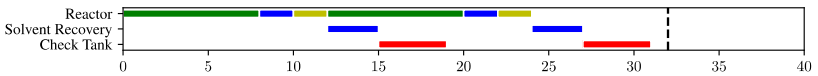
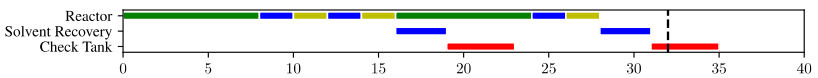
Solvent recovery (regular)	3	-	Consumes 2 “units” of filter
Clear filter	6	-	Restores filter capacity to 2 “units”
Check tank	4	-	

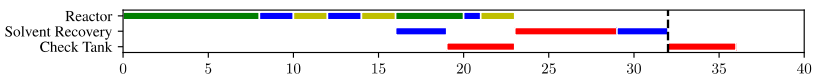
Consider the problem described above, with a deadline of 32 hours. Figure 3(a) shows the nominal optimal schedule, in which two batches of the premium product are completed before the deadline. The nominal schedule is feasible as long as neither batch requires a second decant-sample cycle. If such a disturbance does occur, however, the processing time for that batch will be extended by four hours. Figure 3(b) shows that if a disturbance occurs in the first batch, simply pushing the schedule back will result in the second batch not being completed before the deadline. Figure 3(c) demonstrates that, because the filter in the solvent recovery unit does not have enough capacity to process one premium and one regular batch without maintenance, replacing the second premium batch with a regular batch at time 16 will not work, either.



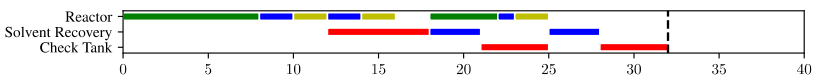
(a) The nominal optimal schedule.



(b) The naïve response to the delay is to simply push the remaining tasks back.



(c) An alternative is to replace the second batch of the premium product with a batch of regular product, which requires clearing the filter.



(d) If the filter is cleared at time 12, then the second batch can be completed before the deadline.

Figure 3. Schedules from the example in Section 3 (color coded to match Figure 2).

If the delay is detected at time 12, when the automation system receives the signal to return to the decant step after the first sampling step, it is already known that the nominal schedule is no longer feasible, because the first batch will not be completed before time 16. This comes from the fact that at time 12, the relaxed specification (where b is the batch number) AG($b = 1 \Rightarrow t < 15$) is falsified, but the further relaxation AG($b = 1 \Rightarrow t < 16$) is not. Solving the rescheduling problem at time 12, with the added constraint that the end time of the first batch is greater than or equal to 16 (i.e., the binary state variables in the RTN formulation that correspond to the first batch being assigned to the reactor between times 12 and 16 are all fixed to 1), produces the

schedule shown in Figure 3(d). The filter is cleared proactively starting at time 12 to overlap with the second cycle of decanting and sampling in the reactor, which allows the regular batch to be completed before the deadline. Note that, because the rescheduled operation finishes at the deadline, with no time to spare, it was only possible because the delay was predicted at time 12. Attempting to reschedule at time 13 (when it would be known that the nominal schedule is no longer feasible even without using the approach from this paper) would be too late, as the second batch could not be completed before time 33, after the deadline.

4. Conclusions

We have shown that knowledge of the automation system's dynamics in a chemical plant can be incorporated in the rescheduling problem to improve the throughput compared to simple periodic rescheduling. This is an early step toward bridging the gap between the detailed models used when analyzing automation systems and the higher-level models of the plant's operations used in a typical scheduling problem. One key question to answer is whether the constraints that are applied when rescheduling after detecting infeasibility are sufficient to push the solution away from the problematic area. Applying our approach to a real industrial process and investigating embedding the automation system's dynamics directly in the scheduling formulation (thereby avoiding schedules that conflict with the automation logic altogether) are the subject of current and future work.

Manufacturing Sustainability Enhancement: A Model Predictive Control Based Approach

Majid Moradi-Aliabadi[a], Yinlun Huang[a*]

[a] *Department of Chemical Engineering and Materials Science, Wayne State University, Detroit, MI 48202, USA*
yhuang@wayne.edu

Abstract

From the sustainability science point of view, a manufacturing system's sustainability status change involves a series of system state transitions in an economics-environment-society-based three-dimensional space. To ensure the achievement of the sustainability goal effectively in this multi-stage process under uncertainty, continuous sustainability assessment and decision making is needed. In this paper, we formulate this type of sustainability problem as a terminal target control problem. A multi-objective optimization approach is applied for generating sustainability goal options for decision makers to select or adjust. A model predictive control (MPC) approach is then employed to derive sustainability actions for implementation in different sustainability improvement stages. The introduced methodology can provide a stage-wised guideline to industries in defining sustainable development strategies and deriving sustainability actions systematically. A comprehensive case study on biodiesel manufacturing is illustrated to demonstrate methodological efficacy.

Keywords: Sustainable manufacturing, MPC strategy, sustainability action

1. Introduction

Industries across the world face increased costs in materials, energy, and compliance coupled with higher expectations of customers, investors and local communities. Thus, making manufacturing economically sound, environmentally clean, and socially responsible is no longer just nice-to-have, but an industry's imperative. Sustainable manufacturing demands (i) triple-bottom-line based practice and (ii) continuous performance improvement. The former reflects the nature of sustainability, which is a multi-objective optimization problem, while the latter is a dynamic control problem. In short, sustainable manufacturing is a multi-objective optimal control problem. Thus, an important research direction is to study how system control science can be effectively used to guide sustainability study in a holistic way.

Over the past decades, various approaches have been proposed to support decision-making for sustainable manufacturing, most of which use Multi Criteria Decision Making (MCDM) techniques (Azapagic and Perdan, 2005; Yue et al., 2013). The collaborative profitable pollution prevention (CP3) idea was introduced by Piluso and Huang (2009), which aid in decision-making for the study of sustainable development of industrial zones. All these methodologies that are applied at different scales focus on the first aspect of the definition of sustainable manufacturing that is a multi-objective problem.

In this work, we formulate manufacturing sustainability problems as a terminal target control problem, which is investigated by resorting to sustainability fundamentals,

system control and engineering science. A multi-objective optimization approach is applied for generating sustainability goal options for decision makers to select or adjust. A model predictive control (MPC) approach is then employed to derive sustainability actions for implementation in different sustainability improvement stages.

2. Methodology

Evaluation of a manufacturing system's sustainability performance requires selection of sets of indicators. The indicators are organized to measure the economic, environmental, and social sustainability of the system over time to determine if desirable progresses are made. Figure 1(a) shows a sustainability valuation model. The sustainability status of any system can be described by a time-variant vector function, $\vec{S}(k)$, that is defined by Moradi-Aliabadi and Huang (2016) as follows:

$$\vec{S}(k) = \langle E(k), V(k), L(k) \rangle, \tag{1}$$

where $E(k)$, $V(k)$, $L(k)$ are, respectively, the composite economic index, the composite environmental index, and the composite social index. Note that each composite index is normalized with the value range of 0 to 1, which is derived from a set of measured indicators in each of the three sustainability categories.

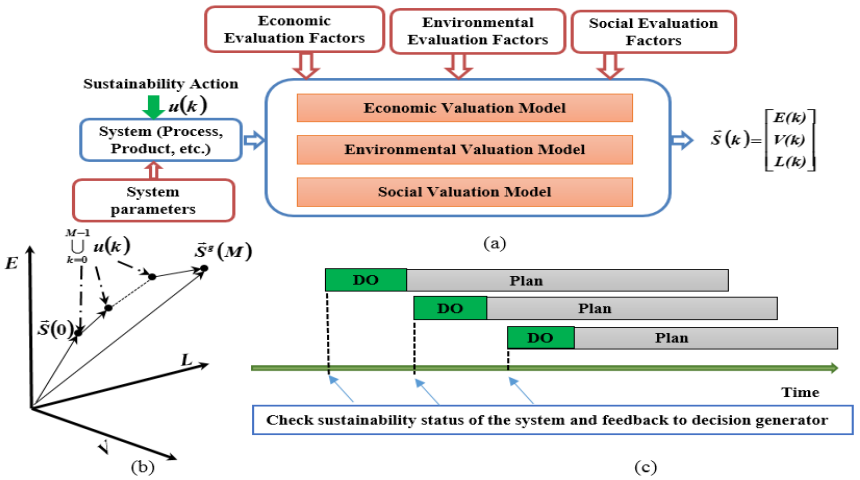

Figure 1. (a) Sustainability valuation model, (b) terminal target problem and (c) Plan-Do-Check-Act cycle.

At any time instant k, $\vec{S}(k)$ is a vector from the origin of the space (0, 0, 0) to the point, $(E(k), V(k), L(k))$ as shown in Fig. 1(b). As an illustration, $\vec{S}(0)$ is a vector pointing to the system's sustainability status at time $k = 0$. The sustainability status of the system is changed when sustainability action $u(k)$ is taken by the decision makers at that time. Thus, the sustainability status at a given time is determined by the pervious sustainability status and the action received by the system in the last period of time. In the most general term, this can be represented by:

$$\vec{S}(k+1) = f(\vec{S}(k), u(k)), \tag{2}$$

2.1. Sustainability goal setting

Setting a sustainability goal is a challenging task for decision makers because of the trade-off among economic (E), environmental (V), and social (L) sustainability objectives. Here we formulate the sustainability problem as a Multi-Objective Optimization (MOO) problem, aiming at generating the Pareto optimal solutions (or Pareto set) for decision makers to choose the most preferred solution. A Pareto optimal solution that is also called non-dominated solution is defined as follows: assume that the objective functions, f_i, $i = 1, 2, \ldots, p$, are for maximization, a feasible solution $\vec{x}$ of a MOO problem is a Pareto optimal solution, if there is no other feasible solution $\vec{x}'$ such as $f_i(\vec{x}') \geq f_i(\vec{x})$ for every i with at least one strict inequality. In this work, the ε-constraint method is adopted for generating the Pareto set. This method optimizes one objective function, while the other objective functions are considered as constraints as shown below,

$$\begin{aligned} \max \quad & f_1(\vec{x}) \\ s.t. \quad & f_2(\vec{x}) \geq \varepsilon_2 \\ & f_3(\vec{x}) \geq \varepsilon_3 \\ & \vec{x} \in S \end{aligned} \tag{3}$$

Pareto optimal solutions are obtained through changing the values of the constrained objective functions (ε_i). Here S denotes a feasible decision space.

2.2. MPC strategy for sustainability improvement

The MPC strategy for industrial sustainability development is implemented by following the steps below:

Step 1**.** The sustainability status of the system, $\vec{S}(t)$, is measured/estimated at each instant t using the sustainability valuation model.

Step 2**.** The set of future sustainability actions, $U^*(t) = \{u^*(t|t), u^*(t+1|t), \ldots, u^*(t+M-1|t)\}$, is calculated for the entire planning window, M, by optimizing a determined criterion. For example, in a terminal target problem shown in Fig. 1(b), we are interested in minimizing the error between the desired sustainability target position, $\vec{S}^g(M)$, and the actual sustainability status of the system, $\vec{S}(M)$, at the end of the final time M.

Step 3**.** The first sustainability action, $u^*(t|t)$, is implemented, whilst the other sustainability actions are rejected, because at the next sampling instant, $\vec{S}(t+1)$ is already known and Step 1 is repeated with this new value.

The MPC strategy for sustainability performance improvement can be viewed as a sustainability management system (SMS), which is based on the well-known Plan-Do-Check-Act cycle for continuous improvement (see Fig. 1(c)).

2.3. Decision generator

In this work, sustainability performance improvement is through implementing appropriate technologies. Here we use the sustainability performance improvement methodology developed by Moradi-Aliabadi and Huang (2016). In the second step of the MPC strategy described above, the decision generator needs to identify sets of technologies (among N technology candidate) by solving an optimization problem for implementation in M stages to achieve a pre-set sustainability goal, $S^g(M)$. For the terminal target problem, the following optimization model should be solved at each sample time t.

$$
\begin{aligned}
&\underset{U_t}{argmin}\ \ J=\left(\vec{S}^{g}(M)-\hat{\vec{S}}(M)\right)^{T} W\left(\vec{S}^{g}(M)-\hat{\vec{S}}(M)\right)\\
&s.t.\\
&\quad \hat{\vec{S}}(0)=\vec{S}(t)\\
&\quad \hat{E}(k+1)=\hat{E}(k)+\sum_{j=1}^{N} y_{k,j}\Delta E(T_j,P) \qquad k=0,1,\ldots,M-1\\
&\quad \hat{V}(k+1)=\hat{V}(k)+\sum_{j=1}^{N} y_{k,j}\Delta V(T_j,P) \qquad k=0,1,\ldots,M-1\\
&\quad \hat{L}(k+1)=\hat{L}(k)+\sum_{j=1}^{N} y_{k,j}\Delta L(T_j,P) \qquad k=0,1,\ldots,M-1\\
&\quad \hat{E}(k+1)\geq \hat{E}(k) \qquad k=0,1,\ldots,M-1\\
&\quad \hat{V}(k+1)\geq \hat{V}(k) \qquad k=0,1,\ldots,M-1\\
&\quad \hat{L}(k+1)\geq \hat{L}(k) \qquad k=0,1,\ldots,M-1\\
&\quad Cost\left(u(k)\right)\leq B^{up}(k) \qquad k=0,1,\ldots,M-1
\end{aligned}
\tag{4}
$$

where the objective function, *J,* is the weighted Euclidian distance; *W* is a diagonal weighting matrix that its diagonal elements (w_{11}, w_{22}, w_{33}) are the weights associated to economic, environmental, and social composite indexes respectively; $\Delta E(T_j,P)$, $\Delta V(T_j,P)$, and $\Delta L(T_j,P)$ are, respectively, the economic, environmental, and social sustainability improvements of system *P* when technology T_j is adopted; $y_{k,j}$ is a binary variable ("1" if technology *j* is selected at stage *k*; otherwise "0"). The equality constraints describe the sustainability status transition of the system, the inequality constraints show the sustainability space, and the last constraint is a budget limit for project implementation. The hat notation is used for the sustainability status of the system predicted by the models. There are several logical constraints associated with this optimization model that are not discuss here for the sake of brevity. Details about the constraints and methodology can be found in Moradi-Aliabadi and Huang (2016).

3. Case study on biodiesel manufacturing

The developed methodology is used to investigate the sustainability performance improvement problem of an alkali-catalyzed biodiesel manufacturing plant. The plant seeks cost-effective technologies to reduce waste, improve energy efficiency and product quality. A three-year (i.e., $M = 3$) sustainability performance improvement goal is set, and 10 candidate technologies (T_1, T_2, …, T_{10}) are available for selection. The technology specifics and sustainability related data can be found in Moradi-Aliabadi and Huang (2016).

To simplify the description of methodological application, only the economic (*E*) and environmental (*V*) performance improvement is illustrated. The economic sustainability indicators are the value added (E_1) and the gross margin per direct employee (E_2). The indicators in the environmental sustainability category are the total raw materials used per pound of product produced (V_1), the hazardous solid waste per unit value added (V_2), and the energy intensity (V_3). The budget limits for technology adoption are \$300k, \$200k, and \$100k for the first, second and third stages, respectively. The weighting factors (w_{ii} in matrix W in Eq. (4)) are set equal that shows equal importance of the categorized sustainability improvement.

Table 1. Pareto optimal solutions in *E-V* space

Plan	Pareto optimal solution	Final sustainability state vector	Overall sustainability $\left\|\vec{S}(3)\right\|$
P_1	$\{T_6\},\{T_1,T_2,T_9\},\{T_4\}$	$\vec{S}_1(3)=0.78\vec{i}+0.54\vec{j}$	0.67
P_2	$\{T_6\},\{T_2,T_7,T_9\},\{T_1\}$	$\vec{S}_2(3)=0.76\vec{i}+0.57\vec{j}$	0.67
P_3	$\{T_6\},\{T_2,T_7,T_9\},\{T_{10}\}$	$\vec{S}_3(3)=0.71\vec{i}+0.60\vec{j}$	0.66
P_4	$\{T_2,T_4,T_5,T_8\},\{T_1,T_7\},\{T_9\}$	$\vec{S}_4(3)=0.68\vec{i}+0.62\vec{j}$	0.65
P_5	$\{T_5,T_7,T_8\},\{T_1,T_2,T_9\},\{T_{10}\}$	$\vec{S}_5(3)=0.65\vec{i}+0.65\vec{j}$	0.65
P_6	$\{T_3,T_4,T_5,T_7\},\{T_2,T_9,T_{10}\},\{T_8\}$	$\vec{S}_6(3)=0.60\vec{i}+0.66\vec{j}$	0.63

In this case, the initial sustainability status of the system is $\vec{S}(0)=\langle 0.50,\ 0.40\rangle$. To provide sufficient decision support to the decision makers for sustainability goal achievement, a set of Pareto optimal solutions are derived using the ε-constraint method. The derived solutions are summarized in Table 2. Each listed plan (P_i) is a solution that can be selected for future sustainability improvement of the biodiesel manufacturing process. The finial sustainability status of the system and the overall sustainability that is defined as the norm of sustainability status vector are shown in the third and fourth columns of the table. As the results show, the overall sustainability performances using different plans are similar (see the values in the fourth column). However, the range of each composite sustainability index is considered large. The Pareto front curve in the *E-V* space that shows a trade-off opportunity between the economic and environmental objectives is plotted and shown in Fig. 2(a). The Pareto optimal solutions (P_1 to P_6) are marked on the curve in the figure and any of these points can be selected by the decision maker. Note that all the points above the Pareto curve are infeasible solutions; the points below the curve are feasible but suboptimal. Here, the decision makers set the final goal for the categorized sustainability to $S^g(M)=\langle 0.71,0.6\rangle$ that is located on the Pareto curve.

The measured initial sustainability status of the system, $\vec{S}(0)=\langle 0.50,0.40\rangle$, is used as a feedback to the *decision generator*, where the MPC strategy is implemented, to generate an optimal policy for the next three years. At $t=0$, the *decision generator* outputs the optimal policy, $U^*(t=0)=\{\{T_2,\ T_4,\ T_5,\ T_8\},\{T_1,\ T_7\},\{T_9\}\}$, for the next three years by solving the terminal optimization problem shown in Eq. (4). The sustainability development path (see the dotted arrowed line in Fig. 2(a)), and the dynamic sustainability value of the system after implementation of this optimal policy is shown in the Fig. 2(a) and (b), respectively. As the results show, the plant can achieve the preset sustainability goal after three years. The investments for taking sustainability actions are \$289k, \$190k, and \$60k in the first, second, and third years, respectively.

Based on the MPC strategy, the first sustainability action, $\{T_2,\ T_4,\ T_5,\ T_8\}$, is implemented at $t=0$ and other sustainability actions are rejected. After the first stage of sustainability enhancement, technologies T_2, T_4, T_5, and T_8 are removed, and the sustainability status of the system, $\vec{S}(1)=\langle 0.56,0.52\rangle$, is measured again. The assessment result is sent to the decision generator. If the plant operation is not affected by the environment and other conditions, the sustainability actions will not be changed in the follwing sample times based on the principle of optimality. In this case, the predicted sustainability status of the system will be same as the actual one, $\vec{S}(1)$, after the first stage of sustainability enhancment. However, if there is a disturbance (assume a disturbance $v=\langle -0.02,\ 0\rangle$

because of a change in demand or product price) that perturbs the sustainability status of the system, the optimal policy for the next two years will be different to reach the same sustainability goal. Based on the MPC strategy, the new sustainability status of the system will be $\vec{S}(1)=\langle 0.54, 0.52\rangle$; this information is sent to decision generator as a new initial point, which requires a derivation of a new policy for the next two years. In this scenario, the results show that the final sustainability goal is achievable, if the budget limit be increased from \$200k to \$300k for the second stage. The optimal policy would be $U^*(t=1)=\{\{T_6\},\{T_9\}\}$ that is different from the previous one ($\{T_1, T_7\}$). The sustainability development path is shown in Fig. 1(a) (see the solid arrowed line) for this scenario.

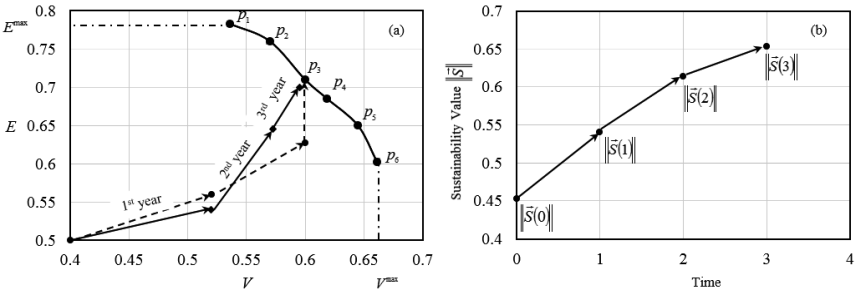

Figure 2. (a) Pareto front curve and sustainability development path with disturbance (solid path) and without disturbance (dotted path), and (b) dynamic of sustainability value of the system.

4. Conclusions

In this paper, we formulate industrial sustainability enhancement problem as a dynamic control problem. As sustainability seeks solutions for triple-bottom-line-based development, a multi-objective optimization approach is applied to derive a set of optimal sustainability alternatives for the decision makers to set the most desirable sustainability goal(s). The MPC strategy is effectively used to derive optimal sustainability improvement strategies and implement them in a dynamic domain. The introduced methodology is general in application, and can provide a structured step-by-step guideline for industries to define sustainability goals derive sustainability actions systematically.

