for each crude type calculated by giving a perturbation to the optimal crude profile.

The content of this paper is organized as follows. In Section 2, the studied refinery system is described and the optimization problem is cast as an MINLP problem. A method of estimating the weight parameter for a deviation between optimal demand and actual input is introduced in Section 3. In Section 4, a case study involving a refinery operation for a 6-months period (From May 2015 to October 2015) is performed with real price data of crude oil and product and the results are presented. Finally, Section 5 concludes the paper.

2. Problem Description & MINLP Model Design

The graphical diagram of the studied refinery procurement and production system is presented in Figure 1. The purpose of the procurement planning is to supply crude oils to the refining system by meeting the crude demand profile requested by the refining process. In practice, it is not always possible to do this exactly and some deviation of supply from desired demand is unavoidable. Optimization can help to reconcile such differences. In the optimization of procurement planning, crude oil purchase and inventory management decisions are determined as well as supplying crude profile into the processing unit. On the other hand, the refinery optimization calculates the optimal profile of crude oil to maximize the gross margin of the refining system. In such a context, the procurement system would use the optimal crude profile obtained from the refining process optimization as input parameters, whereas the refining process optimization would need the optimal input crude profile calculated by the procurement model as input parameters to achieve the highest possible final gross operational margin.

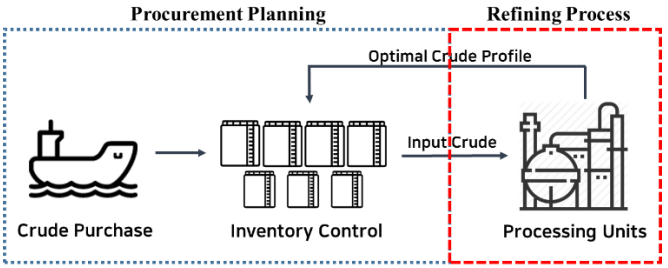

Figure 1. Refinery procurement and production system

In this study, the refinery optimization model developed by Noh et al. (2017) is used for determining one-period (5 days) optimal crude demand. In the multi-period optimization problem of procurement planning, the required parameters such as the number of tanks and their capacity, and purchase cycle and delivered time of crude are chosen to reflect the practical refinery situation. The general procedure for the procurement is as follows: 1) Order decision of which crude oil will be purchased is made every 5 days; delivered period is one month from ordering. 2) Arrived crude is unloaded to the port and distributed to the inventory tanks. 3) The crude from each inventory tank is gathered into buffer tanks. 4) The crude is finally put into the processing unit (the crude distillation unit). The specific amounts of crude flows from the purchase to the processing unit are determined by optimization.

The corresponding optimization problem takes a form of MINLP due to the nonlinear constraints related to the crude composition in the inventory tank through various types of crude oil mixing and the binary variables for the crude purchase decisions.

Positive or negative deviation of crude supply profile from the optimal demand (calculated from a separate optimization of refinery operation without considering constraints from the supply side) is expressed as in Eq.(1), where $P_{o,i,t}$ is the proportion of crude oil *o* in tank *i* at time *t*, and $FO_{i,t}$ is the amount flow put into the CDU from tank *i* at time *t*. Thus, $\sum_{i\in I}\left(P_{o,i,t}\cdot FO_{i,t}\right)$ represents the total amount of crude *o* going to CDU at time *t*. And $D_{o,t}$ is the optimal crude demand of crude *o* at time *t*, which is determined from the production optimization. $DVP_{o,t}$ represents the absolute value of positive deviation of crude *o* at time *t*, whereas $DVN_{o,t}$ represents the absolute value of negative deviation of crude *o* at time *t*.

$$\sum_i\left(P_{o,i,t}\cdot FO_{i,t}\right)-\ D_{o,t}=\ DVP_{o,t}-DVN_{o,t}\ \ for\ \forall o,t \tag{1}$$

When the amount of oil *o* going to CDU at time *t* exceeds the optimal demand, a positive deviation occurs and the value of $DVP_{o,t}$ equals to the value of $\sum_{i\in I}\left(P_{o,i,t}\cdot FO_{i,t}\right)-\ D_{o,t}$ while $DVN_{o,t}$ is zero. On the other hand, when the amount of oil *o* going to CDU at time *t* is below the optimal demand, a negative deviation occurs and the value of $DVN_{o,t}$ equals to the value of $D_{o,t}-\sum_{i\in I}\left(P_{o,i,t}\cdot FO_{i,t}\right)$ while $DVP_{o,t}$ is zero. This relation between positive and negative values of the deviations are incorporated into the objective function of the procurement model, which is to minimize the sum of positive or negative deviations of the crude supplies from the optimal demands requested by the production system, as shown in Eq.(2).

$$obj=\sum_o\sum_t(DVP_{o,t}+DVN_{o,t}) \tag{2}$$

Further detailed formulations are omitted here due to the length constraint, but one can refer to the model used in Oddsdottir et al. (2013).

Despite the reduction in the problem size achieved through the hierarchical separation of the two systems, the resulting MINLP is still very difficult to solve exactly within reasonable time. 'PROcurement-NO-DIScrepancies (pronodis)' approach (Oddsdottir et al., 2013) is used as a relaxation method of MINLP, where the MINLP is decomposed into MILP and NLP to avoid solving the MINLP directly.

3. Estimation of weight parameter for the deviance between the crude demand and supply for individual crude type

Separate implementations of the production planning and the procurement planning (Chapter 2) result in sub-optimal, or even infeasible operation of the refining system. In this study, such sub-optimality and infeasibility are reduced by estimating an appropriate weight parameter for deviation between the crude oil demand and supply for each individual crude type. To quantify the effect of supply deviation from optimal demand, the marginal value is computed for each crude type by giving a perturbation to its optimized demand value. Then the calculated values are set as the weight parameters of the deviations in the objective function of Eq. (2).

The procedure for the weight parameter estimation method is as follows: 1) A set of tested crude profile scenarios is generated by giving perturbations to the optimal crude profile for each crude type. Since too large a size of perturbation results in an infeasible operation in the production planning, the size of perturbation is chosen to be as large as possible, ~ 0.02 % of the maximum crude availability. Here, the sum of the total amount of crude supplied to the processing unit is kept constant in each scenario. 2) Among the scenarios generated from 1), physically unrealizable cases are eliminated where the amount of supplied crude is negative or exceeds the allowed availability. 3) For all feasible scenarios, loss in the operating margin is measured by solving the refinery optimization problem. 4) For each negative or positive deviation in the supply of a crude type, scenarios that contain the matching deviations are picked. Summing up the losses in the operational margin for the selected scenarios and dividing it by the number of scenarios picked, an average effect of each deviation on the gross margin is quantified. The average marginal values are then directly used as a $WP_{o,t}$ and $WN_{o,t}$. Then, estimated values of positive weight parameters $WP_{o,t}$ and positive weight parameters $WN_{o,t}$ are multiplied to each deviation in the objective function of procurement planning as in Eq.(3)

$$obj\ w/weight = \sum_o \sum_t (WP_{o,t} * DVP_{o,t} + WN_{o,t} * DVN_{o,t}) \quad (3)$$

Note that this estimation method is based on the assumption that the relationship between the gross margin and deviation of crude supply from an optimal value is linear and the effect of each crude type is independent from those of others.

4. Case Study

In order to validate the MINLP model of the procurement planning system and effectiveness of the weight estimation method, a case study involving a real industrial refinery is presented, based on its operational record for a six-month period, from May to October of 2015. Based on the historical price data for crude oil and refinery products for the 6 months period, the refining process model selects optimal crude oil profiles that maximize the gross refining margin. (Table 1)

Then, the weight parameters for the positive and negative deviations of each crude supply from the optimal demand are estimated at each month (Table 2). The weight parameters of positive deviations from the maximum available (50 kbbl) are set as zero since there is no case where the actual input exceeds the maximum amount of availability, both the optimization problem the and actual system. In a similar manner, the weight parameters of negative deviations from the optimal demand of zero are also set as zero.

Then, MINLP problem is decomposed into MILP and NLP using ProNoDis relaxation, and solved for 2 cases, with or without the weight parameters. The MILP and NLP are solved by CPLEX and NLP respectively using the GAMS software. The resulting solution from the IPOPT solver is a local optimum, which is common in dealing with large size non-convex systems.

Due to the large size of the complete problem involving the whole 6 months period, the rolling horizon method is used in this paper where it solves the scheduling problem with a 2 month period after an update of the problem at each month.

Finally, the refinery optimization is re-solved using the input crude profile, which are determined in the procurement planning as input parameters. The resulting refining margin are compared with the optimal margins (Figure 2). The zero value of gross margin in Figure 2 indicates an infeasible operation in the refining system where it was impossible to calculate a feasible solution with given input to the system due to a violation in the product specification. The total gross margin when the weight parameters are applied is 37.83 million dollars, which is 1.55 times higher than the gross margin achieved when the weight parameters are not applied. In addition, the operation result with the supplies determined with the weight parameters was feasible for 14 periods (38.89 %), compared to just 9 periods (25 %) for the case without using the weight parameters. This result demonstrates the effectiveness of varying the weight parameters of the deviations in terms of ensuring feasibility and increasing the refining margin.

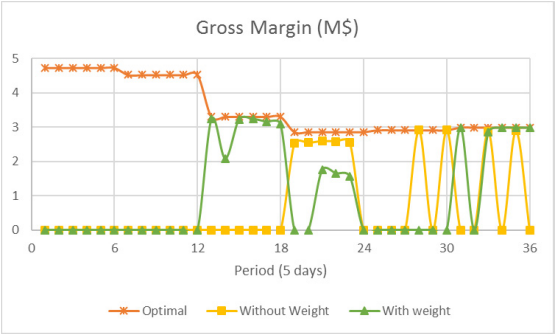

Figure 2. Refining margin for optimal operation, and actual operation with and without weight parameters

5. Conclusions

This paper discussed the integration of procurement planning and production process in petroleum refinery. This study sought to integrate the two systems by reducing the gap between the supply and demand by the two systems rather than by solving the combined mathematical programming problem. The MINLP problem, which aims to minimize the difference between the optimal crude portfolio calculated by the production system and the actual input was formulated for procurement planning. However, simply minimizing the value of deviance of crude profile resulted in substantial sub-optimality and sometimes even infeasibility. In order to resolve these drawbacks, weight parameter for each crude type was estimated at each time period. As a case study, the MINLP model and weight estimation were conducted for an actual industrial petroleum refinery based on historical data of crude and refinery product price information from May to October 2015. The performance of weight parameter estimation scheme was verified in simulation using these data and the results were significantly improved: the gross margin was 1.55 times higher and feasible region was 1.55 times longer compared to the operation without the weight estimation.

Abstract

This work aims at developing sustainable processes for pulp and paper industry by integration of the biorefinery concept to an existing pulp and paper process. A systematic methodology employing a superstructure-based process synthesis approach is used with support from computer-aided tools to determine potential pathways for long-term sustainable growth. A superstructure of the multi-product biorefinery process network for the pulp and paper industry is developed. It is divided into three sub-networks, a chemical pulping section, a biochemical production section and a black liquor utilization section. Lignocellulosic biomass extracted from eucalyptus and bagasse is applied as feedstock for the network. Potential products from the biochemical production section include ethanol, lactic acid (LA) and succinic acid (SA) while those from black liquor utilization section include dimethyl ether (DME) and lignin apart from its conventional utilization as low-heating value energy for the pulp and paper process. Superstructure optimization is performed with the objective to maximize profit to determine optimal integrated networks for three scenarios. The obtained results provide useful insights for further development of optimal networks as sustainable integrated biorefinery combined with pulp and paper mills.

Keywords: Pulp and paper industry, Biorefinery, Process integration, Process synthesis, Superstructure optimization

1. Introduction

The pulp and paper industry today has the world's largest woody biomass utilization system and is a large user and producer of bioenergy. However, the pulp and paper production require large consumption of chemicals, energy and water, and is characterized by low efficiency of raw material and energy utilization, low innovation development and high product price volatility. Moreover, the printing paper consumption has been diminishing because of increased use of digital media through computers, tablets and smart phones. The traditional pulp and paper industry needs to transform to respond to the current situation. Integration of biorefinery into an existing pulp mill has been identified as a potential pathway for long-term sustainable growth of

not only the paper industry but also biorefineries. The integrated process could transform a low-margin paper manufacturing production into a marketable multi-product production system involving new revenue streams through the production of biomaterials, bioenergy, biofuels and bio-chemicals and thereby achieve efficiency and profitability improvements (Rafione et al., 2014).

Superstructure-based process synthesis approach provides the overview and analysis needed for commercial development of biorefinery integrated with pulping processes. Here, the superstructure represents all possible pathways in an integrated network of processing options. Superstructure optimization can be performed to find out the most effective pathways in terms of the defined criteria (Zondervan et al., 2011). This study aims to identify a promising process pathway for a biorefinery integrated with an existing pulp mill considering different objectives (scenarios). The superstructure consists of three main sections, which are pulping section as the receptor, the biochemical production section and the black liquor utilization section. The three scenarios considered, include pulp sale and biochemical production as alternatives (Scenario I), biochemical co-production with pulp sale (Scenario II) and multiple biochemical production (scenario III). The appropriate integrated networks for each scenario are presented.

2. Synthesis Methodology

Process synthesis problems involving many alternative technologies for each processing step is complex and a systematic methodology supported by computer-aided tools are needed for their solution. Super-O (Bertran et al., 2017) with GAMS (GAMS Development Corporation, 2011) is applied for process synthesis and the four steps solution approach is employed in this paper.

2.1. Step I :Problem definition

First the synthesis problem is defined. A pulp and paper mill is selected as the receptor mill. Biorefinery platforms, involving biochemical production, and black liquor utilization are integrated into the selected receptor mills to share raw material, by-products and some utilities. The objective function here maximizes profit of the integrated network. The profit is calculated as the difference of income from product sale and expenditure consisting of raw materials, chemicals added, utility and capital cost.

2.2. Step II :Superstructure generation

A superstructure represents all processing routes that are possible as alternatives in terms of processing steps and intervals (processing technologies for each step). Interval information on raw materials, main products, side products, reactions, chemical added, utilities and economic data such as product price, raw material cost, chemical cost and capital cost are collected from published articles and scientific literatures, available industrial data and databases. Receptor pulp mill configuration consists of Kraft process, where eucalyptus is a raw material, and Soda process with bagasse as a raw material. Overview of the superstructure is illustrated in Figure 1 and intervals for biochemical production are shown in Figure 2. The biochemical process includes productions of ethanol, lactic acid and succinic acid. Alternatives of pulp pathway are to market pulp for sale and as feedstock for biochemical production. Bark and pith can be alternatively applied for energy supplement with black liquor utilization. Three

technologies including Black Liquor Gasification Combined Cycle (BLGCC), Black Liquor Gasification for Dimethyl Ether Production (BLG/DME), and Lignin Extraction (LE) are considered as efficient processes to replace a conventional process, the Tomlinson boiler. For all black liquor utilization technologies, the generated steam and electricity is supplied to meet pulping process demand. The excess electricity is sold to grid while any deficit electricity is purchased. Regarding DME production, the process can supply energy for the pulping section with DME production for sale. Lignin extraction is designed to supply extracted lignin as biofuel instead of fuel oil from petroleum in the lime kiln operation. Incomes from extra pulp productivity due to lignin extraction are also considered.

2.3. Step III :*Mathematical model*

Each process interval is represented by corresponding mathematical models (Bertran et al, 2017). The mathematical programming problem, process constraints, logical constraints and the variable bounds are formulated as a mixed-integer (non)linear programming problem or MI(N)LP model (Quaglia et al., 2015).

2.4. Step IV :*Problem Solution*

The optimization problem can be solved with GAMS through the user interface Super-O. The generic model for the intervals, the user defined objective function, process interval constraints, superstructure flow constraints and logic constraints are all defined through Super-O. The necessary data to solve the synthesis problem is given as input through a database. The problem is solved to find the optimal processing route with associated generated output data.

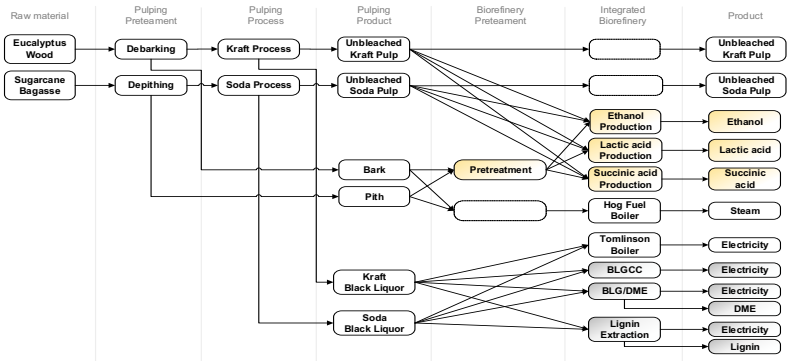

Figure 1. Overview of superstructure for integrated biorefinery network

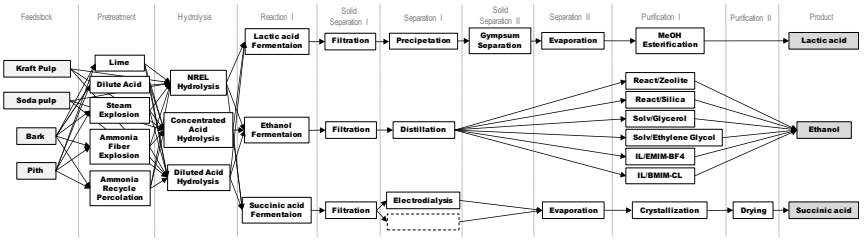

Figure 2. Superstructure of biochemical production

3. Results and Discussion

The superstructure optimization was carried out to determine optimal integrated networks for three scenarios. For all cases, raw material flow rate is maintained at 100,000 tons per year and project life is assumed to be 20 years.

Table 1. Statistics of the superstructure optimization problem (one scenario)

Problem	NI	71
	NF	2
	NP	15
	NC	51
	NR	55
Model and Solver	NEQ	825,633
	NV	812,856
	Problem type	MIP
	Solver	CPLEX

(Abbreviations as follows: NI is the number of processing intervals; NF is the number of feedstocks; NP is the number of products)note that NPI includes NF and NP(; NC is the number of components; NR is the number of reactions; NEQ is the number of equations; NV is the number of variables)

3.1. Scenario I: Biochemical production and pulp sale as alternatives

For economic decision on selecting one of the possible alternatives of conventional pulp sale and production of a biochemical product from unbleached pulp, superstructure optimization is performed to maximize profit (scenario 1). Economic results of the optimal networks are given in Table 2. The optimal network is Soda process with succinic acid production and black liquor gasification for DME production that produce 31,227 tons per year of succinic acid and 3,950 tons per year of DME from 100,000 tons per year of bagasse. Electrodialysis with crystallization is a suitable method for succinic acid purification. Ammonia recycle percolation is used for pith pretreatment with steam explosion for bark. Concentrated acid hydrolysis is employed before fermentation. Integrated biorefinery network without pulp sale increases revenue to 60 M$/year, which is higher than the conventional route with Soda process (48 M$/year) when integrated with the Kraft process. Optimization results for scenario I illustrate that top value-added biochemical products like succinic acid, lactic acid and DME with the existing pulp mill provide higher profit than the traditional pathway, whereas, the one with ethanol product is uneconomical. Instead of conventional recovery system, black liquor gasification with DME production is obviously an optimal black liquor utilization technology with Soda process that can also supply energy for the pulping process with high value biofuel production. However, lignin extraction is selected in case of Kraft process due to benefit of extra pulp production with lower capital cost.

Table 2. Economic results of optimal networks of overall superstructure and integrated biorefinery with Kraft process for scenario I.

Network	Profit (M$/y)	Sale (M$/y)	Raw material Cost (M$/y)	Chemical Cost (M$/y)	Utility Cost (M$/y)	Capital Cost (M$/y)
Soda pulping process with SA production and BLG/DME	67.68	96.36	2.30	2.48	22.21	1.69
Kraft pulping process with SA production and LE	63.28	89.30	2.90	1.83	21.20	0.09

3.2. Scenario II: Biochemical co-production with pulp sale (20, 50, 80 and 100% of the pulp sale)

In scenario II, the amount of pulp sale is specified at different percentages of total unbleached pulp production; i.e. 20, 50, 80 and 100% (Total pulp sale). Results of optimal networks are given in Table 3. The integrated network with Soda process shows the highest profit for all cases. With Soda pulp sale, succinic acid and DME production is an optimal pathway but the lactic acid process provides higher profit with 100% pulp sale) with pith employed as feedstock for lactic acid production. Although the integrated biorefinery with Kraft pulp sale offers 7% lower profit than with the Soda pulp, it provides rather high benefit with succinic acid production and lignin extraction. The profit of network decreases by about 21% with 60% increase of pulp sale due to the reduction of biochemical production but it can respond to the market need of paper pulp.

Table 3. Economic results of the optimal networks for scenario II

Optimization case	20 % pulp sale	50 % pulp sale	80 % pulp sale	100 % pulp sale
Pulp/SA or LA Flow (t/y)	7,128/26,857	17,820/20,022	28,512/12,824	35,640/10,388
Product sale (M$/y)	85.40	68.10	49.71	37.27
Profit (M$/y)	59.78	47.26	34.47	25.14

3.3. Scenario III: Multiple biochemical production integrated with pulping process

Production of multiple biochemical products has the flexibility to respond to fluctuating markets. According to scenarios I and II, succinic acid is an optimal product for the integrated biochemical plant with pulping process. Scenario III presents optimal pathways and economic data of integrated multiple biochemical production with pulping process along with co-production with pulp sale. The optimization in scenario III was performed with varying succinic acid productivity in terms of conversion of sugar to succinic acid: 30, 50 and 80 %. Multi-biochemical co-production with pulp sale is considered by maintaining the succinic acid production to around 10,000 tons per year, based on current succinic acid demand surveyed in Thailand. Table 4 gives product flow and economic results of integrated network with Soda process for scenario III. Multiple biochemical production integrated with Soda process gives the highest profit with succinic acid, lactic acid and also DME productions. Integrated multi-production with Kraft process is also a potential network, even if it has lower profit. The results of different succinic acid productivity indicate that the increase of succinic acid leads to a profit drop but only 3-8 %. Pulp split for sale makes profit dwindle to about 10-50 % depending on % of pulp sale. However, multiple biochemical streams have

great potential to improve economic benefit along with supplying pulp according to market need and especially to respond to the volatile market.

Table 4. Economic results of the optimal networks for scenario III

Optimization Case	30 % sugar division	50 % sugar division	80 % sugar division	20 % pulp sale	50 % pulp sale	80 % pulp sale
SA/LA flow (t/y)	9,368/ 25,195	15,613/ 17,997	24,982/ 7,199	10,144/ 19,141	10,149/ 11,363	10,065/ 3,142
Product sale (M$/y)	88.74	90.92	94.19	79.28	64.61	48.66
Profit (M$/y)	61.85	63.28	65.42	55.04	44.49	33.45

4. Conclusions

Superstructure optimization has been performed to generate optimal integrated network alternatives considering three scenarios that indicate promising future trends for pulp and paper industry transformation. From the results, top value-added biochemicals have been identified, such as succinic acid and lactic acid but not ethanol to improve the profitability of pulp mill as well as black liquor gasification with DME production that can supply bioenergy and biofuel. Soda pulping mill is a suitable receptor for the integrated biorefinery. However, Kraft process implemented with succinic acid and lignin extraction is a feasible network even though it has lower profit. Also, the cases with integrated multiple bio-product with/without pulp sale illustrate that they provide higher profit than the conventional pathway, only pulp sale, together with responding the fluctuated market. Superstructure-based process synthesis approach supported by Super-O as a user-friendly software interface with GAMS solver is an effective systematic methodology for the synthesis of integrated biorefinery networks with pulp and paper industry. The case studies solved so far have demonstrated the applicability of the synthesis methodology through Super-O, which can manage large and complex problems with a fast problem formulation, robust solution and efficient data management.

Multi-period Optimization of Hydrogen Networks with Sulfur Content Variation

Jing Li[a] and Qiao Zhang[a,*]

[a]*School of Chemical Engineering & Technology, Xi'an Jiaotong University, Xi'an, Shaanxi Province, China, 710049*
q.zhang1986@stu.xjtu.edu.cn

Abstract

Crude oil is becoming heavier and lower-quality worldwide, especially the increase of sulfur content, which significantly influence on hydrogen consumption and products quality. At present, mathematical programming for hydrogen network integration can effectively conserve hydrogen resource. However, existing model hardly consider sulfur variation of crude oil. In this paper, a mixed integer nonlinear programming (MINLP) model is established to address hydrogen networks with feed oil sulfur content variation in multi-period. Hydroprocessing units are classified as upstream and downstream ones and new connections are added to perform integration. Fresh hydrogen minimization are employed as objective to optimize the hydrogen networks. Case study indicates that the novel model can achieve optimal strategy for sulfur content variation.

Keywords: Hydrogen network; MINLP model; sulfur content variation; Multi-period

1. Introduction

In recent years, daily demand for petroleum oil products is increasing rapidly. The problem of processing much heavy crude oil become more serious (Wang & Zhang 2005). Because of it, sulfur, as an important impurity in crude oil which has greatly influence on the hydrogen consumption of hydrogenation process, whose content in some areas is lower than 0.5%, while others are 2% or even higher (Xiang et al., 2006). Hydrogen network integration can effectively reduce the waste of hydrogen resources. Mathematical programming method based on superstructure is widely used in research and application. It was early proposed by Hallale and Liu (2001) to address hydrogen networks with basic constraints. Zhou et al. (2012) considered desulfurization to improve hydrogen resource utilization. Liang et al. (2016) discussed flexible and debottlenecking of multi-period hydrogen networks by considering possible operational conditions fluctuation to minimize total annual cost. By releasing the total flow rate and concentration normalization constraints, relative concentration basis was first put forward in hydrogen in 2016a (Zhang et al.) to synthesize single impurity hydrogen networks and then generalized to multi-impurity case (2016b).

Although some mathematical programming based literature aforementioned can address multi-period hydrogen networks, sulfur content variation is not considered. When sulfur content of source crude oil varies, hydroprocessing units in upstream and downstream will be both affected. To offset such variation, probably more fresh hydrogen is needed to guarantee production. For a certain sulfur content of crude oil, the hydrogen network should be optimized holistically and thus for variational sulfur content multi-period hydrogen network is the solution to refinery hydrogen network integration. In order to

minimize additional fresh hydrogen demand, this paper proposed a MINLP model to address multi-period hydrogen networks with sulfur content variation. Results show that the total fresh hydrogen with this method can be reduced compared to that obtained traditional methods.

2. Theory

2.1. Problem illustration

There are many hydrogenation units in petroleum processing, and they locate in system with upstream and downstream relationship, which is typically shown in Figure 1. The source crude oil contains sulfur and such impurity will be removed in upstream and downstream hydroprocessing units.

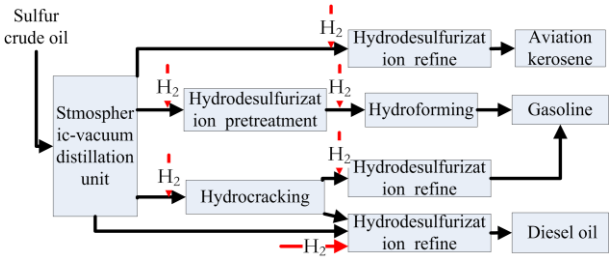

Figure 1: Upstream and downstream sites of hydrodesulphurization in petroleum processing

Therefore, when the crude oil sulfur content varies, the sulfur removal amount and hydrogenation performance in following upstream and downstream units will change accordingly and thus both the hydrogen supply and product oils quality cannot be guaranteed with constant hydrogen allocation network. This paper aims to optimize hydrogen network under sulfur content variation circumstance for minimizing fresh hydrogen consumption and the caused influence on the production of whole system.

2.2. Superstructure

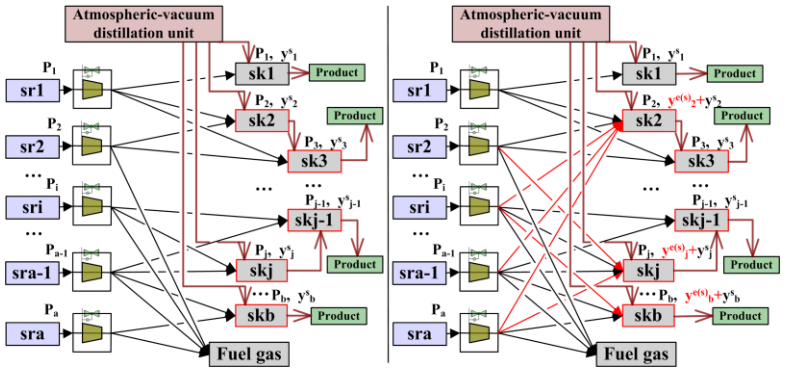

Figure 2: Original structure (left) and superstructure (right)

In Figure 2, *sr* represents hydrogen source; *sk* is hydrogen sink; the left one is a hydrogen network in steady state, where y^s_j is sulfur content of oil processed in *skj*. Sinks in red frame line, whose hydrogen demand affected by the sulfur content of the crude oil. In particular, units with upstream and downstream relationship like *sk2* and

sk3, if the influence of sulfur content variation is eliminated in *sk2*, *sk3* will not be influenced. Because of the heavier crude oil, if there is sulfur content change ($y^{e(s)}_j$) in those units, the superstructure on the right of Figure 2 is built to optimize hydrogen network. To achieve the optimal hydrogen network without adding compressor, only cases that hydrogen sources with enough pressures for sinks are considered to save hydrogen by only adding pipelines (red lines).

2.3. Mathematical model

Relative concentration basis in this paper refers to Zhang et al. (2016b).

$$RC_{k,sr/sk} = \frac{y_{k,sr/sk}}{y_{H,sr/sk}} \tag{1}$$

Relative concentration is used to quantify the impurity concentration while hydrogen flow rate is employed to quantify total flow rate.

Generally, data of the processing throughput (V_j) and its hydrogen demand (H_j) about different hydrogenation reactors is provided by refineries. However, when sulfur content of the oil processed by hydrogen sink changes $y^{e(s)}_j$, the hydrogen consumption need to change $H^{e(s)}_j$ at least to eliminate the influence. This paper establishes a direct proportional relationship between sulfur content and hydrogen consumption, and q is the coeffcient of proportionality. q is influenced by heuristic factors like origin of crude oil, while generally, there is an empirical value from refineries.

$$H^e_j = H_j + H^{e(s)}_j \tag{2}$$

$$H^{e(s)}_j = q \cdot y^{e(s)}_j \cdot V_j \tag{3}$$

About the constraints of sk_j, Eq.(4) means the amount of hydrogen provided by all sources should meet the demand of sk_j; Eq.(5) indicates that the average impurity concentration ($RC_{k,i}$) should be no larger than the upper limit of sk_j ($RC_{k,j}$).

$$\sum_{i=1}^{a} H_{i,j} + \sum_{i=1}^{a} H^{new}_{i,j} \geq H^e_j \tag{4}$$

$$\sum_{i=1}^{a} H_{i,j} \cdot RC_{i,k} + \sum_{i=1}^{a} H^{new}_{i,j} \cdot RC_{i,k} \leq RC_{j,k} \cdot (\sum_{i=1}^{a} H_{i,j} + \sum_{i=1}^{a} H^{new}_{i,j}) \tag{5}$$

For the adjustment of hydrogen supply from sources, hydrogen can be supplied according to the original state. In Eq.(6), $d_{i,j}$ is current allocation network matrix.

$$H_{i,j} \leq H^{up}_{i,j} \cdot d_{i,j} \tag{6}$$

In order to add new pipelines ($H^{new}_{i,j}$) described in superstructure, binary variables, $Bin1_{i,j}$ and $Bin2_{i,j}$ have been set.

$$If \quad P_i > P_j \ and \ d_{i,j} = 0 \Rightarrow Bin1_{i,j} = 1 \tag{7}$$

$$Bin2_{i,j} \leq Bin1_{i,j} \tag{8}$$

$$H^{new}_{i,j} \leq H^{up}_{i,j} \cdot Bin2_{i,j} \tag{9}$$

Main constraint for *sr* is availability of hydrogen resource: the sum of $H_{i,j}$ and $H^{new}_{i,j}$ (hydrogen from sr_i to sk_j) should be less than the total hydrogen flow rate of *sri* (H_i).

$$H_i = F_i \cdot y_{H,i} \tag{10}$$

$$\sum_{j=1}^{b} H_{i,j} + \sum_{j=1}^{b} H_{i,j}^{new} \le H_i \tag{11}$$

Fresh hydrogen is highest in the total cost. So in this paper, objective function is minimum the consumption of fresh hydrogen. In Eq.(12), *sr1* is fresh hydrogen.

$$Min{:}FSR1 = \frac{\sum_{j=1}^{b} H_{sr1,j}}{y_{H,sr1}} \tag{12}$$

This mathematical model consists of Eq.(1) ~ (12). There are endogenous variables $H_{i,j}$, $H^{new}_{i,j}$, and binary variables $Bin1_{i,j}$ and $Bin2_{i,j}$, so it is a mixed integer nonlinear programming (MINLP) model.

3. Case study

The data of hydrogen network comes from a refinery in China. Simplified by concept of hydrogen source and sink, data has been collated in Table 1 and 2.

Table 1. Data of hydrogen sources.

	F (Nm^3/h)	$y_{H,i}$	*P* (MPa)	$y_{k,i}$ (%)		
				H_2S	N	C
sr1	<20000	0.9999	2.2	0	0.01	0
sr2	17100	0.872	17.5	1.0	2.3	9.5
sr3	26015	0.884	8.0	1.3	1.5	8.8
sr4	13320	0.942	7.2	1.7	1.5	2.6
sr5	11790	0.932	4.0	0.6	5.1	1.1
sr6	22390	0.914	5.0	2.3	3.2	3.1
sr7	14630	0.897	4.0	4.2	2.6	3.5

Table 2. Data of hydrogen sinks.

	V (t/h)	$y_{H,j}$	H_j (Nm^3/h)	*P* (MPa)	$y_{k,j}$ (%)		
					H_2S	N	C
sk1	17.6	0.884	15621	18.4	2.0	2.8	6.8
sk2	60.4	0.913	22141	13.0	1.2	2.4	5.1
sk3	34.2	0.951	12087	8.0	1.4	1.9	1.6
sk4	38.6	0.939	17076	6.5	0.7	4.6	0.8
sk5	59.4	0.847	18982	4.8	3.0	1.2	5.1
sk6	29.7	0.908	13875	3.3	1.8	3.3	4.7

This hydrogen network has 7 sources and 6 sinks. There are three impurities in hydrogen streams, and they are sulfur, nitrogen and carbon, respectively. The original oil of the refinery is low sulfur content crude oil with 0.4% sulfur mass fraction. While due to the heavier crude oil, the variation range of sulfur content is large. Through the analysis of the categories and quantities of sulphide in this case, as the upstream hydrogenation units, sk5 and sk6 and *q* is 1388.9 Nm^3/t. The variation of sulfur content in crude oil is random, in order to optimize hydrogen networks, this paper takes a group of sulfur content to perform optimization. Meanwhile, the total fresh hydrogen

consumption obtained by this method is compared with that by existing methods for same sulfur content crude oils. Results are summarized as follows.

Table 3. Total hydrogen consumption calculation at the upstream hydrogen sinks 5,6

Sulfur content (%)	Fresh hydrogen consumption (Nm^3/h)		
	Original strategy	New allocation strategy	New allocation strategy with new connection
0.4	19311.2	19311.2	19311.2 (None)
0.8	19806.2	19424.7	19424.7 (None)
1.2	20361.2	19542.2	19542.2 (None)
1.6	20841.2	19663.2	19663.2 (None)
2.0	21351.2	19793.3	19786.6 (sk6-sr3)
2.4	21861.2	19991.8	19971.9 (sk6-sr3)
2.8	22381.2	20200.1	20068.9 (sk6-sr3)
SUM	145913.4	137926.5	137768.7

In Table 3, Original strategy is variation of sulfur content eliminated only by adding fresh hydrogen directly; column of New allocation strategy is adding fresh hydrogen with redistribution of hydrogen resources without new pipelines; the last column, with the reallocation of hydrogen network, sometimes requires additional pipelines. Results show that, redistribution of hydrogen resources can save lots of fresh hydrogen. Specifically described as, the amount of sulfur content increases by 0.4%, and the average of hydrogen saving is 385 Nm^3/h based on New allocation strategy without new pipelines; new pipelines can be further economical on this basis.

Analysis of the whole period of sulfur content variation, only by adding fresh hydrogen, the total fresh hydrogen consumption is 145913.4 Nm^3/h; original structure but new hydrogen allocation strategy, the total fresh hydrogen consumption is 137926.5 Nm^3/h, 7986.9 Nm^3/h less than the Strategy 1; new hydrogen allocation strategy with few new connections, the total fresh hydrogen consumption is the least, 137768.7 Nm^3/h. The results of three strategies are illustrated in Figure 3.

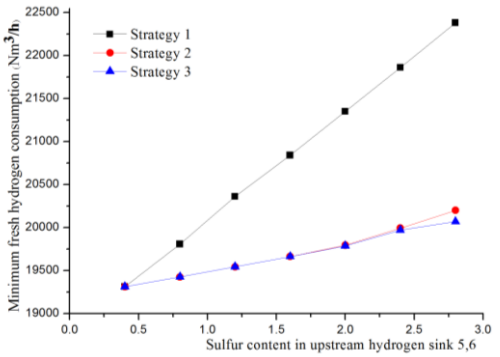

Figure 3: Fresh hydrogen consumption in three strategies

Figure 4 shows the hydrogen allocation networks of minimum and maximum sulfur content optimized by strategy 3. By comparison, the network is slightly changed only with one pipeline addition and none of new compressor equipments. Therefore, such retrofit is very economical for refineries to improve its hydrogen resource utilization.

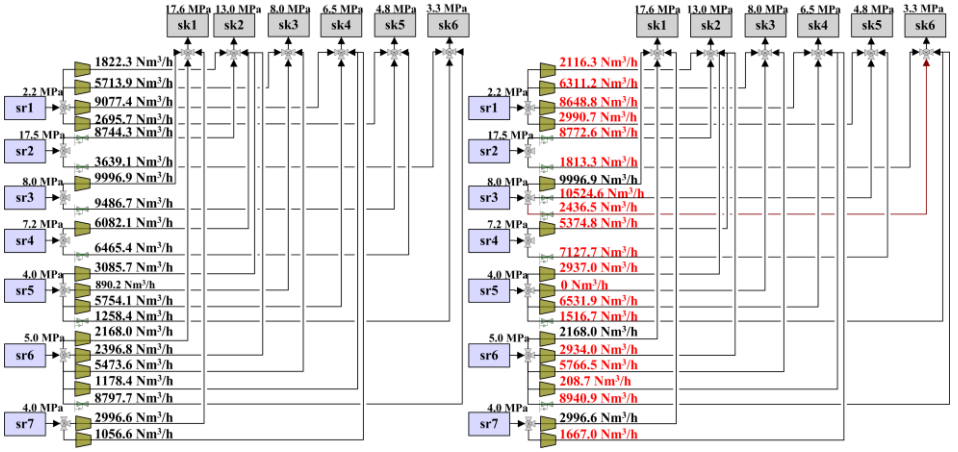

Figure 4 Optimal network of 0.4 % sulfur content (left) and 2.8% sulfur content (right)

4. Conclusions

According to sulfur content variation in refining process, a superstructure and MINLP model is proposed in this paper to optimize hydrogen resources distribution strategy under different states. Results prove that, during the same period of sulfur content variation, this model can effectively save fresh hydrogen consumption and eliminate the influence of impurity variation with very small change of the original structure and the hydrogen allocation network.

Abstract

Heat exchanger networks (HENs) are often analysed with simplified models which are not sufficiently predictive in the presence of fouling, in particular for operations monitoring, diagnosis and support. A comprehensive approach is presented, with application to oil refining, that moves substantially beyond the usual simplifying assumptions and incorporates: i) far more detailed models of the physics involved ii) detailed dynamics for both slow and fast changes; iii) detailed reaction engineering models of the deposition of fouling deposits on thermal surfaces as well as deposits removal in chemical and mechanical cleanings; iv) the ability to easily generate multi-scale, detailed models of individual exchangers and whole networks; v) consideration of the complex thermal and hydraulic interactions between exchangers and effects on performance; vi) exploiting the abundant plant data available (historical and current) in conjunction with the more sophisticated models; vii) solution of all problems within an easy to use engineering software environment.

Keywords: heat exchanger networks; energy integration; high-fidelity modelling; design and retrofit; scheduling and control; monitoring and data analysis.

1. Introduction

Energy recovery in integrated processes may be achieved through a complex network of heat exchangers (HEN), aimed at transferring as much as possible of the energy from a set of hot streams to cold streams. In crude oil refining, particularly relevant are the extensive heat exchanger network and energy recovery in the crude distillation units (CDU) at the front end of every refinery, which process essentially the entire world crude oil. Indeed, it may be argued that the whole fields of Pinch Analysis, HEN synthesis and HEN optimisation resulted from the exceptional economic motivation in this area, generating much research (e.g. Furman and Sahinidis, 2002), innovation and benefits over the last 50 years. In spite of the many advances, the drive towards additional efficiencies in the design and operation of such HENs is continuing, with strong economic incentives. To achieve such improvements, one must focus on aspects which have not been (sufficiently) considered, simplifying assumptions which may be limiting, the nature of residual efficiencies, and tools required to exploit them. In particular, the simplified exchanger models often used in Pinch analysis, HEN synthesis and optimization have been found in practice to poorly represent and support actual operations.

In this paper, a comprehensive modelling and software system is presented that moves substantially beyond the usual simplifying assumptions and incorporates the following main aspects: i) a far more detailed description of the physics involved in the process (from characterisation of the fluids and equipment geometry, to description of the heat transfer mechanisms and hydraulics and all aspects that affect them); ii) moving away from a steady-state or pseudo steady-state description of the process to properly include dynamics in detail, not just in a simplified way; iii) detailed reaction engineering models of the deposition of fouling deposits on thermal surfaces, considering deposit composition and coking (ageing) and their key effects on thermal and hydraulic performance, as well as the removal of such deposits in chemical and mechanical cleaning activities to restore thermal/hydraulic performance. This enables a seamless simulation of operation/cleaning cycles; iv) the ability to easily generate individual exchangers and networks from multi-scale models in such detail; v) proper consideration of the interactions between exchangers, and very complex shifts of thermal and hydraulic performance within a network which depend on its structure; vi) exploiting the abundant plant data available (historical and current) in conjunction with the more sophisticated models to analyse and improve operations and verify design retrofits in realistic scenarios that include variable feed and other conditions; vii) efficient solution of the resulting multi-scale, large PDAE equation systems within an easy to use engineering software environment.

2. Heat exchanger and Network models

The model framework used for individual (shell and tube) exchangers (Coletti and Macchietto, 2011, Diaz-Bejarano *et al*., 2016) is schematically shown in Figure 1. Basically, 2D distributed (axial and radial) dynamic mass and energy balances are developed for each tube. A detailed, moving boundary deposit layer model accounts for its growth and (2D distributed) properties, as a function of local deposition (and possibly removal) rates at the oil/deposit boundary. These depend on temperature and shear stress, hence fluid velocity (hence available flow area, which depends on deposit thickness). This dictates the temperatures profile (hence ΔT and heat transferred) and contribution to pressure drop at each axial position. The temperature history of each point in the deposit affects its coking (ageing), hence thermal conductivity, hence the temperature profiles. Physical and transport properties of the fluids are also a function of temperature, as well as the nature of the fluids. Tube side models are coupled with shell side models and a whole exchanger model is assembled, accounting for geometry, co-current or counter-current configuration, single or multiple passes, etc. Of course, this results in quite a large number of coupled partial differential and algebraic equations (PDAEs), which nowadays can however be solved efficiently. As the extent, nature and location of the deposit and its effects are the sole difference between a clean and a fouled exchanger, capturing these highly complex interactions in detail is key to faithfully describing its operation and ensuring confidence in the results for simulation, design, monitoring, diagnosis of abnormal events, performance prediction and performance improvement purposes. A multiscale, high fidelity, thermo-hydraulic dynamic model of an entire HEN undergoing fouling is then simply developed by assembling its various heat exchanger units according to the network topology, with the addition of stream sources and sinks, mixers and dividers, by-passes, pumps (usually, just one), control elements, and (in refining applications) the final furnace (Figure 2). The Hexxcell Studio™ software by Hexxcell Ltd is used for this purpose and all other applications mentioned in this paper.

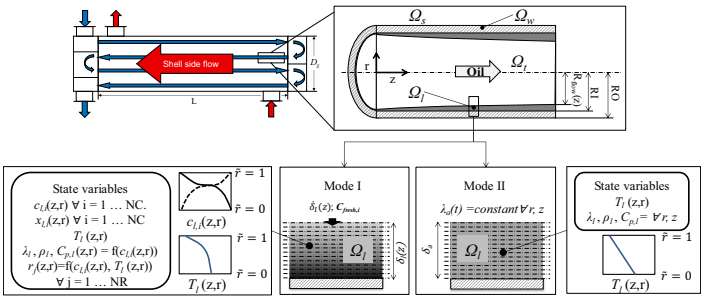

Figure 1. Schematic representation of exchanger modelling framework

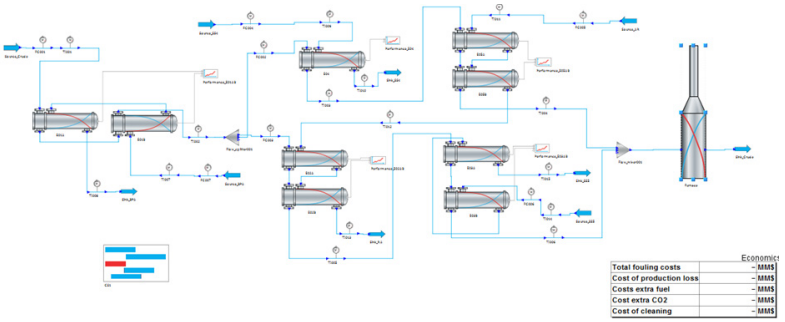

Figure 2. Preheat Train – Refinery X.

The fouling propensity of crude oils is notoriously difficult to predict (or even measure). Here, the *local* deposition rates are based on semi-empirical functional models of the Ebert and Panchal type. Typical fouling and ageing parameters for these models may be stored in a library, or estimated from primary plant data: flowrates, temperatures and, if available, pressure drops. This challenging dynamic parameter estimation problem is successfully performed for both individual and multiple exchangers, even with large data sets, making use of plant data are usually collected, stored and available but seldom used. They are usually noisy and there is no such thing as steady-state (Figure 3a). Extracting value from them is challenging. A Dynamic Data Analysis™ of such data (Figure 3b) allows "inverting" the above models and estimating an operational signature for each exchanger, including a wealth of normally unavailable quantities, e.g. time profiles of deposition rates, depth of deposits and their thermal conductivity, shear rates, etc. In a project carried out with a major US oil company, >120 year of operating data were analysed for 31 heat exchanger shells of diverse types in 7 refineries, operating a large variety of crudes in different conditions (Chunangad *et al*., 2016). The usual temperature and flowrate measurements were available for all the units, pressure drop measurements only for some. After parameter estimation, the model predictions were validated against plant data, confirming very good predictive ability (duty predicted within ±10% and ΔP within ± 0.2 bar) and parameters portability to other units in similar conditions. Refitting parameters may be needed when oil slates change significantly.

A new plot, the TH-Plot visualizes performance losses relative to a clean exchanger operating in the same dynamic conditions. Figure 4a) (and 4b for noisy data), shows the combined duty and pressure drop evolution (TH-line) in a heat exchanger against set operational reference lines (thermal limit, TL and hydraulic limit, HL). This unit is clearly heading to hit TH before TL. Using the models, additional reference lines may be

calculated and plotted, representing different degrees of deposit coking (Figure 4c). The TH-line of an exchanger allows monitoring its current vs. expected evolution, gives very useful early indication of deviations and provides diagnostic information about potential underlying causes. Figure 5a) shows the very distinct signatures of acute organic fouling and deposition of inorganic material (e.g. salts, oxides). The latter would not be detected using conventional monitoring of thermal fouling resistance. The TH-Plot of four years of operation of a problematic exchanger in a refinery hot end (Figure 5b), points to various periods of acute fouling and possible inorganics. A model-based analysis of the data estimated characteristics (thermal conductivity and inorganics fraction) of each layer of the deposit that matched surprisingly well a laboratory analysis of deposit samples collected from the exchanger tubes at the end of run (Figure 6), Diaz-Bejarano *et al*. 2017.

In Hexxcell Studio™ deposit removal is simulated in the same way as deposition. Chemical cleaning is incorporated using similar semi-empirical kinetic-type models. Its parameters may be fitted to actual cleaning performance of different chemicals and dosages. An entire campaign of operation (deposition) and cleanings (removal) may therefore be seamlessly simulated (Diaz-Bejarano *et al*., 2015), giving the ability to calculate, rather that assume, the initial state of a unit after a chemical clean. In Dynamic Data Analysis™ mode, the initial cleaning state may be back-estimated from a small number of data after the unit is returned to service.

Changing an exchanger design or operation to reduce fouling does not always deliver the expected improvement within a HEN. Increasing its duty changes temperatures and ΔTs elsewhere in the network, modifying its pressure drop shifts flowrates between parallel branches, all changing in time in ways hard to predict. A clear example was shown in a work with a European refiner (Diaz-Bejarano *et al*. 2017b). Validation for an existing exchanger confirmed model simulations were within the uncertainty of the measurement (±5% of the heat duty) for the entire 4.5-year period. A exchanger retrofit, checked on its own by re-running operating history (with the same inputs to the original design) for 4 years (Dynamic Retrofit Test™), confirmed its improved fouling mitigation effectiveness and higher energy recovery by 4.5 MW. With the same check for the network as a whole (Dynamic Network Retrofit Test™), due to complex interactions across parallel branches, only 60% of the 4.5 MW was recovered, however still reducing the fuel requirement at the furnace by $2.8 MM after 4 years, with high confidence in the results achieved.

Figure 3. Exchanger inlet temperatures and flowrates a); Dynamic Data Analysis of plant data b)

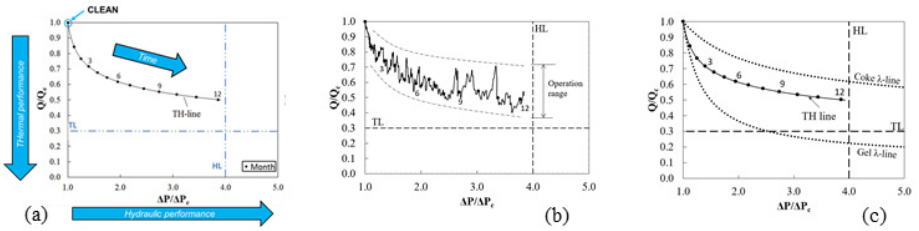

Figure 4. Thermo-hydraulic plot and reference lines are useful for monitoring and diagnosis (Diaz-Bejarano *et al* 2016b).

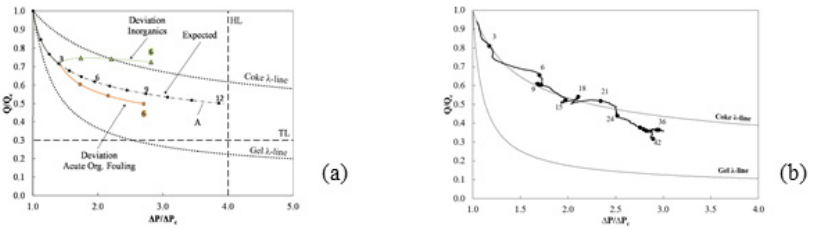

Figure 5. Monitoring and diagnosis of inorganics deposition a) (Diaz-Bejarano *et al* 2015) and TH-Plot for 4 years of operation in a refinery indicates period of acute fouling and inorganic deposition b).

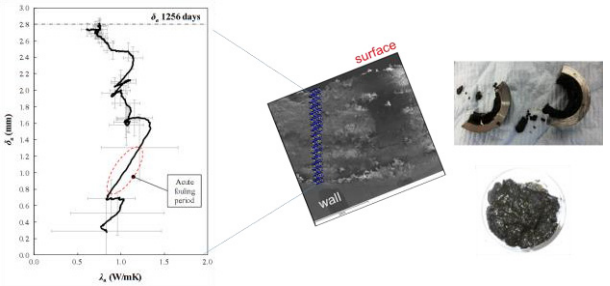

Figure 6. Model-based diagnosis of layering of deposit in a 4 years of operation in a refinery heat exchanger a) matched well with experimental composition analysis of the deposit b).

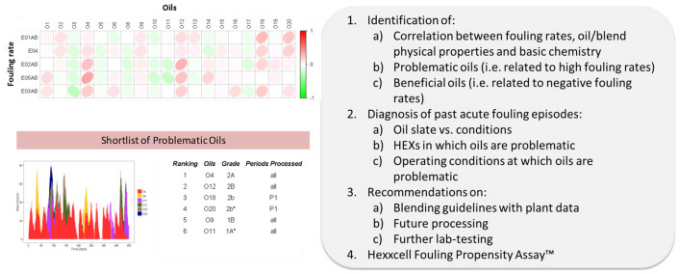

Figure 7. Model-based statistical analysis of large operational data sets identifies which crude oils are problematic, in which parts of the network, and in which operating conditions.

The ability to accurately predict the network performance and "soft-sensing" un-measured quantities, opens a further opportunity: a statistical analysis correlating fouling and performance indicators to inputs and operating conditions. With representative data (to protect client confidentiality) Figure 7 (top left) shows correlations of (soft-sensed)

fouling rates in 5 exchangers in a HEN to 20 crude oils used at different times and in different quantities in the oil blends fed to a refinery. The analysis identifies problematic or beneficial oils, in which combinations, and in which operating conditions. Scheduling and control aspects are covered in Lozano Santamaria and Macchietto (2017).

3. Conclusions

Numerous industrial applications have shown that integration of the predictive models described with the analysis of large scale sets of (already available) plant data delivers: i) excellent estimation of the current state of the exchangers and HEN overall ii) estimation of selected model parameters in the detailed dynamic models so as to fit the recent/current state iii) detailed monitoring and problems diagnosis of individual heat exchangers and the HEN overall iv) accurate long-range prediction of the HEN state and performance v) the ability to simulate and improve flow split and pressure driven control, cleaning schedules, and simultaneous control and scheduling vi) the use of such models in conjunction with plant data to statistically analyse the contribution of operational events and decisions to overall performance, in particular the effect of oil slates and "good" and "bad" oils in a blend vii) the ability to drive all above from economic as well as technical objectives. A shift in approach is therefore warranted from the simple models mostly used so far towards the more rigorous and predictive models described, analogous to moving from McCabe Thiele diagrams to rigorous models in distillation. The integration of advanced models with appropriate statistical analysis significantly increases the ability to extract useful information from data, predictive accuracy and improved economics.

Design of Circular Economy Plants – The Case of Waste Textiles to Chemicals

Foteini Barla[a*], Athanassios Nikolakopoulos[a], Antonis Kokossis[a*]

[a]*National Technical University of Athens, Department of Chemical Engineering, 9 Heroon Polytechniou Street, Athens 15780, Greece.*
fbaria@mail.ntua.gr

Abstract

Circular Economy (CE) plants act as intermediate facilities, transforming waste resources produced from one industry to raw materials utilised by another. The main feedstock of such chemical plants is multi-component wastes. Currently, there is an abundancy of feasible chemical and biochemical pathways to achieve these transformations but their integration to result to an integrated CE plant is not trivial. In the course of a European Research Project, RESYNTEX, focusing to convert waste textile to chemicals, the task of process synthesis has raised various alternative process configurations, which are assessed by mathematical optimisation (MILP). This work investigates the most economically viable strategy to valorise waste textiles, comparing various configurations of CE plant (waste-to-chemicals) to what is currently practised (landfill and waste-to-energy). The results of this work suggest that waste-to-chemicals is the most feasible strategy due to chemicals' selling prices. Further, the study presents that the most economically favourable configuration is the one, where the waste textiles are not separated in fractions but treated as whole in cascaded process. The presented model can be utilised for examining how the uncertainty of landfill tariffs, the technology's efficiency and CAPEX can affect the selection of the optimal waste valorisation strategy and the CE plants' configuration.

Keywords: circular economy, waste textiles, biorefinery, process design, process synthesis

1. Introduction

The dual problem of waste management and scarcity of resources has sparked renewed interest in exploiting raw materials from waste resources. Circular Economy (CE) promotes the concept of interconnecting linear production lines into a closed loop. European Commission forecasts that by redesigning product lifecycles, there could be an increase up to 7% in GDP by 2035, resulting from creation of 580,000 new jobs and €600 billion savings for EU businesses. Additionally, there could be a reduction up to 450 million tonnes of carbon emissions (European Commission, 2015[1]). More than 10 EU research projects have been funded working towards circular economy, incorporating examples such as utilizing dairy byproducts to produce rich-protein feedstock, noise protection panels from recycled tyres, production of chemicals from end-consumer textile waste and others (European Commission, 2015[2]). Leading companies such as DuPont, Dell, HP, Levi Strauss and many others have also embraced the concept of circular economy by demonstrating in practise eco-innovation (Hower, 2016).

The textile and apparel industry is an ideal case, where the CE concept could be applied since it is among the most profitable industries, with a market value of €0.82 trillion and it strongly follows the linear business model dictated by the inexpensive and "fast fashion" trend. Furthermore, it is notoriously known for producing vast amounts of post-industrial and post-consumer textile wastes, with an average recycling portion of only 15%. The EU and the USA generated 10 and 14.3 million tonnes of waste textile respectively in 2016, attaining 5% of solid waste found in the landfills (EASME, 2015) (Leonas, 2017).

Currently, there are four main reclamation strategies for waste textiles. They are sold directly in (a) the used-clothing markets, they can (b) be down-cycled to stuffing for automotive components, building material, insulation, carpet underlays and others, they are (c) closed-loop recycled through the use of mechanical transformation to produce once again fibres and (d) open-loop recycled through chemical and biochemical processing to produce chemicals, materials and energy. Down-cycling is not a lucrative business line and thus little innovation has been achieved. Closed-loop recycling is still facing many obstacles in converting blended fibres due to lack of processing equipment. For open-loop recycling, multiple chemical and biochemical recycling routes have been developed at laboratory and pilot level to valorise only pure polymers found in textiles such as polyester (Paszun & Spychaj, 1997), cotton (Gallezot, 2012) and polyamide (Sethi, 2016). However, more than 50% of the global waste textile is blend-fibres (inseparable by mechanical means) and to the best of our knowledge, there is no real-world application that integrates the existing process pathways to valorize the waste textiles holistically other than the work performed in the RESYNTEX project.

RESYNTEX is a collaborative project that involves several industrial partners, research institutions, textile collectors, sorting companies and chemical industry end-users (RESYNTEX, 2015). Its goal is to transfer the lab and pilot chemistries into an integrated industrial scale process, promoting chemical/biochemical textile recycling, aiming to create a new circular economy concept for the textile and chemical industries. Some of the key challenges in the early stage of the process design are how to integrate and in what order to arrange different processes valorizing different part of waste textile? Which is the most feasible process configuration in a given policy frame for waste textile, along with a given technology readiness level (TRL)? The paper demonstrates a case study, intending to assess alternative process configurations of pre-specified chemistries (dictated by RESYNTEX), with the objective to attain maximum economic feasibility. The work further investigated how waste-to-chemicals strategy compares to the current practices of landfill and waste-to-energy.

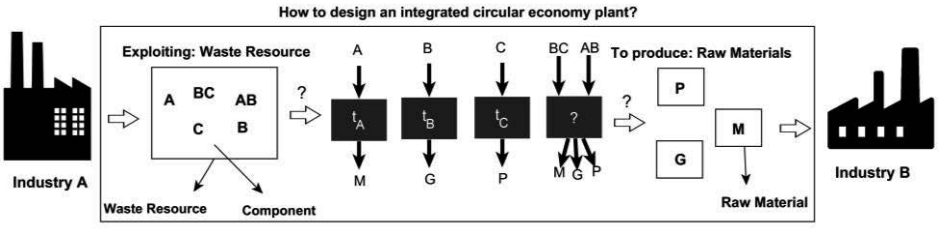

Figure 1: In what manner to combine waste-to-chemicals transformation processes in order to design a feasible integrated circular economy plant? A, B, C are pure materials, while AB and BC are blended, inseparable material.

2. Problem description

The problem assumes (given) a list of feasible, pre-specified chemistries demonstrated at lab and pilot, converting individual textile polymers to group of desired products such as wool: α-keratin (A) to wood-panel adhesives (M), cotton: cellulose (B) to glucose (G) and PET (C) to terephthalic acid (P). Figure 1 theoretically illustrates the transformation routes, linking two industries. It also assumes (given) fixed waste textile composition (percentage of polymers types, percentage of pure fibres and blended fibres). Furthermore, the problem assumes (given) fixed policies on the waste textile valosation within a specific time horizon, including tax breaks, landfill tariffs and mandatory waste textile collection. The problem is then to optimally determine:

(a) Waste valorisation strategy: no valorisation (landfill), Waste-to-Energy, Waste-to-chemicals or a combination of options.
(b) Feasible configuration of CE plant: to select among sorting waste to all separable components (A, B, C, AB, BC) and process individually, to process waste textile as whole in cascaded process or to sort to pure (A, B, C) and blend fibres (AB, BC) and treat in combined discrete-cascaded process configuration.

3. Methodology

3.1 Synthesis

The synthesis problem is represented using the *biomass bipartite graph* (BBR), presented in previous work (Kokossis et al., 2015). The transformation pathways are composed of flows (nodes) and enabling technologies (bar). The flows are divided in three sets, waste feedstock (inlet to a pathway), intermediate chemicals (component produced by a process and consumed by another) and final raw materials (not further processed). Figure 2 demonstrates the synthesis representation of a transformation pathway.

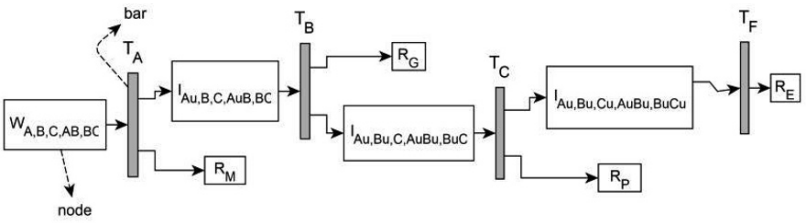

Figure 2: Synthesis representation of a transformation pathway.

3.2 Development of circular economy plant superstructure

To develop a superstructure, dedicated to wastes, a sequence of steps should be followed in prior: (a) any multi-component waste needs to be analyzed in terms of separable entities, composed of single-components (i.e. A, B, C) and inseparable components (i.e. AB, BC). (b) In case, two or more components are found in an inseparable mixture, then the order of the transformations should be identified as dictated by the governing phenomena of the processes such as reaction temperature and pressure, limiting alkali concentration, sensitivity of the material, etc. In order to map out the various waste valorization options:

(i) When no valorization: landfilled
(ii) When valorization: Waste-to-Energy
(iii) When valorization: Waste-to-Chemicals

And for the Waste-to-Chemicals strategy, the portfolio of configuration options is expanded:
CASE A: Waste feedstock is not sorted to its separable components and it is processed in cascaded configuration according to the order identified ($T^{all}_{A} \rightarrow T^{all}_{B} \rightarrow T^{all}_{C}$).
CASE B: Waste feedstock is sorted to all separable components and processed independently. For the inseparable mixture components, a cascaded process can be applied. (T^{pure}_{I}, T^{blends}_{I})
CASE C: Waste feedstock is separated to single-component (A, B, C) and mixture components (AB, BC). The configuration is processing the mixed-components in cascaded manner, whilst injecting pure component in the relevant process (T^{pnb}_{I}).

None of the Waste-to-Chemicals transformation technologies is converting 100% waste feedtstock to raw material. The unconverted components are denoted by subscript *u* and they are either delivered to another transformation process or sent to thermal valorisation and/or landfill. All options are depicted by Figure 3 and elucidated in Table 1.

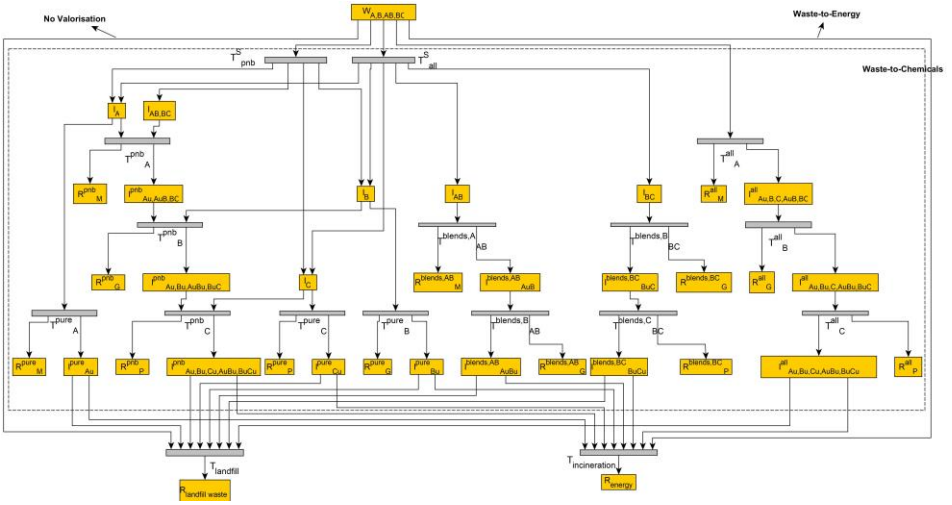

Figure 3: Development of circular economy plant: superstructure development indicating different valorization strategies and different plant configurations.

Table 1: Superstructure features of circular economy plant configuration

Sorting Process	**Transformation Processes**	**Description**
N/A	T^{all}_{A}, T^{all}_{B}, T^{all}_{C}	Processes that treat A, B, C respectively when no prior sorting is performed
Sorted all separable components- T^{S}_{all}	T^{pure}_{A}, T^{pure}_{B}, T^{pure}_{C} $T^{blends,A}_{AB}$, $T^{blends,B}_{AB}$, $T^{blends,B}_{BC}$, $T^{blends,C}_{BC}$	Processes that treat all separable components independently. These processes can only accept a well-sorted feedstock. They have high yields and not specialised separation equipment.
Sorted to blended and pure components (T^{S}_{pnb})	T^{pnb}_{A}, T^{pnb}_{B}, T^{pnb}_{C}	Cascaded process that can treat blended material with the corresponding injection of pure material.

3.3 Mathematical Formulation

The optimisation problem is formulated as Mixed Integer Linear Programming (MILP), following the work previously presented by Kokossis et al, 2015. In this work, the objective function is the maximisation of economic potential attained by the optimal circular economy process configuration. The optimisation problem is subject to mass balance, utility requirements (water & energy) as well as economic balance constraints. The mathematical formulation can account simultaneously for other objectives by scalarizing the problem.

4. Implementation

The presented methodology is applied in the main case study of RESYNTEX. The waste textile feedstock is mixture of pure and blended fibres, more specifically wool, cotton, PET, wool-cotton, cotton-PET denoted as A, B, C, AB, BC. The waste textile can be valorised according to strategy (i)-(iii) presented in section 3.2. For the textile waste and the chemistries dictated by the project, the order of the processes is set by the solvolysis' temperature of natural and synthetic fibres. The processes treating only pure materials ($T^{pure}_{A/B/C}$) have almost twice higher yields than the ones treating waste as a whole ($T^{all}_{A/B/C}$) and this is due to the immaturity of technologies available for separating the renewed raw materials from unconverted materials, when blended feedstock is processed. The CAPEX of processes treating blended waste ($T^{all}_{A/B/C}$) is higher by approximately 40% in comparison to the corresponding process treating pure. The OPEX for cascaded process is higher as more water is needed to wash out unreacted waste textile from liquid products. Although the yields, CAPEX and OPEX are more desirable for process treating pure materials, the pathway resulting to the highest economic potential is when waste is not sorted and it is processed in a cascaded manner due to the smaller total of processing steps.

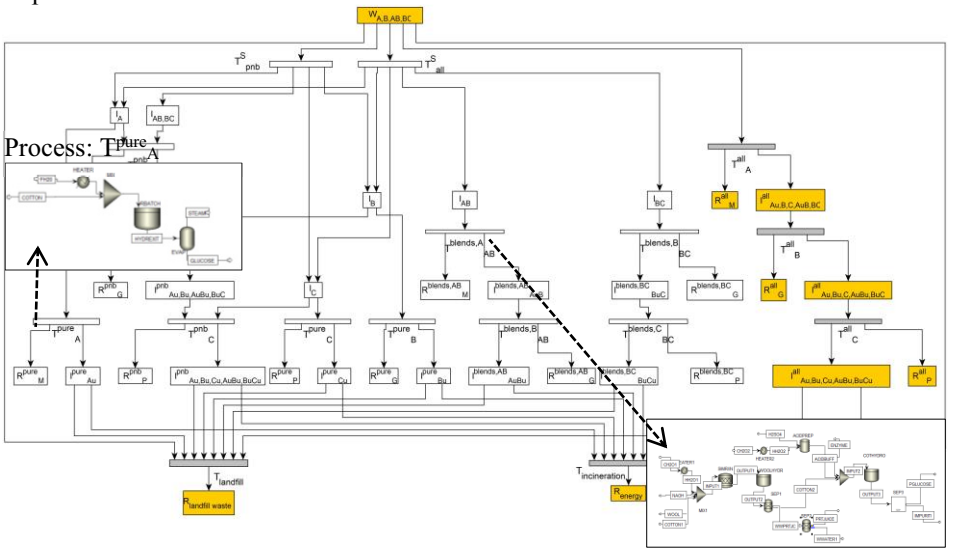

Figure 4: Circular economy process configuration achieving highest economic potential is the cascade process ($T^{all}_{A/B/C}$)

The unreacted product (Au, Bu, Cu, AuBu, BuCu) is given 70% to landfill while the rest 30% is thermally valorised. This choice is due to the relatively low landfill tarrif, $60/ton. In total, the cascaded process has a much lower capital expenses than discrete and discrete-cascaded configuration. It should be noted that sorting processes correspond to 30% of CAPEX when they are selected.

5. Conclusions

Circular economy promotes to interconnect linear production lines between industries so that no major raw materials are lost from our resource system. Textile industry is an ideal example, where circular economy can be introduced, since it has no standard strategy to collect and recycle its post-consumer waste. Evidence of chemical and biochemical chemistries exist for most individual textile polymers, however there is no real world application that combines existing processes to design an integrated circular economy plant other than the work performed in RESYNTEX project. The integration of chemistries to holistically recuperate waste is not straightforward task and there are many configuration options to select from. This work applied mathematical optimisation (MILP) to assess various process configurations aiding in the early stage process synthesis. Data from RESYNTEX project are used in the mathematical formulation. The most integrated and simplest configuration (cascaded process when no prior sorting is performed) is suggested to be the most technically and economically feasible in a specific time horizon. The model can be used to assess the impact of key parameters in the final plant configuration selection and it is planned as future work.

Abstract

This study aims to optimise the structural design of industrial central utility systems to while taking full advantage of intra-day electricity spot price fluctuations. Surges renewable electricity generation uptake has amplified the rises and falls between peak and off-peak electricity prices. Industrial Total Sites and Locally Integrated Energy Sectors can take maximum advantage of periods of both low and high electricity prices through appropriate technology investment. Using P-graph, a Utility Systems Planner superstructure is extended to apply a multi-period analysis to optimally select the fuels, energy conversion technologies, and the requires sizes to install for a representative case study. A key difference between the multi-period solution and the single-period solution is an Electric Boiler that operates when the electricity price is low. This results in a Total Annual Cost saving of 7.5 %.

Keywords: Process Integration; Total Site; utility systems; energy planning.

1. Introduction

Sustained growth in renewable electricity generation has changed the dynamics of many electricity markets. Large swings between high-peak and low-off-peak electricity prices resulting from the complex interplay between intermittent renewable energy supply, continuously fluctuating electricity demands, and market structure and policy (Aflaki and Netessine, 2017). To maintain a functional grid, electricity spot prices decrease to encourage greater consumption and increase to discourage. Locally Integrated Energy Sectors – LIES (Perry et al., 2008) and Total Sites (Klemeš et al., 1997), i.e. large industrial sites, can profit from periods of both low and high electricity prices through the right technology investments. For example, with Combined Heat and Power (CHP), a site may increase electricity exports when the price is high and, with heat pumps, a site may increase electricity imports when the price is low. The structural design of the central utility system with built-in degrees of freedom (e.g. spare capacity) holds the key to a system becoming responsive to grid dynamics.

Design and optimisation of Total Site central utility systems in literature for both retrofit and greenfield cases have chiefly focused on the operational optimisation of steam and gas turbine networks with some studies considering various uncertainties. For example, Sun et al. (2017) studied the multi-period operational optimisation of an existing utility system that consists of boilers, gas turbines, steam turbines, condensers, and let-down valves, with natural gas as the fuel, under both time- and probability-based uncertainties.

Zhu et al. (2016) applied Mathematical Programming (MP) to optimise a network of complex steam turbines. Luo et al. (2014) applied a multi-objective optimisation to determine a low-emissions utility system using similar technologies as Sun et al. (2017) without emissions abatement, fuelled by coal and natural gas. In other works, forecasting utility price increases over the entire lifetime of a project was considered by Nemet et al. (2015) as part of Total Site system optimisation. These studies, and other similar works, have focused on only a few fuels and energy conversion technologies in an optimisation with highly constrained structures and no consideration was given for how sites can benefit from a variable electricity spot price.

The aim of this study is to optimise the structural design of a Total Site (or LIES) central utility system, which cogenerates heating, cooling and power, considering electricity spot price fluctuations such that Total Annual Cost (TAC) is minimised. The study extends the work of Walmsley et al. (2018) that introduced a new Utility Systems Planner (USP) tool built as a P-graph superstructure. Using a multi-period approach in P-graph (Heckl et al., 2015), the USP is transformed to model electricity price fluctuations and to solve for the cost-optimal utility system structural design. The USP superstructure includes 5 energy sources, 16 energy conversion technologies, and 9 intermediate utility levels. A case study is presented to illustrate the extended USP tool for a LIES case study.

2. P-graph

P-graph is a combinatorial optimisation framework specifically for Process Network Synthesis (PNS) problems (Friedler et al., 1996), and the basis of P-graph Studio (2017). Underpinned by five fundamental axioms, P-graph has proven effective at reducing computational burden by very quickly identifying the sub-set of feasible structures for optimising PNS problems with high combinatorial complexity. Three other advantages over standard MP software are: (1) the use a graphical user interface for inputting superstructures and displaying results, (2) the locating of optimal and near-optimal solutions, and (3) the software is free. A key limitation of P-graph Studio is it only allows input of Mixed-Integer-Linear (MIL) type problems, where non-linear functions must be handled using a piece-wise linear approach (Ong et al., 2016). Recent applications of P-graph have included Total Site mass, heat and power integration (Ong et al., 2017) and multi-period optimization of sustainable energy systems (Aviso et al., 2017). P-graph is selected as the optimisation tool for this work due to its excellent visualisation of the problem and its solution as well as its inherent capability to reduce computational burden that helps solve the complex multi-period superstructure.

3. Utility Systems Planner - USP

Figure 1 presents the USP superstructure from P-graph Studio. Energy resources (circles) at the top of the superstructure, from left to right, are Electricity Import from the grid, Biomass, Coal, Natural Gas (NG), and Geothermal heat. Located at the bottom are the industrial and district energy users. Considered energy conversion technologies (rectangles) are: solid fuel and gas-fired boilers, NG Combined Cycle Gas Turbine (CCGT), NG Reciprocating Gas Engine (GE), Thermal Vapour Recompression (TVR), Mechanical Vapour Recompression (MVR), Organic Rankine Cycle (ORC), Heat Pump (HP), Absorption Chiller (ACH), Electric Chiller (EC), Steam Turbine, and Let-down Valves (LV). The intermediate energy levels (circles) are Electricity (EL), four steam levels (VHPS, HPS, MPS, LPS), High-Pressure Hot Water (HPHW), Hot Water (HW), Cooling Water (CW), and Chilled Water (CHW). Dark red lines represent electricity

flows, other shades of red and orange lines represent different hot utility levels, blue lines are cold utility, and light blue lines are condensate and water flows. The USP model requires specifying (i) user energy demands, (ii) energy conversion performances ratios, (iii) energy prices, (iv) capital and operating costs, and (vi) GHG emissions factors.

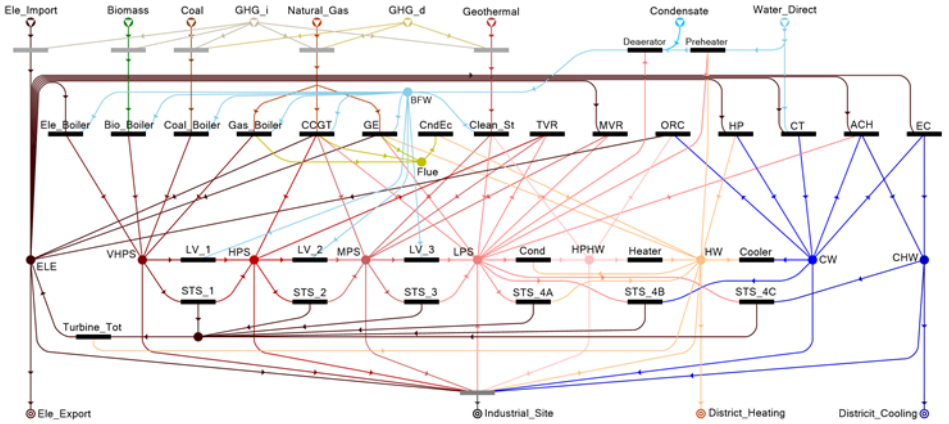

Figure 1: Utility Systems Planner tools – initial superstructure.

4. Method

The optimisation method in this study involved four stages: (1) Analyse historical electricity spot prices. This step included looking at the daily cyclic profile and the ordered value plots for the electricity prices. (2) Determine electricity prices for the multi-period analysis. Multi-period analysis is applied to approximate electricity price variations based on the ordered value plot of the electricity price. This step calculates the average price for each period. (3) Convert the USP superstructure into a multi-period equivalent to include electricity prices variations. This step uses the method of Heckl et al. (2015) to duplicate the initial superstructure (e.g. Figure 1) for n periods so that different electricity prices may be inputted for each period. Attention must be given to the multi-period superstructure to ensure capital cost is accounted appropriately. (4) Solve the P-graph superstructure for cost-optimal and near-optimal feasible structures. The objective function of the optimisation in P-graph Studio is to minimise TAC in Eq(1).

$$\mathrm{TAC} = \mathrm{UC} + \mathrm{CC} + \mathrm{OM} \tag{1}$$

Where UC is the utility cost, CC is the annualised capital cost, and OM is the operating and maintenance costs.

5. Locally Integrated Energy Sector - LIES Case Study

The considered LIES encompasses a representative industrial chemical processing site and the heating and cooling needs of the surrounding district. Figure 2 presents the Site Utility Grand Composite Curves for the industrial site and the entire LIES. The industrial site has a Utility System Pinch between the MPS and LPS levels, which extends to between the MPS and CW levels once the district heating/cooling demands are included for the LIES. Table 1 presents the prices for energy use while fresh water is 0.2 €/t and on-site GHG emissions are 5 €/t. For details on capital costs and performance ratios of each energy conversion process refer to Walmsley et al. (2018).

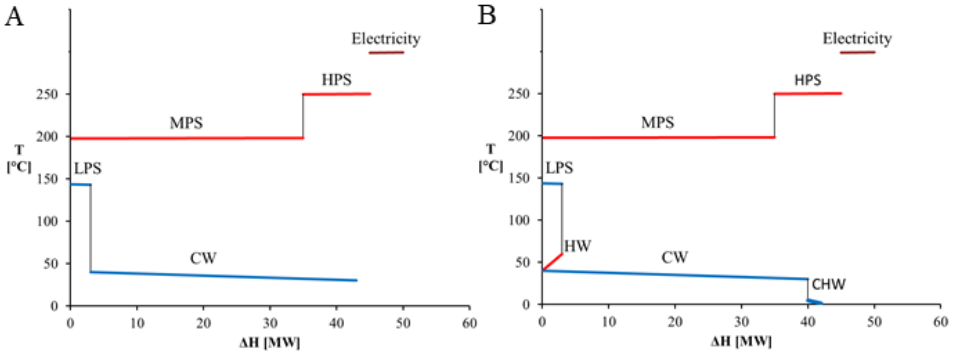

Figure 2: Site Utility Grand Composite Curves for the industrial site (A) and LIES (B).

Table 1: Industrial energy, GHG emissions and water prices and GHG emissions factors (EF).

	Electricity	Biomass	Coal	Natural Gas	Geothermal
Consumption (€/GJ)	22.3*	10.0	5.0	7.0	3.0
Generation (€/GJ)	16.7*	-	-	-	-
GHG emissions (kg/GJ)	-	-	91.4	55.2	1.3

*Average electricity prices (80.1 €/MWh), minus lines charge for sale (20 €/MWh)

The historical price fluctuations in wholesale electricity index for the EU-28 are presented in Figure 3. The median hourly electricity price trend for a daily cycle shows a low trough (4 a.m.) during the night, a small peak in the morning (8 a.m.) followed by a downturn in the afternoon before rising to a high peak in the evening (7 p.m.). The absolute electricity price is heavily influenced by the season as indicated by the individual trends for the different days. Ordering all electricity price provides a sense of the frequency that each price point arises. A three-period approximation of the ordered electricity price profile can be formulated (Figure 3B). There is a trade-off between the accuracy of the approximation (i.e. more periods) and the computational burden and is an area that may attract attention in future work.

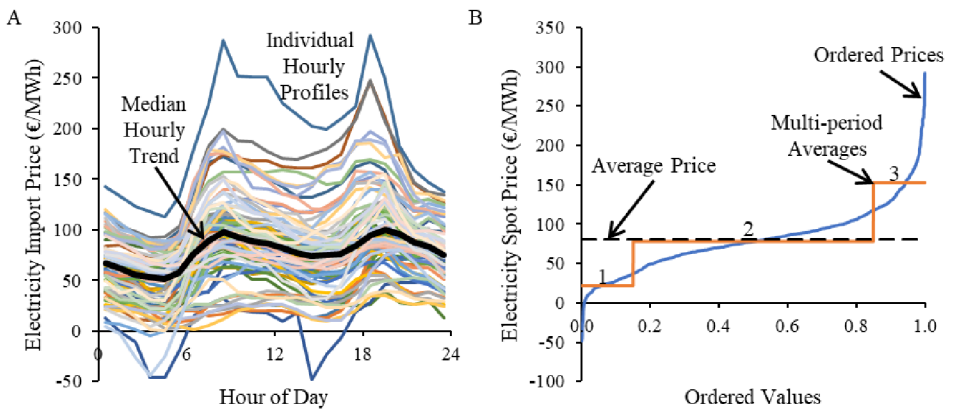

Figure 3: Electricity price with daily profiles for a sample of 84 d in 2017 (A) and by ordered values with single average and multi-period averages (B).

Using the average prices of the three periods from Figure 3B, the USP superstructure may be converted into a multi-period problem. This means the superstructure is replicated

three times. Nodes that represent the physical unit operation and its capital cost connect to each of the three superstructures. This is necessary to ensure that when a unit operation is required in any period, the capital cost is precisely accounted.

Solving the new multi-period superstructure to minimise TAC leads to the structural design as shown in Figure 4. Compared to the base case without multi-period analysis, the TAC savings is 7.5 % but a 90 % increase in GHG emissions due to the export of electricity, 29.3 MW_e. The final design includes an electric boiler, a gas boiler and a gas engine. When the electricity price is low, the electric boiler is switched on and the gas engine off. As the electricity price rises from period 1 to 2, it becomes uneconomic to use electricity as the heat source rather the site becomes a net electricity exporter. During the two higher electricity price periods, the gas engine runs at peak capacity to maximise electricity exports. The gas boiler has a steady load through all three periods of about 43 MW_f. The optimal solution suggests that an intensified and integrated gas boiler and engine with electric water heating as a single unit is a key technological solution.

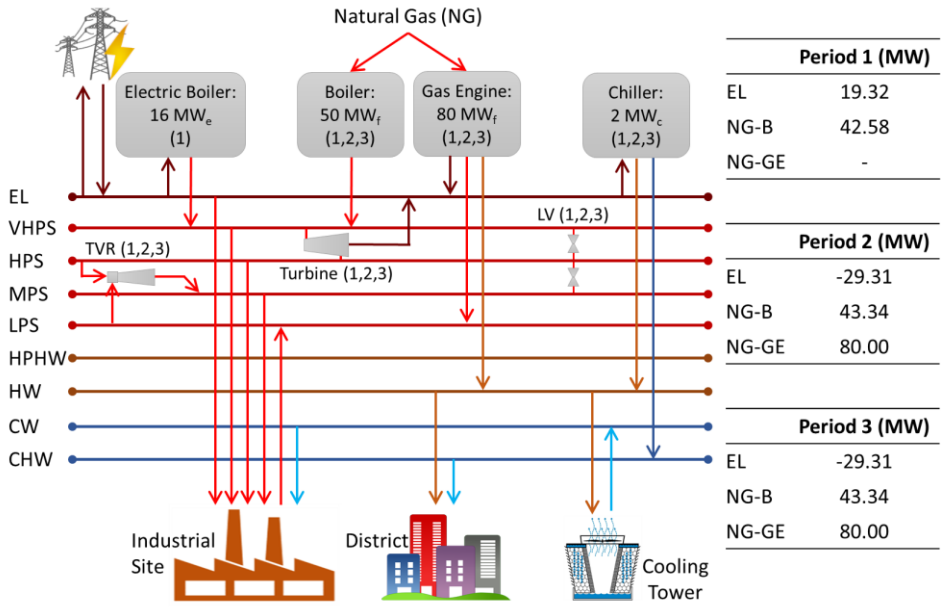

Figure 4: Utility systems structural design with key fuel and equipment for minimum TAC.

6. Conclusions

The Utility Systems Planner (USP) model, built using P-graph, incorporated a comprehensive range of possible fuels, resources, energy conversion operations, and auxiliary equipment. This superstructure has been extended in this study to encompass a multi-period analysis. This step forward enabled consideration for considering peak and off-peak electricity prices as part of the utility systems design phase. A comparison of the best utility systems structural designs showed the addition of an Electric Boiler (EB). The installation of an EB unlocked a Total Annual Cost savings of 7.5 % but a 90 % increase in GHG emissions due to an electricity export of 29.3 MW. Future work will focus on applying the USP to additional case studies as well as greater emphasis on environmental concerns beyond GHG emissions.

Abstract

Chemical and related industries need to find more sustainable and innovative processes, as due to rising environmental concerns and strict governmental policies it is no longer sufficient for the synthesized-design processes to be just profitable and operable. Process intensification as an integrated part of process synthesis design methods has the potential to determine more sustainable and innovative solutions. In this paper, an integrated and systematic framework based on a generic 3-stage approach to perform sustainable process synthesis, design and intensification is presented. The database and algorithms in the framework have been extended to be applicable over a wide range of applications and have been validated through a case study for the production of bio succinic acid. In this case study, a novel superstructure of alternatives has been generated to identify the optimal processing route followed by the application of an extended phenomena based synthesis-intensification step to generate non-trade off, more sustainable and intensified solutions for the production of bio succinic acid.

Keywords: Generic methodology, Process Intensification, Sustainable solutions.

1. Introduction

Process Intensification (PI) can be defined as improvements of a process at unit operational, functional and/or phenomena levels that can be obtained by integration of unit operations, integration of functions and phenomena's or targeted enhancement of the phenomena for a target operation. Earlier process synthesis methodologies operated at the unit operations (Unit-Ops) level (Jaksland et al. 1995) and functional (task) level (Jaksland et al. 1995, Siirola 1996) which has further been extended to incorporate intensification at phenomena level (Babi et al., 2015). Generation of novel and more sustainable designs, i.e., going beyond the existing intensified unit-ops one must target lower level of aggregation, i.e. phenomenon level (Papalexandri et al. 1996, Lutze et al., 2013). At this level one can investigate underlying driving forces associated with unit-ops to create new versions of them.

In this framework, the process flowsheets options are synthesized and/or evaluated that corresponds to acceptable design based on a given set of process specifications. This defined set of performance parameters is then referred to as the base case for intensification and through evaluation of the base case design, process "hot-spots" are identified and transformed into targets for improvement. Then at phenomena level, the phenomena involved in performing specific tasks are identified and while increasing search space these phenomena are recombined using a systematic and generic approach to find novel and innovative intensified alternatives that match the improvement targets.

These alternatives match the same specifications as the base case, but because they also satisfy the new targets for improvement, are by definition, non-trade off and more sustainable than the base case. That is, more flowsheet options that improve the base case and correspond to even better values of performance parameters are generated.

In this work, the phenomena based synthesis approach is extended by applying it to bio processes. It includes the expansion of database and algorithms to identify phenomena building blocks (PBB's) and generation of basic structures translating to unit-ops. In its application, new synthesis tasks have also been introduced, which is a novel approach for selection of different fermentation cell strains that are formulated in the form of a superstructure to identify the optimal along with downstream separation process.

2. Integrated framework for Process Synthesis, Design and Intensification

An integrated, systematic and computer aided framework for process synthesis, design and intensification is shown in figure 1. This computer aided framework is based upon a generic 3 stage approach to sustainable process design (Babi et al., 2015).

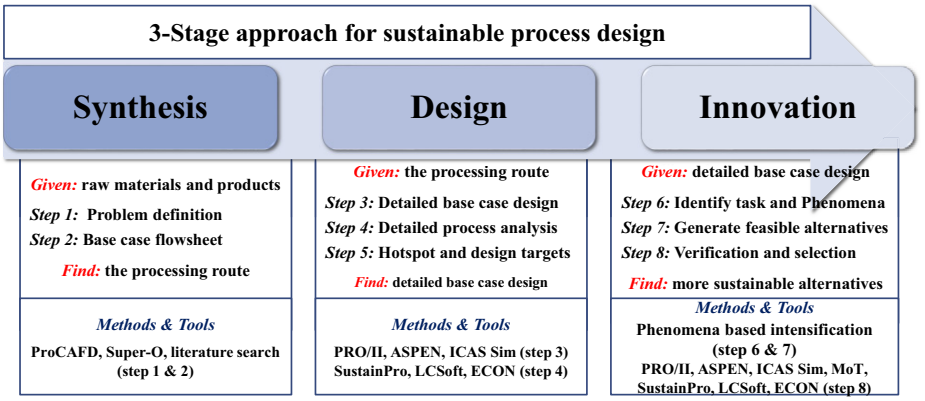

Figure 1. Overview of integrated framework for Process Synthesis, Design and Intensification

As shown in figure 1, the first stage of the framework involves process synthesis where an optimal process flowsheet is identified from numerous alternatives. In step 1 the synthesis problem is defined while in step 2, the optimal process flowsheet is identified. This can be done by using computer aided flowsheet design (ProCAFD) (Tula et al., 2015), performing the superstructure optimization using Super-O tool (Bertran et al., 2017) or by doing literature search. In stage 2, detailed simulation is performed to extract the detailed mass and energy balance data (step 3) and perform process analysis (step 4) in terms of sustainability, life cycle assessment and economics to identify the process "hot-spots" and based on these, set the targets for improvement (step 5) to be achieved in stage 3. In stage 3, a phenomenon based process synthesis intensification method (Babi et al., 2015) is applied to generate flowsheet alternatives that match the specified set of design targets and therefore determines more sustainable alternatives compared to the base case. In this approach the tasks performed by the unit operations involved in the optimal route are identified and from which further associated phenomena are also identified (step 6). These phenomena are combined using combination rules to generate new and/or innovative, intensified and more sustainable flowsheet alternatives (step 7). The final designs are then verified and compared with base case (step 8) through a set of pre-defined performance parameters or criteria.

3. Case study

The generic framework is applied to the production of bio succinic acid. Succinic acid is one of the most widely used platform chemical with broad range of industrial applications in food, pharma and chemical industries (Cok et al., 2014). Thus, the main objective of this case study is to identify more sustainable, intensified and non-trade off solutions along with testing of current methods and identify limitations for improvement in production of succinic acid.

3.1. Stage 1: Synthesis

Step 1 Synthesis problem definition: The synthesis problem as defined is to find the optimal route for production of bio succinic acid with a purity of at least 99.9%. The starting raw materials considered are Glucose, Glycerol, Maltose and Sucrose along with CO_2. Using these raw materials different reaction paths with different bacterial and yeast strains are identified from literature along with required reaction data.

Step 2 Generation of base case flowsheet: The base case flowsheet is generated using the superstructure optimization approach. Here, a novel superstructure with 8 processing steps and 33 processing intervals excluding raw material and product steps is generated that includes new synthesis tasks such as inclusion of different cell strains to produce bio succinic acid. Overall a superstructure describing the network of configurations for different processing routes, consists of 10 different fermentation models followed by 7 recovery and purification processing steps, where data was collected through available information on reaction as well as succinic acid production related technologies reported in literature. Then the superstructure based optimization problem is set up in Super-O, where the MILP problem is solved to determine the optimal processing route.

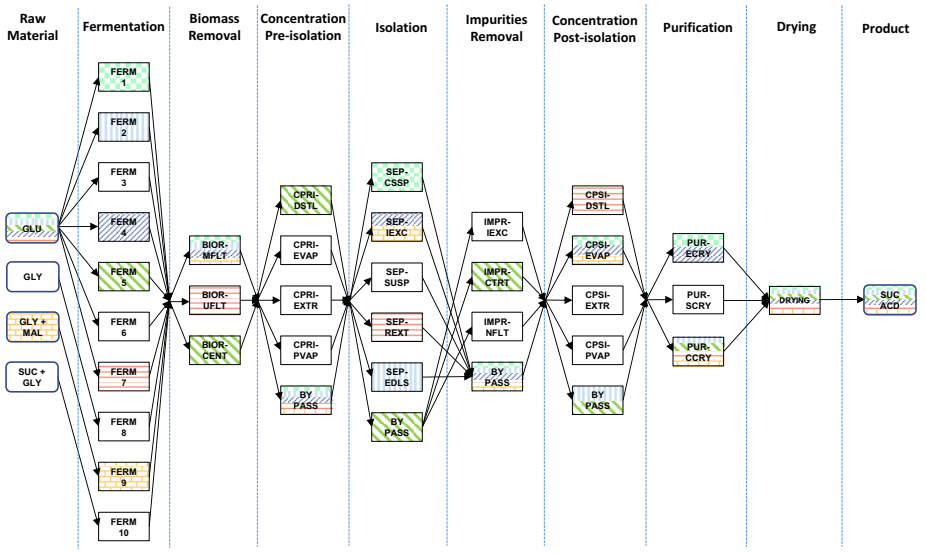

Figure 2. Superstructure (PSIN) of alternatives for succinic acid case study

The optimal process flowsheet alternative obtained is a novel processing route (intervals with green slanted lines) while five other existing processing routes (rest of the notations) reported in literature for example by Schroder et al., 2014 are also identified in the superstructure as shown in figure 2. Thus, potentially from this superstructure

2604 novel and existing feasible process flowsheets alternatives can be generated. The optimal process synthesis flowsheet (figure 3) consists of a fermenter, centrifuge for broth clarification, distillation to concentrate the broth and remove unwanted organic acids and alcohols, followed by carbon treatment for removal of soluble solids causing colour and then finally crystallization and drying to get pure crystals of succinic acid.

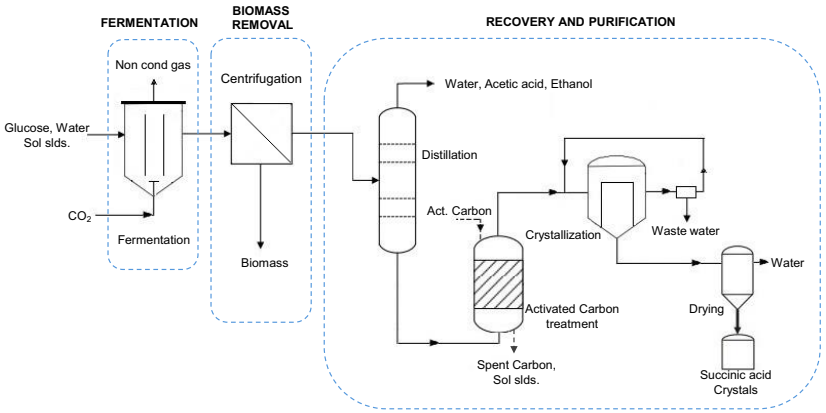

Figure 3. Novel and optimal processing route (Base case flowsheet)

3.2 Stage 2: Detailed design and analysis

Step 3 Detailed base case design: The detailed design for the optimal process flowsheet is performed using PRO/II simulator to extract the mass and energy balance data.

Step 4 Process analysis: The process analysis is performed using in-house tools SustainPro (Carvalho *et al.* 2013), LCSoft (Kalakul et al., 2014) and ECON (Saengwirum 2011). The sustainability analysis indicates loss of product and raw material in open path (in-out streams) containing crystallizer. The economic analysis shows high utility costs related to unit-op in open path i.e. reboiler of distillation column. As expected, the LCA analysis confirms with the high carbon footprint for reboiler of the distillation column.

Step 5 Identify process hotspots and design targets: Based on above analysis, process hot-spots are identified that are translated into design targets. The identified process hot-spots are high energy consumption/demand for succinic acid recovery and loss of product in above mentioned open paths. The corresponding translated design targets are reduction of energy demand, increase in product recovery, reduction in number of unit operations and improvement in sustainability and LCA factors.

3.3 Stage 3: Innovation (Phenomena based intensification)

Step 6 Identify desirable tasks and phenomena: The base case flowsheet is represented in terms of tasks and then in terms of phenomena. The identified PBBs that make up the initial search space of PBBs are R (reaction), M (mixing), 2phM (two phase mixing), PC(VL), PT(VL), PS(VL), PC(LS), PT(LS), PS(LS), H (heating) and C (cooling) where, PC is phase contact; PT is phase transfer and PS is phase separation; while V, L and S represents vapor, liquid and solid phases. Here, the tool library to identify the PBB's has been extended in order to incorporate wide range of unit-ops. The pure component and mixture property analysis is performed using ICAS (Gani et al., 1997), which identified one azeotrope between water and ethanol. As in this case study, the

main objective is to get pure succinic acid, the separation of water and ethanol is not considered in further steps. Additional phenomena are identified from the database based on process hotspots to increase the search space. The phenomena's identified are PT(PVL), PT(VV), PS(VV), PC(LL) and PS(LL). Thus, the total list contain 20 PBB's. The total number of possible combinations of these PBB's to form simultaneous phenomena building blocks (SPB's) are 519252. However, all combinations are not possible. Thus, using connectivity rules, 244 SPB's are found to be feasible.

Step 7 Generation of feasible flowsheet alternatives: Intensified flowsheet alternatives are generated by combining the SPB's to form basic structures. These basic structures are formed in a way that they satisfy the identified reaction and separation tasks. In alternative 1, starting with the first task of reaction, the second task, cell removal or clarification of broth could be combined to obtain a new basic structure of phenomena's that translates into a membrane bioreactor (figure 4). In this unit operation, the fermentation broth is clarified i.e. the reaction product is removed continuously and the cell culture remains in the membrane bioreactor leading to increase in cell concentration and high product yield, also observed by Wang et al. (2014).

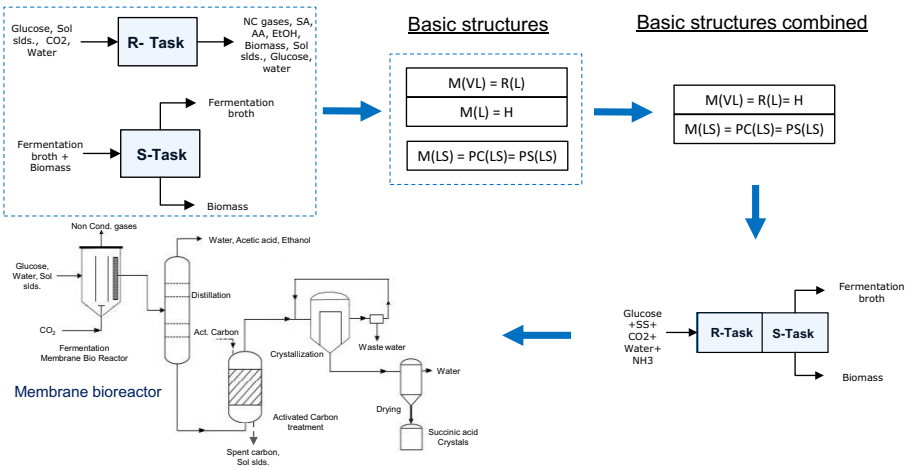

Figure 4. Intensified flowsheet alternative 1 (Identified task, combination of basic structures)

In alternative 2, the integration of basic structures for the last two separation tasks is considered. This is possible as both the separation tasks involve SPB involving separation of crystalline product from the liquid phase. Thus, a basic structure having phenomena PT(LS) and PS(LL) is selected. Additional PBB like cooling, heating and mixing can also be added to the selected SPB's. Thus, in flowsheet alternative 2 the combined basic structure is translated to membrane crystallizer to obtain desired purity crystals of succinic acid. Alternative 3 is a combination of alternative 1 and 2 consisting both membrane bio reactor and membrane crystallizer.

Step 8 Verification and selection: The generation of more sustainable and non-trade off process designs by matching a set of design targets is illustrated via radar plot in figure 5, where, the ratios of different performance criteria with respect to the base-case multiplied by 100 have been plotted (for profit, the inverse has been taken). The base-case design is at the boundary while the more sustainable alternatives are all within the boundary, indicating that these intensified alternatives are non-trade off alternatives. Note that for each alternative the required purity of product has been achieved, no

solvents have been used and the number of unit operations have been reduced from 6 (the base case) to 4 (alternative 3). Out of the intensified alternatives generated, alternative 3 give the best results.

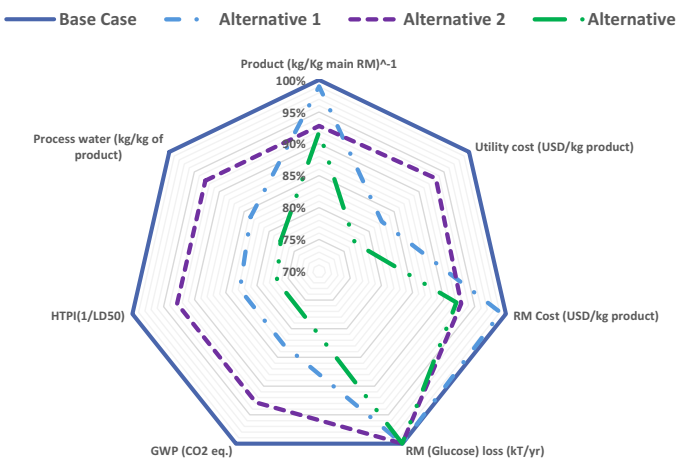

Figure 5. Economic, sustainability and LCA improvements relative to the base case design (HTPI: Human toxicity potential by ingestion, GWP: Global warming potential)

4. Conclusions

An integrated and systematic framework for process synthesis intensification has been extended and further applied to bio processes (bio succinic acid). The application of the extended framework gave a novel optimal process flowsheet along with more than 2600 other alternatives at the synthesis stage while 3 intensified and more sustainable alternatives were generated at the innovation stage for production of bio succinic acid. Current and future work will further extend the phenomena based approach and its implementation in a computer aided tool.

Abstract
In this work we investigate the integrated planning, scheduling and control (iPSC) of process systems under uncertain conditions throughout the three levels of decision making. The planning problem is explored in a rolling horizon fashion coupled with demand forecasts. Proactive and reactive approaches are employed to handle the effect of stochastic variations. Depending on the nature of the uncertain parameters robust optimisation and chance constrained programming are employed. For the closed-loop implementation of the control, novel multi-parametric controllers are designed. The proposed framework is tested on the iPSC of a polymerisation process. Finally, Monte Carlo simulations are conducted to highlight the benefits of the "uncertainty-aware" solutions when compared to the deterministic ones.

Keywords: enterprise wide optimisation, uncertainty, robust optimisation, multi-parametric programming, chance constrained programming.

1. Introduction
Contemporary process industries are part of a progressively complex global market network and the need to account for efficient and integrated solutions has become increasingly mandatory. Integrating control with operations has gained considerable amount of research interest (Chu and You, 2013; Zhuge and Ierapetritou, 2012). So far, most of the research works have dealt with integrating cyclic scheduling and control with little work done on the iPSC (Dias and Ierapetritou, 2016). Guittierez-Limon et al. (2014) studied the iPSC using a time-slot based formulation and solved a monolithic MINLP problem, while Shi et al. (2015) studied the iPSC based on a flexible recipe method and formulated the problem as an MILP for which bilevel decomposition was employed. Charitopoulos et al. (2017a) used a TSP-based model for the integration of planning and scheduling, with the control decisions modelled through the use of offline calculations and linear metamodels. Later, Charitopoulos et al. (2017b) investigated the use of explicit controllers (mp-MPC) for the efficient closed-loop iPSC. Even though the integrated problem can lead to improved operations, because of the synergies between the different levels of decision

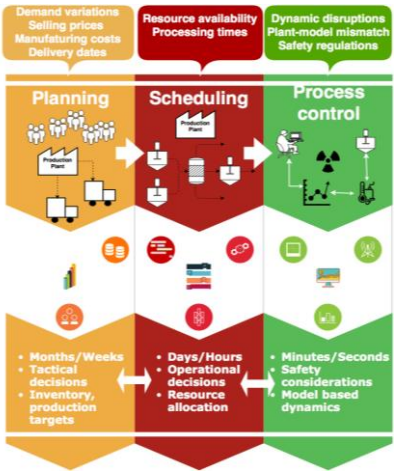

Figure 1. Integrated planning, scheduling and control problem under uncertainty

making, uncertainty is ubiquitous and its impact on optimal operations can be tremendous. To the best of our knowledge, no previous research work has addressed the iPSC under uncertainty in all three levels of decision making (Dias and Ierapetritou, 2016). As shown in Figure 1, the integrated nature of the problem results in diverse kinds of uncertainties that call for different policies. To this end, in the present work we employ reactive and proactive approaches by means of multi-parametric programming (mp-P) at the level of control (Charitopoulos et al., 2017b), robust optimisation, chance constrained programming and rolling horizon with demand forecasts for the planning and scheduling (Li and Ierapetritou, 2009). The uncertainty-aware integrated framework is applied to the iPSC of a polymerisation process and its benefits are highlighted via Monte-Carlo analysis.

2. Mathematical modelling of iPSC

In this section a brief overview of the mathematical modelling of the iPSC with emphasis on the uncertain entities under consideration is given; for a detailed exposition the reader is referred to Charitopoulos et al. (2017a). Planning periods (p) are modelled as discrete time points and the scheduling decisions use continuous-time formulation. The overall scope of the integration has as follows:

$$\text{iPSC Problem: } \begin{cases} \max\limits_{\mathbf{x_{pl}},\mathbf{x_{sc}},\mathbf{x_c}} \ \text{Profit} \\ \text{Subject to: } \mathbf{x}_{\text{pl}}, \mathbf{x}_{\text{sc}}, \mathbf{x}_{\text{c}} \in \Omega^{\mathbf{p}} \times \Omega^{\mathbf{s}} \times \Omega^{\mathbf{c}} \end{cases}$$

where $\mathbf{x_{pl}}, \mathbf{x_{sc}}, \mathbf{x_c}$ stand for the planning, scheduling and control decisions respectively while $\Omega^{\mathbf{p}}, \Omega^{\mathbf{s}}, \Omega^{\mathbf{c}}$ their related feasible sets. The production output (Q_{ip}) of each product (i) per planning period is calculated by eq. (1) and is a function of the production rate (r_{ip}), which is considered to be fluctuating, and the production time (T_{ip}). The sales (S_{ip}) that satisfy the demand for each product (D_{ip}) are calculated by eq. (2) along with the level of backlogged demand in each period (B_{ip}).

$$Q_{ip} = r_{ip} T_{ip} \ \forall i, p \qquad \text{and} \qquad S_{ip} = D_{ip} + B_{i,p-1} - B_{ip} \ \ \forall i, p \qquad (1)\text{-}(2)$$

For the closed loop case a rescheduling framework has been proposed in our previous work (Charitopoulos et al., 2017b) where variations in transition times were considered from a systems dynamics' perspective. An open question in the literature, that has yet to be addressed, is the systematic treatment of uncertainty that is present simultaneously across the three different levels of decision making and this constitutes the main contribution of the present work.

3. A hybrid framework for uncertainty-aware iPSC

3.1. Rolling horizon for planning decisions

A rolling horizon (RH) approach is proposed to deal with planning decisions under uncertainty. Firstly, an initial demand forecast (d_{ip}) which is known in advance for the whole planning horizon is considered. The uncertainty on the demand forecast is modelled as a uniform distribution between minimum and maximum values ($\pm \delta_{ip}$) of the demand forecast for the current time period (Liu et al, 2009). This demand uncertainty is revealed only at the beginning of the current time period p^* allowing for rescheduling in order to revise the schedule based on the new state of the system. Then, the new demand of the current time period is calculated by the eq. (3) while for the subsequent time periods the demand forecast is considered.

$$d_{ip} = \text{Uniform}\left[\left(1-\delta_{ip}\right)\cdot d_{ip}, \left(1+\delta_{ip}\right)\cdot d_{ip}\right] \quad \forall i, p = p^* \tag{3}$$

For its implementation, a control horizon (L^{CH}) should be defined. The control horizon determines implicitly the scheduling horizon (H) to be solved. Thus, starting from the first time period $p^* = 1$ our control horizon is solved iteratively considering a fixed step size until the end of the planning horizon $p^* = PH$. At each step, an MILP is solved with relaxed integer variables for the time periods outside of the control horizon. At each iteration, all the information and decisions taken of the current time period are fixed and the scheduling horizon is updated as $H = [p^*, p^* + L^{CH} - 1]$. At each run, new information about the future demand is revealed and the optimal solution of the planning problem is re-computed.

3.2. Proactive scheduling formulations

In order to secure smooth operations on the level of scheduling, a hybrid chance constrained (CCP)/robust optimisation (RO) approach is employed. Within the context of iPSC the production rates are related to the performance of the dynamic system and in order to avoid excessive need for rescheduling, chance constrained programming is employed (Li et al., 2006). Assuming normal distribution of $\sigma_{r_{ip}}$ standard deviation, a mean value of the production rate $\hat{r}_{ip}$ and a desired reliability level α, the equivalent deterministic chance constraint of eq. (1) is derived as follows:

$$\Pr\left(Q_{ip} \le r_{ip} T_{ip}\right) \ge \alpha \leftrightarrow Q_{ip} \le \left(\hat{r}_{ip} - \Phi^{-1}(\alpha)\sigma_{r_{ip}}\right) T_{ip} \tag{4)-(5}$$

where $\Phi^{-1}(\alpha)$ stands for the inverse cumulative distribution for reliability α. Next, the budget parameter approach of Bertsimas and Thiele (2006) was chosen in order to account for deviation in products demand. The nominal demand ($\overline{d_{ip}}$) is considered to vary as $[\overline{d_{ip}} - \check{d}_{ip}, \overline{d_{ip}} + \check{d}_{ip}]$ and its scaled deviation is defined as follows: $z_{ip} = \frac{d_{ip} - \overline{d_{ip}}}{\check{d}_{ip}}$

In brief, eq. (2) is rewritten as eq. (6).

$$S_{ip} \le \max_{w \in U}\{d_{ip}\} \quad + B_{i,p-1} - B_{ip} \tag{6}$$

The uncertainty set (U) is defined by eq. (7)-(9) so as to avoid a cumulative overestimation of the uncertain demand using the budget parameter (Γ_p).

$$D_{ip} = \check{d}_{ip} z_{ip}, \forall i, p \text{ and } 0 \le z_{ip} \le 1 \ \forall i, p \text{ and } \sum_{k=1}^{p} z_{ip} \le \Gamma_p \quad \forall, i, p \tag{7)-(9}$$

Next, the robust counterpart (RC) is derived based on the related dual problem and eq. (6) is substituted by eq. (10)-(11) using the related dual variables (q_{ip},y_{ipk}).

$$S_{ip} \le \overline{d_{ip}} + \Gamma_p q_{ip} + \sum_{k=1}^{p} y_{ipk} + B_{ci,p-1} - B_{cip} \tag{10}$$

$$q_{ip} + y_{ipk} \ge \check{d}_{ip} \ \forall i, p, k \le p \tag{11}$$

3.3. The hybrid framework for uncertainty-aware iPSC

Overall, the hybrid framework consists of proactive policy at the scheduling level while the reactive policy is considered at the levels of planning and control and is shown in Figure 2. The rolling horizon solution of the problem allows for consideration of updated demand forecasts and in order to prevent low levels of customer satisfaction, the variations in the demand are addressed proactively through the RO approach. Uncertain production rates that affect the scheduling relevant decisions are handled through individual chance constraints and based on the profitability of each product, in order to avoid over-conservative solutions, a different level of reliability is specified. For the control layer novel mp-MPC controllers are employed. The novelty is the

consideration of kinetic/quality data as uncertain parameters that results in left-handside uncertainty along with the different set-points that are provided by the level of scheduling (Charitopoulos et al., 2017b). Overall the integrated hybrid framework is an MILP problem with the control decisions made in an outer loop resulting in an additional rescheduling mechanism that reactively handles variations in transition times as shown in Figure 2.

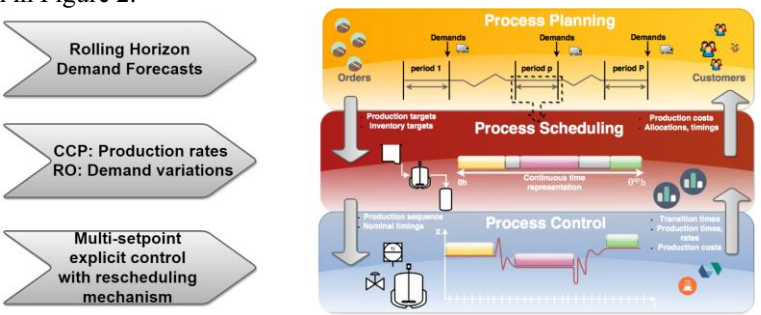

Figure 2. Conceptual graph of the hybrid framework for the uncertain iPSC

4. Case study: MMA polymerisation process

The proposed approach was tested on the iPSC of a continuous MMA polymerisation process. Related data about the economics and dynamics of this case study can be found in Chu and You (2013). In this instance, 16 products and a planning horizon of 6 weeks are examined.

4.1. Design of the hybrid framework for uncertainty-aware iPSC

The tuning parameters of the integrated framework are as follows: $L_{CH} = 2, a = 70 - 95\%, |\sigma_{r_i}| = 0.2 r_i, \check{d}_{ip} = [0.05\ 0.1\ 0.2\ 0.15\ 0.15\ 0.2]\overline{d_{ip}}, \Gamma_p = [0\ 1\ 2\ 2\ 3\ 3\ ]$. At the level of control the uncertain parameters are: (i) the states of the system at each sampling instance, (ii) the desired setpoints and (iii) the inlet initiator concentration ($C_{l_{in}}$). The model of the system is given by eq. (12)-(15) while a total of 9 uncertain parameters were considered during the design of the mp-MPC.

$$\dot{C_m} = -(k_p + k_{fm})C_m\Psi + \frac{F(C_{m_{in}} - C_m)}{V} \tag{12}$$

$$\dot{C_l} = -k_l C_l + \frac{F_l C_{l_{in}} - F C_l}{V} \tag{13}$$

$$\dot{D_0} = (0.5k_{Tc} + k_{Td})C_l\Psi^2 + k_{fm}C_m\Psi - \frac{FD_0}{V} \tag{14}$$

$$\dot{D_I} = M_m(k_p + k_{fm})C_m\Psi - \frac{FD_I}{V} \tag{15}$$

First the mp-MPC is designed (Charitopoulos et al., 2017b). The solution of the related mp-P is computed using Mathematica 11 and it involves 5 explicit expressions of the control law, with an example given by eq. (16) while the detailed results are omitted for the sake of brevity.

$$\text{if } \boldsymbol{\theta} \in CR_1 \ \rightarrow F_l(t_0) = \frac{988.98(1.0114\theta_6 - \theta_2)}{\theta_9} \tag{16}$$

where $\theta_6, \theta_2, \theta_9$ represent the set-point for C_l, the measurement of C_l at each instance and the $C_{l_{in}}$ respectively. Note that for this case study, a prediction horizon of 1 was used for simplicity.

4.2. Monte Carlo simulation results

Once the solution from the hybrid framework is computed the benefits of the proactive mechanisms and the RH- planning are evaluated through Monte Carlo (MC) simulation

runs. For the MC runs all the binary variables are fixed and 1,000 iterations were conducted. At each iteration, a different value of the uncertain parameters is realised, i.e. r_{ip}, and d_{ip}. Within the MC runs the problem is solved with the addition of eq. (17)-(18) that represent a nervousness cost for the deviation of backlog and inventory levels, respectively, to be penalised during the MC runs.

$$DV_{ip} \geq V_{ip} - V_{ip}^{MC} \quad \forall i, p \tag{17}$$

$$DB_{ip} \geq B_{ip} - B_{ip}^{MC} \quad \forall i, p \tag{18}$$

Notice that the backlog (B_{ip}), acts as a slack variable and prevents infeasible runs. The modified objective of the MC simulations is given by eq. (19).

$$Prof_{MC} = Prof - \sum_{ip}[\delta_{ip} DV_{ip} + \beta_{ip} DB_{ip}] \tag{19}$$

The expected value (EV) of the MC runs is computed as the average objective over all the runs, i.e. $EV = \sum_{n}^{N_{MC}} \frac{Prof_{MC}}{n}$, where N_{MC} is the total number of runs. In Figure 3, the comparative results are illustrated.

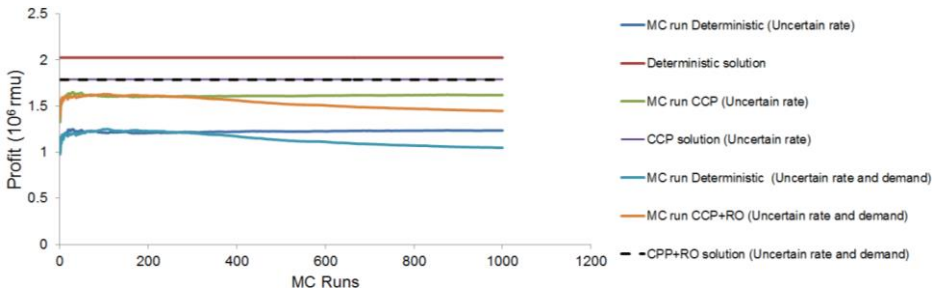

Figure 3. Comparative plot of results from MC simulations.

As indicated in Figure 3 the consideration of uncertain variations in the production rate has a significant impact on the profitability of the process, something that is exacerbated when the demand variations are also taken into account. Following the proposed framework, even though less profit is achieved, the deviation from its EV as computed by the MC simulation is significantly less when compared to the deterministic one. More specifically, the reduction on the profit for the deterministic case is 48.22% while for the one computed by the hybrid framework is less than 18.5%. With regards to the computational statistics an overview is given in Table 1.

Table 1. Overview of computational statistics using CPLEX 12.7 / GAMS 24.8.3

	Deterministic	**Hybrid framework**
Continuous variables	7,835	8,267
Equations	9,656	10,088
Integer variables	3,104	3,104
CPU (s)	24.23	31.42

As shown in Table 1, the time needed for the solution by the hybrid framework allows for the online implementation of the iPSC-relevant decisions, despite the increased number of variables and equations. The reactive components of the proposed framework are next tested by imposing a number of different dynamic disruptions that lead to rescheduled solutions. More specifically, dynamic disruptions during both transition and production periods were successfully handled due to the computational merits of the

proposed novel mp-P controllers and the rescheduling mechanism. In Figure 4 different instances of the uncertainty-aware iPSC solution for the planning horizon are shown.

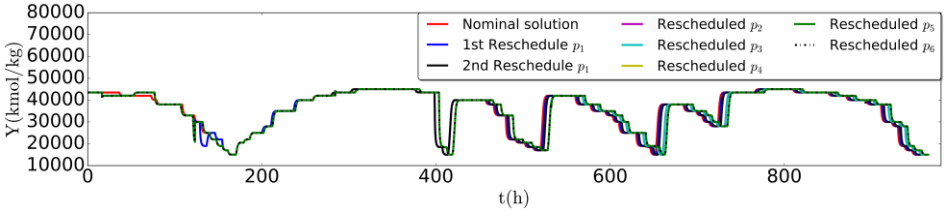

Figure 4. Y=f(t) plot for the uncertainty-aware iPSC solution computed by the hybrid framework

5. Concluding Remarks

Uncertainty is ubiquitous within the integrated problems considered by enterprise wide optimisation and can lead to significant loss of profitability, if left untreated. In the present work, we solve the iPSC problem under multiscale uncertainty using a hybrid proactive/reactive framework based on the nature of the stochastic variations. The results underline the benefits of the proposed approach that through the rolling horizon solution and the outer multi-parametric control loop allow for online implementation of the integrated planning, scheduling and control decisions, thus safeguarding optimal operations. Ongoing research in our group involves the development of decomposition techniques that will enable further improvements in terms of computational times and the solution of industrial-scale case studies.

Abstract

This work presents a fuzzy optimisation model for the synthesis of refinery hydrogen networks under uncertainty. Based on a generic superstructure that incorporates all the possible connections between the hydrogen system elements (sources, sinks, compressors etc.), the mathematical formulation consists mainly of flowrate and impurity load balances, where fuzzy intervals are introduced to account for parametric uncertainties. Pressure constraints and the optimal placement of compressors are also taken into account. A case study is presented to illustrate the proposed approach.

Keywords: hydrogen management, process integration, mathematical programming, fuzzy optimisation.

1. Introduction

Hydrogen is an important and expensive utility in oil refining and petrochemicals processing, required in operations such as hydrotreating and hydrocracking. Demand for hydrogen in refineries and petrochemical plants has increased with stricter regulations on sulphur content in fuels and gasoline aromatic composition, as well as increased processing of heavier crude oils and the shrinking market for heavy fuel oil. Increased hydrogen requirements can lead to a deficit of hydrogen in a refinery, resulting in the need for additional hydrogen production or hydrogen import. Therefore, it is desirable for refineries to make efficient use of hydrogen, in order to reduce the capital investment of a new hydrogen plant or the operating costs of existing hydrogen plants or imports.

Synthesis of refinery hydrogen networks is widely accepted as a useful means of improving the efficiency of hydrogen systems. The methodologies can be classified into pinch analysis and mathematical programming approaches. Alves and Towler (2002) proposed the hydrogen surplus diagram to set targets for the minimum flowrate of fresh hydrogen before detailed network design. Various pinch-based targeting techniques were later developed, such as the material recovery pinch diagram (El-Halwagi et al., 2003), the source composite curve (Bandyopadhyay, 2006) and gas cascade analysis

(Foo and Manan, 2006). However, most of the pinch methods cannot handle cost considerations, multiple impurities or pressure/connection constraints effectively. Hallale and Liu (2001) presented a superstructure-based mathematical approach to hydrogen network retrofitting. Their method accounts for pressure constraints, existing equipment and capital costs. Many other mathematical techniques were later developed, including those for the design of hydrogen networks under uncertainty using chance constrained programming (Jiao et al., 2012), robust optimisation (Lou et al., 2014) and stochastic programming approaches (Jagannath and Almansoori, 2014).

It is normally assumed in the synthesis problems that the stream flowrates and qualities are known precisely. In practice, however, process data may be subject to uncertainty or variability. In this work, a fuzzy optimisation model is developed for refinery hydrogen network synthesis with parametric uncertainties. Based on a superstructure incorporating all possible options for hydrogen recovery, the mathematical formulation consists mainly of mass balance equations and pressure constraints, with the objective function considering both the hydrogen requirement and the total annualised cost. The optimal placement of compressors is also taken into account. A case study is solved to illustrate the proposed approach.

2. Problem statement

The problem addressed in this paper may be briefly stated as follows. Given a system with a set of internal hydrogen sources $i \in \mathbf{I}$ and a set of hydrogen sinks $j \in \mathbf{J}$. These sources and sinks may be matched to meet the objective of minimising the requirement for additional hydrogen from external sources, as well as the total annualised cost. A fuzzy resource consumption/cost goal is specified in terms of upper and lower bounds, corresponding to the least and most desirable fresh hydrogen usage/total cost levels. Each internal source is characterised by a flowrate and one or more quality indices, which are defined in terms of fuzzy intervals. Similarly, each sink is defined in terms of fuzzy flowrate and fuzzy quality limits. The model covers a range of solutions ranging from optimistic (i.e. high-risk) and conservative (i.e. low-risk) extremes. Solving the model identifies an optimal solution that achieves the optimal compromise between the need to conserve fresh hydrogen/reduce cost on one hand, and the need to avoid adverse process effects on the other hand. The final source-sink network has to satisfy all the flowrate/component balances, quality constraints and resource conservation/cost saving goals defined by the fuzzy intervals.

3. Model formulation

The fuzzy optimisation model is presented below. The objective function is to maximise the overall degree of fuzzy constraint satisfaction:

$$\max \lambda \tag{1}$$

The fuzzy degree of satisfaction lies between 0 and 1; 0 corresponds to unsatisfactory, 1 is completely satisfactory, and fractional values indicate partial satisfaction.

$$0 \le \lambda \le 1 \tag{2}$$

In fuzzy optimisation using "max-min" aggregation, every fuzzy constraint should be satisfied partially at least to the degree λ. Fuzzy goals for hydrogen consumption (ϕ_{HC}) and total cost (ϕ_{TC}) are specified for the network using the linear membership function, as follows:

$$\phi_{\mathrm{HC}} - \phi_{\mathrm{HC}}^{\mathrm{U}} \le \lambda\left(\phi_{\mathrm{HC}}^{\mathrm{L}} - \phi_{\mathrm{HC}}^{\mathrm{U}}\right) \tag{3}$$

$$\phi_{\mathrm{TC}} - \phi_{\mathrm{TC}}^{\mathrm{U}} \le \lambda\left(\phi_{\mathrm{TC}}^{\mathrm{L}} - \phi_{\mathrm{TC}}^{\mathrm{U}}\right) \tag{4}$$

Note that the hydrogen consumption or total cost is at the upper bound when $\lambda = 0$, and at the lower bound when $\lambda = 1$.

Eq. (5) describes the flowrate balance for each hydrogen source. The hydrogen from source i may be sent to hydrogen sinks j (f_{ij}), compressors m (f_{im}) and fuel systems w (f_{iw}). It can be seen that when $\lambda = 0$, the amount of hydrogen available from source i is F_i^{U}, while when $\lambda = 1$, the amount available is F_i^{L}. This relationship means that lower values of λ are inherently more optimistic (and thus riskier), while higher values of λ are inherently more conservative. The objective function thus forces the model towards a more conservative solution with a robust network. If the hydrogen available from source i is known precisely, then $F_i^{\mathrm{L}} = F_i^{\mathrm{U}}$ and the fuzzy interval has zero width.

$$F_i^{\mathrm{U}} + \lambda\left(F_i^{\mathrm{L}} - F_i^{\mathrm{U}}\right) = \sum_{j\in\mathbf{J}} f_{ij} + \sum_{m\in\mathbf{M}} f_{im} + \sum_{w\in\mathbf{W}} f_{iw} \quad \forall i \in \mathbf{I} \tag{5}$$

Eq. (6) describes the flowrate balance for each hydrogen sink. The hydrogen to sink j may come from hydrogen sources i, compressors m (f_{mj}) and external fresh hydrogen sources r (f_{rj}). It can also be seen that the hydrogen demand of sink j is F_j^{L} when $\lambda = 0$, and is F_j^{U} when $\lambda = 1$; the logic used is similar, with higher values of λ denoting more conservative (or less risky) conditions. In addition, if the hydrogen demand of sink j is known precisely, the fuzzy interval will also have zero width.

$$F_j^{\mathrm{L}} + \lambda\left(F_j^{\mathrm{U}} - F_j^{\mathrm{L}}\right) = \sum_{i\in\mathbf{I}} f_{ij} + \sum_{m\in\mathbf{M}} f_{mj} + \sum_{r\in\mathbf{R}} f_{rj} \quad \forall j \in \mathbf{J} \tag{6}$$

Eq. (7) describes the impurity load balance for each hydrogen sink. It is stated that the load of component c for the mixed stream entering a given sink cannot exceed its load tolerance. Note that when $\lambda = 0$, the streams entering the sink are of the best quality (Y_{ic}^{L} and Y_{rc}^{L}), leading to an optimistic solution with maximised opportunities for hydrogen reuse/recycling. However, the hydrogen recovery potential has to be counterbalanced by considerations of data uncertainty. Thus, $\lambda = 1$ corresponds to the most conservative solution, which in turn assumes that the available streams are of the poorest quality (Y_{ic}^{U} and Y_{rc}^{U}). Likewise, it can be observed from the right-hand side of Eq. (7) that the least conservative solution ($\lambda = 0$) assumes maximum sink tolerance to the quality load (M_{jc}^{U}), while the most conservative solution ($\lambda = 1$) assumes minimum tolerance (M_{jc}^{L}).

$$\sum_{i\in\mathbf{I}} f_{ij}\left[Y_{ic}^{\mathrm{L}} + \lambda\left(Y_{ic}^{\mathrm{U}} - Y_{ic}^{\mathrm{L}}\right)\right] + \sum_{m\in\mathbf{M}} f_{mj} y_{mc}^{\mathrm{out}} + \sum_{r\in\mathbf{R}} f_{rj}\left[Y_{rc}^{\mathrm{L}} + \lambda\left(Y_{rc}^{\mathrm{U}} - Y_{rc}^{\mathrm{L}}\right)\right]$$
$$\le M_{jc}^{\mathrm{U}} + \lambda\left(M_{jc}^{\mathrm{L}} - M_{jc}^{\mathrm{U}}\right) \quad \forall c \in \mathbf{C}, j \in \mathbf{J} \tag{7}$$

Eqs. (8)-(10) are used to determine the compressor inlet and outlet pressures. The inlet pressure of compressor m (p_m^{in}) should be lower than or equal to the pressures of all inlet streams from internal (P_i) and external hydrogen sources (P_r), whilst the outlet pressure of compressor m (p_m^{out}) should be higher than or equal to the operating pressures of all hydrogen sinks connected to it.

$$p_m^{\text{in}} \le P_i + \Gamma\left(1 - z_{im}\right) \quad \forall i \in \mathbf{I}, m \in \mathbf{M} \tag{8}$$

$$p_m^{\text{in}} \le P_r + \Gamma\left(1 - z_{rm}\right) \quad \forall m \in \mathbf{M}, r \in \mathbf{R} \tag{9}$$

$$p_m^{\text{out}} \ge P_j z_{mj} \quad \forall j \in \mathbf{J}, m \in \mathbf{M} \tag{10}$$

where z_{im}, z_{rm} and z_{mj} are binary variables indicating if the connection exists; Γ is a large positive value. Note that the inlet compressor pressure will be forced to the lowest of the inlet streams, and the outlet pressure to the highest of the downstream hydrogen sinks, with the inclusion of the compressor cost in the objective function to be minimised.

The pressure and connection constraints are given in Eqs. (11)-(13). In particular, Eq. (13) forbids the connections from lower pressure to higher pressure.

$$\varepsilon - \Gamma\left(1 - z_{ab}^{\text{P}}\right) \le P_b - P_a \le \Gamma z_{ab}^{\text{P}} \tag{11}$$

$$F_{ab}^{\text{L}} z_{ab} \le f_{ab} \le F_{ab}^{\text{U}} z_{ab} \tag{12}$$

$$z_{ab}^{\text{P}} + z_{ab} \le 1 \tag{13}$$

where ε is a small positive value; z_{ab}^{P} is a binary variable indicating if P_b ($\in \left\{P_j, p_m^{\text{in}}\right\}$) is higher than P_a ($\in \left\{P_i, p_m^{\text{out}}, P_r\right\}$), with $ab \in \{ij, im, mj, rj, rm\}$.

The hydrogen consumption and the total cost of the network are given by Eqs. (14) and (15) respectively. Detailed cost functions for hydrogen utility (φ_{H_2}), compressor power (φ_{power}), fuel (φ_{fuel}) and piping (φ_{pipe}) as well as the relevant parameters can be found in the previous works (Hallale and Liu, 2001; Deng et al., 2014).

$$\phi_{\text{HC}} = \sum_{r \in \mathbf{R}} \sum_{j \in \mathbf{J}} f_{rj} + \sum_{r \in \mathbf{R}} \sum_{m \in \mathbf{M}} f_{rm} \tag{14}$$

$$\phi_{\text{TC}} = \varphi_{\text{H}_2} + \varphi_{\text{power}} - \varphi_{\text{fuel}} + \varphi_{\text{pipe}} \tag{15}$$

Other mass balance equations for compressors and the fuel system are omitted here due to space limitations.

4. Case study

This case study is representative of a real refinery system. The data used is adapted from Hallale and Liu (2001), but fictitious uncertainty margins are added to the flowrates and concentration levels to demonstrate the developed fuzzy model. There are six hydrogen consumers using hydrogen from a catalytic reformer and a hydrogen plant. There are two make-up compressors in the system and all the consumers except the isomerisation plant have an internal recycle compressor. The process flowrate and pressure data are given in Table 1. The lower and upper limits of the fuzzy goal for fresh hydrogen consumption and total annual cost are based on the results reported by Hallale and Liu (2001) of 45 MMscfd and \$22.5 million/y, and the total fresh hydrogen demand and system cost of 55.57 MMscfd and \$27.55 million/y without hydrogen management, respectively.

Solving the model yields the network shown in Figure 1, where it can be seen that the fresh hydrogen requirement is 48.96 MMscfd. The corresponding level of satisfaction of the fuzzy limits is $\lambda = 0.625$. At the optimal value of λ, the actual allocation of hydrogen to sink HCU-K is 38.94 MMscfd (= 38 MMscfd + 0.625 × (39.5 − 38 MMscfd)), and the amount of hydrogen from source HCU is 11.13 MMscfd (= 13 MMscfd + 0.625 ×

(10 − 13 MMscfd)). As a result, the corresponding hydrogen flowrate to the fuel system is 26.75 MMscfd. By comparison, the solution to the crisp (non-fuzzy) problem is 45 MMscfd of fresh hydrogen from the hydrogen plant and 23.67 MMscfd of low-purity hydrogen to the fuel system (Hallale and Liu, 2001).

The optimal value of λ can be interpreted as follows. For any given process, the parameters may be defined in terms of a fuzzy interval, which ranges from an optimistic (or risky) value to a conservative (or low-risk) value. For example, the concentration limit for JHT-K ranges from 30 to 40 %. The lower limit of this range corresponds to a conservative or safe assumption, whilst the upper limit entails more risk by assuming that the process is able to physically tolerate more impurity. In other words, using 30 % as the limit for this sink is equivalent to setting $\lambda = 1$, whilst using 40 % assumes that $\lambda = 0$. As the optimisation model allows λ to be adjusted until the optimal value of 0.625 is found, it follows that the corresponding concentration limit for this solution is 33.75 % (= 40 % − 0.625 × (40 − 30 %)). Note that this result is closer to the conservative assumption than to the risky one. A similar argument applies for all the fuzzy parameters in the model.

Table 1. Process Data for the Refinery Case Study

Source	Flowrate (MMscfd)	Impurity concentration (%)	Pressure (psia)	Sink	Flowrate (MMscfd)	Impurity concentration (%)	Pressure (psia)
CRU	(23,25)	(25,30)	300	DHT-K	11.31	(19.03,30.03)	600
DHT	(8,9)	(30,40)	400	CNHT-K	8.21	(15.47,20,47)	500
CNHT	3.47	(37,40)	350	JHT-K	(7,9.5)	(30,40)	500
JHT	4.32	(30,40)	350	NHT-K	(12,13.5)	(27.56,33.56)	300
NHT	(6,8)	(15,45)	200	IS4-K	0.04	(25,30)	300
IS4	0	-	-	HCU-K	(38,39.5)	(7,13)	2000
HCU	(10,13)	(20,50)	1200				
H_2 plant	(45,55.57)	(8,10)	300				

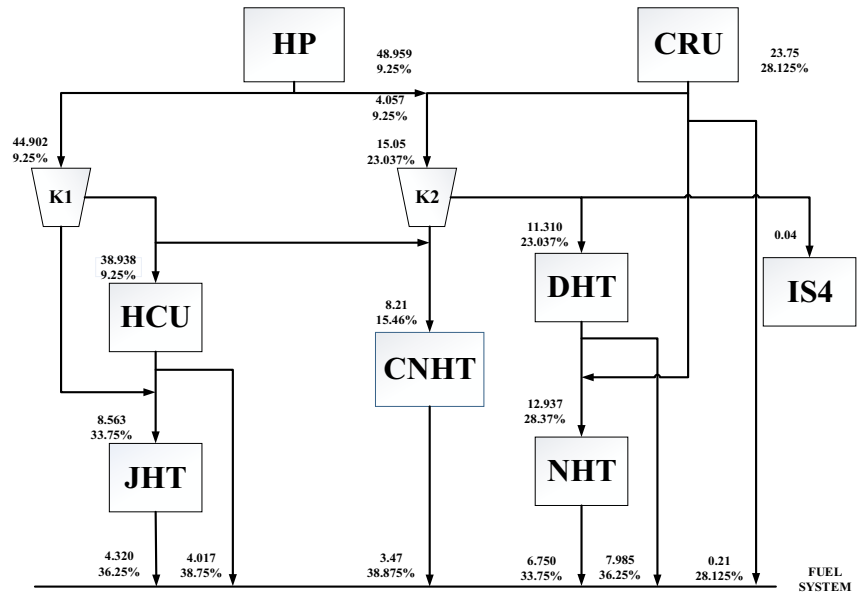

Figure 1. Optimised network considering uncertainties.

Table 2. Comparison of Results

Results	Hallale and Liu (2001)	This work
Hydrogen cost	$32,900,000/y	$35,740,310/y
Electricity cost	$1,770,000/y	$2,209,399/y
Fuel cost	$12,200,000/y	$14,691,790/y
Piping cost	-	$693,491/y
Total cost	$22,470,000/y	$23,951,410/y
Degree of satisfaction	-	0.625

Table 2 shows a result comparison. Though not reported, the piping cost of the existing hydrogen system should account for only a small portion of the total, as is presented in this work. Therefore, the slight increase in the total annual cost (as well as the hydrogen utility requirement/cost) is the penalty incurred to provide a margin of safety based on process mass balances, particularly with regard to the impurity load.

5. Concluding remarks

A fuzzy optimisation model for refinery hydrogen network synthesis with parametric uncertainties has been developed in this work. The formulation consists mainly of mass balance equations and pressure constraints, and accounts for the compromise between resource conservation and cost saving. A case study was solved to illustrate the proposed approach. Future work will consider the placement of purification units and carry out more detailed cost analysis.

Abstract

In this work, we propose a rigorous model for the simulation and optimization of a dividing-wall configuration known as Kaibel column (KC). The rigorous model, based on the well-known MESH equations of a conventional Continuous Distillation Column (CDC), is separated into four sets of equations that represent the main sections of the column: above, below, left side, and right side sections of the dividing wall, including secondary sections formed by the trays in between the side feed and outlets. The non-linear programming optimization of this rigorous model is performed in order to determine the Kaibel Column potential benefits, such as energy savings and greater purities for the middle products within a single column. The proposed steady-state Kaibel Column performs the separation of a quaternary methanol, ethanol, propanol, and butanol mixture while minimizing a total annual cost function using the reflux ratio, vapor and liquid rates, the product rates, and the heat duties as the manipulated variables of the system. The results show that the Kaibel Column is able to reduce the energy consumption in the reboiler and condenser by more than 40 % compared to the conventional sidedraw continuous counterpart. Also, the reduction in the number of trays of the dividing wall proves to be an important factor since small reductions in energy consumption were observed. The model was coded in Pyomo and solved using the NLP solver IPOPT.

Keywords: Dividing Wall Columns, Kaibel Columns, NLP Optimization.

1. Introduction

Over the last decades, the study of new dividing wall configurations has been addressed with the purpose of solving the inherent problem of the traditional distillation processes: their high energy consumption. One of the innovative solutions to overcome this energy problem is the use of intensive configurations, such as Dividing Wall Distillation Columns (DWDC), created by the addition of a wall that splits the column in two sections. While its construction and control might still represent a challenge, this configuration has proven to generate savings up to 30 % in energy consumption and, in some cases, savings in the capital and investment costs by reducing the number of distillation columns needed to perform a multicomponent separation (Dejanovic et al., 2010). Among these divided columns different configurations have been proposed where the Kaibel Column (KC) (Kaibel, 1987) is considered a promising option since it

can replace a sequence of two, three or more distillation columns needed to purify a multicomponent mixture (Yildrim et al., 2011) since it is able to separate more than three products within a single column (Kiss et al., 2012). The simulation and optimization of this multi-product configuration has been performed first by using commercial software to simulate the column then by the use of an external algorithm which performs the optimization. These results have shown for KC good controllability properties and energy savings (Qian et al., 2016, Tututi-Avila et al., 2017) but no rigorous open-source model has been reported for its study.

In this paper, we propose a model to simulate and optimize a Kaibel Column to obtain the system variable profiles that minimize a total annual cost while producing four high purity products: methanol, ethanol, n-propanol, and butanol. The proposed equations are presented in Section 3 while the case study and operational conditions are given in Section 2. Finally, the results are presented in Section 4 followed by the Conclusions in Section 5.

2. NLP Problem Statement

In a general form, the problem is stated as follows. Given a Kaibel Column configuration and a desired final product purity, a feed mixture of NC components is to be separated into NC high-purity products while minimizing the total annual cost function. To accomplish this goal the reflux ratio, the vapor flowrate, the liquid distributors, and the heat duties are used as the manipulated variables in the NLP optimization problem, allowing the purification (to some pre-specified tolerance) of the NC components in the feed.

3. Model Equations

The proposed model for the KC was obtained by modifying the mass and energy balances on the internal trays of a conventional Continuous Distillation Column (CDC) with two side outlets, S_1 and S_2. This model is given in Eq.(1) to Eq.(13) with the objective function (TAC) in Eq.(14). The proposed set of MESH equations is split into four main sections: above and below the dividing wall and the left and right sections of the dividing wall (section 1 and 2, respectively). Some secondary sections, such as the trays in between the side feed F and the side outlets S_1 and S_2, are also considered in the model. All these sections can be seen in the KC scheme in Figure 1. Due to space limitations, only the mass balances per component are given here and will have to be further modified by the reader to complete the MESH equations of the model. The mass balances equations are given in the next order: reboiler and vapor distributor in Eq.(1) and Eq.(2), starting tray of the dividing wall in section 1, side feed tray, and ending tray of the dividing wall in section 1 in Eq.(3) to Eq.(5), starting tray of the dividing wall in section 2, side outlet 1, side outlet 2, and ending tray of the dividing wall in section 2 in Eq.(6) to Eq.(9), and liquid distributor and condenser in

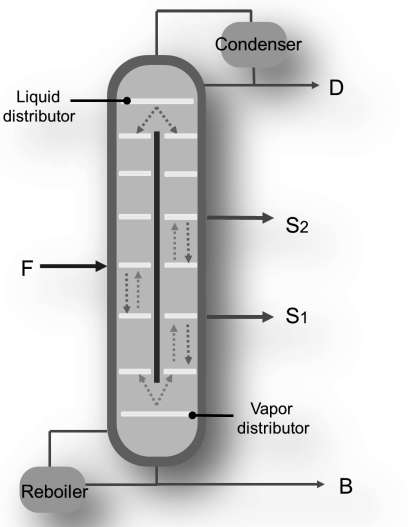

Figure 1. Kaibel Column.