Abstract

A combined cycle power plant (CCPP) is a complex system with a Gas Turbine, Steam Turbine and a Heat Recovery Steam Generator (HRSG) working together. These three units work together and make the process highly interdependent. The onset of any fault in one of the above units would results in a significant reduction in overall efficiency and potentially lead to catastrophic accidents. Such failures can occur due to process faults because of large abrupt variations of operating conditions and structural faults due to corrosion, uneven stresses due to frequent cyclic operations. Conventionally, the identification of such leakage locations is made via visual inspection which is a time consuming and tedious. In the present work, we discuss a fault diagnosis strategy for an actual industrial HRSG present in a CCPP. Various steady state models at different loads of CCPP as well as a dynamic model are developed. Various structural faults in the form of leakages are incorporated in the heat exchangers. An Artificial Neural Network (ANN) model is developed based on data from the above simulations to detect the leaking heat exchangers.
Keywords: Combined Cycle Power Plants, Heat Recovery Steam Generators, Fault Diagnosis, Artificial Neural Networks

1. Introduction

Combined Cycle Power Plants (CCPP) are popular for electricity production in power industry. Unlike other electricity production options such as Gas Turbine and Steam Turbine alone, CCPP can offer up to 60% efficiency (Hoang and Pawluskiewicz, 2016). A CCPP consists of a topping cycle (Gas Turbine) and a bottoming cycle (Steam Turbine) with an HRSG connecting the two. Because of their strong interdependency (Dev et al., 2015), a failure or an inception of fault can quickly propagate and result in drastic reduction of the efficiency of the power plant and catastrophic accidents. There are several reasons for faults in CCPPs. Process faults occur due to large variations in the temperatures/pressures of feed water or exhaust gas; additionally, structural faults such as leakages occur due to corrosion of the water/steam tubes, uneven stresses generated by cyclic operations of CCPP, (Fontaine and Galopin, 2007) etc. Trips due to the sequential propagation of faults are often seen in CCPPs.
An HRSG is a critical part of a CCPP. The heat from exhaust gas coming out of the Gas Turbine is utilized by HRSG to produce steam. This steam is fed to Steam Turbine to generate additional electricity. A typical HRSG has a series of heat exchangers

consisting of superheaters, evaporators, and economizers. HRSGs can be classified by the direction of the exhaust gas flow (vertical or horizontal) and numbers of steam circuits (single, double or triple pressured). In the horizontal arrangement, the exhaust gas passes through vertical tubes whereas in the vertical arrangement the exhaust gas passes through horizontally arranged tubes (Ganapathy, 2015).

HRSGs are prone to structural faults leading to leakages in the tubes arising from over and prolonged heating, varying cyclic operations due to discontinuous electricity load demand and retention of active corroding materials such as NaOH used for cleaning of tubes of HRSG. The detection of the location of leaking and fractured tubes within such large structures is conventionally carried out by non-technical methods (Bain and Christophersen, 2003). The operators in the control rooms usually get an indication of leaks by observing changes in pressure drops in water/ steam lines and exhaust gas temperature instabilities. Further, visual inspections are done during shutdown/maintenance periods to identify the location of leaking sections. Online fault detection and isolation techniques can help to identify the process and structural faults in a timely fashion.

Although fault diagnosis and health monitoring of HRSGs have not received much attention in the literature, various mathematical and data-driven modelling approaches to enhance the performance have been reported. Kumar and Raju (2012) reported that there is a significant effect of heat exchanger arrangement in HRSG on the overall efficiency of CCPP. Feng et al. (2014) provided a generalized model for analyzing the performance of HRSG. Asgari et al. (2013) utilized the operating data to optimize performance and condition monitoring. Nowak and Rusin (2016) developed an Artificial Neural Network-based model for fast prediction of stresses in steam turbine casing. Sharma and Singh (2016) indicated the potential for performance improvement with exergy and economic analysis. Various authors have also analyzed the dynamic behavior of HRSGs during start-up and shutdowns. Benato et al. (2015) developed a dynamic model of triple pressure HRSG and showed that the most stressed component in transient operations are High-Pressure Superheaters and High-Pressure Drum. Alobaid et al. (2014) simulated the startup and shutdown of HRSG. Zhou et al. (2017) performed CFD analysis of an HRSG and showed that unburnt fuel causes structural damage to tubes due to sudden pressure rise.

In the present work, the prime focus is on leakages arising from structural faults. A fault diagnosis strategy is developed for a triple pressure vertical HRSG present in an industrial CCPP. The steady-state models of HRSG at various loads of CCPP are simulated in Aspen Plus®. Verification and validation studies are conducted to ensure that the simulated data is in good congruency with the observed temperatures, pressures and flow-rates at various loads. Further, one of the steady-state models is extended to a dynamic model in Aspen Plus Dynamics®. Various failure modes of leakages are introduced in this dynamic model. Data from these are used to train an Artificial Neural Network (ANN) to classify the location of leakages.

2. HRSG in an Industrial CCPP

The considered HRSG is from an industrial CCPP with a capacity of 368 MW. The schematic diagram of a typical CCPP with vertical Heat Recovery Steam Generator is shown in Figure 1. The HRSG has three levels of high, intermediate, and low pressures. Typically, each pressure circuit in the HRSG has superheater(s), evaporator and economizer(s). In the HRSG in Figure 2, a Boiler Feed Pump draws water from Low-Pressure Drum and supplies it to Intermediate-Pressure and High-Pressure circuits.

High-Pressured Superheaters (HPSH-1,2), Reheaters (RH-1,2) and Low-Pressure Superheater (LPSH) deliver the superheated steam to respective Steam Turbines. The High and Intermediate Drums draw water from the economizers from their respective pressure circuits whereas Low-Pressure Drum draws water from Condensate Preheater (CPH). The evaporators in each circuit evaporate the water coming from the drums and feed the saturated steam to the drums again; they maintain this close circulation. Further, the superheaters in all circuits draw saturated steam from their respective drums and convert it into superheated steam suitable for Steam Turbine operation.
The exhaust gas from Gas Turbine enters HRSG at a temperature of 613.9 $^{\circ}$C with a flow rate of 2192 t/h (at 100% load of CCPP). The gas flows downstream through all

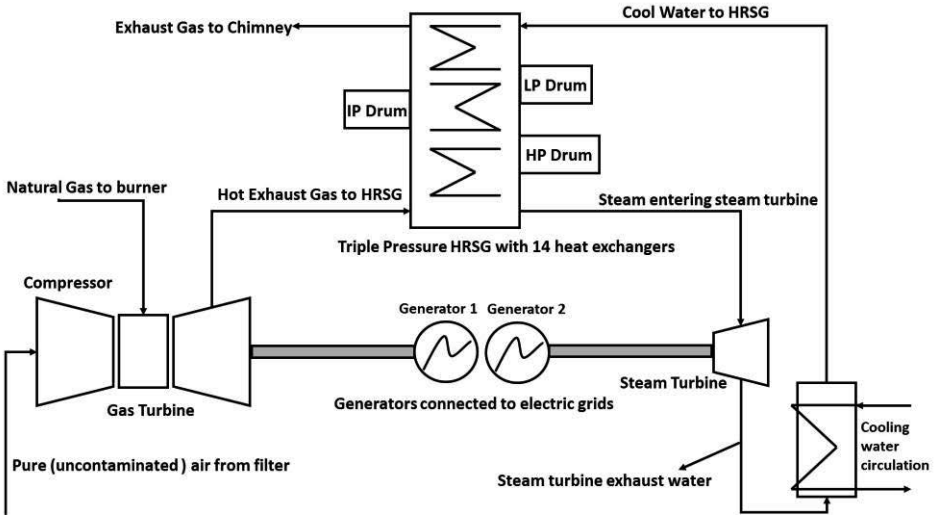

Figure 1. Schematic of CCPP with vertical HRSG

the heat exchangers as shown in Figure 2. Finally, it is relieved to the atmosphere through the stack. To extract maximum energy, the used steam from in higher pressured circuits is fed to lower pressure circuits. The low-pressure circuit outlet stream is cooled in an Air Cooled Condenser (ACC). The water is again circulated into these circuits. The lost water is compensated with the addition of make-up water to ACC.

3. HRSG Simulations and Fault Incorporation

Detailed steady-state HRSG models at loads of 100%, 80%, and 50% of CCPP were simulated in Aspen Plus®. The heat exchangers are cross flow with finned-tube bundles. These crossflow bundles are developed in Aspen Exchanger Design and Rating®. Real geometry data of the exchangers are used to develop these models. Peng-Robinson Equation of State is utilized to simulate the system with rigorous calculations. The performance of the developed models is in good congruency with the data observed from the real HRSG.
Further, the steady state HRSG model at 80% of the CCPP load was extended to a dynamic model in Aspen Plus Dynamics®. Various control loops are also included in this model to maintain pressures, liquid levels of drums and steam flow temperature in all the pressure circuits. They are tuned with a relay-feedback test to get the ultimate

gain and frequency in a feedback loop. The developed dynamic models were run for a period of 10 h.

Once the normal dynamic operation of the system has been successfully simulated, various heat exchanger leaks scenarios were created in Aspen Plus Dynamics®. The heat exchangers chosen to introduce the leakages in the steam lines are the three High-Pressure Economizers, two Reheaters, two High-Pressure Superheaters and an Intermediate-Pressure Superheater. A total of 104 leak fault cases were generated – 13 examples from each of the above eight heat exchangers. A set of 6 examples without any fault were also generated.

IPSH	: Intermediate Pressure Superheater	**LPEVAP**	: Low Pressure Evaporator

Figure 2. Vertical triple pressure HRSG under consideration

Time series data from 21 sensors for various temperatures, pressures, levels, and flow-rates across the HRSG are emulated in the simulation. Each simulation run corresponded to an operating period of 10 h, with samples obtained over 0.01 h. This data was utilized to train an ANN for HRSG fault diagnosis.

4. ANN-based identification of Leakage Locations in HRSG

From the dynamic simulation, the time series data for each of the 21 sensors is obtained. However, the range of each sensor is different and varies in magnitude; rescaling of this time series across each sensor is done in the range of (-1, 1). As per Table 1, the fault locations are divided into four types according to their accessibility from each manhole in the actual plant.

Table 1: Classes along with associated heat exchangers.

Location wise class	Heat Exchangers associated with leaks
Type 1 (No Faults)	--
Type 2 (Accessible from Manhole 1)	High-Pressure Superheater-1, 2, Reheater-1,2
Type 3 (Accessible from Manhole 2)	Intermediate-Pressure Superheater, High-Pressure Economizer-3
Type 4(Accessible from Manhole 3)	High-Pressure Economizer-1,2, Intermediate-Pressure Economizer

The multi-label classification problem is solved with a back propagation ANN. Out of the 75872 total examples, 60% were utilized for training the ANN. 20% examples were utilized for validation and testing each. The confusion matrix for the trained ANN is shown in Figure 3. This final optimized ANN was able to classify 99.8% of the testing examples successfully.

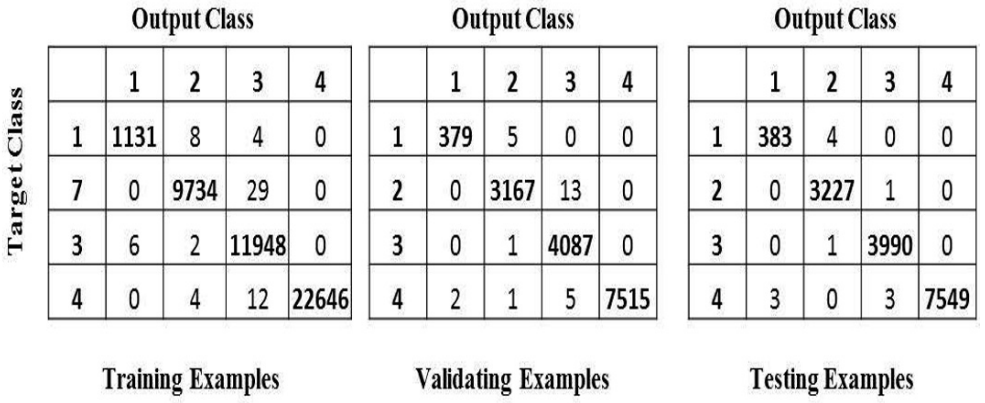

Figure 3. Confusion Matrices for trained ANN

5. Conclusions and Future Work

Fault diagnosis is an important need and challenge in HRSGs. In this work, we have focused on leakages in HRSG heat exchangers – the most commonly occurring faults. Steady State models for an industrial triple pressure HRSG were developed at various loads of CCPP. After verifying and validating the accuracy of these models, one of these steady-state models is utilized to develop a dynamic model. Faults are introduced in these dynamic models at various locations. The data from the dynamic simulation was used to develop a multi-label classification ANN to identify the location of leaking

heat exchangers (as per accessible manhole nearer to it). The developed neural network can classify all the testing faults with 99.8% accuracy. In future, all possible off-load conditions based dynamic models could be used to train the ANN to identify the leak locations in HRSG.

Statistics Pattern Analysis: A Statistical Process Monitoring Tool for Smart Manufacturing

Q. Peter He[a*], Jin Wang[a]

[a]*Department of Chemical Engineering, Auburn University, Auburn AL 36849, USA*
qhe@auburn.edu

Abstract

Statistical process monitoring (SPM) is an important component in the long-term reliable operation of any system and its importance can only become greater in the era of smart manufacturing (SM). Previously we proposed statistics pattern analysis (SPA) based on the idea of using various statistics to quantify process characteristics, and monitoring these statistics instead of process variables themselves to perform process monitoring. In this work we examine the SPA's capability in handling process characteristics including dynamics, nonlinearity and data non-Gaussianity, and compare its performance to representative state-of-the-art SPM methods. In addition, we discuss how SPA can help address new challenges presented by smart manufacturing big data.

Keywords: statistical process monitoring, fault detection, fault diagnosis, smart manufacturing, statistics pattern analysis.

1. Introduction

The goal of process monitoring is to detect the onset and identify the root cause of any change that causes a manufacturing environment to deviate from its desired operation. Process monitoring is an important component and key enabler for the long-term reliable operation of any process (Severson et al., 2016). It has been recognized that the importance of process monitoring can only become greater when the controlled systems are getting more complex, equipped with more sensors, operated under non-steady state, controlled at tighter margins, and getting yet closer to autonomous operations in the era of smart manufacturing (He and Wang, 2017). Principal component analysis (PCA), partial least squares (PLS), and their variants based multivariate SPM methods, which are the state-of-the-arts for industrial applications, have limitations when applied to the processes that are not operated at steady-state. This is mainly due to the underlying assumption for the PCA and PLS based SPM methods that the process data are assumed independent and identically distributed (i.i.d.) samples drawn from a multivariate Gaussian distribution. When a process exhibits strong dynamics, nonlinearity or non-Gaussian distribution, to name a few, the performance of SPM methods may deteriorate significantly, depending on how well the normal process operation data can be approximated by a multivariate Gaussian distribution. To address these limitations, many SPM methods, such as Kernel PCA (KPCA), and independent component analysis (ICA), have been developed recently. However, as discussed in Section 2, these methods have their own challenges and only achieved limited success (He and Wang, 2017). On the other hand, a feature based method that we recently proposed, termed statistics pattern analysis (SPA), has demonstrated superior performance in different applications such as fault detection, fault diagnosis and soft sensor or virtual metrology for both batch and continuous processes (He and Wang, 2011; He and Wang, 2017;

Shah et al., 2017; Wang and He, 2010). Since then, many extensions and variants of SPA have been proposed by others (Deng et al., 2016; Deng and Tian, 2013; He and Xu, 2016; Ma et al., 2011; Ning et al., 2014; Song et al., 2015; Zhang et al., 2015). In the rest of the paper, we first briefly review the SPA framework in Section 2. Section 3 compares SPA with several representative methods in addressing process characteristics using a simulated example; Section 4 discusses how SPA could help address the challenges of smart manufacturing big data and Section 5 draws conclusions.

2. Statistics Pattern Analysis (SPA) Framework

Recently we proposed statistics pattern analysis (SPA) based on the idea of using various statistics to quantify process characteristics, and monitoring these statistics instead of process variables themselves to perform process monitoring (He and Wang, 2011; Wang and He, 2010). In other words, SPA models the variance-covariance structure of the process statistics, instead of the variance-covariance structure of the process variables used in PCA and PLS based methods. Figure 1 shows the schematic plot of how SPA can be applied for continuous and batch process monitoring.

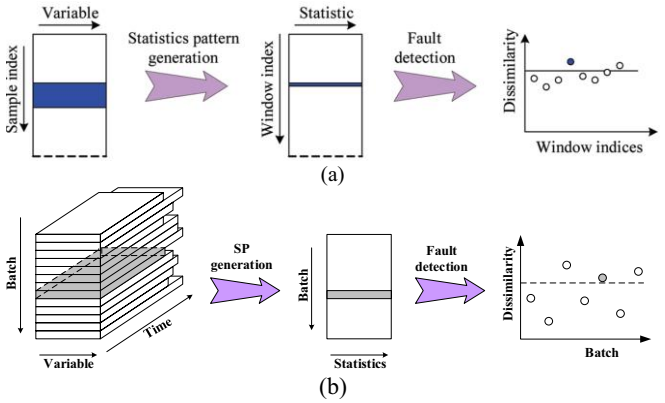

Fig. 1: SPA based fault detection for continuous (a) and batch (b) processes.

For continuous processes, statistics are computed using a window-based approach as shown in Figure 1 (a). The generated process variable statistics, also known as statistics patterns (SPs), are monitored for fault detection. For batch processes, SPs are computed for each batch as shown in Figure 1 (b); then the generated SPs are being monitored. Various simulated and real industrial case studies have demonstrated that SPA is a good platform for SPM (He and Wang, 2011; He and Wang, 2017; Wang and He, 2010). Different process statistics can be included in the SPA framework to capture the key process characteristics: such as those of each individual variable (such as mean, variance, and skewness), the interactions among different variables (such as correlation), as well as process dynamics (such as autocorrelation and cross-correlation). It is worth noting that SPA makes explicit use of higher order statistics (HOS) to measure the extent of nonlinearity and quantify the non-Gaussianity of the probability distribution of the process variables. In addition, process knowledge based landmark features (Wold et al., 2009); profile-driven features (Rendall et al., 2017); geometry based features (Wang et al., 2015) can be included in SPA as well. Therefore, the exact form or the number of statistics/features in SPA varies with applications.

3. SPA in Addressing Current Challenges in SPM

Several key characteristics, such as process dynamics, nonlinearity, and process data non-Gaussianity, are ubiquitous for manufacturing processes, and will become even more so for smart manufacturing. In this section we use a simple yet realistic example to evaluate how several representative methods address these challenges.

The simulated example is a stirred tank heater (Bequette, 1998) as shown in Figure 2, where the objective is to raise the temperature of the inlet stream to a desired value. Detailed descriptions and model assumptions can be found in (Bequette, 1998).

The material and energy balances yield the following two modelling equations:

$$\frac{dT}{dt} = \frac{F}{V}(T_i - T) + \frac{UA(T_j - T)}{V\rho c_p} \tag{1}$$

$$\frac{dT_j}{dt} = \frac{F_j}{V_j}\left(T_{ji} - T_j\right) + \frac{UA(T_j - T)}{V_j \rho_j c_{pj}} \tag{2}$$

where A is the heat transfer area, c_p heat capacity, F volumetric flowrate, ρ density, T temperature, t time, V volume, subscripts i, j, and ji for inlet, jacket, jacket inlet, respectively. To excite the system so that various characteristics such as nonlinearity, dynamics and non-Gaussianity are amplified, a sinusoidal disturbance is injected into :

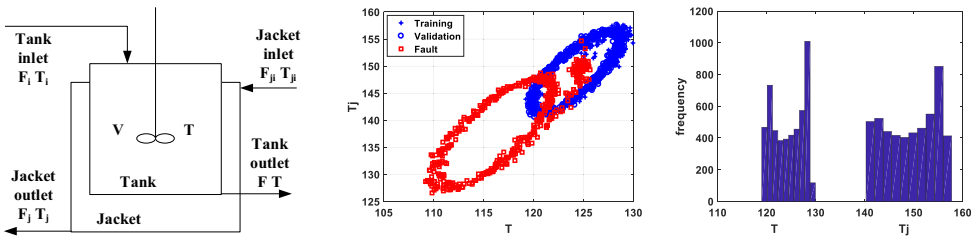
$$F_j = F_{js} + 0.5sin\left(\frac{t \cdot \pi}{10}\right) + n(0, 0.01) \tag{3}$$

where steady-state $F_{js} = 1.5$, and $n(0, 0.01)$ represents white noise with zero mean and standard deviation 0.01.

To illustrate whether the models, reflected as the scores (i.e., samples projected onto the models), can differentiate faulty behavior from normal operation, we also introduce a fault into the process where a leakage in jacket inlet stream is introduced at some point.

$$F_{jf} = F_j - 0.3 \tag{4}$$

The normal data are divided into training and validation subsets. The behaviors of normal and faulty operations are shown in Figure 2 (b) where the tank temperature T is plotted against the jacket temperature T_j. The histograms of T and T_j (Figure 2 (c)) show that the observations obtained from this nonlinear process are highly non-Gaussian.



(a) (b) (c)

Figure 2. (a) Jacketed stirred tank heater (Bequette, 1998); (b) Process behaviors under normal (blue pluses and circles) and faulty (red squares) operations; (c) Histograms of T and T_j.

It is worth noting that the disturbance and fault introduced are rather large for illustrative purposes. In addition, we only investigate the principal or dominant

components while ignoring residual or excluded components. The purpose is to study how each modelling approach would capture or transform certain process characteristics.

For process nonlinearity, kernel based methods, such as kernel PCA (KPCA) and its variants have been studied (Lee et al., 2004a). However, it has been reported that the performances of KPCA-based methods are greatly affected by the choice of kernel and parameters and often the resulted PCs (or mapped features) are still nonlinearly correlated (Wang et al., 2013). This is validated using the stirred tank heater example. Figure 3 (a) and (b) shows the normal and faulty data projected onto the first two PC's of KPCA using Gaussian and sigmoid kernels, respectively. For the same kernel but different parameters, the shapes could be significantly different too. It has been suggested that there is no proper way to guide the choice of kernel and determination of parameters other than cross-validation. Other nonlinear SPM methods such as neural networks and principal curves based methods are not investigated in this work.

To address process dynamics, time lag shifting methods, including dynamic PCA (DPCA) (Ku et al., 1995) and its variants were commonly used SPM methods. However, it has been reported that the resulted PCs are often still auto-correlated. This is also validated using the simulated example. As can be seen from Figure 3 (c), the PC's are still auto-correlated.

For process data non-Gaussianity, independent component analysis (ICA) (Lee et al., 2004b) has been adapted to address it and has gained some popularity in the SPM community. It has been argued that for such cases, the ICA mapped samples would conform to a Gaussian distribution. However, Figure 3 (d), which shows the first two IC's using the default nonlinearity setting of FastICA algorithm (Bingham and Hyvärinen, 2000), indicates that the non-Gaussianity of the process data was not removed or transformed.

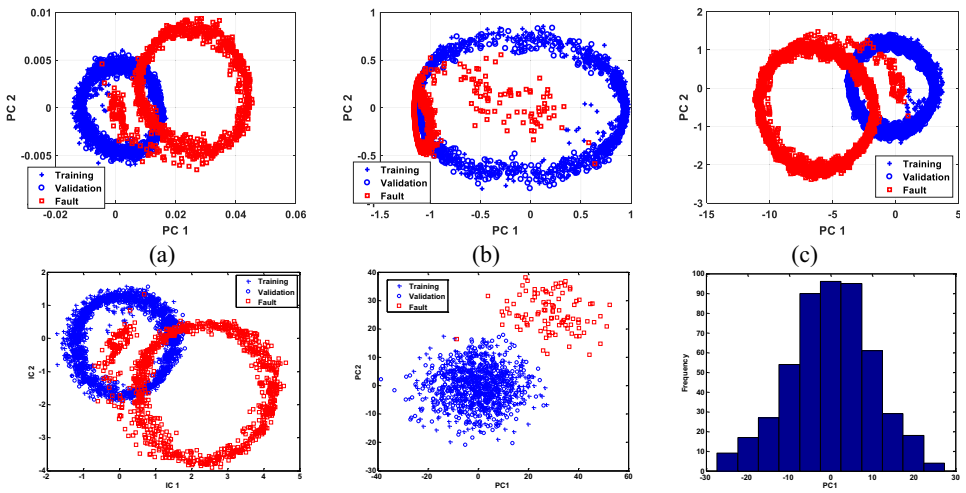


Figure 3. (a) KPCA – Gaussian kernel; (b) KPCA – sigmoid kernel; (c) DPCA; (d) ICA; (e) SPA; (f) Histogram of PC1 from SPA (normal data)

Next we apply SPA to the simulated case study. Window width was chosen to include about ten cycles of T and T_j. Statistics of mean, standard deviation, skewness, kurtosis,

auto- and cross-correlations with maximum lag of 20 are used. Figure 3 (e) shows the score plot of the statistics extracted from the data. It can be seen that the nonlinear dynamic data under normal operation has been transformed into a multivariate Gaussian distributed scores, which is also validated in the histogram of the first score of the statistics in Figure 3 (f). In other words, the SPA transformation has completely transformed the dynamic, nonlinear, and non-Gaussian original process measurements into independent Gaussian distributed statistics. In addition, the cluster of faulty samples are clearly separately from the normal samples.

This simulated example demonstrates that SPA has some advantages in dealing with these common process characteristics, which have contributed to its good performances in fault detection for both batch and continuous processes. Other process characteristics such as multimode, noises, and outliers are not studied in this work.

4. SPA in Addressing Smart Manufacturing Big Data

Smart manufacturing (SM) and big data from SM have drawn increased attention in the SPM community in the past few years (Qin, 2014; Severson et al., 2016). As detailed in (He and Wang, 2017), SPA has many advantages in addressing the 4V challenges of big data. In reducing the number of observations, SPA has been used to reduce an entire batch (or batch step) into batch (or batch step) features. For continuous processes, it has been shown a window-based SPA approach is efficient in significantly reducing number of observations. In reducing number of variables, SPA has been used to extract features from optical emission spectroscopy (OES) and UV-Vis spectra, which effectively reduce number of variables (equal to the number of wavelengths at which the intensities were measured) to much smaller number of features. SPA can help address big data variety as statistics extracted from different data sources can be conveniently integrated. Because SPA can significantly reduce problem size in both time/sample wise and variable wise, and it does not require data pre-processing, SPA has the potential to be used for monitoring real-time streaming data. SPA can also help address big data veracity as data uncertainty will have much less impact on extracted statistics (*e.g.*, mean) than variable themselves.

5. Conclusions

In conclusion, previous work has demonstrated the potential of SPA for SPM in the area of fault detection. But its capability in capturing and transforming process dynamics, nonlinearity, and process data non-Gaussianity and its potential in fault diagnosis and soft sensor or virtual metrology have not been well studied. In this work, we demonstrate that SPA can transform dynamic, nonlinear process data that exhibit strong non-Gaussianity into multivariate Gaussian statistics, which capture the key process characteristics and can be conveniently modelled by multivariate statistical methods such as PCA for various applications such as fault detection and diagnosis, and soft sensor or virtual metrology. Because SPA-based fault diagnosis method breaks down the contribution of a fault to different variable statistics, it provides extra information in addition to identifying the major fault-contributing variable(s), such as whether the fault is due to a change in the variable mean or variance. It is worth noting that SPA is not without its limitations, such as the amount of data required to estimate various statistics, tradeoff between robustness and sensitivity, which will be studied more systematically in the future. In addition, under what conditions that SPA would outperform or underperform other methods needs further investigation.

Abstract

Rapid detection and identification of process faults in industrial applications is crucial to sustain a safe and profitable operation. Today, the advances in sensor technologies have facilitated large amounts of chemical process data collection in real time which subsequently broadened the use of data-driven process monitoring techniques via machine learning and multivariate statistical analysis. One of the well-known machine learning techniques is Support Vector Machines (SVM) which allows the use of high dimensional feature sets for learning problems such as classification and regression. In this paper, we present the application of a novel nonlinear (kernel-dependent) SVM-based feature selection algorithm to process monitoring and fault detection of continuous processes. The developed methodology is derived from sensitivity analysis of the dual SVM objective and utilizes existing and novel greedy algorithms to rank features that also guides fault diagnosis. Specifically, we train fault-specific two-class SVM models to detect faulty operations, while using the feature selection algorithm to improve the accuracy of the fault detection models and perform fault diagnosis. We present results for the Tennessee Eastman process as a case study and compare our approach to existing approaches for fault detection, diagnosis and identification.

Keywords: Fault Detection and Identification, Process Monitoring, Data-driven Modeling, Feature Selection, Support Vector Machines.

1. Introduction

Maintaining a safe operation while minimizing the losses in productivity is one of the major goals in chemical processing. Timely detection, diagnosis and identification of faults occurring during the operation is critical and necessary, and this is continuously encouraging researchers to develop novel process monitoring techniques. Today, with the advances in automation and sensor technologies as well as novel smart manufacturing frameworks, real time process data acquisition has become effortless and created an immense opportunity for manufacturing and process industries by enabling

data-driven real time decision making through it. A fault is defined as an abnormal process behaviour where controllers lack the capability of reversing it. Faults can occur due to mechanical reasons such as equipment failure and/or wear as a result of equipment aging or process-based reasons stemming from severe process disturbances (Chiang et al., 2001). Once a fault is detected during an operation, revealing the root-cause by identifying the key process variables is of utmost importance for rapid counteraction to avoid abnormal event progression (Venkatasubramanian et al., 2003). The most prevalent data-driven process monitoring techniques include Principal Component Analysis (PCA), Dynamic PCA (DPCA), Partial Least Squares (PLS), Independent Component Analysis (ICA), and Fischer Discriminant Analysis (FDA) as dimensionality reduction step followed by Q and T^2 statistics, contribution plots, and discriminant analysis (Qin, 2012). The aim of dimensionality reduction is to ensure robustness of the analysis. Dimensionality reduction methods are classified into (a) feature extraction, and (b) feature selection. The dimensionality reduction methods adopted within the listed techniques are based on feature extraction, which project input process data onto another space and alter the original representation of input data, thus may cause loss of information. On the other hand, feature selection is the process of selecting the most informative and relevant original features (e.g. process variables) characterizing the system. Therefore, there is a prominent need for novel data-driven process monitoring methods incorporating feature selection techniques for dimensionality reduction. In this work, we modify a well-known, powerful machine learning algorithm formulation, Support Vector Machines (SVM) (Cortes and Vapnik, 1995), for simultaneous modelling and feature selection. Then, we present the application of the nonlinear (Kernel-dependent) SVM-based feature selection algorithm to process monitoring of continuous processes. Previous studies have used SVM for fault detection in chemical processes (Mahadevan and Shah, 2009; Yin et al., 2014; Xiao et al., 2016). Fault detection is achieved through two-class SVM models, where the feature selection algorithm further improves the model accuracy and also reveals diagnosis of the detected fault. We test the performance of the proposed data-driven framework through the 21 faults introduced in the Tennessee Eastman process data and provide comparisons to existing approaches. The methodology can be implemented as an online decision support tool for continuous process monitoring purposes.

2. Nonlinear Support Vector Machine-based Feature Selection Algorithm

Here, we define a supervised learning problem with l training instances, where $x_i \epsilon R^n$. Indices $i, j = 1,2, \dots, l$ correspond to instances, whereas indices $k, k' = 1,2, \dots, n$ correspond to input data features. Accordingly, the input data has become $x_i = (x_{i1}, x_{i2}, \dots, x_{ik}, \dots, x_{in})^{\mathrm{T}}$. From process monitoring perspective, instances represent distinct continuous operations while features are the collected process measurements from distinct variables. We formulate the fault detection problem in a classification setting with C −parameterized SVM (C −SVM) with hinge loss, l_2 −norm penalty, and linear Kernel as follows:

$$\begin{aligned} & \min_{w,b,\xi} \frac{1}{2}\|w\|_2^2 + C\sum_{i=1}^{l}\xi_i \\ \text{s.t.} \quad & y_i(w.x_i + b) \geq 1 - \xi_i \qquad i = 1,2, \dots, l \\ & \xi_i \geq 0 \qquad\qquad\qquad\quad i = 1,2, \dots, l \end{aligned} \tag{1}$$

where $y_i \in \{-1,1\}$ denotes the class label of instance i. Eq.(1) is a convex nonlinear problem satisfying a first-order qualification, hence strong duality holds. When Eq.(1) is solved to global optimality, resulted optimal solution (w^*, b^*, ξ^*) is then used to determine the linear decision function $f(x) = w^*.x + b^*$, which yields the sign, thus class, of a new instance x.

One of the major advantages of exploiting Support Vector Machines in modelling is to be able to use Kernel functions, $K(x_i, x_j)$. These functions implicitly map the input feature space, where data is nonlinearly separable, onto a different, possibly higher feature space, where the data become linearly separable. Since most of the chemical processes are nonlinear in nature, we adopt nonlinear (Kernel-dependent) C-SVM formulation, where Kernel functions are introduced in the Lagrange dual formulation of Eq.(1). Next, we introduce binary variables $z \in \{0,1\}^n$ in Eq.(2), which control elimination or selection of feature k, and aim to minimize the number of selected features while maximizing model accuracy via traditional C −SVM formulation:

$$\min_{z} \max_{\alpha} \sum_{i=1}^{l} \alpha_i - \frac{1}{2} \sum_{i=1}^{l} \sum_{j=1}^{l} \alpha_i \alpha_j y_i y_j K(x_i \ z, x_j \ z)$$

$$\text{s.t.} \quad \sum_{i=1}^{l} \alpha_i y_i = 0 \tag{2}$$

$$\alpha_i \epsilon [0, C] \qquad i = 1,2, \dots, l$$

$$\sum_{k} z_k = m$$

$$z_k \in \{0,1\} \qquad k = 1,2, \dots, n$$

where α_i are dual variables. In Eq.(2), is the Hadamard product operator for componentwise multiplication, and m is the number of optimal subset of features, where the aim is to attain highest C −SVM model accuracy with minimum number of input features. Since Eq.(2) is a challenging and impractical problem to solve to global optimality, we propose an algorithmic solution procedure, which utilizes the Lagrangian sensitivity of the objective function value of Eq.(2) with respect to z_k at $(\alpha^*; z)$, where z_k is treated as a fixed parameter. The procedure is iterative where in each step, the features are eliminated individually according to the following criterion:

$$crit_k = -\frac{1}{2} \sum_{i=1}^{l} \sum_{j=1}^{l} \alpha_i^* \alpha_j^* y_i y_j \frac{\partial K(x_i \ z, x_j \ z)}{\partial z_k}\bigg|_{z=1}$$

$$k_{worst} = arg_k \max crit_k \tag{3}$$

Eq.(3) delineates the nonlinear SVM-based feature selection algorithm adopted in this study. In particular, the algorithm is equivalent to well-known recursive feature elimination (RFE)-SVM classification algorithm when performing a linear classification that is using a linear Kernel. The presented algorithm (Kieslich et al., 2016) has been implemented in C++/Python environment using LibSVM library (Chang and Lin, 2011), and has been successfully utilized in our previous studies in bioinformatics.

3. Tennessee Eastman Process

The Tennessee Eastman process simulation, an extensively used benchmark study to evaluate and further develop process monitoring algorithms, was designed by the Eastman Chemical Company (Downs and Vogel, 1993). It is based on a real industrial process, in which the components, kinetics, and operating conditions have been modified for proprietary reasons (Chiang et al., 2001). The process includes five primary units: a reactor, condenser, compressor, separator, and a stripper. It describes the production of chemicals G and H from feedstocks A, C, D and E with byproduct F and inert compound B. The simulated process data used in this study is adopted from Chiang and Braatz, 2001, where the process contains 41 measured and 11 manipulated variables. The variables are sampled every 3 minutes and the dataset includes measurement samples from normal and 21 distinct faulty operations. For further information on the process and simulation, the interested reader can refer to Downs and Vogel, 1993 and Chiang et al., 2001.

4. Proposed Framework

In this study, we are building 21 fault-specific C −SVM binary classifiers for 21 different faults introduced in the process data. Thus, for each of the 21 model building, we combine data from normal and faulty operation from each of the 21 faults. The initial step in data-driven modelling is normalization of the input data. Normalization is performed on each of the 21 faulty-normal process data by subtracting the mean of measurements across the operations from each measurement and then dividing into the standard deviation of them.

4.1. Offline Phase Model Building

The initial step in the offline phase is to create balanced train and test sets. Imbalanced data sets may significantly increase risk of overfitting problem. Therefore we create train and test sets from each 21 datasets with 100 runs of 5-fold cross-validation. Next, we build binary classifier models iteratively for each feature subset. In each iteration we (i) tune C −SVM parameters using train and test data sets with the active set of features (whole feature set in the first iteration), (ii) train C −SVM classifiers with Gaussian Radial Basis Function, where the class probabilities are smoothened via taking median of probabilities with a window size of 3, (iii) calculate Lagrangian sensitivity of dual C −SVM objective function with respect to the parameter z_k to obtain a rank list of features, (iv) eliminate the most redundant, "worst" feature satisfying Eq.(3) from data. This procedure is repeated until we are left with 1 feature in the train and test sets. The result of this framework yields 1092 C −SVM classifiers, which includes 21 fault-specific C −SVM classifiers for each of 52 feature subsets. Particularly, in the first step, we tune C −SVM hyperparameters C and γ. Tuning is done via grid search for all combinations between 2^{-10} and 2^{10}. Hyperparameter combination yielding the highest average testing accuracy and recall is chosen in each iteration of the framework above. The final stage in the offline phase is selection of fault-specific end-models for fault detection. Among all feature subsets, the C −SVM classifier yielding the highest fault detection rate and accuracy is chosen to be the fault-specific end-model.

4.2. Online Phase Model Building

21 fault-specific end models that are built in offline phase are implemented in industrial setting to monitor the incoming online process data. When online process data is fed,

models generate a binary answer for detection of each fault. If a fault is detected, alarm rises and the optimal set of features of the corresponding end-model yield the root-cause analysis of the detected fault instantaneously.

5. Results

We present the results of the proposed data-driven process monitoring framework on the Tennessee Eastman process below (Table 1), where we have adopted a five consecutive fault alarm policy to report a fault. The performance of the end-models is evaluated via (i) fault detection rate, (ii) accuracy, and (iii) latency.

Table 1. Performance of the Fault Specific End Models.

Fault	Optimal Feature Subset Size	Fault Detection Rate	Accuracy	Latency (min)
1	2	99.88	99.90	6
2	8	98.13	98.44	48
3	4	100.00	83.33	3
4	1	100.00	100.00	3
5	25	100.00	100.00	3
6	1	100.00	100.00	3
7	1	100.00	100.00	3
8	6	99.38	96.88	3
9	6	99.50	83.33	3
10	9	98.25	83.85	3
11	29	96.63	86.46	3
12	9	100.00	96.15	3
13	2	95.00	89.48	3
14	3	100.00	100.00	3
15	7	98.25	82.81	3
16	26	100.00	87.92	3
17	7	97.63	84.69	3
18	24	90.38	91.56	183
19	3	100.00	83.33	3
20	4	100.00	83.75	3
21	1	100.00	99.90	3

Table 2 compares the performance of this study to the other existing data-driven process monitoring techniques (Mahadevan and Shah, 2009; Yin et al., 2014; Xiao et al., 2016) in terms of fault detection rate. This comparison demonstrates the power of the proposed data-driven process monitoring framework. Additionally, the average latency among the reported faults has been provided as 306.19, 145.58, 263.12, 151.00, and 98.50 min for PCA-T^2, PCA-Q, DPCA-T^2, DPCA-Q, and 1-class SVM respectively in Mahadevan and Shah, 2009; whereas it is significantly lower for the proposed framework (15.67 min for the Table 2 reported faults, and 13.86 min among all 21 faults).

6. Conclusions

In this study, we have presented a nonlinear SVM-based feature selection algorithm procedure and implemented it for data-driven process monitoring of continuous processes. The proposed framework establishes a promising decision support tool for

online fault detection and identification. This research was funded by U.S. National Institute of Health (NIH) grant P42 ES027704.

Table 2. Comparison through Fault Detection Rate. Best results of Xiao et al., 2016 is adopted.

Abstract

In semiconductor manufacturing, virtual metrology (VM), a.k.a. soft sensor, is the prediction of wafer properties using process variables and other information available for the process and/or the product (*i.e.*, machine data) without physically conducting property measurement. VM has been utilized in semiconductor manufacturing for process monitoring and control. In this work, we discuss the shortcomings of some of the commonly used VM methods and propose a feature-based VM framework. An industrial case study is used to demonstrate the effectiveness of the proposed method.

Keywords: semiconductor manufacturing, virtual metrology, process monitoring, statistics pattern analysis.

1. Introduction

In semiconductor manufacturing, a wafer undergoes hundreds of different steps to yield the final product. After a processing step, typically a few (1–3) wafers within a lot are measured at the metrology station, and this sampled metrology data represent the whole lot. However, this methodology using the traditional off-line metrology tools (*e.g.*, ellipsometer, atomic force microscope (AFM)) becomes insufficient when the device dimensions continue to decrease and the lot-to-lot process control is being increasingly replaced with the wafer-to-wafer (W2W) control. W2W control requires metrology measurements of every wafer and it has been proposed to use the integrated metrology (IM) sensors at the processing tool to provide such measurements (Lensing and Stirton, 2006). However, issues such as impact on throughput, increase in cycle time, and higher cost make IM less attractive in many process environments. On the other hand, virtual metrology (VM) technology has been suggested as an alternative to 100% wafer measurement to support W2W control (Gill et al., 2010; He et al., 2012; Hung et al., 2007). Because machine data are usually sampled much more frequently compared to metrology data, and machine data are instantly available compared to delays often associated with metrology tools, an accurate VM can significantly improve process monitoring and control performance by providing real-time predicted metrology data.

One of the most important factors that need to be considered when implementing any VM for industrial applications is the level of data pre-processing required, which affects the deployment and maintenance of the VM. Generally speaking, the more automated the data pre-processing step is, the more sustainable the method is likely to be in a production environment. To address this challenge, in this work, we propose a feature-based VM framework, which is based on the statistics pattern analysis (SPA) process modeling and monitoring framework we proposed previously (He and Wang, 2011; Wang and He, 2010). The most significant difference between the proposed VM approach and other existing approaches is that instead of extracting correlations between

process variables and metrology measurements, the proposed method extracts the correlations between process features and metrology measurements to build VM models. By doing so, the proposed method can not only eliminate most data pre-processing steps, but also provide superior prediction performance. In addition, the proposed feature-based VM framework is advantageous in handling big data challenges. The rest of the paper is organized as follows: Section 2 provides a brief review on existing VM approaches; Section 3 presents the feature-based VM framework; Section 4 uses an industrial case study to demonstrate the performance of the proposed VM method, which is compared with several other VM approaches; finally Section 5 presents the conclusion and discussion.