Eq.(10) and Eq.(11). The total mass balances are obtained when the liquid and vapor compositions terms are removed from Eq.(1) to Eq.(13) while the energy balances are obtained when the liquid and vapor composition terms are replaced by the liquid and vapor enthalpy terms in Eq.(1) to (13). The vapor compositions, composition summations, vapor-liquid equilibrium constants, activity coefficients (UNIQUAC), and vapor and liquid enthalpy equations are also included and solved in the model. The Total Annual Cost (TAC) is given in Eq.(14). The trays are numbered from the bottom to the top of the column, with tray *1* the reboiler and tray *NT* the condenser.

$$0 = \left(L_{j+1} + F - S_1 - S_2\right)x^1_{j+1,i} - V_j y_{j,i} - B x_{j,i} \tag{1}$$

$$0 = \left(L^1_{j+1} + F\right)x^1_{j+1,i} + \left(L^2_{j+1} - S_1 - S_2\right)x^2_{j+1,i} + V_{j-1}y_{j-1,i} - \left(L_j + F - S_1 - S_2\right)x_{j,i} - V^1_j y_{j,i} - V^2_j y_{j,i} \tag{2}$$

$$0 = \left(L^1_{j+1} + F\right)x^1_{j+1,i} + V^1_{j-1}y_{j-1,i} - \left(L^1_j + F\right)x^1_{j,i} - V^1_j y^1_{j,i} \tag{3}$$

$$0 = \left(L^1_{j+1} + F\right)x^1_{j+1,i} + \left(L^2_{j+1} - S_1 - S_2\right)x^2_{j+1,i} + V_{j-1}y_{j-1,i} - \left(L_j + F - S_1 - S_2\right)x_{j,i} - V^1_j y_{j,i} - V^2_j y_{j,i} \tag{4}$$

$$0 = \left(L^1_{j+1} + F\right)x^1_{j+1,i} + V^1_{j-1,i}y_{j-1,i} - \left(L^1_j + F\right)x^1_{j,i} - V^1_j y^1_{j,i} \tag{5}$$

$$0 = L^1_{j+1}x^1_{j+1,i} + V^1_{j-1}y^1_{j-1,i} - \left(L^1_j + F\right)x^1_{j,i} - V^1_j y^1_{j,i} + F x_{F,i} \tag{6}$$

$$0 = L^1_{j+1}x_{j+1,i} + V^1_{j-1}y^1_{j-1} - L^1_j x^1_{j,i} - V^1_j y^1_{j,i} \tag{7}$$

$$0 = (L^2_{j+1} - S_1 - S_2)x^2_{j+1,i} + V^2_{j-1}y_{j-1,i} - (L^2_j - S_1 - S_2)x^2_{j,i} - V^2_j y^2_{j,i} \tag{8}$$

$$0 = (L^2_{j+1} - S_2)x^2_{j+1,i} + V^2_{j-1}y^2_{j-1,i} - (L^2_j - S_1 - S_2)x^2_{j,i} - V^2_j y^2_{j,i} - S_1 x^2_{j,i} \tag{9}$$

$$0 = L^2_{j+1}x^2_{j+1,i} + V^2_{j-1}y^2_{j-1,i} - \left(L^2_j - S_2\right)x^2_{j,i} - V^2_j y^2_{j,i} - S_2 x^2_{j,i} \tag{10}$$

$$0 = L^2_{j+1}x_{j+1,i} + V^2_{j-1}y^2_{j-1,i} - L^2_j x^2_{j,i} - V^2_j y^2_{j,i} \tag{11}$$

$$0 = L_{j+1}x_{j+1,i} + V^1_{j-1}y_{j-1,i} + V^2_{j-1}y^2_{j-1,i} - L^1_j x_{j,i} - L^2_j x_{j,i} - V_j y_{j,i} \tag{12}$$

$$0 = V_{j-1}y_{j-1,i} - L_j x_{j,i} - D x_{j,i} \tag{13}$$

$$TAC = C_H Q_{Reb} + C_c Q_{Con} + \frac{I_R(I_R+1)^{PL}}{(I_R+1)^{PL}}(C_{shell} + C_{int} + C_{HE}) \tag{14}$$

The notation is: j are the trays, i are the components, superscripts 1 and 2 represent the section 1 (left side) and 2 (right side) of the dividing wall, x and y are the liquid and vapor composition, S_1 and S_2 are the side outlets flowrate, D and B are the distillate and bottoms flowrate in kg-mol/h, F is the side feed flowrate in kg-mol/h, L and V are the liquid and vapor flowrate in kg-mol/h, Q_{Reb} and Q_{Con} are the energy consumption in the reboiler and condenser in kW, rr is the internal reflux ratio, I_R and PL are the interest rate and plant life, C_H, C_C, and C_{HE} are the costs of heat and cold utilities and the heat exchangers, while C_{shell} and C_{int} are the costs of the column shell and internal with installation. The costs for the TAC are: I_R = 0.1, PL = 10 y, C_H = 0.0091 \$/kWh, C_C = 0.0023 \$/kWh, C_{HE} = 4,500 \$, C_{shell} = 70,000 \$, and C_{int} = 132,600 \$.

3.1. Case Study

The study of the KC is performed by separating an equimolar quaternary mixture of methanol (1), ethanol (2), n-propanol (3), and butanol (4). The separation is carried out with the objective of obtaining four high-purity products with the following specifications: product flowrates higher than 0.2 kg-mol/h and final compositions higher than 0.99 for the four components. The proposed model was solved under steady-state conditions with the operational conditions given in Table 1 and considering the following degrees of freedom: the condenser and reboiler duties, the product flowrates, the reflux ratio, the liquid and vapor rates, and the liquid distributor. The vapor distributor is assumed to be constant since it is known to be a very difficult variable to control during the column operation (Yildrim et al., 2011). The problem is initialized by performing the simulation of the KC column (*obj=1*) while using the warm start option in IPOPT. This simulation is followed by the solution of the NLP optimization problem using the TAC as the objective function. In order to compare the energy consumption in the reboiler and condenser, the KC results are compared to the results obtained from the optimization of a conventional CDC under the same operational conditions. The proposed KC and the CDC NLP models were written in Pyomo and solved using IPOPT.

4. Results

Table 1. Operating conditions for the KC.

Number of trays	70
Side outlets trays, S_1-S_2	20-40
Side feed tray, F	35
Dividing wall starting tray,	10
Dividing wall ending tray,	50
Vapor distributor, dv_1	0.60
Initial vapor flowrate, V	5
Initial liquid composition	$x_{i\,i}^{0}$
(1) Methanol	0.25
(2) Ethanol	0.25
(3) n-Propanol	0.25
(4) Butanol	0.25
Side feed liquid composition	$x_{i\,i}^{0}$

The optimization results for the KC and the conventional CDC for the quaternary methanol-ethanol-propanol-butanol mixture separation are presented in Table 2. The four high-purity products specification of 0.99 was achieved by the KC while the CDC achieved it only in the distillate and bottom products with middle products a purity of 0.93. The KC comprises 8,226 equations solved in 481 seconds while the CDC comprises 5,258 equations solved in 190 seconds. Even though the middle products were not highly purified by the CDC, the conventional column energy consumption is higher than the heat duty consumed by the KC column. This is consistent with the behavior observed for other mixtures, where savings around 14 % are observed with respect to the conventional CDC separation sequence (Tututi-Avila et al., 2017). For this separation case, a comparison between the results in Table 2 shows that KC reduces the energy consumption in the reboiler by 42.14 %, followed by a reduction of 45.6 % in the condenser. The change in the position of the dividing wall slightly affects the energy consumption when the number of dividing-wall trays is reduced (34 dividing-wall trays, from tray 13 to tray 47 of the main column), slightly higher energy savings of 42.6 % in the reboiler and 46 % for the

condenser are observed when compared to the base case (40 dividing-wall trays, from tray 10 to 50 of the main column). On the other hand, the addition of trays on the dividing-wall will lead to a reduction on the energy efficiency by moving from energy savings from the base case of 42.14 % for the reboiler to 41.73 while the condenser changes from 45.6 % to 45.13 %. These changes might not seem significant but it is important to point out the importance on the selection of the dividing wall trays and their position. The side feed flowrate also has a direct effect on the energy savings. On the KC we observed that for flowrates between 0.80 and 1 kg-mol/h, the KC still consumes less energy when compared to the CDC. We can therefore say that the proposed KC model gives a consistent solution that can predict the behavior of the different non-linear variables involved in this intensified distillation configuration.

To study the behavior of the variables in the system we present the KC liquid composition profiles in Figure 2. The composition profiles above and below the dividing wall with section 1 and section 2 of the dividing column are given in Figures 2(a) and 2(b), respectively. In Figure 2(a) we observe how the propanol composition is diluted by the side feed *F* on tray 35, with smaller composition values on the trays below it. On the other hand, section 2 profiles in Figure 2(b) show how the four products achieve the desired purity by keeping a reflux ratio value close to 1 and a temperature profile on the internal trays of the column close to the pure component boiling points, allowing for a better separation compared to section 1. Even though a remixing effect on the middle products after their removal from tray 20 and 40 (shaded area in Figure 2(b)) is observed, it is not significant for this particular case since we are already achieving energy savings. This dilution could lead to small thermal inefficiencies in the KC, reducing the energy savings. However, in order to reduce these inefficiencies in further examples we would have to perform a more in depth study on the optimal position of the side outlets.

Table 2. Results for the CDC and the KC.

	CDC	KC		
Dividing Wall Trays		10-50*	13-47	9-51
Q_{Reb}	61.628	35.652	35.405	35.911
Q_{Con}	56.950	30.997	30.764	31.249
Reflux ratio	0.963	0.937	0.937	0.937
Side feed	0.855	0.802	0.801	0.803
Distillate/Bottoms	0.203[1]/0.199[1]	0.200/0.202	0.200/0.201	0.200/0.202
Side outlet 1	0.227[2]	0.200	0.200	0.200
Side outlet 2	0.224[2]	0.199	0.200	0.199
Liquid distributor, dl_1	-	0.50	0.50	0.50

* Base case. [1] Methanol and butanol composition in *D* and *B* is 0.99.

[2] Ethanol and propanol composition in S_1 and S_2 is 0.93.

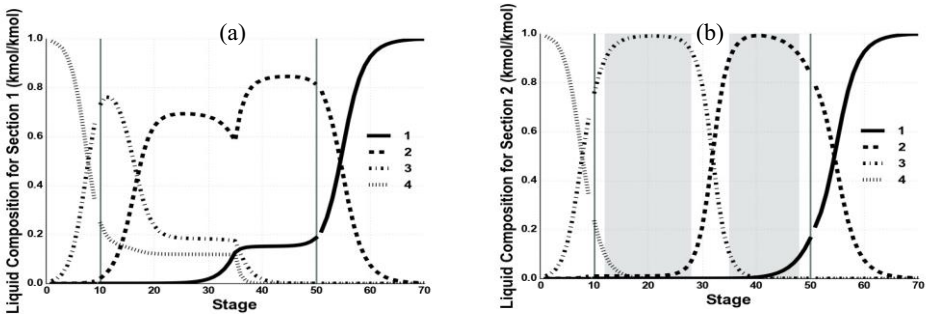

Figure 2. Liquid composition profiles of the Kaibel Column. (a) Liquid composition profiles of the main column with section 1 of the dividing wall. (b) Liquid composition profiles of the main column with section 2 of the dividing wall.

5. Conclusions

In this work, we proposed a model for the simultaneous simulation and optimization of a Kaibel Column for the separation of high-purity products of a methanol-ethanol-propanol-butanol mixture. In order to study the behavior of all the variables involved in a distillation process and the energy efficiency of a KC, a simulation was performed first, followed by the NLP optimization problem that minimizes a total annual cost function under fixed product specifications. To be able to compare and define possible energy savings, a conventional Continuous Distillation Column was also solved. By comparing these two columns we observe that the KC proposed model shows accurate profiles by achieving energy savings of around 42 % in the reboiler and 45 % in the condenser for the base case, while the reduction of 2 trays in the dividing wall increased this savings by an extra 0.50 %, proving how important it is to decide the number of trays and their position in a distillation configuration. These results show that the proposed model can be used as an accurate option for the solution of Kaibel Column configurations.

Abstract

Over the years, the Water Sources Diagram (WSD) has become a consolidated approach to determine the minimum freshwater consumption and simultaneously generate the system structure in water networks in many kinds of industrial processes. Some efforts have been employed to, for example, automatically determine the reference contaminant and reference operation and to predict in which operation(s) violations will occur, before the beginning of the calculations. Those violations are then removed as part of the last step of the method and it is currently performed by hand. Seeking to improve this step and to create an automated procedure that can be linked with the MINEA software was the motivation of this research.

Keywords: Concentration Violation, Water Networks, Automated Procedure.

1. Introduction

The WSD is an algorithmic-heuristic technique (Gomes et al., 2007) that has been employed in many water allocation problems in industry over the years. Notwithstanding, some authors focused their attention on innovative methods to improve both the performance and quality of the WSD results. For example, one of the WSD drawbacks reported by many users in the past, was the lack of an automated way to generate scenarios (water networks (WN)) without made-by-hand. This cumbersome procedure was solved by the development of a software called MINEA (Mirre et al., 2013). The user was then able to solve many problems in less time with more confidence in the results. Since then, MINEA has been updated to add the most recent algorithms, improve performance and to become more user-friendly.

The algorithms to determine the reference contaminant and reference operation were proposed by Calixto et al. (2015). It's now possible to skip these choices right to the WSD generation. Francisco et al. (2015) extended the WSD method to fixed flowrate operations with one contaminant and (Francisco et al., 2015). Francisco et al. (2017) added new characteristics to determine the reference operation and reference contaminant in fixed flowrate operations involving multiple contaminants. These works filled a gap in the WSD method. However, even those efforts are not enough to avoid the presence of violations in the final water network when dealing with multiple contaminants. With this in mind, Calixto et al. (2015) provided an approach to identify the violated contaminants and the operations in which that occurs. It helps to previously know the violations and

take the proper action while the flowsheet is elaborated. Removing violations in the mass balance flowsheet is one of the last step of the WSD procedure and it is currently made almost by hand. This is one of the reasons that affects the time to get the final results.

This last step is responsible for the removal violation process and it is based on the increasing of the external fresh water consumption or by redirecting the outlet streams of some splitters that are upstream of the operation where the violation is observed. The second option consists of removing the violation without increasing the external fresh water consumption when the operation does not require external fresh water.

Currently, MINEA software provides only the WSD and the flowsheet generation is made separately in conjunction with the violations removal and evolution of the WN. In future version of the software, it will be possible to get the final flowsheet without the presence of violations and evolve the WN. Note that in this work the attention is only on the removal of the violations without observe other options to reduce the freshwater consumption like discussed by Gomes et al. (2013) and Francisco et al. (2015,2017), which means that the evolution of the WN is not performed.

We propose a mathematical model to remove violations with (or without) the minor increasing in the fresh water consumption in water allocation problems with multiple contaminants for the respective WN. This novel approach will be implemented in the future version of the software MINEA. For brevity reasons the WSD will not be explained in detail here, for more details see Gomes et al. (2007, 2013) or Francisco et al. (2015, 2017).

2. Mathematical model

The violations are present in each inlet or outlet of an operation *u*. Figure 1 illustrates the mass flowrate in t/h and concentrations in ppm for the inlet and outlet of an operation *u*.

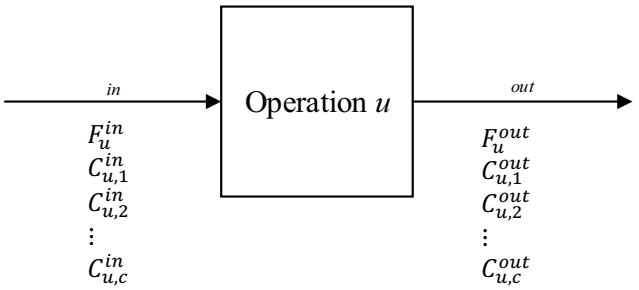

Figure 1. Representation of an operation *u* and its inlet and outlet contaminants concentrations and flowrates.

Where F_u^{in} and F_u^{out} are the inlet and outlet flowrates of an operation *u*, $C_{u,c}^{in}$ and $C_{u,c}^{out}$ are the inlet and outlet concentrations for the operation *u* for a certain contaminant *c*. $C_{u,c}^{out}$ can be determined by the following linear mass transfer equation:

$$C_{u,c}^{out} = \frac{\Delta m_{u,c}}{F_u^{out}} + C_{u,c}^{in} \tag{1}$$

Where $\Delta m_{u,c}$ is the mass load of the contaminant *c* in the operation *u* in kg/h.

A violation usually occurs when a mixer is present upstream the operation u, due to the additional contribution of a poor-quality water stream. Figure 2 shows the representation of a mixer m with an operation u in a flowsheet.

If an amount of s mixed streams is not enough to provide an operation without violations, another water stream supply must be added, from internal or external sources. Eq. (2) shows the mass balance in this system.

$$\sum_{s} C_{m.c}^{s} F_{m}^{s} + C_{m.c}^{a} F_{m}^{a} = F_{u}^{in} C_{u,c}^{in} \tag{2}$$

Where $C_{m.c}^{s}$ is the inlet concentration of contaminant c for a mixer m in a stream s, F_{m}^{s} is the inlet flowrate of the stream s for a mixer m, $C_{m.c}^{a}$ is the inlet concentration of contaminant c in the supplied stream a, that can be internal or external. F_{m}^{a} is the inlet flowrate of the supplied stream a for a mixer m.

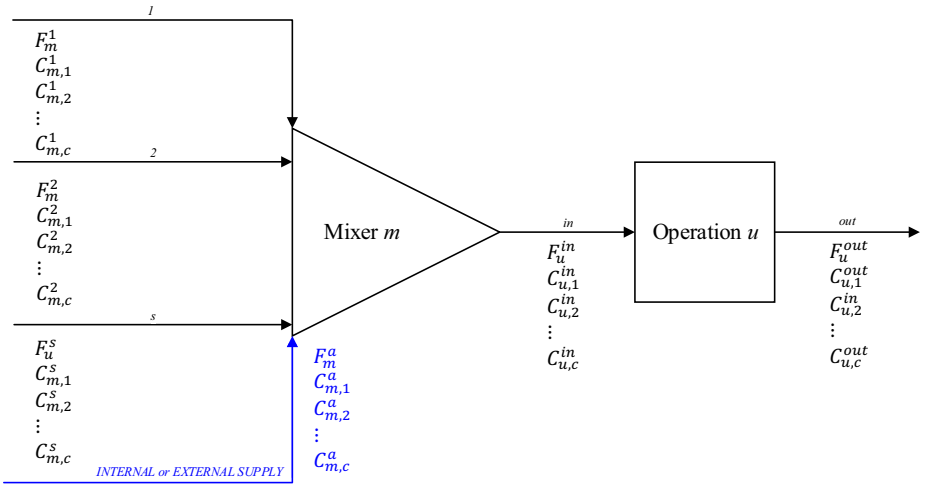

Figure 2. Scheme for the addition of water supply.

We need to know the minimum amount of external or internal water that must be added or allocated to meet the restrictions imposed by operation u. If, $C_{m.c}^{s}$and F_{m}^{s} are known, then it becomes a nonlinear optimization problem.

$$\begin{aligned} &Min \sum_{a} F_{m}^{a} \\ &\text{s. t.} \\ &C_{u,c}^{in} \leq C_{u,c}^{in,max} \\ &C_{u,c}^{out} \leq C_{u,c}^{out,max} \\ &F_{u}^{in} \leq F_{u}^{max} \\ &C_{u,c}^{in}, C_{u,c}^{out} \geq 0 \end{aligned} \tag{3}$$

Where $C_{u,c}^{in,max}$ and $C_{u,c}^{out,max}$ are the maximum inlet and outlet concentrations in the operation u for a contaminant c, respectively and F_{u}^{max} is the maximum allowable flowrate in the operation u.

The model is nonlinear because it is not known the value of $C_{m.c}^{s}$and F_{m}^{s}in Eq. (3). The term $C_{m.c}^{s}F_{m}^{s}$ brings the nonlinearity. If we know some of these values the model can be modeled as linear. Another way to linearize the model is by changing the variables, which can be done by replacing the nonlinear term.

Besides the mathematical model, some basic rules are necessary to be performed in the last step when the water network is obtained by WSD, as follows: a) all the operations are "checked" to verify if there are some violation; b) If any violation is observed, the method starts by considering the addition or removal of internal water streams that are used in the operations which present violation. This is done to minimize the total value of internal streams that are possible to remove the violation in each operation subjected to the respective restrictions. c) If it is not possible to remove the violations in each operation by splitting or redirecting internal water streams, the minimization of external water source with the internal water sources consumptions is carried out. The optimization model was implemented in Microsoft Excel and solved using the GRG nonlinear solution method presented in the *Solver* package.

To better explain how the approach works, a classical case study introduced by Doyle and Smith (1997) is presented. This case study is composed by four water-using processes and three contaminants.

3. Case Studies

3.1. Example 1

This case study was introduced by Doyle and Smith.(1997). Table 1 shows the limiting data. Figure 3 shows the WSD generated.

Table 1. Limiting data for Example 1.

Op.	f_u (t/h)	Cont.	$C_{u,c}^{max}$(ppm)	$C_{u,c}^{out,max}$(ppm)	$\Delta m_{u,c}(kg/h)$
1	34	A	0	160	5,44
		B	0	450	15,3
		C	0	30	1,02
2	75	A	200	300	7,5
		B	100	270	12,75
		C	500	740	18
3	20	A	600	1240	12,8
		B	850	1400	11
		C	390	1580	23,8
4	80	A	300	800	40
		B	460	930	37,6
		C	400	900	40

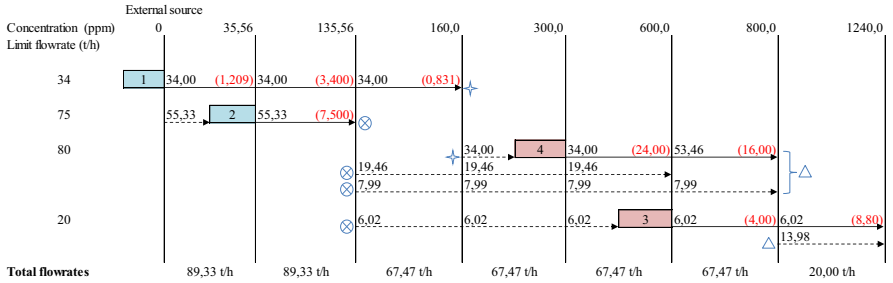

Figure 3. WSD generated for example 1.

Operation 1 and 2 use 34 t/h and 55,33 t/h from the external fresh water source. Part of this amount is distributed to operation 3 and 4. Operation 4 uses all 34 t/h from operation 1 and 27,45 t/h from operation 2. Therefore, operation 3 uses 6,02 t/h from operation 2 and in the last interval of the diagram, a flowrate of 13,98 t/h is calculated to operation 3 that comes from operation 4. The total fresh water consumption is 89,33 t/h. Figure 4 shows the representation of the diagram in a form of a flowsheet.

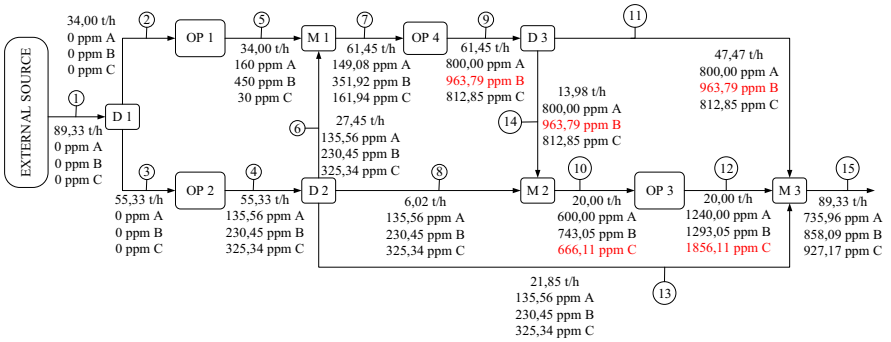

Figure 4. WN for maximum reuse with violations.

The highlighted concentrations in operations 3 and 4 are violated for the contaminants B and C. To remove them, the rules previously described must be performed. Initially, the available internal water supply flowrates need be identified and minimized using Eq. (3). In this case, the flowrates for the streams 6, 8 and 14 are adjusted to meet the limiting concentration data in the operations 3 and 4. Figure 5 shows the new flowsheet with the new minimum internal flowrate supply.

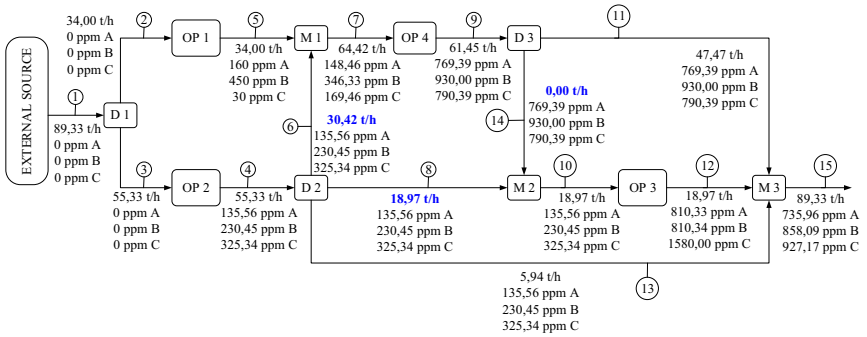

Figure 5. New WN for maximum reuse without violation and new internal flowrate.

The internal flowrates were successfully adjusted, and no violation is present in operations 3 and 4. In this case, the use of external water was not necessary, but only a rearrange of the internal water streams. It is important to note that the WN is not optimal, because, in this step, only the violations are removed, and the evolution step was not implemented. With the evolutionary step the WN will be improved to achieve its optimal freshwater value, modifying or not the WN.

4. Conclusions

A systematic way to remove violations in WNs that were generated by the WSD is presented. For the analyzed case study, the use of internal water supply was enough to eliminate the violations in the flowsheet. In the cases where internal sources are not available, the use of external fresh water supply is possible. For future implementations, this method will be integrated with MINEA WSD algorithm, Microsoft Excel *Solver* and GAMS *Solvers* in only one software package. Research directions are also made to improve this algorithm and to include other options for reducing the freshwater consumption in the WN obtained by WSD, as part of the evolutionary step.

Abstract

Energy consumption in industrial processes is mainly in the form of heat. Thus, heat recovery is one of the main focuses in industrial energy efficiency problems. Heat integration (HI) techniques have been studied extensively to solve such problems. One of the main drawbacks of the classical heat integration approaches is that heat can be transferred from any stream to another as long as it flows from higher temperature intervals to lower ones, which results in impractical scenarios, in which heat is recovered over long distances. This work proposes a heat integration method which takes into account heat distribution losses. The heat losses are calculated as a function of the distance between the original location of the stream and the location it is used and the supply and return temperatures. The heat cascade is written so that the energy balance is closed for each location. This way, while heat recovery within the same or close location is promoted, heat transfer over long distances is discouraged. Using the proposed method, practically infeasible solutions are eliminated at the level of optimisation. At the same time, the temperature drop and the heat losses resulting from heat exchange over long distances are calculated. The method is applied to a case study with two plants. While the total operating cost can be reduced by 25% by heat integration within and between the sites, not exchanging heat between the two sites is found to be more beneficial when heat losses are taken into account.

Keywords: hear integration, heat distribution losses, multiple locations

1. Introduction

Energy efficiency has been a research-intensive field for more than forty years, initially motivated by fossil fuel prices and afterwards by environmental concerns. As one of the main energy consumers, the industrial sector, and more specifically process industry, has become the target of energy efficiency research. Energy consumption in industry is mainly in the form of heat. Hence, the research in the field focuses primarily on heat recovery and waste heat valorisation. Pinch analysis (PA) is a technique proposed by Linnhoff and Hindmarsh [1] which uses thermodynamics and a graphical representation of the streams to obtain the maximum energy recovery (MER) between the processes. Although PA has proven to be effective in setting targets for energy consumption, it can yield scenarios that are practically inefficient because of direct heat exchange between the processes. Dhole and Linnhoff [2] developed total site analysis (TSA), a method based on PA, to overcome this drawback. In TSA, heat is recovered from processes by means of utilities (e.g. steam, hot water, hot oil) and transferred to other processes that require heating. HI methods using mathematical programming (MP) have emerged to find the optimal utility configuration satisfying the MER. Typically, the problem is formulated

with mixed integer linear programming (MILP), where the selection of the utilities is decided using binary variables and the size of each utility using continuous variables [3].

HI has been used for problems at different scales, including the optimization of a single process unit, a single plant and multiple plants. HI across industrial plants is typically achieved using intermediate fluids. Ahmad and Hui [4] used steam at different pressure levels to transfer heat between plants. Hackl et al. [5] proposed using a hot water loop to recover heat at low temperature in a chemical cluster. Rodera and Bagajewicz [6] studied both direct and indirect heat transfer across plants and concluded that more energy savings can be achieved by direct heat transfer and that steam is not always effective in indirect heat transfer.

Chew et al. [7] listed the layout of the plants as one of the crucial issues to be considered in heat integration. Several authors addressed this issue using different techniques. Wang et al [8] proposed a graphical method to consider interplant heat integration in parallel, split and series connection patterns and compared the energy savings and pipe length under different configurations. Song et al. [9] developed a graphical technique called interplant shifted composite curve to determine the maximum feasible heat recovery by indirect heat integration between plants. Chang et al. [10] proposed a mixed integer non-linear programming (MINLP) method to optimize waste heat integration between plants, including piping cost in the objective function. Stijepovic and Linke [11] presented a two-step optimization framework: in the first step, a linear programming (LP) problem is solved to obtain the maximum possible heat recovery; in the second step, a MINLP is used to achieve waste heat recovery with optimal design, accounting for piping cost.

A gap is identified when considering interplant heat integration since most of the existing methods do not consider the distance between plants in different locations. Some authors addressed the issue from an economic perspective, by including the cost of piping. However, the heat losses and the temperature drop due to the heat transfer over long distances have not been considered. This work focuses on heat losses resulting from interplant heat integration and proposes a MILP method based on [3] to obtain optimal heat integration scenarios for problems with multiple locations.

2. Methodology

2.1. Estimation of heat losses

The heat losses due to interplant heat transfer depend both on the pipe geometry and on the temperature of the heat transfer fluid. This work considers heat losses from pipes buried under ground as well as pipes above ground.

Heat losses from underground pipes

Heat distribution using pipes buried underground is common in urban district energy networks since it would be impossible to have the pipes above the surface in urban centres. This application is not very common in industry since urban planning rules do not apply to the industrial zones and installing pipes underground is costly. However, it is considered as an option in this work, since the ground provides insulation for the pipes, resulting in lower heat losses.

The formulas used in this work are adapted from the calculation of steady-state heat losses from buried pre-insulated district heating pipes (Bohm [12]) (Eqns. 1-5)

$$H = H \ + \frac{\lambda_g}{\hbar_{air}} \tag{1}$$

where H represents the depth at which the pipes are buried, λ_g the thermal conductivity of the ground and $\hbar_{air}$ the convective heat transfer coefficient of air.

$$R_m = \frac{1}{4\cdot\pi\cdot\lambda_g}\ln\left(1+\left(\frac{2\cdot H}{E}\right)^2\right),\quad R_g = \frac{1}{2\cdot\pi\cdot\lambda_g}\ln\left(\frac{4\cdot H}{D_i}\right),\quad R_i = \frac{1}{2\cdot\pi\cdot\lambda_i}\ln\left(\frac{D_i}{D_p}\right) \tag{2}$$

where R_m, R_g, and R_i are the thermal resistance of the mutual action of the two pipes (i.e. supply and return), the ground and the insulation material, respectively. E is the distance between the pipes, λ_i is the thermal conductivity of the insulation material, and D_i and D_p are the diameter of the insulated pipe and of the pipe itself, respectively.

$$U_1 = \frac{R_g+R_i}{\left(R_g+R_i\right)^2-R_m^2},\quad U_2 = \frac{R_m}{\left(R_g+R_i\right)^2-R_m^2} \tag{3}$$

$$\dot{Q}_{sup} = ((U_1 - U_2)\left(T_s - T_g\right) + \ U_2(T_s - T_r)) \cdot L_p \tag{4}$$

$$\dot{Q}_{ret} = ((U_1 - U_2)\left(T_r - T_g\right) - \ U_2(T_s - T_r)) \cdot L_p \tag{5}$$

where U_1 and U_2 are heat loss coefficients, L_p is the pipe length, T_s, T_r, and T_g are the temperatures of supply, return and ground, and $\dot{Q}_{sup}$ and $\dot{Q}_{ret}$ are the specific heat losses from supply and return.

Heat losses from above surface pipes

A simplified formulation is used to calculate the heat losses from above-ground pipes (Eq. 6-9). The temperature of the pipe is assumed to be equal to the temperature of the fluid flowing inside the pipe. This way, the convective heat transfer inside the pipe can be neglected.

$$\frac{1}{U} = \frac{1}{\hbar_{air}} + \frac{t_p}{\lambda_p} + \frac{t_i}{\lambda_i} \tag{6}$$

$$A = 2 \cdot \pi \cdot D_i \cdot L_p \tag{7}$$

$$\dot{Q}_{sup} = U \cdot A \cdot (T_s - T_{amb}) \tag{8}$$

$$\dot{Q}_{ret} = U \cdot A \cdot (T_r - T_{amb}) \tag{9}$$

where t_p and t_i are the thickness of the pipe wall and of the insulation material, respectively, U is the overall heat transfer coefficient, A is the surface area of the insulated pipe and T_{amb} is the temperature of the ambient air.

Heat losses in the supply and return pipes are subtracted from the total heat load of the stream (Eq. 10).

$$\dot{Q}_s = \dot{Q}'_s - \dot{Q}_{sup} - \dot{Q}_{ret} \tag{10}$$

where $\dot{Q}'_s$ and $\dot{Q}_s$ are the heat loads of the stream prior to and after heat losses.

2.2. Modified MILP formulation

Maréchal and Kalitventzeff's MILP formulation [3] is modified to take into account the location of the streams and the heat losses. The set of locations (***L***) is introduced and all units (***U***) and streams (***S***) are assigned to their corresponding locations by units of location

(**UL**) and streams of location (**SL**) sets. The streams that can exchange heat over distances are defined in a new set of interlocation streams ($\boldsymbol{IS} \in \boldsymbol{S}$) and added in **SL**. The temperature and heat load ($\dot{Q}_{s,t,k}$) of the interlocation streams are modified accounting for heat losses using Eq. 10. A stream can be split and used in several locations and to enforce the mass balance, a set of parents (**P**) and streams of parents in locations (**SP**) are defined to assign the usage of the same stream in different locations to the same parent.

The objective function (Eq. 11) is selected as the minimisation of the operating cost. The heat cascade equations (Eq. 12-14) ensure that heat flows from higher temperature intervals to lower ones. The objective function and the heat cascade are adapted from [3]. In the classical formulation, the heat cascade equations are written for each time step ($t \in \boldsymbol{T}$) and temperature interval ($k \in \boldsymbol{K}$). In the proposed formulation, they are also indexed over locations ($l \in \boldsymbol{L}$), to close the heat balance for each location.

$$\min_{y,f} \sum_{u=1}^{\boldsymbol{U}} \sum_{t=1}^{\boldsymbol{T}} (C_{u,t}^{op1} \cdot y_{u,t} + C_{u,t}^{op2} \cdot f_{u,t}) \cdot t^{op} \tag{11}$$

$$\sum_{u=1}^{\boldsymbol{U}} \sum_{s=1}^{\boldsymbol{SL}} \dot{Q}_{s,t,k} \cdot f_{s,t} + \dot{R}_{t,k+1,l} - \dot{R}_{t,k,l} = 0 \quad \forall\, t \in \boldsymbol{T},\ k \in \boldsymbol{K},\ l \in \boldsymbol{L} \tag{12}$$

$$\dot{R}_{t,k,l} \geq 0 \quad \forall\, t \in \boldsymbol{T},\ k \in \boldsymbol{K},\ l \in \boldsymbol{L} \tag{13}$$

$$\dot{R}_{t,1,l} = 0,\ \dot{R}_{t,k+1,l} = 0 \quad \forall\, t \in \boldsymbol{T},\ l \in \boldsymbol{L} \tag{14}$$

The contribution of this work is on determining the sizing factor of the streams ($f_{s,t}$). In the classical formulation, it is equal to the sizing factor of the unit ($f_{u,t}$) to which the streams belong. However, this must be modified as several streams are created to represent a stream in different locations. Eq. 15 is used instead, to set the sum of the sizing factor of a parent in different locations ($f_{p,l,t}$) to the sizing factor of the unit. Afterward, the stream sizing factors are fixed to the sizing factor of their parents (Eqn. 16).

$$\sum_{l=1}^{\boldsymbol{L}} f_{p,l,t} = f_{u,t} \quad \forall\, p \in P,\ u \in \boldsymbol{U}, t \in \boldsymbol{T} \tag{15}$$

$$f_{p,l,t} = f_{s,t} \quad \forall\, p \in P,\ l \in \boldsymbol{L}, s \in \boldsymbol{SP}, t \in \boldsymbol{T} \tag{16}$$

The descriptions of the parameters and variables used in the MILP formulation are given in Table 1.

Table 1. Description of the parameters and variables (bold) in the MILP formulation

Symbol	Description
$C_{u,t}^{op1}$	Fixed operating cost [€/h]
$C_{u,t}^{op2}$	Variable operating cost [€/h]
t^{op}	Operating time [h]
$\dot{Q}_{s,t,k}$	Heat from/to streams [kW]
$\boldsymbol{y_{u,t}}$	Binary variable to use a unit or not [-]
$\boldsymbol{f_{u,t}}$	Sizing factor of a unit [-]
$\boldsymbol{f_{p,l,t}}$	Sizing factor of a parent in a location [-]
$\boldsymbol{f_{s,t}}$	Sizing factor of a stream [-]
$\boldsymbol{\dot{R}_{t,k}}$	Residual heat in a temperature interval [-]

3. Case study and results

A case study with a single time step and two industrial plants that are 500 m apart from each other in both coordinates is considered (see Figure 1). Currently, both sites operate independently, using their own boilers and steam networks. However, the capacity of the boiler and of the steam network on Site2 can be extended in case the sites share their utility network.

Several scenarios are considered and compared with each other:

- Scenario 0 (s0): Both sites are operated at business as usual state. This scenario forms a basis for comparison with the energy saving solutions;
- Scenario 1 (s1): Heat integration is allowed within the boundaries of each site;
- Scenario 2 (s2): Heat integration is allowed within and between locations, without considering losses;
- Scenario 3 (s3): Heat integration is allowed within and between locations, considering losses for underground pipes. The steam network of Site2 is shared, Site1 does not have additional heating utilities;
- Scenario 4 (s4): Heat integration is allowed within and between locations, considering losses for the pipes above the ground. The steam network of Site2 is shared, Site1 does not have additional heating utilities.

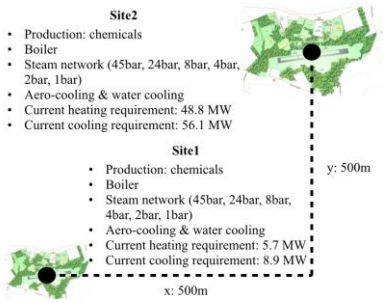

Figure 1. Case study layout

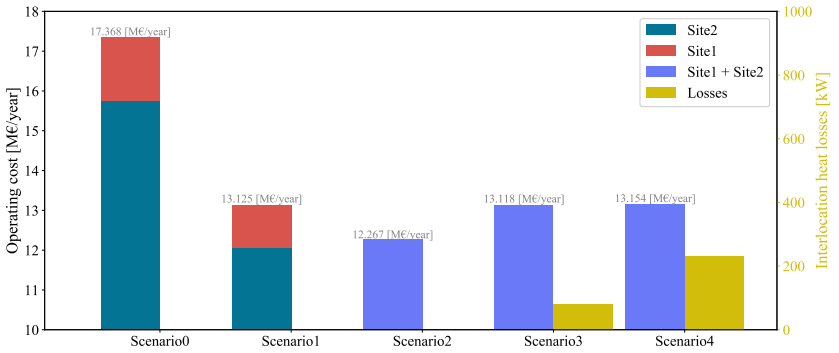

Figure 2. Operating cost and heat losses comparison of scenarios

The introduction of locations results in 10% increase in the number of variables, while a significant change in the solution time is not observed. The results of the case study are depicted in Figure 2. Comparing s0 and s1, when the two sites are optimised internally (i.e. without interplant heat transfer), the total operating cost reduces by 25% due to internal heat recovery on both sites and more efficient use of the steam network. In s2, the overall operating cost reduces by 30% compared to s0, due to heat recovery within and between sites. This scenario, representing the current state of the art in the literature, assumes no heat losses for interplant heat transfer. Hence, it sets the theoretical maximum heat recovery but it is likely to be impractical. In s3 the operating cost is 25% less compared to s0 and slightly less compared to s1. Thus, it is economically beneficial for the sites to use a common steam network with underground pipes. Heat is transferred

using 1 bar and 2 bar steam between sites, which results in 82 kW of heat losses. In s4, the heat losses increase to 232 kW, since the pipes are considered to be above-ground. This scenario yields in an operating cost lower than the business as usual case, but slightly higher than s1. Therefore, it is better to optimise both sites internally, instead of using a common steam network.

4. Conclusions

In this work, a mathematical programming method is proposed to solve heat integration problems with several locations in which interplant heat exchange occurs. While the state of the art either neglects layout issues or considers them only from an economic point of view by accounting for piping cost, the proposed method gives additional insights by considering heat losses due to heat transfer over long distances. The method is applied to a case study with two sites in different locations. The total operating cost of the sites reduces by 30% applying the state of the art methods however the reduction becomes 25% when interplant heat losses are taken into account. While interplant heat transfer is still beneficial when heat distribution pipes are underground, it is not economically attractive when the piping is above the ground. In order to have a better economic analysis, the cost of piping should be included as a post calculation or in the objective function. This will be addressed in future work. The method can be used in heat integration studies to properly consider heat transfer over long distances and therefore obtain more realistic results.

Abstract

Our study evaluates membrane processes to recover helium from natural gas as an alternative to the current cryogenic distillation technologies used in liquefied natural gas (LNG) plants. The process simulations were implemented in Aspen HYSYS v.10 to separate helium >90% purity at a recovery 99% of helium from a feed gas containing 1% He + 98.3% N_2 + 0.7% CH_4, which is a typical gas coming from a N_2 rejection unit (NRU) in an LNG plant. In this study, we designed six four-stage cascade membrane process configurations (cross-flow and counter-current flow pattern used) based on the glassy membranes such as Hyflon AD60X, Polyimide and Polysulfone: Concept-A-1, A-2, B, C-1, C-2 and D. A techno-economic analysis for the process configuration of >90% He purity was conducted using a net present value (*NPV*) method and internal rate of return (*IRR*). Advanced cascade membrane configuration concepts-C-2, C-1 and A-1 show the best performance in terms of upgraded-He production price respectively.

Keywords: Helium recovery, Multi-stage membrane process, Techno-economic analysis

1. Introduction

Membrane-based gas separation process could be complicated when the concentration of the target component in the inlet feed gas is comparatively low such as 0.5-4% helium concentration in the natural gas source (Xiong et al. 2017; Scholes and Ghosh 2017). In that case the membrane can neither achieve high purity permeate nor low-concentrate retentate. At such low feed-concentration, the selectivity and permeability of membranes available in market determine that a single-stage or two-stage membrane cannot produce high helium purity and recovery from natural gas even at a very high inlet pressure and/or over large membrane areas (Alders et al., 2017). The solution is a combination of few-stage membranes, in cascade, parallel or in series to reach higher qualities of permeate and retentate (Scholes and Ghosh 2016). Such arrangements result in higher capital costs (CAPEX) (due to high membrane area) and operation costs (OPEX) (due to high compression costs) making the appropriacy of membrane debatable for such conditions of low concentration feeds. Therefore, selection of the right option will require detailed techno-economical investigations. The success of membrane systems will be very much

dependent on process synthesis, advanced configuration, and design (Scholes et al., 2017).

This paper evaluates cascade membrane processes integrating two different materials in each design concept for helium recovery from natural gas. We introduce six multi-stage cascade membrane process design concepts using combinations of Hyflon AD60X, Polyimide and Polysulfone glassy polymeric membranes that are commercially available. An economic evaluation was completed for each design concept.

2. Approach to performance and cost estimation

2.1. Membrane materials and conditions for the simulation

For the multi-stage hollow-fibre membrane processes simulation, three commercially available glassy polymeric membranes–Hyflon AD60X, Polyimide and Polysulfone, used to produce a He stream with at least 90% purity at a recovery 99 % of helium from natural gas (Table 1). The same N_2 rejection unit (NRU) feed gas composition and parameters were used in all multiple-stage hollow fiber cascade membrane processes. The NRU exit gas conditions are shown in Table 2. NRU off-gas temperature, pressure and flow rate took from BOC Helium Plant, Darwin Australia (Lindemann et al. 2010).

Table 1. Permeabilities of selected glassy membrane materials and He-selectivities over N_2 and CH_4.

Materials	He (Barrer)	CH_4 (Barrer)	N_2 (Barrer)	He/CH_4 selectivity	He/N_2 selectivity	Ref.
Hyflon AD60X	476	3.03	9.46	157.1	50.30	(Macchione et al. 2007)
Polyimide	98.5	0.63	1.27	156	77.5	(Walker and Koros 1991)
Polysulfone	12	0.07	0.09	171	133	(McHattie et al., 1991)

1 barrer = 1×10^{-10} cm^3 (STP) cm cm^{-2} s^{-1} $cmHg^{-1}$

Table 2. Feed gas compositions and conditions of NRU off gas for all multi-stage membrane processes.

NRU-stream Feed Conditions		*Composition*	
Temperature	286 k (12. 85^{0}C)	He	1%
Pressure	120 kPa	N_2	98.3%
Flow arte	876.6 kmol/h	CH_4	0.7%

2.2. Membrane material integration and process combination

Six different membrane processes combination and material integration such as concept-A-1 & A-2, concept-B, concept-C-1 & C-2, and concept-D were designed and simulated. All processes were simulated with a target of 90% helium purity in product stream (peremate4) and fixed 99% recovery from the feed. Another stream output of the whole is retentate1 which is nitrogen-rich stream with small methane composition. All membrane simulations were undertaken in Aspen HYSYS simulation software package (AspenTech, Bedford, MA, USA) V.10 using the Peng-Robinson fluid package. Aspen HYSYS does not have a gas separation membrane process unit, so an in-house programmed module was incorporated into HYSYS. Crossflow, co-current and counter-current flow module pattern with or without sweep gas on the permeate side are

considered in this program in hollow fiber membrane module. Advanced process configurations are summarised in Figure 1 and description in Table 3.

Table 3. Descriptions of advanced multi-stage cascade membrane process design concepts

Design concepts	Descriptions of advanced multi-stage cascade membrane configurations
A-1	Cross-flow: High permeability (P) Polyimide material in module Mem1 & Mem2 + high selectivity (α) Polysulfone material in module Mem3 & Mem4.
A-2	Cross-flow: High permeability (P) Hyflon AD60X material in module Mem1 & Mem2 + high selectivity (α) Polysulfone material in module Mem3 & Mem4.
B	Cross-flow: High selectivity (α) Polysulfone material in module Mem1 & Mem2 + high permeability (P) Polyimide material in module Mem3 & Mem4.
C-1	Counter-current flow: High permeability (P) Polyimide material in module Mem1 & Mem2 + high selectivity (α) Polysulfone material in module Mem3 & Mem4.
C-2	Counter-current flow: High permeability (P) Hyflon AD60X material in module Mem1 & Mem2 + high selectivity (α) Polysulfone material in module Mem3 & Mem4.
D	Counter-current flow: High selectivity (α) Polysulfone material in module Mem1 & Mem2 + high permeability (P) Polyimide material in module Mem3 & Mem4.

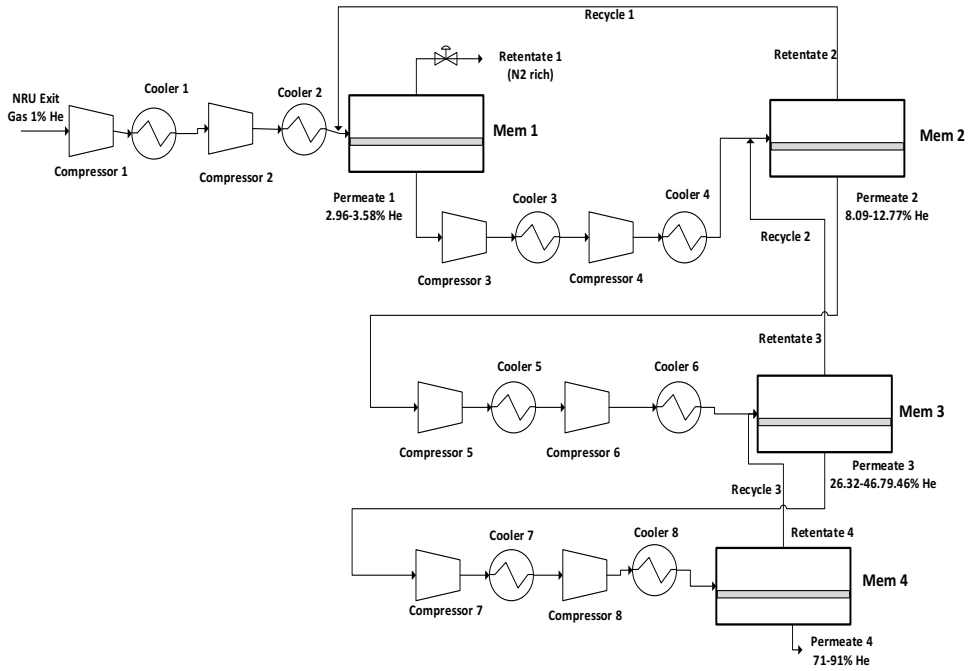

Figure 1. Illustration of four-stage cascade membrane processes with cross-flow and counter-current flow patterns used for Concept-A-1 & A-1, Concept-B, Concept-C-1& C-2 and Concept-D. All simulations are performed to produce >90% He with fixed 99% recovery from 1% He feed concentration at Nitrogen Rejection Unit off-gas.

3. Results and discussions

3.1. Simulation of multi-stage cascade membrane process concepts

Figure 2 (a-c) show the He purity, total membrane area, and compressor power required, in four-stages/cross-flow cascade membrane processes A-1 (Polyimide+ Polysulfone), A-2 (Hyflon AD60X+Polysulfone), and B (Polysulfone+Polyimide). Simulations were performed with a pressure range 19-25 bar to meet the target purity >90% He by fixing 99% recovery from the feed. In terms of permeate He mole fraction concept-A-1 shows better performance rather than concept-A-2 and B. Both design concept-A1 and A-2 ensure minimum required membrane area while concept-B shows less compressor energy conception.

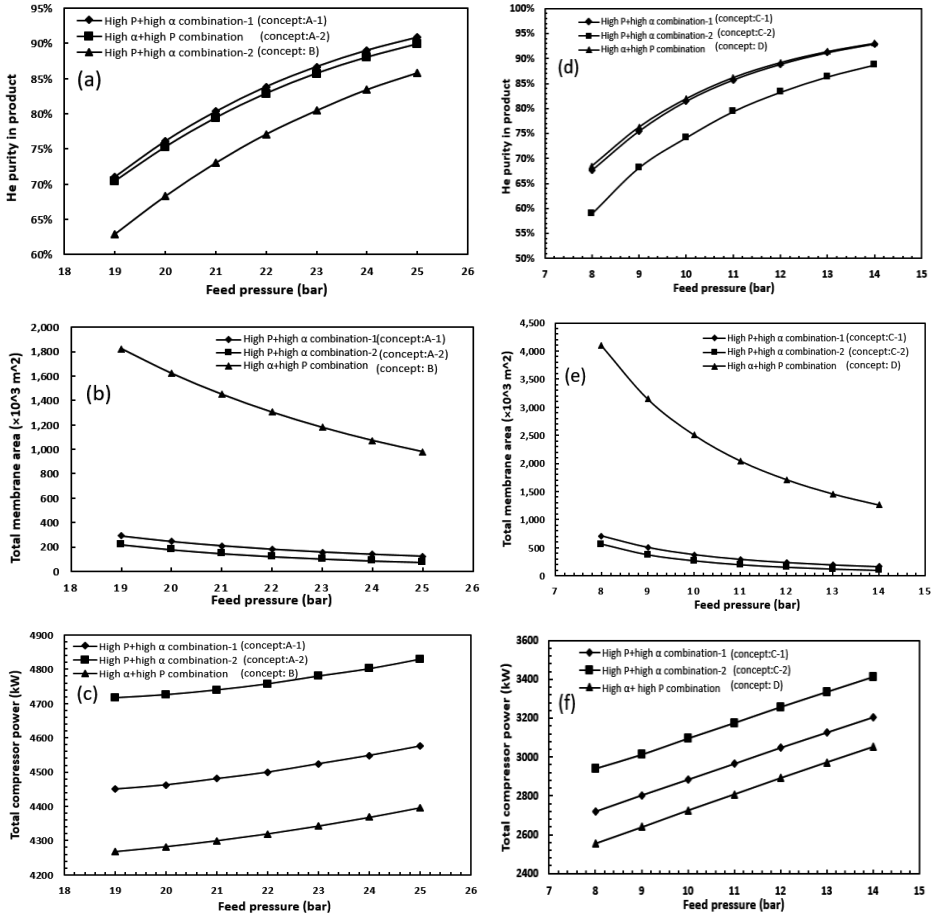

Figure 2. Helium purity in product, total membrane area, and required compressor power consumption in 4-stages/cross flow cascade membrane design concepts-A1, A-2 &-B (a-c),and 4-stages/counter-current flow cascade membrane design concepts-C-1, C-2 &-D (d-f).

On the other hand, Figure 2 (d-f) show results of four-stages/counter-current flow pattern cascade membrane processes C-1 (Polyimide+Polysulfone), C-2 (Hyflon AD60X+Polysulfone), and D (Polysulfone+Polyimide). These simulations were performed with pressure range 8-14 bar to meet the target purity >90% He with 99%

recovery from the feed stream. Cascade membrane design concept-C-1 and concept-D show same purity level against same feed pressure. Concept-D needs much more membrane area then C-1 and C-2 while compressor energy conception for concept-D is less. It was expected that high permeability membrane needs less membrane area and high selective membrane consume less compressor power and give higher purity.

3.2. Economic evaluation of multi-stage membrane processes

Economic analysis of the flowsheet was carried out only for the case that produced >90% He purity with 99% recovery. Techno-economic analysis (TEA) reported here incorporates capital cost estimates with relatively high contingency factors, reflecting a higher risk investment of first-of-a-kind (FOAK) facility. Aspen Process Economic Analyzer (APEA) v.10 was used to develop a conceptual process model for calculating the purchased cost of equipment (PCE) from equipment sizing and costing data. The economic model considered 35% company tax rate, 10% internal rate of return (*IRR*), and 15% project contingency. The total project capital cost was considered to depreciate, via straight-line depreciation method, over the 10 years of the economic life of the facilities. Membrane module cost considered \$50/m^2 for all stages during capital investment and replacement cost considered \$10/m^2 with 5 years membrane lifetime. This skid cost includes the cost of membrane modules, module housings, connecting valves, supporting structure, and instrumentation. The economic model was used to calculate minimum helium production price to reach a breakeven point for a 10% internal rate of return (*IRR*) for all selected design concepts of helium upgrading plant (i.e. >90% purity). The Economic evaluation was undertaken using an *NPV* (Net Present Value) method based on the amount of helium produced (thousand cubic feet, MSCF). The *NPV* calculation does not include high-pressure final compression of helium product to meet transport pressure specification.

Table 4. Helium production price (\$/thousand cubic feet) from natural gas with IRR, NPV value for different design concepts.

Membrane process concepts	**Feed pressure (bar)**	**Purity**	**Recovery**	**Total Power (kW)**	**Total Area (m^2)**	**US. \$/MSCF**	**IRR**	**NPV (US.\$ billions)**
Concept-A-1	25	>90%	99%	4575.8	1.23E+05	9.04	118.89%	2.107
Concept-B	25	>90%	99%	4396.6	9.81E+05	20.16	64.55%	1.984
Concept-C-1	13	>90%	99%	3127.7	1.93E+05	8.89	115.87%	2.109
Concept-C-2	14	>90%	99%	3413.5	9.54E+04	7.72	130.00%	2.122
Concept-D	13	>90%	99%	2972.4	1.46E+06	25.4	53.94%	1.927

Table 4 shows the results of *NPV* value, *IRR* and helium production price (\$/ thousand cubic feet) for selected flowsheets of upgraded helium (>90% purity). It is seen that concept-C-2 have maximum *NPV* of \$ 2.122 billion at 14 bar feed pressure with minimum helium production price \$ 7.72/MSCF. Membrane process design concept-C-1 and concept-A-1 can produce helium with the second (\$8.89/MSCF) and third (\$9.04/MSCF) most low price from natural gas where 1% He feed concentration respectively, which is much lower than current US crude helium (50-70%) auction price \$119.31/MSCF (2018).

Overall, a combination of high permeability membrane in the initial stage and high selective membrane in the last stage shows low cost-optimal and efficient process.

4. Conclusions and Outlook

In this paper, the effect of combined membrane process was evaluated in four-stage cascade hollow fiber membrane process to recover helium from natural gas where 1% helium concertation considered. Hollow fiber membrane module pattern such as cross-flow and counter-current were considered. To separate helium from a mixture of $He+N_2+CH_4$ with minimum 90% purity and 99% recovery, total six different process concepts were designed and simulated by using there different glassy polymeric membranes such as Hyflon AD60X, Polyimide, and Polysulfone. Design concept-C-2, C-1 and A-1 show the best performance for He upgrading respectively. The three-stage membrane process will be evaluated by integrating membrane materials to produce helium product such as crude-He, upgraded-He and A grade-He from feed 1-4% He with different recovery rate in the future.

Design of Flexible Multiperiod Heat Exchanger Networks with Reducing Redundancy in Heat Transfer Areas

Lixia Kang[a], Yongzhong Liu[a*]

[a]*Department of Chemical Engineering, Xi'an Jiaotong University, Xi'an, Shaanxi, 710049, China*
yzliu@mail.xjtu.edu.cn

Abstract

This paper addresses a design procedure for flexible multiperiod heat exchanger network (HEN) with consideration of bounded disturbances in subperiods, aiming to minimize the total annual cost and reducing redundancy of heat transfer areas in the multiperiod HEN. In the proposed procedure, an initial multiperiod HEN is determined by the optimal stream matches and heat transfer area assignment of the HEN in each subperiod, which is then used as the basis for the design of flexible multiperiod HEN after identification of the critical points. The flexibility of the resulting multiperiod HEN is tested by calculating the flexibility index of each subperiod. The application of the proposed procedure is finally verified through a case study of a three-subperiod HEN. The results of this work are compared with those obtained by using the previous methods.

Keywords: multiperiod operation; heat exchanger network; flexible analysis.

1. Introduction

In process industries, stochastic shocks in both external environment and internal operating parameters may cause operational fluctuations in heat exchanger networks (HENs). Under these circumstances, the design of HEN can be achieved by partitioning the recurrent operational conditions into a finite number of subperiods with fixed operational parameters, which is referred as multiperiod HEN optimization problems.

Theoretically, the multiperiod HEN synthesis problem is formulated as a mixed-integer nonlinear programming (MINLP) model that can be solved by either simultaneous methods or sequential ones. Studies on simultaneous methods are mainly focused on the development of the decomposition strategies, such as the Lagrangean approach(Escobar et al., 2014), interval-based frameworks(Isafiade and Fraser, 2010) and the advanced algorithms(Ahmad et al., 2012). However, when the number of subperiods and/or streams in multiperiod HEN increases, these methods become time-consuming due to the complexity of the models and the limitation of the algorithms. Therefore, the MINLP models of multiperiod HEN are usually solved in a stepwise manner, where a promising structure of multiperiod HEN is determined in the synthesis step, and the operational parameters are optimized in the optimization step. Examples of this kind of methods are the simplified model methods where a simplified multiperiod model is built by fixing the promising stream matches that obtained through single period optimization(Kang et al., 2016) or multiperiod optimization(Isafiade et al., 2015), the representative subperiod methods where a representative subperiod is selected

according to the durations of subperiods(Kang et al., 2015) or the temperature profile of streams(Isafiade and Short, 2016), and the time sharing methods where the time sharing mechanism is introduced to assign the heat transfer areas(Jiang and Chang, 2013).

However, the abovementioned methods are mainly developed to meet the operational requirement of multiperiod HEN in nominal conditions. The fluctuations of operational parameters in subperiods are usually ignored. Moreover, the heat transfer areas are conventionally assigned to be the maximum ones required in all subperiods, which causes a remarkable redundancy in heat transfer areas of the multiperiod HENs. To some extent, this redundancy may render the HEN deviating from their optimal operational conditions, leading to unnecessary increases in both the capital cost and operational cost.

To address these problems, a method for design of flexible multiperiod HENs with reducing redundancy in heat transfer areas is proposed, taking the disturbances of parameters in subperiods into consideration. The rest of this paper is organized as follows. In section 2, the problem of the design of flexible multiperiod HEN is stated, followed by the proposed procedure in section 3. A case study for a three-subperiod HEN is adopted to illustrate the application of the proposed method in section 4, and the conclusions are drawn in section 5.

2. Problem statement

There are N_h hot streams and N_c cold streams, spanning N_s subperiods. Given are (1) nominal multiperiod conditions, including the inlet and outlet temperatures, heat capacity flow rates, heat transfer coefficients of all streams in each subperiod; (2) the parameters related to the utilities in each subperiod, such as the types, inlet temperatures, outlet temperatures and annual costs; (3) cost coefficients of heat transfer units, including the fixed cost coefficients, area cost coefficients and area cost exponents etc.; (4) the expected variations of uncertain parameters, mainly the inlet conditions. The main aim of the proposed method is to determine a cost-effective multiperiod HEN with less redundancy of heat transfer area and enough flexibility to accommodate the disturbances during operations.

3. Method for design of flexible multiperiod HENs

Figure 1 shows the proposed procedure for the design of flexible multiperiod HEN. In this procedure, an initial multiperiod HEN is first synthesized and taken as the basis to design the flexible multiperiod HEN. The flexibility of the multiperiod HEN is then tested through the calculation of the flexibility index of each subperiod.

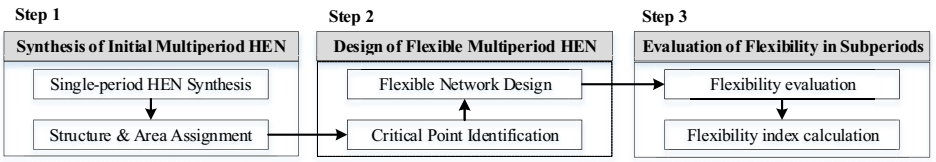

Figure 1 Procedure for design of flexible multiperiod HEN

3.1. Step 1: Synthesis of initial multiperiod HEN

In this step, an initial multiperiod HEN is first determined based on single period HEN synthesis, where the nominal multiperiod parameters are taken as the inputs. For the $p^{\text{-th}}$ subperiod, the outcome of the single period synthesis model is the set of the optimal stream matches $\mathbf{M}_p$, and the corresponding area set $\mathbf{A}_p$. The initial multiperiod HEN is then constructed according to the following rules.

$$\begin{cases} \mathbf{M^I} = \bigcup_{p=1}^{p=N_s} \mathbf{M}_p \\ \mathbf{A^I} = \{a^I \mid a^I = \min(a_p),\ a_p \in \mathbf{A}_p\} \end{cases} \tag{1}$$

It implies that the stream matches in the initial multiperiod HEN is a union of the optimal stream matches in all subperiods, and the minimum areas of heat exchangers in different subperiods are chosen as the initial areas. Note that although the structure determined by eq. (1) ensures the optimal operation of multiperiod HEN, the areas are insufficient to meet the requirement of the multiperiod operation.

3.2. Step 2: Design of flexible multiperiod HEN

Based on the initial stream matches and area assignment, the set of critical points **S**, which restrict the flexibility of the initial multiperiod HEN are identified by solving the model proposed by Novak Pintarič and Kravanja (2015). The Initial areas are then increased to accommodate the disturbances in subperiods by solving the following multi-scenario model.

$$\begin{cases} \min\limits_{d,y,x,\theta} TAC = c^{inv} + \sum_{s\in\mathbf{S}} c_s^{\text{oper}} \\ s.t. h(d_s, y_s, x_s, \theta_s \mid \mathbf{M}^I) = 0 \\ \quad g(d_s, y_s, x_s, \theta_s \mid \mathbf{M}^I) \le 0 \\ \quad g_{\text{A}}(d_s, y_s, x_s, \theta_s \mid \mathbf{M}^I) \le A^I + \Delta A \\ \quad \theta_s = \theta_s^N + \text{sgn}_s\, \delta_s \Delta\theta_s \\ \quad \delta_s = 1, \text{sgn} = \{-1, 1\}, s \in \mathbf{S} \end{cases} \tag{2}$$

where TAC is the total annual cost, consisting of the investment cost, c^{inv} and operating cost, c^{oper}. h and g are equality and inequality constraints. d, x, y and θ stand for design variables, state variables, control variables and uncertain variables, respectively. A^I and ΔA are the initial area and increased area of a stream match included in $\mathbf{M}^{\text{I}}$. θ^N are the nominal values of uncertain variables; sgn represents the direction of deviation from the nominal point towards the critical point either in the negative or positive sides. $\Delta\theta$ are the expected variations of uncertain variables. δ is the flexibility index, where the network is sufficiently flexible to meet the requirements of the expected change range of uncertain parameters when $\delta \geqslant 1$. Note that the flexibility index, in this case, is set to be one, aiming to obtain the least area increase that is just sufficient to meet the requirement of flexibility.

3.3. Step 3: Evaluation of flexibility in subperiods

In this step, the flexibility of the resulting flexible multiperiod HEN is evaluated by solving a flexibility index problem(Swaney and Grossmann 1985).

$$\begin{cases} F = \min\limits_{s} \max\limits_{y,x,\theta} \delta_s \\ s.t. \mathrm{h}(y_s, x_s, \theta_s \mid d) = 0 \\ \mathrm{g}(y_s, x_s, \theta_s \mid d) \le 0 \\ g_A(y_s, x_s, \theta_s \mid d) \le A^I + \Delta A \\ \theta_s = \theta_s^N + \mathrm{sgn}_s \cdot \delta_s \cdot \Delta\theta_s \end{cases} \tag{3}$$

The resulting multiperiod HEN is considered flexibility-qualified when the flexibility indexes in all subperiods are greater than one.

4. Case study

In this section, a three-subperiod HEN, including two hot streams and two cold ones, is employed to illustrate the proposed procedure. To consider the disturbances in subperiods, we assume ±5% disturbances of inlet temperatures and heat capacity flowrates of all streams in this work. In addition, the cost of the heat exchanger is calculated by $5500+4333A^{0.6}$, where a fixed cost efficient of 5500 is added to take the effect of the number of heat exchangers on TAC into account. The rest of the parameters are consistent with those in the literature(Jiang and Chang, 2013).

All the calculations in this work were carried out on GAMS 24.3. ALPHAECP was used as the global solver, and the CPLEX and IPOPTH were used as the MIP and NLP solver, respectively.

4.1. Design of the flexible multiperiod HEN with redundancy control

Table 1 Initial and final assigned heat transfer areas of the multiperiod HEN

Stream matches	Heat transfer areas/m^2			Initial areas/m^2	Additional areas/m^2	Final areas//m^2
	Subperiod 1	Subperiod 2	Subperiod 3			
(1,1,1)	80.9	66.8	3.9	3.9	77.1	81.0
(1,2,2)	102.4	83.2	72.2	72.2	46.0	118.1
(2,1,2)	85.3	264.3	188.1	85.3	171.7	257.0
(2,2,2)	/	14.6	/	0	23.7	23.7
(2,CU,3)	42.2	52.7	59.7	42.2	26.2	68.4
(HU,1,0)	9.6	8.1	14.3	8.1	22.3	30.4
Total	320.5	489.7	338.2	211.8	366.9	578.7

According to the proposed procedure in Figure 1, the single period HEN synthesis model is first solved to determine the optimal stream matches and area assignment of the HEN in each subperiod, as listed in the first four columns in Table 1. Then, the fifth column gives the stream matches and the corresponding areas of the initial multiperiod HEN according to the rules presented in eq. (1). After identifying the critical points, the increased areas and final areas of the multiperiod HEN are obtained by solving the flexible design model in eq. (2), as is given in the last two columns.

Results in Table 1 show that the initial areas of all six heat exchangers need to be increased to accommodate the disturbances in subperiods. Note that, for the stream match (2, 1, 2), the area after expansion (257 m^2) is smaller than the maximum one (264 m^2) obtained by single period synthesis in different subperiods. This indicates that it is necessary to adopt the minimum area of a heat exchanger in different subperiods as the initial area of the multiperiod HEN.

4.2. Discussion on the economic efficiency of flexible multiperiod HENs

To verify the economic-effectiveness of the resulting flexible multiperiod HEN, the flexibility of the multiperiod HENs obtained by the methods in literature are checked and improved to meet the requirement of flexibility in all subperiods by solving the proposed flexible design model presented in eq. (2).

Table 2 Comparison of the results obtained in this work and those obtained by previous methods

Methods	No. of units	Total areas/m^2	Capital cost/$	Operating cost /$ · y^{-1}	Total annual cost /$ · y^{-1}
Representative subperiod method	7	486	380,967	225,253	263,349
Time sharing method	6	602	416,567	176,077	217,733
The proposed method	6	579	407,641	175,865	216,629

Results in Table 2 show that, when the disturbances in subperiods are considered, the multiperiod HEN obtained by the proposed method has the lowest TAC. Although the total areas and capital cost of the multiperiod HEN obtained by the representative subperiod method are less than those obtained by the proposed method, the TAC is 22% higher than the one obtained in this work. Although the time-sharing method is effective for reducing area redundancy and lowering both capital cost and operating cost in multiperiod HEN, the proposed method does get a better result.

4.3. Discussion on the flexibility of multiperiod HEN

Figure 2 shows a comparison of flexibility indexes and area redundancy of the multiperiod HENs obtained in this work and those obtained on the basis of previous methods. Results in Figure 2(a) show that the multiperiod HEN obtained by the proposed method has sufficient flexibility to accommodate the disturbances in subperiods. It has the greatest flexibility in the subperiod 1, followed by the subperiod 3, and features the least flexibility in subperiod 2. Note that this order is exactly the same as that of area redundancy in Figure 2(b). It indicates that the more the area redundancy of the subperiod is, the greater the flexibility of the subperiod will be. Although the flexibility indexes of three subperiods obtained by the time-sharing method are similar to those obtained by the proposed method, the proposed method obtains less area redundancy. In contrast to the results obtained by these two methods, the flexibility indexes of three subperiods obtained by the representative subperiod method are much closer to each other, as well as the redundancy of their heat transfer areas.

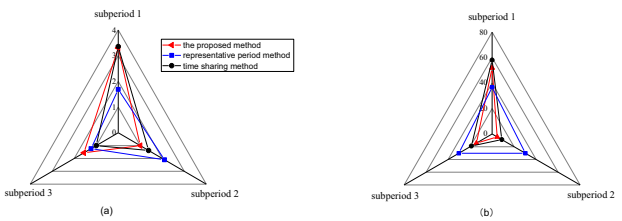

Figure 2 Comparison of results obtained by the proposed method and those in literature
(a) Flexibility index and (b) area redundancy in each subperiod

5. Conclusions

In this work, a stepwise method for the design of flexible multiperiod HEN is proposed, where the disturbances of the parameters in subperiods are considered. In the proposed method, an initial multiperiod HEN is determined on the basis of the single period HEN synthesis. Then, the critical points that restrict the flexibility of the initial multiperiod HEN are identified to finalize the design of the flexible multiperiod HEN by solving a multi-scenario model. The flexibility index of the resulting multiperiod HEN in each subperiod is finally calculated to verify the effectiveness of the proposed method. The results of the case study show that the proposed method can reach a cost-effective multiperiod HEN with sufficient flexibility and less area redundancy.

Abstract

This paper addresses the integration of scheduling of on-line blending and distribution for refinery oil products, which needs to determine simultaneously the blending recipes and the distribution times of oil products in every oil pipeline, satisfying the time-varying demand and product properties specifications for each oil product. We formulate a novel hybrid Mixed-Integer Nonlinear Programming (MINLP) and Generalized Disjunctive Programming (GDP) model for the integrated scheduling problem. Instead of using a general reformulation, we design an improved logic-based Outer-Approximation to solve the hybrid model directly. Numerical experiments demonstrate the usefulness and efficiency of the proposed model and the solution method.

Keywords: On-line blending, scheduling, Mixed Integer Nonlinear Programming, Generalized Disjunctive Programming, Outer Approximation

1. Introduction

The blending and distribution operations are placed at the end of refinery operations, which determine the qualities of oil products and part of production and transportation cost. On-line blending and distribution operation in a refinery is an integrated process, which blends the oil products in pipelines and directly distributes it to customers. Different from traditional off-line blending and distribution operations, on-line blending and distribution needs fewer blending units and storage tanks for different kinds of oil products. Research on the on-line blending and distribution scheduling can optimize the blending recipes, control the qualities of oil products, and reduce the product inventory and market response time.

Pinto et al. (2000) addressed the on-line blending scheduling as a subproblem of the planning in a refinery production. The authors proposed a mathematical model that represents this scheduling problem without consideration of nonlinear blending properties. Jia and Ierapetritou (2003) considered the gasoline blending and distribution scheduling problem, which is off-line blending operation. Xue et al. (2005) proposed a MINLP model for off-line blending problem, which determined the blending recipe through a predicting function for oil product qualities. Li et al. (2005) presented a nonlinear blending functions for components and oil products. Méndez et al. (2006) considered the off-line batch blending scheduling problem with varying blending recipes. Kelly et al. (2014) proposed a new method to optimize both the component

distillation curve and the blending recipes using monotonic interpolation. We can notice that most of the previous work focused on the blending operations including nonlinear blending functions, but few aimed at the integration of on-line blending and distribution.