2. A Brief Review of Existing VM Approaches

VM is not unique to the semiconductor industry, which essentially serves the same purposes as the soft sensor, a term used in the process industry. VM or soft sensor makes use of secondary variables that are measured online frequently to predict the product quality variables that are not measured online or not measured frequently, which could be modeled using either model-based approaches or data-driven approaches. For industrial processes, data driven approaches are usually easier to develop and to implement online, therefore they are potentially more attractive. Due to the limited space, only some of the data-driven VM approaches applied to semiconductor manufacturing processes are reviewed in this work.

Among data-drive approaches, the commonly used ones are time series analysis (TSA), Kalman filter (KF), multiple linear regression (MLR), principal component regression (PCR), and partial least squares (PLS).

2.1. Time series analysis (TSA)

Because the metrology data are generally sequential in time, auto-regressive-integrated-moving average (ARIMA) models can be identified, e.g., following the procedure proposed by Box and Jenkins. Once the model structure is determined and parameters are estimated using the historical metrology data, the model can be used to predict the future values of the metrology data. It is worth noting that TSA only utilizes the metrology data for model building and prediction, while the process or machine data are completely ignored. This could be the reason for the poor prediction performance of TSA in the industrial case study presented in Section 4.

2.2. Kalman filter (KF)

Kalman filter was proposed in the early 1960s and has been extensively used for the state estimation of dynamic systems. It has also been formulated for VM (Gill et al., 2010):

$$\boldsymbol{K} = \boldsymbol{P}_{old}\boldsymbol{C}^T(\boldsymbol{C}\boldsymbol{P}_{old}\boldsymbol{C}^T + \boldsymbol{R})^{-1} \quad (1)$$

$$\boldsymbol{x}_{new} = \boldsymbol{x}_{old} + \boldsymbol{K}(y - \boldsymbol{C}\boldsymbol{x}_{old}) \quad (2)$$

$$\boldsymbol{P}_{new} = \boldsymbol{P}_{old} - \boldsymbol{K}\boldsymbol{C}\boldsymbol{P}_{old} \quad (3)$$

$$y_{est} = \boldsymbol{C}\boldsymbol{x}_{new} \quad (4)$$

where $\boldsymbol{K}$ is the Kalman gain, $\boldsymbol{P}$ the state error covariance matrix, $\boldsymbol{R}$ the measurement noise covariance matrix, $\boldsymbol{x}$ the independent or process variables, y the dependent or metrology variable.

2.3. Multiple linear regression (MLR)

Multiple linear regression (MLR) aims to model the relationship between multiple explanatory or independent variables from machine data and a response or dependent variable of metrology data by fitting a linear equation to the historical data, which takes the following form:

$$y = \sum_{i=1}^{p} \beta_i x_i + v \quad (5)$$

where y represents the metrology measurement, $x_i (i = 1,2, \cdots p)$ the process variables, v the intercept and β_i the coefficients. The coefficients are estimated by minimizing the sum of squares of the differences between the actual and modeled metrology measurements, and the obtained model is used to predict metrology measurement when a new set of process variables are available. The potential issue with MLR for VM is that, more often than not, the process variables are (highly) correlated and the collinearities among x_i can cause severe problems for MLR – the estimated coefficients $\hat{\beta}_i$ can be very unstable, which makes predictions by the regression model unstable or poor.

2.4. Principal component regression (PCR)

Principal component regression (PCR) is a regression analysis technique based on principal component analysis (PCA). Due to limited space, the technical details of PCR and PCA are not reviewed here. In short, instead of regressing the dependent variable (i.e., the metrology measurements) on the explanatory or independent variables (i.e., the process variables) directly as in MLR, the principal components (PCs) of the explanatory variables are used as regressors in PCR. Compared to MLR, PCR has the advantage of addressing the multicollinearity problem. In addition, PCR handles noisy process variables better as usually only a subset of all the PCs are used to build the model. However, the PCs are derived without any reference to the dependent variables. In other words, PC's explain the most variation in independent variables, which may not be (highly) related to the variation in the dependent or metrology variables. Due to this reason, the performance of PCR for VM is not guaranteed.

2.5. Partial least squares (PLS)

Partial least squares (PLS) has all the benefits of PCR while also taking the variation of dependent variables into account. Specifically, PLS models the inner relation that correlates the scores of independent variables with the scores of dependent variables. Therefore, PLS usually has better prediction performance than PCR, which explains why PLS and its variants are the most commonly used VM methods in industrial applications.

Other methods, such as artificial neural networks (ANNs) and support vector machine (SVM) have also been used for VM, which are not reviewed here.

It is worth noting that all existing VM methods discussed above make predictions by extracting linear or nonlinear correlations between process variables and metrology measurements. One drawback of utilizing process variables is that because of the characteristics associated with batch processes, such as unequal batch and/or step length, and unsynchronized or misaligned batch trajectories, various data preprocessing steps are usually required for the existing VM methods. These preprocessing steps, including trajectory alignment/warping and data unfolding, are often performed off-line and could be difficult to automate. To address this limitation, in the following section, we present the proposed feature-based VM framework, where batch statistics and other features are used as the regressors to predict metrology measurements, which eliminates the data preprocessing step. In addition,

we show that the feature-based VM framework provides superior prediction performance compared to the traditional VM methods in Section 4.

3. Feature-based Virtual Metrology (FVM)

The feature-based VM (FVM) framework is developed based on statistics pattern analysis (SPA), a process monitoring framework we proposed previously. In SPA, various statistics are used to quantify process characteristics, and monitoring these statistics instead of process variables themselves to perform process monitoring. SPA has been applied for fault detection, fault diagnosis and virtual metrology. In this work, we extend the features to not just statistics, but also other features such as integrals, derivative, etc. In the FVM framework, we hypothesize that the batch behavior can be better characterized by the *process features* than by the *process variables*. Therefore, in the FVM framework, process features instead of process variables are used as input variables to build the VM model. Figure 1 provides a schematic diagram of the FVM framework which consists of two steps. In the first step, various features are extracted from batch trajectories such as various statistics that characterize individual variables (such as the mean, variance, autocorrelation), the interactions among different variables (such as the cross-correlations), as well as other features that characterize the process (such as batch and step durations, the time integrals of power input). In the second step, a regression method, such as PLS, is used to extract the relationships between the features and the metrology measurements. As can be seen from Figure 1, unequal batch/step length and unsynchronized batch trajectories will have no effect on the FVM framework.

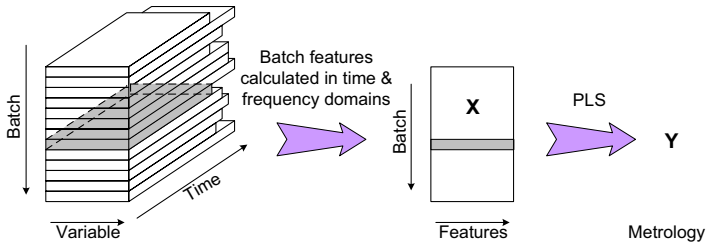

Figure 1. The schematic diagram of the feature-based virtual metrology

4. Application to an Industrial Case Study

In this work, a dataset collected from a plasma etch system at one of Texas Instruments' wafer fabs (Gill et al., 2010) is used to compare the proposed feature-based VM and other VM methods. The dataset contains the recorded values of 18 Optical Emission Spectroscopy (OES) signals collected every 0.1 second for 1121 wafers. The dataset also contains the metrology measurement values of the sheet resistance, which is one of the most important electrical- test parameters used in the semiconductor manufacturing industry to assess the electrical quality of a product. The goal of VM is to predict the end-of-batch sheet resistance using the OES signals.

One independent variable (*i.e.*, one OES signal) of several wafers is shown in Figure 2, which shows the typical characteristics of a semiconductor machine data: unequal run times or process durations; large variations between wafers and unsynchronized trajectories. To apply traditional VM methods such as PLS on this type of data, several

data pre-processing steps have to be taken, including trajectory alignment or time warping to make trajectories equal length, and trajectory unfolding to flatten the 3-D structure into 2-D matrix.

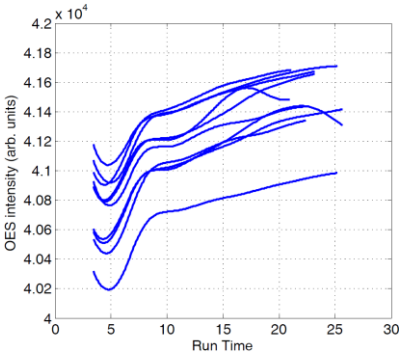

Figure 2. A sample OES signal of several wafers

4.1. Settings and performance measures for the VM methods

In this work, we compare the proposed feature-based VM (FVM) with the following VM modeling approaches: time series analysis (TSA); Kalman filter (KF); multiple linear regression (MLR); principal component regression (PCR); partial least squares (PLS) and recursive PLS (RPLS).

All methods were optimized using cross-validation. For feature-based VM, time integral of the OES signals, along with univariate statistics including mean, variance, skewness and kurtosis were included as the features. PLS and RPLS were used as the regression methods for static and recursive FVM methods. The prediction performance of the VM methods are quantified by mean absolute percentage error ($MAPE$) and the coefficient of determination (R^2) as defined below.

$$MAPE = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{y_i-\hat{y}_i}{y_i}\right| \times 100\% \quad (6)$$

where n is the total number of samples, y_i the actual metrology value of the output, and $\hat{y}_i$ the VM predicted value of the output.

$$R^2 = 1 - \frac{SS_{err}}{SS_{tot}} \quad (7)$$

where $SS_{err} = \sum_{i=1}^{n}(y_i - \hat{y}_i)^2$, $SS_{tot} = \sum_{i=1}^{n}(y_i - \bar{y})^2$, and $\bar{y} = \frac{1}{n}\sum_{i=1}^{n} y_i$.

4.2. Performance comparison of static VM methods

In this subsection, the static FVM is applied to the dataset discussed previously to predict the sheet resistance using the OES data. The performance is compared with other VM methods. For all VM methods, 70% of the data (784 wafers) were utilized for model building and the rest 30% of the data (337 wafers) were used for testing. The VM models were not updated even when new data becomes available. Table 1 compares the *MAPE* and R^2 of the static FVM to those of TSA, MLR, PCR, and PLS. It can be seen that FVM outperforms all other methods in terms of both *MAPE* and R^2. Compared to other methods, the *MAPE* of FVM is reduced by 24.7%~58.5%, while the R^2 of feature-based VM is improved by 20.5%~67.1%.

Table 1. Comparison of different static VM methods

Model	MAPE	%change	R^2	%change
TSA	8.46	53.8%	0.40	-45.2%
MLR	8.72	58.5%	0.24	-67.1%
PCR	7.19	30.7%	0.55	-24.7%
PLS	6.86	24.7%	0.58	-20.5%
FVM	5.50	0%	0.73	0%

4.3. Performance comparison of recursive VM methods

Here the recursive FVM is applied to the dataset. The performance is compared with other recursive VM methods. For recursive VM, the initial VM model is built based on the training data of 784 wafers, and is updated when new data becomes available. It can be seen that the recursive FVM outperforms other recursive VM methods in terms of both *MAPE* and R^2.

Table 2. Comparison of different recursive VM methods

Model	MAPE	%change	R^2	%change
RPLS	5.67	13.4%	0.70	-9.1%
KF	5.07	1.4%	0.72	-6.5%
FVM	5.00	0%	0.77	0%

5. Conclusions

A feature-based VM (FVM) framework is proposed to address the challenges presented in semiconductor VM applications, such as unequal batch/step duration and/or unsynchronized trajectories; and large number of variables caused by data unfolding. Because FVM does not require any data preprocessing steps, it is uniquely suited for automatic online applications. The performance of FVM is compared with several commonly used VM algorithms using an industrial data set. Both static and recursive versions of FVM outperforms those of commonly used static and recursive VM methods, respectively.

Abstract

Epilepsy is a group of neurological disorders which is caused by excessive neuronal activities in cerebrum and characterized by recurrent seizures. A quarter of patients have intractable epilepsy and do not become seizure-free with medication. We are developing an implantable and wearable focal brain cooling system, which enables the patients to lead ordinary daily life. The system cools the epileptic focus, where the excessive neuronal activities begin, by delivering cold saline to a cranially implanted cooling device. In this research, we developed a whole system model through the first principles and animal experiments. The results of system design have shown that a cooling device with more complex channel structure achieves higher temperature uniformity in the brain with lower flow rate of saline. The optimal structure was derived by taking account of the trade-off between pressure drop and temperature uniformity. In addition, the results have demonstrated that the cooling duration is less than 10 minutes for the average temperature 2 mm below the cooling device (inside the brain) to reach 25 °C; it is short enough to cool the brain after seizure is predicted by existing electroencephalogram (EEG)-based algorithms. Moreover, the frequency of battery charging would be once in several days for most patients.

Keywords: epilepsy, focal brain cooling, computational fluid dynamics, Pennes bioheat equation, medical systems engineering

1. Introduction

Epilepsy is a chronic disorder, the hallmark of which is recurrent, unprovoked seizures. There are many different types of seizures, e.g. convulsion, consciousness disturbance, and unusual feeling. The seizures may increase the risk of injury and affect the social life of the patients. The epidemiological studies have reported that the epileptic patients consist of approximately 1% of the population, and that one-quarter of them do not become seizure-free by the existing treatments. Anti-epileptic drug therapy is the first option for most patients, and it provides seizure freedom for two-thirds of them. The remaining one-third is usually treated by surgery. The only surgical option for seizure freedom is the resection of the epileptic focus, where the excessive neuronal activity

begins. The resection cannot be applied to the patients whose epileptic foci are identified in cerebral hemispheres, difficult to localize precisely, or cannot be resected without irreversible brain dysfunction. These patients are treated by other surgical options such as callosotomy, vagus nerve stimulation (VNS), and responsive neurostimulation. They provide palliative treatments and rarely result in seizure freedom. Thus, a new effective treatment of epilepsy needs to be developed.

The potential treatments include focal brain cooling, which cools the epileptic focus. The stimulation-evoked seizures during intraoperative brain mapping were suppressed within 5-10 seconds by pouring the cold Ringer's lactate solution over the surface of the stimulated cortex (Sartorius and Berger, 1998). In addition, abnormality in the interictal electroencephalogram (EEG) was suppressed by applying the cold saline onto the brain surface near the epileptic focus (Karkar et al., 2002). The suppression effect of the focal brain cooling would result from the cooling of layers II and III in gray matter (Hiraishi et al., 2013). The target temperature in this region would be 25-30 °C (Imoto et al., 2006). In the experiments with rats, the penicillin G solution or the cobalt powder was applied on the brain surface and then a Peltier device was placed on the area of application. The Peltier device in some rats was activated and that in the other rats was not. As a result, the rats without the activation of the Peltier device had frequent seizures, while the rats whose brain surface was cooled to 20 or 15 °C had less frequent seizures, and the rats whose brain surface was 10 °C had no seizures (Fujii et al., 2012).

The aim of our project is the world's first clinical application of an implantable and wearable focal brain cooling system, with which the patients can lead ordinary daily life. The target patients are those who have their epileptic focus in their gyrus, because the surgical treatment of neocortical epilepsy is difficult (Rothman et al, 2005) and the gyrus is easier to cool by pressing the cooling device on the brain surface. The clinical application is preceded by the animal experiments and the system design. The present research aims to design the focal brain cooling system by using newly developed models: a whole system model and a pressure drop model.

2. Focal brain cooling

The use of a Peltier device is a potential way for the focal brain cooling. There is a safety risk in touching the Peltier device onto the brain, because it requires large electrical current and is not made of biocompatible materials. Figure 1 shows our focal brain cooling system. A patient wears a jacket with two pockets on his/her chest. One pocket contains the Peltier device in contact with a tank of saline. The tank is connected to a titanium cooling device implanted in the skull. The location of the implantation is just above the epileptic focus. The cooling device measures 30 x 30 x 7 mm, and the thickness of the top and bottom covers is 1 mm, and that of the middle layer is 5 mm. The saline circulates throughout the system; it is cooled in the tank by the Peltier device and pressurized by a pump attached on the chest. The Peltier device and the pump are powered by a mobile battery attached on the other side of the chest.

For determining when to activate and deactivate the system, a seizure prediction algorithm will be constructed in the future. The algorithm will use EEG, brain temperature, intracranial pressure, and oxygen saturation and concentration of oxyhemoglobin in cerebral blood flow. These indices are measured by sensors implanted in the skull (Yamakawa et al., 2014). Epileptic seizures could be predicted 90 minutes prior to their onset with an existing EEG-based algorithm (Iasemidis, 2005).

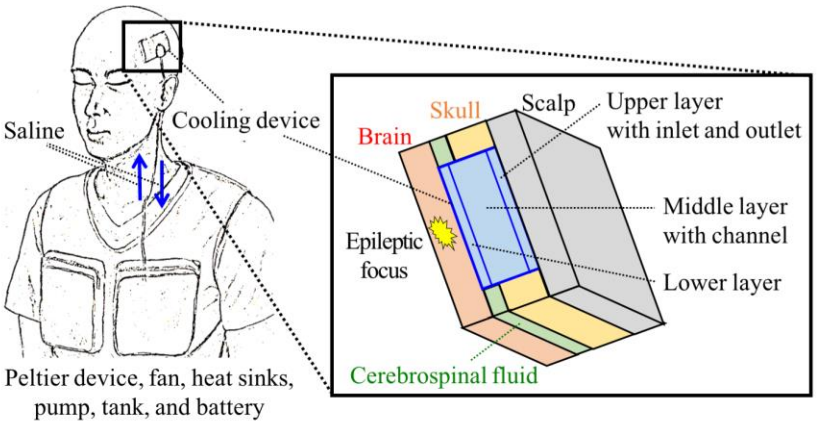

Figure 1. Focal brain cooling system.

3. Model of focal brain cooling system

The developed model consists of a whole system model and a pressure drop model. Figure 2 shows the hemispheric head model, which is the main part of the whole system model. It consists of a titanium cooling device, saline, and biological tissue. The biological tissue is further divided into soft tissue, skull, cerebrospinal fluid (CSF), and brain (Nelson and Nunneley, 1998). The channel structures in the middle layer of the cooling device are shown in Table 1. The tubes for inflow and outflow of the saline are implanted under the layer of the soft tissue.

The temperature of the titanium device was calculated by the heat conduction equation. The velocity, pressure, and temperature of saline were calculated by regarding flow as laminar flow. In addition, the temperature of biological tissue was calculated by the modified Pennes bioheat equation, which was based on the original bioheat equation proposed by Pennes (1948). The original equation describes the energy conservation, assuming that the heat convection rate by blood flow is proportional to the difference between the tissue temperature and the body core temperature. We modified the original equation in two ways. First, the metabolic heat production was neglected because its rate is much smaller than the heat convection rate by the blood flow (Orr and Eberhart, 1998). Second, the blood perfusion rate was set at 0 in the CSF, the skull, and the soft tissue; the blood perfusion rate in the brain was determined by an animal experiment so that the experimentally obtained temperature distribution would fit the theoretically obtained one.

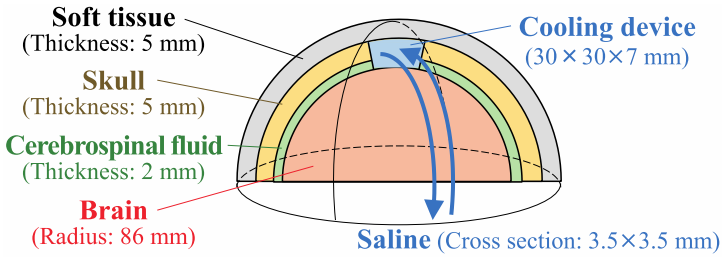

Figure 2. Geometrical representation of head model.

Since the whole system model imposes heavy computational burden, a simpler model called the pressure drop model was constructed. This model defines the relationship between the flow rate of the saline and the pressure drop for the circulation of saline; the tube was approximated to be cylindrical and 2 m in length. Computational fluid dynamics (CFD) simulations were conducted with COMSOL Multiphysics 5.1.

4. Comparison of channel structures

An optimization problem was formulated for finding the optimal channel structure that minimizes the pressure drop for the circulation of saline under the following constraints; 1) the average temperature 2 mm below the cooling device is 25.0 °C, and 2) the difference between the maximum and the minimum temperatures on the bottom of the cooling device at steady state is 2.3 °C. The temperature and the pressure drop were calculated with the whole system model and the pressure drop model, respectively.

The results in Table 1 have demonstrated that the most complex channel structure (device C) can achieve the desired temperature uniformity with the lowest flow rate and pressure drop. The more complex device than device C might result in higher temperature uniformity or lower pressure drop, which results in the use of a smaller pump. The upper limit of the channel complexity is given by the technical difficulty or the cost of manufacturing.

Table 1. Comparison of channel structures in cooling device. The blue and red regions represent the inlet and the outlet of saline.

Device	A	B	C
			Width [mm] (channel, fin)	13.5, 1.0	3.83, 1.0	1.9, 1.0
Temperature on bottom of cooling device [°C] (max, ave, min)			
	19.9, 17.8, 17.6	19.7, 17.7, 17.4	19.6, 17.8, 17.3
Temperature 2 mm below cooling device [°C] (max / ave / min)			
	29.2, 25.0, 24.3	29.1, 25.0, 24.3	29.1, 25.0, 24.3
Flow rate [L/min]	1.0	0.1	0.06
Pressure drop [kPa]	20	2	1

5. Duration for focal brain cooling

Two unsteady-state analyses were performed for device C. The results shown in Fig. 3 have indicated that it took less than 10 minutes for the average temperature 2 mm below the cooling device to reach 25 °C. The temperature on the hot and the cold sides of the Peltier device was lower than 40 °C and higher than 5 °C, respectively.

The duration required for cooling the brain is much shorter than the time from seizure prediction to seizure onset, which is around 90 minutes with an existing EEG-based

algorithm. The maximum temperature 2 mm below the cooling device does not reach 25 °C after 20 minutes cooling. Since the maximum temperature is marked in the peripheral area of the cooling device, the cooling device should be larger than the target region for cooling.

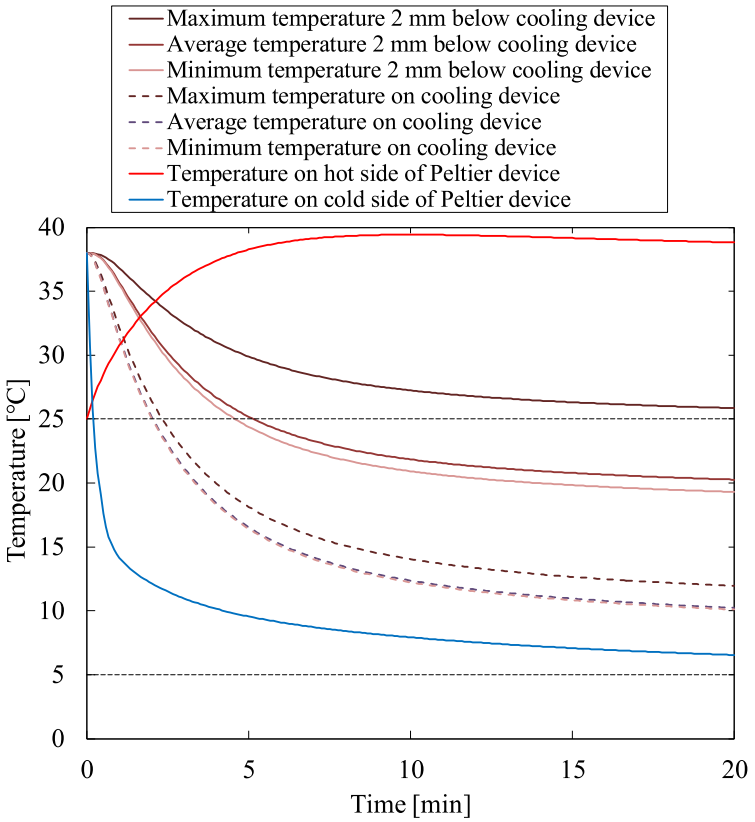

Figure 3. Temporal change of temperature in brain and Peltier device.

6. Frequency of Battery Charging

The cooling time per seizure is the sum of the time required for lowering and maintaining the temperature. The former was determined to be 10 minutes or less, and the latter is 10 minutes based on the experiences in Yamaguchi University School of Medicine. It was found that the battery has to be charged every two or three seizures. Since the quartile frequency of seizures with awareness impairment in temporal lobe epilepsy is 0.10, 0.16, 0.47 times in a day (Wiebe et al., 2001), most patients would need to charge the battery once in several days.

7. Conclusions

In the present work, the physical model of the focal brain cooling system was developed. It is characterized by the hemispheric head model, which utilizes the heat conduction equation, the basic equations of fluid dynamics, and the modified Pennes bioheat equation. To determine a constant in the modified Pennes bioheat equation, an

animal experiment was performed. To reduce the computational burden, the pressure drop model was constructed, which describes the relationship between the flow rate and the pressure drop of the saline. With these models, three types of cooling devices were compared. The results have shown that the more complex channel structure results in the desired temperature uniformity in the brain with the lower flow rate and pressure drop of saline.

The results have also shown that it takes less than 10 minutes for the average temperature 2 mm below the cooling device to reach 25.0 °C. It is much shorter than the duration from seizure prediction to seizure onset by using an existing EEG-based algorithm. In addition, the frequency of battery charging would be once in several days for most patients. The present work demonstrates the feasibility of the focal brain cooling system in clinical application.

Abstract

Pharmaceutical tablets are film coated for several reasons, the most common being the enhancement of taste and appearance, the protection of sensitive ingredients and the control of active ingredient release. In this work, we developed a mathematical model that simulates coating spray impact, film formation and drying on pharmaceutical tablet surfaces. To describe spray impingement and liquid film formation we developed a 1-D film-spreading model. To predict the drying of the liquid film, we used the "mixture modeling" theory and the "lubrication approximation" theory to simplify the equations describing the liquid-particle system. The current model allows predicting the thickness of an evaporating coating layer applied on a curved tablet. We performed variance-based sensitivity analysis to study the effect of spray parameters on coating spreading and initial liquid film thickness and to investigate the influence of tablet and film properties on drying.

Keywords: pharmaceutical, film coating, drying, modeling.

1. Introduction

Coating is an important step in the manufacture of pharmaceutical tablets. Film coatings are usually applied on tablets by spraying polymer solutions or dispersions on their surface (Felton, 2013). After impinging on the surface, the droplets spread forming a liquid film. As the solvent evaporates, a polymeric coating develops, covering the tablet core (Fig.1). In our work, to model droplet impingement we assumed the spray to be uniform and we divided it into arrays of droplets that impinge successively on the substrate orthogonally to its surface. We assumed that over a time interval of magnitude $t_i = \overline{D}_0/\overline{U}_0$ the droplets in the first array impinge and spread without being affected by subsequent droplets. Here $\overline{D}_0$ and $\overline{U}_0$ denote the initial diameter and velocity of a single droplet, respectively. We estimated the initial wetted area by calculating the spreading of a single droplet and by assuming that all the droplets of the first array behave independently and identically as they impact on the dry surface. Then, subsequent droplet arrays impingement makes the wetted area spread further.

To model the drying of the liquid coating film, we employed the "mixture modeling" approach which is based on the assumption that the mean velocity fields of the solid (polymer particles) and liquid (solvent) phases relax to local equilibrium (Schwartz et al., 2001). The model (briefly presented in Section 2) yields both the spreading rate and the thickness of the liquid film as well as the drying rate and final thickness of the polymer coating.

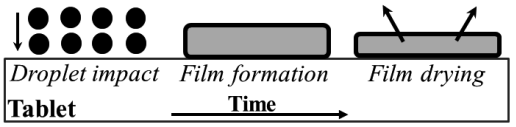

Figure 1. Outline of the coating application process during pharmaceutical coating.

After the tablet leaves the spray-zone, the film spreading caused by spray impingement stops. At this stage, we can ignore inertial forces and simplify the momentum and mass balance equations governing the thin film behavior using the lubrication approximation. In our model, the main equations that describe coating drying are a height evolution equation that calculates the film thickness during solvent evaporation and a convection-diffusion equation that predicts the polymer mass fraction in the film. The final outputs of the model are the time required by the film to dry completely and the final thickness of the dry polymer film.

Additionally, we performed variance-based sensitivity analysis (Sobol sampling; Process Systems Enterprise, 2017) to study the effect of spray parameters (droplet size, impact velocity, and coating viscosity, density and surface tension) on film spreading rate and thickness and to investigate the influence of coating and tablet properties (particle diffusion coefficient, evaporation rates, tablet curvature) on film drying times.

2. Mathematical model

In this section, we present the mathematical model we developed to simulate film application and drying during the coating process. The impact of the first array of droplets leads to tablet wetting. The initial wetted area will spread further when the subsequent droplets impinge (Fig.2). We assumed that the tablet curvature has negligible effect on the wetted area spreading while the tablet is under the spray. The liquid film height calculated from the spreading model is then considered as an initial condition for the film drying equations that give us the evolution of the film thickness during solvent (water) evaporation.

2.1. Droplet impact on dry substrate

To model the impingement of the first droplet array on the dry tablet we developed a 1D spreading model for a single droplet that before impact has the average velocity and size of the spray droplets. Assuming that all the droplets of the first array do not interact and behave in the same way, we calculate the initial wetted area. The spreading model is based on the mechanical energy equation, written as follows:

$$\frac{dE_k}{dt} + \frac{dE_p}{dt} + \Phi = 0 \tag{1}$$

where E_k and E_p are the kinetic and potential energies of a spreading droplet of volume V, respectively, and Φ is the rate of viscous dissipation of kinetic energy. The kinetic and potential energies are:

$$E_k = \frac{1}{2}\rho \int_V \boldsymbol{u} \cdot \boldsymbol{u}\, dV \;\; ; \;\; E_p = \sigma(A_d - \pi R_d cos\theta_e) \tag{2}$$

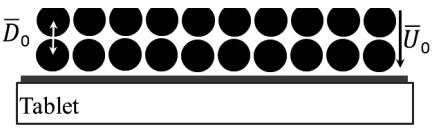

Figure 2. Spray (droplet arrays) impingement on the tablet during film-coating.

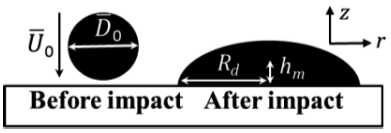

Figure 3. Single droplet impingement on a dry tablet. Droplet shape before and after impact.

where $\boldsymbol{u}$ is the velocity field in the spreading droplet and ρ, σ, A_d, R_d and θ_e are the droplet density (assumed to be constant), surface tension, air-droplet area, wetted area radius and contact angle, respectively. The kinetic energy loss rate is given by:

$$\Phi = \int_V \boldsymbol{\tau} : \nabla \boldsymbol{u} \; dV \; ; \; \boldsymbol{\tau} = \mu(\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T) \tag{3}$$

where $\boldsymbol{\tau}$ is the deviatoric stress tensor and μ is the viscosity of the droplet (assumed to be constant, but dependent on the solid concentration). To use Eqs. (2) and (3), we need to assume a functional form for the field **u** within the droplet. Following our previous approach (Christodoulou et al. 2017), we assumed irrotational axisymmetric stagnation point flow. The velocity components (u_r, u_z) in cylindrical coordinates are then given by:

$$u_r = -\frac{1}{2}\frac{1}{h_m}\frac{dh_m}{dt}r \; ; \; u_z = \frac{1}{h_m}\frac{dh_m}{dt}z \tag{4}$$

where h_m is the position of the center of mass of the droplet. By assuming that the droplet has a spherical cap shape after impact, we reduced the number of unknown variables to one (the wetted area radius, R_d) and we solved the 1D mechanical energy equation (Eq.1). We show the shape of the droplet before and after impact in Fig.3. At any given time $t<ti$, the equivalent radius of the wetted area is taken equal to $R_i^2 = N_d \cdot R_d^2$, where N_d is the number of droplets in each array, which depends on the spray mass flowrate Q and on the characteristic time t_i ($Q \cdot t_i = N_d \cdot \rho \cdot V$).

2.2. Spray impingement – film formation

After the first array impacts on the dry tablet surface, the subsequent droplets that impinge will contribute to the spreading of the initial wetted area. We assumed that at this stage the wetted area is made up of disconnected cylindrical films. The spreading of these films is governed by the mechanical energy equation:

$$\frac{dE_{kf}}{dt} + \frac{dE_{pf}}{dt} + \Phi_f + \frac{dW_d}{dt} = 0 \tag{5}$$

where E_{kf} and E_{pf} are the total kinetic and potential energies in each film, while Φ_f is the rate of kinetic energy dissipation in each film. The last term on the left hand side of Eq. (5) is the rate of work done on the surface of each film by the impinging droplets (of mass flowrate Q_f), which is given by:

$$\frac{dW_d}{dt} = -\frac{1}{2}Q_f \bar{U}_0^2 \tag{6}$$

We calculated the energy terms in a similar way as in Eqs. (2) and (3). Following Madejski (1976), we assumed that the components of the velocity field are given by:

$$u_{r,f} = \frac{2}{H_f}\frac{1}{R_f}\frac{dR_f}{dt}rz \; ; \; u_z = -\frac{2}{H_f}\frac{1}{R_f}\frac{dR_f}{dt}z^2 \tag{7}$$

where dR_f/dt is the rate of expansion of the cylindrical film and R_f and H_f are the wetted area radius and film height, respectively. We considered the spreading to be completed when the wetted area covers the entire tablet surface; this occurs when the disconnected cylindrical films get into contact with one another.

The film formation equations can provide information about the liquid coating film (thickness and wetted area on the tablet) that is applied on the tablet during one pass through the spray zone.

2.3. Film drying

Pharmaceutical coatings are multicomponent liquids. We assumed that the liquid film applied on the surface of the curved tablet surface after spray impingement (Sections 2.1 and 2.2) consists of a carrier fluid and polymer particles. To describe the liquid-particle system we used the mixture modeling approach that is based on three equations: a continuity and a momentum balance equation written for the mixture (which is treated as an effective fluid) and a continuity equation written for the solid phase:

$$\rho \frac{D\boldsymbol{u}}{Dt} = -\nabla p + \nabla \cdot \boldsymbol{\tau} + \rho \boldsymbol{g} \tag{8}$$

$$\partial_t \rho + \nabla \cdot (\rho \boldsymbol{u}) = 0 \ ; \ \partial_t (\rho w) + \nabla \cdot (\rho \boldsymbol{u} w) + \nabla \cdot \boldsymbol{J_p} = 0 \tag{9}$$

where $\boldsymbol{J_p}$ and w are the particle mass flux with respect to the mass averaged velocity of the mixture and the particle mass fraction, respectively. Because the coating dries more quickly in the thinner regions close to the corners of the tablet (Schwartz et al., 2001), the liquid-particle system will develop concentration gradients during drying. Following Weidner et al. (1996), we assumed Fickian diffusion of polymer particles in the coating film and wrote a linear relation between the species flux and mass fraction:

$$\boldsymbol{J_p} = -\rho \mathcal{D} \nabla w \tag{10}$$

where $\mathcal{D}(m^2 s^{-1})$ is the particle diffusion coefficient given by $\mathcal{D} = \mathcal{D}_0 \exp[-A(w - w_{t=0})]$ (Weidner et al., 1996). For the parameters $\mathcal{D}_0$ and A we used the characteristic values for coating film drying found in Weidner et al. (1996). This assumption is quite general and therefore future work should focus on specifying these parameters for a pharmaceutical system.

After the initial stage of spray impact (Sections 2.1 and 2.2), the thin film flow and drying are significantly slower. This allows us to use the lubrication approximation for the mixture continuity and momentum balance equations. The film height evolution equation for a Newtonian, incompressible coating reads (Schwartz et al., 2001):

$$\partial_t h = -\nabla \cdot \boldsymbol{F} - J_e \text{ , where } \boldsymbol{F} = \int_0^h \boldsymbol{u}\, dz = -\frac{h^3}{3\mu} \nabla p \tag{11}$$

In Eq. (11), $\boldsymbol{F}$ is the coating (mixture) flux rate on the surface of the tablet, h is the height of the film and p and J_e are the pressure in the film and the evaporation velocity, respectively:

$$p = -\sigma \kappa - \sigma \Delta h \ ; \ J_e = J_{e0}(1 - w)^{\nu} \tag{12}$$

where κ is the curvature of the tablet and Δh is the curvature of the surface of the liquid coating film. Characteristic values for J_{e0} and ν can be found in the literature (Weidner et al. 1996; Schwartz et al. 2001). The lubrication theory also allows us to simplify the continuity equation for the solid phase (Eq. 9b). We derived the following equation that agrees with the one reported in the work of Schwartz et al. (2001):

$$\frac{Dw}{Dt} \equiv \partial_t w + \boldsymbol{u} \cdot \nabla w = \frac{J_e}{h} w + \frac{1}{h} \nabla \cdot (h' \mathcal{D} \nabla w) \tag{13}$$

where h' is the polymer particle "height" given by $h' = \varepsilon_p h$, where ε_p is the volume fraction of the polymer particles.

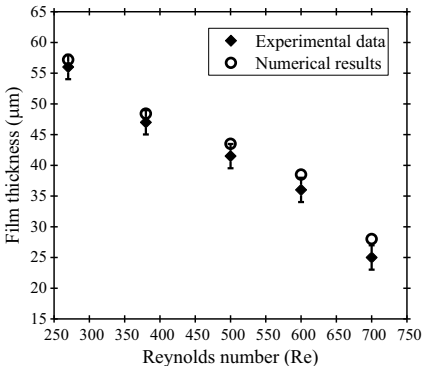

Figure 4. Validation for the liquid film thickness. Experiments by Kalantari and Tropea (2014).

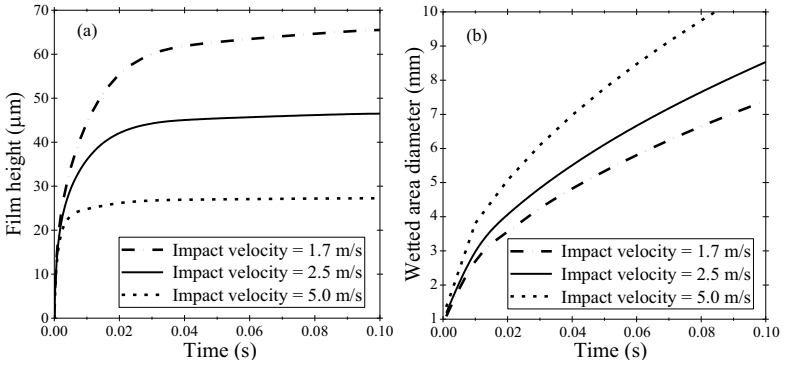

Figure 5. Effect of droplet impact velocity on a) film height and b) film spreading.

Solution of Eqs. (11) to (13) provides information about the film thickness at different positions on the tablet and about the drying time. We implemented the entire model in gPROMS, employing the DASOLV solver (backward differentiation formulae) of the Modelbuilder platform (Process Systems Enterprise Ltd., 2017).

3. Results

In this section, we present the numerical results that describe the film behavior on the tablet after spray impingement in the spray zone. We validated the model predictions for the liquid coating film thickness during spraying with experimental data from the literature and studied the effect of process parameters on the polymer film thickness.

In Fig. 4, we compare our numerical predictions for the liquid film thickness after spray impact with experimental data from the literature. Kalantari and Tropea (2014) experimentally investigated viscous liquid spray impact on rigid surfaces. Fig. 4 shows that higher spray impact Reynolds numbers ($Re \equiv \rho \overline{U}_0 \overline{D}_0 / \mu$) lead to thinner liquid films. The numerical results are in good agreement with the experimental data. In Fig. 5, we illustrate the effect of the mean droplet impact velocity on the film thickness and spreading. Higher impact velocities lead to thinner films and faster spreading.

In Fig.6, we present the model prediction for the film thickness evolution during drying in coating process conditions. The simulation shows that the tablet curvature ($\kappa = -1/L$, where L is the tablet surface curvature radius $\cong$ 13.5mm) affects the final dry film thickness since the film is thinner at the corner. This prediction agrees with the results of Weidner et al. (1996) and Schwartz et al. (2001).

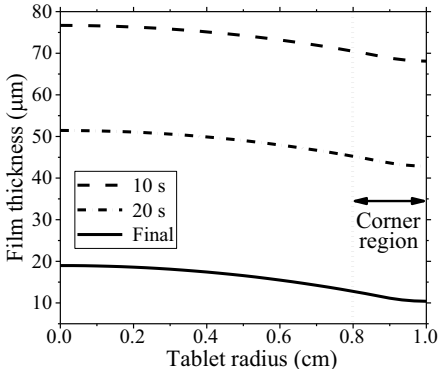

Figure 6. Film thickness during drying (simulation with J_{e0} =2.0μm/s, ν =0.5, A=15, $\mathcal{D}_0$=2·10^{-5}cm^2/s).

To determine the effect of spray parameters on film thickness and time required to cover a tablet surface we performed variance-based sensitivity analysis for a tablet with diameter 1cm. The total sensitivity indices appear in Table 1. The droplet mean velocity is the most important parameter followed by the mixture viscosity. For the drying model, only the tablet curvature significantly affects coating uniformity (thickness difference) and parameters J_{e0} and v influence drying times. The rest of the parameters have very small total sensitivity indices (<0.001).

Table 1. Variance-based sensitivity indices for spray impingement.

Factor	Film thickness (S_{Hf})	Spreading time (S_{tf})
Density, surface tension (σ ,ρ)	0.006	0.001
Droplet mean diameter ($\bar{D}_0$)	0.008	0.007
Droplet mean velocity ($\bar{U}_0$)	0.822	0.940
Coating viscosity (μ)	0.164	0.052

4. Conclusions

The mathematical model developed in this work calculates the liquid coating spreading after spray impingement on a tablet and the subsequent polymer film drying on its surface. The numerical results are in good agreement with experimental data from the literature (Kalantari and Tropea, 2014). The sensitivity analysis yields useful insight into the effect of model parameters on coating application. Future work will include investigation of the non-Newtonian behavior of coatings and a detailed evaporation model that accounts for polymer particle coalescence during drying.

Abstract

Von Willebrand disease is one of the most severe inherited bleeding disorders in humans, characterized by qualitative and/or quantitative defects of the von Willebrand factor protein. Diagnosis is difficult due to the high heterogeneity of the disease. Pharmacokinetic models have been recently proposed and applied to help in the disease characterization and diagnosis. However, the complexity of the models requires long and invasive dynamic non-routine tests to be carried out on the subjects to achieve a statistically satisfactory estimate of the individual metabolic parameters. In this work, it is demonstrated how the use of basal clinical tests and a shorter dynamic clinical test may allow for the identification of a mechanistic model of the disease. An existing mechanistic model of von Willebrand disease has been modified to account for the basal tests, where new model equations are derived using response surface methodology. Results show a good agreement between the model response and the clinical data.