In this work, we define the on-line blending and scheduling problem with consideration of nonlinear blending operation and distribution in oil product pipelines described in Section 2. We formulate a hybrid MINLP and GDP model to descripe the problem in Section 3. In order to solve the proposed model, we design a logic-based Outer Approximation (OA) algorithm in Section 4. Section 5 presents some numerical experiments, to show the validity of the model and efficiency of the solution method. Finally we give a conclusion for this work.

2. Problem description

The refinery on-line blending and distribution process is shown in Fig. 1.

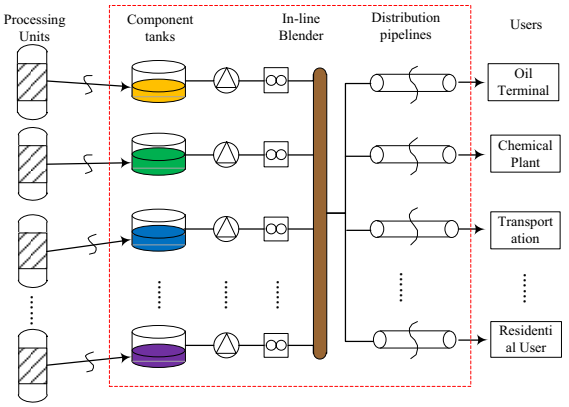

Fig. 1 Illustration of on-line blending and distribution process in a refinery

All kinds of component oils are produced from refinery units and stored respectively in the component tanks. Through pumps and valves, different kinds of component oils are injected into the in-line blender. After the blending operation, the oil products are transported into the long-distance oil product pipelines, which are connected with terminal users of the refinery. We consider the standing times in in-line blender negligible. The consistency for the pipelines is considered, which is once the blending operations happen, that they continue until the end of scheduling horizon.

The model presented here receives as parameters:

1) Scheduling horizon H; 2) Set of component oils, supplying capacity, initial inventory quantity, properties; 3) Set of pipelines, transportation capacity; 4) Set of oil product, demand quantity in each pipeline, properties standard; 5) Parameters of blending operations, bounds of blending ratios for components to each oil products; 6) Operations constraints; and 7) Set of cost, component oil cost, pumping cost, changeover of different oil products in pipelines.

Using these parameters, it determines:

1) Blending recipes for each oil product in every pipeline; 2) Properties of oil product in every pipeline; 3) Inventory quantity of each component oil during each time periods; and 4) Distribution time of each oil product in pipelines. The objective function is to minimize the total cost, which includes the cost of blended components, blending operations, changeover of oil products in pipelines and penalties for extra qualities of oil products.

3. Mathematical Formulation

The discrete-time representation is adopted in the following mathematical formulation. We use the following indices: i to refer to a blending component, j as an oil product pipeline, p as oil product and t as discrete time point. The objective function of the on-line blending and scheduling problem is to minimize the total cost, as Eq. (1).

$$\min Z = \sum_{i,j,p,t} \left(\left(C_i + CP_i\right) \cdot FI_{ijpt} + CN_i \cdot V_{it} + CL_p^{ON} \cdot (OL_{jpt} - ON_p^L) + \sum_{p'} CH_{pp'} \cdot w_{jpp'} \right) \tag{1}$$

Here, C_i is the unit cost of component i, CP_i is the cost of pumping operation for component i, FI_{ijpt} is the flow rate of component i to blend oil product p in pipeline j at time t, CN_i is the unit inventory cost of component i, V_{it} is inventory quantity of component oil i in time t, CL_p^{ON} is the penalty for the extra Octane number of oil product p, OL_{jpt} is the variable for Octane number of oil product p in pipeline j at time t and ON_p^L is the lower bounds of the Octane number for oil product p, $CH_{pp'}$ is the changeover cost between oil products in pipelines, $w_{jpp'}$ is the binary variable whether exits a changeover from p to p' in pipeline j.

The mass balance equations of component tanks are considered with general inventory constraints. The inventory quantity must be within the limiting ranges. The upper bound of component inventory is storage capacity. The lower bound is the requirement of blending operation, which is used to ensure the constant component properties.

For oil pipelines, the flow rate of one oil product is the total of the injected components. The ratio relationship between the amount of components and oil product is the blending recipe. The properties of oil products, like Octane number, Sulphur content and RVP, are calculated based on nonlinear blending functions (Alhajri and Elkamel, 2008), which should satisfy the national standard criterions for each kind of oil product. The demand quantity of all kinds of oil product in each pipeline must be satisfied.

The time constraints include the starting and ending times of blending oil product p in pipeline j. The starting blending time must be prior to the ending time. Once an oil product is beginning to blended, which must be ended on the horizon.

The disjunctive constraint is introduced as Eq. (2). X_{jpt} is the boolean variable, which is true when blended oil product p in pipeline j at time point t. The blending ratio R_{ijpt}, the component flow FI_{ijpt} and the flow of oil product FL_{jpt} should be within proper ranges, given by their bounds. And the properties of blended oil product, like Octane number, sulfur content and RVP for gasoline, must satisfy the quality standards. If X_{jpt} is false, all the left variables are equal to zero.

$$\begin{bmatrix} X_{jpt} \\ \sum_i R_{ijpt} = 1, R_{ip}^L \le R_{ijpt} \le R_{ip}^U \\ L_j^L \le FL_{jpt} \le L_j^U \\ R_{ip}^L \cdot L_j^L \le FI_{ijpt} \le R_{ip}^U \cdot L_j^U \\ ON_p^L \le ON_{jpt}, SL_{jpt} \le S_p^U, RL_{jpt} \le RVP_p^U \end{bmatrix} \vee \begin{bmatrix} \neg X_{jpt} \\ R_{ijpt} = 0, FI_{ijpt} = 0 \\ FL_{jpt} = 0 \\ ON_{jpt} = 0 \\ SL_{jpt} = 0 \\ RL_{jpt} = 0 \end{bmatrix} \quad \forall j, p, t \tag{2}$$

The Eq. (3) is the logic proposition, which means there is only one oil product being blended in one time period, or the pipeline is idle.

$$\left(\vee_p X_{jpt} \right) \vee X_{jt}^{Free} \quad \forall j, t \tag{3}$$

Here the boolean variable X_{jt}^{Free} is true if the pipeline j at time t is idle.The constraints of operation rule include that there is only one blending operation per oil product in a pipeline if there is demand for it in this pipeline.

For the logic variable X_{jpt}, we also define responding binary variable x_{jpt} to formulate the assignment constraints. The relationships between the assignment variables and changeover variables are presented with algebraic equations. The unique sequence constraints and the number of changeovers are also included in the presented formulation.

The proposed mathematical model is a hybrid MINLP and GDP model with nonconvex nonlinear functions, such as the blending equations and the octane number functions.

4. Solution method of Logic-based OA

Based on the structure of the proposed model for the on-line blending scheduling of oil products, we design a logic-based OA solution method, which solves the proposed model directly without transforming it into an MINLP problem. Making use of the logic relationships behind the formulation can derive tighter bounds (Turkay&Grossmann, 1996).

The presented logic-based OA is also decomposition methods, which divides the hybrid model into a MILP master problem and a NLP subproblem. The NLP subproblems are obtained by fixing integer and logic variables. When the NLP subproblem is feasible, we get an upper bound of the original minimization problem. The master problems are constructed with gradient based linearization generated at the NLP solutions for the nonlinear constraints (OA cuts) and the convex hull reformulation for the constraints in disjunctive terms. The solution of the master problem is a local lower bound of the original problem, given that it is a relaxation of the original problem. Iterating the NLP subproblem and MILP master problem, we can continuously decrease the gap between lower and upper bounds given by their solutions and terminate the solution process when the gap is within a tolerance, or the MILP problem becomes infeasible. The procedure of the logic-based OA methods is as follows.

Step1. Design a heuristic to obtain few initial scheduling solutions of oil-product in the pipelines, which satisfies the end demands for oil products.

Repeat.

Step2. Construct the NLP subproblems by fixing the assignment and logic variables in the scheduling solutions.

Step3. Solve the NLPs, where feasible or unfeasible solutions of the original problem can be obtained. The upper bound of the original problem is updated with the minimal objective value among all feasible NLP subproblems.

Step4. Based on the solutions of NLPs, we construct the master problem with OA linearization cuts for nonlinear equations and convex hull reformulation constraints for disjunctive terms.

Step5. Solve the constructed master MILP problem, which provides a lower bound, and simultaneously obtaine a new solution for the integer, logic variables.

Until the termination conditions are satisfied.

The heuristic for generating the initial distribution scheduling is sequencing the demanding oil products in each pipeline at once. Here the changeovers of oil products are not considered in the initial step.

5. Numerical experiments

Our proposed solution method is implemented and used to solve three study cases. The network includes 5 components, 2-4 pipelines, 2 kinds of oil products. The range of scheduling horizon varies from 5 to 10 hours, and 3 kind of properties of oil product are considerated (Pinto et al., 2000).

The implementation is made in GAMS 23.7 (Bussieck&Meeraus, 2004) and solved using a desktop running Windows 10, with Intel Core 2 Duo processor, CPU 3.3 GHz and RAM 4.00 GB. The NLP solver is CONOPT3.14, and MILP solver is CPLEX12.3.

The computational results of the three cases are compared against LOGMIP2.0 solver (Vecchietti&Grossmann, 1999). Here the big-M reformulation is used in LOGMIP. For the MINLP model of LOGMIP, the numbers of binary variables in three cases are 88, 148, 176, the numbers of continuous variables are 618, 1108, 1170, the number of constraints are 1106, 1981, 2060. The solution iterations of LOGMIP are 4, 5, 4, and CPU solution times are 3.9, 8.9, 8.6 seconds. The problem size of our proposed hybrid model includes the numbers of boolean variables 24, 44, 48, integer variables 64, 104, 128, disjuntive term constrains 24, 44, 48. We construct 2 initial boolean and integer solutions to generate 2 NLP sublproblems. The solution iterations of our logic-based OA is 1, 1, 3, and CPU solution times changes from 1.5, 7.7, 4.5 seconds. For the same case, two solution methods obtain the same optimal solution. Our proposed method needs fewer iterations and shorter CPU time than LOGMIP solver. The reason is that we directly solve the proposed model otherwise solve the big-M reformulation as LOGMIP solver.

The optimal scheduling solution for case 3 and the optimization blending recipes for $97^{\#}$ gasoline is shown in Fig. 2. The Octane Numbers of the blended gasoline $97^{\#}$ are 97.207, which is close to the criteria value and the sulphur content of gasoline $97^{\#}$ is 28.383 ppm, which is near half of the criteria value 50. Our proposed method provides a optimization scheduling and blending recipes simultaneously for on-line blending and distribution process.

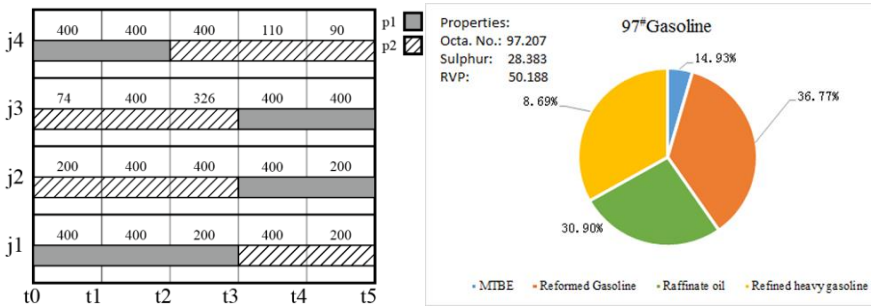

Fig. 2. Scheduling results of case 3 and blending recipe for one oil product

6. Conclusions

In this paper, we discussed an integrated scheduling for on-line blending and distribution problem with simultaneous consideration of blending recipes and distribution schedule. Based on discrete-time representation, a hybrid MINLP and GDP model is formulated. We also designed a logic-based OA method to solve the proposed model. Using some numerical experiments, a comparison with the LOGMIP solver demonstrates the usefulness and efficiency of the proposed model and solution method.

Abstract

Emission reduction becomes increasingly important for petroleum refineries nowadays as more environmental concerns and stringent regulations have been posted. Cost-effective solution strategies require emission reductions to be addressed from the entire plant point of view, where emission source generation and utilization should be well balanced. In this paper, a new methodology framework and a general plant-wide scheduling model have been developed for emission-conscious crude unloading, transferring, and processing (ECUTP) operations, which couple generic production activities and characterizations of major air emissions from refineries, such as CO_2, VOCs, NO_X, and PM. The efficacy of the proposed ECUTP scheduling model has been demonstrated by a large-scale case study.

Keywords: Refinery processing, production scheduling, MINLP, optimization.

1. Introduction

Scheduling of front-end crude supply and refinery operations is an important part of petroleum supply-chain management. Emissions from refineries are significant and the emission reduction is a very challenging task. It involves a large-scale complex manufacturing system, which consists of over 17 major facilities with more than 85 main operation units, and thousands of streams. Due to the increasingly strict economic competitions and environmental regulations, refineries in one hand are eager to improve production solutions to leverage profitability margins in nowadays volatile market; on the other hand, they have to pursue cost-effective pollution prevention technologies to comply with more stringent environmental mandates, such as air emission requirements.

Cost-effective solution strategies require emission reductions to be addressed from the entire plant point of view. Mendez et al. presented a simultaneous optimization approach for blending and scheduling of refinery plant (Méndez et al. 2006). Meanwhile, Pinto et al. presented a general modelling framework for petroleum supply chain optimization (Neiro and Pinto, 2004). Very recently, Xu et al. simultaneously optimized crude unloading, transferring, and processing (CUTP) operations (Xu et al. 2017a). It should be highlighted that plant-wide scheduling model with emission characterization is still lacking based on our conducted literature survey.

In this paper, a new methodology framework and a general plant-wide scheduling model have been developed for emission-conscious CUTP (ECUTP) operations. Major

emissions from refineries: such as CO_2, volatile organic compounds (VOCs), nitrogen oxides (NO_X), and particulate matters (PM) are characterized and quantified. The scheduling model is a large-scale mixed integer nonlinear programming (MINLP) problem. The efficacy of the proposed model has been demonstrated by a case study.

2. Methodology framework

The methodology starts with collecting economic, process, and initial operating data. Since this paper addresses emission characterization from the system point of view to optimally balance the emission source generation and utilization, the emission conscious plant-wide scheduling model is the major focus. Based on the collected data, a continuous time CUTP scheduling model will be developed. Then, to address the profit maximization and air emissions simultaneously, the emission characterization formulas should be coupled, which help generate emission conscious CUTP scheduling model, called ECUTP scheduling model. The model will be solved with OA based decomposition method (Duran and Grossmann, 1986) and comprehensive analysis based on the scheduling results will be conducted.

3. Emission characterized CUTP scheduling model

The whole scheduling model contains two main sections: (i) a front-end crude oil transfer model, which covers crude movement from vessels to portside storage tanks, inland charging tanks, and refinery CDUs; (ii) a refinery crude processing model, which addresses the detailed processing strategy based on the given input of crude blends. Since the integrated crude scheduling model is very complicated, including more than 200 equations, for conciseness, only emission characterization equations are elaborated in the following section. The detailed CUTP model is based on the previous paper (Xu et al. 2017a) with modest modifications.

A typical refinery process includes crude distillation, cracking, coking, reforming, hydrotreating, product blending, gas processing, and sulfur recovering facilities. To address air emission reductions in a refinery, spatial emission allocations in the plant need to be first identified. Then, emission species at each allocation and their emission quantities under process operating conditions have to be identified.

Emission from heating furnaces and processing units. Most refinery facilities employ furnaces for heating inflow streams. When fuel gas or heavy oil utilities are burned, a large quantity of air emissions will be generated, such as CO_2, VOCs, NO_X, and PM. Emissions may come from two types of processing facility:(i) The hydrogen plant generates high-purity hydrogen for hydrocracking and hydrotreating facilities. (ii) In the FCC unit, coke is generated and deposited on the catalyst surface. It has to be burnt immediately in a catalyst regenerator to recover catalyst functionality. This burning process will generate large amounts of waste gas containing CO_2, VOCs, NO_X, and PM.

Emission from flaring system and crudes storage and transport. Flaring system is designed to burn out waste gas under normal conditions, or large amounts of off-spec product stream for air pollution mitigation. In this study, we only consider normal operation conditions of refineries. We could expect the flaring emission amount is near zero based on optimized scheduling solutions. And the storage and transport of crudes produce emissions of VOCs and toxic air pollutants. Most VOC emissions from upstream processes may be from evaporation of storage tanks, hoses, and vehicles; equipment leakage; as well as wastewater treatment systems.

Table 1. Emission characterization under various sources

Emission Source	Main Emission Species	Emission Factor from Literature (lb/1,000 barrels)	Emission Factor (T/kT)
Dry gas	CO_2	---	2864.79
	VOCs	5.8	1.25269
	NOx	140	30.2372
	PM	3	0.64794
LPG	CO_2	---	3014.20
	VOCs	6.5	1.40387
	NOx	150	32.397
	PM	3.5	0.75593
Fuel oil	CO_2	---	3233.13
	VOCs	1.28	0.16763
	NOx	55	7.20265
	PM	7	0.91670
Burning coke	CO_2	---	3655.62
	VOCs	N/A	N/A
	NOx	71	9.50574
	PM	45	6.02476
Crude Oil	CO_2	N/A	N/A
	VOCs	12.12	0.042
	NOx	N/A	N/A
	PM	N/A	N/A

Overall, major emission sources under normal operation conditions include dry gas, LPG, fuel oil, burning coke and evaporation of crude oil. As reported, every emission source would have some emission factor, which can characterize its emission distribution with respect to per unit weight of the emission source (Kassinis, 1998).

Table 1 has summarized the emission characterizations under various emission sources. The unit of the original formulas is lb/1,000 barrels, which should be transferred to SI unit as T/kT. The transfer transformation is:

$$\phi_{SI} = \phi_{EN} \frac{0.45359 \times 10^{-3}}{1000 \times 0.15899 \times 10^{-6} \rho} \tag{1}$$

where ϕ_{SI} is the emission factor in SI unit as T/kT, ϕ_{EN} is the emission factor in lb/1,000 barrels. 0.45359×10^{-3} is the conversion factor from pound to ton. 0.15899 is the conversion factor from barrel to m^3. ρ is the density of emission source, and the unit of ρ is kg/m^3. The transferred emission factors are listed in the 4th column in Table 1.

It should be noted that the CO_2 emission is estimated through mass balance. Since CO_2 comes from burning of hydrocarbon (C_xH_y), the general reaction formula is:

$$C_xH_y + (x + \frac{y}{4})O_2 = xCO_2 + \frac{y}{2}H_2O \tag{2}$$

Meanwhile, a part of hydrocarbon will be transferred to VOCs or PM. The left amount is assumed to be totally transformed to CO_2. To calculate the CO_2 emission, the average

molecular weights of all emission sources, VOCs, and PM should be known. They can be estimated based on the plant data. Thus, the CO_2 emission factor can be obtained as:

$$\phi_{SI,\mathrm{CO}_2} = 1000\frac{44x}{12x+y} - \phi_{SI,VOCs}\frac{44x_{VOCs}}{12x_{VOCs}+y_{VOCs}} - \phi_{SI,PM}\frac{44x_{PM}}{12x_{PM}+y_{PM}} \tag{3}$$

where ϕ_{SI,CO_2} is the emission factor of CO_2 in SI unit as T/kT. $\phi_{SI,VOCs}$ and $\phi_{SI,PM}$ are emission factors of VOCs and PM in SI unit. The x and y values are based on the average molecular formula of C and H of different emission sources, VOCs and PM. In summary, the listed emission factors in Table 1 will be used to characterize various emissions in the ECUTP scheduling model. For every concerned emission species, m, the final emission amount is the summation of every stream containing m. It is formulated as:

$$FE^m = \sum_t \sum_{v\in V_{uo}} \sum_{s\in S_{v,uo}} \left(F_{v,s,uo,t}\ \phi^m_{v,s,uo}\right),\ \forall\, m \in ME \tag{4}$$

where FE^m is the amount of emission species m. $F_{v,s,uo,t}$ is the flowrate of emission source, and $\phi^m_{v,s,uo}$ is the emission factor.

The objective function of the ECUTP model is to maximize total process profit, which is defined in Eq.(5). It contains three main items. The first summation item represents the total refinery revenue, which includes plant product sale income and utility sale income. The second one represents the front-end crude operational cost. The third one is the total refinery cost, which includes feedstock costs, utility costs, and inventory costs.

$$\begin{aligned}\max Profit = &\sum_n \left(Sale\_PO_n + Sale\_UO_n\right) - \sum_n \left(Cost\_OP_n\right) \\ &- \sum_n \left(Cost\_FD_n + Cost\_UD_n + \sum_{u\in UINV} \Delta IV_{u,n}\right)\end{aligned} \tag{5}$$

4. Case study

4.1. Given data

The problem consists of three single-parcel vessels, one single docking berth, four storage tanks (ST), four charging tanks (CT), and a refinery plant starting from two CDUs. The refinery process includes crude distillation, cracking, coking, reforming, hydrotreating, gas processing, product blending, and component recovery. The specified scheduling time horizon is 15 days. For simplicity, the crude unloading and transferring data, crude property data, refinery product specifications, and economic data of the studied case are the same as those in the previous study (Xu et al. 2017a), and they have been provided by Tables 1-4 from that paper. Meanwhile, the detailed crude transfer network and schematic diagram of the studied refinery plant have also been provided by Figures 3 and 4 from that paper.

The whole scheduling problem is developed and solved in GAMS v24.8.3 on an Intel 3.6 GHz Windows PC with 12.0 GB memory. It is a mixed integer nonlinear programming (MINLP) problem. The nonlinearity mainly comes from crude oil and refinery product blending sections. We use DICOPT (CPLEX for the MIP subproblem and BARON for the NLP subproblem) as a solver to solve the MINLP problem.

4.2. Results of front-end crude scheduling

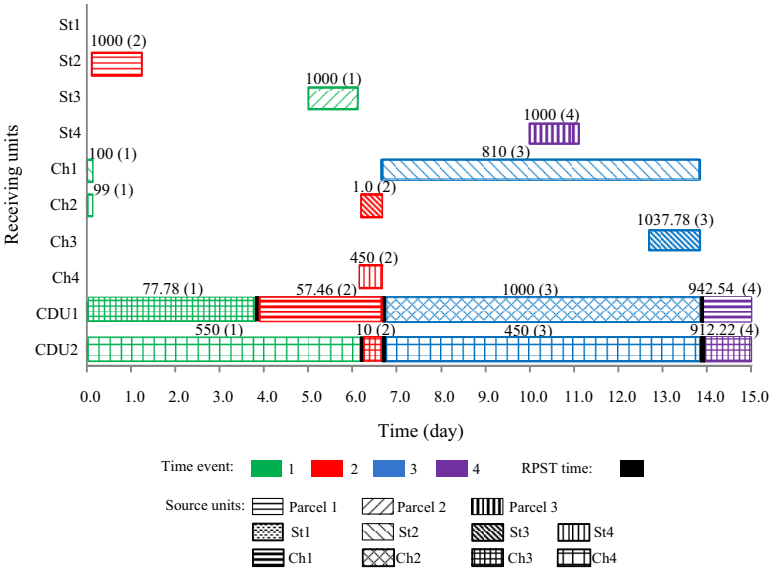

Figure 1. Front-end crude transfer scheduling results.

The optimal Gantt chart of front-end scheduling result for the ECUTP scheduling model is presented in Figure 1. As shown, the scheduling time is adopted as the horizontal axis, and crude "receiving units" are adopted as the vertical axis. The numbers close to the schedule bars represent the total volumes (Mbbl) transferred, while the number in parentheses denotes specific time events when particular operations occur. Here, various filling patterns indicate the source units of crude transfers. Overall, four time events are adopted for the ECUTP scheduling case. Small solid black schedule bars represent the RPST time (Xu et al. 2017b). It can be seen that two refinery CDUs have utilized all four time events, and they are continuously operated during the entire scheduling time horizon. RPST time is located where a crude changeover does occur.

4.3. Results of refinery processing

The refinery products include diesel, gasoline, petroleum coke, kerosene, utility fuel gas, liquefied petroleum gas, benzene, utility fuel oil, and naphtha etc. Diesel and gasoline are the main products of this refinery compared to others. Table 2 gives economic performance based on optimal scheduling results. Based on the proposed ECUTP methodology, the optimal solution gives the maximum total gross profit of \$104,844 K. In comparison, ratios of the gross profit, total net utility income, and crude purchasing cost over the total revenue are 33.16 %, 1.32 %, and 65.19 %, respectively. This matches the reality that the major expenditure of a refinery is for crude purchasing.

Table 2. Economic performance based on optimal scheduling results

Crude Oil Buy(k$)	206,094	Profit(k$)	104,844
Product Sell(k$)	316,152	Profit/Sell	33.16%
Operation Cost(k$)	5,214	Utility/Sell	1.32%
Front-end Operation Cost(k$)	1,059	Crude/Sell	65.19%

4.4. Emission results analysis

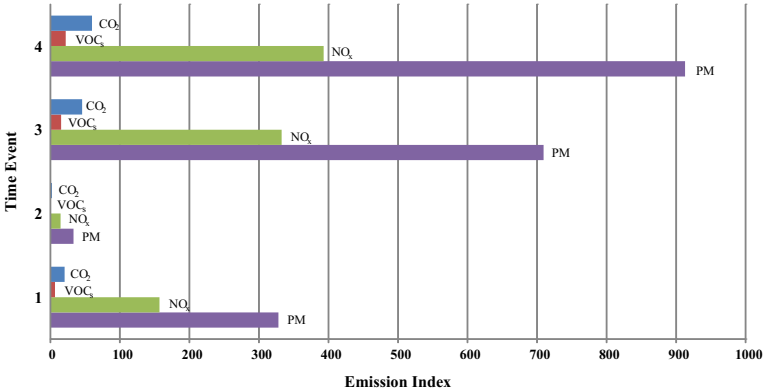

Figure 2. Refinery emission results

The refinery emission results are shown in Figure 2, where CO_2, VOCs, NO_X and PM emissions under current plant design and operations are shown, respectively. Note that the unit of CO_2 index is t while others are kg. It is understandable since the emission of CO_2 should be way more than other emissions.

5. Conclusions

In this paper, a systematic methodology has been developed for emission conscious crude unloading, transferring, and processing (ECUTP) system to achieve profit maximization. Compared to recent studies, the major contribution of this paper is that characterization and quantification of major air emissions from refineries are coupled with the model. The efficacy of the model has been demonstrated by a large-scale case study. As for our future work, we will propose a concept called profitable emission reduction (PER). Since the plant profit and emission can be quantitatively evaluated, alternative plant design and operations for PER opportunities might be raised.

Abstract

This paper expands the Resource-Task Network (RTN) scheduling formulation to allow tasks to be interrupted when encountering a planned break period in production. The benefit from a more flexible mode of operation, is the improvement of overall equipment efficiency. This is illustrated by solving a benchmark problem from the literature. To address one of the major limitations of discrete-time approaches, we revisit solution strategies for the objective of makespan minimization, before proposing a method to reduce the number of iterations in the search for the optimal solution.

Keywords: Optimization; Mixed-integer linear programming; Algorithms.

1. Introduction

Enterprise-wide optimization (Grossmann, 2005) aims to simultaneously account for key performance indicators across multiple business units by looking into the integration of supply chain management, production control, planning and scheduling. To accomplish this goal, we need to be able to transfer data and information efficiently between different industrial production management systems. The ISA-95 standard can act as a data-exchange platform for production scheduling (Harjunkoski and Bauer, 2014) but it needs to be linked to a scheduling formulation that can cope with the wide variety of features that may be encountered at a process plant.

The most general scheduling formulations, based on unified frameworks for process representation (State-Task and Resource-Task Network), lack the possibility of processing tasks to be interrupted. Yet, preemption is often encountered in daily practice, with the ISA-95 input including planned break periods (e.g., due to preventive maintenance, weekends), number of stops allowed per task, minimum duration of each active partial task and possible penalties for interrupting a task.

Models that allow for preemption exist in the context of project scheduling. For instance, van Peteghem and Vanhoucke (2010) assume that an activity with discrete duration τ can be interrupted up to τ times, with the time(s) of interruption being determined by a genetic algorithm. In this paper, we consider a more constrained for of preemption, where tasks can be interrupted at given points in time, provided that they continue immediately after. We focus on the RTN discrete-time formulation (Pantelides, 1994), which is known to be very tight and better than continuous-time formulations at handling discrete events (Harjunkoski et al. 2014). Interestingly, the required changes occur at the level of the structural parameters and excess resource balance constraints, with the model variables

remaining the same. It is straightforward to extend a STN discrete-time formulation (Kondili et al., 1993; Lee and Maravelias, 2017) to handle preemption in a similar way.

2. Preemptive vs. non-preemptive scheduling

Non-preemptive scheduling is the standard mode of operation in PSE models, see Figure 1. Given a break period br occurring in time window $[b_{br}^{L}, b_{br}^{U}]$, task i can either be completely executed before the start of the break or start after the end of the break. In the context of a continuous-time model (Castro et al. 2014a), it can be formulated as an exclusive disjunction featuring starting variable Ts_i and duration parameter p_i. When using a discrete-time model, break periods help to reduce model size by restricting the domain of task extent 0-1 variables $N_{i,t}$. In the example in Figure 2, the break lasts for 5 time intervals, including slots $\{9, \ldots, 13\}$ (in red). Noting that durations p_i in minutes or hours are rounded up to multiples of δ (parameter specifying the length of every slot in the uniform grid), $\tau_i = \lceil p_i/\delta \rceil$, since the task lasts 5 slots (in grey), it can only start between slots 1 ($N_{i,1} = 1$) and 4 ($N_{i,4} = 1$), if the plan is to end before the break, or at slot 14, if started after the break, i.e. $T_i \in \{1, \ldots, 4, 14\}$.

The goal of preemptive scheduling is to reduce idle times by allowing part of the task to be executed before the break and part after the break, see middle of Figure 3. Since the location of break periods is known a priori, one can easily determine the duration of a task $\bar{\tau}_{i,t}$ as a function of its starting point t. In the alternatives illustrated in Figure 3, the duration of the task changes between 5 (non-preemption duration), 10 (one interruption) and 12 (two breaks). The domain of the task is thus wider when allowing for preemption.

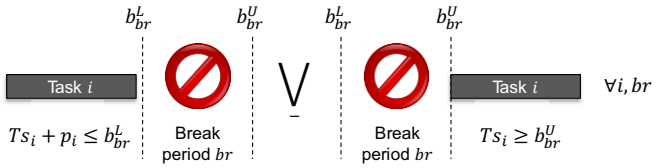

Figure 1. In non-preemptive scheduling, a task can either end-before or start-after a break.

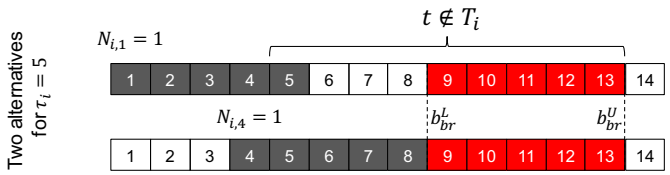

Figure 2. In non-preemptive scheduling, break periods allow reducing domain of processing tasks.

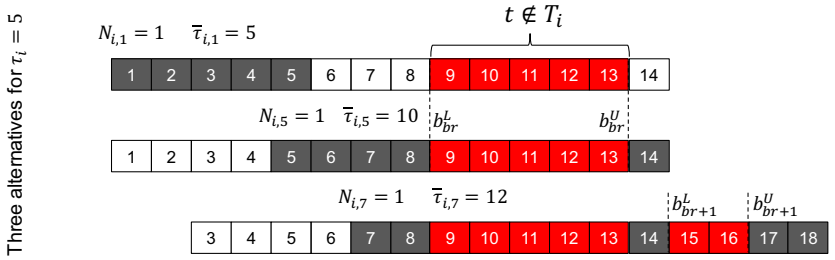

Figure 3. In preemptive scheduling, a task can be split over multiple periods.

3. New RTN discrete-time formulation

The remaining changes needed to extend the RTN discrete-time model to handle preemptive tasks occur at the level of the structural parameters and excess resource balances. Representing $\mu_{r,i,\theta}$ the amount of resource r consumed (-) or produced (+) by non-preemptive task i at a time θ relative to the start of the task, its preemptive counterpart $\bar{\mu}_{r,i,t,\theta}$ gains one index to identify the starting interval t. With the new structural parameters, resource consumption during task interruption can differ from normal execution. An example would be a residual energy consumption to compensate for heat losses during the break, which in our illustrative case study was set to 5%.

Considering that non-preemptive tasks are a special case, we simply need to make $\bar{\tau}_{i,t} = \tau_i \; \forall t \in T_i$, the excess resource balances of the new RTN formulation are given by Eq. (1). It features non-negative excess resource variables $R_{r,t}$ and parameters $\pi_{r,t}$, which account for the interaction with system boundaries (e.g. electricity purchase). Note that Eq. (1) is all that is needed to model preemption.

$$R_{r,t} = R_r^0|_{t=1} + R_{r,t-1} + \pi_{r,t} + \sum_{i'} \sum_{0 \le \theta \le \bar{\tau}_{i,t}: t-\theta \in T_i} \bar{\mu}_{r,i,t-\theta,\theta} N_{i,t-\theta} \; \forall r, t \tag{1}$$

4. Alternatives to minimizing makespan

Makespan minimization is perhaps the most difficult objective function in scheduling because it leads to poor linear programming (LP) relaxations of the mixed-integer linear programming (MILP) models. This is true for both discrete- and continuous-time formulations but it is more noticeable in the former for two reasons: (i) discrete-time formulations are very tight for cost-based objective functions (integrality gap very close to zero); (ii) problem sizes can be orders of magnitude larger, meaning more nodes to explore in the branch-and-bound tree, which is often translated into a poor computational performance. It is thus worth to revisit the alternatives for makespan minimization and evaluate their performance in the new preemptive tasks environment.

4.1. Most popular (option 1)

Makespan (MS) is defined as the maximum finishing time Tf_i over all tasks i, see Eq. (2). Assuming that all tasks are executed at most once during the time horizon, it can be expressed as a function of binary variables $N_{i,t}$ and parameters ft_t that define the position of slot t in minutes or hours. The standard way to minimize makespan is then to consider the linearization of the maximum function, Eq. (3). In cases where multiple instances of a task can be executed over the time horizon, one just needs to move index t from the domain of the summation in Eq. (3) to the inequality domain. Note that in a sequential facility, it suffices to include the subset of tasks linked to the last processing stage.

$$MS = \max_i Tf_i = \max_i (Ts_i + p_i) = \max_i (\textstyle\sum_t N_{i,t} \cdot ft_{t+\bar{\tau}_{i,t}}) \tag{2}$$

$$MS \ge \textstyle\sum_t N_{i,t} \cdot ft_{t+\bar{\tau}_{i,t}} \; \forall i \tag{3}$$

4.2. Defining a last task (option 2)

The second option was used by Castro et al. (2002) for an industrial problem with a superstructure with a task that was to be executed exactly once and was the last in the production sequence. In general, we can define an instantaneous last task i^* as one that consumes all given product demand. This is represented in Figure 4 for the case of a single batch per product (handled as unary resources). The makespan is then given by Eq. (4).

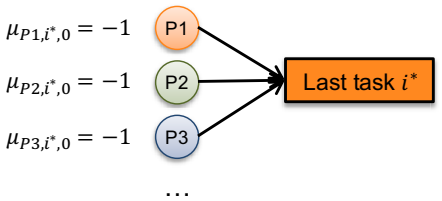

Figure 4. Structural parameters of the RTN associated to the definition of a last task.

$$MS = \sum_t N_{i^*,t} \cdot ft_t \quad (4)$$

4.3. Algorithmic search (option 3)

Maravelias and Grossmann (2003) proposed a very efficient iterative procedure for makespan minimization. Starting with a short time horizon H, insufficient to meet the demand, the problem is solved considering an objective function that is very sensitive to the schedule, e.g. total electricity cost. The solver will find very quickly that the problem is infeasible and so the next step is to keep adding one more time slot to the discrete-time grid per iteration until the problem becomes feasible. The number of slots then gives MS. The solution time per iteration will grow as we approach the optimal makespan (check chart in Castro et al., 2014b) and we want to start close enough. We thus propose to use the LP relaxation from option 2 (tighter than option 1), to set the initial number of slots. The drawback of option 3 is that the optimal solution is the first and lone feasible solution returned by the search procedure and is found only at the very end.

5. Computational results

We consider the demand side management problem of a steel plant with day-ahead, hourly electricity prices. The system and electricity price profile are taken from Castro et al. (2013). Note that to simplify the model, we allow idle times in the continuous caster units when handling heats belonging to the same group. The new RTN discrete-time scheduling formulation was implemented in GAMS 24.8.3 and solved with CPLEX 12.7 running in parallel deterministic mode using up to eight threads. The termination criteria were either a relative optimality tolerance of 10^{-6} or a maximum wall time limit of 7200 CPUs. The hardware consisted of a Windows 10, 64-bit desktop with an Intel i7-4790 (3.6 GHz) processor and 8 GB of RAM.

Table 1 presents the result for total cost minimization when considering breaks between [450, 510] and [930,990] (min). As expected, the wider domain of preemptive tasks, reflected in the larger number of discrete variables $N_{i,t}$, leads to a cost reduction. The difference to the non-preemptive case decreases from €16,253 (344,818-328.549) for time grids with δ=15 min slots, to a mere €147 for the more accurate δ=5 min. In the latter case, the optimal solution in Figure 5 features five tasks in preemptive mode. The computational time increases as δ decreases, as expected, but interestingly, only increases by a factor of two when considering preemptive tasks. Notice also that the formulation is very tight.

Table 2 and Table 3 present the results for makespan minimization. It can be seen that the standard way to minimize the makespan (option 1) is the worst since it can be as much as 5 times slower than the others and it returned a suboptimal solution of 1300 min for δ=5 min. The optimal solution of 1290 (Table 3) features 10 tasks being split over the two breaks to save 20 min of production time compared to the non-preemptive case

(makespan=1310 min, see Table 2). Option 2 was better for the non-preemptive mode, while option 3 prevailed otherwise. Overall, the impact of preemptive tasks in solution quality and computational time is similar for makespan and cost minimization.

Table 1. Computational statistics for total cost minimization

	Non-preemptive tasks				Preemptive tasks			
δ (min)	Discrete variables	RMIP (k€)	MIP (k€)	CPUs	Discrete variables	RMIP (k€)	MIP (k€)	CPUs

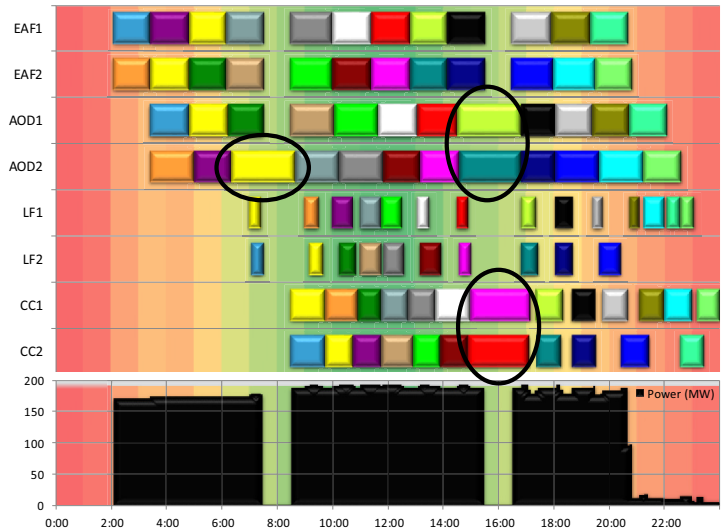

Figure 5. Optimal solution when minimizing electricity cost with δ=5 min time slots.

6. Conclusions

Whenever there is insufficient time to complete the execution of a processing task before a planned break, schedulers may be able to save time by splitting the execution of the task over the periods before and after the break. This preemptive mode of operation has mostly been neglected by scheduling formulations in process systems engineering. In this work, we have expanded a well-known and powerful discrete-time formulation to preemptive tasks. It involves acting at the level of structural parameters generation for the RTN, while keeping the same set of model variables and constraints. The benefits of considering preemption to improve solution quality where illustrated using an industrial case study from the literature, involving the demand side management of a steel plant. The results have also shown that while preemption makes the problem more difficult to solve, the computational time is of the same order of magnitude.

Abstract

This paper studies a planning problem encountered in the aluminum industry that is to select a pre-specified number of standard ingot types from the candidate pool to fill current orders and combine plates of different orders into batches, each corresponding to an ingot, so as to minimize the total weight of material waste. We formulate the problem as a novel integer programming model in which both *p*-median subproblem and cutting-stock subproblem are involved. The model is decomposed into a master problem and a set of subproblems using the Dantzig-Wolfe decomposition, and then column generation based branch-and-price solution approach is developed to obtain optimal solutions. Computational tests on a diverse set of random instances extended from the real production data show that our solution approach is much more effective than the direct MIP solver of CPLEX. In addition, our solution approach reduces the material waste by over 10.98 % as compared to the model in an existing article.

Keywords: aluminum industry, production planning, integer programming, column generation, branch-and-price

1. Introduction

Aluminum plates are widely accepted by the market due to their excellent properties. With the continuous innovation of manufacture technology and process, aluminum factories are capable of producing enormous variety of plates to meet the diversified and customized requirements. According to the past management mode, the aluminum factory first designs a dedicated ingot type for each order. Then, several rectangular ingots with same alloy and size are produced at the continuous caster for each order. The weight of an ingot is far greater than the weight of individual plate because the continuous caster prefers producing larger weight ingots to exploit economies of scale. Thus, each ingot will be cut into several pieces after casting. Each piece is rolled into a plate with required dimensions at the rolling mill. Based on the past management mode, the weight of the dedicated ingot for each order is an integer multiple of the weight of individual plate plus the necessary loss for cutting operation.

At the first glance, designing a dedicated ingot for each order can match customer requirements accurately and avoid material waste as well. However, with the increase of number of dedicated ingot types, it requires considerable investment and time to purchase and test moulds and related tools. Moreover, changing moulds at the continuous casting process incurs both a setup time resulting in productivity loss and a setup cost to repair the used tools. Thus, from the production control perspective, the aluminum factory prefers producing a fewer standard ingot types.

There is a serious conflict between customers' diversified requirements and the mass production model of the aluminum factory. This brings the new challenge to the production management. Faced with an increasingly competitive market environment, many Chinese aluminum factories have transited their production management mode from mass production to mass customization to enhance its core competence. Using a limited number of standard ingot types to meet a wide variety of orders is a key issue for the aluminum factory production planning under mass customization.

Selecting a given number of standard ingot types to produce in the following planning horizon is first decision in the production planning. With a given number of standard ingot types, several ingot types can be used to produce the finish plates for each order according to its specification on alloys and sizes. However, it is almost impossible to choose a suitable ingot type for each order such that the required plates for each order can be cut from ingots having same type without material waste. Thus, using a single ingot to jointly produce multiple plates from different orders with similar specifications on alloys and sizes is a more economic manner. How to combine plates of different orders into batches such that a batch of plates can be cut from a single ingot is the second decision in the production planning. It is obvious that decisions on selecting a set of standard ingot types and on packing the plates into ingots are actually intertwined, and thus it is beneficial to make these decisions jointly. The purpose of this paper is to find an efficient method to select standard ingot types and then generate production batches such that material utilization can be improved significantly.

There are only a few of studies available to solve the problem of selecting standard ingot types and combining orders into batches. Ventola (1991) discussed a set process rules for order batching involved in an aluminum rolling facility. Gopalan (1992) proposed the selection of standard pipes for the aluminum pipe production problem and classified it as facility location problem. Balakrishnan and Gopalakrishnan (1996) studied the problem of selecting standard ingot sizes to facilitate joint processing of finished sheets which is similar to our problem. However, they gave a set of strict rules for order batching which decreases the flexibility to combine different orders together. Similar studies have also been conducted in the steel industry. Tang *et al.* (2014) studied an integrated problem of charge batching and casting width selection arising in steelmaking and continuous casting production.

The rest of this paper is arranged as follows. Section 2 describes the problem studied and the mathematical model. The solution method based on column generation is introduced in section 3. In section 4, we present computational results and discuss the efficiency of proposed solution method. Finally, we draw conclusions in section 5.

2. Problem Description and Mathematic Formulation

The problem we study can be precisely described as follow. Let $N=\{1, 2, \ldots, n\}$ be a set of n orders, each order $i \in N$ contains d_i identical plates. The plate of order i is associated with several specific properties: alloy type a_i, weight q_i, width w_i and thickness t_i. Let $K=\{1, 2, \ldots, m\}$ be a set of m candidate ingot types, for each $k \in K$, let A_k, Q_k, W_k, and T_k respectively denote the alloy type, weight, width and thickness of ingot type k. We define N_k as a subset of orders that can be fulfilled by ingot type k. More precisely, for each order $i \in N_k$, the technological constraints including alloy, width and thickness compatibility should be satisfied, i.e. $a_i = A_k$, $w_i \leq W_k$ and $t_i \leq T_k$. Let l be the maximal number of standard ingot types that can be produced in the current planning horizon.

The problem is to select no more than l standard ingot types from the candidate pool K and then pack all ordered plates into ingots by using the selected ingot types, such that the waste material cut from the used ingots is minimized. To understand the decisions better, a general diagram representing the essential decisions is shown in Figure 1.

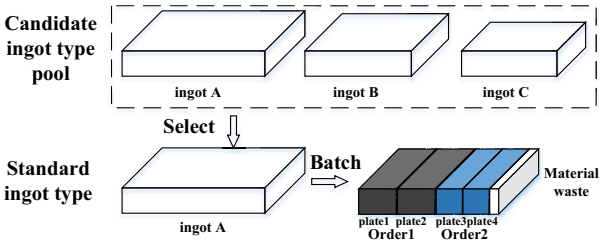

Figure 1. The integrated process of ingot type selection and order batching

For each ingot type k, the number of used ingots is unknown in advance. Let J_k be the set of ingots with type k to be used. By introducing three types of decision variables: x_{ijk} denotes the number of plate of order i packed in the j^{th} ingot of type k, y_{jk} denotes whether the j^{th} ingot of type k is used or not, z_k denotes whether type k is used or not. With the notations and variables described above, this problem is formulated as the following integer programming (IP).

$$\min \sum_{k\in K}\sum_{j\in J_k}(Q_k y_{jk} - \sum_{i\in N_k} q_i x_{ijk}) \tag{1}$$

$$s.t.\ \sum_{k\in K}\sum_{j\in J_k} x_{ijk} = d_i,\ \forall\ i\in N, \tag{2}$$

$$\sum_{i\in N_k} q_i x_{ijk} \le Q_k y_{jk},\ \forall\ k\in K, j\in J_k, \tag{3}$$

$$y_{jk} \le z_k,\ \forall\ k\in K, j\in J_k, \tag{4}$$

$$\sum_{k\in K} z_k \le l, \tag{5}$$

$$x_{ijk} \ge 0, \text{ and integer},\ \forall\ k\in K, j\in J_k, i\in N_k, \tag{6}$$

$$y_{jk},\ z_k \in \{0, 1\},\ \forall\ k\in K, j\in J_k. \tag{7}$$

The objective function (1) minimizes the material waste, *i.e.*, the total used ingots minus total customer demands. Constraints (2) imply that each order should be assigned with the demanded number of plates. Constraints (3) ensure that the total weight of plates cut from a single ingot should not exceed the weight of the ingot. Constraints (4) guarantee that a single ingot can be used if and only if the corresponding ingot type is selected. Constraint (5) limits the upper bound of selected ingot types. Constraints (6-7) define the value range of decision variables.

If the decision of selecting standard ingot types is given, the model is reduced to the cutting-stock problem. If a single ingot can only be used to fulfil a single plate, the problem is to select a given number of standard ingot types from the candidate pool to cover all orders, which becomes a p-median problem. Since both cutting-stock problem and p-median problem are NP-hard, so is our problem.

3. Solution Method

Since a direct commercial optimization solver such as CPLEX would fail to solve the IP model to optimality within limited CPU times, we decompose the IP model into a master problem and a set of subproblems using the Dantzig-Wolfe decomposition, and then column generation based branch-and-price algorithm is developed to obtain optimal solutions. In the literature, branch-and-price algorithm have been developed to

solve successfully practical instances of many batching problems arising in steel industry (Tang *et al.*, 2011, Tang *et al.*, 2014, Tang *et al.*, 2016).

For each ingot type k, we define a pattern as a combination of plates that can be cut from a single ingot of type of k. A pattern p for ingot type k is described by an integer array (a_{1kp}, a_{2kp}, . . . , a_{nkp}), where a_{ikp} gives the number of plates of order i that are contained in pattern p, and satisfies:

$$\sum_{i\in N_k} q_i\, a_{ikp} \le Q_k, \tag{8}$$

$$0 \le a_{ikp} \le d_i \text{ and integer}, \forall\ i\in N_k. \tag{9}$$

Let us introduce an integer variable λ_{kp} that gives the number of times pattern p for ingot type k is used. By using the Dantzig-Wolfe decomposition, the IP can be reformulated as the following master problem (MP).

$$\min \sum_{k\in K}\sum_{p\in P_k} c_{kp}\,\lambda_{kp} \tag{10}$$

$$s.t.\ \sum_{k\in K}\sum_{p\in P_k} a_{ikp}\,\lambda_{kp} = d_i,\ \forall\ i\in N, \tag{11}$$

$$\sum_{p\in P_k} \lambda_{kp} \le |J_k| z_k,\ \forall\ k\in K, \tag{12}$$

$$\sum_{k\in K} z_k \le l, \tag{13}$$

$$\lambda_{kp} \ge 0, \text{ and integer}, \forall\ k\in K, p\in P_k, \tag{14}$$

$$z_k \in \{0, 1\},\ \forall\ k\in K. \tag{15}$$

Note that $c_{kp} = Q_k - \sum_{i\in N_k} a_{ikp}\, q_i$ is the waste of material cut from pattern p for ingot type k. The objective function (10) is to minimize total material waste for all used patterns. Constraints (11) guarantee that the demand of each order is satisfied. Constraints (12) ensure that the patterns can be used if and only if the corresponding ingot type is select.

Since the MP usually contains an exponential number of patterns, it is impractical to solve MP directly. If the integrality requirement on λ-variables and z-variables is relaxed, we obtain the LP relaxation of the MP, denoted as (LMP). A lower bound for MP is generated by solving LMP using column generation. The column generation starts with a limited number of columns in LMP and generates necessary columns iteratively. In each iteration, we first solve a restricted master problem (which is a restricted version of LMP with the columns generated so far). Then we generate columns with negative reduced costs by solving a set of pricing problems. Let dual variable value be π_i for index i in (11), δ_k for index k in (12), the reduced cost of a column $p\in P_k$ for ingot k, denoted as rc_{kp}, is given by:

$$rc_{kp} = c_{kp} - \sum_{i\in N_k} \pi_i\, a_{ikp} - \delta_k = Q_k - \sum_{i\in N_k} (q_i + \pi_i) a_{ikp} - \delta_k \tag{16}$$

To generate a column with most negative reduced cost for each ingot type, we need to solve the following knapsack type subproblem (SP).

$$\min\ Q_k - \sum_{i\in N_k} (q_i + \pi_i) a_{ikp} - \delta_k, \text{ subject to constraints (8)-(9).} \tag{17}$$

For each ingot $k\in K$, if the objective value of SP is negative, this new generated column is added to the restricted master problem which is then updated. When no new columns with a negative reduced cost can be found in solving all pricing subproblems, the column generation procedure terminates and LMP is solved to optimality.

When the solution of LMP is fractional, we can embed the column generation lower bound into a branch and bound tree, thus obtaining a branch-and-price algorithm. We use a simple but efficient branching rule, that it, branching on a fractional λ_{kp} variable

and generating two children nodes by setting a lower bound $\lceil \bar{\lambda}_{kp} \rceil$ on λ_{kp} to right node and a upper bound $\lfloor \bar{\lambda}_{kp} \rfloor$ on λ_{kp} to left node, respectively.

4. Computational experiments

This section presents the result of the computational experiments designed for testing the effectiveness of developed model and algorithm. The column generation based branch-and-price algorithm was coded in C++ with all the LP problems solved by the LP solver of CPLEX.

We tested our model and algorithm on a set of 10 random instances extended from the real production data. Table 1 shows the computational results. The first few columns (first part) describe the problem structure, where n denotes the number of orders, m denotes the number of candidate ingot types, l denotes the number of standard ingot types to be selected, and $r=\sum_{k=1}^{m}|N_k|/(m\times n)$ represents the ratio of compatible order-ingot pairs to all order-ingot pairs. The second part of the table reports the computational results obtained by using the MIP solver of CPLEX to solve the existing model developed by Balakrishnan & Gopalakrishnan (1996). The third part of the table reports the computational results obtained by using the MIP solver of CPLEX to solve our IP model. The last part of the table reports the computational results obtained by branch-and-price algorithm.

To test the algorithm effectiveness, we compare solution of IP model solved by CPLEX with the solution obtained by branch-and-price algorithm. From the results presented in the third part and the last part of Table 1, we can observe that all the instances can be solved to optimality by branch-and-price algorithm within 2 minute, but CPLEX can't get optimal solutions for some instance within 1 hour. This indicates that the solution approach we developed is much more effective than the direct MIP solver of CPLEX. To test the model effectiveness, we compare the solution of the MP model solved by branch-and-price algorithm with the solution of B&G's model solved by CPLEX. By comparing the second part and the last part of Table 1, we can observe that both our MP model and B&G's model can be solved to optimality within acceptable computational time. However, the optimal solution of B&G's model is consistently larger than the optimal solution of our model. This is because the former deals with a more constrained version of the problem. In average, our model reduces the material waste by over 10.98 % as compared to B&G's model.

Table 1. Computational results for testing instances

Instances				B&G model		IP model				B&P Algorithm		
n	m	l	r	OPT	CPU (s)	LB_{best}	UB	Gap(%)	CPU (s)	LB_{root}	OPT	CPU/s
10	10	5	0.49	57,694	1.50	34,851	50,694	31%	3,600	49,194	50,694	1.48

100	10	5	0.46	260,265	9.66	206,061	479,265	57%	3,600	224,398	235,265	82.94

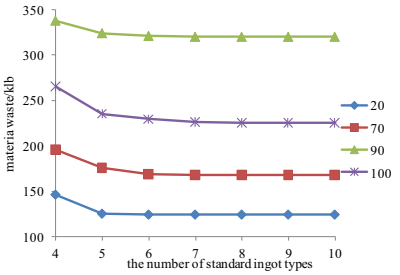

Fig. 2. The trendlines of the total waste material along with different l values

To analyze the impact of the number of selected standard ingot types (l) on the solution performance, we tested different values of $l \in \{4, 5, 6, \ldots, 10\}$ on 4 instances. The trendlines of the total waste material along with different l values are illustrated in Figure 2. As we can see, for all instances, the total waste material decreases with l increasing. However, there is a little reduction of the waste material after l reaches to 6 for all tested instances. The above sensitivity analysis can provide planners more support policy decisions about how to select the number of standard ingot types.

5. Conclusion

Selecting standard ingot types and batching plates of different orders together are very important planning decisions for daily operational management in the aluminum industry. This paper studies an integrated problem of ingot type selection and order batching. To address this problem, we formulated it as an integer programming model in which both p-median subproblem and cutting-stock subproblem are involved. To find solutions, a column generation based branch-and-price algorithm is developed. Computational results on a set of random instances demonstrate the effectiveness of developed model and algorithm.

Abstract

Large consumers' electricity bills depend on many factors including: different electricity purchasing contracts and markets, deviation penalties, and grid fees. Two key markets are the intraday and the day-ahead markets. On the day-ahead market, the consumer commits to a load of electricity that stacks on top of their longer-term contract commitments. The next day, the consumer must follow this demand profile to avoid paying deviation penalties. The demand curve can be modified on the existing day using the intraday market. A novel demand side response formulation is proposed that considers a two-day horizon for both the intraday and the day-ahead markets by a separate modeling approach. Results show that this formulation can effectively combine intraday and day-ahead market concerns and that the resulting demand profile from the two-day problem is more realistic than current models, which consider only a single-day problem.

1. Introduction

Demand Side Management (DSM) provides grid operators the opportunity to improve efficiency and stability of the power grid by flattening the electricity load curve and will play a crucial role in the improvement of grid efficiency and reliability for years to come. Simultaneously, DSM provides an opportunity for electricity consumers to lower their operating costs by responding to time-dependent electricity costs (Merkert, *et al.*, 2015).

The bill for an electricity consumer is dependent on many factors. One factor is the type of electricity purchase contract. These contracts include: long-term (up to a year) base load (BL) contracts, short-term (a few months) Time-of-Use (TOU) contract, and the day-ahead market in which consumers can purchase hourly electricity loads at hourly prices up to 12 hours in advance of the first delivery the next day. The total load from these contracts represents the hourly committed load curve for a consumer for the next day (24 hours). This load curve must then be followed to within a tolerance else so called deviation penalties must be paid. If a consumer experiences a major shift in electricity demand (for example, in the event of unit-breakdown) there exists an intraday market in which consumers can modify their committed loads to avoid paying deviation penalties. In addition, companies also need to pay various grid fees. One such grid free is a peak-pricing scheme in which a company must pay a fee based on their highest simultaneous electricity consumption over a given time-interval (Frontier Economics, 2016).

Due to the strong time-dependence of these electricity-related concerns, effective scheduling is essential in DSM, especially when a complex manufacturing process is involved. Several works have looked at DSM for scheduling, including Nolde & Morari, 2010 and Hadera, *et al.*, 2015 who investigate scheduling of steel manufacturing based on a multi-contract variable electricity pricing load commitment problem using continuous-time precedence-based scheduling models. Castro, *et al.,* 2013 also studied the load commitment problem for steel manufacturing but using a discrete-time Resource-Task Network (RTN) representation. The downside of only studying a 24-hour commitment problem is two-fold: the first is that this unrealistically makes the day-ahead and the intraday markets overlap by considering them to both be active at the same time, or by ignoring one of the markets. The second drawback is that the committed electricity load drops off towards the end of the schedule as the jobs are completed. This is unrealistic as production is performed on a continuous basis and is one of the factors hindering the application of DSM in industrial settings.

In this work, the current-day problem of load commitment (considering the intraday market) is combined with the problem of future load prediction (on the day-ahead market) in order to pay less deviation penalties and to achieve more realistic electricity-demand profiles that do not drop off towards the end of the scheduling horizon. In addition, this work considers penalties paid on the maximum electricity consumption. The problem is formulated as a discrete-time RTN (Pantelides, 1994) and is applied to the industrial problem of steel melt shop scheduling.

2. Problem Definition

This work looks at the problem of steel melt shop scheduling considering multiple electricity contracts and markets as well as peak-related grid-operator fees in order to minimize total cost. Stainless-steel production is an energy-intensive batch process with complicated processing constraints. The typical production process has four processing steps. The first involves melting the scrap in an Electric Arc Furnace (EAF) to form a so-called heat (a batch of liquid metal). This is a very energy intensive process and accounts for the majority of the electricity consumed. From there, the heat is transported to the next station where the carbon content of the steel is reduced in a process known as Argon Oxygen Decarburization (AOD). Next, the heat is transported to a Ladle Furnace (LF) to further adjust the chemistry and temperature of the heat. The final stage of the process is the Continuous-Casting (CC), where a group of several heats must be processed in an uninterrupted sequence according to a strict set of rules. The considered example here contains two parallel machines at each stage. A diagram of the process, including the RTN diagram of the process, can be viewed in Castro *et al.* 2013.

3. Model Formulation

A discrete-time model is chosen, as the location of every time point in the grid is known in advance allowing for straightforward modelling of intermediate events (such as changes in electricity pricing or power availability). Note that this formulation contains many different time intervals, but they are all matched to the underlying discrete grid.

An RTN model is applied, as it is general, yet simple, and has been shown to be both capable of handling problems of industrial relevance and expandable to account for DSM (Castro et al. 2013). The notation for the model can be viewed in Table 1. Note that all variables are non-negative continuous variables unless otherwise specified.

Table 1: Model notation

Index/Set	**Description**	**Set**	**Description**
$r \in R$	**Resources**	θ	**Relative time to start of task**
$i \in I$	**Tasks**	T_{hr}	**Set of hours in the horizon**
$h \in H$	**Set of steel heats**	T_{peak}	**Set of times over which the peak is calculated**
$g \in G$	**Set of steel groups**		
$k \in K$	**Set of processing stages**	T_{intra}	**Set of times over which electricity is sold**
$t \in T$	**Set of time points**		
$u \in U$	**Set of units**		
Parameter	Description	Parameter	Description
τ_i	Duration of task i in time slots	δ_T	Time grid discretization size for the RTN
$\mu_{r,i,\theta}$	Extent of discrete interaction of r with i at time point θ	$\delta_{T_{peak}}$, $\delta_{T_{intra}}$	Interval size for the peak and electricity selling times respectively
y_{hr}^{TOU}, y^{BL}	Respectively, amount of electricity load from a TOU or baseload contract	T^s	Time until the next trading on the intraday market
y_{hr}^{CL}	Total amount of current day committed electricity load	T^*	Hour marking the split between following a pre-committed electricity curve and predicting the future curve
$pw_{h,u}$	Power usage of h in u		
c_{pf}^{DA}	Penalty-free tolerance on load tracking		
Variable	Description	Variable	Description
N_{it}	Binary, execution of task i at time slot t	ξ	Maximum electricity peak
$R_{r,t}$	Amount of r available at t	ω_t^{DA}	Free var. penalty free zone from day-ahead contract
$\Pi_{r^{pw},t}$	Power consumption at t	$\sigma_{t_{intra}}^{DA}$	Free var. amount of day-ahead load sold or bought on the intraday market
y_{hr}^{PL}	Total amount of day-ahead predicted load		
Δ_t^{DA+}, Δ_t^{DA-}	Respectively positive and negative deviations from the day-ahead committed load	$\sigma_{t_{intra}}^{TOU}$, $\sigma_{t_{intra}}^{BL}$	Respectively amount of load sold from TOU or BL contract on the intraday market
Δ_t^{TOU-}, Δ_t^{BL-}	Respectively negative deviations from the TOU and BL contracts		

3.1. Model Constraints

Resource availability over the time grid is managed by the excess resource balance given in Eq. (1).

$$R_{r,t} = R_{r,t=1}^{0} + R_{r,t-1} + \Pi_{\mathrm{r^{pw}},t} + \sum_i \sum_{\theta=0}^{\tau_i} \mu_{r,i,\theta} N_{i,t-\theta} \quad \forall r, t \in T \tag{1}$$

Eq. (2) and (3) are used to ensure that all heats are processed exactly once at each stage, while Eq. (4) and Eq. (5) enforces transfer task tasks and times.

$$\sum_{u \in u_k} \sum_{i \in I_{h,u}} \sum_t N_{i,t} = 1 \quad \forall h, k = 1,2,3 \tag{2}$$

$$\sum_{u \in u_k} \sum_{i \in I_{g,u}} \sum_t N_{i,t} = 1 \quad \forall g, k = 4 \tag{3}$$

$$\sum_{u \in U_k} \sum_{u' \in U_{k+1}} \sum_{i \in hu,u'} \sum_t N_{i,t} = 1 \quad \forall h, k = 1,2,3 \tag{4}$$

$$\sum_{u' \in U_{k+1}} \sum_{r \in R_{h,u}^{IL}{}'} \sum_t R_{r,t} \leq \left\lceil \max_{u \in U} \frac{maxtr_{u,u'} - mintr_{u,u'}}{\delta_T} \right\rceil \quad \forall h, k = 1,2,3 \tag{5}$$

$$R_{r^{pw},t} = 0 \; \forall t \in T \qquad \forall t \in T \tag{6}$$

$$\Pi_{r^{pw},t} \leq \sum_h \sum_u pw_{h,u} \quad \forall t \in T \tag{7}$$

$$y_h^{PL} \leq \sum_h \sum_u pw_{h,u} \qquad \forall hr \in T_{hr} \tag{8}$$

$$\xi \leq \left\lceil \delta_T / \delta_{T_{peak}} \right\rceil \sum_h \sum_u pw_{h,u} \tag{9}$$

To prevent a buildup of electricity over time Eq. (6) is used. Eqs. (7), (8), and (9) set upper bounds on electricity consumption, predicted, and maximum electricity consumption. In order to calculate the deviations from the load that has been committed to within the current day, Eqs. (6) and (7) are used. Two equations are needed in order to account for the time before and after it is possible to trade on the intraday market.

$$\Pi_{r^{pw},t} = y_h^{CL} + \omega_t^{DA} - \Delta_t^{DA-} + \Delta_t^{DA+} - \Delta_t^{TOU} - \Delta_t^{BL} \;\; \forall\, t \in T_{hr}, T_{hr} < T^S \tag{10}$$

$$\Pi_{r^{pw},t} = y_h^{CL} + \omega_t^{DA} - \Delta_t^{DA-} + \Delta_t^{DA+} - \Delta_t^{TOU} - \Delta_t^{BL} + \sigma_{t_{intra}}^{DA} + \sigma_{t_{intra}}^{TOU} + \sigma_{t_{intra}}^{BL} \quad \forall\, t \in t_{intra}, t_{intra} \in T_{hr}, T^S \leq T_{hr} \leq T^* \tag{11}$$

The amount of load to commit on the day-ahead market is set by Eq. 12.

$$\Pi_{r^{pw},t} = y_h^{PL} + \omega_t^{DA} - \Delta_t^{DA-} + \Delta_t^{DA+} - \omega_t^{TOU} - \Delta_t^{TOU} - \omega_t^{BL} - \Delta_t^{BL} \quad \forall\, t \in T_{Hr}, \; T^* < T_{hr} \tag{12}$$

Since the penalty-free region is a percentage of the contracted load, the upper and lower bounds on the penalty free region for the day-ahead contract are enforced through Eqs. (9) and (10). Note that because the BL and TOU contracts represent loads that should always be met there is no penalty free region for these contracts.

$$-c_{pf}^{DA} * \left(y_h^{CL} - y_{hr}^{TOU} - y^{BL} - \sigma_{t_{intra}}^{DA}\right) \leq \omega_t^{DA} \leq c_{pf}^{DA} * \left(y_h^{CL} - y_{hr}^{TOU} - y^{BL} - \sigma_{t_{intra}}^{DA}\right) \forall\, t \in T_{hr} \;\; T_{hr} \leq T^* \tag{13}$$

$$-c_{pf}^{DA} * (y_h^{PL} - y_{hr}^{TOU} - y^{BL}) \leq \omega_t^{DA} \leq c_{pf}^{DA} * (y_h^{PL} - y_{hr}^{TOU} - y^{BL}) \forall t \in T_{hr}, T^* < T_{hr} \tag{14}$$

If the actual consumption strays outside of the penalty-free region defined above penalties must be paid. Eqs. (15) to (19) define the bounds on the magnitude of the deviations per contract. Note that because the contracts build on top of one another, deviations from 'lower' contracts are more costly than deviations from 'higher' contracts. Therefore, an extra variable is not needed to account for which contract is being violated, as the optimal solution will first penalize the higher contracts before proceeding to the lower ones.

$$\Delta_t^{DA-} \leq \left(1 - c_{pf}^{DA}\right)\left(y_h^{CL} - y_{hr}^{TOU} - y^{BL} - \sigma_{t_{intra}}^{DA}\right) \;\; \forall\, t \in T_{hr} \;\; T_{hr} \leq T^* \tag{15}$$

$$\Delta_t^{DA-} \leq \left(1 - c_{pf}^{DA}\right)\left(y_h^{PL} - y_{hr}^{TOU} - y^{BL} - \sigma_{t_{intra}}^{DA}\right) \;\; \forall\, t \in T_{hr}, T^* < T_{hr} \tag{16}$$

$$\Delta_t^{DA+} \leq \sum_h \sum_u pw_{h,u} \qquad \forall t \in T \tag{17}$$

$$\Delta_t^{TOU-} \leq y_{hr}^{TOU} - \sigma_{t_{intra}}^{TOU} \quad \forall t \in T \tag{18}$$

$$\Delta_t^{DA-} \leq y^{BL} - \sigma_{t_{intra}}^{BL} \qquad \forall t \in T \tag{19}$$

The last constraint given by Eq. (16) calculates the maximum peak power achieved.

$$\xi \geq \sum_{t \in t_{peak}} \Pi_{r,t} \quad \forall t_{peak} \in T_{peak} \tag{20}$$

The objective function of the problem is to minimize the total cost of production. This includes cost of the electricity from each of the contracts, the cost of deviations from each of the contracts, revenue or costs incurred by trading on the intraday market, and a flat fee paid on the maximum peak attained during production.

4. Results

Three case studies were solved using GAMS 24.7.4/CPLEX 12.6.3.0. They are defined as follows: Case 1 considers a two-day commitment to a predetermined load with no consideration of the intraday market or the maximum peak. Case 2 is similar to Case 1 but it includes the intraday market. The aforementioned case studies were run with a daily production of 12 and 17 heats as two separate sub problems (SP1/SP2), one for each of the two days considered. Lastly, Case 3 is the proposed novel approach that highlights the importance of considering a longer horizon comprising current day load commitment and day-ahead prediction. In this case, it is not possible to trade on the intraday market to highlight the fact that fewer penalties can be paid simply by shifting production between the two days and changing the day-ahead consumption. This case was run with a time horizon of 54 hours (two days + six hours) with the total two-day forecasted production, plus two additional heats to account for production on the third day. The additional heats are necessary to highlight the fact that production should not drop off towards the end of the day, resulting in an unrealistic load profile. To facilitate a fair comparison, the total-two day production (24 and 34 heats respectively) was constrained to be completed by the end of day two, with the additional two extra heats exiting the last stage on the final day. A summary of the results is presented in Table 2 and Figure 1.

Results indicate that the novel formulation is able to avoid deviation penalties simply by transferring production across the current/next day boundary to better track the current day committed load while modifying the day-ahead demand to avoid future penalties. In the 12-heat case, this was accomplished by pushing production forward to the current day in order to avoid paying negative deviation penalties. In the 17-heat case, it was more favorable to slow down production to avoid paying positive deviation penalties. That being said, Case 3 cannot avoid as many deviations as the case that has no limit on selling or buying on the intraday market, however the intraday market is often avoided by large consumers unless it is necessary. In addition, the new formulation is able to manage the largest peak within the flexibility of production; in Case 2-12H when peak management was not considered, both EAFs were operated at the same time, resulting in a peak nearly twice as high as when the maximum peak was penalized. In the 17-heat case, peak management was more difficult due to the higher production amount; however, a smaller peak was still achieved. Figure 1 indicates that the two-day formulation is also able to avoid a drop off in production towards the end of the day when compared to considering two one-day problems. This presents a more realistic production scenario as each stage of the plant is operated constantly, as opposed to operating the first stages only until the daily production has been met. The major drawback of the new approach is that it results in very large models and it has difficulty in converging to a provably optimal solution.

Table 2: Comparison of results for the different cases.

Case	Deviations Paid (€)	Max Peak (MW)	CPU Time (s) [SP1/SP2]	Rel. Gap (%) [SP1/SP2]
Case 1-12H	190,600	96	10,000/6,893	<0.1/0
Case 2-12H	120	177	3,505/10,000	0/0.3
Case 3-12H	25,100	94	10,000	8.6
Case 1-17H	305,400	185	265/10,000	0/0.1
Case 2-17H	7,217	192	10,000/10,000	2.6/1.3
Case 3-17H	16,500	177	10,000	19.3

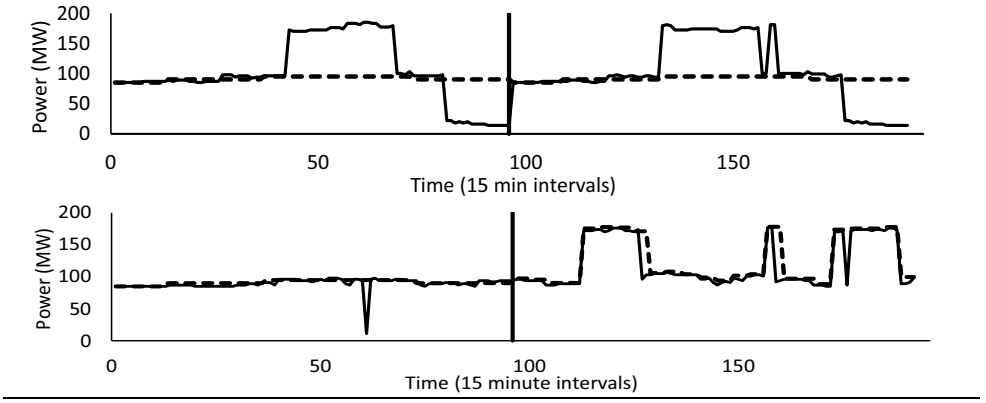

Figure 1: Comparison of committed load for Case1-17H (top) and Case 3-17H (bottom). Actual consumption is represented by the solid line and committed load by the dashed line.