Keywords: von Willebrand disease; model identification; basal clinical tests

1. Introduction

Von Willebrand disease (VWD) is one of the most frequent human bleeding disorders, caused by an alteration of von Willebrand factor (VWF), a multimeric glycoprotein present in the bloodstream. VWF has a fundamental function in the hemostatic process. It mediates platelet aggregation and thrombus growth, and binds, transports and protects the coagulation factor VIII. VWD is caused by defects of VWF, with symptoms ranging from sporadic nosebleeds and mild bleeding from small lesions to acute thrombocytopenia and/or prolonged bleeding episodes (Lillicrap, 2007). Diagnosis of VWD may be complicated due to the existence of different VWD types (1, 2A, 2B, Vicenza) depending on the nature of VWF defect. Pharmacokinetic (PK) models have been recently proposed for the classification of the disease, elucidating the critical pathways involved in the disease characterization (Galvanin et al, 2013). However, the complexity of the models requires the execution of the long (at least 24 h) and invasive 1-desamino-8-D-argine vasopressin (DDAVP) test (Casonato et al, 2011) on the patients to achieve a statistically satisfactory estimate of the individual metabolic parameters. Hence, there is the need to propose alternative easier and less costly clinical investigations to identify the PK model of VWD. A possible solution is to take advantage of basal clinical trials, *i.e.* the VWF antigen (VWF:Ag), VWF collagen-binding (VWF:CB) and VWF propeptide (VWFpp), which can be carried out taking a single blood sample. In this

work it will be shown how basal clinical trials can be used effectively to estimate a subset of the kinetic parameters in a PK model of VWD. Specifically, response surface methods will be used to develop regression models based on a set of available clinical data. Furthermore, an analysis of the dynamic Fisher Information Matrix (FIM) (Bard, 1974) will be then used to design a shorter DDAVP test for the estimation of the PK parameters. The procedure will be validated on clinical data with the aim of demonstrating the potential for an identification approach based on shorter and less costly clinical tests.

2. Clinical data

Our research work has been carried out using clinical data derived by 20 VWD patients belonging to 2B and Vicenza VWD categories, and 42 normal subjects with HnonO and HO blood group. Patients and normal subjects were studied in accordance with the Helsinki Declaration, after obtaining their written informed consent, and the approval of the Hospital ethical board for the study. Clinical data and experimental methods have been supplied by the Hospital of Padova and they mainly come from the standard diagnostic procedure for VWD, which consider both basal and dynamic tests. The basal tests that have been considered in our study are: i) VW:Ag, to evaluate the concentration of VWF in the bloodstream. Plasma VWF:Ag was measured with a home-made ELISA method, using a horseradish peroxidase (HRP)-conjugated anti-VWF antibody. A pool of normal plasma was used to construct the reference curve. The results are given in U/dL, taking the first reference curve dilution as 100 U/dL; ii) VWF:CB, to evaluate the ability of VWF to bind collagen, and explore the presence of large, hemostatically more efficient, multimers. VWF:CB is assessed by ELISA using type III collagen diluted in acetic acid. The results are given in U/dL, taking the first reference curve dilution as 100 U/dL; iii) VWFpp to quantify the elimination rate of VWF from the bloodstream. VWFpp was measured using a home-made ELISA method, using CLB-Pro 35 and CLB-Pro 14.3-HRP antibodies. From these tests, two other basal quantities are derived: the VWFpp ratio, defined as VWFpp/VWF:Ag, which gives an indirect measure of VWF survival and the VWF:CB ratio, expressed as VWF:CB/VWF:Ag, which is suggestive of the amount of large VWF multimers in the bloodstream (Casonato et al, 2011). The dynamic test used is the DDAVP trial, which consists in the collection of blood samples before and 15, 30, 60, 120, 180, 240, 480 min and 24 h after administration of DDAVP subcutaneously at a dose of 0.3 μg kg^{-1}. The changes in VWF:Ag and VWF:CB plasma concentrations at different time points after the DDAVP are then analysed to get important information on the three most important VWF pathways, which are: VWF release, VWF proteolysis and VWF elimination.

3. The PK model of VWD

The PK model taken as reference in this research work has been recently proposed by Ferrari et al (2018). As reported in Figure 1, this PK model of VWD assumes that after DDAVP administration, high molecular weight (HMW) and ultralarge molecular weight (UL) VWF multimers are released from the endothelial cells. Then, the HMW and UL multimers are cleaved into low molecular weight (LMW) multimers by the metalloproteinase ADAMTS-13 and then eliminated from the bloodstream. The model is described by a system of differential and algebraic equations where each subject is characterized by three main PK parameters, namely the VWF release rate k_0 [h^{-1}], the proteolysis rate k_1 [h^{-1}] and the elimination rate k_e [h^{-1}]. The amount of released VWF is represented by parameter D [U/dL]. It is important to notice that, for a given subject,

parameter k_0 quantifies the rate of release, while D quantifies the amount of VWF released from the endothelial cells.

The model differential and algebraic equations are:

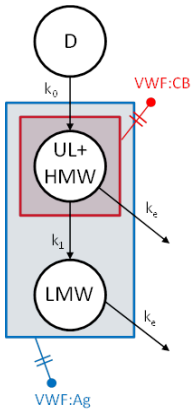

Figure 1. *The simplified PK model of VWD by Galvanin et al.*

$$\frac{dx^{UL+HMW}}{dt} = k_0 D\, e^{-k_0(t-t_{max})} - k_1\left(x^{UL+HMW} - x_b^{UL+HMW}\right) - k_e\left(x^{UL+HMW} - x_b^{UL+HMW}\right) \quad (1)$$

$$\frac{dx^{LMW}}{dt} = k_1\left(x^{UL+HMW} - x_b^{UL+HMW}\right) - k_e\left(x^{LMW} - x_b^{LMW}\right) \quad (2)$$

$$y^{AG} = \frac{x^{UL+HMW} + x^{LMW}}{V_d} \quad (3)$$

$$y^{CB} = \frac{x^{UL+HMW}}{V_d} \quad (4)$$

where: V_d = 40 mL/kg$_{bw}$ is the approximate distribution volume. Basal conditions are assumed at $t(0)$, i.e. $x(0) = [x_b^{UL+HMW} x_b^{LMW}] = [y_b^{CB} V_d y_b^{AG} V_d - y_b^{CB} V_d]$.

The model is able to correctly characterize the three most important VWF pathways, which are: VWF release (identified by k_0), VWF proteolysis (identified by k_1) and VWF elimination (identified by k_e). However, to estimate the model parameters, which means to quantify the rate of VWF release (k_0), proteolysis (k_1) and elimination (k_e) and to describe the time courses of VWF:Ag and VWF:CB, the DDAVP test needs to be carried out. The set of parameters to be estimated from the available measurements is $\boldsymbol{\theta} = [k_0\ k_1\ k_e\ D\ t_{max}]$. A maximum likelihood parameter estimation has been carried out using the commercial software gPROMS®. Measurements are assumed to be normally distributed with a standard deviation of 2 U/dL. The parameter set $\boldsymbol{\theta}$ is determined for each individual by iteratively solving an SQP optimization problem. A crucial step in the parameter estimation exercise is setting the value of the first guess $\boldsymbol{\theta}_0$ for $\boldsymbol{\theta}$. In this study, $\boldsymbol{\theta}_0$ was obtained from a preliminary parameter estimation for each group of subjects (healthy, VWD type 2B, and VWD type Vicenza) using average concentration profiles obtained from subjects belonging to the same group. Then the parameter estimation routine was initialized with $\boldsymbol{\theta}_0$, and the set of parameters was estimated for each individual subject based on his/her own concentration profiles.

4. Proposed methodology

The PK model of Ferrari et al (2018) shows two significant limitations. Firstly, it requires the execution of the invasive DDAVP test to achieve a statistically satisfactory estimation of the PK parameters; secondly, it does not consider the information that can be obtained from basal tests. Therefore, to overcome these issues, it is reasonable: (i) to investigate methods which allow to calculate the PK parameters from basal clinical trials through regression models; (ii) to include the correlations derived by a regression procedure in the set of model equations, leading to a first level and to a second level of model modification; (iii) to suggest a shorter DDAVP test for the estimation of the remaining (reduced) set of parameters.

The PK model parameters, which are directly calculated from basal clinical trials are the elimination kinetic constant k_e and the proteolytic kinetic constant k_1. It is possible to demonstrate that these parameters require the longest DDAVP execution time for being identified with the maximum information. To achieve this conclusion, information content analysis has been carried out on the simplified PK model of VWD in order to quantify the DDAVP execution time that is required to maximize the information content. The metric that is used to evaluate the information content of the clinical test is the trace of Fisher Information Matrix (FIM), which is defined as $I_d = \sum_{t_{sp}} tr[H_\theta]$. Approximatively, the FIM can be mathematically expressed as the product of the sensitivity of the *j*-th output variable with respect to the *k*-th parameter in the conditions investigated in the i-th experiment divided for the variance $[\mathrm{H}]_{\mathrm{kl}} \cong \sum_{\mathrm{i}=1}^{\mathrm{N_{exp}}} \sum_{\mathrm{j}=1}^{\mathrm{N_m}} \left[\frac{1}{\sigma_{\mathrm{ij}}^2}\left(\frac{\partial \hat{y}_{\mathrm{ij}}}{\partial \theta_{\mathrm{k}}}\frac{\partial \hat{y}_{\mathrm{ij}}}{\partial \theta_{\mathrm{l}}}\right)\right]$ (Bard, 1974). The remaining PK parameters k_0, D and t_{max} are all related to the description of the VWF release from the endothelial cells. However, it was demonstrated (Ferrari et al, 2018) that k_0 and D are highly correlated and are difficult to estimate separately without dynamic experiments. Furthermore, t_{max} is not strictly related to any basal clinical quantity, but it is function of the intrinsic release mechanism. Hence, regression methods cannot be applied to obtain k_0, D and t_{max}, but a shorter DDAVP test may be used for their estimation.

4.1 The response surface methodology (RSM)

The regression method used in this research work is known as response surface methodology (RSM). RSM is a technique developed by Box-Behnken (1960), used to define black-box models, which allows to investigate possible correlations between inputs and outputs in systems where nothing is known of the inside. Basal clinical data (§2) and the estimation of the PK model parameters (k_0, k_1, k_e, D, t_{max}) (§3) were available for each patient considered in the pool and they constitute the experimental data set. The experimental data set has been used for the construction of basal state correlations, which relate the PK model parameters k_e and k_1 to basal clinical trials thorough a response surface methodology (RSM). The first objective of RSM is to hypothesize an analytical form of the response surface, which manages to approximate the experimental data. Based on the Akaike information criterion (Akaike, 1974), a linear response surface model with interactions appears to be the best candidate for representing the real system. The fitting procedure has been executed in OriginProand the sum of squared errors (SSE) and the R-square (R^2) statistics were used to assess the goodness of fit. Two basal state correlations have been defined, which allow to estimate the elimination kinetic constant k_e (Eq. 5) and the proteolytic kinetic constant k_1 (Eq. 6) from basal clinical trials (VWF:Ag, VWF:CB and VWFpp) and the related basal quantities (VWFpp ratio and VWF:CB ratio, indicated in the equations as VWF:R):

$$k_e = A + B \cdot VWFppratio + C \cdot VWF{:}R + D \cdot VWFppratio \cdot VWF{:}R \quad (5)$$

$$k_1 = A + B \cdot VWF{:}Ag + C \cdot VWFppratio + D \cdot VWF{:}Ag \cdot VWFppratio \quad (6)$$

In Figure 2, it can be observed that the fitting of the experimental data of HnonO subjects using (Eq.5) appears to be good and this is confirmed also by the goodness of Fit statistics reported in Table 1, where the R^2 is higher than 90% for all the considered categories. The same observation can be derived considering the fitting of the experimental data using (Eq.6). The two correlations (Eq. 5 and 6) have been included in the PK model of VWD. From Table 2, it appears that the modified PK model can estimate both the elimination kinetic constant k_e and the proteolytic kinetic constant k_1 in an accurate way:

the relative error based on the difference between the kinetic parameters calculated with the modified PK model and estimated with the original PK model is lower than 10% (except for k_1 for the HO category). Hence, in the modified PK model the proteolytic kinetic constant k_1 and the elimination kinetic constant k_e are calculated from basal clinical trials, whereas only the release kinetic constants k_0, D and t_{max} require the DDAVP execution. Information content analysis has been performed on the modified PK model of VWD. The metric used to evaluate the dynamic information content is the FIM trace. The position in time at which the trace reaches the peak corresponds to the maximum information content that can be achieved in the DDAVP. Looking at the dynamic profiles of four randomly selected subjects (Figure 3), an information peak can be observed at around three hours of DDAVP execution.

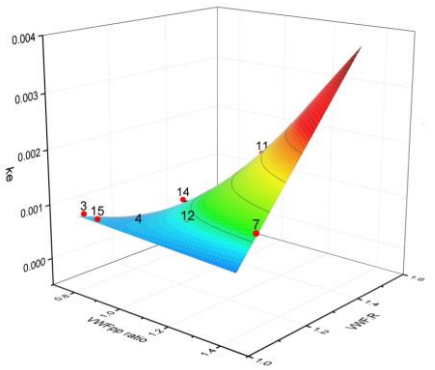

Figure 2. *Fitting of the HnonO category experimental data with the linear RSM presented in Equation 5 (k_e as function of VWFpp ratio and VWF:CB ratio)*

Table 1. *Summary of goodness of fit statistics for k_e as in Eq. 5.*

	Reduced chi-sqr	Residuals sum of squares	R^2	$\acute{R}^2$
HnonO	2.0E-08	8.1E-08	0.926	0.750
HO	9.3E-08	4.6E-07	0.910	0.724
2B	1.4E-07	2.7E-07	0.979	0.896
Vicenza	3.2E-07	3.2E-07	0.929	0.455

Table 2. Average k_1 *and* k_e *calculated and estimated values.*

	k_e calculated by modified model	k_e estimated through the original model	relative error	k_1 calculated by modified model	k_1 estimated through the original model	relative error
HnonO	6.73E-04	7.04E-04	0.046	2.55E-04	2.37E-04	0.0759
HO	0.001858	0.00152	0.082	4.53E-04	6.25E-04	0.2752
2B	0.003332	0.00323	0.031	0.00484	0.00471	0.0268
Vicenza	0.008406	0.00818	0.027	0.00155	0.00149	0.0345

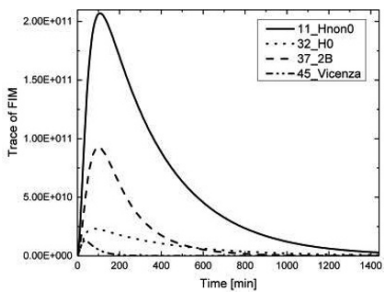

Figure 3. *Trace of FIM executed with the modified PK model of VWD.*

The amount of information introduced by basal data is sufficient to reduce the DDAVP execution down to 180 minutes. The DDAVP sampling schedule considered in this work is: [0, 15, 30, 60, 120, 180], which is a simple reduction in time of the original DDAVP protocol. Optimized sampling procedures could be obtained, *e.g.* by exploiting Model Based Design of Experiments (MBDoE) techniques (Castaldello et al, 2017).

The modified VWD model with the time reduced DDAVP has been validated considering four subjects that were excluded from the original pool (named as patients: 1, 19, 39, 50). The VWF:Ag and VWF:CB profiles of response of the subjects have been generated by simulation of the original model of VWD (Ferrari et al, 2018) and compared with those obtained with the modified model proposed in this work. As an example, in Figure 5, the VWF:Ag profiles of patient 1 (Figure 4a) and 19 (Figure 4b) have been reported.

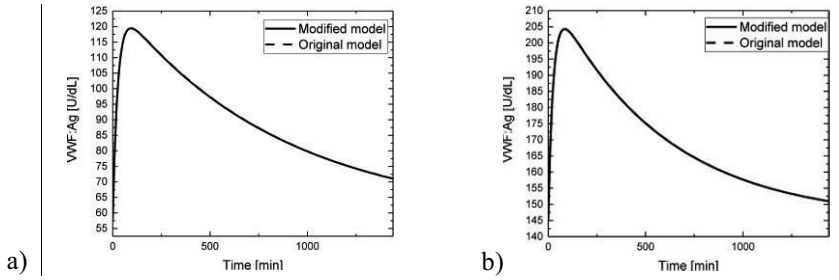

Figure 4. *Comparison between the simulated profiles of VWF:Ag response with the original PK model and modified PK model for patient 1 (a) and 19 (b).*

It can be seen that the VWF:Ag profiles generated with the original and modified PK model of VWD overlap, meaning that the predictive capability of the original PK model of VWD has been retained.

5. Conclusions

In this work the possibility to use basal clinical tests to estimate a subset of kinetic parameters of a PK model of VWD has been demonstrated. Response surface methods have been used to define regression models, which have been substituted into the original model. Other parameters can be estimated via a shorter DDAVP test, lasting only 3 hours instead of the standard 24 hours. Clinical data have allowed assessing the predictive performance of the modified model, which appears to be highly satisfactory. Future work will be carried out to optimize the time reduced DDAVP protocol among the different VWD categories and to reinforce model validation by applying the modified model and the time-reduced DDAVP to characterize new subjects.

Abstract

In this work, a plant-wide model-based shortcut approach for decision-making and operational analysis of integrated end-to-end continuous pharmaceutical processes is developed and tested. The proposed hierarchical approach is implemented through a computer-aided framework. Using concepts of Layer of Protection Analysis (LOPA) combined with Net Present Value (NPV) are embedded in the framework from a model-based point of view to comprehensively assess the overall benefits of a specific operational point. This in turn can be used to make an informed decision between competing operation alternatives. The application of the framework is demonstrated through a validated dynamic process model of an integrated end-to-end continuous pharmaceutical pilot plant. In this application, the implications of changing process operations from single pass operation to raw material recycling have been investigated.

Keywords: Decision-making, layer of protection analysis (LOPA), NPV

1. Introduction

The pharmaceutical industry has traditionally been dominated by batch processing which has many inherent disadvantages, such as high costs and environmental footprint, long processing time and poor flexibility. Moreover, drug development is a complex, long and costly process, entrenched with high degrees of uncertainty regarding the success of the clinical trials and scale-up (Mascia et al. 2013). To address some of these issues more effectively, the economic and regulatory drivers are more than ever pushing the pharmaceutical industry towards continuous manufacturing, which demonstrated tremendous advantages over batch processing. Integrated end-to-end continuous pharmaceutical manufacturing has particularly attracted a lot of interest over the last few years. However, the integrated continuous approach can be very challenging and requires more rigorous and robust decision making tools for design, development and supply chain management, to meet the regulatory, economic, and resource recovery and safety requirements (Mansouri et al. 2017; Udugama et al. 2017). In pharmaceutical process development, the standard is to first develop different production scales to supply clinical trials. Afterwards, feasible and viable technologies for full production scale and

operational windows are identified in a very short time during the post approval period, to be able to produce as long as possible while the API is still patent protected. These singularities make the pharmaceutical process design and development very challenging and several operational alternatives (within a fixed design space) need to be systematically evaluated during start-up, steady-state and non-routine process upsets (presence of disturbances) (Benyahia et al., 2012, Lakerveld et al., 2013).

2. Decision-making approach

In this section, the decision-making framework for operational analysis of an end-to-end integrated pharmaceutical process is described. Figure 1 shows an overview of framework embedded in a computer-aided work-flow is given.

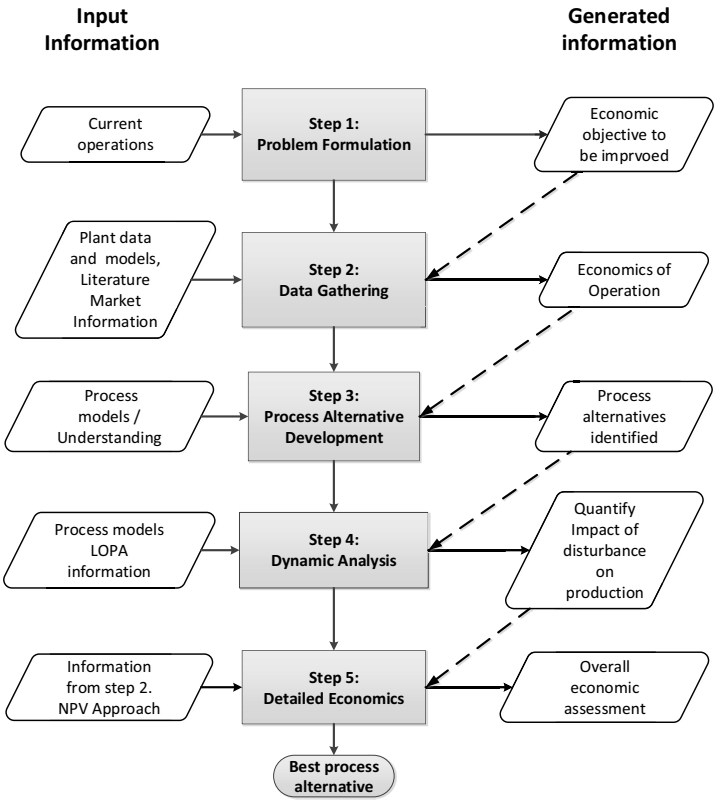

Figure 1: The decision-making workflow

Step 1 – Problem formulation: In the first step the overall objective(s) to be optimized improved is defined. The formulated objective primarily has economic elements, which in turn would influence decision-making in throughout the application of the framework. This could be also in form of identifying and evaluating various process alternatives subject to satisfying feasible economic objectives.

Step 2 – Data gathering: In this step all the relevant information that are required to carry out the analysis are systematically gathered. The information that is relevant to is categorized into three main categories, these are i) technical/process information, ii)

process and operational information related to process upsets, and iii) economic and market information. This Information related to technical/process information can be gathered from plant data or validated process models, while economic information can be obtained from literature and stakeholders.

Step 3 – Process alternative development: In context of pharmaceutical industry the development of process alternatives are constrained by regulatory agencies. Thereby, it is often necessary to develop process alternatives within the fixed approved design space. As such, operational alternatives are more worthwhile for retrofit design of an existing process. The development of process alternatives should be carried out using plant setup or validated process models taking into account the practical limitations such as operating temperatures, recycle ratios, unit mechanical constraints, solvent usage, as well as regulatory certified unit specifications.

Step 4 – Dynamic analysis: Once process alternatives are identified and developed, it is important to take into account their dynamic performance. This is because pharmaceutical processes are prone to non-routine process disturbances, which may have significant economic impact. This is due to high value of product as well as tight specifications. To this end, the disturbance probability and its economic influence on the process needs identification. The concept of layer of protection analysis (LOPA) is one method that can be adapted to calculate the probability and the consequences of process disturbances. The information generated in this step will be input to *Step 5* for detailed economic analysis.

Step 5 – Detailed economics: This step will provide a comprehensive analysis for the economics of the process alternatives identified in Step 3 taking into consideration information generated in Step 4. The final objective of this step is generation of a Net Present Value (NPV) number for a given process alternative that illustrates the economic incentives. Thereby, making decision to implement that process alternative over the current operations. To calculate the NPV value one requires i) the quantification of net profit generated by the process alternative ii) net profit/loss generated by the process alternative (based on information generated from LOPA analysis) iii) Cost of implementing the process alternatives (which will be at a minimal). As such, Eqs. 1 and 2 can be employed to carry this analysis

$$\Delta Profit_{p.a} = \Delta Profit_{cycle} \times \frac{cycles}{year} + \Delta Profit_{nro} \quad (1)$$

$$\mathrm{NPV} = \Delta\mathrm{Profit}_{\mathrm{p.a}} \times \frac{1-(1-\mathrm{r})^{\mathrm{n}}}{\mathrm{r}} - \mathrm{IC} \quad (2)$$

Where Eq. 1 calculates the annual change profit between the process alternative and current operations by taking into account the change in profit during improved operations during process cycles, while also considering the economics of non-routine operations generated in Step 4. Once the annual change in profit is calculated in can be used in a NPV analysis taking into account the time value of money by factoring in r the cash discount rate and n the number of years the analysis will be carried out while also taking into consideration the internal cost IC.

3. Application example

Step 1 – Problem formulation: In this work, a continuous end-to-end pharmaceutical process for organic synthesis of an API selected as case study. Benyahia et al. (2012) first proposed the dynamic model of the continuous pharmaceutical plant presented in Figure 2, which will be used as case study in this work. The objective in this example is to

improve the overall economics of the integrated end-to-end pharmaceutical through development of process alternatives within the given process design space.

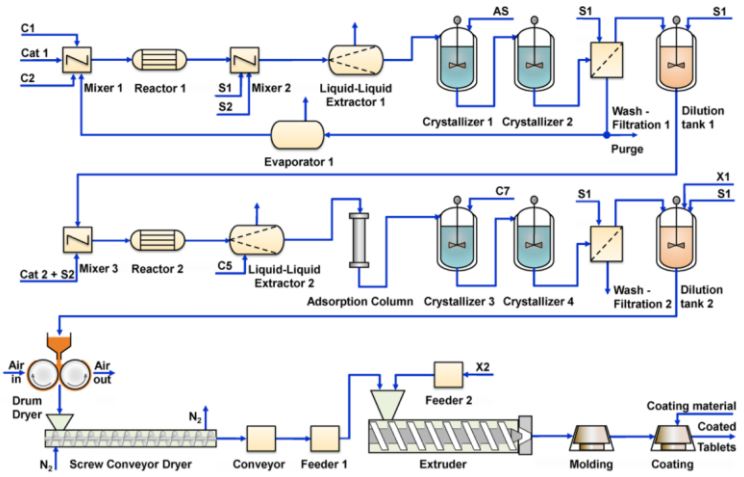

Figure 2: Flowsheet for continuous pharmaceutical pilot plant (Benyahia et al., 2012)

Step 2 – Data gathering: Here, the technical process information is collected through a validated dynamic model from Step 1. The market information is gathered from literature and open source information. The process-upset information is also obtained from Benyahia et al. (2012).

Step 3 – Process alternative development: In this example, the process alternatives are selected based on the recycle ratios (see recycle loop from wash filtration 1 in Figure 2). Four alternatives are selected i) base case – 13% purged (87% recycle) with wash factor 2 equal to 1.5, ii) case A – 0% recycle, and iii) case B – 100% recycle, iv) optimized base case – with wash rate of 2,and v) optimized case B - with wash factor 2 of 5.6. This is to evaluate the economic benefits of recycling at different rates in an integrated end-to-end pharmaceutical process.

Step 4 – Dynamic analysis: In this step, the dynamic process performance in the presence of upset scenarios is evaluated. Figure 3 shows the key plant dynamics for case B it is more sensitive to process disturbances than Case A and Optimized base case due to the employment of total recycle that amplifies process disturbances (due to the limited number of pages and for sake of brevity , the results are not fully presented here). It can be observed from Figure 3a and 3b that the in presence of a process upset the levels of the main impurities are above acceptable specification, which results in off spec tablets. Due to the tight regulations around processes in the pharmaceutical industry, these products cannot be easily recycled to be used as feedstock's, or purified to meet acceptable standards. Because of these reasons, Case B, which makes more products (due to a higher recycle rates), will also produce more off-specification products, especially during non-routine process disturbances. In Figure 3c and 3d, this effect is illustrated where Case B has a higher total production rate but a lower on-specification production, despite high API production. Therefore, when analyzing process control alternatives with a total recycle, it is important to consider the sensitivity to process disturbances, which will influence the overall NPV calculation.

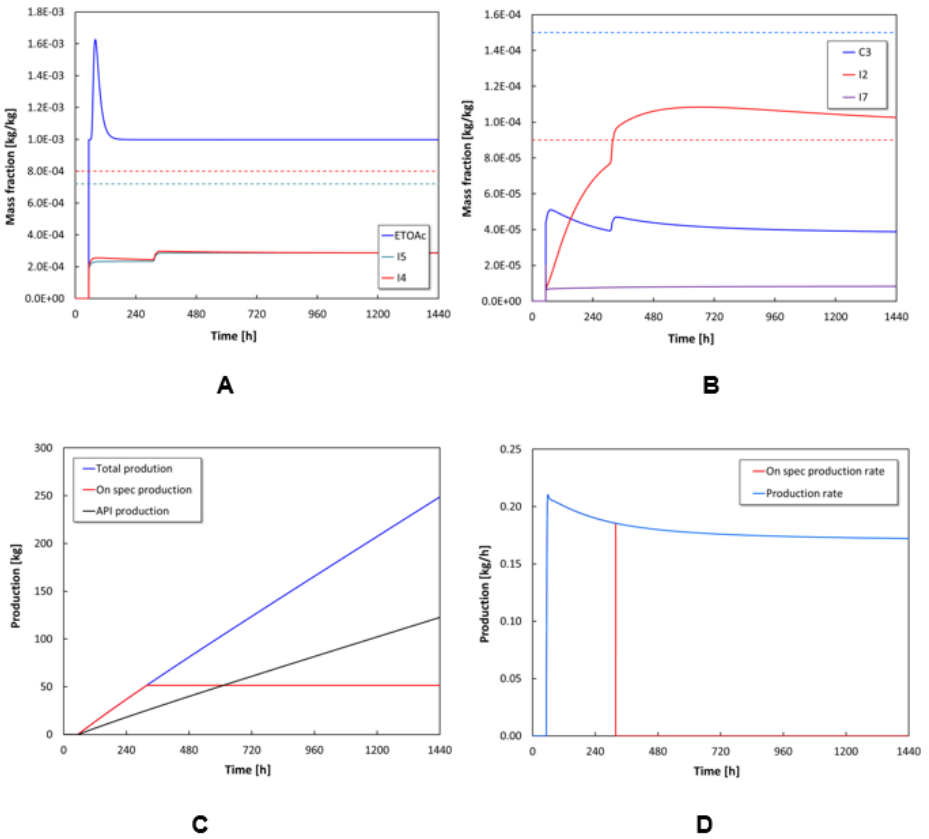

Figure 3: Plant key dynamics under total recycle (purge ratio = 0) at optimal wash factors (f_{w1} = 1.5 and f_{w2} = 5.6) with a process upset at t =300 hours, (a) I5, I4 and Ethyl acetate in the tablet (b) C3, I2 and I7 in the tablet overall impurities, (c) Total production (both on spec and off spec) and total API production, (d) on spec production rate and total production rate

Step 5 – Detailed Economics: In Table 1, the overall economics of the four process control alternatives during a standard operational cycle are listed where they have been compared against base case (originally reported in Benyahia et al. 2012). Analysis of the table illustrates all cases except for case B has better economic performance than the current base case. The best performing process alternative is the optimized base case. Analysis of optimized case B illustrates economically favourable operations in comparison to the current base case. However, concurrently analysing the optimized case B's performance during non-routine process operations illustrates that some of the economic gains during routine operations cycles will reduced due to the process alternatives increased sensitivity to non-routine process disturbances. Based on calculations performed on optimized case B, this case will lose the equivalent of 20,000-25,000 USD per production cycle due non-routine disturbances. Based on information listed in Table 1 as well as the understanding of process disturbances identified in Step 4, the optimized base case provides the best economic outcome out of the four process control alternatives examined. Since the optimized base case performed similarly to the current base case during process upsets

and because this type of operational change has minimal installation cost we can calculate the NPV of the optimized base case. Based on these values the NPV of the optimized base case would be 2.26 million USD in comparison to current operations. Note that this NPV is a differential analysis between base case and the optimized base case (case iv), which reduces the complexity and information required to carry out the analysis.

Table 1: Detailed economics of the process alternatives during routine operation cycles

	Costs ($/kg)	Case a	Case B	Optimized base case	Optimized case B
C8 (aliskiren free base - Lactone)	3,000	54,270	-31,350	-	-31,350

Marginal change in Profit per cycle		**$ 750,960**	**-$ 101,080**	**$ 839,272**	**$ 801,918**

4. Conclusions

In this work, a systematic shortcut decision-making framework for operational analysis of process alternatives with an application on integrated end-to-end pharmaceutical processes was proposed. Through the application of the framework, it was demonstrated that economic considerations need to be taken into account for routine and non-routine operations when selecting an operating mode. This framework can be advantageous for both retrofit design of existing pharmaceutical processes as well as early-stage process design development activities. Current and future work is to extend the application of the framework to select economic control structures to better manage process routine and non-routine operations.

Abstract

Antibodies are medically and experimentally important immune system proteins. By binding to foreign molecules with high specificity and affinity, they act as flags that guide the immune response. The high-quality binding characteristics of antibodies have led to their widespread use as both experimental reagents and therapeutic molecules. Due to their importance, the interactions between antibodies and antigens has been an ongoing area of research. Here, a non-redundant database of 492 antibody – protein complexes was studied. Using the CHARMM and Amber force fields, the energies of the complexes were minimized and the interaction energies of individual residues were determined. This revealed that the percent contributions to binding energy of amino acids follows an exponential decay, with only a few residues being responsible for most of the energy.

Keywords: Antibody, Antigen, Epitope.

1. Introduction

Antibodies are vital to the immune system as a line of defense against infectious diseases. The body continues to make antibodies even after an infection has been cured because the immunological memory lives long after infection or vaccination; and the antibodies undergo clonal expansion and differentiation after an immune response (Janeway et al. 2001). Antibodies are often used in research and are powerful tools in the study of proteins (Edwards et al. 2011). Antibodies are also a $100 billion global market as therapeutic agents (Ecker et al. 2015), including for autoimmune diseases and cancer (Zhou and Zhou 2014)(Buss et al. 2012). Identification of the binding sites of antibodies and their target molecules (i.e. antigens) is crucial for development in biomedical research applications such as pharmaceutical molecules and immuno-therapeutics (Chevalier et al. 2017).

The key performance feature of antibodies is the high specificity, high affinity manner in which they bind antigens. The portions of antigens that antibodies recognize are known as epitopes and antibodies bind only at these locations. This is achieved with six complementarity-determining regions (CDRs), which form the paratope of the antibody. Epitope residues must be close to one another in space and may also be located within a short stretch of continuous sequence. If so they are classified as linear epitopes and if not as structural epitopes.

For over two decades, features of antibody-antigen binding interfaces have been studied in detail. Initially, Mian et al. (1991) studied six antibody structures which included only one antigen. Work by Lo Conte et al. (1999) and Sundberg and Mariuzza (2002) studied 19 and 30 complexes respectively. The former analyses studied paratope features in more

detail when compared with epitope properties. W. Chen et al. (2009) studied interaction methods and molecular surface properties of both paratopes and epitopes in 155 protein-antibody complexes, with 53 unique structures. The work of Fellouse et al. (2004) constructed paratope libraries with a diversity of only four amino acids and studied the features of two complexes for the generation of synthetic antibody libraries. Ramaraj et al. (2012) studied features of 53 non-redundant complexes using change in solvent accessible surface area and distance cut offs. Kuroda and Gray (2016) studied the features of hydrogen bonds and shape complementarity in 6637 non-redundant protein-protein interfaces which included 191 antibody-antigen complexes. Nguyen et al. (2017) analyzed 403 antibody-antigen complexes using computational methods to find hydrogen bonds and van der Waals, hydrophobic and ionic interactions.

These previous studies have identified numerous features of paratopes and epitopes, including which amino acids are most commonly used, the distribution of linear versus structural epitopes, and the types of interactions that can occur. However, these studies have done so using binary metrics (e.g. residues are in contact or not, an epitope is linear or structural). Here, we use the CHARMM (Brooks et al. 2009) and Amber (Case et al. 2017) molecular mechanics force fields to quantify the percent contribution to binding of every residue in a database of 492 antibody-protein complexes. This permits a more nuanced assessment of interactions. To our knowledge, a similar study has not previously been conducted.

2. Methodology

Initially, 2498 antibody structures were gathered from the International Immunogenetics Information System 3D Structure Database (Ehrenmann et al. 2009). 1344 antibodies with at least five CDR mutations from one another were identified, of which 492 were in complex with protein antigens. Those structures were selected for this study.

Molecular mechanics force fields allow for the computational study of protein structures and interactions. Rosetta is the most commonly used force field for protein engineering. However, it is not well-suited for studying this database because its electrostatics potential is parameterized for the hydrophobic interiors of proteins rather than the polar exteriors (Alford et al. 2017). Instead, the CHARMM and Amber force fields were selected. Missing atoms were added and the overall energies of each of the 492 complexes were minimized in each force field. Next, the energies of interaction between every antibody residue and every antigen residue were tabulated. Due to the pairwise additive nature of the energy functions, the total energy can vary significantly from complex to complex and generally increases in magnitude as the total number of amino acids increases. Therefore, the energies were converted to the percent of total energy for each complex to facilitate comparisons between complexes.

In CHARMM, the calculated energies included van der Waals and electrostatic forces, while Amber accounted for van der Waals, electrostatics and solvation (columbic and non-columbic) energies. The usage of solvation energy in Amber can be explained by the differences in the electrostatic equations in CHARMM and Amber. The CHARMM equation includes an additional distance-dependent scaling factor that reduces energies to zero at distances of 12 Å or greater and accounts for the electrostatic shielding due to the solvent. Amber does not include this term but instead calculates solvation energy using the modified implicit Gibbs-Born model by A. Onufriev, D. Bashford and D.A. Case and

the Linear Combination of Pairwise Overlaps (LCPO) method. The van der Waals energy was calculated using the 12-6 Lennard Jones potential in both CHARMM and Amber.

3. Results and Discussion

3.1. Percent contributions to binding

The percent contribution to binding energy of residues was determined to follow an exponential decay, as shown in Figure 1. This was true for both antibody and antigen residues and with both force fields. The average R^2 of the exponential fits for antibodies were 0.957 ± 0.023 and 0.965 ± 0.021 with the Amber and CHARMM force fields, respectively. The corresponding antigen values were 0.958 ± 0.025 and 0.963 ± 0.023. For both force fields, the first several antigen residues typically contribute more to binding energy than an equal number of antibody residues. This suggests that on average some antigen residues have strong interactions with multiple antibody residues. Also, the percent contributions to binding energy of the first several residues are greater using CHARMM than with Amber. This is a result of the differences in the force fields and how they handle electrostatics shielding from solvent. Without experimental testing, it is not clear which is a more accurate prediction, but both force fields show the same exponential decay trend.

3.2. Antigen

Experimental studies have found that in most complexes five antigen residues are sufficient for specific and high affinity binding (Sykes et al. 2013; Pellois et al. 2002). To remove effects of small antigens biasing results, only the 385 complexes with protein antigens of 50 or more amino acids were considered in the antigen calculations. The five most attractive antigenic residues contribute an average of 62 % and 74 % of the total Amber and CHARMM binding energies, respectively. Notably, as can be seen in Figure 1, on average the sixth residue contributes less than 6 % of total binding energy for both force fields, which is less than 10 % of these values. Thus, residues that are "significant to binding" were defined as those that contribute at least these percentage thresholds to binding energy. It is important to note that these values are likely an overestimate of critical binding requirements, as five residues are enough to establish binding for the majority of antigens rather than half.

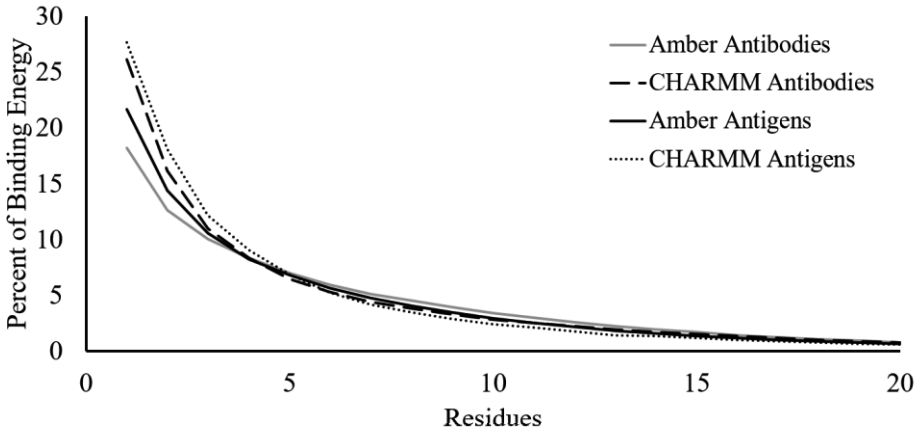

Figure 1: Average percentage of binding energy contributed by antibody and antigen residues

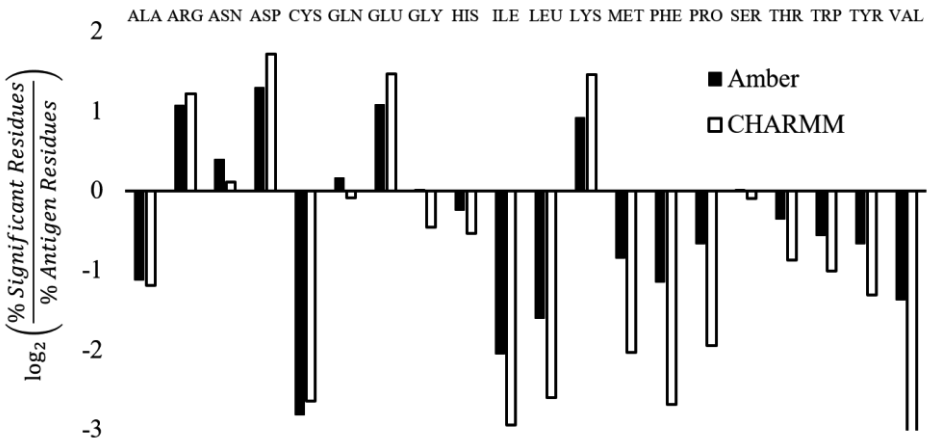

Figure 2: Log_2 change in amino acid usage in significant residues versus the antigens as a whole

Figure 2 depicts the Log_2 change in the relative usages of amino acids in the significant residues versus the antigens as a whole. The trends are consistent with expected behaviours: charged and acidic amino acids are overrepresented in the significant residues, hydrophobic amino acids (which are expected to be in the interior of antigens) are underrepresented, and most polar amino acids are significant at a rate that is comparable to their usage in antigens. In nearly all cases, the CHARMM values show larger magnitude over / underrepresentation than the Amber values, which arises from differing treatment of electrostatics shielding.