5. Conclusions

A novel DSM model was presented in this work. The model differs from its predecessors, as it is able to effectively combine the problems of current day electricity load following considering the intraday market and day-ahead future load prediction considering the day-ahead market. Results show that this novel formulation is more realistic than its existing models as it is able to follow and predict more realistic load curves while minimizing maximum electricity peaks. The downside of this approach is that it results in very large, difficult to solve problems. Future work could investigate speed-up algorithms or decomposition approaches for such a formulation to ensure that good quality solutions can be found in industrially relevant time frames.

Abstract

This paper presents a multi-period mathematical programming model for the planning of unconventional gas field development, taking into account variations in the gas production rates and the gas demand. Based on a superstructure, the model consists of gas flowrate and impurity load balances and operational constraints. The proposed approach is demonstrated through a modified literature case study.

Keywords: gas sweetening, process integration, superstructure, optimisation.

1. Introduction

Human activities have caused serious environmental issues such as climate change and pollution. Despite increased use of renewable energy, fossil fuels will remain dominant although these conventional energy sources are a major contributor to greenhouse gas emissions. Among fossil fuels, natural gas (NG) is relatively clean with lower carbon dioxide (CO_2) intensity compared to coal and oil.

Development of unconventional gas fields has recently become common practice in the oil and gas industry, with the growing demand for NG as part of the global shift towards low-carbon energy sources. Unconventional gas fields produce low quality NG with high CO_2 content. Such sour gas needs removal of CO_2, or sweetening, in the offshore facilities before proceeding to the onshore gas processing plant (GPP), so as to meet the sales gas specifications for downstream applications (e.g. power generation). Removal of CO_2 offshore reduces the gas flowrates and hence the compressor duty, with reduced need for corrosion resistant pipes. The captured CO_2 may then be injected around the gas field for permanent geological storage or enhanced oil recovery (EOR). In addition, blending sour gas with sweet gas of lower CO_2 content to meet the specifications for gas processing is also a common practice in the industry. This strategy helps to reduce the dependence on gas sweetening and optimise the capacities of the units. However, sweet gas from conventional fields normally has limited availability; therefore, its utilisation also needs to be optimised.

Planning the development of gas fields thus involves determining: 1) which gas sweetening technique(s) should be used; 2) how much sour gas should be treated; and 3)

how much sweet gas should be used. Process integration techniques may be extended to address the gas field planning problem, which is analogous to the effluent treatment problem. Smith and co-workers (Wang and Smith, 1994; Kuo and Smith, 1997) developed graphical pinch analysis methods for the design of distributed effluent treatment systems, where impurity loads are to be removed from wastewater streams to comply with the environmental discharge limit. Other types of pinch-based techniques were also developed for effluent treatment networks (Ng et al., 2007; Bandyopadhyay, 2009). In these previous works, the main aim is to identify the minimum treatment flowrate, thus reducing the capital cost. Furthermore, the methods are designed to handle dilute waste streams with very low impurity content (typically at ppm levels), in which case flowrate losses due to impurity removal is negligible.

However, in the gas sweetening problem, sour NG streams can contain 30-50% of CO_2. This indicates that the sweetening process involves significant flowrate losses. Therefore, the earlier developed methods for waste treatment are not directly applicable before appropriate modifications. Foo et al. (2016) proposed pinch-based graphical and optimisation approaches to identify the minimum extent of CO_2 removal, based on the techniques for waste treatment systems (Ng et al., 2007) and carbon capture planning for the power generation sector (Ooi et al., 2013).

Apart from the aspects already addressed in the recent literature, variations in the gas production rates and the required flowrate for gas processing are also important operational issues to be taken into account. In this work, a multi-period mathematical model is developed for optimal planning of gas field development, considering the flowrate variability. Comprised of mass balance equations and operational constraints based on a superstructure, the time-dependent formulation can also be used to analyse the effect of development scheduling on the overall planning. A case study is solved to illustrate the proposed approach.

2. Problem statement

The problem addressed in this paper is formally stated as follows. Given:

- A set of high-CO_2 sources $i \in \mathbf{I}^{H}$, where CO_2 needs to be removed before the NG streams proceed to the downstream GPP, which tolerates a specified maximum CO_2 content. It is assumed that each high-CO_2 source produces gas at a constant CO_2 concentration but a varying flowrate based on the production forecast. A set of time periods $t \in \mathbf{T}$ are defined to capture such variability in gas flowrates.
- A set of gas sweetening technologies $k \in \mathbf{K}$ (e.g. membrane separation and amine absorption) of known performance for CO_2 removal (i.e. fixed product recovery factor and fixed CO_2 concentration of the purified stream).

Due to the necessary removal of CO_2 from sour NG streams to meet the requirement for gas processing, the total flowrate to the GPP will be lower than that originally from the high-CO_2 gas fields. Such flowrate losses will then be made up by introducing low-CO_2 sweet gas from an existing or new field. However, sweet gas has limited availability due to extensive exploitation and development of conventional gas fields over the years. The decision on the amount of CO_2 removal from sour gas is made by considering the cost of gas sweetening and/or the availability of sweet gas. The objective is to determine the minimum extent of CO_2 to be removed/captured to give the required NG quality, whilst minimising sweet gas supply.

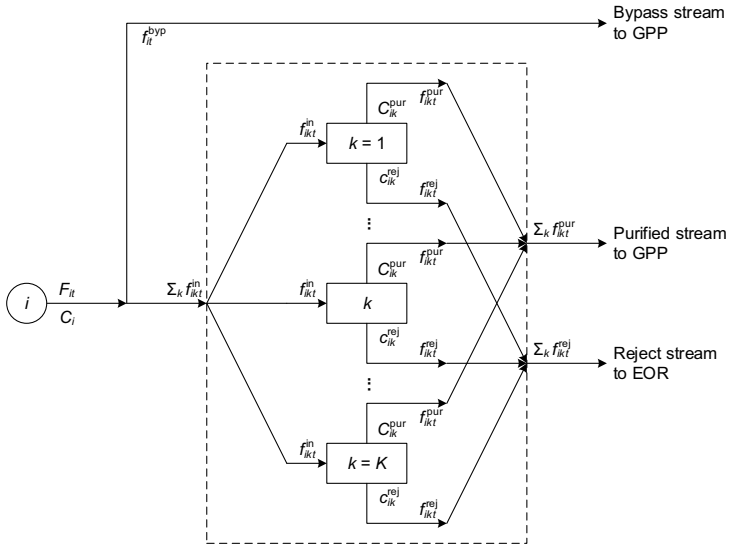

Figure 1. Schematic of Gas Sweetening

3. Model formulation

Figure 1 shows a schematic diagram of gas sweetening at a high-CO_2 source in a given time period. It can be seen that the sour gas from the source can be partially treated with available gas sweetening technologies. The bypass stream and the purified stream are then sent to the GPP, whilst the CO_2-rich reject stream may be used for EOR. Eq. (1) describes the flowrate balance for source *i* in time period *t*.

$$F_{it} = \sum_{k \in \mathbf{K}} f_{ikt}^{\text{in}} + f_{it}^{\text{byp}} \quad \forall i \in \mathbf{I}^{\text{H}}, t \in \mathbf{T} \tag{1}$$

where F_{it} is the flowrate of gas from source *i* in time period *t*, f_{ikt}^{in} is the inlet flowrate of gas sweetening unit *k* at source *i* in time period *t*, and f_{it}^{byp} is the bypass flowrate of gas from source *i* in time period *t*.

Eq. (2) states that only one technology can be selected for in-situ gas sweetening at each high-CO_2 source. Eq. (3) sets the upper limit on the inlet flowrate, whilst ensuring that no gas will be treated with unselected technology ($y_{ik} = 0$).

$$\sum_{k \in \mathbf{K}} y_{ik} \le 1 \quad \forall i \in \mathbf{I}^{\text{H}} \tag{2}$$

$$f_{ikt}^{\text{in}} \le F_{it} y_{ik} \quad \forall i \in \mathbf{I}^{\text{H}}, k \in \mathbf{K}, t \in \mathbf{T} \tag{3}$$

where y_{ik} is a binary variable indicating if technology *k* is selected for source *i*.

Eqs. (4) and (5) describe the flowrate and CO_2 load balances around gas sweetening unit *k* at source *i* in time period *t*, respectively.

$$f_{ikt}^{\text{in}} = f_{ikt}^{\text{pur}} + f_{ikt}^{\text{rej}} \quad \forall i \in \mathbf{I}^{\text{H}}, k \in \mathbf{K}, t \in \mathbf{T} \tag{4}$$

$$f_{ikt}^{\text{in}} C_i = f_{ikt}^{\text{pur}} C_{ik}^{\text{pur}} + f_{ikt}^{\text{rej}} c_{ik}^{\text{rej}} \quad \forall i \in \mathbf{I}^{\text{H}}, k \in \mathbf{K}, t \in \mathbf{T} \tag{5}$$

where f_{ikt}^{pur} and f_{ikt}^{rej} are the flowrates of the purified and reject streams, C_i is the CO_2 concentration of gas from source i, whilst C_{ik}^{pur} and c_{ik}^{rej} are the CO_2 concentrations of the purified and reject streams. The gas sweetening process is also characterised by the product recovery factor R_{ik} in Eq. (6).

$$f_{ikt}^{\text{pur}}\left(1-C_{ik}^{\text{pur}}\right)=R_{ik}f_{ikt}^{\text{in}}\left(1-C_i\right) \quad \forall i\in\mathbf{I}^{\text{H}},k\in\mathbf{K},t\in\mathbf{T} \tag{6}$$

Eqs. (7) and (8) impose the specification constraints on flowrate and CO_2 concentration for gas processing.

$$\sum_{i\in\mathbf{I}^{\text{H}}}\left(f_{it}^{\text{byp}}+\sum_{k\in\mathbf{K}}f_{ikt}^{\text{pur}}\right)+\sum_{i\in\mathbf{I}^{\text{L}}}f_{it}^{\text{SG}}\geq f_t^{\text{GP}} \quad \forall t\in\mathbf{T} \tag{7}$$

$$\sum_{i\in\mathbf{I}^{\text{H}}}\left(f_{it}^{\text{byp}}C_i+\sum_{k\in\mathbf{K}}f_{ikt}^{\text{pur}}C_{ik}^{\text{pur}}\right)+\sum_{i\in\mathbf{I}^{\text{L}}}f_{it}^{\text{SG}}C_i\leq f_t^{\text{GP}}C^{\text{GP}} \quad \forall t\in\mathbf{T} \tag{8}$$

where f_{it}^{SG} is the flowrate of sweet gas from low-CO_2 source $i\in\mathbf{I}^{\text{L}}$ in time period t, f_t^{GP} is the gas processing flowrate in time period t, and C^{GP} is the maximum CO_2 content for gas processing.

The objective may be to minimise the supply of sweet gas from low-CO_2 sources over the planning horizon, as given in Eq. (9), or alternatively to minimise the total operating cost associated with sweet gas supply and gas sweetening, as given in Eq. (10).

$$\min\phi_1=\sum_{i\in\mathbf{I}^{\text{L}}}\sum_{t\in\mathbf{T}}f_{it}^{\text{SG}}\Delta_t \tag{9}$$

$$\min\phi_2=\sum_{i\in\mathbf{I}^{\text{L}}}\sum_{t\in\mathbf{T}}UC_if_{it}^{\text{SG}}\Delta_t+\sum_{i\in\mathbf{I}^{\text{H}}}\sum_{k\in\mathbf{K}}\sum_{t\in\mathbf{T}}TC_{ik}f_{ikt}^{\text{in}}\Delta_t \tag{10}$$

where Δ_t is the length of time period t, UC_i is the unit cost of sweet gas, and TC_{ik} is the treatment cost for gas sweetening.

Due to the bilinear terms for CO_2 loads in Eq. (5), the overall model is a mixed integer nonlinear programme (MINLP), which is solved utilising global solver BARON in the GAMS environment on a Core i5-4340M, 2.90 GHz processor. Solutions for the case study presented in the next section were obtained with negligible processing time (< 1 CPU s), although global optimality may not always be guaranteed.

4. Case study

A modified literature example is solved to illustrate the proposed approach (Foo et al., 2016). Table 1 shows the data based on an actual commercial project in Southeast Asia. There are three high-CO_2 gas fields (A-C) to be developed. The gas production forecast over the 30-y planning horizon is shown in Figure 2(a). For onshore processing, the CO_2 content of the gas has to be reduced to 3% or below. A membrane separation unit with 95% product recovery and a fixed outlet CO_2 concentration of 2% may be used for in-situ CO_2 removal. Alternatively, an amine absorption unit with 90% product recovery and a 5% outlet CO_2 concentration can be used. Sweet gas is available from field D to compensate for the flowrate losses due to gas sweetening. It is assumed that the required total flowrate to the GPP is 1000 MMscfd in 1-10 y, 1200 MMscfd in 11-20 y, and 1500 MMscfd in 21-30 y to meet the growing energy demand. Two scenarios are analysed in this case study.

Table 1. Data for the Gas Sweetening Case Study

Gas field	Flowrate (MMscfd)	CO_2 content (%)
A	50-500	15
B	20-300	30
C	0-200	50
D (sweet gas)	To be determined	2

Scenario 1 aims to minimise the flowrate of sweet gas because of its limited availability. Solving the MINLP model (Eq. (9) subject to Eqs. (1)-(8)) gives the minimum sweet gas supply of 9111093 MMscf. The flowrates of the inlet streams for gas sweetening are shown in Figure 2(b), and the flowrates of the bypass streams in Figure 2(c). In addition, the sweet gas flowrate is shown in Figure 2(d). From these results, the design capacities of the gas sweetening units and the pipelines can be determined. For example, the CO_2 removal unit at field A requires a 423.1-MMscfd capacity, and its bypass line a 115.4-MMscfd capacity. Figure 3(a) shows the resulting gas sweetening system. It is worth noting that only membrane separation is selected for gas sweetening, because its higher product recovery helps to minimise the sweet gas flowrate.

In scenario 2, the objective is to minimise the operating cost of the system. The unit cost of sweet gas is taken to be 0.2 USD/MMscf, whilst the treatment costs for membrane and amine absorption units are taken as 0.5 and 0.3 USD/MMscf respectively (Foo et al., 2016). Solving the MINLP model (Eq. (10) subject to Eqs. (1)-(8)) gives the minimum operating cost of 3,878,226 USD. Figure 3(b) shows the corresponding gas sweetening system. Note that amine absorption is selected for fields B and C instead of membrane separation because it is less expensive, though this increases the sweet gas flowrate (due to the lower product recovery of amine absorption).

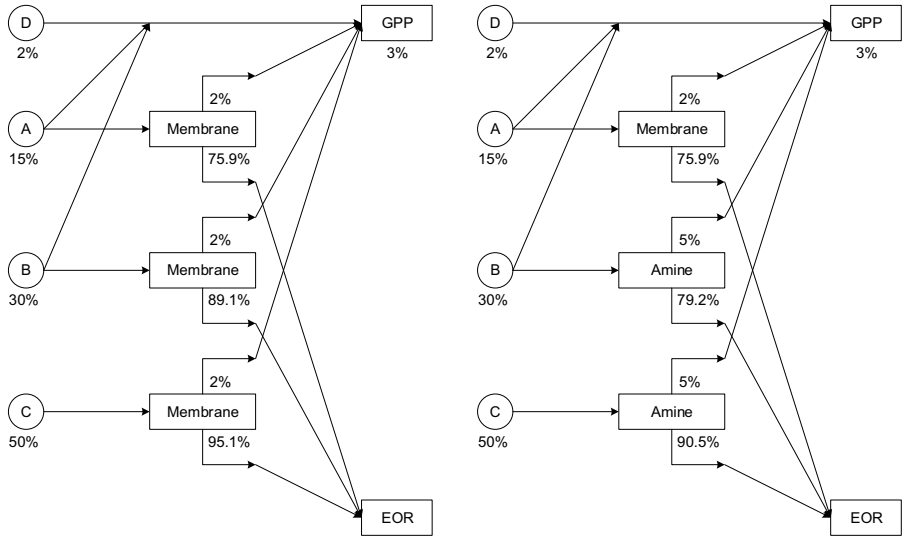

Figure 3. Gas Sweetening System for (a) Scenario 1 and (b) Scenario 2.

5. Concluding remarks

Based on a superstructure, a multi-period mathematical model for gas field development planning has been developed in this work. The formulation captures the variability in gas production and demand. A modified case study was solved to illustrate the proposed approach. Future work will consider capital investment for optimal cost trade-offs. The effects of development scheduling and parametric uncertainties on the planning may also be analysed.

Multi-period operational optimization of natural gas treating, blending, compressing, long-distance transmission, and supply network

Wen W. Zhang, Bing J. Zhang, Chang He, Ming Pan, Qing L. Chen*

School of Chemical Engineering and Technology, Guangdong Engineering Center for Petrochemical Energy Conservation, Sun Yat-Sen University, No. 135, Xingang West Road, Guangzhou, 510275, China
chqlin@mail.sysu.edu.cn

Abstract

Natural gas has emerged as a promising energy source due to its high quality and massive reserves. Operational optimization of natural gas networks including gas treating, blending, compressing, long-distance transmission, supplying and power generation are quite challenging since it contains highly nonlinear processes, complex thermodynamics, and a set of partial differential equations (PDE). In this article, we first introduce a multi-period optimization framework for the large scale natural gas network. Then, we develop a nonconvex mixed-integer nonlinear programming (MINLP) model aiming for better economic performance for the network. Various levels of market price and demand for electricity are considered. The MINLP framework integrates the models of CO_2 removing processes, compressors, pipeline transmission and combined-cycle gas and steam turbines. The optimization framework and mathematical model are applied to a case study extracted from an industrial park at South China. Economy and energy performances are investigated and an optimum operating strategy is drawn out. The practicability of the optimization framework and mathematical model makes it more possible to apply to real world problems.

Keywords: Operational optimization, Natural gas, Network, Mathematical modelling.

1. Introduction

Natural gas is one of the cleanest energy sources on earth. Raw natural gas exploited from offshore reservoirs is pre-processed and dried at the wellheads before it enters onshore treating plants (Zhang *et al.*, 2017). The remaining CO_2 in dry natural gas (DNG) is further removed to a certain level at onshore treating plants due to downstream users' restrictions on fuel specifications. This brings attention to DNG network (DNGN), which is designed for a network of DNG treating, blending, compressing, long-distance transmission, supplying and power generating.

A DNGN receives DNG, which varies in pressure and chemical compositions from several terminals. The DNGN is employed to process and transmit DNG, and generate power to fulfil power consumers' requirements. It's very complicated to model a DNGN because it would involve bilinear, quadratic, polynomial, exponential, and other higher order terms. The multi-period operations make it even more challenging. Therefore, it is necessary to apply advanced techniques of multi-period MINLP models to the systems for economic performance and energy savings, and customer satisfaction improvements.

Complex chemical process systems including the optimization of natural gas industry has been studied. Most of these contributions in the natural gas industry focused on the natural gas production planning and control, gas pipeline network, and supply chains. Selot *et al.* (2008) developed a nonconvex MINLP short-term operational planning model of natural gas transporting integrated with processing to minimize the operational costs for the network. Cafaro & Grossmann (2014) developed a large-scale MINLP model for a shale gas supply chain network. Gao & You (2015) also studied operation and design problem of a shale gas supply chain. Recently, J. Li et al. (2016) develop a global optimization-based planning and modelling to predict overall product yields and properties in an integrated refinery-petrochemical complex.

To our best knowledge, very little work has been dedicated to the optimization planning of multi-period operational process and supply network for DNG. In this paper, the entire planning model is carried out as a large-scale nonconvex MINLP optimization problem. The global optimization approaches are applied to solve the model to global optimality.

2. Problem statement

A typical DNGN is illustrated in Figure 1. The DNGN receives DNG from several offshore terminals. DNG is processed, compressed and transmitted to power plants through pipelines to produce power which should meet the demand of downstream customers. It's not economical for power plants to work at full load persistently when demands fluctuate with seasons or other external reasons. We aim to optimize operation parameters for production and consumption to match in a period to avoid unnecessary energy consumption for the purpose of maximizing the total profit.

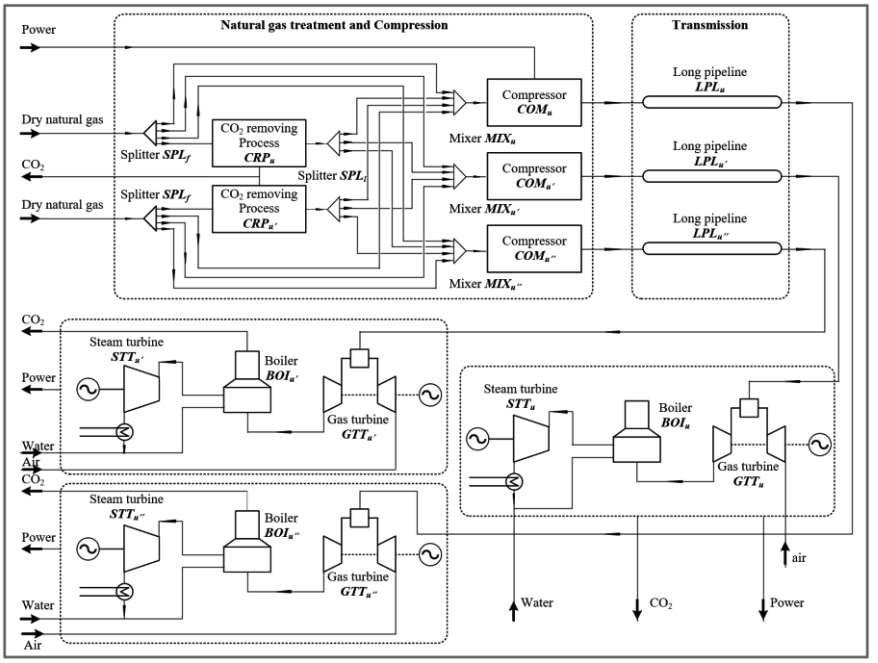

Figure 1. A schematic diagram of a typical DNGN

Methyl diethanolamine (MDEA) process was adopted for removing CO_2 in DNG. As being processed, DNG is then transmitted through a set of long pipelines to power plants in which gas turbines, boilers and steam turbines are installed. DNG can be stored on a short-term basis inside the pipelines due to its compressibility and the massive pipeline length. The challenges to model pipelines lie primarily in demand uncertainty and the dynamic behaviour of the long-distance pipelines.

3. Mathematic models

The whole DNGN is consisted of three parts: DNG treatment and compression, DNG transmission, and power generation. The mathematic models are presented as follows.

3.1. DNG treatment and compression

3.1.1. The model for CO_2 treating process

Absorption of CO_2 is achieved mainly by the use of amine in an absorber column. CO_2-rich amine solvents are regenerated in a stripper column and then pumped back to the absorber. a relationship between molar flow rate of solvent and CO_2 removal studied by *Mofarahi et al.* (2008) can be used to calculate the molar flow rate of solvent. Hence, the power consumption by pump can be calculated in Eq. (1), where h is a set of periods, u is a set of processes, Δp is pressure drop between absorbers and regenerators, $F_{h,u}^{sol}$ is mole flow rate of solvent, γ^{sol} is molar density of solvent, and η_u is pump efficiency. The sets in the domains are corresponded to the sets illustrated in Figure 1.

$$E_{h,u}^{pump} = \frac{\Delta p_u F_{h,u}^{sol}}{3600\gamma^{sol}\eta_u} \quad \forall u \in CRP \tag{1}$$

Eq. (2) expresses the mass balance for CH_4 before and after being treated by MDEA.

$$M_{h,u',u,c}F_{h,u} = M_{h,u,u',c}F_{h,u,u'} \quad \forall c = CH4, u \in CRP \tag{2}$$

where $M_{h,u,u',c}$ is the molar fraction of component c.

Low-pressure steam is used to meet the energy requirement of the reboilers in the regenerators. According to energy balance, Eq. (3) is presented to express that the heat provided to the reboilers $Q_{h,u}$ should equal the heat removed from the condensers, the reaction heat for CO_2 desorption, and the heat to increase the solvent temperature from the inlet to outlet of regenerator.

$$Q_{h,u} = \epsilon^{reg}\iota^{reg}F_{h,u}^{CO2} + \delta^{reg}F_{h,u}^{CO2} + \varepsilon^{sol}\Delta\tau^{reg}F_{h,u}^{sol} \quad \forall u \in CRP \tag{3}$$

where parameters ϵ, ι^{reg}, δ^{reg}, ε^{sol}, $\Delta\tau^{reg}$ are the specific latent heat of reflux stream in the regenerator, the reflux ratio of regenerator, the heat of desorption reaction, the specific heat capacity of solvent, and the temperature difference between solvent entering and exiting the regenerator, respectively.

3.1.2. The model for compressors

For isentropic compression, isentropic efficiency is defined to calculate the practical enthalpy change. Hence, the required power is computed using Eq. (4).

$$E_{h,u} = \frac{1}{\eta_{h,u}}\sum_{c\in C}\left(\varepsilon_c M_{h,u',u,c}F_{h,u}\right)\left[\left(R_{h,u}\right)^{\frac{\theta_u-1}{\theta_u}} - 1\right] \quad \forall u \in COM \tag{4}$$

where, variable $E_{h,u}$ is power consumed or generated, M is mole fraction of component c, isentropic exponent θ_u is the ratio of heat capacities of gas streams at constant pressure and temperature, ε_c is specific heat capacity, and c is a set of chemical components.

3.1.3. The model for mixers and splitters

Streams that comes from different processes are mixed together in the mixers. Eq. (5) expresses the pressure constraints in mixers. Binary variable $X_{h,u',u}$ is used to express whether a corresponding process is in operation. m is a large number.

$$P_{h,u} \le P_{h,u'} + m\,(1 - X_{h,u',u}) \quad \forall u \in MIX \tag{5}$$

Streams which go through splitters are divided into several streams with the same chemical components. Hence mass balance for the splitters and mass balance for individual chemical components can be easily modelled.

3.2. The model for transmission

A continuity equation across the pipelines is given in Eq. (6) under the assumption of ideal gas and isothermal conditions.

$$\frac{WA}{RT}\frac{\partial P}{\partial h} + \frac{\partial F_{h,u}}{\partial x} = 0 \quad \forall u \in LPL \tag{6}$$

where, A_u is cross-sectional area in pipeline u, $\frac{\partial F_{h,u}}{\partial x}$ is partial derivative of molar flow rate with respect to position, R is gas constant, T is temperature. The PDE above is derived from fundamentals of mass balance and is suitable for any given pipes. Baumrucker & Biegler (2010) proposed an approach that solves the problem using an integrated form of the continuity equation. Applying the approach to the continuity equation, the result takes the form in Eq. (7).

$$\frac{W_{h,u}A_uL_u}{RT_{ref}}\left(\bar{P}_{h+1,u} - \bar{P}_{h,u}\right) = \frac{1}{2}\left[\left(F^{in}_{h,u} - F^{out}_{h,u}\right) + \left(F^{in}_{h+1,u} - F^{out}_{h+1,u}\right)\right]\Delta h \quad \forall u \in LPL \tag{7}$$

where, variables $\bar{P}_{h,u}$, $W_{h,u,c}$ are average pressure, molecular weight of component c, parameters T_{ref} and L_u are reference temperature and length of pipeline u, respectively.

3.3. The model for power plant

A typical power plant consists of gas turbines, boilers and steam turbines. The model for power plant is represented as follows. Eq. (8) is the model of gas turbines (Smith, 2005), Eq. (9) is the model of boilers (Shang & Kokossis, 2004), and Eq. (10) is the model of steam turbines (Mavromatis & Kokossis, 1998). In Eq. (8), $J_{h,u}$ is work production, $\Delta H^{comb}_{h,u}$ is net heat of combustion, and $Q_{h,u,u''}$ is the heat of flue. In Eq. (9) variable $FB^{steam}_{h,u}$ is flow rate of steam produced by boilers, α_u and β_u are operational parameters for boilers, parameter $F^{steam,max}_{h,u}$ is the upper bound of boilers. $Q^{exh}_{h,u}$ is the heat of exhaust from boilers. In Eq. (10) $FT^{steam}_{h,u}$ is the molar flow rate of steam consumed by turbines, ϑ_u and σ_u are operational parameters for steam turbines, ϵ^{ise}_u is specific isentropic enthalpy change of streams in turbines.

$$J_{h,u} = F_{h,u',u}\Delta H^{comb}_{h,u} - Q_{h,u,u''} - J^{loss}_{h,u} \quad \forall u \in GTT \tag{8}$$

$$\alpha_u F^{steam,max}_{h,u} X_{h,u} + (1 + \beta_u) FB^{steam}_{h,u} = Q_{h,u,u''} - Q^{exh}_{h,u} \quad \forall u \in BOI \tag{9}$$

$$3600E_{h,u} = \frac{6}{5}\frac{1}{\vartheta_u}\left(\epsilon_u^{ise} - \frac{\sigma_u}{F_u^{max}}\right)\left(FT_{h,u}^{steam} - \frac{1}{6}F_u^{max}Y_{h,u}\right) \quad \forall u \in STT \tag{10}$$

3.4. Economic objective

The objective is to obtain maximum profit of the total DNGN, as is expressed in Eq. (11). The first item on the right side of Eq. (11) is product income, the second item is the costs of raw natural gas, the third item is the cost of electricity purchased for compressors, the forth item is steam consumed in CO_2 treating processes, ζ is the price per unit of power, DNG, or steam. π is other fixed costs.

$$OBJ = \sum_h \left[\sum_{u\in GTT\cup STT}(\zeta^s E_{h,u}) - \sum_s\left(\zeta^D F_{h,s}^{DNG}\right) - \sum_{u\in COM\cup CRP}(\zeta^p E_{h,u}) - \sum_{u\in CRP}\zeta^h Q_{h,u}\right] - \pi \tag{11}$$

4. Case study

A DNGN from South China is taken as an example and is investigated in this study. The data for the case is shown in Table1. 3 periods are considered and each period is 168h.

Table 1. Basic data for the case

Period	Maximum Flow (kmol/h)		Composition(CH_4)		Pressure(MPa)
	1#	2#	1#	2#	DNG
H1	3500	2000	0.95	0.90	2.48
H2	3500	2000	0.89	0.91	2.52
H3	3500	2000	0.87	0.90	2.50

The MINLP model includes a large number of bilinear items which makes it difficult to solve within limited computational time. For example, $(M_{h,u,u',c}F_{h,u,u'})$ in Eq. 2 is used to calculate the flowrate of component c from process *u* to *u'*. In order to reduce bilinear items, we initialize the variable $M_{h,u,u',c}$ at the outlet of mixers, and use $F_{h,u,u',c}$ to replace the item $(M_{h,u,u',c}F_{h,u,u'})$. As a result, the original MINLP model can be simplified and only includes the nonlinear equations for compressors. Hence, a strategic iteration approach is created to solve the problem. Through this method, a satisfying result within tolerance range is gained. The solution strategy is illustrated in Fig. 2. The simplified MINLP model is solved using global optimization solver BARON 16.3.4 in GAMS. The model involves 871 variables and 18 binary variables. The computational time is 2.33s.

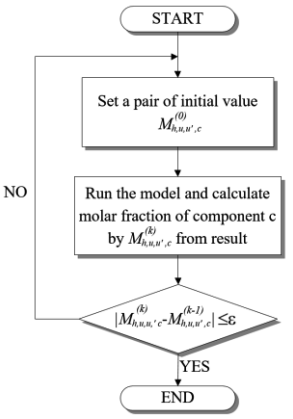

Figure 2 A solution strategy for the model

Table 2. Flowrate of DNG in sources

Period	H1	H2	H3
#1 (kmol/h)	2869	3400	2882
#2 (kmol/h)	2000	2000	2000

The result showed that the total profit reaches $ 5,419,052 within 3 periods. As is shown in Table 2, the DNGN received maximum flowrate from the DNG source 1, while varied the flowrate in different periods from source 2. Moreover, the flowrate in the processing section showed a different blending map and the network varied the power upload rate over elapsing time. The result indicates that the profitability can be improved by changing the operation parameters, the schedule of blending and the load of CO_2 removing process.

5. Conclusions

A large-scale nonconvex MINLP formulation is developed for a DNGN. The planning model integrates CO_2 removing processes, compressor models, transient pipeline transmission models and combined-cycle gas and steam turbine power plant models. Multiple DNG streams and different product specifications are taken into account in the MINLP formulation. A strategy for linearization is applied to the large-scale nonconvex MINLP optimization model and a reasonable result is gained.

Abstract

Lagrangean decomposition has been used to overcome the difficulties in optimizing large-scale supply chain planning models. Decomposing the problem by time periods has been established as a useful technique. In this paper a novel decomposition scheme by products is presented. The decomposition is based on a reformulation of knapsack constraints in the problem. The new approach also allows for simultaneous decomposition by products and time periods, enabling the generation of a large number of subproblems, with the potential benefit of using parallel computing. The case study shows that product decomposition shows a similar performance than temporal decomposition. Selecting different orders of products and aggregating the linking constraints can improve the efficiency of the algorithm.

Keywords: Supply Chain Planning, Lagrange Decomposition, Product Decomposition.

1. Introduction

Tactical planning of supply chains involves the decision of material flows and inventories throughout a network of manufacturing sites and warehouses to satisfy the demand of each customer. To ensure that best decisions are made for the mid-term, optimization models are employed. These models can be very large and hard to solve. To obtain the optimal solution in reasonable time, decomposition techniques such as Lagrangean decomposition (Guignard and Kim, 1987) can be used. In this type of decomposition, the model is broken into subproblems, and the constraints linking them are dualized, i.e. transferred to the objective function with a penalty term known as Lagrange multiplier. The objective is to find the multipliers that yield the tightest bound for the problem.

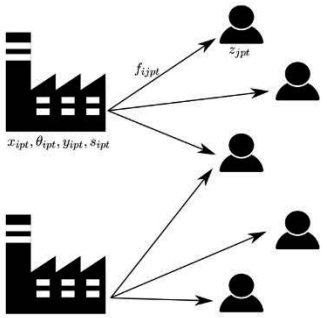
Jackson and Grossmann (2003) use temporal decomposition to solve a multi-site, multi-period planning problem. Terrazas-Moreno et al. (2011) compare spatial and temporal decomposition for the same kind of problem. They conclude that the temporal decomposition gives tighter bounds than spatial decomposition for some types of production planning problems. In temporal decomposition, the problem is decomposed by time periods, which are linked by an inventory balance constraint. There is a natural dynamic structure when decomposing by time periods. The solution of a subproblem at a given time period depends only on the inventory at the end of the previous period.

The horizon of a typical supply chain planning problem is between 6 months to 2 years, usually divided into monthly periods (Brunaud and Grossmann, 2017). At the same time the optimal decisions must be determined for a number of products that ranges typically from 50 to 1,000. However, products do not exhibit the same dynamic structure as time periods; it is not possible to say that one product comes before another. In this paper we show that such a dynamic structure can be exposed through reformulation allowing to decompose the problem by products and apply Lagrangean decomposition. Furthermore, we show that the problem can be decomposed simultaneously by products and time

periods. van Elzakker et al. (2014) propose a decomposition by SKU based on heuristics, different to the exact reformulation followed by Lagrangean decomposition from this paper. We evaluate each decomposition scheme, and explore the effects of subproblem aggregation, linking constraint aggregation, and order of products through a multi-period multi-product production planning example.

2. Problem Description

Given is a demand forecast for a set of products p ∈ P. It is required to determine the optimal production amounts, inventory levels, and shipments to markets j ∈ J at several multi-product facilities i ∈ I. The objective is to maximize the profit for a finite horizon divided in time periods t ∈ T of length L_t. For example, if a plan for 2 months is divided into weekly periods (t), each week has a length of 168 hours (L_t).Since the production rate is different for each product, the production amount is expressed in terms of the number of hours devoted to produce a product in a given period. Fig. 1 describes the problem and the main variables used.



Variables		Parameters	
x_{ipt}	production amount	β_p	price
θ_{ipt}	production time	γ_{ip}	production cost
s_{ipt}	stock	H_i	holding cost
y_{ipt}	production executed	σ_p	setup cost
f_{ijpt}	flow	TC_{ij}	transportation cost
z_{jpt}	Sales	SUT_{ip}	setup time
		R_{ip}	production rate
		D_{jpt}	demand

Figure 1. Problem diagram and nomenclature

The problem is formulated as an MILP from Eqs. (1)-(7), a standard supply chain planning problem (Brunaud and Grossmann, 2017).

$$\textit{Max} \quad \sum_i \sum_j \sum_t \beta_p z_{jpt} - \sum_i \sum_p \sum_t \left(\gamma_{ip} x_{ipt} + H_i s_{ipt} + \sigma_p y_{ipt}\right) - \sum_i \sum_j \sum_p \sum_t TC_{ij} f_{ijpt} \tag{1}$$

$$s.t. \quad s_{ipt} = s_{ipt-1} + x_{ipt} - \textstyle\sum_j f_{ijpt} \quad \forall ipt \tag{2}$$

$$\sum_p \theta_{ipt} + SUT_{ip} y_{ipt} \le L_t \quad \forall it \tag{3}$$

$$R_{ip}\theta_{ipt} = x_{ipt} \quad \forall ipt \tag{4}$$

$$\sum_i f_{ijpt} = z_{jpt} \quad \forall jpt \tag{5}$$

$$z_{jpt} \le D_{jpt} \quad \forall jpt \tag{6}$$

$$x_{ipt}, \theta_{ipt}, s_{ipt}, f_{ijpt}, z_{jpt} \ge 0, y_{ipt} \in \{0,1\} \tag{7}$$

3. Temporal Decomposition

In temporal decomposition, the goal is to divide the problem into individual time periods, which are linked by inventory variables. In Fig. 2 the inventory balance constraint is represented by the nodes, and the inventory continuity constraint ensuring that the final inventory at a given period is equal to the initial in the next period, is represented by the box. The problem can be decomposed dualizing the inventory continuity constraint.

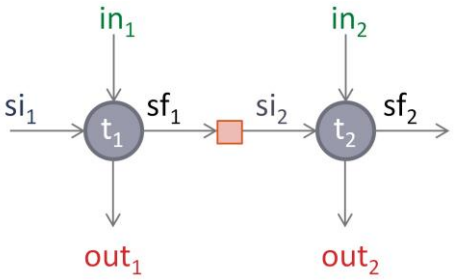


Figure 2. Representation of temporal linking constraints

Following the representation from Fig. 2 the previous model needs to be reformulated including variables to represent the initial (*si*) and final stock (*sf*). With these variables, Eq. (2) is replaced by Eqs. (8) and (9). Eq. (9) is then dualized to decompose the problem. The term $\lambda_{ipt}(sf_{ipt} - si_{ipt+1})$ is added to the objective function for each of the constraints represented by Eq. (9).

$$sf_{ipt} = si_{ipt} + x_{ipt} - \sum_j f_{ijpt} \quad \forall ipt \tag{8}$$

$$sf_{ipt} = si_{ipt+1} \quad \forall ipt \tag{9}$$

4. Product Decomposition

Unlike time periods, products do not have the same dynamic structure. They are usually sharing capacity in a knapsack constraint, whether is production, transportation, or inventory capacity. To reformulate the problem and obtain an equivalent dynamic structure, consider a planner that optimizes one product at a time. After the first flows and inventory for the first product have been optimized, the planner needs to know how much capacity is left for the next product. This process is shown in Fig. 3. We reformulate Eq. (3) according to the representation in Fig. 3 to obtain Eqs. (10) and (11), where ci_{ipt} represents the number of available hours for product p, and ci_{ipt} is the number of available hours after planning product p.

$$cf_{ipt} = ci_{ipt} - \theta_{ipt} - SUT_{ip}y_{ipt} \quad \forall ipt \tag{10}$$

$$cf_{ipt} = ci_{i(p+1)t} \quad \forall ipt \tag{11}$$

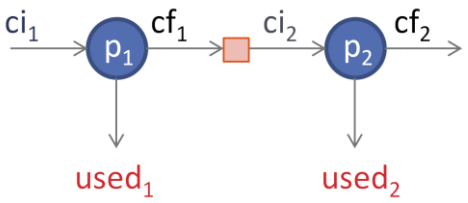

Figure 3. Product decomposition representation

The production capacity is a local variable for each product. The initial available hours for the first product is the entire length of the period L_t. Note that in order to write down Eq. (11) an arbitrary order is given to the products. When Eq. (11) is dualized, the problem is decomposed into subproblems for each product. The dualization adds the term $\mu_{ipt}\left(cf_{ipt} - ci_{i(p+1)t}\right)$ to the objective function for each constraint defined by Eq. (11).

Note that once the problem is decomposed, each subproblem is still a multi-period problem. Thus, it can also be decomposed by time periods following the reformulation from the previous section. This leads to a simultaneous decomposition by products and time periods where a subproblem can be as small as containing a single product and a single time period, opening the door to generating thousands of subproblems if desired.

5. Case Study

The computational performance of the proposed decomposition schemes is assessed through their application on the problem described in Section 2, motivated by an industrial application and described in Terrazas-Moreno, et al. (2011). The problem studied has 6 manufacturing sites and 10 markets. The number of products and time periods was set to 6 and 20, keeping the number of products equal to the number of time periods to ensure a fair comparison between product and temporal decomposition. Each time period represents 720 hours. The MILP formulations are modeled in JuMP and solved with Gurobi 7.5 in an Intel i7 machine with 16 Gb of RAM. Problem sizes are shown in Table 1.

Table 1. Case study problem sizes

Problem Size	Constraints	Variables	Binaries
6	2,232	4,032	216
20	24,800	44,800	2,400

5.1. Decomposition Schemes Comparison

Product decomposition (P), temporal decomposition (T), and simultaneous product and temporal decomposition (PT) were compared using two options to initialize the Lagrange multipliers: (1) zero ($\lambda = 0$), and (2) the multipliers obtained from solving the LP relaxation (λ = LP). The multipliers where updated using the subgradient method. The results for the wall clock time and optimality gap for 50 iterations are presented in Table 2.

Even though the performance of the product decomposition was superior in the examples presented, in other cases the temporal decomposition obtained a lower gap. It is not possible to conclude that one decomposition scheme is superior to the other. The simultaneous product and temporal decomposition does not result in an increased

performance for small problems, because with a larger number of subproblems there is a larger number of multipliers that need to optimized.

Table 2. Comparison of decomposition schemes for 50 iterations

	λ = 0			λ = LP		
	P	T	PT	P	T	PT
Size = 6						
Time (s)	65	144	4	288	12	17
Gap (%)	6.8	6.1	19	2.7	12	13
Size = 20						
Time (s)	106	905	18	132	131	152
Gap (%)	8.8	18	62	40	76	146

5.2. Aggregation of linking constraints

Since the difficulty of the Lagrangean decomposition algorithm lies in finding the optimal set of multipliers giving the tightest bound, the algorithm can benefit from reducing the number of multipliers. One way to accomplish this while keeping the size of the subproblems, is to aggregate the linking constraints before dualization. For example, Eq. (9) linking initial and final inventories can be replaced by the surrogate constraint from Eq. (12).

$$\sum_i sf_{ipt} = \sum_i si_{ipt+1} \quad \forall pt \tag{12}$$

The results of applying this aggregation for the three decomposition schemes is presented in Table 3. The column header indicates the summation indices of the aggregated constraint. For example, (ip) indicates sum Eq. (9) over sites and products.

Table 3. Effect of linking constraint aggregation

	P				T				PT	
	none	i	t	it	none	i	p	ip	none	ip/it
Size = 6										
Time (s)	288	6	2476	6	9	48	62	27	17	17
Gap (%)	2.8	0.0	1.28	0.0	12	0.6	0.3	2.4	13	9.2
Size = 20										
Time (s)	132	1,072	114	300	131	65	156	49	151	160
Gap (%)	40	20	24	41	76	124	42	2.8	146	57

The results show that the aggregation can help in improving the performance of the algorithm. The improvements are problem dependent and require experimentation.

5.3. Order of products

As mentioned before, in order to decompose the problem by products, an arbitrary order is given to the set. This effect was explored by solving the problem of size 6 for 1,000 random orderings of the products. The gap obtained after 10 iterations is presented in the histogram in Fig. 4. With most orderings, the gap obtained is less than 10%. However, there is a significant number of orderings that yield a large gap with this algorithm

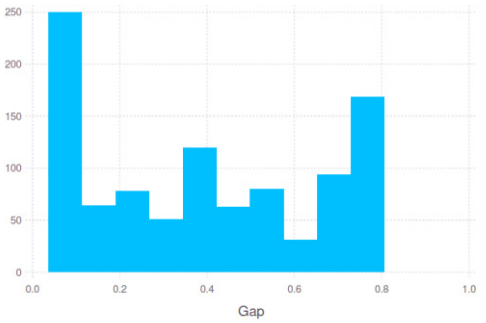

Figure 4: Effect of ordering of products

6. Conclusions

Product decomposition is a novel decomposition scheme that can potentially lead to improved results when applied to Lagrangean decomposition. Decomposing the problem by products is not consistently better or worse than decomposing by time periods. This is explained by the mathematical equivalency of both reformulations. This novel decomposition scheme is then presented as an alternative to modelers to experiment during the implementation of Lagrangean decomposition. Simultaneous product and temporal decomposition allows to generate a larger number of smaller subproblems that can be solved faster. The number of subproblems used is also a matter of experimentation in the implementation phase of the algorithm.

Abstract

Uncertainty and variability are inherent characteristics of industrial environments that affect production schedules and could turn them unfeasible or economically unattractive. Process-inherent uncertainty, one of the multiple stochasticity sources, influences task processing times, transforming them into one of the main uncertain parameters. This work proposes a scheduling approach to consider this situation in a proactive fashion at the decision stage, without resorting to the generation of scenarios. It relies on a Constraint Programming (CP) model that focusses on the Capacity Constrained Stage (CCS) to reduce its complexity and size. The proposal is tested with various instances of three case studies, showing that the approach is computationally efficient. The attained agendas can effectively absorb the processing times variabilities in an efficient way, exhibiting a resilient behaviour. To assess the schedules, they are compared with those reached by a deterministic CP formulation and with the agendas obtained by means of another proactive methodology proposed by the same authors.

Keywords: Scheduling, Uncertain processing times, Constraint programming, Theory of constraints, Multiproduct multistage batch plants.

1. Introduction

Industrial schedulers daily face uncertainty and unforeseen events that affect production agendas: incoming rush orders, changes in resource availability, raw materials late arrivals, stochasticity of processing times and other parameters, etc. Particularly, processing times variability is one of the most common issues that could lead to the generation of idle and wait times. While the first ones cause equipment under-utilization and reduce plant productivity, wait times can generate order delays and/or batch rejections due to material deterioration. Additionally, unexpected variations on processing times could lead to infeasible agendas and the need to frequently update them. Every time a schedule is revised, a phenomenon called shop-floor nervousness may occur and inefficiencies may be aggravated. To minimize this negative effect, a resilient agenda, able to absorb the influence of uncertain processing times without the need of introducing major changes, is pursued. To carry out this proactive scheduling, knowledge of uncertainty has to be considered at the decision stage.

Several academic approaches have been proposed to deal with uncertain processing times, such as fuzzy programming (Balasubramanian and Grossmann, 2003), genetic algorithms (Bonfill et al., 2008), two-stage stochastic programming (Bonfill et al., 2005), and constraint programming (Novara and Henning, 2017). Several techniques meant to cope with uncertainty (Li and Ierapetritou, 2008) rely on the generation of

scenarios, which increases the problem size, its computational expense, and prevents the solution of real-size problems. This contribution tackles uncertainties in an a priori manner, during the decision stage, by proposing a methodology able to generate resilient agendas that minimize the expected total tardiness. The short-term scheduling problem of multiproduct, multistage batch plants with uncertain operation times is addressed in a proactive fashion by means of a novel Constraint Programming (CP) model that makes use of Theory of Constraints (TOC) concepts. The model, which does not rely on the generation of scenarios or worst case formulations, takes advance of capacity limited resources; in particular, the capacity constrained stage (CCS), in order to minimize the complexity of the resulting CP model.

The remainder of this paper is organized as follows. The approach foundation is presented in the next section, including a description of how to capture uncertainties in the processing times. Then, the stochastic CP-TOC proposal is described, followed by a discussion of the results reached when applying the model to various instances of three case studies. Final remarks and future work are included in the last section.

2. Methodology

According to the TOC, every system has a capacity constrained resource (Spencer and Fox, 1995), whose operation subordinates that of the other resources. Tasks at this resource have to be carefully managed in order to prevent it becoming a bottleneck resource, with all its negative consequences. In this work it is assumed that multiproduct, multistage batch plants have a stage (CCS) that behaves as a capacity constrained resource. The proposed approach tries to prevent that delays due to processing time variabilities, taking place in units located upstream of the CCS, may introduce deferrals at this critical stage that can no longer be recovered.

Provided that processing times uncertainty directly affects the end time of each processing task, the proposed methodology associates a stochastic variable with the completion time of each batch. The value of this variable, which is named *end time subject to deviation* (*et-StD*$_b$), has a P probability of occurrence. For any given batch b, the accurate representation of *et-StD*$_b$ in a CP model requires a significant CPU effort during the solution stage. Nevertheless, such variable can be estimated in a practical way. The approximated variable that participates in the CP model is named *eetStD*$_b$, *estimated end time of batch b*. This variable is calculated as the expected end time of batch b plus n times the standard deviation of this estimated completion time, with n being the number of standard deviations associated with a P probability. The expected end time of batch b is computed by adding nominal processing times, that are assumed to have normal probability distributions, as well as idle times and changeover/setup times, which are supposed to have a deterministic behaviour. Therefore, the expected end time is also presumed to have a normal distribution. In order to estimate the *eetStD*$_b$ variable value with a reduced computational load, the CP-TOC model estimates the end time of batch b by taking into account the variance associated with the end time of batch b in a certain unit u belonging to the CCS, as well as the variance of the processing times of batch b in units located downstream the CCS.

3. New CP-TOC stochastic model

Uncertainties in the processing times are handled by means of two associated schedules that are simultaneously built. The first one, the production schedule, is created by just

using nominal processing times. It does not resort to buffer times or overestimated (conservative) processing times. Therefore, this agenda does not attempt to compensate possible delays that may result from the realizations of the uncertainties. Nevertheless, the assignment and sequencing decisions that are made try to better anticipate positive variabilities (greater than the nominal processing times) and their impact on total tardiness. The second schedule, which is not an operational agenda, is employed to capture the processing time variances of those tasks that are assigned to each equipment unit belonging to the CSS. When focusing on the CCS the structure of both schedules is similar; they have the same task-unit assignments and task sequencing. However, in the variance agenda, the length of any element takes into account the variance of the associated task ($task_{b,u}$) processing time, plus a fraction of the variance of the processing times of those activities required by batch *b* and located upstream of the CCS.

3.1. Model implementation

The CP model was developed using the OPL programming language, supported by the IBM ILOG CPLEX Optimization Studio environment (IBM ILOG, 2013).

Sets/Indexes. *B/b*: batches to be produced within the planning horizon. UC_u/-: units of stage s+1, which are unconnected to unit u, belonging to stage s. F_p/-: products that are forbidden as successors of product *p* when assigned to the same unit. *P/p*: products to be manufactured. *S/s*: processing stages. *U/u*: equipment units.

Parameters. $co_{u,p,p'}$: changeover time between products *p* and *p'* in unit *u*. dd_b: batch *b* due-date. *n*: number of standard deviations associated with probability *P*. $pt_{p,u}$: nominal processing time required by a batch of product *p* in unit *u*. $ptVar_{p,u}$: variance of $pt_{p,u}$.

Variables. $eetStD_b$: *et-*StD_b estimation (float). $nomEt_b$: nominal end time of batch *b* (integer). $stTask_{b,s}$: processing task of batch *b* at stage *s* (interval). $task_{b,u}$: processing task of batch *b* in unit *u* (interval). $unitBatchSeq_u$: sequence of the $task_{b,u}$ variables related to unit *u*, each one characterized by the *p* product concerning batch *b* (sequence). $var_{b,u}$: variance associated with the processing time of batch *b* in unit *u* and its preceding operations (interval). $varCCS_{b,u}$: variance of the processing time of batch *b* in unit *u* belonging to the CCS (interval). $varDS_b$: variance of the processing times of batch *b* in units located downstream of the CCS (integer). $varEnd_b$: variance associated with the end time of batch *b* in a given unit belonging to the CCS (integer). $varSeq_u$: sequence of the $var_{b,u}$ variables related to unit *u*, each one characterized by the *p* product concerning batch *b* (sequence). $varUS_b$: variance of the processing times of batch *b* in those units located upstream of the CCS (integer). *totalTardiness*: sum of the batches tardiness, each one computed as the non-negative difference between $eetStD_b$ and dd_b (float).

Constraints. Eq.(1) obliges each batch to be assigned to a single processing unit at each stage. Eq.(2) ensures the fulfillment of precedence relationships between consecutive operations of any batch *b*. Topology restrictions are captured by means of Eq.(3). Eq.(4) avoids overlapping the execution of tasks in any unit *u* and simultaneously inserts changeover times between successive tasks assigned to such unit. Eq.(5) avoids forbidden sequences with the aid of sequence variables and the *typeOfNext* construct (IBM ILOG, 2013).

$$alternative\left(stTask_{b,s}, all(u \in U_s)\ task_{b,u}\right), \qquad \forall\, s \in S, \forall\, b \in B \tag{1}$$

$$endAtStart\left(stTask_{b,s}, stTask_{b,s'=s+1}\right), \quad \forall\, b \in B, \forall\, s, s' \in S, s \neq Card(S) \tag{2}$$

$$minl\left(endOf\left(task_{b,\mathrm{u}}\right), endOf\left(task_{b,\mathrm{u}'}\right)\right) = 0, \forall\, b \in B, \forall\, \mathrm{u}' \in UC_u, \forall\, u, \mathrm{u}' \in U \quad (3)$$

$$noOverlap(unitBatchSeq_u, \mathrm{co}), \qquad \forall\, u \in U \quad (4)$$

$$typeOfNext\left(unitBatchSeq_u, task_{b,u}\right) \neq p', \forall (p, p')\ \in Fp, \forall\, u \in U, \forall\, b \in B_p \quad (5)$$

Eq.(6) and (7) express the calculation of the variables associated with the variance of the processing times of batch *b* in those units located upstream and downstream of the CCS, respectively, while Eq.(8) describes the variance related to the processing time of batch *b* in the assigned unit of the CCS. Eq.(9) and (10) capture the variance pertaining to the end time of batch *b,* when processed in unit *u* belonging to the CCS.

$$varUS_b = \sum_{\forall\, u \in U_s, \forall\, s \in \mathrm{S}, s < \mathrm{CCS}} presenceOf\left(task_{b,u}\right) \cdot ptVar_{b,u}, \forall\, b \in B \quad (6)$$

$$varDS_b = \sum_{\forall\, u \in U_s, \forall\, s \in \mathrm{S}, s > \mathrm{CCS}} presenceOf\left(task_{b,u}\right) \cdot ptVar_{b,u}, \forall\, b \in B \quad (7)$$

$$varCCS_{b,u} = presenceOf\left(task_{b,u}\right) \cdot ptVar_{b,u}, \quad \forall\, b \in B, \forall\, u \in U_{s=CCS} \quad (8)$$

$$sizeOf\left(var_{b,u}\right) = presenceOf\left(var_{b,u}\right) \cdot \left(maxl\left(0, varUS_b - startOf\left(var_{b,u}\right)\right)\right) + varCCS_{b,u}\ , \forall\, b \in B, \forall\, u \in U_{s=CCS} \quad (9)$$

$$varEnd_b = \max_{\forall\, u \in U_s, s \in \mathrm{S}, s = CCS}\left(endOf(var_{b,u})\right) \quad (10)$$

Eq.(11) - (13) relate the operational agenda to the variance schedule. Whenever the interval variable *task*$_{b,u}$, describing the processing task of batch *b* in unit *u*, participates in the solution, the corresponding interval variable capturing the variance of this task has to be incorporated too, as shown in Eq.(11). Eq.(12) prevents the overlapping of interval variables describing variances. Eq.(13) enforces those interval variables representing processing and variance tasks to follow the same sequence in each unit.

$$presenceOf\left(task_{b,\mathrm{u}}\right) = presenceOf\left(var_{b,u}\right), \ \forall\, b \in B, \forall\, u \in U_s, \mathrm{s} = CCS \quad (11)$$

$$noOverlap(varSeq_u), \qquad \forall\, u \in U_S, \mathrm{s} = CCS \quad (12)$$

$$typeOfNext\left(unitBatchSeq_u, task_{b,u}\right) = typeOfNext\left(varSeq_u, \mathrm{var}_{b,u}\right), \ \forall (p, p') \forall\, b \in B, \forall\, u \in U_s, \mathrm{s} = CCS \quad (13)$$

Eq.(14) captures the nominal end time expected for each batch *b*. Eq.(15) shows how the estimated end time of any batch *b* is calculated by combining deterministic and stochastic variables. Finally, Eq.(16) describes the expected total tardiness, which is the objective function to be minimized.

$$nomEt_b = \max_{\forall\, u \in U}\left(endOf(task_{b,u})\right), \qquad \forall\, b \in B \quad (14)$$

$$eetStD_b = nomEt_b + n \cdot \sqrt{(varEnd_b + varDS_b)}\ , \forall\, b \in B \quad (15)$$

$$totalTardiness = \sum_{\forall\, \mathrm{b} \in B} maxl(0, eetStD_b - dd_b) \quad (16)$$

4. Results

The CP-TOC model was validated by means of three case studies (C1-C3) available in the literature, which were slightly adjusted and are described in detail in Novara and Henning (2017). They correspond to the scheduling of multiproduct, multistage batch plants operating under a NIS-UW policy, and considering the expected total tardiness as the objective function. **C1:** It corresponds to a facility having 5 processing stages and 12 non-identical units. Sequence dependent changeovers and topology constraints are considered. **C2:** It is based on a multiproduct batch plant having 5-stages, 25 non-identical units and topological constraints. Product orders and processing units are characterized by release and ready times, respectively. In addition, some orders cannot be processed in certain units and there are forbidden processing sequences. **C3:** The facility has 5 stages with 20 dissimilar processing units. Fifty product orders are to be scheduled. Sequence dependent changeovers are considered.

The attained agendas have been contrasted by means of simulation to test their resilience to uncertainty (see Table 1). Stochastic processing times were described by means of various asymmetrical triangular distributions mimicking the behavior of real plants, with more delays than anticipations. Each distribution was obtained by adopting the deterministic processing time as the mode. The lower value was randomly created by subtracting to the mode the result of multiplying its value by an aleatory number that pertains to the [0, *inf*] interval. Likewise, the upper limit was obtained by adding to the mode the result of multiplying its value by a random number pertaining to [0, *sup*]. Different values to the *inf* and *sup* parameters have led to distinct problem instances.

Table 1. Comparison of deterministic and stochastic approaches by means of simulation. Expected total tardiness is reported

Case study	inf	sup	CP deterministic model (Novara and Henning, 2017)	Stochastic approaches	
				CP model (Novara and Henning, 2017)	CP-TOC approach
C1a	0.050	0.12	1.8	1.2	0.0
C1b	0.075	0.18	6.4	3.8	0.0
C1c	0.100	0.24	14.5	0.1	0.0
C1d	0.125	0.30	24.7	14.4	0.3
C1e	0.150	0.36	39.2	23.4	1.3
C1f	0.175	0.42	58.7	33.9	5.5
C1g	0.200	0.48	83.2	45.1	8.9
C1h	0.225	0.54	105.2	56.8	12.2
C1i	0.250	0.60	148.0	74.1	23.2
C1j	0.275	0.66	191.4	94.3	39.0
C2	0.200	0.50	739.1	693.2	0.0
C3	0.070	0.20	1307.4	112.8	223.2

As seen in Table 1, all the solutions obtained by means of the CP-TOC model exhibit a better behavior than the ones attained by the deterministic CP formulation. In addition, in 11 out of 12 examples the solutions reached by means of the current approach are of better quality (four of the resulting schedules are optimal) than the ones reported in the previous stochastic proposal (Novara and Henning, 2017) (see Fig. 1). The ten instances corresponding to Case 1 show that the new approach renders more resilient agendas in a wide range of processing time variabilities (see Fig. 2). The solution of Case 3 is the only one exhibiting worse quality. Nevertheless, it is a good solution that shows an improvement with respect the deterministic one, in a similar fashion to the all the other

examples. It is worth mentioning that the Case 3 solution obtained with the previous stochastic approach had an unusual high performance.

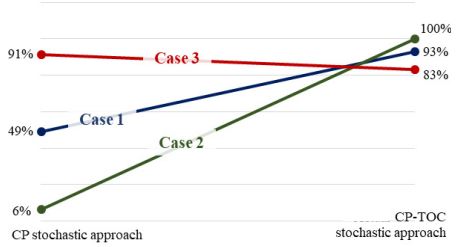

Fig. 1. Improvement percentage of the two stochastic approaches solutions compared with the deterministic one.

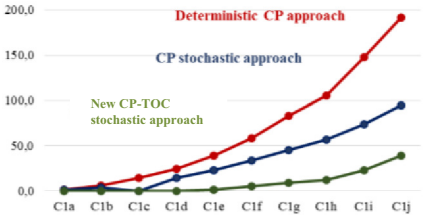

Fig. 2. Total tardiness for increasing processing times variability scenarios (10 instances of C1)

5. Conclusions and future work

This paper presents a novel CP-TOC stochastic scheduling methodology that addresses processing time uncertainty in an a priori fashion. When contrasted with another CP stochastic proposal (Novara and Henning, 2017), 11 out of 12 examples rendered better solutions (several of which are optimal) with less computational effort and without providing good quality initial solutions. It is worth mentioning that the lower computational expense is achieved due to a reduction in the model size. The CP-TOC model has $Card(B) \cdot (Card(U) - Card(U_{CSS}))$ less interval variables and $(Card(U) - Card(U_{CSS})$ less sequence variables than the CP stochastic model proposed by Novara and Henning (2017). In addition, the attained schedules exhibit more resiliency and are better prepared to soften uncertainty consequences. This conclusion was accomplished after simulating the agendas obtained with this proposal and the ones reached with a deterministic CP model and a stochastic one under various uncertainty conditions. The proposed CP-TOC model has the same inherent limitations that were discussed by Novara and Henning (2017). Future work will extend the approach to address other intermediate storage/inter-stage waiting policies.

Abstract

Electrolysis is a high energy consumption production process in aluminium industry. This paper investigates the electrolysis cells scheduling problem considering the crucible and caster. A precedence-based model and a novel unit-specific event based continuous-time mixed integer programming model are proposed to describe the problem. The two models are solved by CPLEX. Computational experiments show that the proposed continuous-time formulation is efficient when comparing with a precedence-based model for medium and large size instances.

Keywords: aluminium electrolysis, scheduling, precedence-based, unit-specific event based, continuous-time.

1. Introduction

Aluminium is the most widely used nonferrous metal, the production process of aluminium includes bauxite mining, alumina production, electrolysis aluminium, castings, rollings, the production of consumer products and recycling. In the electrolysis aluminium production line, more than 99% pure molten aluminium is formed at the cathode deposited at the bottom of the electrolytic cell, and is tapped from the cell into a crucible by a vacuum siphoning system. The molten metal is transported and poured into a holding furnace and caster to be cast into ingots, extrusion or rolling ingots.

In a typical aluminium smelter, there may be hundreds of electrolysis cells. Each crucible taps the metal from up to three cells that contain different purity of the molten aluminium. The capacity of the holding furnace is more than three times the crucible, so there can be several different crucibles feeding one holding furnace. The molten aluminium which is mixed and stabilized synchronously in one holding furnace is called a charge. Therefore, both crucible and holding furnace are batch production mode. Therefore, in the aluminium electrolysis process, the production schedule is to form the batch tapping of the cells into crucibles and arrange batch feeding of the crucibles into holding furnaces, considering the constraints of the electrolysis and cast.

Ryan (1998) formulated the tapping of the cells problem as a set-partitioning model and solved it by the LP relaxation. Piehl (2000) used the revised simplex method and branch and bound with a constraint branching approach to solve the similar cell batching problem. Prasad et al. (2006) provided a MILP model for the scheduling of aluminium

casts of different alloys with respect to the actual number of batches to be processed in multistage. For the formulation of the scheduling problem, we refer to Floudas and Lin (2004) and Harjunkoski et al. (2014).

The remainder of this paper is organized as follows. In Section 2, a precedence-based model is presented for this problem. In Section 3, a novel unit-specific event based continuous-time mixed integer programming model are proposed to describe the problem. Section 4 reports the experimental results of the two models solved by CPLEX. Finally, Section 5 presents the conclusions.

2. Precedence-based model

To formulate the proposed problem, the following notations are given. The indices of electrolysis cells are i and j, m is index of crucible, r is index of the batches of a crucible, and k, h are indices of holding furnaces. N, C, Cl, and B are sets of electrolysis cells, crucibles, batches of crucible, and batches of holding furnace, respectively. $Cap1$ is the capacity of crucible, $Cap2$ is the capacity of holding furnace. p_{im} is the processing time of cell i on crucible m. t_{ik} is the processing time of cell i on furnace k. a_{ij} is the setup time of cells i and j in a furnace. And M is a large number.

For 0-1 decision variables, x_{imr} is whether cell i is assigned to batch r of crucible m, y_{ik} is whether cell i is assigned to furnace k, z_{kh} is whether k is followed by h directly. For continuous decision variables, S_{mr} is starting time of batch r of crucible m, C_{mr} is completion time of batch r of crucible m, R_k is release time of furnace k, Sl_k is starting time of furnace k, Cl_k is completion time of furnace k, pl_k is processing time of furnace k, d_{kh} is the setup time of furnaces k and h. Using the above symbols, the precedence-based model is constructed as follows:

Minimize $C_{\max}$

s.t.
$$\sum_{m\in C}\sum_{r\in Cl} x_{imr} = 1 \qquad \forall i \in N \tag{1}$$
$$\sum_{i\in N} x_{imr} = Cap1 \qquad \forall m \in C, r \in Cl \tag{2}$$
$$\sum_{k\in B} y_{ik} = 1 \qquad \forall i \in N \tag{3}$$
$$\sum_{i\in N} y_{ik} = Cap2 \qquad \forall k \in B \tag{4}$$
$$S_{m1} = 0 \qquad \forall m \in C \tag{5}$$
$$S_{mr} \geq C_{m,r-1} \qquad \forall m \in C, r \in Cl \tag{6}$$
$$C_{mr} = S_{mr} + \sum_{i\in N} x_{imr} \cdot p_{im} \qquad \forall m \in C, r \in Cl \tag{7}$$
$$R_k + (1 - y_{ik}) \cdot M \geq C_{mr} \cdot x_{imr} \qquad \forall i \in N, m \in C, r \in Cl, k \in B, h \in B \tag{8}$$
$$Sl_k \geq R_k \qquad \forall k \in B \tag{9}$$
$$p_k = \sum_{i\in N} t_{ik} y_{ik} \qquad \forall k \in B \tag{10}$$
$$Cl_k = Sl_k + p_k \quad \forall k \in B \tag{11}$$
$$z_{kk} = 0 \quad \forall k \in B \tag{12}$$
$$z_{kh} + z_{hk} = 1 \qquad \forall k \in B, h \in B, k < h \tag{13}$$
$$Sl_h + (1 - z_{kh}) \cdot M \geq Cl_k + d_{kh} \qquad \forall k \in B, h \in B, k \neq h \tag{14}$$
$$Sl_k + z_{kh} \cdot M \geq Cl_h + d_{hk} \qquad \forall k \in B, h \in B, k \neq h \tag{15}$$
$$d_{kh} \geq y_{ik} . y_{jh} . a_{ij} \qquad \forall i \in N, j \in N, k \in B, h \in B \tag{16}$$
$$C_{\max} \geq Cl_k \qquad \forall k \in B \tag{17}$$

$$y_{ik} \geq y_{jk} - M(2 - x_{imr} - x_{jmr}) \qquad \forall i \in N, m \in C, r \in Cl, k \in B, h \in B \tag{18}$$

$$y_{ik} \leq y_{jk} + M(2 - x_{imr} - x_{jmr}) \qquad \forall i \in N, m \in C, r \in Cl, k \in B, h \in B \tag{19}$$

$$x_{imr}, y_{ik}, z_{kh} \in \{0,1\} \quad i \in N, m \in C, r \in Cl, k \in B, h \in B \tag{20}$$

Constraints (1) ensure that each cell must be assigned to one batch of a crucible. Constraints (2) ensure that the total amount of aluminium assigned to every crucible is equal to the capacity *Cap*1. Constraints (3) ensure that each cell must be assigned to a furnace. Constraints (4) ensure that the total amount of aluminium assigned to every furnace is equal to the capacity *Cap*2. Constraints (5) ensure the starting time of the first batch in a crucible is zero. Constraints (6) ensure the starting time of a batch in a crucible is larger than or equal to the completion time of the previous batch in the same crucible. Constraints (7) represent the completion time of a batch in a crucible is equal to the starting time plus the processing time. Constraints (8) represent the release time of a batch in a furnace is larger than or equal to the completion time of each cell that assigned to this batch. Constraints (9) ensure the starting time of a batch in a furnace is larger than or equal to its release time. Constraints (10) represent the processing time of a batch in a furnace is equal to the processing time of every cell that assigned to it. Constraints (11) represent the completion time of a batch in a furnace is equal to the starting time plus the processing time. Constraints (12) and (13) represent the relationship between two directly adjacent batches in a furnace. Constraints (14) and (15) ensure the starting time of a batch in a furnace is larger than or equal to the completion time of the previous batch plus their setup time. Constraints (16) represent the setup time of two batches in a furnace is the largest setup time among the cells that assigned to them. Constraints (17) ensure the makespan is larger than or equal to each batch of the furnaces. Constraints (18) and (19) ensure two cells are assigned to the same batch of a furnace if they were assigned to the same batch of a crucible. Constraints (20) specify the integrity and continuous conditions on the decision variables.

3. Unit-specific event based model

The notations of unit-specific event based continuous time model are given as follows. *i* is the index of cells, *m* is the index of crucibles, *k* is the index of furnaces. *n* is the index of event point for crucibles, *n'* is the index of event point for furnaces. Correspondingly, *I* is the set of cells, *C* is the set of crucibles, *B* is the set of furnaces, *N* is the set of event point for crucibles, *N'* is the set of event point for furnaces.

For the parameter, $p(i,m)$ is the processing time when assigning *i* to *m*, $t(i,k)$ is the processing time when assigning *i* to *k*. $tTotal(k,n')$ is the processing time of a batch in a furnace, $a(i,i')$ is the setup time between two batches. *Cap*1 is the capacity of crucible, *Cap*2 is the capacity of holding furnace.

0-1 decision variables include: $w(i, m, n)$ is whether assign cell *i* to the event point *n* of crucible *m*. $w'(i, k, n')$ is whether assign cell *i* to the event point *n'* of furnace *k*. $v(m, n)$ is whether the event point *n* of crucible *m* is empty. $v'(k, n')$ is whether the event point *n'* of furnace *k* is empty. And the continuous variables include: $S(i, m, n)$ is the starting time of cell *i* in event point *n* of crucible *m*. $C(i, m, n)$ is the completion time of cell *i* in event point *n* of crucible *m*. $Sl(i, k, n')$ is the starting time of cell *i* in event point *n'* of furnace *k*. $Cl(i, k, n')$ is the completion time of cell *i* in event point *n'* of furnace *k*.

$d(n',n'+1)$ is the setup time between two batches of a furnace. Based on the above notation, the continuous time model is given as follows.

Constraints (21)-(32) represent the assignment and scheduling of cells to crucibles. Constraints (33)-(45) represent the assignment and scheduling of cells to furnaces. Constraints (46) ensure the starting time of a batch in a furnace is larger than or equal to the completion time of a batch in a crucible. Constraints (47) ensure two cells are assigned to the same batch of a furnace if they were assigned to the same batch of a crucible. Constraints (48) and (49) represent the relationships of makespan and the starting/completion times.

4. Computational experiments

To evaluate the proposed models, randomly instances are generated and solved by CPLEX 12.5. The scale of problem mainly depends on the number of electrolysis cells, crucibles and furnaces. The process parameters are randomly generated according to the scope of the practical production data in an aluminium fabrication company of China. It is assumed that the number of the electrolysis cells in the crucible batch and the furnace batch is fixed. All computational experiments are performed on a PC with 64 bits of Intel Core i5 2.0GHz CPU. The maximum computation time of CPLEX is set to 5000 seconds. Table 1 gives 12 groups of instances. Table 2 are results that compare the computational time and the best value between precedence-based model and continuous time model.

Table 1 The scale of computation instances

Instances	Number of cells	Number of crucibles	*Cap*1	Number of batches of a crucible	Number of furnaces	*Cap*2
1	12	2	3	2	2	6
2	18	2	3	3	2	9
3	18	2	3	3	3	6
4	24	2	3	4	4	6
5	24	4	3	2	2	12
6	27	3	3	3	3	9
7	36	3	3	4	6	6
8	36	3	3	4	4	9
9	36	4	3	3	3	12
10	45	3	3	5	5	9
11	48	4	3	4	8	6
12	48	4	3	4	4	12

Based on the results shown in these tables, the following conclusions could be made. For small and medium-scale instances, the average computational time of continuous time model is smaller than the precedence-based model. However, precedence-based

model could obtain better LB for more instances and could obtain better solutions for some instances. When the size of the instances increases, for an instance of the same scale, the gap of continuous time model is smaller than precedence-based model, which indicates that continuous time model has a tighter lower bound than precedence-based model.

Table 2 The statistics of experimental result

Ins.	Precedence-based model				Continuous time model			
	opt	Time(s)	LB	Gap (%)	opt	Time(s)	LB	Gap (%)
1	98.6	20.75	97.7	0.93	97.3	0.31	97.2	0.09

9	234.3	5000.00	211.7	9.65	235.7	3765.59	233.4	0.98
10	309.6	5000.00	297.3	3.97	307.3	1075.65	307.0	0.09
11	672.0	5000.00	613.9	8.65	671.8	5000.00	666.5	0.79
12	568.3	5000.00	501.8	11.7	564.5	5000.00	555.8	1.54

5. Conclusions

This paper studies the batch scheduling problem of aluminium electrolysis and caster process. Precedence-based and unit-specific event based models are proposed to formulate the problem. Computational experiments are carried out using CPLEX solver. The experimental results show that both models can get the optimal solutions within a reasonable time for small and medium scale instances, and the proposed continuous time model could be used to obtain the optimal solutions for larger scale instances.

Abstract

Demand response (DR) scheduling of air separation units (ASUs) can be beneficial to both process and grid operations. It requires frequent changes in production schedules and the integration of dynamics and control in scheduling calculations. Model dimensionality and nonlinearity make this a challenging task, especially under practical execution-time constraints. This work focuses on DR operation of an industrial ASU system. Historical data are used to construct scheduling-relevant, Hammerstein-Wiener models of (MPC) closed-loop plant dynamics, which are then embedded in a DR scheduling calculation formulated as a nonlinear dynamic optimization problem. The approach ensures dynamic feasibility of the optimal schedule and exhibits excellent computational performance, demonstrated in an industrial case study.

Keywords: Integrated Scheduling and Control, Model Identification, Air Separation

1. Introduction

Air separation units (ASUs) provide important feedstocks to several major manufacturing industries. For example, argon is used in welding, oxygen is used in steel production, and nitrogen is used as an inert gas in food and metals processing. Cryogenic ASUs dominate bulk industrial gas production and are electricity intensive: large volumes of air are compressed to high pressures using compressors driven by electric motors. As a result of fast, significant electricity price fluctuations created by modern deregulation of electricity markets, process economics of power-intensive manufacturing processes can be improved by frequently adjusting process outputs in response to electricity price changes (Du et al., 2015). In the ASU case, this is achieved by ramping up production during low-price periods and storing excess products as cryogenic liquids, which can be vaporized to satisfy gas demand during high-price periods (Pattison and Baldea, 2014).

With utility prices and production targets changing at hourly or shorter intervals, ASU dynamics must be considered in scheduling calculations to ensure production rate target sequences are both dynamically feasible and economically optimal. Integrating knowledge about process dynamics in production scheduling calculations requires an approach that allows for fast solutions while considering a reasonably long time horizon (Baldea and Harjunkoski, 2014). Recent theoretical works have proposed using scale-bridging models (SBMs), or low-order representations of closed-loop process dynamics, to account for controlled process dynamics in scheduling calculations (Du et al., 2015; Touretzky et al., 2016). A novel framework was presented for selecting scheduling-relevant process variables and constructing SBMs from detailed, first-principles process

models, and a simulated ASU case study showed that the SBMs achieved a dynamically feasible optimal schedule with reasonable computational expense (Pattison et al., 2016).

In this work, we consider the DR operation of an existing industrial ASU. A framework is presented for creating SBMs using a historical industrial dataset to predict production rates, power consumption, and variables limiting the dynamic agility of the process. The controller setpoints and ambient temperature (a disturbance variable) act as SBM inputs. The framework accounts for the fact that the process operates under model predictive control (MPC). The SBMs can be easily updated if the controller or plant are modified. A test case considering DR operation over a four-day window shows that operating costs can be lowered compared with the constant-setpoint operation base case.

2. Process Description

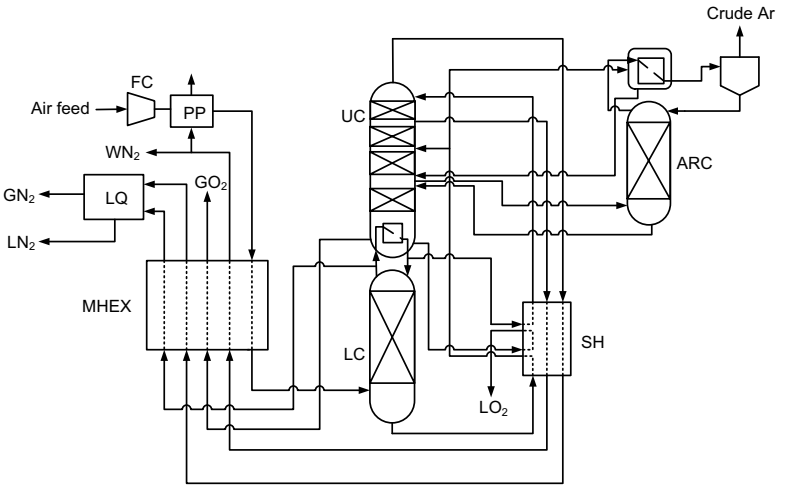

Figure 1: Industrial Air Separation Process Flowsheet.

The industrial cryogenic ASU process considered in this work is shown in Figure 1. Air is compressed in the feed compressor (FC) and is pre-processed to remove impurities (PP). The air stream is then cooled in the multistream heat exchanger (MHEX) by the cryogenic products and passed to the lower column (LC), where it is separated into a nearly pure nitrogen distillate (shelf gas) and an oxygen-rich bottoms stream. A portion of the shelf gas is used to boil the purified oxygen bottoms product of the upper column (UC) before being refluxed, and the rest of the shelf gas is passed through the MHEX and combined with the nitrogen product from the top of the UC. The bottoms stream of the LC passes through the nitrogen superheater (SH) and provides condensing utility to the argon column (ARC) before entering the UC.

The combined nitrogen stream is liquefied in the liquefier (LQ), resulting in both gaseous and liquid nitrogen products. A waste nitrogen stream is drawn at an intermediate stage of the UC to provide additional refrigeration in the MHEX and to purge pressure-swing adsorption beds in PP. Purified oxygen product is collected at the bottom of the UC: a portion of the gas vaporized by the shelf gas is passed to the MHEX, and the liquid portion is passed through the SH. Argon accumulates on an intermediate stage of the UC, where the ARC feed is drawn; argon is obtained as the ARC distillate.

3. Scheduling-Relevant Scale-Bridging Models

3.1. Model Identification Framework

Dynamic flowsheet optimization with detailed flowsheet models presents many mathematical challenges and can require extensive computational time and effort (Tsay et al., 2017). We therefore construct a set of low-order models that can accurately describe the closed-loop dynamics of scheduling-relevant variables and that can be used in scheduling calculations in lieu of the detailed dynamic model. Pattison et al. (2016) showed that the set of scheduling-relevant variables can be a small subset of the process variables, further reducing the scheduling problem size. In particular, only i) variables relevant to the scheduling objective/constraints and ii) variables near their bounds during historical static or transient operation should be modelled and included in scheduling optimization computations. The remaining variables are not considered relevant to optimal scheduling calculations as they do not hinder process agility.

The identification of such scale-bridging models (SBMs – Figure 2) can be carried out using historical operating data, system identification experiments, simulations using a detailed model, or a combination of these of sources. For the industrial ASU process in Figure 1, historical process data involving many production transitions are available and are used to construct an SBM for each output variable.

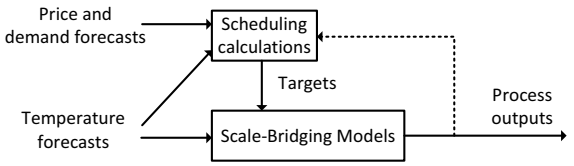

Figure 2: Scheduling Using Scale-Bridging Models (SBMs).

SBMs are identified in the Hammerstein-Wiener (HW) form (Pattison et al., 2016), with the linear dynamics represented as a state-space model:

$$h_i = H_i(u_i) \tag{1}$$

$$\dot{\vec{x}}_i = A\vec{x}_i + Bh_i$$

$$y_i = C\vec{x}_i$$

$$w = W(\sum y_i)$$

where H and W are nonlinear input and output transformations, A, B, and C are the matrices of the linear state-space system, u_i denotes the i^{th} model input (a setpoint of the MPC or a measured disturbance), and w is the system output.

3.2. Application to Industrial Air Separation Process

In deciding the input-output structure of the SBMs, the following factors were considered. On the input side, while the process is controlled by a model predictive controller (MPC) with six operator setpoints (targets), it was found that the production rates and scheduling-relevant state variables could be modelled accurately using only two operator setpoints, suggesting that the remaining four operator setpoints either have negligible effects on the modelled variables or are correlated with the two modelled setpoints. Additionally,

ambient temperature (a measured disturbance) has a large effect on process variables and was included as an input to the SBMs. Therefore each SBM has three inputs, [T SP1 SP2].

We focused on identifying models for operation during summer months, which tend to have larger fluctuations in electricity prices. 110 days of historical operating data, recorded at one minute intervals, were available for model identification after removing periods of start-up, shutdowns, and process or measurement faults. The first 88 days (80% of the data) were selected as training data, with the remaining 22 days used as test data. The nonlinear functions H and W in (1) are modelled as piecewise-linear functions, with the number of segments determined by minimizing the normalized Akaike information criterion (nAIC) for each SBM. The order of each linear state-space model is also determined using the nAIC, and all parameters are fitted using least-squares regression.

Although the industrial ASU produces five products, the liquid oxygen production rate was relatively constant throughout both the training and test datasets, indicating that a constant amount of liquid oxygen product is drawn from the UC (Figure 1) and only gas O2 production rate changes. Additionally, changing the operator setpoints has small effect on the argon production rate. Several variables are constrained in the MPC controller, but only two controlled process variables (CV1 and CV2) closely approach their bounds during operating point transitions, indicating they are the primary factors limiting the agility of the ASU. We therefore created SBMs for three production rates (gas O2, liquid N2, and gas N2), two state variables, and the total ASU power consumption. The SBM predictions for CV1 and CV2 for a week of test data are plotted in Figure 3, showing that the low NMSE values are largely due to high-frequency dynamics in the historical data. We note that all plotted variables have been scaled and filtered due to the confidential nature of industrial data. The number of piecewise-linear input segments, the order of the linear systems, and the number of piecewise-linear output segments are reported in Table 1 along with the normalized mean square error (NMSE) for each model.

Table 1: Identified Scale-Bridging Model Details

SBM output variable	Piecewise linear segments for inputs T, SP1, SP2	Linear system order for inputs T, SP1, SP2	Piecewise linear output segments	Training NMSE (%)	Test NMSE (%)
LN2 flow	[2,1,3]	[1,3,2]	5	91.56	69.15
GN2 flow	[4,3,3]	[3,2,1]	5	76.17	61.52
GO2 flow	[3,3,2]	[4,3,3]	3	66.39	65.55
CV1	[2,2,2]	[3,3,3]	4	67.53	61.86
CV2	[4,4,2]	[2,3,2]	4	42.22	42.65
Power	[4,3,3]	[3,3,1]	5	82.18	82.67

4. Optimal DR Operation with Time-Sensitive Electricity Pricing

The complete ASU scheduling problem using SBMs is formulated as a dynamic optimization problem. The objective is to minimize the total cost over a four-day horizon by manipulating the trajectories of SP1 and SP2, such that production constraints are met and scheduling-relevant CVs stay within their bounds. It is assumed that, i) the only production constraints are on total production (i.e. there is unlimited storage over four days) and ii) perfect forecasts of ambient temperature and electricity price are available for the four day period. While these assumptions may not hold true in practice, the approach provides valuable insights on the maximal benefits of DR scheduling of ASUs.

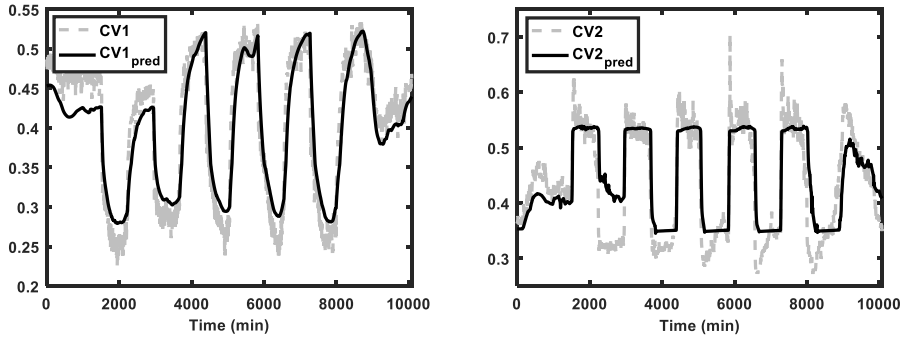

Figure 3: Controlled Variable SBM Predictions for One Week of Test Data.

A four-day period from the test data with constant operator setpoints is simulated with the SBMs as the base case, and the total amounts of each product produced are used as the lower bound for scheduling calculations. Historical ambient temperature profiles were obtained from the process historian, and historical electricity prices from the nearest location were used. The dynamic optimization is formulated with the SBM inputs (operator setpoints) parameterized as piecewise-constant functions over 2-hour intervals. The operator setpoints and production outputs are constrained to be within the range of operation found in the training dataset. The optimization problem was solved in two cases: Problem P1, where the CVs are constrained to be within their bounds as specified in the MPC settings. Here, the CVs did not reach their bounds in the optimal schedule. Because the SBMs for CVs cannot predict high-frequency dynamics, the optimization problem was then solved with the CVs constrained to be within their minimum and maximum values found in the base case simulation (Problem P2). The constraints for P2 are more conservative, and the solution revealed that the lower bound for CV1 limits the dynamic feasibility of the process, as shown in Figure 4.

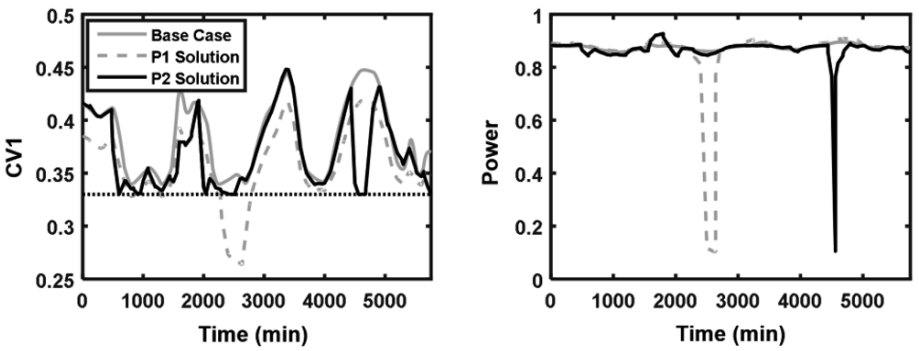

Figure 4: Selected Optimized Variable Profiles.

Both nonlinear optimization problems were solved to local optimality in gPROMS in less than one hour each, using reduced sequential quadratic programming (rSQP); it is expected that solution time can be further reduced using linearization and decomposition techniques (Kelley et al., 2018), noting that the employed objective function is linear. Tightening the bound for CV1 in P2 noticeably limits the dynamic agility of the process, and Figure 4 shows that the power consumption is decreased dramatically during peak electricity prices (near 2500 minutes) in the solution to P1, but not in that to P2.

Nevertheless, there are promising savings in total cost compared to the base case: a 16.0% reduction in operating cost (compared to the base case simulation) over the four-day time horizon for P1 and a 1.4% savings for P2. The significant savings found in the solution to P1 can be attributed to the ability to shut-down the plant during peak electricity price periods and overproduce during some periods with negative electricity price. Moreover, perfect forecasts for *both* price *and* ambient temperature (i.e., process disturbance) were included in the optimization problem. On the one hand, imperfect electricity price predictions and temperature forecasts, and storage constraints may reduce these values; on the other hand, DR benefits may be improved by designing the process for variable operation (Pattison and Baldea, 2014; Tsay et al., 2017). Note that, since all variables are scaled for confidentiality, a value of zero does not indicate zero power consumption, but rather a power consumption equal to the minimum value in the historical dataset.

5. Conclusions

In this work, we propose a framework for the identification of scheduling-relevant dynamic models for an ASU process based on industrial operating data. The models are in Hammerstein-Wiener form and implemented as scale-bridging models (SBMs) to integrate knowledge of process control and dynamics in scheduling calculations. We compute optimal schedules for the modelled industrial ASU process and find significant savings from DR operation, compared to the base case reflected in the historical dataset, where the operator setpoints remain relatively constant over long periods of time.

Abstract

Integrated scheduling optimization comprising the battery limits of crude-oil refineries is a challenging problem to be solved as it includes decisions concerning the quantity and quality of the crude-oil feedstocks and final products (such as fuels and petrochemicals) as well as production, processing or make-side of the refinery flow network. So far, the literature on crude-oil scheduling optimization covered the problem from the crude-oil unloading and storage up to the distillation straight-run streams. To go further, this research extends the scope of the problem from the raw material deliveries up to product liftings through the refinery process-shop by using closed-loop, online and routine process feedback data from field and laboratory measurements for better process predictions, integrated within the scheduling cycle. For such engine, past routine operating data calibrates gains and biases as $y_{measured} = gain \times y_{model} + bias$, whereby the data updating in y considers both process yields and variables such as throughputs, flows, holdups and properties, whose effects propagate throughout the process network. Parameter feedback is applied, after data reconciliation computation, in a complete crude-oil refinery blend scheduling problem considering real tank topology, cascaded distillation towers, process-shops and blend-shops to effectively optimize the complex process system. The feedback strategy is solved within an iterative mixed-integer linear and nonlinear programming (MILP-NLP) decomposition by updating NLP results of process-shop's yields and properties, and recipes of blend-shops in the next MILP solution until convergence is achieved.
Keywords: Scheduling, parameter feedback, process-shops, blend-shops, crude-oil refinery.

1. Introduction

An effective optimization integrating the operations of scheduling in refining of crude-oils into fuels, lubes, asphalts and petrochemical feeds is a challenging problem to be solved. It involves decisions concerning logistics and storage of crude-oil feedstocks and final products as well as the processing and blending in the refinery network. Approaches to promote the integration of these multi-entity, multi-activity and multi-resource decision-making require efficient modeling and solving strategies that considers the difficulties posed by these logistics and quality aspects.

In terms of modeling, previous literature on crude-oil scheduling optimization covers the scheduling from the crude-oil unloading and storage up to the representation of the crude-oil atmospheric and vacuum distillation towers and their immediate straight-run streams (Kelly et al., 2017a). Predictions of product yields and properties from process-

shops, where the crude-oil blend *diet* feed is separated into straight-run distillation intermediate products for further downstream reactions, conversions, separations, treatments and blending throughout the remaining refinery unit-operations and tanks, remain a substantial limitation to better scheduling. Modeling such processes reliably and accurately is difficult due to the complexities and uncertainties in feed quality, operating conditions, process measurements, etc. and therefore parameter feedback is required.

In terms of solving, the search for optimized solutions in crude-oil scheduling may succeed with an MILP-NLP decomposition strategy instead of a full space MINLP approach, since in the latter a binary variable relaxation of the logistics problem is solved along with the non-convex blending and processing relationships in the NLP steps. Recently, Kelly et al. (2017a) solved a discrete-time benchmark for a 1-week time horizon with 2 h time-step involving the logistics details of ship arrivals, tanks and process units in an MILP as well as the quality calculations in an NLP for the blending of streams (e.g., feed *diet* of distillation towers) and for transformation of crude-oils into their main distillates. However, the benchmark excludes further physical and chemical transformations in other process units beyond the initial distillation towers. In this work a problem covering the whole scheduling process is modeled, from crude-oil unloading and storage up to fuel deliveries by including process- and blend-shops as well as the fine tune adjustments regarding on online measurement updates from the field.

With the evolution of solving capabilities determining crude-oil blend scheduling problems around 1 h as discrete time-step, there are reasons to evolve into a more complex scope and scale in the modeling frontier by including cascaded distillation towers, downstream process-shops and blend-shops (e.g., to specify products at their contracted deliveries). Furthermore, an online scheduling algorithm can better predict the model by including the valid plant state (measured) by using parameter feedback and operational updates from the field. According to Subramanian et al. (2012), disruptions or arrival of new information can make the incumbent schedule suboptimal or infeasible, motivating the need for online scheduling. Major considerations on strategies (Gupta and Maravelias, 2016; Gupta et al., 2016), design (Gupta and Maravelias, 2017a) and formulations (Gupta and Maravelias, 2017b) introduce the online scheduling modeling aspects, although other essential elements as re-scheduling activation and frequency as well as handling of process uncertainty are imperative.

For such online scheduling improvement, the use of parameter feedback is proposed considering the past routine operating data to calibrate *gains* and *biases* as: $y_{measured} = gain \times y_{model} + bias$. Data reconciliation and estimation steps are necessary for the next scheduling cycle. Two are the datasets for the parameter updating. First, by offsetting the lower, upper and target bounds of variables for output-uncertainty. Second, by creating new flow or quality variables for input-uncertainty overriding when these variables are propagating in the flowsheet.

2. Problem statement

The flowsheet in Figure 1 shows the operational scheduling optimization of a refinery with a real scale topology considering crude-oil supply, storage and feed tank operations, production in cascaded distillation towers, operations of process-shops and blend-shops of both crude-oils and products. The marine vessels or feedstock tanks

(CO1 to CO12) supply a crude-oil refinery with different quality of raw materials. The assignment of crude-oil feedstocks to storage tanks (S1 to S12) can be pre-defined by clustering similar quality raw materials (Kelly et al., 2017b). Storage tanks are connected to crude-oil blenders for preparation of distillation tower feeds or *diet* to be stocked temporarily in feed tanks (F1 to F4) before starting the crude-oil charging.

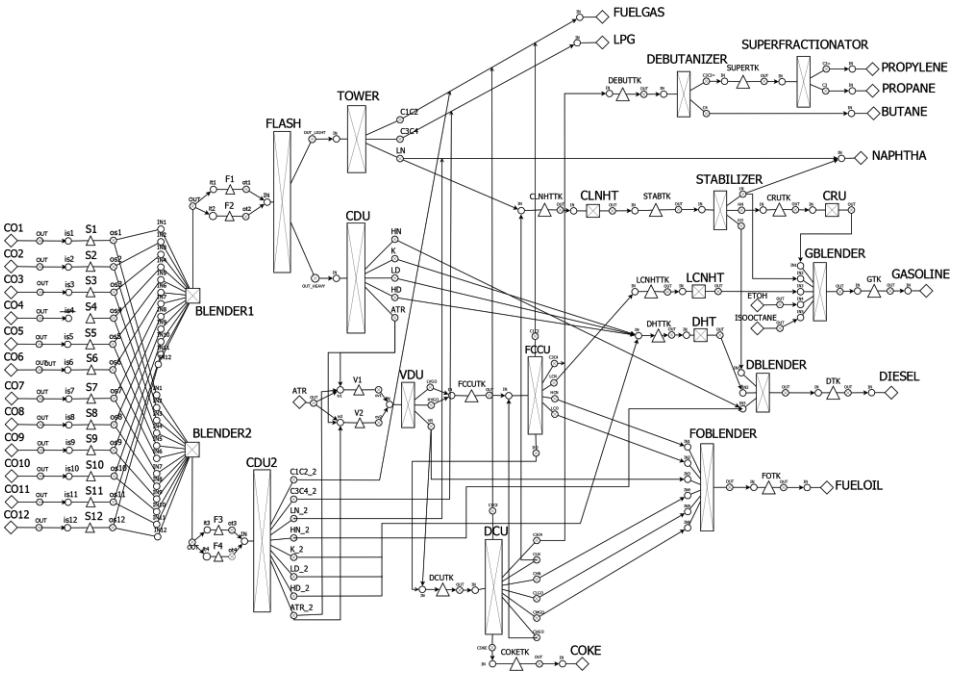

Figure 1. Crude-oil refining scheduling flowsheet.

The network in Figure 1 is constructed in the unit-operation-port-state superstructure (UOPSS) formulation (Kelly, 2005; Zyngier and Kelly, 2012). The UOPSS objects are detailed in the illustrative example in Figure 2 as: a) unit-operations m for sources and sinks (◇), tanks (△) and continuous-processes (⊠) and b) the connectivity involving arrows (→), inlet-ports i (○) and outlet-ports j (⊗). Unit-operations and arrows have binary and continuous variables (y and x, respectively) and the ports can hold the states as process yields or properties. The port-states j' and i'' represent upstream and downstream ports connected, respectively, to the in-port i and out-port j of a unit-operation m.

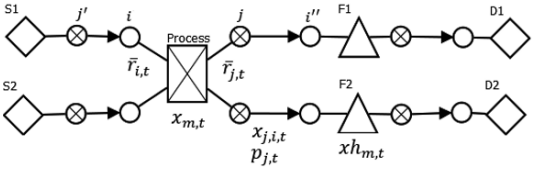

Figure 2. Illustrative example.

In the mixed-integer nonlinear (MINLP) problem (*P*), the objective function (1) maximizes the gross margin of fuels revenues by subtracting operational performance terms. Eq. (2) shows the types of performance constraints, considering deviations on

variables in consecutive time-periods (x_{t+1} and x_t) or around a target ($\bar{x}_t$). x_t^{LD} and x_t^{UD} are lower and upper deviation variables valid for any variable as flows of process-units $x_{m,t}$ and arrows $x_{j,i,t}$ as well as holdups $xh_{m,t}$ and properties $p_{j,t}$. The remaining logistics and quality calculations and the details of the MILP-NLP decomposition are presented by Kelly et al. (2017a). Unit-operations m for tanks, blenders, columns and final products belong, respectively, to the sets M_{TK}, M_{BL}, M_{CL} and M_{FP}. The deviation variables are represented in the set $DVAR$. For $x \in \mathbb{R}^+$, $p \in \mathbb{R}$ and $y = \{0,1\}$:

$$(P)\ \ Max\ Z = \sum_t \left(\sum_{m \in M_{FP}} price_{m,t}\, x_{m,t} - \sum_{x \in DVAR} weight (x_t^{LD} + x_t^{UD}) \right)\ \ s.t. \tag{1}$$

$$x_{t+1} - x_t + x_t^{LD} - x_t^{UD} = 0\ \ \forall\, t \quad \vee \quad x_t - \bar{x}_t + x_t^{LD} - x_t^{UD} = 0\ \ \forall\, t \tag{2}$$

$$\bar{x}_t^L\, y_t \le x_t \le \bar{x}_t^U\, y_t\ \ \forall\, t \tag{3}$$

$$\frac{1}{\bar{x}_{m,t}^U} \sum_{j'} x_{j',i,t} \le y_{m,t} \le \frac{1}{\bar{x}_{m,t}^L} \sum_{j'} x_{j',i,t} \ \wedge\ \frac{1}{\bar{r}_{i,t}^L} \sum_{j'} x_{j',i,t} \le x_{m,t} \le \frac{1}{\bar{r}_{i,t}^U} \sum_{j'} x_{j',i,t}\ \ \forall\, i,m,t \tag{4}$$

$$\frac{1}{\bar{x}_{m,t}^U} \sum_{i''} x_{j,i'',t} \le y_{m,t} \le \frac{1}{\bar{x}_{m,t}^L} \sum_{i''} x_{j,i'',t} \ \wedge\ \frac{1}{\bar{r}_{j,t}^L} \sum_{i''} x_{j,i'',t} \le x_{m,t} \le \frac{1}{\bar{r}_{j,t}^U} \sum_{i''} x_{j,i'',t}\ \ \forall\, j,m,t \tag{5}$$

$$xh_{m,t} = xh_{m,t-1} + \sum_{j'} x_{j',i,t} - \sum_{i''} x_{j,i'',t}\ \ \forall\, (i,m,j) \in M_{TK}, t \tag{6}$$

$$\sum_{j'} x_{j',i,t} = \sum_{i''} x_{j,i'',t}\ \ \forall\, (i,m,j) \in M_{CL} \wedge M_{BL}, t \tag{7}$$

$$\sum_{m \in U} y_{m,t} \le 1\ \ \forall\ t \tag{8}$$

$$H_{j,t}\, p_{j,t} = 0\ \ \ \forall\, j,t \tag{9}$$

The semi-continuous constraints to control the quantity-flows of the arrows $x_{j,i,t}$, the throughputs of the unit-operations $x_{m,t}$ (except tanks) and tank holdups or inventory levels $xh_{m,t}$ are bounded in Eq. (3). Eq. (4) imposes that the sum of the arrows arriving in the inlet-ports i (or uncontrolled mixers) of unit-operation m ($m \notin M_{TK}$) are bounded by their throughputs (flows) and connected inverse yields ($\bar{r}_{i,t}^L$ and $\bar{r}_{i,t}^U$), respectively, at the right and left side of Eq. (4). Similarly, in Eq. (5) the sum of the arrows leaving from the outlet-ports j (or uncontrolled splitters) of m ($m \notin M_{TK}$) must be between bounds of their throughputs and yields ($\bar{r}_{j,t}^L$ and $\bar{r}_{j,t}^U$). The unit-operations m ($m \notin M_{TK}$) can have more than one stream arriving in or leaving from their connected ports.

The quantity balance of inventory or holdup for unit-operations of tanks ($m \in M_{TK}$) in Eq. (6) considers the heels or initial inventories $xh_{m,t-1}$ and the material inlet and outlet of the tanks. Eq. (7) is a material balance in fractionation columns M_{CL} and blenders M_{BL} to assure that there is no accumulation of material in these types of units. In Eq. (8), for all physical units, at most one unit-operation m (as $y_{m,t}$ for procedures, modes or tasks) is permitted in U at a time t. Eq. (9) represents the NLP quality constraints to calculate the properties $p_{j,t}$ of the blends and certain process transformations as to convert crude-oil raw materials to the main distillates.

3. Online parameter feedback

The parameter updating of variables ($x_{m,t}$, $xh_{m,t}$, $x_{j,i,t}$, $p_{j,t}$) and hard bounds of yields ($\bar{r}^L_{i,t}$, $\bar{r}^U_{i,t}$, $\bar{r}^L_{j,t}$, $\bar{r}^U_{j,t}$) uses real, measured or valid values defined as $y_{measured} = gain \times y_{model} + bias$, considering *gain* and *bias* as the proportional and the linear deviations between the measured and model values. Two sets are defined for the data updating in the next scheduling cycle. For variables of unit-operation throughputs $x_{m,t}$, tank holdups $xh_{m,t}$ and parameters of inverse yields ($\bar{r}^L_{i,t}$, $\bar{r}^U_{i,t}$) and yields ($\bar{r}^L_{j,t}$ and $\bar{r}^U_{j,t}$), there is no need to create intermediate variables to update their ordinated values (or ordinates) in the model since the flowsheet structure is identical (same rows and columns in the modeling, although with different coefficients). For this type of updating, gains and biases are added directly in their soft bounds (target) and hard bounds of unit-operations variables ($x_{m,t}$ and $xh_{m,t}$) and their yields, procedure named as offsetting.

However, for flow of material and properties of unit-operation to unit-operation connections ($x_{j,i,t}$, $p_{j,t}$), there is a need to create intermediate variables to update their flowsheet propagation that overrides neighbor structures connected by arcs, paths or arrows (→). Therefore, the total number of variables increases by the additional flows and properties overriding the connected objects for the re-scheduling step with parameter feedback, representing new columns in the re-scheduled model. In such way, the effects of all measurement updates propagate throughout the network.

4. Examples

The examples run in an Intel Core i7 machine at 3.41 GHz (in 8 threads) with 64GB of RAM and uses the structural-based UOPSS framework found in the semantic-oriented modeling and solving platform IMPL (Industrial Modeling and Programming Language) from Industrial Algorithms Limited. By updating the overriding variables in the illustrative case (Figure 2), the number of continuous variables increases around 40%, hence for industrial cases this type of variable can be applied only in the initial time windows for less complex solving steps. For each scheduling cycle before the parameter feedback updating, a simultaneous data reconciliation and parameter estimation is performed considering the raw data collected in the past time window. The examples use the reconciled data of the measured variables as targets and the *gains* and *bias* are feedback in the next re-scheduling model to be executed continuously.

Figure 3 shows the measured and the optimized values with and without the parameter feedback (both using reconciled data as target) for the illustrative case in Figure 2. A time horizon of 8 hours considers fixed setups of unit-operations and arrow flows, resulting in an NLP problem. The plots for flow-in, flow-out, and holdup of the tank F2 consider 60 m^3/d and 90 m^3 as flow and holdup baseline, respectively.

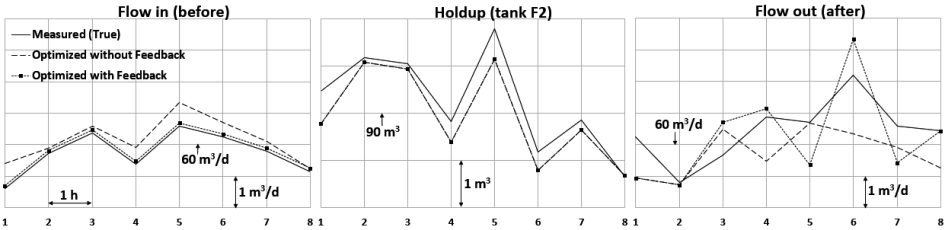

Figure 3. Measured and optimized solutions for tank F2 (see Figure 2).

For the optimized case with feedback (--■--), the flow after the tank F2 (on the right side) is the result of the effects of its flow-in (slightly) and holdup (significantly). The variations of tank flow-out delay one-time window to follow the new holdup value at each re-scheduling step and only the first time-window in the future of the optimized values are pointed in the Figure 3, therefore there are 8 cycles to schedule in this case.

In the industrial-sized example in Figure 1, the logistics MILP optimization for 5 days of time-horizon with 4 hours as time-step (30 time-periods) is solved in 86 seconds (with Gurobi 7.5.1) at 3.9% MILP gap. There are 12,568 constraints (2,545 equalities) for 5,777 continuous variables and 3,412 binary variables with 6,664 degrees-of-freedom. The quality NLP optimization is solved in 184 seconds (with IMPL's SLPQPE linked to Gurobi 7.5.1). There are 4,103 constraints (3,663 equalities) for 3,821 continuous variables with 278 degrees-of-freedom.

5. Conclusions

Efficient scheduling solutions in a near online fashion are becoming reality by the virtue of all advances in decision-making modeling, solving algorithms and computer-aided resources in terms of faster CPU clock speeds and memory. The major challenge now is to integrate proper or correct data (in timeliness and quality) to the decision automation core. An online scheduling engine with parameter updating might be useful to cope with uncertainties and to reduce the offsets or inaccuracies over the life-time of the problem as an effective way to close the gap among predictions and productions.

Multistage Stochastic Models for Shale Gas Artificial Lift Infrastructure Planning

Zuo Zeng, Selen Cremaschi*

Department of Chemical Engineering, Auburn University, Auburn, AL 36849, USA
selen-cremaschi@auburn.edu

Abstract

Artificial lift methods (ALMs) are used to lift the accumulated fluids from wells and to help sustain their performances. This paper presents two multistage stochastic programming models (SMILP1 and SMILP2) to solve the artificial lift infrastructure planning problem by maximizing the expected net present value. The models incorporate endogenous uncertainty of production after a selected ALM is installed. The decisions are which ALMs to deploy, and their installation and removal times. Both models are applied to determine the artificial lift infrastructure plan (ALIP) for a hypothetical case study constructed based on Woodford Shale Horizontal Well for three different planning horizons. For the 16-month planning horizon case, the value of the stochastic solution is $163,831, which is a 5 % increase with respect to the deterministic solution. The solution times for SMILP2 are up to two orders of magnitude shorter when compared to those for SMILP1.

Keywords: Artificial lift methods, horizontal shale gas, stochastic programming, endogenous uncertainty

1. Introduction

Horizontal drilling has been around since 1950s. Recent advances in equipment and in hydraulic fracturing techniques allowed the production of natural gas from previously inaccessible sources such as shale formations (Robbins, 2013). This new and significant increase in shale gas production opened novel research areas for process systems engineering (PSE) community, and it, in turn, benefited from PSE contributions (e.g., Tavallali et al., 2014; Cafaro and Grossmann, 2016; Drouven and Grossmann, 2016; Gao and You, 2017). For example, Cafaro and Grossmann (2016) presents a continuous-time nonlinear programming model and a multi-period mixed-integer programming model to solve refracturing planning problem for horizontal shale gas wells. The models determine which wells to refracture, and the frequency of refracturing and its schedule.

Large amounts of liquids are injected into the shale formation during the fracturing process. The accumulation of liquids at the bottom of the well and gradual decline of well pressure, in general, halts the production prematurely. ALMs are used to lift the accumulated fluids from the well and to help sustain well performance. The ALIP is important for the long-term profitability of horizontal wells. A poor plan may reduce production and increase cost substantially. The ALIP depends on the production and reservoir conditions, the completion details, and field information, some of which change during production. The construction of ALIP is further complicated due to highly stochastic nature of well production: after an ALM is installed, the production rate is uncertain and depends on the chosen ALM. Hence, the production rate might violate the operating envelope of the installed ALM in the future.

This paper presents two multistage stochastic programming models (SMILP1 and SMILP2) to generate ALIPs for shale-gas producing horizontal wells. The solution determines: (a) which ALM(s) to install, and (b) their operating period. We incorporate the uncertain ALM-dependent production rates to the model, which yields multistage stochastic programs with Type II endogenous uncertainty (Apap and Grossmann, 2016).

2. Problem Statement

Nine candidate ALMs are considered: Plunger Lift, Foam Lift, Well Head Compression, Velocity Strings, Gas Lift, Electrical Submersible Pump (ESP), Sucker Rod Pump (SRP), Progressing Cavity Pump and Jet Pump. Givens are the characteristics of a candidate horizontal shale-gas well such as its geometry, operating conditions, and production history to date; and the economical parameters such as the prices of gas and natural gas liquids, and the costs of ALMs' equipment, installation, and operation. Each ALM has design and operational limitations obtained from Artificial Lift R&D Council guidelines, from previous expert experience (Wittfeld, 2005), and from typical attribute tables (e.g., Weatherford, 2013). The goal is to determine the optimal ALM(s) and their installation plan that yield the maximum expected net present value (ENPV) for the well.

2.1. Production decline curve of a horizontal well

The production rate is described using a hyperbolic curve (Fetkovich et al., 1996). The planning horizon is discretized into equal time periods $t = 1, 2, 3 \ldots T$, where period t starts at time t-1 and ends at time t. At first, the well is producing naturally, the solid curve in Figure 1. After liquid loading, the production becomes unstable, and is halted (at $t = p - 1$) unless an appropriate ALM is installed to stabilize it. Dashed line in Figure 1 represents a potential production rate after ALM i is installed at time p. We define the ratio of the production rate at time p (with ALM i installed) to the production rate at p-1 (the production right before ALM i installation) as the flowrate change ratio, Qrc_i, of ALM i.

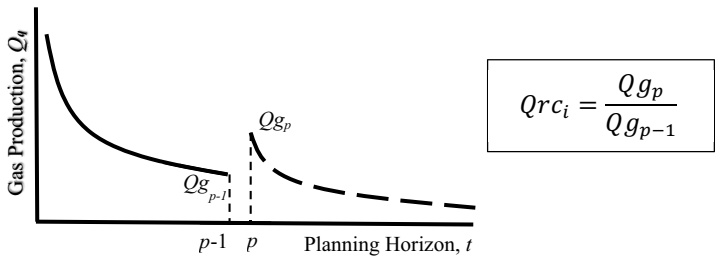

Figure 1. Production decline curve before and after ALM i is installed.

2.2. Flowrate uncertainty, scenario representation and future non-anticipativity

The flowrate change ratio, Qrc_i, is uncertain, and it is only revealed when ALM i is installed. Let ξ_i represent the random variable associated with the endogenous uncertain parameter Qrc_i. Assuming ξ_i has two outcomes, i.e., Ω_i = {High(H), Low(L)}, the scenario set, $s \in \boldsymbol{S}$, is generated as the Cartesian product of all possible outcome sets. With nine candidate ALMs, $|\boldsymbol{S}| = 2^9 = 512$.

Scenarios differ in the outcomes of Qrc_i. If ALM i is installed at period t, scenarios s and s' remain indistinguishable if they have the same outcome for Qrc_i. We define the subset $\boldsymbol{B}$ of $\boldsymbol{S} \times \boldsymbol{S}$ as scenarios s and s', which are still indistinguishable in the outcome of one

Qrc_i. The non-anticipativity constraints (NACs) should be enforced for scenario pairs $(s, s') \in \boldsymbol{B}$ that remain indistinguishable after ALM i is installed at period t.

3. Mathematical Programming Models

3.1. The first multistage stochastic mixed integer linear program (SMILP1)

The main decision variable is $w_{i,p,s}$, which is equal to one if ALM i is operational at the beginning of time period p under scenario s, and zero otherwise. We also introduce a binary variable $z_{i,t,s}$, which is equal to one if ALM i is uninstalled at period t in scenario s. Equations (1) and (3) state that each method can be installed and uninstalled at most once. Equations (2) and (4) limit the number of ALMs that can be installed and uninstalled at any given time period to a maximum of one. Equations (5) and (6) ensure that each ALM is only uninstalled once and the removal happens after its installation time. The last constraint, Eq. (7), prevents the overlap of two ALMs.

$$\sum_i w_{i,p,s} \leq 1 \qquad \forall p, s \tag{1}$$

$$\sum_p w_{i,p,s} \leq 1 \qquad \forall i, s \tag{2}$$

$$\sum_i z_{i,t,s} \leq 1 \qquad \forall t, s \tag{3}$$

$$\sum_t z_{i,t,s} \leq 1 \qquad \forall i, s \tag{4}$$

$$\sum_p w_{i,p,s} - \sum_t z_{i,t,s} = 0 \qquad \forall i, s \tag{5}$$

$$z_{i,t,s} w_{i,p,s} = 0 \quad \forall i, t, p, s, t \leq p \tag{6}$$

$$z_{i,t,s} y_{i,p,s} + z_{i,k,s} y_{j,l,s} \leq 1 \; \forall j \neq i, p+1 \leq l \leq t, t+1 \leq k \leq T, s \tag{7}$$

Once the well is unloaded, the production rates of gas ($Qg_{r,s}$), oil ($Qo_{r,s}$), and natural gas liquids ($Qn_{r,s}$) at period r in scenario s are defined by Eqns. (8) - (10), respectively. In Eqns. (8)-(10), D is the decline exponent and b is the nominal decline rate.

$$Qg_{r,s} = \sum_{i,t,p} z_{i,t,s} w_{i,p,s} \, Qg_{p-1,s} Qrc_{i,s} \big(1 + bD(t-r+1)\big)^{-\frac{1}{b}} \quad \forall r \geq 2, s \tag{8}$$

$$Qo_{r,s} = \sum_{i,t,p} z_{i,t,s} w_{i,p,s} \, Qo_{p-1,s} Qrc_{i,s} \big(1 + bD(t-r+1)\big)^{-\frac{1}{b}} \quad \forall r \geq 2, s \tag{9}$$

$$Qn_{r,s} = \sum_{i,t,p} z_{i,t,s} w_{i,p,s} \, Qn_{p-1,s} Qrc_{i,s} \big(1 + bD(t-r+1)\big)^{-\frac{1}{b}} \quad \forall r \geq 2, s \tag{10}$$

Design and operational envelopes of each ALM are incorporated as technical limitation constraints in the model (Eqns. (11) - (13)). Examples of these constraints can be found in Zeng and Cremaschi (2017). The most common constraints limit the ranges of liquid flow rates ($LFR_{r,s}$) that an ALM can operate within, and are given in Eqns. (11) and (12).

$$f_{i,p,r,s}\big(LFR_{r,s}, w_{i,p,s}\big) \leq 0 \qquad \forall i, p, r, s \tag{11}$$

$$f_{i,t,r,s}\big(LFR_{r,s}, z_{i,t,s}\big) \leq 0 \qquad \forall i, t, r, s \tag{12}$$

$$g_{i,p,s}\big(w_{i,p,s}\big) \leq 0 \qquad \forall i, p, s \tag{13}$$

The objective function maximizes the ENPV (Eq.(14)), which is calculated using minimum acceptable rate of return (*MARR*), gross income at period *r* in scenario *s* ($GI_{r,s}$), the taxable income at period *r* in scenario *s* ($TI_{r,s}$), the federal tax rate (*FT*), and the capital cost in scenario *s* (CC_s). The binary variable $x_{r,s}$ is equal to one if $TI_{r,s}$ is nonnegative.

$$ENPV = \sum_s P_s \left(\sum_r \left(GI_{r,s} - TI_{r,s} \cdot x_{r,s} \cdot FT \right) \left(\frac{1}{(1+MARR)^r} \right) - CC_s(1-FT) \right) \tag{14}$$

The first set of NACs (Eq. (15)) are for $p = 2$, the installation time of the first ALM. Our model assumes that the well is loaded at the first time period, and the first ALM is installed at the second time period. At this stage, all scenarios are indistinguishable because none of the ALMs are installed.

$$w_{i,2,s} = w_{i,2,1} \qquad \forall\, i, s \in \boldsymbol{S} \backslash \{1\} \tag{15}$$

The remaining NACs equate the decisions in scenarios *s* and *s′* for the later time periods, if $(s, s') \in \boldsymbol{B}$ are still indistinguishable after observing the outcome of only one ALM, denoted by $i^{s,s'}$. Because new ALMs cannot be installed before the existing ALM $i^{s,s'}$ is uninstalled, the remaining NACs are expressed in terms of variable $z_{i^{s,s'},t,s}$ as follows:

$$w_{j,l,s} - w_{j,l,s'} \leq 1 - z_{i^{s,s'},t,s} \qquad \forall l \geq t+1, (s,s') \in \boldsymbol{B} \tag{16}$$

$$w_{j,l,s} - w_{j,l,s'} \geq z_{i^{s,s'},t,s} - 1 \qquad \forall l \geq t+1, (s,s') \in \boldsymbol{B} \tag{17}$$

The model defined by Eqns. (1) – (17) yields a mixed-integer nonlinear program (MINLP). All nonlinear terms can be linearized using exact linearization (Oral and Kettani, 1990), and the detailed steps of this linearization can be found in Zeng and Cremaschi (2017). The resulting large-scale mixed integer linear program (MILP) is referred to as SMILP1.

3.2. The second multistage stochastic mixed integer linear program (SMILP2)

For this model, we introduce one more binary variable, $y_{i,t,p,s}$, which is equal to one if ALM *i* is installed on period *p* and uninstalled on period *t* in scenario *s*. The new binary variable satisfies the logical expression $y_{i,t,p,s} \Leftrightarrow w_{i,p,s} \wedge z_{i,t,s}$. Equations (18) - (20) translate this logical expression into constraints.

$$y_{i,t,p,s} \geq z_{i,t,s} + w_{i,p,s} - 1 \qquad \forall i, t, p, s \tag{18}$$

$$z_{i,t,s} \geq y_{i,t,p,s} \qquad \forall i, t, p, s \tag{19}$$

$$w_{i,p,s} \geq y_{i,t,p,s} \qquad \forall i, t, p, s \tag{20}$$

The planning constraints, Eqs. (21) – (25), replace Eqs. (1) - (7) of SMILP1.

$$\sum_{t,p} y_{i,t,p,s} \leq 1 \qquad \forall i, s \tag{21}$$

$$\sum_{i,t} y_{i,t,p,s} \leq 1 \qquad \forall p, s \tag{22}$$

$$\sum_{i,p} y_{i,t,p,s} \leq 1 \qquad \forall t, s \tag{23}$$

$$y_{i,t,p,s} = 0 \qquad \forall i, t, p, s \tag{24}$$

$$y_{i,t,p,s} + y_{j,k,l,s} \leq 1 \qquad \forall j \neq i, p+1 \leq l \leq t, t+1 \leq k \leq T \tag{25}$$

The multiplication of two binary variables ($z_{i,t,s} w_{i,p,s}$) in flowrate constraints (Eqns. (8) - (10)) are replaced by the new binary variable ($y_{i,t,p,s}$). Furthermore, instead of relating

$w_{i,p,s}$ and $z_{i,t,s}$ to the upper and lower bounds of liquid flow rate separately (Eqns. (11) and (12)), the constraint given in Eq. (26) is used to define these operational envelops.

$$f_{i,t,p,r}\left(LFR_{r,s}, y_{i,t,p,s}\right) \leq 0 \qquad \forall i,t,p,r,s \tag{26}$$

$$g_{i,t,p,s}\left(y_{i,t,p,s}\right) \leq 0 \qquad \forall i,t,p,s \tag{27}$$

The objective function and the NACs of SMILP1 are retained for this model, which, after linearization, is a large scale MILP, and is referred to as SMILP2.

4. Case Study

4.1. Field application: Woodford shale horizontal well

The well was hydraulically fractured in eight different stages. The production before the loading indicated a gas rate of 800 thousand standard cubic feet per day (Mscf/D), a liquid rate of 520 barrels per day (BPD) (of which 500 barrels were water and the remaining oil), a water cut of 96%, and a gas-to-liquid ratio of 1,950 standard cubic feet per stock tank barrel (scf/STB). The well is currently operated using gas lift with a well-site compressor (Valbuena, 2015). The case study assumes that the planning was carried out at the first loading prior to the installation of gas lift. For uncertain parameter Qrc_i, High outcome is assumed to be 20% above its nominal value, and Low outcome 20% below with equal probabilities. The planning horizon is 12 months, which is divided into 12 equal time periods. The mathematical programs are constructed in GAMS 24.6.1, and solved using CPLEX 12.6.3 on a Lenovo ThinkStation P900 with Intel 2.3 GHz CPU and 24 GB RAM. The solutions of SMILP1 and SMILP2 recommend installing SRP throughout the planning horizon for all scenarios. The ENPV is \$2,805,092, which is 8.8% higher than the ENPV if gas lift were used. For this problem, SMILP1 and SMILP2 are solved to 0.1% optimality gap in 7039 seconds and 27 seconds, respectively.

4.2. Comparison of the formulations for a hypothetical case study

We also constructed a hypothetical case study where the operating envelope of SRP is modified by setting the minimum allowable liquid flow rate to 300 BPD. The planning horizons are 12, 16 and 20 months. The maximum CPU time is limited to 20 hours. Table 1 summarizes the results.

Table 1. The ENPVs, optimality gaps, and solution times for SMILP1 and SMILP2

	SMILP1			SMILP2		
Months	ENPV (\$)	GAP (%)	Times (s)	ENPV (\$)	GAP (%)	Times (s)
12	2,783,894	0.08	4948	2,783,894	0.08	20
16	3,416,506	42.51	72000	3,416,507	0.1	1959
20	3,840,889	49.39	72000	3,916,996	11.89	72000

The SMILP1 cannot be solved to optimality for 16-month and 20-month planning horizons (Table 1), whereas SMILP2 cannot be solved to optimality only for 20-month planning horizon. We hypothesize that the additional binary variable $y_{i,t,p,s}$ helps CPLEX to branch better when solving SMILP2.

The solution of the deterministic model, using nominal values of Qrc_i, recommends installing and operating SRP throughout the planning horizon. If the deterministic solution were implemented, the ENPV would have been \$3,252,676. With the deterministic solution, under scenarios with Low outcome of $Qrc_{,SRP,}$ the production rate

violates the operational envelope of SRP in month 13, and the production is halted. The optimal plan obtained as the solution of SMILP2 installs SRP initially for all scenarios. At the 7th time period, the ESP is installed for scenarios with Low outcome of $Qrc_{,SRP}$ while SRP stays in operation for the rest of the scenarios. The difference between the ENPVs of the stochastic and deterministic solutions, i.e., the value of the stochastic solution, is $163,831, a 5% increase from the deterministic solution.

5. Conclusions and Future Directions

This paper contributes to the new and growing body of literature in PSE on shale-gas production and infrastructure planning from horizontal wells. We presented two stochastic models for generating ALIPs for shale gas producing horizontal wells. Both models incorporate the stochastic ALM-dependent well production, which is an endogenous uncertainty. The first model, SMILP1, has two decision variables, which track the installation and uninstallation times of each ALM separately. In the second model, SMILP2, a new binary variable that integrates both installation and uninstallation times of each ALM is introduced, and the production rate and planning constraints are expressed using it. The additional binary variable in SMILP2 reduced the solution times up to two orders of magnitude. We hypothesize that a similar reduction in solution times of traditional PSE planning problems may be expected with the addition of a similar binary variable, and our future work will focus on investigating this hypothesis.

Abstract

For the optimal operation of power-intensive plants, a challenge which is addressed in this work is to simultaneously determine the optimal production schedule and the optimal procurement of electric power. Electricity procurement decisions involve load commitment decisions, meaning that the consumers have to commit themselves to the amount of electricity they are going to purchase before the actual electricity demand is revealed. A major challenge here obviously is the uncertainty about the future demand. To cope with this uncertainty, a stochastic multi-stage mixed-integer linear programming model is proposed that considers uncertain product demands and equipment breakdowns to determine a solution to the integrated electricity procurement and production scheduling problem. The proposed model is applied to a continuous power intensive plant and the results show that there are significant improvements obtained from solving the stochastic model.

Keywords: Electricity procurement, Production scheduling, Stochastic programming, Demand Side Management, Load deviations.

1. Introduction

The increasing share of renewable energies, time-sensitive electricity prices and the flexibility of the production processes render industrial Demand-Side Response (iDSR) a promising strategy to improve profitability for the process industries (Merkert et al., 2014) and to simultaneously make production "greener". A challenge of iDSR as the integration of electricity procurement and production scheduling is to avoid the risk of having competing optimization solutions resulting in no improvements. This means the introduction of electricity purchasing decisions into the scheduling problem. For large consumers of electric power, the electricity purchase options include different types of power contracts:

- Long-term contract (base load) - constant price, constant amount of electricity delivered over time and a horizon of at least 1 year;
- Time-of-Use contract (TOU) - of the price is determined by a time-dependent component and an amount-dependent component; TOU contracts usually cover a period of time between 1 week and 3 months;
- Day-ahead market (spot market) - hourly-varying prices.

The day-head spot market is characterized by hourly varying electricity prices, according to the fluctuations of the availability of electric power. The day-ahead electricity price is assumed to be known 24 hours ahead. Apart from the volatility of the electricity price, a main feature of the day-ahead spot market is load commitment and

the related deviation penalties. For large consumers, the electricity suppliers impose a daily day-ahead hourly electricity commitment, and in case the actual consumption deviates from the pre-agreed values, financial penalties, which are often in the same range as the net electricity cost, are incurred. In (Hadera et al., 2015), the authors take into account these multiple electricity contracts and the load deviation problem to determine the optimal production schedule. However, the contract-related decisions (in particular the load commitments) are assumed as given and are not optimized. In this work, we address the challenge of determining simultaneously the optimal electricity purchase strategy and the production scheduling including the load commitments, i.e. the commitment of the consumers to the amount of electricity that they are going to use during a certain period of time. Depending on the time-scale, we can distinguish between the TOU commitment, which covers up to 3 months, and the daily day-ahead hourly commitment. Since decisions regarding the commitment to power contracts have to be made before the actual electricity demand is known for the time horizon of interest, it is crucial to account for uncertainties in the decision-making process. A recent work in this direction (Zhang et al., 2016) integrates production scheduling and TOU-contract decisions by applying two-stage stochastic programming (Birge and Louveaux, 2011) to model price and demand uncertainties. However, this work does not consider the day-ahead electricity commitment and the associated load deviation problem. To include the day-ahead commitment and the load deviation problem, we propose a three-stage stochastic programming approach. The first-stage variables represent the electricity commitment decisions related to the TOU power contracts. The second stage faces demand uncertainty and for each demand scenario the second-stage variables represent the day-ahead electricity commitment. The third stage takes into account plant capacity uncertainty and the third-stage variables for each scenario are the operating decisions of the plant (production levels, inventories etc.) and the deviations of the power demand from the day-ahead commitment. A similar approach has not been considered in this context before. In Section 2, the model of the uncertainty and the proposed three-stage MILP are presented. Section 3 applies the proposed framework to a power-intensive process and the results are evaluated in terms of the Value of the Stochastic Solution (VSS). The main outcomes are discussed in Section 4 before drawing a final conclusion in Section 5.

2. Problem statement

2.1. Uncertainty modeling strategy

To integrate electricity procurement and production scheduling, we propose a multi-stage stochastic programming approach (Birge and Louveaux, 2011). In stochastic programming, uncertainty is represented by discrete scenarios, and decisions are made at different stages which are defined by the realization of the uncertainty. In the proposed approach, we consider two sources of uncertainty: product demand uncertainty faced by the second stage and equipment breakdown faced by the third stage. For each source of uncertainty, we consider three different levels—low, medium, and high around the same expected value. The low, medium and high uncertainty levels represent a variation of 5, 10 and 20 percent of the product demand and a 10, 30 and 40 percent reduction of the maximum plant production capacity. The production capacity reduction is modeled by 8 breakdown scenarios: in scenario 1 no breakdown occurs, whereas the production capacity is reduced in periods 1-4 for scenario 2, in periods 5-8 for scenario 3, etc. The probabilities are 50% for scenario 1 and (50/7) % ≈ 7.14% for scenarios 2–8 since scenarios 2-8 are considered equiprobable.

2.2. Plant model

To demonstrate the main features of the proposed approach, we apply it to a continuous-production plant. The plant model is the same as in (Zhang et al., 2016). In the proposed mathematical formulation first-stage variables have no scenario subscript, second stage variables have the scenario subscript s and the third-stage variables have a double scenario subscript $s,\bar{s}$. The plant produces two products i (*P1* and *P2*) and it can operate in three different modes m: *off*, *startup*, and *on*. The possible mode transitions are *off* to *startup*, *startup* to *on*, and *on* to *off* and they can happen only after fixed periods of time that have been spent in the modes (*off*: 8 h, *startup*:2 h, *on*:6 h) (Eq.6). The transitions between the modes of operation and the relations with the active modes are modelled by Eq.(7). The binary variable (Eq.(4)) is 1 if mode m is selected in time period t of the horizon T. For each mode the operating conditions are expressed as a convex combination of the extreme points v_{mi} of the feasible region of operation (Eq.(2)). Eq.(1)-(2) define the hourly production levels $\overline{PD}_{mits\bar{s}}$ for each product i and operating mode m and the aggregated production $PD_{its\bar{s}}$.

$$PD_{its\bar{s}} = \sum_{m} \overline{PD}_{mits\bar{s}} \qquad \forall\, i,t \in T, s, \bar{s} \qquad (1)$$

$$\overline{PD}_{mits\bar{s}} = \sum_{m} \lambda_{mits\bar{s}} * v_{mi} \qquad \forall\, i,t \in T, s, \bar{s} \qquad (2)$$

$$\sum_{m} \lambda_{mits\bar{s}} = y_{mt} \qquad \forall\, i,t \in T, s, \bar{s} \qquad (3)$$

$$\sum_{m} y_{mt} = 1 \qquad \forall\, t \in T \qquad (4)$$

$$EU_{its\bar{s}} = \sum_{m} \left(\delta_m * y_{mt} + \sum_{i} \gamma_{mi} * \overline{PD}_{mits\bar{s}} \right) \qquad \forall\, i,t \in T, s, \bar{s} \qquad (5)$$

$$\sum_{k=1}^{\theta_{mm\prime}} z_{mm\prime t-k} \le y_{m\prime t} \qquad \forall\, (m,m') \in M, t \in T, s, \bar{s} \qquad (6)$$

$$\sum_{m\prime} z_{m\prime m,t-1} - \sum_{m'} z_{mm',t-1} = y_{mt} - y_{m,t-1} \qquad \forall\, m,t \in T \qquad (7)$$

Eq. (8) defines the inventory level $IV_{its\bar{s}}$ at time t as the sum of the inventory level at time period *t-1* and the production at time *t*, $PD_{its\bar{s}}$, minus the amount of product sold, $SL_{its\bar{s}}$, and the amount of products wasted, $PW_{its\bar{s}}$, at time period *t*. Note that all these quantities are defined for each scenario of the second and third stage. Eq.(9) sets upper and lower bounds of the inventory levels and Eq. (10) ensures that the demand of product i as the sum of the amount of product i sold, $SL_{its\bar{s}}$, and the amount of product i purchased from other sources, $PC_{its\bar{s}}$, is satisfied

$$IV_{its\bar{s}} = IV_{i,t-1,s\bar{s}} + PD_{its\bar{s}} - SL_{its\bar{s}} - PW_{its\bar{s}} \qquad \forall\, i,t \in T, s, \bar{s} \qquad (8)$$

$$IV_{it}^{min} \le IV_{its\bar{s}} \le IV_{it}^{max} \qquad \forall\, i,t \in T, s, \bar{s} \qquad (9)$$

$$SL_{its\bar{s}} + PC_{its\bar{s}} = D_{its} \qquad \forall\, i,t \in T, s, \bar{s} \qquad (10)$$

Eq. (11) - (14) provide the initial and final condition of the plant in terms of inventory levels and active operating modes.

$$IV_{i,0,s,\bar{s}} = IV_i^{initial} \qquad \forall\, i, s, \bar{s} \qquad (11)$$

$$y_{m,0} = y_m^{initial} \qquad \forall\, m \qquad (12)$$

$$IV_{i,t^{final},s,\bar{s}} \ge IV_i^{final} \qquad \forall\, i, s, \bar{s} \qquad (13)$$

$$z_{mm\prime t} = z_{mm\prime t}^{ini} \qquad \forall\, (m,m') \in M, s, \bar{s}, -\theta^{max} + 1 \le t \le -1 \qquad (14)$$

2.3. Power contract model

Eq.(15)-(21) define the amount of electric power $\widehat{EC}_c$ purchased from TOU contract c. B_c is the set of blocks of contract c, and $x_{cb}$is a Boolean variable that is true if block b of contract c is chosen. $\widehat{EC}_{c,b}^{max}$ is the amount of electricity that one has to purchase in block b before reaching the next block; β_{cb} is the quantity dependent price. Eq.(22) models the electricity commitments of the plant: EC_{ct} represents the amount of energy the consumer purchases from the TOU contract and ES_{ts} is the day-ahead electricity commitment. According to the timing of the decisions, TOU commitment decisions are first-stage variables and day-ahead commitment decisions are second-stage variables. Eq.(23) defines the over-consumptions ($\Delta e_{ts\bar{s}}^{+}$) and under-consumptions ($\Delta e_{ts\bar{s}}^{-}$) (third stage variables) to compute the penalty costs. The over- and under- consumption variables are the load deviations respect to the electricity commitments.

$$\widehat{EC}_c = \sum_t EC_{ct} \qquad \forall\, c \tag{15}$$

$$\widehat{EC}_c = \sum_b \widehat{EC}_{cb} \qquad \forall\, c \tag{16}$$

$$BC_c = \sum_b \beta_{cb} \widehat{EC}_{cb} \qquad \forall\, c \tag{17}$$

$$\widehat{EC}_{c,b-1}^{max} x_{cb} \le \widehat{EC}_{cb} \qquad \forall\, c, b \in B_c, b > 1 \tag{18}$$

$$\widehat{EC}_{cb} \le \widehat{EC}_{c,b}^{max} x_{cb} \qquad \forall\, c, b \in B_c \tag{19}$$

$$\sum_{cb} x_{cb} = 1 \qquad \forall\, c \tag{20}$$

$$EC_{ct} = \overline{EC}_{cp} \qquad \forall\, c, p \in P_c, t \in T_{cp} \tag{21}$$

$$Q_{ts} = EC_{ct} + ES_{ts} \qquad \forall\, t \in T, s \tag{22}$$

$$EU_{ts\bar{s}} - Q_{ts} = \Delta e_{ts\bar{s}}^{+} - \Delta e_{ts\bar{s}}^{-} \qquad \forall\, t \in T, s, \bar{s} \tag{23}$$

2.4. Objective function

The model minimizes the total expected operating costs, z, defined in Eq.(24) as the cost of purchasing energy from the TOU contract, the expected first-stage cost of purchasing electricity from the spot market and the expected second-stage cost of deviation penalties and purchasing of products on the market.

$$\begin{aligned} z = \sum_c BC_c + \sum_t \sum_c p_{ct}^{TOU} EC_{ct} \\ + \sum_s \varphi_s \sum_t \Bigg(p_t^{day-ahead} ES_{st} \\ + \sum_{\bar{s}} \varphi_{\bar{s}} \left(p_t^{+} \Delta e_{ts\bar{s}}^{+} + p_t^{-} \Delta e_{ts\bar{s}}^{-} + \sum_i p_i PC_{its\bar{s}} \right) \Bigg) \end{aligned} \tag{24}$$

where $p_{ct}^{TOU}, p_t^{day-ahead}, p_t^{+}, p_t^{-}, p_i$ represent the TOU electricity price, the day-ahead electricity price, the penalty cost for over-consumption and under-consumption and the product purchasing prices; φ_s , $\varphi_{s\bar{s}}$ denote the probability of scenario s and $\bar{s}$.

3. Results

To measure the improvement that can be achieved by solving the stochastic model instead of its deterministic counterpart, we compute the value of the stochastic solution

(VSS). The VSS (Eq. (25)) and the relative $\overline{VSS}$ (Eq. (26)) show the impact of the uncertainty on the first-stage variables:

$$VSS = z^*_{det} - z^*_{stoc} \quad (25) \qquad \overline{VSS} = \frac{z^*_{det} - z^*_{stoc}}{z^*_{det}} \quad (26)$$

Where z^*_{stoc} is the optimal solution of the stochastic problem and z^*_{det} is the optimal solution of the stochastic problem with first-stage variables fixed to the optimal deterministic solution (obtained with the expected value of the uncertain parameters). For the multi-stage formulation, the VSS_1 shows the cost reduction achievable solving the stochastic model instead of fixing the first-stage variables to the optimal deterministic solution. The VSS_2 shows the cost reduction achievable solving the stochastic model instead of fixing both the first- and the second- stage variables to the optimal deterministic solution. Table 1 shows that the VSS can be quite significant and that it grows with the uncertainty level. The VSS clearly shows the benefit of adopting the stochastic model instead of the deterministic one. Each model has up to 19,000 continuous variables, 212 binary variables, and 11,000 constraints. All models were solved to zero integrality gap in less than 20 s applying the solver CPLEX 12.6.3.0.

Table 1 Value of the stochastic solution for the proposed 3-stage stochastic model for different levels of uncertainty

Demand Uncertainty level	**Breakdown uncertainty level**	$\boldsymbol{VSS_1}$	$\boldsymbol{\overline{VSS}_1}$	$\boldsymbol{VSS_2}$	$\boldsymbol{\overline{VSS}_2}$
Low	Low	105	4.3%	144	5.8%
Low	Medium	140.4	5.3%	168.5	6.3%
Low	High	130.3	4.7%	157.8	6.0%
Medium	Low	158.7	6.3%	229	8.9%
Medium	Medium	194.5	7.1%	242.4	8.8%
Medium	High	185.8	6.6%	230.1	8.0%
High	Low	222.8	8.4%	338.3	12.2%
High	Medium	249	8.7%	367.6	12.4%
High	High	245.2	8.3%	348.8	11.4%

4. Discussion

Fig.1 shows the electricity purchase profiles that were obtained for a medium uncertainty level when solving the proposed 3-stage stochastic model (Fig.1 a) and the 2-stage stochastic model (Fig.1 b) proposed in (Zhang et al., 2016), where the day-ahead electricity commitment and the related deviation problem are neglected. In the 2SSP model, the uncertainty source is the product demand, as in the second stage of the proposed 3SSP approach. Both approaches model the TOU contract decisions as first-stage variables. The base load profiles are supposed to be given and therefore not optimized since base load contract decisions have to be made before the time horizon of interest. The shown day-head electricity purchase profiles are the expected values computed over all scenarios. In the 3SSP solution, the plant operates longer in order to accommodate for the high-demand and breakdown scenario providing more flexibility for load shifting. Accounting for breakdown scenarios means purchasing more electricity (when convenient) in order to be able to compensate reductions of the production capacity. This renders the TOU contract (according to the electricity prices) more convenient than the day-ahead market and therefore the 3SSP solution purchase a higher amount of electricity from the TOU contract. It is remarkable how different the optimal electricity purchase strategy can be when considering the day-ahead commitment and the load deviation penalties.

5. Conclusion

This work addresses the integrated electricity procurement and production scheduling under uncertainty for continuous power-intensive processes. A three-stage stochastic programming model is proposed to model electric power purchase commitments accounting for uncertainties in product demands and equipment breakdowns. The application of the proposed approach instead of the deterministic counterpart shows that the total operating cost reduction for a power-intensive plant can be quite significant.

Abstract

Due to the varying feedstocks and operating conditions in refinery routine operations, the current process models (i.e. outlets yield prediction and operating cost model) for scheduling mismatch much from the industrial reality. How to obtain the more accurate and feasible models to describe refining processes remains an open problem and is the key challenge for successful industrial application use. In this paper, an industrial data-based modelling method considering both varying feedstocks and operating conditions of process units is presented. In details, for a certain unit, feedstocks composition rates and outlets properties are introduced to indicate the varying feedstocks and operating conditions respectively. For catalytic reformer and diesel hydrotreater, outlets yield and operating cost models about feedstocks composition rates and outlets properties (here, specific properties variables are selected for each process) are determined by data-based regression. Furthermore, the resulted process models are embedded into the scheduling model. A computational case originated from a real refinery in China is solved by BARON in GAMS 24.0.2 using a CPU Intel Xeon E5-2609 v2 @2.5 GHz with RAM 32.0GB. Result shows that, (1) the operation schedule of units are well adjusted dynamically with the demand trend of different product oils, (2) the resulted schedules increase the outlet yield and reduce the operating cost of process units and thus, improve the economic profit of refinery.

Keywords: Refinery scheduling, Process model, Feedstock, Operating Condition

1. Introduction

Optimal scheduling will contribute to improving economic profit of refinery industry and addressing the growing challenges, such as increasing requirement for product quality, strict environmental regulations, frequent fluctuation of crude oils caused by tighter supply, changes in demand for product oils, and so on (Gao, et al, 2015).

A number of scheduling methods have been developed over the past few years. A novel refinery optimization modeling and decomposition strategy was proposed (Zhang and

Zhu, 2000; Pinto et al, 2000). Smania and Pinto (2003) pointed out that the operating conditions and inflow properties should be taken into consideration. However, how to model it remains an open problem. Continuous time formulation and decomposition method are proposed by many scholars. The yield model is usually described as constant regardless of operation and feed changes (Jia and Ierapetritou, 2004; Dogan and Grossmann, 2006; Wu and Ierapetritou, 2007). Shah and Ierapetritou (2011) early treated outlet yields of production units as optimized variable with predefined bounds. The predefined operation state with fixed feedstock and unit operation condition was used by Göthe-Lundgren (2002). However, this multi-fixed unit operation point method does not well cover the entire scheduling domain.

Although there are many valuable reports in refinery scheduling, very limited attention has been placed on the modeling of the yield and operating cost of refinery units (response variables) as function of decision variables. In the majority of existing studies, the yield and cost are fixed for each predefined operating mode, i.e. models resembling look-up tables (Göthe-Lundgren et al., 2002); this strategy does not well represent the real processes. However, if highly complex nonlinear models are adopted, such as neural networks or piecewise linear models (Gao et al., 2014a), the subsequent optimization becomes nonlinear and is hard to solve efficiently. More recently, Gao et al. (2014b) considered the impact of variations in crude oil on scheduling, and proposed a deep belief network based crude oil classification and multi-model method to describe the impact caused by crude oil changes. And also, Gao et al. (2015) proposed a piecewise linear modeling method to consider the operation condition changes using simulation data from Petro-SIM. How to model the impact caused by both feed and operating condition changes simultaneously is not considered yet. In this paper, we present a data-driven modeling method considering both varying feedstocks and operating conditions of process units. The operational data of process units are collected from a real-world refinery in China.

The rest of the paper is organized as follows. Section 2 provides the problem statement. The proposed process modeling method is presented in Section 3. After that, a case study is given in Section 4 to demonstrate the effectiveness of the proposed methodology. Finally, a brief conclusion is drawn in Section 5.

2. Problem statement

We consider a real-world refinery in China in this paper. For this refinery, the supply of crude oils keeps steady and the operation of the primary (including preliminary, atmospheric and vacuum distillation units) and secondary processing units (fluidized catalytic cracking (FCC), hydro-cracking, delayed coking, etc.) does not change. In this case, we take the downstream of the primary and secondary operations as the adjustable units including the hydro-upgrading processing units (HUPUs) and product oil blenders. The feedstocks and operation conditions of HUPUs observably influence the yield and quality of the outlet flows. Blenders making use of the outlets from HUPUs directly determine the amount of each product which impacts revenue (Singh et al., 2000). The flow diagram in Figure 1 illustrates these adjustable units.

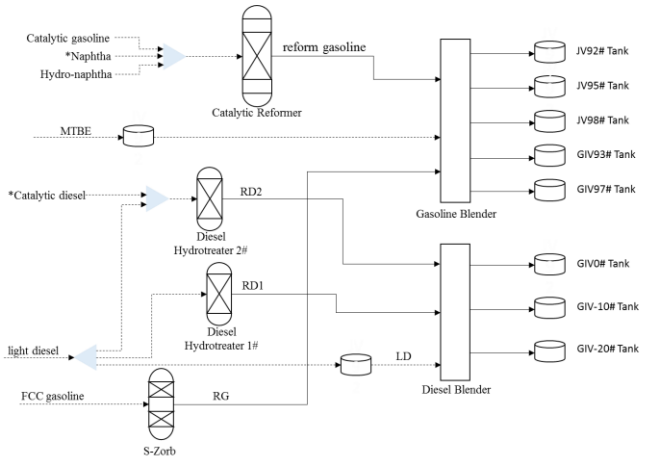

Figure 1. Flow chart of the refining units subject to scheduling

The HUPUs includes catalytic reformer, a FCC gasoline desulfurizer S-Zorb, a light diesel hydrotreater (Diesel Hydrotreater 1#) and a heavy diesel hydrotreater (Diesel Hydrotreater 2#) in this case. The dash lines represent material streams with fixed property from the upstream units. For catalytic reformer and diesel hydrotreater 2# having multiple inlets, key feed material (marked by * in Figure 1) is determined based on both mechanism and data analysis, which is then selected as the indicator to describe the feedstocks changes.

The objective is to maximize the profit subject to the process and operations constraints, and quality specifications. To formulate the optimal scheduling problem, models are needed to describe the yield and operating cost of each processing unit as a function of the feedstock decision variables and operating conditions decision variables. When HUPUs have more than one feed material, there is normally a key material which dominates the feedstock properties. Approximately, the percentages of the key material can be taken as an indicator of feedstock changes and thus introduced as the feedstock decision variables. In details, for catalytic reformer, the naphtha percentage is the feedstock decision variable, while for diesel hydrotreater 2#, the catalytic diesel percentage is treated as feedstock decision variable. Since the outlets of HUPUs will be blended as final products, the final product properties are key operation decision variables. Moreover, the outlet properties can also represent the operating conditions changes. In particular, for gasoline HUPUs (catalytic reformer and S-Zorb), the desulfurization amount (ΔSC) and delta research octane number (ΔRON) are the operation decision variables, whereas for diesel HUPUs (the two hydrotreaters), the desulfurization amount (ΔSC) and delta freezing point (ΔFP) are taken as operation decision variables. Besides these HUPU-specific decision variables, the inlet and/or outlet mass flows also need to be determined for each unit and blending/storage tank. For blenders, the outlet property is assumed as a linear function of those of the inlets. There are eight kinds of product oil, including five grades of gasoline and three grades of diesel. Dedicated tanks are assigned for each grade product.

3. Linear regression model

In this case, there are four HUPUs. For both outlet yield and operation cost model, in detail, decision variable refers to key feed material percentage $P_{u,n}$, desulfurization

amount $\Delta SC_{u,n}$, delta research octane number $\Delta RON_{u,n}$ for gasoline HUPUs, and delta freezing point $\Delta FP_{u,n}$ for diesel HUPUs, respectively. In order to obtain their process models, we have collected a whole year's operational data from real production processes of a refinery in China. For the sake of concision, we take outlet yield model of diesel hydrotreater 2# and operating cost model of catalytic reformer for examples to illustrate the effectiveness of the proposed data-based linear regression model.

3.1. Outlet yield model

For diesel hydrotreater 2# (HTU2 for short), the main product is refine diesel (i.e. RD2 in Figure 1) as one kind of diesel blending component oils. Here, the freezing point is firstly transformed into the freezing point factor in order to guarantee a linear relation for blending. Linear regression result for outlet yield model is shown in Eq. (1). The root mean square error (RMSE) and mean relative error (MRE) for this regression are 3.2905 and 4.505% respectively.

$$Yield_{HTU2,n} = 122.076 - 0.527 \cdot P_{HTU2,n} + 16.371 \cdot \Delta FP_{HTU2,n} + 0.0154 \cdot \Delta SC_{HTU2,n} \quad (1)$$

3.2. Operating cost model

For catalytic reformer (RF for short), the main product is reform gasoline, which is used to blend high quality gasoline as a gasoline component oil. Specifically, the pre-processing unit of RF desulfurize the feed material to 0.5ppm (sulfur content) to prevent the catalyst in reformer from poisoning. Linear regression model for the operating cost is written as Eq. (2). Similarly, the root mean square error (RMSE) and mean relative error (MRE) are 4.176 and 4.692% respectively.

$$OpCost_{RF,n} = -5.843 + 0.658 \cdot P_{RF,n} + 1.768 \cdot \Delta RON_{RF,n} + 0.048 \cdot \Delta SC_{RF,n} \quad (2)$$

4. Case study

Due to the frequent change of product oil demand in the investigated refinery, the scheduling problem is of short term with a horizon of 96 hours. The four orders are determined by monthly plan, as listed in Table 1.

This case is solved by BARON in GAMS 24.0.2 using a CPU Intel Xeon E5-2609 v2 @2.5 GHz with RAM 32.0GB. The obtained process model is embedded into the continuous time representation based scheduling model (Ierapetritou and Floudas, 1998a; Ierapetritou and Floudas, 1998b). The model involves 1473 continuous variables, 384 binary variables and 3328 constraints.

Table 1 Product Oil (due time & quantity)

Order	Due time/hours	Gasoline/ton					Diesel/ton		
		JV92	JV95	JV98	GIV93	GIV97	GIV 0	GIV-10	GIV-20
1	24	400	0	200	450	300	600	700	500
2	48	300	300	300	0	400	800	550	650
3	72	200	600	450	0	200	750	650	600
4	96	200	250	0	800	0	700	600	620

Clearly, the demand for premium and high grade gasoline (i.e. JV95#, JV98# and GIV 97#) firstly increases and then decreases. The schedule for the catalytic reformer is depicted in Figure 2 and 3. To satisfy the demand change of premium and high grade gasoline, the catalytic reformer first tries to increase the RON of refine gasoline (higher quality, higher operating cost and lower yield level), and then reduce the RON when demand for low-grade fuel is high. In addition, the desulfurization amount of S-Zorb also exhibits the same pattern, as shown in right part of Figure 2. Such fine tuning of the operation provides more flexibility, and thus opportunities to improve the profit while meeting the demand.

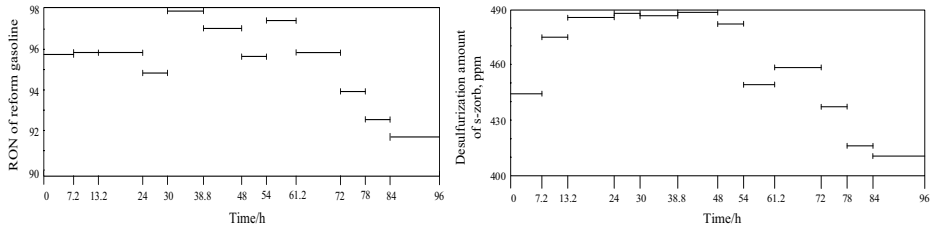

Figure 2. Left: refine gasoline RON of catalytic reformer; Right: desulfurization amount of S-Zorb

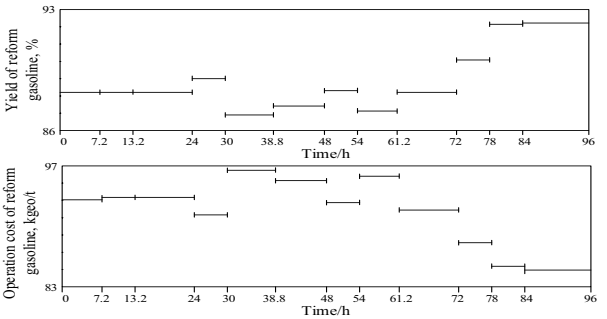

Figure 3. Yield and operation cost of Catalytic Reformer.

5. Conclusion

In this paper, both varying feedstocks and operating conditions are taken into consideration for refinery scheduling problem. To well model the impact caused by both varying feedstocks and operating conditions, the key feed percentage and outlet properties are introduced as independent variables. An industrial operational data based regression method is used and the model results prove its effectiveness. The resulted process model is then organized in the scheduling model and was further demonstrated through a scheduling case study, which was originated from a real refinery in China. The operation schedule of units are well adjusted dynamically with the demand trend of different product oils. This dynamic feature improves the operation ability to satisfy the quality specifications on edge, which is significant to increase the outlet yield and reduce the operation cost of process units and thus, improve the economic profit of refinery. Cleary, an updating strategy for the proposed linear regression model along the time is needed and it is further considered in our undergoing research.

Abstract

In this study, we present the simultaneous planning and scheduling of shale gas production using bi-criterion mixed-integer linear programming (MILP) to help guide the long-term corporate strategy for developing assets over multiple shale gas production systems. By analyzing the existing gas production and considering the economic costs of developing new prospective systems, the programming model will help determine the optimal asset development and gas production, subject to physical and financial constraints. We apply the planning and scheduling to a case study to quantify the value of utilizing multi-objective optimization for shale gas development and production.

Keywords: shale gas, bi-criterion optimization, planning, mixed integer programming.

1. Introduction

Shale gas production is expected to increase by over 50 % in the next 34 years, going from 14 trillion cubic feet (TCF) in 2016 to approximately 29 TCF in 2040 (EIA, 2016). This increase in production makes shale gas a major player in the natural gas field, with shale gas production fulfilling 69 % of the expected total dry gas natural demand (EIA, 2016). With this expected growth, all stages of the natural gas supply chain will need modification, either by adding new capacities or expanding existing capabilities (Drouven et al., 2016). To accommodate this expected growth, companies must make informed decisions of where, when, and how to develop their assets.

2. General problem statement

The problem can be stated as follows. Consider the representative core development area superstructure in Figure 1, which contains a collection of natural gas sales points, gathering and midstream pipelines, and producing and perspective pads and well groups. At each pad, all wells are bundled together into groups based on their physical characteristics and current production capabilities. All pads have been grouped together into systems, based on their physical proximity to a central midstream pipeline, and are connected, via gathering pipelines, to at least one midstream pipeline. If a well group is producing gas, then the associated pad is also producing. However, not all well groups at a pad must be developed to production. Utilizing this superstructure and knowledge specific to the core development area, the goal is to understand the long-term asset development needed to maximize asset value and production given available infrastructure and financial constraints.

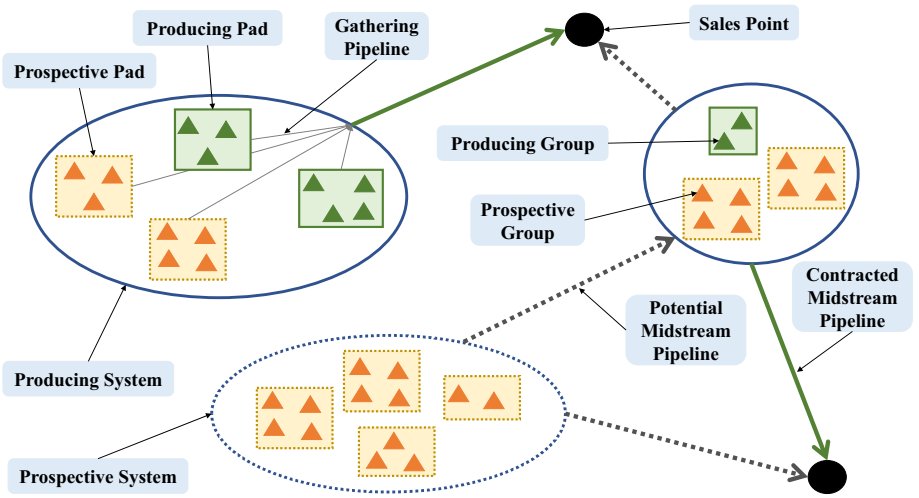

Figure 1. Representative illustration of the core development area superstructure.

From an executive level, the driving force behind maximizing long-term asset development may be divided, with shareholders expressing conflicting interests (Gao et al., 2017). While it is important to consider all conflicting interests when developing the assets, it can be impossible to maximize one interest without sacrificing the value of another. However, it is possible to identify an ideal compromise, where all interests sacrifice the least possible with respect to their maximum benefit.

The purpose of this work is to maximize the long-term asset value of a shale gas development area, considering two conflicting objectives that are to be maximized: the net present value (NPV) and the shale gas production volume. Intuitively, maximizing volume is thought to increase the NPV, but one goal of this research is to determine if this logic holds true for the shale gas sector. The NPV and production volume will both be determined via a long-term planning and scheduling, which identifies: a) when and which groups of wells should be developed, b) how much natural gas production should be curtailed over time, c) which midstream pipeline options should be selected, d) how to utilize the available midstream pipeline capacity, and e) when and how much gas should be delivered to each gas sales point. The planning and scheduling optimization, formulated as a bi-criterion mixed integer linear program (MILP), is solved using the ϵ-constrained method and finding the ideal compromise solution. The results will provide informed guidance for executive-level decisions in a sector where economic efficiency is imperative with the current low price of natural gas (Gao et al., 2017).

3. The bi-criterion development problem

The bi-criterion development problem consists of two parts: 1) the multi-system development planning and scheduling, and 2) the bi-criterion optimization. When combined, these parts will identify one solution where both interests will sacrifice the least that is possible with respect to their maximum benefit.

3.1. Multi-system development planning and scheduling problem

The first part of the multi-system development planning and scheduling is to transform the physical and operational aspects of the core development area superstructure into a discrete-time MILP formulation. The objective is two-fold: 1) maximize the NPV, and 2) maximize the production volume *(VOL)*:

$$\boldsymbol{NPV = Rev^{D} - \left(Cost^{DDev} + Cost^{DPipe} + Cost^{DGather}\right)} \tag{1}$$

$$\boldsymbol{VOL = \sum_{sp \in SP} \sum_{t \in T^{rev}} P_{t,sp}^{fin}} \tag{2}$$

where Rev^{D} is the discounted revenue from selling gas at the sales points, $Cost^{DDev}$ is the discounted cost of developing the well groups, $Cost^{DPipe}$ is the discounted cost of midstream pipeline contracts, $Cost^{DGather}$ is the discounted cost to collect and transport natural gas from the pads to the midstream pipelines, and $P_{t,sp}^{fin}$ is the volume of gas sold at sales point *sp* at time *t*. Due to the high cost of development and the long horizon needed to recover gas to cover these expenses, the development decisions (development and contracts) are only optimized during the first T^{dev} time steps, while the gas production is scheduled through the optimization horizon, T^{rev}, where $T^{rev} \gg T^{dev}$

The objectives are limited by both developmental and production-based constraints, equating to legal, resource, and physical limits. These constraints include:

- Permit dates: Well groups cannot be developed until all permits have been acquired
- Resource constraints: Limits on the amount of drilling allowed at the system and core development levels
- Pipeline contract terms: Midstream pipeline contracts can last over 10 years
- Capacity limits: Well group production (characterized by very high initial production rate, followed by a sharp decline within the first year (Drouven et al., 2016)) and pipeline capacity may not be exceeded
- Production repression: Well group production may be curtailed or stopped
- Gas balances: All gas produced from well groups must be delivered to a sales point

Both the objectives and constraints are driven by three sets of Boolean variables, $x_{t,j,k}^{con}$, $y_{t,g}^{start}$, and $z_{t,g}^{st}$, where the first set is *true* if a contract exists to allow transport of gas in a midstream pipeline from node *j* to node *k* at time *t*, the second set is *true* if well group *g* has been developed at time *t*, and the third set is *true* if well group *g*'s production is curtailed at time *t*, with the withheld gas saved in "underground storage".

By initially formulating the multi-system development planning and scheduling using General Disjunctive Programming (GDP), we can systematically derive mixed-integer inequalities for all disjunctions and logic propositions (Grossmann and Trespalacios, 2013) to obtain a discrete-time MILP formulation. This MILP formulation can then be used with the bi-criterion optimization to help understand and guide the long-term asset development needed to maximize asset value given available infrastructure and financial constraints.

3.2. Bi-criterion optimization

The second part of the multi-system development planning and scheduling is to identify the relationship between two conflicting interests, and determine one solution where

both interests will sacrifice the least that is possible with respect to their maximum benefit. Let f_1 represent the NPV and f_2 represent the total shale gas volume produced, where the objective is to maximize both f_1 and f_2. The multi-objective optimization, utilizing the ϵ-constrained method (Haimes et al., 1975) is formulated as follows:

$$\begin{aligned} \boldsymbol{max} \quad & \boldsymbol{f_1} \\ & \boldsymbol{f_2 \geq \epsilon} \end{aligned} \tag{3}$$

where ϵ is an adjustable parameter that lies in the interval $[f_2^L, f_2^U]$. By adjusting ϵ and maximizing formulation (3), a set of points is obtained, which defines a trade-off curve, demonstrating how improving one objective negatively impacts the other conflicting objective.

While the ϵ-constrained method gives a set of non-inferior solutions, an ideal compromise can be obtained by determining the closest non-inferior solution to the utopia point (i.e., the infeasible point where both the volume and NPV are at their maximum value) (Yu, 1973), (Grossmann et al., 1982). This is done by minimizing the distance between the utopia point and a non-inferior solution. To account for differences in magnitudes between f_1 and f_2, the objective functions are scaled based on their upper and lower limits. Selecting a particular norm of one, the following optimization is solved to obtain the ideal compromise:

$$\textbf{max} \quad \left[\frac{(\boldsymbol{f_1} - \boldsymbol{f_1^L})}{(\boldsymbol{f_1^U} - \boldsymbol{f_1^L})} + \frac{(\boldsymbol{f_2} - \boldsymbol{f_2^L})}{(\boldsymbol{f_2^U} - \boldsymbol{f_2^L})}\right] \tag{4}$$

where f_1^U is the upper bound obtained by maximizing f_1, and f_1^L is the lower bound obtained by selecting the minimal value of f_1 from the ϵ-constrained method and the trade-off curve.

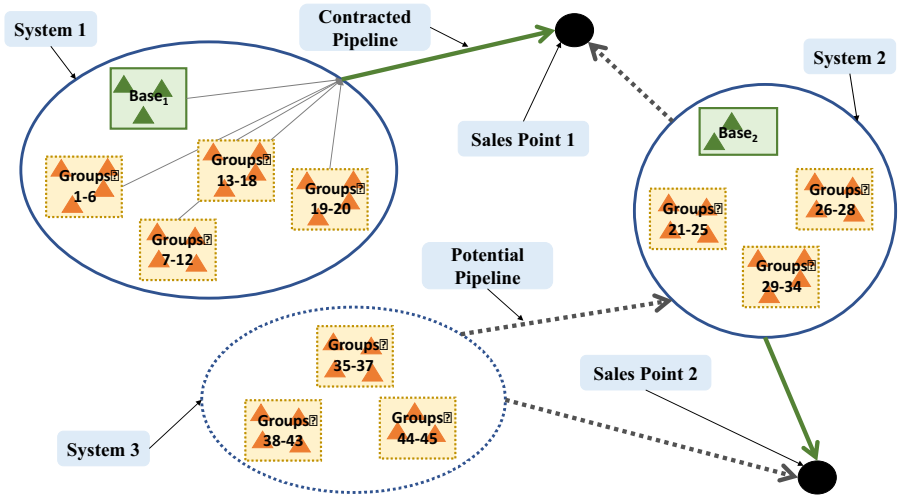

Figure 2. Prospective core development area used in the case study.

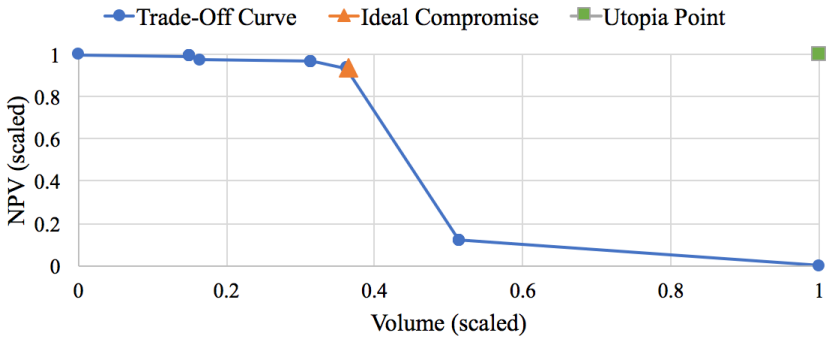

Figure 3. Scaled trade-off curve, created using the ϵ-constrained method.

4. Case study

In this case study, we apply the bi-criterion optimization and multi-system development planning and scheduling to an illustrative example (Figure 2) with a one-year planning horizon, a five-year revenue horizon, and a one month time step. The proposed multi-system development area includes two producing systems with potential for additional well group development (Systems 1 and 2), and a third undeveloped system (System 3). The two producing systems are connected to two sales points with different natural gas prices, but other midstream pipelines are available to be contracted. The prospective core development in Figure 2 was optimized with GAMS 24.8.5 using the commercial solver CPLEX 12.7.1.0 on a PC Intel Core i7, 3.60 GHz, 16 GB RAM, 64 bit, and Windows 10. The largest problem solved had just over 16,000 equations and 17,700 variables, of which 720 were binary, and took 10 seconds to solve.

The trade-off curve, obtained by using the ϵ-constrained method with forty volume-constraint parameters, is shown in Figure 3, where the volume production is scaled from

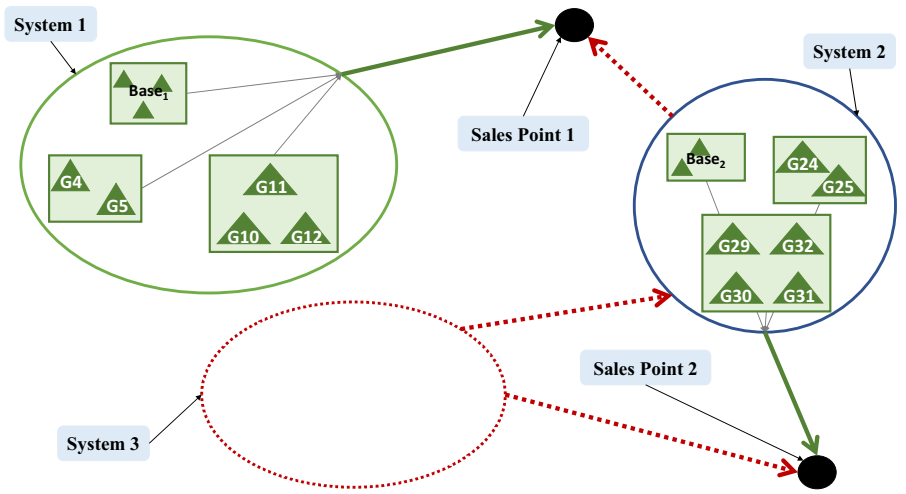

Figure 4. Optimal development of the core development area

267.2 BCF to 328.4 BCF, and the NPV is scaled from $ 25.9 million to $ 135.5 million. The trade-off curve indicates that maximizing volume production is not the best development policy. After producing 267.2 BCF, the NPV of the core development area will continue to decrease as additional well groups are developed and more natural gas is produced. A steep decline in the NPV is seen when the scaled volume production exceeds 0.37. Between 0.37 and 0.5 of the scaled volume production, natural gas production from Systems 1 and 2 is limited by pipeline capacity, so System 3 must be developed to produce additional natural gas. To develop any well group in System 3, a contract must be made to transport the gas from the system to Sales Point 2, introducing a very large development cost and a sharp decrease in NPV.

By scaling and optimizing both conflicting interests simultaneously, an ideal compromise solution was determined, where both the NPV and natural gas volume sacrifice the least, relative to the utopia point (Figure 3). The optimal advancement of the core development area in the ideal compromise is shown in Figure 4. No well groups were developed in System 3 due to the high cost to contract pipelines to deliver the gas to System 2 or Sales Point 2. However, the pipelines already under contract to deliver natural gas to Sales Points 1 and 2 have extra natural gas delivery capacity relative to the initial system base productions, allowing for multiple well groups in both systems to be developed to production.

5. Conclusions

In this paper, we optimized the design of a shale gas core development area taking into consideration developmental and production-based constraints and conflicting objectives to be maximized. Utilizing an illustration of a shale gas development area, we formulated a bi-criterion MILP planning and scheduling optimization and solved for the ideal development configuration using the ϵ-constrained method and compromise programming. The results demonstrated the impact of considering multiple driving forces when maximizing long-term asset development, and the value in using optimization to guide the long-term corporate strategy for developing multiple assets.

Abstract

This paper addresses long-term generation expansion planning considering a high penetration of renewables and the possibility of investing in advanced fossil fuel energy systems and multiple energy storage technologies. We propose a deterministic multi-scale mixed-integer linear programming (MILP) formulation that includes annual investment decisions and hourly unit commitment. We adopt time sampling and clustering techniques to reduce the size of the model and improve its tractability. Additionally, we use the Nested Decomposition algorithm for mixed-integer multi-period problems proposed by Lara et al. (2017) to solve the problem more efficiently. We apply the proposed formulation to a case study in the ERCOT region, and show that for this case study it makes sense to invest in lithium-ion utility batteries and natural gas fuel cells.

Keywords: generation expansion planning, energy storage, advanced fossil fuel.

1. Introduction

Generation expansion planning models consist of finding the optimal investment strategy for building new generation capacity while meeting load demand and satisfying technical and economic requirements. Such models are used to support decision making in power systems, study the impact of new technology developments, identify resource cost trends, and evaluate the impact of policy shifts on the projected generation mix to meet future demand. The increasing penetration of renewable generation in the grid brought new challenges for the long-term planning models. Due to their intermittent and non-dispatchable nature, it becomes crucial to include operating details at the hourly level to ensure flexibility in the system. Therefore, recent publications such as Flores-Quiroz et al. (2016), Heuberger et al. (2017), and Lara et al. (2017) have focused on integrating unit commitment, ramping limits and operating reserves into long-term planning models.

A number of flexible, environmentally sustainable fossil energy systems are under development which can help maintain grid stability by providing baseload power as well as help manage fluctuations that occur with high penetrations of renewables. Such new systems are expected to have increasing flexibility and achieve lower costs over the next several years. In addition, energy storage can play a pivotal role in the future of renewable generation to smooth out the variability of wind and solar power output. Several stationary, large-scale energy storage technologies are under development and are projected (Schmidt et al., 2017) to significantly decrease in capital cost over the next few decades. Liu et al. (2017) considers a generic energy storage technology in their capacity expansion model, which was represented as a multistage stochastic linear programming model, and applied to a case-study in the ERCOT region.

In this paper, we extend the work by Lara et al. (2017) to address long-term planning of electric power infrastructure considering an increasing share of power generation from renewables and the possibility of having new, advanced fossil energy systems and/or electricity storage units incorporated to the grid. The modeling framework, which is based on mixed-integer linear programming (MILP), takes the viewpoint of a central planning entity whose goal is to optimize the generation expansion planning. This model is very comprehensive in terms of alternatives considered, identifying the source, generation technology, electricity storage technology, location, and capacity of future generation and storage units that can meet the projected electricity demand while taking into account detailed operational constraints (i.e., unit commitment), the variability and intermittency of renewable generation sources, and the power flow between regions. The major goal of this model is to help understanding the characteristics needed to develop new advanced energy generation and storage technologies that can be competitive in the anticipated future market considering all sources of competition.

In addition to the challenge of comprehensive grid modeling and solving the resulting MILP, another challenge lies in the multi-scale integration of detailed operating decisions at the hourly level with investment planning decisions over a few decades, significantly exacerbating the computational burden. Therefore, we adopt judicious approximations and aggregations, such as time sampling and generator clustering (Palmintier and Webster, 2014) to reduce the size of the model. In the algorithmic front, we use the Nested Decomposition algorithm for mixed-integer multi-period problems proposed by Lara et al. (2017) to solve the problem efficiently.

2. Problem Statement

For the proposed planning model, an area with a set of existing and potential generators is given. Regarding these generators, their source (nuclear, coal, natural gas, wind, and solar), and generation technology (e.g., steam, combustion and wind turbines, photo-voltaic, concentrated solar panels, solid oxide fuel cells) are known. Also known are: their nameplate capacity; expected lifetime; capital cost; fixed and variable operating cost; maximum yearly installation limit; start-up costs (fixed and variable); cost for extending their lifetimes; CO_2 emission factor; age in the beginning of the planning horizon; location (regions); and operating characteristics such as ramp rates, operating limits, maximum contribution to spinning and quick-start fraction for thermal generators, and capacity factor in an hourly basis for the renewable generators.

Also given is a set of potential storage units, with specified technology (e.g., lithium-ion, lead-acid, and flow batteries), capital cost, power rating, rated energy capacity, charge and discharge efficiency, and storage lifetime. Additionally, the projected load demand is given for each location on an hourly basis, as well as the distance between locations, transmission loss factor per mile, and transmission line capacity between locations.

The objective is to find the location, year, type and number of generators and storage units to install; when to retire the generators, and whether or not to extend their lifetime; the approximate power flow between locations; and the approximate operating schedule in order to meet the projected load demand while minimizing the overall operating, investment and environmental costs.

Modeling strategies are adopted to handle the problem size and its multi-scale nature. Regarding the time scale, we use *k*-means clustering approach to select representative days from historical data that best represent the load demand and renewable capacity

factor for each region (Lara et al, 2017). This reduced set of representative days with hourly resolution is multiplied by a weight to account for the entire year. For the spatial representation, the area considered is divided into regions that have similar climate and load demand profiles, and it is assumed that the potential locations are the midpoints in each region. Additionally, generators and storage units that have the same status (existing or potential) and the same technologies are grouped in clusters per region (Palmintier and Webster, 2014), such that the discrete decisions associated with generators and storage units are integer instead of binary variables, representing the number of units under a specific status in each cluster at each time period. To simplify even further the model, the transmission is determined by an energy balance between nodes, as in the "truck-route" model representation. This approximation ignores Kirchhoff's voltage law, but it is commonly used in long-term planning models that consider a large area.

3. MILP formulation and solution strategy

This section presents the proposed deterministic MILP formulation. For the sake of space, we only include in this paper the constraints that were modified or added to the original model by Lara et al. (2017). In addition to the set of regions $r \in R$, generator clusters $i \in I$, time periods (years) $t \in T$, representative days $d \in D$, and sub-periods of time (hours) $s \in S$, we also have a set of energy storage clusters $j \in J$.

The first modified constraint is the energy balance (1), which was Equation (1) in Lara et al. (2017). This constraint ensures that the sum of the instantaneous power $p_{i,r,t,d,s}$ by the generators in cluster *i*, regions *r*, plus the difference between the power flow from regions *r'* to region *r*, $p^{flow}_{r',r,t,d,s}$, and the power flow from region *r* to regions *r'*, $p^{flow}_{r,r',t,d,s}$, plus the power discharged from all the storage clusters *j* in region *r* $p^{discharge}_{j,r,t,d,s}$, equals the load demand $L_{r,t,d,s}$ at region *r*, plus the power being charged to the storage clusters *j* in region *r* $p^{charge}_{j,r,t,d,s}$, plus a slack for curtailment of renewable generation $cu_{r,t,d,s}$ at all times.

$$\sum_i p_{i,r,t,d,s} + \sum_{r' \neq r} \left(p^{\text{flow}}_{r',r,t,d,s} \cdot (1 - T^{\text{loss}}_{r,r'} \cdot D_{r,r'}) - p^{\text{flow}}_{r,r',t,d,s} \right) + \sum_j p^{\text{discharge}}_{j,r,t,d,s} = L_{r,t,d,s} + \sum_j p^{\text{charge}}_{j,r,t,d,s} + cu_{r,t,d,s} \quad \forall\, r,t,d,s \tag{1}$$

Constraints (2)-(24) from Lara et al. (2017) are also included in this formulation. The objective function (25) is modified to include a term for storage cost,

$$\min \quad \Phi = \sum_t \left(\Phi^{\text{opex}}_t + \Phi^{\text{capex}}_t + \Phi^{\text{PEN}}_t + \Phi^{\text{storage}}_t \right) \tag{25}$$

where the operating Φ^{opex}_t and investment cost Φ^{capex}_t of generators, and the penalties Φ^{PEN}_t are defined in equations (26)-(28) of Lara et al. (2017), respectively. The new term $\Phi^{storage}_t$ accounts for the costs associated with storage and is defined in (29).

$$\Phi^{\text{storage}}_t = If_t \cdot \sum_j \sum_r SIC_{j,t} \cdot Storage^{\max}_j \cdot nsb_{j,r,t} \qquad \forall\, t \tag{29}$$

Additionally, there are constraints related to the energy storage devices, which are assumed to be ideal and generic (Pozo et al., 2014). Constraints (30)-(31) compute the number of storage units that are ready to operate $nso_{j,r,t}$, taking into account the storage units already existing at the beginning of the planning horizon $Ns_{j,r}$, and the ones built

$nsb_{j,r,t}$ and retired $nsr_{j,r,t}$ at year *t*. Due to the flexibility in sizes for storage units, $nso_{j,r,t}$, $nsb_{j,r,t}$, and $nsr_{j,r,t}$ are relaxed to be continuous.

$$nso_{j,r,t} = Ns_{j,r} + nsb_{j,r,t} - nsr_{j,r,t} \qquad \forall\, j,r,t=1 \tag{30}$$

$$nso_{j,r,t} = nso_{j,r,t-1} + nsb_{j,r,t} - nsr_{j,r,t} \quad \forall\, j,r,t>1 \tag{31}$$

Constraint (32) enforces the retirement of storage units that have reached the end of their lifetime LT_j.

$$\sum_{t'' \le t - LT_j} nsb_{j,r,t''} = \sum_{t' \le t} nsr_{j,r,t'} \qquad \forall\, j,r,t \tag{32}$$

Constraints (33) and (34) establish that the power charge $p^{charge}_{j,r,t,d,s}$ and discharge $p^{discharge}_{j,r,t,d,s}$ of the storage units in cluster *j* $nso_{j,r,t}$ has to be within the operating limits $Charge^{min}_j$ and $Charge^{max}_j$, and $Discharge^{min}_j$ and $Discharge^{max}_j$, respectively.

$$Charge^{\min}_j \cdot nso_{j,r,t} \le p^{\text{charge}}_{j,r,t,d,s} \le Charge^{\max}_j \cdot nso_{j,r,t} \qquad \forall\, j,r,t,d,s \tag{33}$$

$$Discharge^{\min}_j \cdot nso_{j,r,t} \le p^{\text{discharge}}_{j,r,t,d,s} \le Discharge^{\max}_j \cdot nso_{j,r,t} \qquad \forall\, j,r,t,d,s \tag{34}$$

Constraint (35) specifies that the energy storage level for the storage units in cluster *j* $nso_{j,r,t}$ has to be within the storage capacity limits $Storage^{min}_j$ and $Storage^{max}_j$.

$$Storage^{\min}_j \cdot nso_{j,r,t} \le p^{\text{level}}_{j,r,t,d,s} \le Storage^{\max}_j \cdot nso_{j,r,t} \qquad \forall\, j,r,t,d,s \tag{35}$$

Constraints (36) and (37) show the power balance in the storage units. The state of charge $p^{level}_{j,r,t,d,s}$ at the end of hour *s* depends on the previous state of charge $p^{level}_{j,r,t,d,s-1}$, and the power charged $p^{charge}_{j,r,t,d,s}$ and discharged $p^{discharge}_{j,r,t,d,s}$ at hour *s*. The symbols η^c_j and η^d_j represent the charging and discharging efficiencies, respectively. For the first hour of the day, the previous state of charge (i.e., *s=0*) is the variable $p^{level,0}_{j,r,t,d}$.

$$p^{\text{level}}_{j,r,t,d,s} = p^{\text{level}}_{j,r,t,d,s-1} + \eta^{\text{c}}_j \cdot p^{\text{charge}}_{j,r,t,d,s} + \frac{1}{\eta^{\text{d}}_j} \cdot p^{\text{discharge}}_{j,r,t,d,s} \qquad \forall\, j,r,t,d,s>1 \tag{36}$$

$$p^{\text{level}}_{j,r,t,d,s} = p^{\text{level,0}}_{j,r,t,d} + \eta^{\text{c}}_j \cdot p^{\text{charge}}_{j,r,t,d,s} + \frac{1}{\eta^{\text{d}}_j} \cdot p^{\text{discharge}}_{j,r,t,d,s} \qquad \forall\, j,r,t,d,s=1 \tag{37}$$

Constraints (38) and (39) force the storage units to begin $p^{level,0}_{j,r,t,d}$ and end $p^{level}_{j,r,t,d,s=S}$ each day with 50% of their maximum storage $Storage^{max}_j$. This is a heuristic to attach carryover storage level form one representative day to the next (Liu et al., 2017).

$$p^{\text{level,0}}_{j,r,t,d} = 0.5 \cdot Storage^{\max}_j \cdot nso_{j,r,t} \qquad \forall\, j,r,t,d \tag{38}$$

$$p^{\text{level}}_{j,r,t,d,s} = 0.5 \cdot Storage^{\max}_j \cdot nso_{j,r,t} \qquad \forall\, j,r,t,d,s=S \tag{39}$$

The integrated planning and operations model for the generation expansion planning is then given by the multi-period MILP model defined by equations (1)-(39).

Even though this formulation incorporates the modelling strategies aforementioned, it can still be very computationally expensive to solve it depending on the size of the area, the length of the planning horizon, and the time resolution of the representative days. Therefore, we use the Nested Decomposition algorithm for deterministic multi-period problems proposed by Lara et al. (2017). This algorithm consists of decomposing the problem per time period (year) and solving Forward and Backward Passes iteratively. The

Forward Pass solves the problem for each time period sequentially, in a myopic fashion, and yields a feasible solution (upper bound). The Backward Pass solves a relaxed version of the subproblems from the last to the first time period, projecting the problem onto the subspace of the linking variables by adding cuts. These cuts provide approximations to predict the cost-to-go functions within the planning horizon, yielding a lower bound to the problem. The only difference between the algorithm framework presented by Lara et al. (2017) and the one used in this paper is that there are two additional state (i.e., linking) variables, $\boldsymbol{nso_{j,r,t}}$ and $\boldsymbol{nsb_{j,r,t}}$. For a detailed description of the algorithm, please refer to Lara et al. (2017).

4. Case study

We applied this formulation to a case study approximating the Texas Interconnection, managed by the Electric Reliability Council of Texas (ERCOT). Within the ERCOT covered area, we considered four geographical regions: Northeast, West, Coastal, and South, and also include a fifth region, Panhandle, which is outside the ERCOT limits but supplies electricity to ERCOT due to its renewable generation potential. Most of the data source information can be found in Lara et al. (2017), Section 6. In this case study we consider 3 types of utility batteries: lithium-ion, lead-acid and flow batteries, for which we use the capital cost forecast provided by Schmidt et al. (2017) and the technical information provided by Luo et al. (2015). We also consider two types of advanced fossil fuel energy systems: integrated gasification fuel cell (IGFC) (Iyengar et al. 2014) and natural gas fuel cell (NGFC) (Newby and Keairns, 2013). We assumed a carbon tax starting at \$10/tonne in year 5, and increasing linearly to \$100/tonne in year 14. The problem is solved for a 30-year planning horizon and 4 representative days per year. We implemented the monolithic formulation and the Nested Decomposition algorithm with Benders cut in Pyomo, and solved the LPs and MILPs using Gurobi version 7.0.1.

The full-space MILP model has 1,730,491 constraints, and 1,310,681 variables (810,181 continuous, and 500,500 integer variables). It takes 4.0 hours for Gurobi to solve the full-space MILP within 1% gap, while it takes 2.8 hours to solve the same problem within 1% gap using the Nested Decomposition algorithm with Benders cuts, which is a reduction of 30% in solution time.

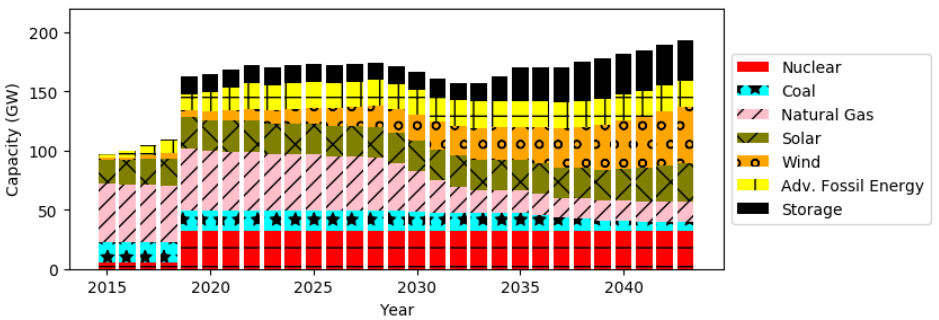

Figure 1: Generation and Storage Capacity: total ERCOT

The results displayed in Figure 1 show that most of the demand growth will be met by an increase in nuclear, solar photo-voltaic and wind capacity. It also shows that in the last year of the planning horizon there are 34.3 GW of lithium-ion batteries, and 22.0 GW of NGFC in the ERCOT region.

5. Conclusions

In this paper we propose an MILP model to solve power systems planning models considering increasing share of renewables and possibility of adding energy storage units. This deterministic formulation is applied to a case study in the ERCOT region. We show that by using the Nested Decomposition algorithm proposed by Lara et. al (2017) we are able to solve the problem more efficiently and predict which technologies show the highest likelihood of deployment and retirement under a variety of scenarios.

Abstract

This paper addresses the inherent upset (IU) issue, for instance, the flowrate fluctuation after switching charging tanks (CTs) for feeding crude distillation units (CDUs), during routine operations of crude supply process. A new MILP model with continuous time formulation is developed for the front-end crude scheduling (FECS) under consideration of inherent upset reduction (IUR). The optimal crude supply schedule can be determined via minimizing the overall operating cost and reducing IUs. Thus, both the process profitability and the operational stability of optimal schedules are guaranteed. In addition, the trans-mixing between adjacent crude slots inside LDPL is considered; and the inventory cost is precisely modeled compared with previous studies. All nonlinearities arising from the original mathematical problem are approached through piecewise linearization. The model efficacy and the IUR effect have been investigated through a refinery case study with a daily production of 160 kbbl.

Keywords: Front-end crude scheduling, Inherent upset reduction, Trans-mixing, MILP

1. Introduction

In recent decades, the front-end crude scheduling (FECS) has drawn considerable attentions from both academia and industry community. The entire scope of the FECS is concisely illustrated in Figure 1. In general, the FECS for inland refineries is to determine crude supply from vessel unloading through berths, temporarily storing in port-side storage tanks (STs), crude transferring via long-distance pipeline (LDPL), blending in refinery-side charging tanks (CTs) and continuously feeding to crude distillation units (CDUs) for processing. Significant profitability and operability benefits will be accomplished if the FECS could be optimally and timely performed. Therefore, lots of research efforts have been paid on the FECS (Li et al. 2012). It should be noted that inherent upsets (IUs) are inevitably generated during routine operations. For instance, the switch among CTs to CDUs may cause upsets in terms of flowrate and compositions. These IUs can affect local unit operations, also accumulate and propagate to downstream. In previous studies, flowrate IUs of feeding one CDU could be as high as 10 times. Conceivably, the implementation of such a schedule will cause huge losses and serious consequences, even shutdown to the entire refining plant. By now, most research works studying the FECS exclusively focused on the optimization of operating cost and gross margin (Xu et al. 2017a,b); few tackled IUs and their consequences. In this study, this tough concern has been taken into account along with other requirements, and simultaneously modeled and solved by the FECS. Thus, IUs can be reduced so as to help the smooth crude supply and stable CDU operations.

In this paper, a new MILP model with continuous-time formulation is developed for the FECS under consideration of inherent upset reduction (IUR). It is to explore the optimal crude supply schedule via minimizing the overall operating cost and reducing flowrate IUs of feeding CDUs. Thus, both the process profitability and the operational stability of the optimal front-end crude schedule can be guaranteed. In addition, the trans-mixing (TM) between adjacent crude slots inside LDPL is considered; and the inventory cost (IC) is also accurately modeled compared with previous studies. All nonlinearities arising from the original mathematical problem are approached through piecewise linearization. The model efficacy and the IUR effect have been investigated through a refinery case study with a daily production of 160 kbbl (1 kbbl=10^3 bbl).

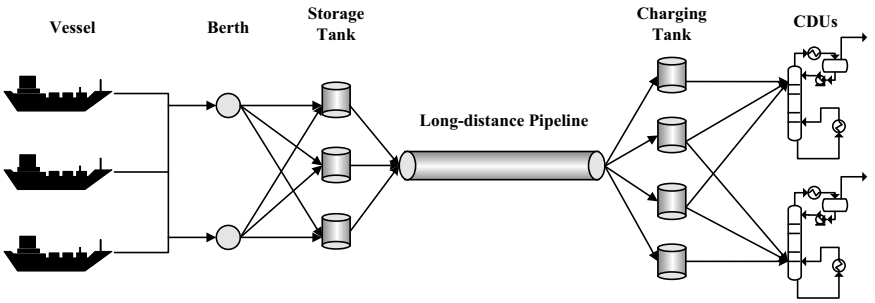

Figure 1. The entire scope of front-end crude scheduling for inland refineries.

2. Problem Statement

As shown in Figure 1, the studied problem includes three single-parcel vessels, two berths, three STs, one LDPL, four CTs and two CDUs. Arrows represent feasible crude transfer operations. Note that feeding operations of LDPL and CDUs are continuous during the entire time horizon. The objective is to determine the best crude supply schedule with minimal operating cost and reduced IUs. The assumption, given information, information to be determined and operating rules are summarized below.

Assumption: (1) no time cost for feed switching operation; (2) perfect blending within STs and CTs, and (3) fixed volume and ideal mixing for TM;

Given information: (1) capacity and initial inventory of vessels, STs, LDPL and CTs; (2) vessel arrival time; (3) allowable IU ranges for CDUs, (4) crude oil properties; (5) blending specs of CTs; (6) FECS time horizon; and (7) economic data;

Information to be determined: within the entire time horizon, (1) the detailed schedule of crude transfer from vessels, through berths, STs, LDPL and CTs, to CDUs; and (2) the inventory profile of the LDPL;

Operating rules: at one time event, (1) any unit can feed at most one downstream unit; (2) any unit except STs can be charged by at most one upstream unit; (3) STs can be charged by any available berths; (4) any STs and CTs cannot simultaneously receive and charge crudes; and (5) STs and CTs need BST right after receiving new crudes.

3. The FECS Model Extension

The FECS model is developed based on our previous work (Zhang and Xu, 2015). Note that the previous work mentioned below refers to this one. For the conciseness purpose,

only the newly developed constraints are provided in this section; other model information can be consulted from the previous work.

3.1. Reformulation of The Crude Transfer via LDPL

In this study, each feeding ST and charged CT is aligned with corresponding crude slots. Thus, unit set is enlarged to "*parcel*, *ST*, *L*, *CT*, *CDU*", where *L* denotes the set of slots and other elements represent the set of corresponding units. In this work, the crude transfer via LDPL is modeled as continuous within the entire time horizon. Hence, Eqs. (1) and (2) are employed.

$$\sum_{u\in ST}\sum_{l\in L^{new}}\sum_{n\in N, n\geq 1}(Te(u,l,n)-Ts(u,l,n))=H \tag{1}$$

$$\sum_{l\in L}\sum_{u\in CT}\sum_{n\in N, n\geq 1}(Te(l,u,n)-Ts(l,u,n))=H \tag{2}$$

where *Ts(u,u',n)* and *Te(u,u',n)* respectively represent the starting and ending time of crude transfer from unit *u* to unit *u'* at time event *n*; and L^{new} denotes new slots that are fed after the time horizon starts.

Due to the TM, the crude volume and its fraction of outlet slots are different with those when slots are injected. Based on the input volume *Vlc(l,c)* and volume fraction *flc(l,c)* of crude *c* in slot *l*, the discharged crude volume in slot *l*, *Vlcd(l,c)*, can be calculated by Eqs. (3) through (5), where *TV* refers to the TM volume of interchanged crudes at each interface. Note that the first and last slots have single interface to share with adjacent slots, while others have two. Thus, different formulations are resulted.

$$Vlcd(l,c)=Vlc(l,c)+TV\,(\,flc(l+1,c)-flc(l,c)\,),\quad \forall l\in L, l=1; c\in C \tag{3}$$

$$\begin{aligned}&Vlcd(l,c)=Vlc(l,c)+TV\,(\,flc(l+1,c)-2\,flc(l,c)+flc(l-1,c)\,),\\&\forall l\in L, 1<l<|L|; c\in C\end{aligned} \tag{4}$$

$$Vlcd(l,c)=Vlc(l,c)+TV\,(\,flc(l-1,c)-flc(l,c)\,),\quad \forall l\in L, l=|L|; c\in C \tag{5}$$

3.2. Inherent Upset Reduction for Feeding CDUs

To accomplish IUR for feeding CDUs, new constraints on the feeding rate are added based on the flexibility of the refinery operation processing capacity. Specifically, the IU is strictly constrained within 5% of the normal flowrate. This specification is enabled by Eqs. (6) and (7). Binary variable *X(u,u',n)* is used to represent the crude transfer operation from unit *u* to unit *u'* at time event *n*.

$$\begin{aligned}&V(u,u',n)\leq FRup\,(Te(u,u',n)-Ts(u,u',n))+M\,(1-X(u,u',n)),\\&\forall u\in CT; u'\in CDU; n\in N, n\geq 1\end{aligned} \tag{6}$$

$$\begin{aligned}&V(u,u',n)\geq FRlo\,(Te(u,u',n)-Ts(u,u',n))-M\,(1-X(u,u',n)),\\&\forall u\in CT; u'\in CDU; n\in N, n\geq 1\end{aligned} \tag{7}$$

where *V(u,u',n)* denotes the transferred crude volume; *FRup* and *FRlo* define the IU range of feeding CDUs; and *M* is for Big-M relaxation.

3.3. Reformulation of Inventory Cost (IC) in Objective Function

Unlike the approximation of IC in most studies, it is accurately modeled using the trapezoid area method following Eqs. (8) through (10). The IU is initially evaluated based on $Inv^0(u)\cdot H$; after the time horizon starts, for each input and output operation, extra cost will be "charged" and "credited" based on *Tin* and *Tot*, respectively. The accurate IU is determined by combing all these elements.

The reformulated IC expressions and crude blending equations contribute nonlinearities of this problem (Castro et al. 2014). In this study, these nonlinearities are approached following the effective piecewise linearization formulation in the previous work.

$$IC = \sum_{u\in ST\cup CT} C^{inv}(u)\left(Inv^0(u)\,H + \sum_{u'\in IU_u}\sum_{n\in N, n\geq 1} Tin(u',u,n) - \sum_{u''\in OU_u}\sum_{n\in N, n\geq 1} Tot(u,u'',n)\right) \tag{8}$$

$$Tin(u',u,n) = V(u',u,n)\,(H - 0.5\,(Te(u',u,n) + Ts(u',u,n))),\quad \forall u\in ST\bigcup CT; u'\in IU_u; n\in N, n\geq 1 \tag{9}$$

$$Tot(u,u'',n) = V(u,u'',n)\,(H - 0.5\,(Te(u,u'',n) + Ts(u,u'',n))),\quad \forall u\in ST\bigcup CT; u''\in OU_u; n\in N, n\geq 1 \tag{10}$$

where $C^{inv}(u)$ and $Inv^0(u)$ represent the IC coefficient and initial inventory of unit u; IU_u and OU_u denote the sets of possible input and output units of unit u.

Table 1. Problem data for charging tanks, flowrate range and economic cost

Charging tanks ID	Capacity (kbbl)	Charging Tanks: Initial Inventory		Spec on Key Component
		Amount (kbbl)	Composition	
CT1	[0, 1000]	300	100% C7	[0.025, 0.035]
CT2	[0, 1000]	500	100% C5	[0.045, 0.065]
CT3	[0, 1000]	300	100% C6	[0.06, 0.085]
CT4	[0, 1000]	500	100% C2	[0.065, 0.09]
Flowrate Range: (kbbl/day)				
Crude unloading	[0, 500]	Inter-tank transfer		[30, 35]
Feeding CDU	[78, 82]			
Economic Cost				
Demurrage ($/day)	30,000	ST inventory ($/day·kbbl)		40
Unloading ($/day)	30,000	CT inventory ($/day·kbbl)		80
Setup ($)	55,000			

4. Case Study

The developed FECS model is applied to a refinery with a daily production of 160 kbbl as shown in Figure 1. The normal daily flowrate of each CDU is 80 kbbl, thus the IU range is set as 78-82 kbbl per day. As comparison, rough flowrate bounds in the previous work are applied to the model without IUR. Parts of updated problem data are provided in Table 1. The time horizon in this case study is set as 12 days.

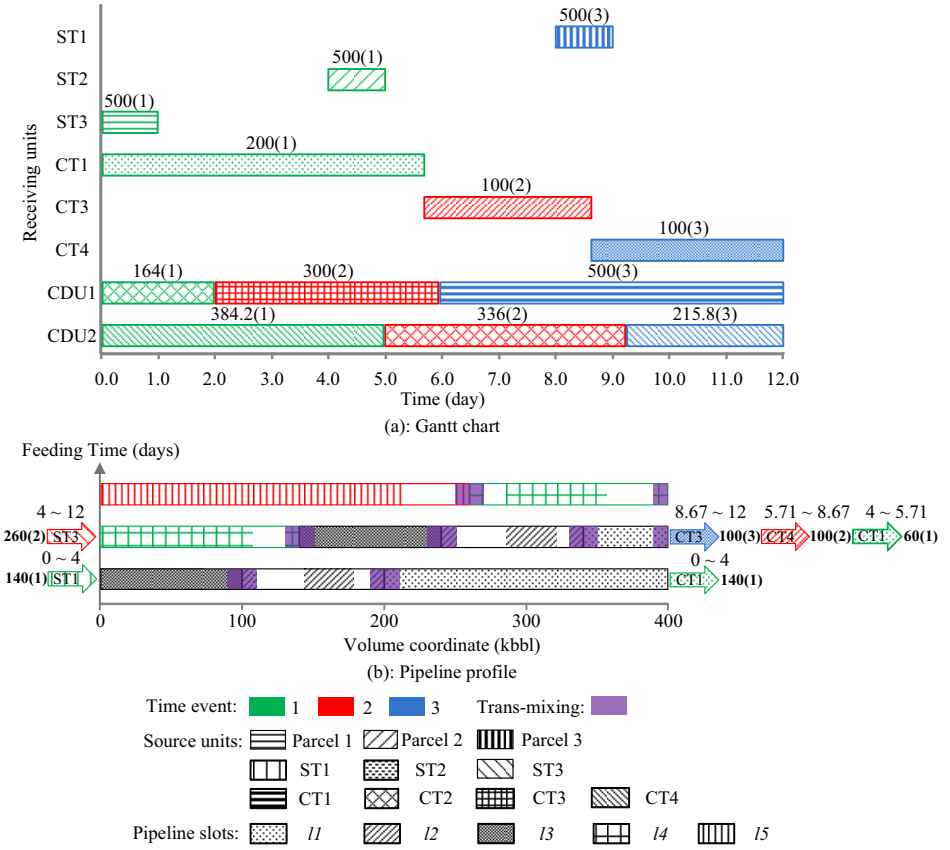

Figure 2. Gantt chart and pipeline profile for case study.

Through the developed model with IUR, the optimal crude supply schedule is successfully obtained. The optimal objective value is $2.08 million. The Gantt chart of optimal schedule and the pipeline profile are shown in Figure 2. With respect to receiving units, crude transfer operations are demonstrated in the Gantt chart. The timing can be read from x-axis, the volume is labelled nearby which is followed by the corresponding time event sequence, and the source is indicated using different filling patterns. As shown, all parcels are unloaded to STs as soon as vessels arrive at the port. The LDPL is continuously fed by STs, so that it keeps feeding CTs. The two CDUs are also continuously charged during the entire time horizon. Through the pipeline profile, information on charging of new slots, LDPL inventories and discharging of existing slots can be collected. TM between adjacent crude slots is marked at slot interface. ST1 feeds 140 kbbl of new crude into LDPL in 4 days, which forms slot *l4*. In the meantime, 140 kbbl of *l1* is charged into CT1. In the rest 8 days, ST3 feeds 260 kbbl of crude into LDPL, generating slot *l5*. From the LDPL outlet, the left 60 kbbl of *l1* is continuously charged into CT1 till 5.71 days; then *l2* is transferred to CT4 from 5.71 to 8.67 days. After that, *l3* is charged to CT3 for the rest 3.33 days. To demonstrate the effect of IUR, comparisons on feeding rate and IUs of CDUs from models with and without IUR are provided in Table 2. Through the model without IUR, all IUs are higher than 15% and it can be as high as -199%, which is for CDU2. Such huge IUs are not acceptable for any CDUs. On the other hand, through the model with IUR, IUs of both CDUs are strictly

kept within 5%. In fact, the highest IU is only 2.5%. From the operational stability point of view, the optimal schedule through the model with IUR is much better than that from the model without IUR.

Table 2. Comparison results of flowrate and IU

		Model without IUR				Model with IUR			
		Time events			Avg.*	Time events			Normal
		1	2	3		1	2	3	
CDU1	Flowrate	142.9	64.1	50	75.4	82	78.7	80.8	80
	IU (%)	89.5	-15	-34	--	2.5	-1.6	1	--
CDU2	Flowrate	247.5	50	--	82.9	78	78	78	80
	IU (%)	-199	-40	--	--	-2.5	-2.5	-2.5	--

The unit of flowrate is kbbl/day; the "avg." represents the average flowrate of feeding CDUs within the entire time horizon and it's calculated using the total crude volume divided by the time horizon.

5. Concluding Remarks

In this study, a new MILP model for optimal FECS is developed considering IUR. Through this model, the optimal crude supply schedule can be obtained via minimizing the overall operating cost and reducing IUs of feeding CDUs. Meanwhile, the TM inside LDPL is considered and the IC is also precisely modeled. The model efficacy has been demonstrated through a case study. IUs of feeding CDUs are strictly constrained within 5% of the normal flowrate, which is a significant improvement as compared with results through the model without IUR. Therefore, both the process profitability and the operational stability can be greatly enhanced through our development.

A General Mixed-Integer Programming State-Space Model for Online Scheduling

Dhruv Gupta, Christos T. Maravelias*

University of Wiscosin-Madison, 1415 Engineering Drive, Madison, WI-53706 USA
christos.maravelias@wisc.edu

Abstract

We present a framework and a generalized state-space model formulation that allows modeling several features that are necessary when a scheduling model is used in an online setting. These features are: (1) task-delays and unit breakdowns (2) robust scheduling through the use of conservative yield estimates and processing times; (3) feedback on task-yield estimates before the task finishes; (4) task termination during its execution; and (5) unit capacity degradation and maintenance. Further, we propose a systematic scheme for updating the state of the process, as well as ability to modify states through disturbance parameters, based on feedback information.

Keywords: uncertainty, rescheduling, model predictive control, bio-manufacturing

1. Introduction

Scheduling is a key operations planning function in any enterprise. Thus, much work has been accomplished in building accurate models and obtaining high quality solutions in a reasonable time-frame. However, due to disruptions or arrival of new information, incumbent schedules can become suboptimal or even infeasible. Hence, the need for rescheduling (Li and Ierapetritou, 2008; Cui and Engell, 2010). Online scheduling is the generalization of rescheduling as an ongoing process (Gupta et al., 2016). It is now gaining increased traction in the industry. However, scheduling models as have been developed till now, require ad-hoc constraints which need to be modified on the fly, so as to represent any disturbances to the schedule. Thus, there is an important need to develop scheduling models with their application in an online setting in mind.

State-space based models, popular in process control, are a natural choice for online scheduling (Subramanian et al., 2012; Nie et al., 2014). There are six advantages of state-space models in scheduling over the conventional models: (1) the status of the plant can be interpreted from states at that moment in time; (2) it is easier to carry-over information from one iteration to next (online "ready"); (3) schedule disruptions can be conveniently modeled as linear additive disturbances; (4) an identical model (structure) is maintained in each online iteration, i.e., no ad-hoc constraints; (5) enables a natural way to integrate scheduling and control; (6) a tool for theoretical analysis to establish closed-loop properties.

2. Online scheduling framework

The standard discrete-time state-space models as popular in process control approaches have the following general form for the state-evolution and input-state constraints:

$$x(t+1) = Ax(t) + Bu(t) + B_d d(t) \quad (1)$$

$$E_x x(t) + E_u u(t) + E_d d(t) \leq 0 \quad (2)$$

where, A, B, and B_d are the state-space matrices, t is the index for time, and E_x, E_u, and E_d are the coefficient matrices of the states, inputs, and disturbances, respectively.

At any given time t, the scheduling decisions, or in other words the inputs, are whether to start a new task, the batch-size of this new task, and the amount of material to ship, if any. The state of the plant comprises of the amount of inventory and backlog of materials, the material in processing, and the resources engaged/available at that time. Typical disturbances are material demand, task delays, unit breakdowns, and material handling losses. Under nominal operation, there are no disturbances, and the inputs are all zero, maintaining the states at a steady value (Subramanian et al., 2012).

In online scheduling, a schedule for next H hours, is computed at every time-point t, but only the first scheduling decisions/inputs are implemented. The state of the plant at the next time-point results from a combination of the injected input and any disturbances. If we reset the time-grid in each online iteration, but label each iteration with index σ, we can still uniquely keep track of all scheduling inputs, states, and disturbances.

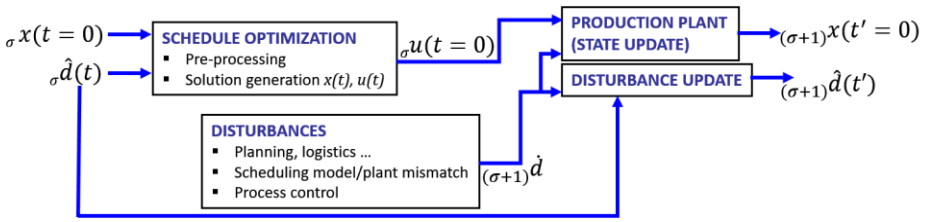

Figure 1: Online scheduling framework based on the state-space model.

In Fig. 1, we show one generic online (open-loop) iteration along with the plant state update step. To limit the scope of complexity in our work, we make a reasonable assumption that all scheduling-related plant states are observable and the scheduling disturbances are measurable. These scheduling disturbances originate due to changes in the planning and control level or due to scheduling model–plant mismatch. In iteration σ, a schedule $(x(t), u(t))$ is generated through the optimization model based on the initial state of the plant $_{\sigma}x(t=0)$ and the disturbances $_{\sigma}\hat{d}(t)$ as data. However, only the first input, $_{\sigma}u(t=0)$, is injected into the plant. Based on this input, and new materialized disturbances, $_{\sigma}\dot{d}$, states evolves to $_{\sigma+1}x(t'=0)$, where t' is the index for the new (reset) time-grid. In addition, as a separate computation, disturbances are updated to $_{\sigma+1}\hat{d}(t')$ based on previously known $_{\sigma}\hat{d}(t')$ and the newly observed disturbances $_{\sigma}\dot{d}$. With the new states and disturbances, the next online scheduling iteration is then carried out.

3. General state-space model

There are several novel features that are present in online scheduling, and not in offline scheduling. For example, terminating a task after it has started but before its completion. This is in particular common in bio-manufacturing. This decision to terminate a batch is typically taken when there is significant parallel growth of toxins along with the molecule of interest, rendering purification in downstream stages infeasible or

uneconomical (Martagan et al., 2016). Other common features are partial or complete yield-losses, and unit capacity degradation (e.g., due to gradual residue formation or sudden blockage) which requires maintenance. These features haven't been addressed in the literature. We model all the above features in our state-space model.

We use the State-Task Network (STN) framework to represent the different elements of the scheduling problem. It primarily comprises of tasks $i \in \boldsymbol{I}$, units $j \in \boldsymbol{J}$, and materials $k \in \boldsymbol{K}$. The processing time of task i, when executed on unit j, is denoted by τ_{ij}. Task i consumes/produces material k equivalent to $\rho_{ik}/\bar{\rho}_{ik}$ mass fraction of its batch-size (ρ_{ik}<0) for consumption and $\bar{\rho}_{ik} > 0$ for production). The subset of tasks that can be carried out on unit j are denoted by $\boldsymbol{I}_j$. An explanation of every variable and equation in the model is not possible within the limited space of this manuscript. Hence, here we present and briefly describe only selected components of the state-space model.

3.1. Disturbances

Single-period delays in task i running on unit j, which has progressed by n periods, are denoted by $\dot{Y}_{ij}^{n}$. Breakdown of unit j, while executing task i is denoted by $\dot{Z}_{ij}^{n}$. Yield-loss in a task is denoted by $\dot{\lambda}_{ij}^{n}$. Sudden partial loss in capacity of unit j to carry out task i is denoted by $\dot{\mu}_{ij}$. When delays span multiple periods, then disturbance parameters $\hat{Y}_{ijt}^{n}$ are needed that represent this extended delay information and, hence, help in correctly predicting when a task will end. Among others, these multi-period disturbance parameters require an update from one iteration to the next. For example, in iteration σ, for a ϕ period delay, ${}_{\sigma}\hat{Y}_{ijt}^{n} = 1$ for $t = \{0,1,2,\dots\phi - 2\}$. This delay decrements by one in the next iteration because the two iterations are spaced by 1-period. This combined with the time-grid shift, implies that now in iteration $\sigma + 1$, ${}_{\sigma+1}\hat{Y}_{ijt'}^{n} = 1$ for $t' = \{0,1,2,\dots\phi - 3\}$ and zero otherwise.

3.2. Inputs

The decision variables (inputs) include W_{ijt} which, when 1, denotes task i starts on unit j at time t; B_{ijt} the corresponding batch-size; T_{ij}^{n} which, when 1, implies that task i, on unit j, with progress index n, is being terminated; V_{kt}, the outgoing shipment of material k at time t. Certain inputs, such as, the task start binary variables W_{ijt}, have a lagged effect on future states. For example, these variables increase the inventory of material being produced after τ_{ij} periods, i.e., on task finish. This makes certain states $x(t)$ dependent on $u(t-\tau)$. This, however, does not conform to the standard state-space formulation (Eq. 1). Hence, these inputs are lifted forward and augmented to the future states, and the state-space is modified appropriately. For task start binary, new states $\bar{W}_{ijt}^{n}$ are defined which denote that task i, on unit j, has progressed by n periods at time t. When a task starts $\bar{W}_{ijt}^{n=0} = 1$, and when a task finishes $\bar{W}_{ijt}^{n=\tau_{ij}} = 1$. In the absence of any disturbances, this lifting is achieved through the following two constraints: $\bar{W}_{ijt}^{n=0} = W_{ijt}\ \forall\ i,j \in \boldsymbol{I}_j, t$ and $\bar{W}_{ij(t+1)}^{n} = \bar{W}_{ijt}^{n-1}\ \forall\ i,j \in \boldsymbol{I}_j, t, n \in \{1,2,\dots,\tau_{ij}\}$.

The lifting equations, for task-start binary, in the presence of disturbances are:

$$X_{ij(t+1)} = \hat{Y}^0_{ijt}\left(1 - T^0_{ij}\right) \forall j, i \in \boldsymbol{I}_j, t \tag{3}$$
$$\bar{W}^0_{ijt} = W_{ijt} + X_{ijt} \forall j, i \in \boldsymbol{I}_j, t \tag{4}$$
$$\bar{W}^n_{ij(t+1)} = \bar{W}^{n-1}_{ijt} - \hat{Y}^{n-1}_{ijt}\left(1 - T^{n-1}_{ij}\right) + \hat{Y}^n_{ijt}\left(1 - T^n_{ij}\right) \forall j, i \in \boldsymbol{I}_j, n \in \{1,2,\dots,\tau_{ij}\} \tag{5}$$

where, X_{ijt} is a dummy state defined to carry forward delays when task has zero progress, i.e., $n = 0$ (see Eq. 9).

3.3. States

The state of the plant is denoted by variables described as follows. $\bar{W}^n_{ijt} \in \{0,1\}$ and $\bar{B}^n_{ijt}$ are the lifted task-states which denote the progress status n and corresponding batch-size of the task. For example, if $\bar{W}^n_{ijt} = 1$, it implies that task i has progressed by n h on unit j at time t; its batch-size is $\bar{B}^n_{ijt}$. $\bar{L}^n_{ijt}$ is a lifted state that denotes the anticipated yield-loss as of time t in task i. S_{kt} and BO_{kt} represent the inventory and backlog level of material k in time-period $(t-1, t]$, while C_{ijt} is the capacity of the unit to perform task i on unit j at time t. With use, the capacity of the unit can degrade, but can then be restored through a maintenance task. ${}^{L}X_{ijt}$ denotes the yield-loss in delayed tasks with progress $n = 0$.

3.4. State update

From one iteration to the next, the plant states, such as, inventory and unit capacity are updated through Eqs. 6 and 7. Please note the use of $\dot{\mu}_{ij}$ disturbance parameter in Eq. 7. Further, the task-states, including yield-loss states, also require an update, to carry-over information about tasks already running. However, these update steps are softened, to allow task termination, and made part of the scheduling model (Eqs. 8-11).

$${}_{\sigma}S_{k(t=0)} = {}_{\sigma-1}S_{k(t'=1)} \forall k \tag{6}$$
$${}_{\sigma}C_{ij(t=0)} = {}_{\sigma-1}C_{ij(t'=1)} + \dot{\mu}_{ij} \forall j \in \boldsymbol{J}_{MT}, i \in \boldsymbol{I}_j \tag{7}$$
$${}_{\sigma}\bar{W}^n_{ij(t=0)} = ({}_{(\sigma-1)}\bar{W}^{n-1}_{ij(t'=0)} - \dot{Y}^{n-1}_{ij})(1 - T^{n-1}_{ij}) + \dot{Y}^n_{ij}(1 - T^n_{ij}) - \dot{Z}^{n-1}_{ij} \forall j, i \in \boldsymbol{I}_j, n \in \{1,2,\dots,\tau_{ij}\} \tag{8}$$
$${}_{\sigma}X_{ij(t=0)} = \dot{Y}^0_{ij}\left(1 - T^0_{ij}\right) \forall j, i \in \boldsymbol{I}_j \tag{9}$$
$${}_{\sigma}\bar{L}^n_{ij(t=0)} = ({}_{(\sigma-1)}\bar{L}^{n-1}_{ij(t'=0)} + \dot{\lambda}^{n-1}_{ij} - {}^{L}\dot{Y}^{n-1}_{ij})\left(1 - T^{n-1}_{ij}\right) + {}^{L}\dot{Y}^n_{ij}(1 - T^n_{ij}) - {}^{L}\dot{Z}^{n-1}_{ij} \forall j, i \in \boldsymbol{I}_j, n \in \{1,2,\dots,\tau_{ij}\} \tag{10}$$
$${}^{L}_{\sigma}X_{ij(t=0)} = {}^{L}\dot{Y}^0_{ij}\left(1 - T^0_{ij}\right) \forall j, i \in \boldsymbol{I}_j \tag{11}$$

3.5. State evolution

One of the state evolution equations, the inventory balance, is as follows:

$$S_{k(t+1)} = S_{kt} + \sum_j \sum_{i \in \boldsymbol{I}_j \cap \boldsymbol{I}^+_k} \theta^{\bar{\rho}}_{ikt} \left(\bar{B}^{\theta^{\tau}_{ijt}}_{ijt} - L^{\theta^{\tau}_{ijt}}_{ijt}\right) + \sum_j \sum_{i \in \boldsymbol{I}_j \cap \boldsymbol{I}^+_k} \rho_{ik} B_{ijt} - V_{kt} + \zeta_{kt} \; \forall j, i \in \boldsymbol{I}_j \tag{12}$$

where, $\theta^{\bar{\rho}}_{ikt} = \begin{cases} \bar{\rho}_{ik} \; \forall k, t = \{0\}; \\ \bar{\rho}^r_{ik} \forall k, t = \{1,2,\dots\} \end{cases}$ and $\theta^{\tau}_{ijt} = \begin{cases} \tau_{ij} \; \forall j, i \in \boldsymbol{I}_j, t = \{0\}; \\ \tau^r_{ij} \forall j, i \in \boldsymbol{I}_j, t = \{1,2,\dots\} \end{cases}$

Three important aspects in Eq. 12, are (1) $\bar{\rho}_{ik}^{r} < \bar{\rho}_{ik}$, hence, the use of $\theta_{ikt}^{\bar{\rho}}$, implies that batches bigger than the nominal size are started anticipating lower mass conversion than average, however, for tasks finishing at $t = 0$, the average mass conversion coefficient is used; (2) lifted yield-loss states ($\bar{L}_{ijt}^{\theta_{ijt}^{\tau}}$) are subtracted from $\bar{B}_{ijt}^{\theta_{ijt}^{\tau}}$ to reflect the actual yield; (3) finally, $\tau_{ij}^{r} > \tau_{ij}$, hence, tasks not finishing at $t = 0$ are anticipated to have a conservative processing time, but at $t = 0$ tasks finish at their average processing times plus any observed actual delays. Hence, we are able to carry out robust scheduling, but correctly account for feedback with regards to late/on-time task finish and actual yield-loss.

3.6. Computational remarks

Discrete time-grid models have been shown to scale well, especially, with the complexities of a larger system (Sundaramoorthy and Maravelias, 2011). When the model is solved, all the lifted variables and lifting equations are typically eliminated by preprocessing (Subramanian et al., 2012). Compared to traditional state-space model, for the generalizations, only a small number of variables are added to enable new features. For example, for maintenance, we only add one binary variable per unit per time. Through computational studies we see that the state-space model is comparable in performance to non state-space scheduling models (data not shown due to space limitation).

4. Case study

We present a simplified case study, from the field of bio-manufacturing, to illustrate the capabilities of our general state-space model, and present the results in brief due to space limitations. The medium size example we have chosen is typical of that found in a biomanufacturing setup and is of great interest to practitioners. For each open-loop iteration, we could solve our model to optimality in less than 0.1 seconds using CPLEX 12.6.1 (default options) via GAMS 24.4.3 on an Intel Xeon (E5520, 2.27GHz, 8 core) machine with 16 GB RAM and Linux CentOS 7 operating system. In the network in Fig. 2, material M3 is a desired pharmaceutical ingredient. As features, we allow for possible delays in the cell culture preparation (T1), and yield losses in the bio-reaction (T2). Thus, we carry out robust scheduling, using a conservative processing time (τ^{r}) for task T1 and a conservative mass-conversion coefficient ($\bar{\rho}^{r}$), against small yield losses, for task T2. Further, in the downstream purification stage, the chromatograph column (U3) loses capacity with usage. Executing a maintenance task (MT) restores capacity on the chromatographs. T4 is a dummy task to model storage of material M2 inside unit U2. The general state-space model we have developed enables us to address these new features in online scheduling (see Fig. 2).

5. Conclusions

We developed a general state-space model, particularly motivated by an online scheduling perspective, that allows modeling (1) task-delays and unit breakdowns (2) robust scheduling through the use of conservative yield estimates and processing times; (3) feedback on task-yield estimates before the task finishes; (4) task termination during its execution; and (5) unit capacity degradation and maintenance. Further, we propose a systematic scheme for updating the state of the process, as well as ability to modify

states through disturbance parameters, based on feedback information. These general features that we address are found in several industrial sectors, namely, pharmaceuticals, fine chemicals, pulp and paper, agriculture, steel production, oil and gas, food processing, bio-manufacturing, etc. Although, here we presented the model using STN based representation, these generalizations can also be adapted to RTN based representation.

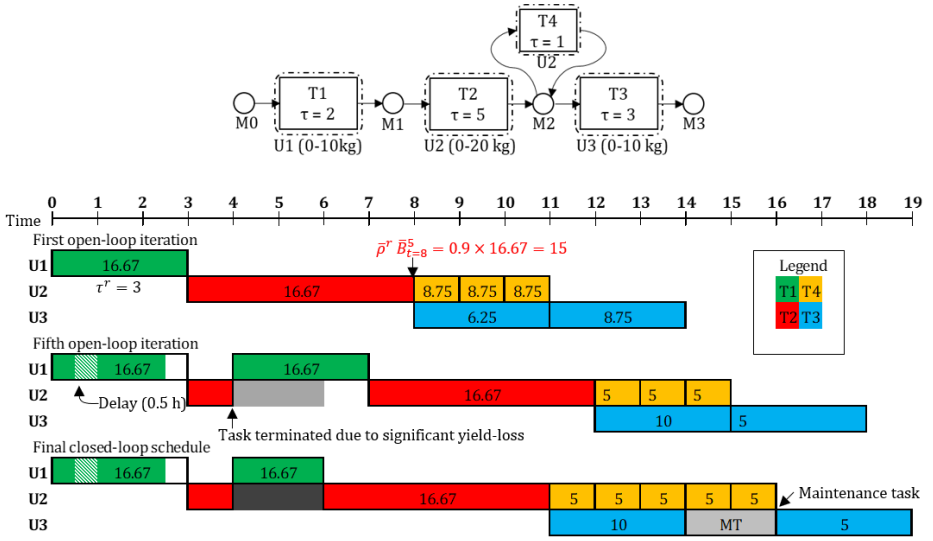

Figure 2: The network, the first and fifth open-loop iterations, and the final closed-loop schedule. The final closed-loop schedule is very different from the first open-loop schedule, due to observation of several disturbances and counter-actions. For example, in the fifth iteration, T2 is terminated due to observation of a significant yield loss.

Abstract

A genetic algorithm (GA) is proposed along with a novel general framework for the scheduling of a typical multipurpose/product batch plant. The majority of literature regarding these problems make use of mathematical programming methods. Modelling problems in this manner leads to numerous binary variables relating to material balance and sequence of batches along long-time horizons, thus resulting in large computational time. The proposed GA does not suffer the same scalability issues of mathematical programming approaches. The GA makes use of a coupled chromosome system with specific crossover and mutation functions utilised with the purpose of profit maximisation. Results show that optimal or close-to-optimal solutions can be achieved with a reduction of up to 98.53 % computational time in certain cases.

Keywords: Scheduling, Metaheuristics, Batch Plants

1. Introduction

Batch process research has seen significant increase in attention from both academic and industrial practitioners over the last two decades. This in part, is due to a modern demand for small volume, high value products of which batch processes are best suited. Batch plant flexibility provides means for the production of multiple products within the same facility. Unfortunately, this is coupled with an increase in complexity of facility scheduling. Much of the recent research has involved the development of optimisation models that provide schedules yielding improved objective values at reduced computational time. While metaheuristics have been well utilised in process engineering from many decades now, its application to multipurpose process scheduling is sparse. A comparison between metaheuristic techniques and MILP models in the scheduling of chemical batch plants can be found in Canton Padilla (2003). However, to date most approaches have generally been in the optimal design of batch plants or the scheduling of single-stage or multi-product batch plants. Work with genetic algorithms on the multipurpose batch plant scheduling with fixed processing times was utilised effectively to minimise makespan in He and Hui (2010), but the more complex variable processing time scenario was not investigated.

The focus of this work is to obtain close-to-optimal solutions at reduced computational times. This is done through a novel representation of integer coded tasks and real valued times generalizable to any particular batch plant configuration and optimizable with any suitable metaheuristic. A well-posed and accepted case study of a multipurpose batch

plant is considered. The literature example is introduced in Kondili et al. (1993) and contains batch mixing and splitting, and includes a recycling stream.

2. Problem description

Utilising a metaheuristic approach, specifically a genetic algorithm, two examples are considered: a motivating example and the aforementioned primary example.

Figure 1, shows the state-task-network (STN) for a motivating example involving a simple multiproduct batch plant (Ierapetritou and Floudas, 1998).

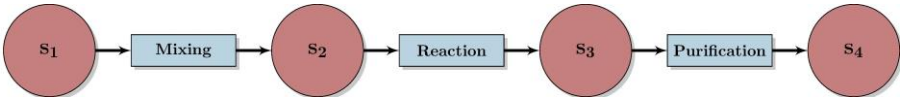

Figure 1: STN for Motivating Example

The corresponding data for Figure 1 is given in Table 1. This literature example has often been used for comparison when introducing new scheduling frameworks.

The primary example considered involves a relatively complex flowsheet introduced by Kondili et al (1993). The STN for the flowsheet is found in Figure 2. The problem data is given in Table 2.

In both examples, variable processing time is considered. Mathematical programming approaches have proven successful in managing constraints where the assignment of tasks to units is dependent on preserving correct material balances. The framework and GA introduced here satisfies all the recipe-dependent constraints in the accepted STN descriptions by Kondili et al. (1993) and Ierapetritou and Floudas (1998). In both cases, the objective is to maximise profit over a given fixed time horizon.

Table 1: Table showing capacity, suitability and mean processing time for the Motivating Example

Unit	**Capacity**	**Suitability**	**Mean Processing Time (τ)**
Unit 1	100	Mixing	4.5
Unit 2	75	Reaction	3.0
Unit 3	50	Purification	1.5
State	**Storage Capacity**	**Initial Amount**	**Price**
State 1	Unlimited	Unlimited	0
State 2	100	0	0
State 3	100	0	0

3. Results

All results were obtained utilizing an Intel® Core™ i7-7700k @ 5.0 Ghz, 32 GB 3200 Mhz DDR4 RAM, running Windows 10 Professional x64 bit. For MILP models, GAMS 24.8.3 was used. The genetic algorithm was implemented in Matlab 2016b.

3.1. Motivating example

Seid and Majozi (2012a) showed that their model had the fastest solution time when compared to other MILP approaches in literature. Hence, the MILP comparisons to the implemented GA are drawn using this model. A GAMS cut-off time of 10,000 seconds was used. All GAMS models were solved to a 0 % relative gap unless otherwise specified. Time horizons ranging from 12 – 168 hours are considered since comparative results exist in Seid and Majozi (2012b). The CPU times listed are resultant from the averaging of 50 trials runtimes. The best obtained objective value from these trials is reported. A cut-off time of 10,000 seconds was imposed on the model by Seid and Majozi (2012b), with the model converging to a zero relative gap in all cases other than 168 hours, when the cut-off was reached. At this time GAMS reported a relative gap of 0.28 %. Considering the computational performance, it can be seen that the GA outperforms the model by Seid and Majozi (2012b) in all cases other than the short time horizons of 12 and 24 hours. A large increase in the time horizon, however, sees a massive increase in solution time for MILP formulation, while the GA does not exhibit this result. The scale of these growths in magnitude when considering solution time is illustrated in Figure 3. Importantly, the GA achieves this computational time reduction at minimal loss of objective value, with the worst performing case being 2.31 % less of the model by Seid and Majozi (2012b). The complete results are found in Table 3. The instance of the GA reporting an improved objective value is due to numerical instability and rounding between the two separate implementations.

Table 3: Results for Motivating Example

Model	Event Points	Time Horizon	Cpu Time (s)	Objective Value	Difference	Pop Size/Gen
S&M	5	12	0.240	71.4703	-	-
GA	5	12	1.035	71.4734	4.3×10^{-3} %	300/15
S&M	9	24	0.262	249.9390	-	-
GA	9	24	1.208	249.2559	-0.27 %	300/15
S&M	14	36	7.709	446.9474	-	-
GA	14	36	2.655	440.6822	-1.4 %	300/15
S&M	19	48	85.262	646.9474	-	-
GA	23	48	3.022	631.9465	-2.31 %	500/25
S&M	57	168	10,020.096*	2,645.4545	-	-
GA	60	168	62.883	2,607.2000	-1.44 %	1,000/100

**S&M = Seid and Majozi (2012b)

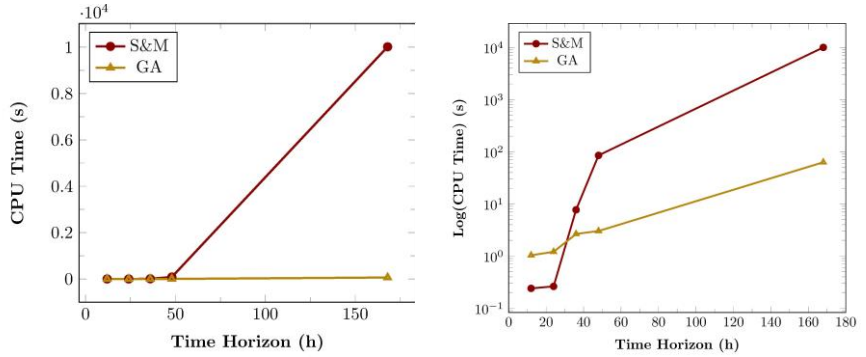

Figure 3: Computational time between Seid and Majozi (2012b) and GA for Motivating Example

3.2. Primary Example

The same time horizons from Seid and Majozi (2012a) were considered, with the additional time horizons of 18 and 20 hours respectively, to further explore longer time horizons. A GAMS cut-off time of 40,000 seconds was used, and models solved to a 0 % relative gap unless specified. As with the Motivating Example, the MILP model by Seid and Majozi (2012a) performed better on short term time horizons but scaled by orders of magnitude for longer time horizons, while the GA reports solutions within a single order of magnitude for all cases. Again, this speedup comes with an objective value reduction of no more than 2.39 %. The complete results are found in Table 4, while the computational scalability is reported in Figure 4. Similarly, the case where the GA outperforms the MILP implementation is due to the aforementioned numerical accuracy.

Table 4: Results for Primary Example

Model	Event Points	Time Horizon	Cpu Time (s)	Objective Value	Difference	Pop Size/Gen
S&M	5	8	0.265	1,489.8169	-	-
GA	5	8	3.949	1,498.1734	1.01 %	1,000/25
S&M	8	10	17.259	1,973.8273	-	-

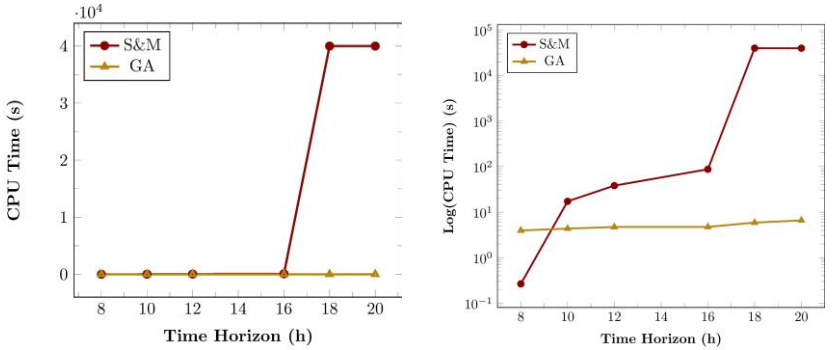

Figure 4: Computational time between Seid and Majozi (2012b) and GA for Primary Example

4. Conclusions

Here, a novel scheduling framework and corresponding metaheuristic technique for multipurpose batch plants is introduced. The technique satisfies all rules and constraints as that of MILP counterparts discussed in literature but does not suffer scaling enumeration from increased time horizons. The technique utilises a coupled chromosome genetic algorithm, where one chromosome is integer coded and the second chromosome is coded with real values. The introduced method does not suffer under increased granularity of the time horizons as seen by the results, especially on medium-to-long-time horizons. In almost all cases the GA outperformed the MILP implementation of Seid and Majozi (2012a) when considering computational time. In the case of long time horizons, solutions were achieved up to three orders of magnitude faster, yielding a 98.53 % reduction in solution time. Importantly, these computational speed-ups were attained at minimal loss of objective value, with the worst case returning an objective value of no less than 2.39 % of accepted literature.

A novel modelling approach to scheduling of multipurpose batch processes

Nikolaos Rakovitis, Jie Li*, Nan Zhang

School of Chemical Engineering and Analytical Science, University of Manchester, Manchester M13 9PL, UK
jie.li-2@manchester.ac.uk

Abstract

A great number of mathematical models have been developed for scheduling of multipurpose batch processes in the last three decades. None of them allow consumption and production tasks related to the same states to take place at the same event. It also seems that most unit-specific event-based models are task-specific instead. In this work, we introduce a new definition of recycling tasks and develop two novel mathematical models using unit-specific and task-specific event-based approaches. Both models allow consumption tasks to take place at the same event points with their related production tasks that are not recycling tasks. The computational results indicate that both models solve all examples to optimality using significantly less number of event points. Furthermore, it seems that the proposed unit-specific event-based model obtains optimal solutions in up to one magnitude less computational time compared to the proposed task-specific event-based model and the model of Shaik and Floudas (2009).

Keywords: Scheduling, Multipurpose, Batch process

1. Introduction

Scheduling of multipurpose batch processes has gained much attention during the last three decades (Harjunkoski et al., 2014). A great number of models including discrete-time (Lee and Maravelias, 2017) and continuous-time models have been developed (Li et al., 2010; Harjunkoski et al., 2014). The continuous-time models can be further divided into global event (Maravelias and Grossmann, 2003), unit-specific event-based (Shaik and Floudas, 2009), process slot (Sundaramoorthy and Karimi, 2005), unit-slot (Sursala et al., 2010) and sequence based (Mendez and Cerda, 2004) models. The advantages of unit-specific event-based models have been well established in the literature (Shaik and Floudas, 2009; Vooradi and Shaik, 2012). However, all models do not allow production and consumption tasks related to the same states to take place at the same event points. This may lead to an unnecessary increase of event points, limiting their capability to solve difficult and large-scale problems. In addition, it seems that many unit-specific event-based models are task-specific, which divides the scheduling horizon based on tasks instead of units.

In this work, we introduce a new definition of recycling tasks and develop two novel mathematical models using unit-specific and task-specific event-based approaches. Both models allow consumption tasks to take place at the same event points with their related production tasks (i.e., related to the same states) that are not recycling tasks. The

computational results demonstrate that the proposed models successfully solve all examples to optimality by using significantly less number of event points. It seems that the proposed unit-specific event-based model generates optimal solutions in up to one magnitude less computational time compared to the proposed task-specific event-based model and the model of Shaik and Floudas (2009).

2. Problem description

A multipurpose batch plant produces P (p = 1, 2, …, P) products in J (j = 1, 2, …, J) processing units with I (i = 1, 2, …, I) tasks. Each unit j is able to process one or more tasks. Tasks that can be processed in a unit j are included in the set $\mathbf{I}_j$. Such a facility stores S (s = 1, 2, …, S) states with different storage policies, which can be categorized in raw materials, intermediate states and products. Given the fixed ($\alpha_{i,j}$) and variable ($\beta_{i,j}$) processing time that a unit j requires to process a task i, unit capacities, the portion of state s produced/consumed from a task i ($\rho_{i,s}$) and product prices (P_s) as well as the scheduling horizon H, the scheduling problem is to determine optimal production schedule involving batch sizes, allocations, sequences and timings of processing units and inventory profiles.

3. Recycling tasks

To allow consumption and production tasks related to the same states to take place at the same event points, we introduce a new definition of recycling tasks, which is slightly different from that of Li and Floudas (2010). A task in a unit j is considered as a recycling task if it produces a state that can be consumed either by a task in its upstream units or by other tasks in the same unit (i.e., unit j). For instance, there are four tasks (i1-i4), two processing units (j1-j2) and three states (S1-S3) as shown in Figure 1. While tasks i1 and i3 can be processed in unit j1, tasks i2 and i4 can be processed in unit j2. Tasks i1 and i2 consume S1 and produce S2, whilst tasks i3 and i4 consume S2 and produce S1 and S3. Task i1 is considered as a recycling task because it produces S2 that can be used by task i3 in the same unit (i.e., j1). Similarly, tasks i2-i4 are also recycling tasks.

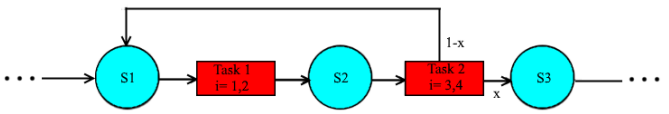

Figure 1. Illustration of recycling tasks. All tasks depicted are considered recycling tasks

In the Example 2 of Shaik and Floudas (2009), task i8 is also considered as a recycling task since it produces S5 that can be used by a task i6 in upstream units. All recycling tasks are included in a set $\mathbf{I}^{Re}$.

4. Mathematical formulations

4.1. Model 1

We develop our model 1 (denoted as **M1**) using unit-specific event-based modelling approach, where consumption tasks are allowed to take place at the same event points

with their related production tasks that are not recycling tasks. We define a new four index variable $y_{i,j,n,n'}$ to denote if a task i is processed in a unit j from event point n to n'.

4.1.1. Allocation constraints

At most one task can be processed in a unit at any time.

$$\sum_{i\in\mathbf{I}_j}\sum_{n-\Delta n\le n'\le n}\sum_{n\le n''\le n+\Delta n} y_{i,j,n',n''} \le 1 \qquad \forall j,\, n \tag{1}$$

4.1.2. Capacity constraints

We define $b_{i,j,n,n'}$ as the batch size of task i in unit j from event n to n'. Any batch size should not exceed the minimum [$B_{i,j}^{\min}$] and maximum [$B_{i,j}^{\min}$] capacities of a unit j.

$$B_{i,j}^{\min} y_{i,j,n,n'} \le b_{i,j,n,n'} \le B_{i,j}^{\max} y_{i,j,n,n'} \qquad \forall j,\, i\in\mathbf{I}_j,\, n \le n' \le n+\Delta n \tag{2}$$

4.1.3. Material balance constraints

The inventory of state s at n is equal to its inventory at $n-1$ plus batch sizes produced by a non-recycling task at n or a recycling task at $n-1$ minus batch sizes consumed at n.

$$ST_{s,n} = ST0_s + \sum_{i\in\mathbf{I}_S^P, i\notin\mathbf{I}^{\mathrm{Re}}} \rho_{i,s} \sum_j \sum_{n-\Delta n\le n'\le n} b_{i,j,n',n} + \sum_{i\in\mathbf{I}_S^C} \rho_{i,s} \sum_j \sum_{n\le n'\le n+\Delta n} b_{i,j,n,n'} \qquad \forall s,\, n=1 \tag{3}$$

$$ST_{s,n} = ST_{s,n-1} + \sum_{i\in\mathbf{I}_S^P, i\notin\mathbf{I}^{\mathrm{Re}}} \rho_{i,s} \sum_j \sum_{n-\Delta n\le n'\le n} b_{i,j,n',n} + \sum_{i\in\mathbf{I}_S^P, i\in\mathbf{I}^{\mathrm{Re}}} \rho_{i,s} \sum_j \sum_{n-1-\Delta n\le n'\le n-1} b_{i,j,n',n-1}$$
$$+ \sum_{i\in\mathbf{I}_S^C} \rho_{i,s} \sum_j \sum_{n\le n'\le n+\Delta n} b_{i,j,n,n'} \qquad \forall s,\, n>1 \tag{4}$$

4.1.4. Duration constraints

We define $Tsi_{i,j,n}$ and $Tfi_{i,j,n}$ to denote start and end times of task i in unit j at event point n. A task i in a unit j can finish after it is processed in this unit.

$$Tfi_{i,j,n'} \ge Tsi_{i,j,n} + \alpha_{i,j} \cdot y_{i,j,n,n'} + \beta_{i,j} \cdot b_{i,j,n,n'} \qquad \forall j,\, i\in\mathbf{I}_j,\, n \le n' \le n+\Delta n \tag{5}$$

Any task i processed in a unit j must start and finish within start ($Ts_{j,n}$) and end ($Tf_{j,n}$) times of this unit j.

$$Ts_{j,n} \le Tsi_{i,j,n} \le Tfi_{i,j,n} \le Tf_{j,n} \qquad \forall j,\, i\in\mathbf{I}_j,\, n \tag{6,7}$$

4.1.5. Sequencing constraints

A unit j can start at event point $n+1$ only after it finishes at time event n.

$$Ts_{j,n+1} \ge Tf_{j,n} \qquad \forall j,\, n<N \tag{8}$$

Since a consumption task is allowed to take place at the same event points with related production tasks that are not recycling tasks, the sequencing constraints for different tasks in different units are imposed for recycling and non-recycling tasks separately.

$$Tsi_{i,j,n} \ge Tfi_{i',j',n} \qquad \forall\, i\in\mathbf{I}_S^C,\, i'\in\mathbf{I}_S^P,\, i\in\mathbf{I}_j,\, i'\in\mathbf{I}_{j'},\, i'\notin\mathbf{I}^{\mathrm{Re}}, j\ne j',\, n \tag{9}$$

$$Tsi_{i,j,n+1} \geq Tfi_{i',j',n} \qquad \forall i \in \mathbf{I}_S^C,\ i' \in \mathbf{I}_S^P,\ i \in \mathbf{I}_j,\ i' \in \mathbf{I}_{j'},\ i' \in \mathbf{I}^{\mathrm{Re}},\ j \neq j',\ n < N \tag{10}$$

For finite or no intermediate storage policy, materials produced from a task should be immediately consumed.

$$Tsi_{i,j,n} \leq Tfi_{i',j',n} + M[1 - \sum_{n-\Delta n \leq n' \leq n} y_{i',j',n',n}]$$

$$\forall s \in S^{\mathrm{dis}},\ i \in \mathbf{I}_S^C,\ i' \in \mathbf{I}_S^P,\ i \in \mathbf{I}_j,\ i' \in \mathbf{I}_{j'},\ i' \notin \mathbf{I}^{\mathrm{Re}},\ j \neq j',\ n \tag{11}$$

$$Tsi_{i,j,n+1} \leq Tfi_{i',j',n} + M[1 - \sum_{n-\Delta n \leq n' \leq n} y_{i',j',n',n}]$$

$$\forall\ s \in S^{\mathrm{dis}},\ i \in \mathbf{I}_S^C,\ i' \in \mathbf{I}_S^P,\ i \in \mathbf{I}_j,\ i' \in \mathbf{I}_{j'},\ i' \in \mathbf{I}^{\mathrm{Re}},\ j \neq j',\ n \tag{12}$$

4.1.6. Objective function

The objective is to maximize productivity during a specified scheduling horizon.

$$z = \sum_{s \in S} p_s \sum_{i \in \mathbf{I}_S^P} \sum_{j \in J} \sum_{n \in N} \sum_{n \leq n' \leq n+\Delta n} \rho_{i,s} b_{i,j,n,n'} \tag{13}$$

This model is easy to extend for other objectives such as makespan (*MS*) minimisation.

4.2. Model 2

Our model 2 (denoted as **M2**) is developed based on task-specific event-based approach where consumption tasks are allowed to take place at the same event points with related production tasks that are not recycling tasks. Since this model is quite similar to that of Shaik and Floudas (2009), only different constraints are presented in the following.

4.2.1. Material balance constraints

Shaik and Floudas (2009) defined if a state *s* is produced at an event *n*, it should be consumed at *n*+1. In this model, a state *s* produced could be consumed at the same event point by a task that is not recycling task, which is similar to that in Model **M1**.

$$ST_{s,n} = ST0_s + \sum_{i \in \mathbf{I}_S^P, i \notin \mathbf{I}^{\mathrm{Re}}} \rho_{i,s} \sum_{n-\Delta n \leq n' \leq n} b_{i,n',n} + \sum_{i \in \mathbf{I}_S^C} \rho_{i,s} \sum_{n \leq n' \leq n+\Delta n} b_{i,n,n'} \qquad \forall s,\ n = 1 \tag{14}$$

$$ST_{s,n} = ST_{s,n-1} + \sum_{i \in \mathbf{I}_S^P, i \notin \mathbf{I}^{\mathrm{Re}}} \rho_{i,s} \sum_{n-\Delta n \leq n' \leq n} b_{i,n',n} + \sum_{i \in \mathbf{I}_S^P, i \in \mathbf{I}^{\mathrm{Re}}} \rho_{i,s} \sum_{n-1-\Delta n \leq n'' \leq n-1} b_{i,n',n-1} + \sum_{i \in \mathbf{I}_S^C} \rho_{i,s} \sum_{n \leq n' \leq n+\Delta n} b_{i,n,n'}$$

$$\forall s,\ n > 1 \tag{15}$$

4.2.2. Different tasks in different units

Similar to **M1**, the sequencing constraints for different tasks in different units are imposed for recycling and non-recycling tasks separately.

$$Ts_{i,n} \geq Tf_{i',n} - M[1 - \sum_{n-\Delta n \leq n' \leq n} w_{i',n',n}] \quad \forall i \in \mathbf{I}_S^C,\ i' \in \mathbf{I}_S^P,\ i \in \mathbf{I}_j,\ i' \in \mathbf{I}_{j'},\ i' \notin \mathbf{I}^{\mathrm{Re}},\ j \neq j' \tag{16}$$

$$Ts_{i,n+1} \geq Tf_{i',n} - M[1 - \sum_{n-\Delta n \leq n' \leq n} w_{i',n',n}] \quad \forall i \in \mathbf{I}_S^C,\ i' \in \mathbf{I}_S^P,\ i \in \mathbf{I}_j,\ i' \in \mathbf{I}_{j'},\ i' \in \mathbf{I}^{\mathrm{Re}},\ j \neq j',\ n < N \tag{17}$$

5. Computational results

We solve five examples to illustrate the capability of our proposed models. The first three examples are Examples 1-3 from Shaik and Floudas (2009). In Example 4, there are five states including one product and four processing units in series with each processing one task and producing one state. In Example 5, there are 27 states including three products and eight processing units in series with each processing 3 tasks and producing 3 states. All tasks in Examples 4-5 are non-recycling tasks.

Table 1: Comparative results for Examples 1-5

Example	Model	Event points	CPU time (s)	RMILP	MILP	Discrete Variables
1	S&F[1]	9	1.295	6601.65	5038.05	45
(H=16 h)	M1	7	1.310	6601.65	5038.05	35

H=144 h	M1	42	1.014	21000	20935.3	1008
	M2	42	43.54	21000	20935.3	1008

[1]Shaik and Floudas (2009) model. All examples are solved in a machine using GAMS 24.6.1. CPLEX 12 in an Intel® Core™ i5-2500 3.3 GHz and 8 GB RAM running Windows 7.

The comparative results are presented in Table 1. It seems that both proposed models successfully generate the same optimal solutions as those of Shaik and Floudas (2009) for all examples. The optimal schedule for Example 1 from the model **M1** is illustrated in Figure 2. It can observed that both production task i1 and consumption task i3 related to the same state take place at the same event N1 as depicted with red circles in Figure 2. Similarly, tasks i1-i2 and task i3 related to the same state take place at the same event N3 as depicted with blue circles. Both models require less number of event points than that of Shaik and Floudas (2009), leading to smaller model sizes. The model **M1** requires less computational time than other models. In some cases, it can generate the same optimal solution in one magnitude less computational time. Furthermore, it leads to much tighter MILP relaxation for Example 4. However, there is no decrease in the number of event points for Examples 2-3 because most of the tasks (6 out of 8 for example 2 and 9 out of 11 for example 3) are recycling tasks.

6. Conclusions and future work

In this work, we introduce a new definition of recycling tasks and develop two novel mathematical models using unit-specific and task-specific event-based modelling

approach for scheduling multipurpose batch processes. Both models allow consumption tasks to take place at the same event points with their related production tasks that are not recycling tasks. The computational results demonstrate that both models could significantly reduce the required number of event points. Furthermore, the proposed unit-specific event-based model generated the same optimal solution in up to one magnitude less computational time than the task-specific event-based model and the model of Shaik and Floudas (2009). Our future work is to propose a number of tightening constraints to further improve the efficiency of the proposed models.

Abstract

Forest industry plays an important role in the national economic and social context, due to the region where it is located (northeastern of the country) and the production volume. The equipment used in the local facilities is not efficiently employed and, therefore, the process performance can be improved in order to reach higher productivity. Sawmill production planning involves determining which logs to process taking into account its diameter and length, with the aim of satisfying finished products demand. Logs are converted into lumber when they are cut according to a set of available cutting patterns (CP). One of the keys to improve sawmills efficiency is to develop a good production planning, and mathematical modeling is a good technique to attain it. Also, an efficient log procurement policy can be developed from the production planning, and therefore, raw material purchases and distribution can be anticipated. In this work, a mixed integer linear programming (MILP) model for the optimal planning in sawmills is proposed. A multiperiod formulation is presented, which involves a set of CPs for each type of log. As a result of this optimization, appropriate log procurement and distribution policy can be also defined which impact on the sawmill performance and profitability.

Keywords: production planning, multiperiod, sawmill, cutting pattern, mixed integer linear programming.

1. Introduction

The Argentinean forest industry is mainly located in the northeastern of the country (85% of the production, approximately 850,000 ha). More than one thousand forest factories (sawmills, plywood mills, pulp mills, and Medium Density Fibreboard factories) are concentrated in this region, where small and medium-sized enterprises represent 98% of these facilities (Broz et al., 2016). For these reasons, forest industry has a very important role in the economic and social development of this region. However, inefficient production and high transport cost have a negative impact on the competitiveness of this sector.

In the particular case of sawmills, efficient production can be achieved through optimal production planning considering raw materials (logs availability), final products (boards) and demands (customers), taking into account the logs diameter, length, grade of each log piece, characteristics of primary products, and industrial parameters, among others.

In a sawmill, logs are converted into boards when they are cut according to cutting patterns (CP). A CP is an arrangement of rectangles (thickness and width of the boards) within a circle. Planning operations at a sawmill is a complex task, since it involves several simultaneous decisions as raw material supply, cutting patterns (CP) allocation to different types of raw material, inventories management and demands satisfaction among others. Moreover, these decisions lead to various tradeoffs that complicate the problem resolution. Mathematical modeling appropriately allows addressing this problem. Also, many heuristics and simulation approaches have been used to face sawmills production planning. Maturana et al. (2010) present a mathematical model for determining the volume and type of logs to be processed according to six proposed CP. They consider the production over 6 weeks, with an ideal scenario of log supply which is then adjusted. Results are compared with a heuristic schedule used by a Chilean company. A similar approach is proposed by Alvarez and Vera (2014) but considering an annual planning period and solving the uncertainties through robust optimization, while in Zanjani et al. (2010) the planning horizon consists of 30 days, and the authors also propose robust optimization for solving the problem with random yields. In this last case, 5 CP are involved in the model. In Lobos and Vera (2016), a decomposition algorithm involving two levels is developed: a tactical planning horizon with monthly information and an operational level with detailed weekly production.

Although the production yield strongly depends on the CP selection and use, there are few practical tools that support the CPs generation and, to the best of our knowledge, there is no optimization model that involves all the possible CPs for the sawmill production planning. On the other hand, many final products can be obtained from different CPs, and therefore several tradeoffs can be assessed. Moreover, when planning is carried out, different decisions must be integrated, as raw material purchase, production, inventory, and demand satisfaction. Then, it is necessary to address this problem from a comprehensive point of view for attaining a good supply procurement policy along the time horizon, in order to reach the desired production for fulfilling the required demand.

In order to face this problem, a mixed integer linear programming (MILP) model for the optimal production planning in a sawmill is proposed in this work. The model embeds all the possible CP for different log diameters, given by an exhaustive generation algorithm. Also, in a multiperiod approach, all the decisions are simultaneously taken, and an appropriate log procurement policy, suitable production according to enterprise requirements, improved stock management, and accurate demand satisfaction are obtained in order to favour sawmill performance and profitability. Through an example, the approach capabilities are highlighted.

2. Problem description

In Fig. 1 the considered process is presented. The raw material (logs) arrives at the sawmill and is classified according to log length and diameter. Then, logs are transferred to the sawing sector where an initial cut is made through a primary saw in which a cant and two flitches are obtained. In the secondary saw, the cant is broken down into dimensional lumber pieces and flitches. Finally, flitches are processed in a re-sawing. This cutting process generates products of medium and large dimension. These products are boards with determined cross section area (characterized by width and thickness), and a length, given by the log length. The log cuts are made according to a selected CP.

Each CP is applied to a log with a determined useful diameter, and is valid for all the different log lengths with that diameter. The useful diameter corresponds to the diameter of the larger cylinder that can be obtained from the log.

At the beginning of the planning horizon, there is an initial logs stock at the sawmill, and daily, logs are bought from different suppliers, which have a limited capacity and different prices. Every day, a minimum production is required for some types of boards, while a final demand must be fulfilled at the end of the planning horizon. The objective is to determine the detailed weekly production planning, i.e. daily decisions about raw material purchases, how many logs of each type (diameter and length) have to be cut, the logs stock level, the finished product stock, demands fulfilment and the produced residues in order to minimize the sawing cost given by raw material, operation, and setups.

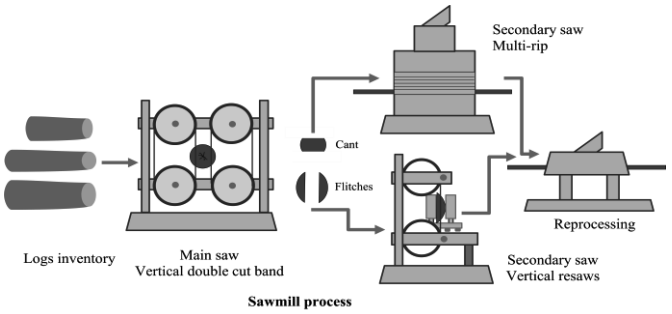

Figure 1. Stages considered in sawmill process

3. Proposed approach

The mathematical model involves, as input data, all the generated CP according to the available log diameters, demanded boards, and efficiency imposed by the enterprise. The objective of the CP generator is to systematically arrange rectangles (thickness and width of the boards) within circles. The insertion of the rectangles is done by simulating the cutting way of logs in sawmills. It divides the log into five sections: a central block, two equal lateral flitches, and upper and lower ones, equal to each other. From each of these sections, the different admissible boards are obtained. For each generated CP, data about the number of included boards, yield, processing time, and setup cost are provided to be used as input for the optimization model.

Following, the mathematical model for the multiperiod sawmill planning is briefly presented. It is assumed that the planning horizon is 5 days (Eq. (9)), but this can be easily generalized. For space reasons, some particular equations are omitted, but the detailed formulation is available for interested readers.

$$min\ Z = \sum_{d,l,a,t} Qb_{dlat}\, Cb_{dla} + \sum_{p,d,l,t} Qt_{pdlt}\, Cp_{pdl} + \sum_{p,t} Cx_p\, x_{pt} \tag{1}$$

$$\sum_{t} Qb_{dlat} \leq Dis_{dla} \qquad \forall d,l,a \tag{2}$$

$$\sum_{a} Qb_{dlat} + S_{dlt-1} = \sum_{p} Qt_{pdlt} + S_{dlt} \quad \forall d, l, t \tag{3}$$

$$\sum_{d,l} Qt_{pdlt} \leq M x_{pt} \quad \forall p, t \tag{4}$$

$$\sum_{\substack{p,d \\ p \in Rel(p,d)}} Qt_{pdlt}\ \rho_{pdi} = P_{ilt} \quad \forall i, l, t \tag{5}$$

$$\sum_{t \leq t'} P_{ilt} \geq \sum_{t \leq t'} Pmin_{ilt} \quad \forall i, l, t' \tag{6}$$

$$\sum_{t} P_{ilt} = VP_{il} + SF_{il} \quad \forall i, l \tag{7}$$

$$SF_{il} \leq Cap_{il} \quad \forall i, l \tag{8}$$

$$\sum_{p} TS_p\ x_{pt} + \sum_{p,d,l} Qt_{pdlt}\ Tp_{pdl} \leq Tmax_t \quad \forall t \tag{9}$$

The objective function considers the raw material cost, given by the amount of logs of diameter *d* and length *l* bought from different suppliers *a* at the day *t*, Qb_{dlat}, by its unit cost (Cb_{dla}), plus the production cost defined by the processed logs (Qt_{pdlt}) by the unit operation cost (Cp_{pdl}), plus the setup cost managed by the binary variable x_{pt} equal to one if the CP *p* is used at day *t*. Cx_p represents the cost for using *p* (setup cost). Eq. (2) limits the purchase of logs to each supplier, where Dis_{dla} represents the supplier capacity, while Eq. (3) defines the log stock management, where S_{dlt} represent the number of logs stored at the end of day *t*. Here, $S_{dl,0}$ are the available logs in the facility, prior to begin the production. Eq. (4) states that no logs of diameter *d* and length *l* are processed on *t* through CP *p*, if that pattern is not selected at day *t* (*M* is a big scalar). The number of boards with cross section *i* and length *l* produced in *t* (P_{ilt}) is defined in Eq. (5) through the parameter ρ_{pdi}, which represents the number of this type of boards generated by CP *p*. *Rel(p,d)* is the set that relates each generated CP *p* with the corresponding log diameter *d*. A minimum required production for boards is stated in Eq. (6), represented by the parameter $Pmin_{ilt}$. At the end of the planning horizon, the total stored boards of type (*i,l*) must fulfil the required demand VP_{il} and a final stock of these boards SF_{il} can be held (Eq. (7)), but with maximum capacity Cap_{il} (Eq. (8)). Finally, in Eq. (9), the operation time for each day *t* is restricted, where TS_p is the CP setup time, Tp_{pdl} the log processing time, and $Tmax_t$ the working day time.

4. Example

The proposed example considers logs classified into 4 diameters and 6 lengths. The logs may come from the sawmill stock or can be bought from 3 suppliers (A, B, and C) that have a limited number of logs. A total of 144 types of products, distributed among 24 cross sections and 6 lengths is considered.

For the CP generation, a yield greater than 80% is taken into account in order to make a better use of the wood. With this constraint and considering all the possible log diameters and demanded final boards, a total of 664 CPs are generated.

The total demand is equal to 32,590 boards, covering 71 different types of products (cross sections and lengths combinations). The first planning day, there are 290 logs of different diameters available at the sawmill. The adopted time horizon is equal to 5 working days with 8 hours each.

The example is implemented and solved in GAMS using CPLEX solver in an Intel(R) Core(TM) i7-3770, 3.40 GHz. The model consists of 86,764 equations, 163,407 continuous and 3,320 binary variables. The solution obtained in a limit of 300 seconds achieves an optimality gap of 1.07 %.

After solving the model, the weekly sawmill planning that fulfils the demand has a total cost equal to $ 895,464, which 58 % corresponds to the used raw material, 39 % represents the production cost and 3 % the setup cost.

Table 1. Planning results for each day

	Period				
	t1	**t2**	**t3**	**t4**	**t5**
Logs purchased [unit]	473	611	500	426	498
Used logs [unit]	484	637	505	426	576
Time used [h]	8	8	7.8	7.2	7.1
Produced boards [unit]	7223	7329	6867	6583	6421

Table 2. Processed logs according to CP and time period

Diameter	**CP**	**Period**				
		t1	**t2**	**t3**	**t4**	**t5**
d1	p3		539			508
d1	p7				104	
d2	p24	51				
d2	p30			247		
d3	p146	199				
d3	p147	176				
d3	p153				337	
d3	p161	24		212		
d3	p200		40			
d3	p311	9				
d3	p444					44
d3	p446			46		
d3	p505		18			
d4	p573		57			
d4	p1272				8	
d4	p1324				11	

In Table 1 general results for each planning day are shown. It can be noted that a total of 2,507 logs are purchased from the different suppliers, while 2,628 logs are used to meet the demand: 40 % from supplier A, 10% from supplier B, 45 % from supplier C, and 5 % from the initial stock. At the end of the planning horizon, 169 logs are stored.
From the production point of view and considering an 8-hour working day, 95 % of the available time is used, and a total of 34,422 final boards are produced. From this amount, at the end of the time period, 1,832 units are stored, which represents 5.6 % of the total demand. Taking into account that the model includes the raw material cost, the solution adjusts the production to reduce the stored units.
Table 2 shows the total logs that are cut in each period for each CP, where log diameter is included without mentioning the lengths due to space reasons. The CPs are identified with the name "*p*" plus a number, for example "*p3*" is the pattern 3 used for diameter d_1. Usually each CP is used with several lengths to reduce de setup time and cost. In this case, 16 CPs are used for producing the 71 different types (cross section area and length of the boards) of demanded products plus those that are generated when a CP is used and they are not demanded. These last boards are part of the final inventory (SF_{il}).
For space reasons, it is not possible to show all the results in detail, but the model determines, among other things, the number of logs, distinguished by diameter and length, that are used in each day and with each CP, the boards of each type and length that are produced and the inventory level at the end of each period of the time horizon.

5. Conclusion

In this work, a MILP model for the optimal multiperiod production planning in a sawmill was presented. Daily logs procurement, suppliers selection, quantity of processed logs, CPs assignment, log and boards inventories, and operation times are simultaneously obtained in order to satisfy the required demands in the proposed horizon time at minimum cost. The complete set of feasible CPs is generated through an exhaustive algorithm, which responds to the enterprise requirement about type of saw, available log diameters, log yields, and board dimensions. The large number of generated CPs complicates the model resolution due to the various tradeoffs among decisions variables. The same product can be obtained from different CPs and logs, and therefore inventory capacity, production times, raw material procurement, demand fulfilment, among others, are simultaneously assessed in order to obtain the best economical solution. Through the proposed example, these tradeoffs evaluations and the approach capabilities were highlighted.

Abstract

The efficient utilization of limited available resources plays a significant role in the operation of hydroelectric power systems. The purpose of scheduling in such systems is to determine the optimal power generation and generating unit commitment schedules so as to optimize an economic performance indicator subject to various system and external constraints. Fluctuations in electricity prices caused by the ever changing market conditions have a significant impact on the generation schedules for hydroelectric power systems. This may also give rise to a phenomenon of significant variation in optimal power generation and unit commitment schedules in response to slight fluctuations in pricing. These variations are undesirable since they warrant changes to the operational policy. This work focuses on the analysis of this "nervousness" phenomenon and the development of two strategies to mitigate its severity. This work involves the development of a mixed-integer nonlinear programming (MINLP) model for the short-term hydro scheduling (STHS) problem and its solution using a computationally efficient successive linear programming (SLP) technique. The effectiveness of the proposed methodology is demonstrated through a case study for daily generation scheduling in a cascaded hydroelectric power system.

Keywords: scheduling, hydroelectric, electricity price, "nervousness"

1. Introduction

Rapidly increasing global competitiveness and the highly dynamic nature of operational and marketplace conditions in the renewable energy sector motivate the need for development of efficient scheduling strategies for the optimal operation of hydroelectric power systems. Short-term hydro scheduling problems typically range from one day to a week and involve hourly or daily scheduling of generation on a system with the objective of optimizing a relevant economic performance indicator such as cost, revenue or generated energy for the given time horizon in view of all the various applicable constraints. These problems are usually composed of two main decision-making stages: unit commitment and economic load dispatch. The former is concerned with finding a subset of the set of available generating units which should be used to serve the forecasted energy demand at minimum operating cost. The latter is concerned with finding an optimal operational policy for a fixed number of units already connected to the system. The STHS problems are typically categorized mathematically as discrete,

nonlinear and non-convex (Wood and Wollenberg, 2012). The existence of hydraulically interconnected reservoirs, limited generating resources, variety of discrete and continuous constraints and decision-making over multiple stages, make these problems fairly large-scale and complex for cascaded hydroelectric power systems, motivating the need for development of effective modeling and solution approaches.

Mathematical programming approaches have been the centre of research in the area of STHS problems. These include methods ranging from linear programming (LP) to MINLP covering their entire spectrum. In order to improve computational efficiency, these approaches have often been applied within the frameworks of or in conjunction with dynamic programming, genetic algorithms, evolutionary computation, artificial intelligence methods, decomposition techniques and linear approximation based approaches such as SLP. A few nonlinear programming (NLP) and MINLP approaches for optimizing power generation efficiency considering hydroelectric power as a nonlinear function of water discharge and hydraulic head (Catalão et al., 2010a) subject to ramping constraints and start/stop of units (Catalão et al., 2010b) have been proposed in literature. SLP has been used to handle state dependencies and nonlinearities in STHS problems reported in literature (Belsnes et al., 2004; Fosso and Belsnes, 2004).

The highly dynamic electricity markets cause the prices to fluctuate frequently and deviate from their nominal profiles forecasted by power producers. These slight variations in pricing sometimes warrant drastic changes in their power generation and unit commitment schedules and they are undesirable from an operational standpoint. Therefore, effective strategies need to be developed to mitigate the negative impact of this "nervousness" phenomenon on system performance. This work focuses on formulating a comprehensive mathematical model for the STHS problem, solving it using a computationally efficient technique and developing two different strategies to effectively mitigate the ill effects of "nervousness". The remainder of the paper is organized as follows. Section 2 briefly describes the developed mathematical model. The employed SLP solution technique is summarized in Section 3. The methodology adopted for "nervousness" analysis and the strategies proposed for the mitigation of its undesirable effects are outlined in Section 4. The case study and its variations used for "nervousness" analysis are presented in Section 5. Finally, Section 6 provides concluding some remarks based on the results from the application of the proposed modeling and solution methods on the cases studied for the "nervousness" analysis.

2. Mathematical Formulation

The developed mathematical formulation takes the form of a non-convex MINLP model. The main assumptions made for its development include constant piecewise inflows to all the reservoirs during all time periods in the horizon, spill flows dependent on water levels in the reservoirs, multiple generating units associated with each reservoir in the system and no start-up/shut-down or operational costs for any generating resources. The objective function in Eq. (1) is the maximization of revenues from the sales of total generated powers from all generating units over the time horizon.

$$rev = \max\left[\sum_t \left\{ep_t . \left(\sum_k P_{k,t}\right)\right\}\right] \quad (1)$$

where k, t, ep_t & $P_{k,t}$ represent the reservoirs, time periods, electricity prices and total generated powers respectively. The major constraints imposed on the system include the multivariate cubic power generation function equation, hydraulic continuity equations,

multivariate nonlinear reservoir storage – water level relationship and spill flow equations. They are mathematically expressed using Eqs. (2), (3), (4) & (5) respectively.

$$p_{i,k,t} = \left(gus_{i,k,t}.A_{k,t}\right) + \left(B_{k,t}.q_{i,k,t}\right) + C_{k,t}.\left(q_{i,k,t}\right)^2 + D_{k,t}.\left(q_{i,k,t}\right)^3, \forall\, i \in I_k, k, t$$

$$\text{where } A_{k,t} = a_1 + a_2.h_{k,t} + a_3.\left(h_{k,t}\right)^2,\ B_{k,t} = b_1 + b_2.h_{k,t} + b_3.\left(h_{k,t}\right)^2,$$

$$C_{k,t} = c_1 + c_2.h_{k,t} + c_3.\left(h_{k,t}\right)^2, D_{k,t} = d_1 + d_2.h_{k,t} + d_3.\left(h_{k,t}\right)^2, \forall\, k, t \quad (2)$$

$$v_{k,t+1} = v_{k,t} - \left(Q_{k,t} + sp_{k,t}\right) + in_{k,t} + \left(Q_{k',t} + sp_{k',t}\right), \forall\, \{k\} \neq 1,\ \{k'\} = \{k\} - 1, t$$

$$v_{k,t+1} = v_{k,t} - \left(Q_{k,t} + sp_{k,t}\right) + in_{k,t}, \forall\, \{k\} = 1, t \quad (3)$$

$$v_{k,t} = C_0 + C_1.\left(l_{k,t} - C_2\right)^{C_3} + C_4.\left\{in_{k,t} + \left(Q_{k',t} + sp_{k',t}\right)\right\}^{C_5},$$

$$\forall\, \{k\} \neq 1,\ \{k'\} = \{k\} - 1,\ \{t\} \leq |T| + 1$$

$$v_{k,t} = C_0 + C_1.\left(l_{k,t} - C_2\right)^{C_3} + C_4.\left(in_{k,t}\right)^{C_5},$$

$$\forall\, \{k\} = 1,\ \{t\} \leq |T| + 1 \quad (4)$$

$$l_{k,min} \leq l_{k,t} \leq E_k^{Sill}.\left(1 - w_{k,t}\right) + l_{k,max}.w_{k,t}, l_{k,t} \geq E_k^{Sill}.w_{k,t},$$

$$0 \leq sp_{k,t} \leq w_{k,t}.sp_{k,max}, \forall\, k, t \quad (5)$$

where i, I_k, $|T|$, $p_{i,k,t}$, $q_{i,k,t}$, $gus_{i,k,t}$, $h_{k,t}$, $v_{k,t}$, $C_0 \ldots C_5$, $Q_{k,t}$, $sp_{k,t}$, $in_{k,t}$, $l_{k,t}$, $l_{k,min}$, $l_{k,max}$, E_k^{Sill} & $w_{k,t}$ are the generating units , generators downstream of reservoirs, set of time periods, powers generated from individual units, water discharges from each generator, generating unit status binaries, hydraulic heads, storage volumes, constant coefficients in storage – level relationship, total water discharges, spill flows, inflows, water levels and their minimum and maximum allowable values, sill elevations and spill flow controlling binaries respectively. The other constraints imposed on the system in the developed mathematical model are not presented here for the sake of brevity.

3. Solution Approach

The solution methodology adopted in this work to solve the developed non-convex MINLP formulation of the STHS problem is based on SLP. This technique was employed as it was found to perform with significantly greater computational efficiency compared to the commercial local (SBB & DICOPT) & global (ANTIGONE, BARON, COUENNE & SCIP) optimization solvers for MINLP problems, which failed to solve the considered STHS problem in reasonable time to within a prespecified optimality gap (1 %). The local and global MINLP solvers failed to solve the case problem within the stipulated time frames of 10^4 s and 1 day respectively whereas the SLP method solved it within 30 s to local optimality. SLP typically involves the iterative solution of a nonlinear problem using a first-order Taylor series based linear approximation around a chosen base point. Step size adjustment/trust-region bounding techniques (Palacios-Gomez et al., 1982), penalty function methods (Zhang et al., 1985) and their combinations (Zhang, 1989) have been used to guarantee feasibility and convergence.

The proposed SLP approach involves the linearization of the nonlinear power generation and reservoir storage – water elevation equations using first-order Taylor series approximations around chosen base points of hydraulic heads and discharge flows. The STHS problem under consideration takes the form of a non-convex MINLP. The novel iterative SLP algorithm employed here involves the solution of a sequence of mixed-integer linear programming (MILP) problems instead of the traditional LP subproblems. A step-size adjustment/trust-region bounding approach similar to the one in literature (Palacios-Gomez et al., 1982) is employed here in order to ensure the convergence of this algorithm in finite steps. Global optima cannot be guaranteed for

the non-convex MINLP problem under consideration here using this SLP technique. However, the convergence of this SLP algorithm to local optima is tested by fixing the binary decision variables in the MINLP using the solutions from the SLP approach, and comparing the solution from the SLP method to that obtained from a commercial local optimization solver for the resulting NLP problem. Local optima were confirmed using the above solution technique for all instances of the case study described in Section 5.

4. "Nervousness" Analysis & Mitigation

The "nervousness" phenomenon, characterized by drastic changes in the developed optimal schedules caused by even slight variations in electricity pricing, manifests itself in the form of significant differences in the power generation and generating unit commitment profiles in the context of the STHS problem. These variations are undesirable from an operational perspective. In order to investigate this phenomenon, a set of cases are developed by perturbing the hourly varying electricity prices in the nominal profile by random amounts within certain allowable ranges of perturbation.

Two different strategies, namely Penalty SLP (PSLP) and Start-Up Costs (STUC) are developed in order to curtail the undesirable effects of this "nervousness" phenomenon. The former involves the addition of a term to the objective function penalizing the sum of deviations in flows through individual generators from one time period to the next over all time periods in the horizon, except the last one. The latter involves the introduction of start-up costs in the objective function applicable only when a particular generator switches on from the switched off condition in any time period in the decision horizon. These "nervousness" mitigation strategies are mathematically expressed below.

$$rev = \max\left[\sum_t \{ep_t.\left(\sum_k P_{k,t}\right)\}\right] - \left[w.\left(\sum_{i,k,t<|T|} \left|q_{i,k,t+1} - q_{i,k,t}\right|\right)\right] \quad (6)$$

$$rev = \max\left[\sum_t \{ep_t.\left(\sum_k P_{k,t}\right)\}\right] - \left[\sum_{i\in I_k,t} \left(stu_{i,t}.stuc_i\right)\right], \text{ where}$$

$$stu_{i,t} = gus_{i,k,t},\ \forall\ k,\ i \in I_k,\ t = 1$$

$$stu_{i,t} \geq gus_{i,k,t} - gus_{i,k,t-1},\ \forall\ k,\ i \in I_k,\ t > 1 \quad (7)$$

where w, $stu_{i,t}$ & $stuc_i$ are the small penalty weight, binary variables signifying the changes in generating unit commitment and the constant start-up costs respectively.

5. Case Studies

The case study under consideration in this work involves the operation of a hydroelectric power system consisting of 3 cascaded reservoirs and the different numbers of multiple downstream generating units associated with them for a total decision horizon of 24 hrs. discretized into 1 hr. time periods. The inflows to the 3 reservoirs are assumed to be constant at 19012, 152 & 34 cfs respectively. The tail-water elevations are assumed to be constant at 801.23, 685.52 & 472.12 ft. respectively. The initial and final water levels upstream of the 3 reservoirs are fixed as the mid-points of their ranges at 1025, 801 & 684 ft. respectively. Sill elevations are assumed to be constant at 1025, 798 & 681 ft. for the 3 reservoirs respectively. The nominal electricity price profile with hourly varying prices is shown in Fig. 1 (EP_Case D). The cases developed for "nervousness" analysis are termed Cases D1, D2 & D3 for allowable random perturbations taken from uniform distributions within ±1, ±5 & ±10 %. The case with the nominal electricity price profile is termed Case D. Multiple scenarios are generated for each of these cases with perturbed profiles but results from only one representative scenario are illustrated here for the sake of brevity. The power generation

and generating unit commitment profiles for the first reservoir (designated as R1) and its first downstream generator (designated as G11) are compared for Cases D & D1 in the left-hand plots in Figs. 1 & 2. It is clear from these figures that the generation and commitment schedules for these cases differ from each other substantially for the small variation of pricing between them. The electricity price profiles in Fig. 1 overlap with no discernible differences due to the slight variation in pricing between Cases D & D1.

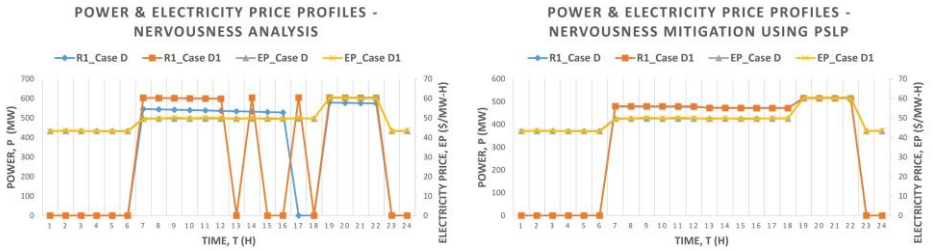

Figure 1. Comparison of power generation schedules between Cases D & D1 for R1 for "nervousness" analysis and mitigation using PSLP.

Table 1. Variation in economic objectives and generating unit commitment for "nervousness" analysis and mitigation strategies.

Case	"Nervousness" Analysis (NA)	PSLP	STUC
D (Nominal)	\$9.7585E5	\$9.7739E5	\$9.7740E5
	$\Delta_{NA} = 0$	$\Delta_{PSLP} = 0$	$\Delta_{STUC} = 0$
	$\Sigma_{NA} = 0$	$\Sigma_{PSLP} = 0$	$\Sigma_{STUC} = 0$
D1	\$9.5271E5	\$9.7615E5	\$9.7613E5
	$\Delta_{NA} = 2.37\ \%$	$\Delta_{PSLP} = 0.13\ \%$	$\Delta_{STUC} = 0.13\ \%$
	$\Sigma_{NA} = 29$	$\Sigma_{PSLP} = 0$	$\Sigma_{STUC} = 0$
D2	\$9.5322E5	\$9.6916E5	\$9.7045E5
	$\Delta_{NA} = 2.32\ \%$	$\Delta_{PSLP} = 0.84\ \%$	$\Delta_{STUC} = 0.71\ \%$
	$\Sigma_{NA} = 26$	$\Sigma_{PSLP} = 0$	$\Sigma_{STUC} = 0$
D3	\$9.6301E5	\$9.7679E5	\$9.7802E5
	$\Delta_{NA} = 1.32\ \%$	$\Delta_{PSLP} = 0.06\ \%$	$\Delta_{STUC} = 0.06\ \%$
	$\Sigma_{NA} = 39$	$\Sigma_{PSLP} = 0$	$\Sigma_{STUC} = 0$

The power generation and unit commitment schedules for the first reservoir (R1) and its first downstream generator (G11) are compared for Cases D & D1 in the right-hand plots in Figs. 1 & 2 upon the application of the PSLP approach for "nervousness" mitigation. Similar results are obtained from the application of STUC approach but are omitted for brevity. It is clear from these figures that this strategy results in smoother power generation profiles and eliminates the differences in the unit commitment schedules between them. A comparison of the economic objective values and two different performance metrics for all the cases studied for "nervousness" analysis and mitigation is given in Table 1. The first metric (Δ) is based on the differences in the objective values between the cases with perturbed and nominal electricity price profiles. The second metric (Σ) is based on the sums of differences in generator statuses for all generators over all time periods between the cases with perturbed and nominal price profiles. It is clear from Table 1 that both the PSLP & STUC approaches perform equally well in eliminating the variation in the generating unit commitment schedules. However, STUC performs slightly better compared to PSLP in terms of reducing the variation in the economic objective values, as evidenced from the results for Case D2 in Table 1. The PSLP method requires the specification of a penalty weighting parameter.

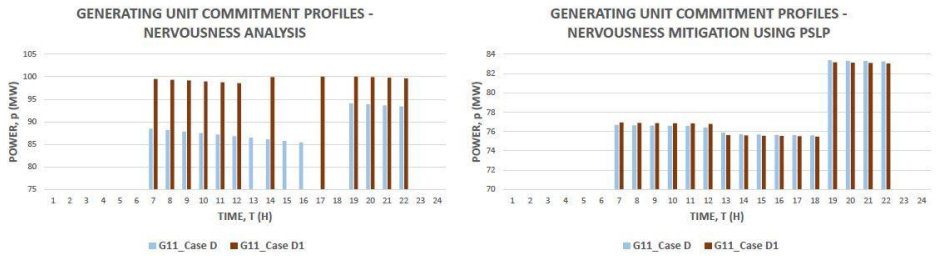

Figure 2. Comparison of generating unit commitment schedules between Cases D & D1 for R1 for "nervousness" analysis and mitigation using PSLP.

The optimal solution was found to be relatively insensitive to variations in the parameter value, provided that it remained within the same order of magnitude. The STUC approach, on the other hand, requires the specification of start-up costs for which reasonable estimates are typically available. All instances of the case study for both "nervousness" analysis and mitigation were solved using the commercial optimization solver CPLEX 12.6.3 within GAMS 24.7.4 on 3.60 GHz Intel Core i7 processor with 16 GB RAM running on Windows 10 operating system. The number of binaries, continuous variables & equations in the model for the "nervousness" analysis, PSLP and STUC case studies were 360, 2024 & 5405, 360, 2300 & 5957 and 648, 2312 & 5693 respectively. The computational times were lower than 30 s for all the cases.

6. Conclusions

The applicability and efficacy of a comprehensive MINLP formulation and computationally efficient iterative SLP solution technique for the STHS problem have been assessed in this work. The "nervousness" phenomenon has been investigated and two effective mitigation strategies (PSLP & STUC) have been applied to mitigate its severity for daily generation scheduling in a cascaded hydroelectric power system.

Abstract

This paper addresses the application of reliability analysis which has been widely accepted as an important tool in the strategy of maintenance management of systems. Reliability analysis of two online analyzers (A1 and A2) at a petrochemical company was carried out. The purpose of this work is to apply parametric and nonparametric methods to evaluate the reliability of two repairable systems and to estimate important parameters to maintenance management, such as mean time between failures (MTBF) and failure rate. The two sets of failure events underwent statistical tests in order to understand their behaviors and then their processes were modeled. It was observed that A1 presents a non-renewal process, better represented by the non-homogenous Poisson process (NHPP), while A2 is a renovation process consistent with the homogenous Poisson process (HPP). The study of A1 was complemented by the simulation the system's age at future times of consecutive repairs, and A2's study returned parameters such as MTBF and failure rate. It is expected that the results contribute to the adequacy of the planned maintenance, and that the presented tools continue to be applied, benefiting the organization maintenance management.

Keywords: reliability analysis, repairable systems, online analyzers, maintenance management.

1. Introduction

The maintenance management is important to ensure the constant improvement of equipment performance, ensuring quality operating within safe conditions for people and the environment (Jiang, 2015). According to Rausand and Hoyland (2004), with respect to a repairable system, the goal of maintenance is to restore it when necessary, but mainly to seek the improvement of the system reliability. Thus, the reliability analysis of a system provides information about its failure process, assisting in the comprehension of system operation and what to expect from its performance to better adjust the maintenance planning (Barringer, 2004). Birolini (2004) points out that reliability analysis is interrelated with cost and system effectiveness. It gives important indicators for the decision making in the maintenance management in order to attain the best possible usefulness of equipment and systems, as higher reliability in general leads to a lower operating cost.

2. A case study

The reliability analysis case study was carried out for two online analyzers (A1 and A2) which are gas chromatographs operating on a petrochemical company. Gas analyzers are of high importance for the quantitative analysis of contaminants (Thomas and Haider, 2013), in order to control and reduce the variability of the products, avoiding losses due to products out of specification.

The data mining was carried out through the company's shift book, by identifying all the failure events with respect to A1 and A2 between January 2012 and December 2016 (i.e. 1826 days). A failure event is given by any occurrence leading to the unavailability of the chromatographic analysis result.

Although A1 and A2 are essentially the same equipment operating in the same environment, they analyze distinct materials which incur different levels of aggression to the system, thus, the reliability analyses were performed separately.

3. Method

The reliability analysis procedure is structured in the following steps:

(1) Identification of all equipment failure events in the time of study

(2) Application of non-parametric graphic method for qualitative identification of possible trends in the system failure times

According to Tobias and Trindade (2012) a common data graph is the mean cumulative function (MCF), where the cumulative number of repairs is plotted against the system age t.

(3) Application of the parametric method (Poisson Process)

A number of observed systems ($m \geq 1$) is considered, with the i-th system being observed in the interval $(a_i, b_i]$, with n_i failures occurring at times T_{ij}, $j = 1, 2, \ldots, n_j$, $i=1, \ldots, m$. Defining $b_i = T_i$, if the case study is truncated at a specified time (t), n_i is the number of failures. $N_i(t)$ is the number of failures occurring in the i-th system in the interval (0, t], $t \leq b_i$ and $P[N_i(t)]$ it's the probability of occurrence (Jiang, 2015), then:

$$P[N_i(t) = \theta] = \frac{\left(\int_0^t \lambda_i(u)du\right)^{\theta} exp\left(\int_0^t \lambda_i(u)du\right)}{\theta!} \quad (1)$$

such that, $N_i(t) = \theta = 0,1,2, \ldots, n$. Thus, the average of $N_i(t)$ is given by Eq.(2):

$$\Lambda_i(t) = \int_0^t \lambda_i(u)du \quad (2)$$

where $\Lambda_i(t)$ is the accumulated intensity function until time t. Thus, $\lambda_i(t)$ is called intensity function of failures, which is required to specify the Poisson

process. A parametric form of $\lambda_i(t)$ widely used in the literature is called power law and is given by the following expression:

$$\lambda_i(t) = \frac{\beta_i}{\alpha_i}\left(\frac{t}{\alpha_i}\right)^{\beta_i - 1} \quad (3)$$

such that $t \geq 0$ and $\beta_i = 1$, where β_i is the reliability growth parameter and α_i is the scale parameter.

Thus, for a system to be characterized as a non-homogeneous Poisson process (NHPP), λ_i must obey the condition $\beta_i \neq 1$. Values $\beta_i > 1$ indicate that the i-th system is degrading, while values $\beta_i < 1$ indicate that the i-th system is improving (Birolini, 2004).

(4) Calculation of MTBF and failure rate (λ) when a process is characterized as a homogeneous Poisson process (HPP)

A HPP's failure rate corresponds to a constant intensity function ($\lambda(t) \equiv \lambda$) and is characterized as a renewal process (Lindqvist, 2007).

$$\text{MTBF} = \frac{T}{N} \quad (4)$$

$$\lambda = \frac{1}{MTBF} \quad (5)$$

with T as the final time of study and N the total number of failures at T.

(5) Simulation of future times of consecutive failures when a process is characterized as a non homogeneous Poisson process (NHPP)

A nonrenewal model, following a nonhomogeneous Poisson process, is a great challenge for maintenance planning, since costs and provisions for spare parts shall vary in time, due to nonstationary characteristics (Tobias and Trindade, 2012). It is expected a nonstable failure rate, so it not possible to obtain a single value for MTBF, as it would be possible to asses in a homogeneous Poisson process. In this way, it is intended to simulate the first N repair times for this NHPP.

An intensity function given by the Eq.(1).

$$\lambda(y) = \alpha\beta y^{\beta - 1} \quad (6)$$

It is possible to simulate as system ages in successive future repairs by Eq.(2, where $Y_1, Y_2, \ldots, Y_n$ are as system ages by generating random units $U_1, U_2, \ldots, U_n$, knowing that $Y_0 = 0$.

$$Y_i = Y_{i-1}^{\beta} - \frac{1}{\alpha}\ln(U_i)^{1/\beta} \quad (7)$$

4. Findings and discussion

4.1. Analyzer 1

Fig. 1 illustrates the mean cumulative function (MCF) for A1's failures with time. It allows us to see an indication of improvement on A1's system by the decreasing frequency of failures with time, observed by the smoothing of the curve's slope with time. From this perspective, it can be concluded that A1 has nonrenewal behavior. Table 1 leads to the same result of a nonrenewal process with respect to A1, since its failure time data failed the tests for randomness and stationarity, considering a significance level of 0.05, which led to the acceptance of the alternative hypothesis of a nonhomogeneous Poisson process.

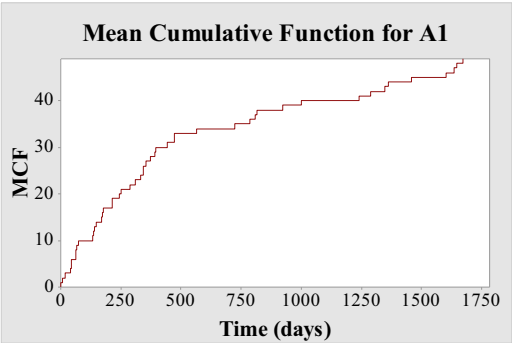

Fig. 1 – Mean Cumulative Function for A1

Table 1 - Randomness and stationarity tests (A1)

Test	H_0	T-test	p-value (α=0.05)	Process
MIL-Hdbk-189	HPP	180.30	$\ll$0.005	NHPP
La Place	HPP	-4.78	$\ll$0.005	NHPP
Anderson-Darling	HPP	14.25	$\ll$0.005	NHPP

Power relation model parameters were specified, by the performance of a parametric study on Minitab. Shape and scale parameters were obtained, by a power law process model: $\beta = 0.544$ and $\alpha = 1.299$. This result confirms the qualitative evaluation, that is, $0 < \beta < 1$ indicates that the system is improving with time. Then, using a unit uniform pseudorandom number simulator, available on Excel, it was possible to obtain the results shown on Table 2, for the first six repair times simulated.

Table 2 – Simulation of the first six repair times (A1)

A		B
1.29893		0.543532
N	U_i	t (days)
1	0.07385	3.69
2	0.46106	6.82
3	0.93614	8.77
4	0.02697	15.33
5	0.70363	18.61
6	0.09372	23.87

4.2. Analyzer 2

Fig. 2 illustrates the mean cumulative function (MCF) for A2's failures with time. Qualitatively, it is possible to say that there is no clear trending in the curve, but it is necessary to apply statistical tests to safely conclude if the variables are independent and identically distributed. Table 3 shows the results of the randomness and stationarity tests, leading to the conclusion that, at the significance level of 0.05, the null hypotheses of a homogenous Poisson process should not be rejected. Therefore, the analyzer 2 has a stable behavior and renewal process, better represented by the homogenous process of Poisson.

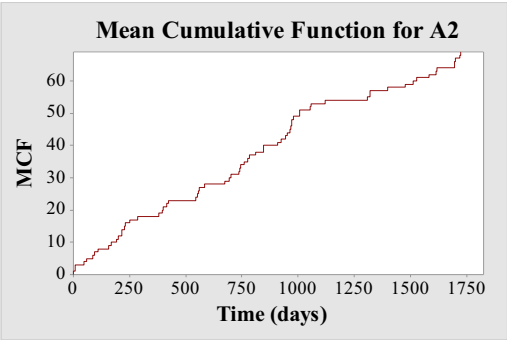

Fig. 2 – Mean Cumulative Function for A2

Table 3 - Randomness and stationarity tests (A2)

Test	Ho	Test statistic	p-value (α=0.05)	Result
MIL-Hdbk-189	HPP	165.15	0.052	HPP
La Place	HPP	-1.68	0.094	HPP
Anderson-Darling	HPP	2.05	0.086	HPP