An important question in classifying epitopes is whether they are structural or linear. With known binding energy contributions, it is now possible to quantify the degree of linearity of epitopes instead of using a binary definition. Figure 3 shows the fraction of the threshold binding energy reached by the best consecutive 12 amino acid sequence in the antigens. 77 % of epitopes were at least 50 % linear, 27 % were at least 80 % linear and 11 % were at least 100 % linear in the Amber results. The corresponding CHARMM values were 70 %, 21 % and 7.5 %, respectively. Using alternative peptide lengths did not significantly change these results.

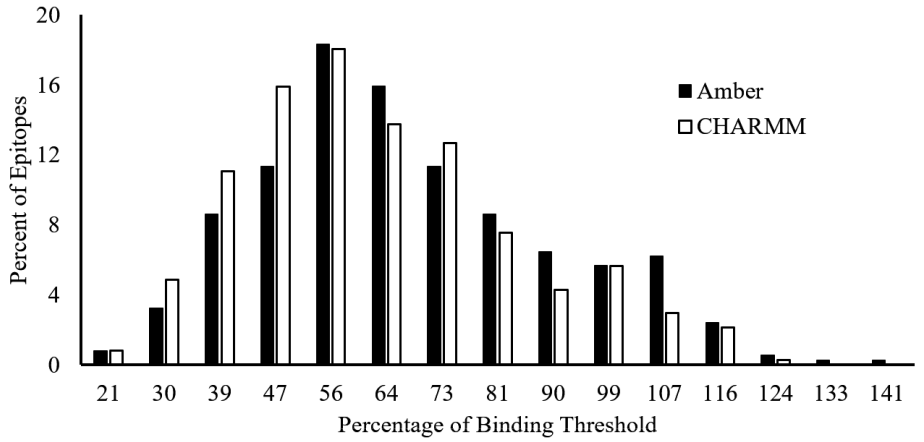

Figure 3: Percentage of binding threshold in the best 12 consecutive antigen amino acid sequence

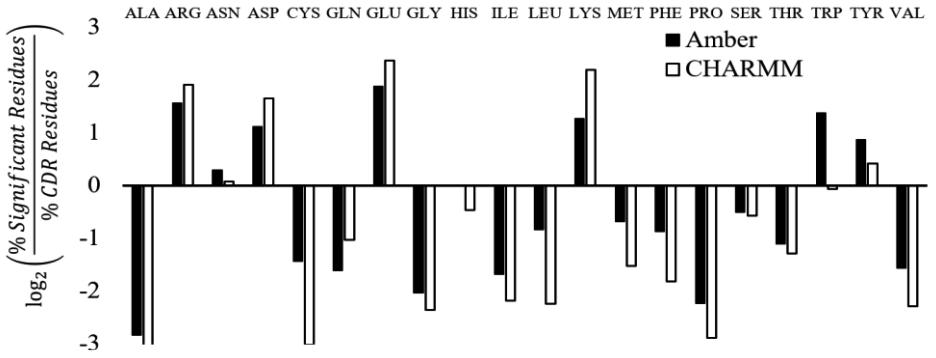

Figure 4: Log2 change in amino acid usage in significant antibody residues versus in the CDRs

3.3. Antibody

For the antibodies, significant residues were defined using the same percentage binding energies as required for the antigens. For both force fields, six amino acids were required on average to reach the thresholds in antibodies instead of five as in antigens. Figure 4 depicts the Log_2 change in amino acid usage in the significant residues versus the CDRs as a whole. The most notable difference between these values and the antigen ones are the increased importance of tyrosine and tryptophan (only in the Amber data). The importance of tyrosine in antigen binding is well-established (Ramaraj et al. 2012).
The distribution of significant amino acids among the CDRs followed expected trends. Using both force fields, the H3 CDR had about 35 % of the significant residues and H2 had ~22 %. The H1, L1 and L3 CDRs each had between 12 and 14 % of the significant residues and the L2 CDR contained around 4 %. This is consistent with the belief that H3 is typically considered the most important CDR for antigen binding and corresponds with previously observed mutation rates during affinity maturation (Pantazes and Maranas 2013).

4. Conclusions

We developed a non-redundant database of 492 antibody-protein complexes and used the CHARMM and Amber force fields to energetically minimize and analyze their binding interactions. To our knowledge, these data are the first quantification of the contributions to binding of single residues in antibodies and antigens. The primary finding is that the contributions follow an exponential decay. Considering the biomedical importance of antibodies, the knowledge that only a few antibody residues contribute most of the binding energy should aid in the creation of novel computational algorithms to design next generation therapeutics, vaccines and diagnostics.

Quantitative Analysis on the Relevance of Regulatory Constraints in Designing Pharmaceutical Manufacturing Processes

Hirokazu Sugiyama[a*], Yusuke Morikawa[a], Mai Matsuura[a], Menghe Xu[a]

[a]*Department of Chemical System Engineering, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan*
sugiyama@chemsys.t.u-tokyo.ac.jp

Abstract

This work presents the relevance of regulatory constraints on the outcome of process design in pharmaceutical manufacturing with a case study on waste solvent recovery. The role of the investigated process was to recover tetrahydrofuran from an azeotropic mixture with water and methanol. As the technologies to overcome the distillation boundary, different alternatives were modeled and evaluated in a multiobjective manner. The target concentration of recovered solvent, which cannot be altered because of regulations, was imagined to be modifiable, and two design problems, initial and extended, were formulated. A type of process that was found to be optimal in the extended problem was better than any of the optimal alternatives in the initial design problem. These results confirmed quantitatively that the way in which regulatory constraints are considered makes a difference in the outcome and that the appropriate formulation of a design problem is critical for pharmaceutical manufacturing processes.

Keywords: Multiobjective optimization, Active pharmaceutical ingredients, Waste solvent recovery, Azeotrope, Decision-making

1. Introduction

In the research & development of pharmaceuticals, time is regarded as the critical factor. Limited time is available for the process design, which makes it difficult to avoid the launch of sub-optimal processes for commercial production. After the launch, compliance to the regulations known as Good Manufacturing Practice (GMP) becomes the most important factor, and GMP itself functions as the hard constraint. The environment hinders companies from substantial changes, such as changes in process technologies, even when the change itself is beneficial.

Many process systems engineering (PSE) researchers are entering the field of pharmaceutical manufacturing in order to design/redesign inherently superior processes. García-Muñoz and Mercado (2013) presented a method for selecting raw materials in active pharmaceutical ingredient (API) manufacturing; Jolliffe and Gerogiorgis presented process models of continuous manufacturing of ibuprofen and artemisinin (2016); Sugiyama, et al. (2017) presented applications of PSE in the design of tablet and injectable manufacturing processes. However, the questions of (i) to what extent the obtained solutions are constrained by the regulations, and (ii) whether different conclusions would be drawn if the regulatory conditions had been treated differently, have not been addressed in previous studies.

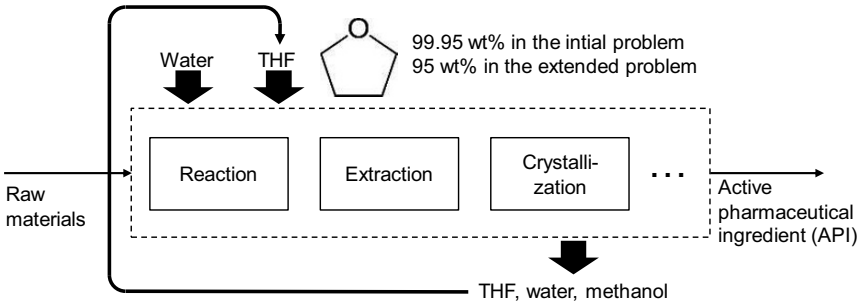

Figure 1. Overview of the main process and the THF recovery process

We present the relevance of regulatory constraints in the design of pharmaceutical manufacturing processes. Case study is performed on solvent recovery process for an actual API manufacturing, which discharges an azeotropic mixture of tetrahydrofuran (THF), water and methanol. Multiple alternatives are generated for recovering THF, and are evaluated considering economy, environmental impacts, and environmental, health and safety (EHS) hazard. Here, the design problem is formulated in two different ways, either considering the regulatory constraint as given (*initial design problem*) or as modifiable (*extended design problem*). The obtained results in both design problems are compared to quantify the impact of the way to consider the regulatory constraint differently. The full results are being submitted elsewhere (Sugiyama, et al, 2018).

2. Definition of design problem

2.1. Process overview

An overview of the investigated process is shown in Figure 1. The API production process (main process) is operated batch-wise with unit operations such as reaction, extraction, and crystallization. The process uses water and THF as solvents, where the concentration of the inlet THF is specified as higher than 99.95 wt%. After each batch operation, an azeotropic mixture of THF, water and methanol is discharged, with the molar ratio of 64.3%, 35.5% and 0.2%, respectively. Methanol is a byproduct of the reaction, i.e., methanol has to be removed constantly in the recovery process in order to avoid accumulation in the main process. In the current status (as-is process), the mixture is sold to an external company at the price of USD 0.5 to 1.0 per kg-mixture. The inlet THF is purchased at a higher price, e.g., USD 4.0 per kg, which triggered the investigation whether and how to separate the solvent mixture to recover THF onsite.

2.2. Problem formulation

Equation (1) presents the general mathematical formulation of the design problem.

$$\begin{aligned} & \max_{x} \left(Y_{\mathrm{NPV}}(x), Y_{\mathrm{CO_2}}(x), Y_{\mathrm{E}}(x), Y_{\mathrm{H}}(x), Y_{\mathrm{S}}(x)\right) \\ \text{s.t.} \quad & \boldsymbol{C}(x) \geq \boldsymbol{C}_{Problem} \\ & y_{\mathrm{NPV}}(x) \geq y_{\mathrm{NPV}}(\mathrm{as-is}) \\ & x \in P_{Problem} \\ & Problem \in \{\mathrm{Initial}, \mathrm{Extended}\} \end{aligned} \tag{1}$$

where x represents a process alternative, Y is a normalized objective function regarding net present value (NPV), CO_2 reduction, and EHS hazard, y is the original objective function before normalization, P is a set of alternatives depending on *Problem*, which is further an element of initial/extended design problems. The first constraint indicates that the concentration vector of the recovered solvent, $\boldsymbol{C}$, needs to be larger than the target $\boldsymbol{C}$ depending on *Problem*; the second indicates that the NPV of an alternative needs to be higher than that of the as-is process. The target THF concentrations were set as 99.95 wt% and 95 wt% in the initial and extended design problems, respectively.

The working assumption of this work is presented in Eq. (2).

$$\boldsymbol{Y}^{\mathrm{opt}}|_{Problem=\mathrm{Extended}} - \boldsymbol{Y}^{\mathrm{opt}}|_{Problem=\mathrm{Initial}} \geq 0 \tag{2}$$

where the vector $\boldsymbol{Y}^{\mathrm{opt}}$ represents the evaluation result of an optimal alternative. If a valid relation in Eq. (2) is found, it indicates that the optimal solution in the extended problem is better than any of the optima in the initial problem, i.e., the way in which the regulatory constraint is considered makes a difference in the final outcome.

2.3. Evaluation indicators

Equations (3) to (7) presents the evaluation indicators: y_{NPV} [USD] for NPV, y_{CO2} [kg-CO_2/kg-inlet] for CO_2 reduction, $y_{\mathrm{E,\,H,\,S}}$ [kg/kg-inlet] for EHS hazard. Eqs. (5) to (7) are adopted from Sugiyama et al. (2008), which is further based on the hazard assessment method of Koller et al. (2001) that translates the physical property of chemicals—e.g., flash point—to a nondimensional index value I. The index I has the range from 0 (least-hazardous) to 1 (most-hazardous) and can be calculated in different categories. In this work, the following 10 categories were considered: mobility, fire/explosion, reaction/decomposition, and acute toxicity for safety; irritation and chronic toxicity for health; and water-, air-mediated effects, and persistency for environment.

$$y_{\mathrm{NPV}} = -INV + \sum_{i=1}^{N} \frac{CF_i}{(1+r)^i} \tag{3}$$

$$\begin{aligned} y_{\mathrm{CO_2}} = {} & \text{Decreased } \mathrm{CO_2} \text{ in THF production} \\ & - \text{Increased } \mathrm{CO_2} \text{ in THF recovery} \end{aligned} \tag{4}$$

$$y_{\mathrm{E}} = \sum_{cE} \left(\sum_{j} (z \cdot \max_{F}(m_j{}^{F}) \cdot I_j{}^{cE}) + \sum_{OUT} \sum_{j} (m_j{}^{OUT} \cdot I_j{}^{cE}) \right) \tag{5}$$

$$y_{\mathrm{H}} = \sum_{cH} \max_{j}(m_j{}^{UN} \cdot I_j{}^{cH}) \tag{6}$$

$$y_{\mathrm{S}} = \sum_{cS} \max_{F} \left(\sum_{j} m_j{}^{F} \cdot I_j{}^{cS} \right) \tag{7}$$

Here, INV [USD], CF_i [USD], r [–], and N [year] represent investment cost, annual cash flow in year i, interest rate, and the planned years of operation, respectively. The

parameter m_j^F [kg/kg-inlet] represents the mass flow of substance j relative to the amount of the inlet solvent mixture in flow F, and m_k^{OUT} [kg/kg-inlet] represents that in waste effluent flow OUT, and m_j^{UN} [kg/kg-inlet] is the unit mass (UN), i.e., 1 kg of substance j in the process. The parameters I_j^{cE} [–], I_j^{cH} [–], and I_j^{cS} [–] are the hazard index values of substance j in category cE, cH, and cS, respectively. The parameter z [–] is the fraction of mass emitted to the environment in case of an accident from maximum mass present in the overall process, and it was set as 0.1 in the calculation.

To facilitate the multiobjective evaluation, the normalized evaluation indicator Y [–] was defined for each design objective, as shown in Eq (8), where x^* is an alternative considered in the initial design problem. The indicators y_{NPV} and y_{CO2} are to maximize; y_{E}, y_{H} and y_{S} are to minimize. The Ys are all to maximize.

$$\begin{cases} Y(x)_{\mathrm{NPV,CO_2}} = \dfrac{y(x)_{\mathrm{NPV,CO_2}}}{\max\limits_{x^*}\left(y(x^*)_{\mathrm{NPV,CO_2}}\right)} \\ Y(x)_{\mathrm{E,H,S}} = \dfrac{y(x)_{\mathrm{E,H,S}} - \min\limits_{x^*}\left(y(x^*)_{\mathrm{E,H,S}}\right)}{\max\limits_{x^*}\left(y(x^*)_{\mathrm{E,H,S}}\right)} \end{cases} \tag{8}$$

3. Generation and analysis of process alternatives

3.1. Generation of process alternatives

Figure 2 (a) shows the ternary phase diagram of the THF/water/methanol system that was calculated using the UNIQUAC property estimation method in Aspen Plus®. The point "inlet" represents the concentration of the waste solvent mixture (64.3%, 35.5%, 0.2%). The constraint lines I and II indicate the required concentration of THF in the initial and extended design problems, respectively; the line III indicates the required methanol concentration, which is common to both problems. The target area of the initial design problem is almost on the vertex of THF; the target area of the extended design problem contains that of the initial problem and is stretched on the top left side of the triangle. For overcoming the distillation boundary, the alternatives of zeolite membrane, pressure swing, azeotropic distillation, and entrainer processes using ethylene glycol or glycerol were generated, and modelled using Aspen Plus®. The main paths of the first three processes are indicated in Figure 2 (a).

3.2. Analysis of process alternatives

The flow rate of the "inlet" was set at 100 kmol/hr, which was fast enough to recover THF within the cycle time of the main process. The annual operating time of this continuous recovery process was estimated based on the annual production amount of the main process. Figure 2 (b) shows the flowsheet of the pressure swing process, where P_1 [atm] indicates the pressure of the first column. The standard pressure P_1 was set as 0.1 atm. Notably, in the extended design problem, the processes inside the dotted line were sufficient to reach the relaxed target concentration, when $P_1 \leq 0.07$ atm. This simplicity lead to several advantages in the evaluation results shown in the next chapter.

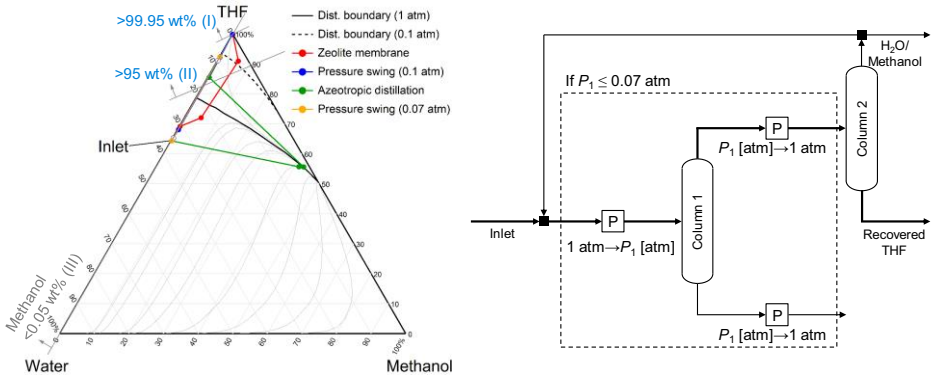

Figure 2. (a) ternary phase diagram of THF/water/methanol (b) pressure swing process

4. Multiobjective evaluation of process alternatives

4.1. Multiobjective evaluation result

Figure 3 (a) shows the result for y_{NPV}. All the alternatives except for the azeotropic distillation process showed a larger y_{NPV} than the as-is process; i.e., economically it makes sense to build and operate a recovery process. The azeotropic distillation process showed a negative value with violation of the constraint on y_{NPV} (see Eq. (1)), because of the poor THF yield and the heavy investment requirements. In the initial design problem, the zeolite and the pressure swing processes resulted in large values of y_{NPV}, which are followed by the two entrainer processes. The main contributors to this result are the THF yield, as well as the investment cost that is affected by the number of columns. In the extended design problem, the value of y_{NPV} increased in all comparable alternatives, and the largest value was given by the pressure swing process (P_1 = 0.07 atm) that is presented in the graph.

Figure 3 (b) shows the result of y_S. As defined in Eq. (7), the indicator highlights the hazard of the flows with the maximum flow rate, which in this case were the flows after recycling. This setup resulted in the large indicator values for the zeolite membrane and the pressure swing processes that showed large maximum flow rates. Similar to y_{NPV}, an improvement was observed between the initial and extended design problems, and the smallest value was given by the pressure swing process (P_1 = 0.07 atm).

4.2. Implications for process design

Figure 3 (c) shows the multiobjective evaluation results using the normalized indicators for the zeolite membrane, pressure swing, and entrainer processes in the initial problem, and for the pressure swing process (P_1 = 0.07 atm) in the extended problem. The validity of Eq. (2) can be seen by investigating the difference in Y between the pressure swing process with P_1 = 0.07 atm and the four alternatives in the initial design problem, all of which were Pareto-optimal. Remarkably, the maximum Y_{NPV} increased by about 17% from the initial to the extended design problem. These results quantitatively confirmed our working assumption that the way in which the regulatory constraint is considered makes a difference regarding the process performance and the alternative to be chosen.

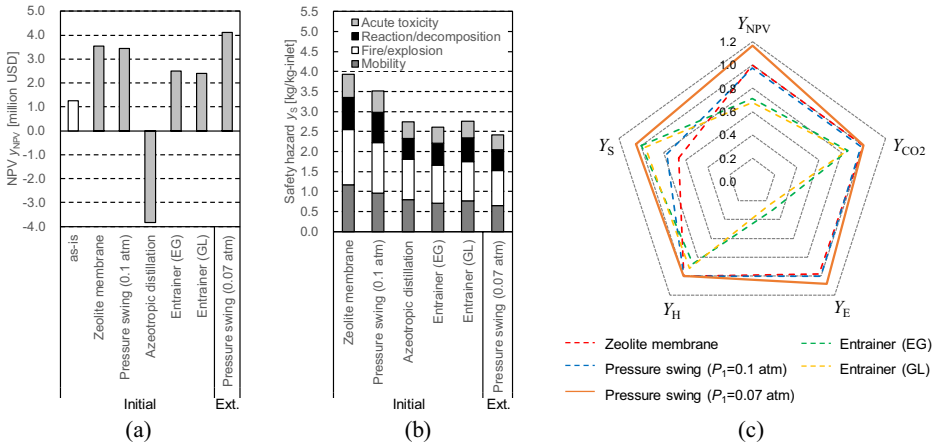

Figure 3. Evaluation results of (a) NPV, (b) safety hazard, and (c) normalized indicators

5. Conclusions

We presented a quantitative analysis of the relevance of regulatory constraints in designing pharmaceutical manufacturing processes. In the case study on waste solvent recovery, an optimal alternative found in the extended design problem showed performance equal to or better than any of the optimal alternatives in the initial design problem. These results confirmed quantitatively that the way to consider the regulatory constraint made a difference in the assessment results and had an impact on the decision.

A Simulation-based Optimization Approach to Develop Personalized Colorectal Cancer Screening Strategies

David Young, Selen Cremaschi*

Department of Chemical Engineering, Auburn University, Auburn, AL 36849, USA
selen-cremaschi@auburn.edu

Abstract

Colorectal cancer (CRC) is the third leading cause of death due to cancer, with survival closely linked to the stage of cancer at diagnosis. This paper presents a simulation-based optimization approach to generate an optimal screening strategy for CRC. We applied our approach to male and female cohorts, and studied the impact of identified strategies on CRC incidence and death rates for the 1975 US population (a population that had little to no screening). The best strategy identified for men was a colonoscopy every 40 years starting at age 32 and ending at age 96 and for women was a FIT every 17 years starting at age 49 and ending at age 100. If those strategies were implemented for the US population of 1975, it would have resulted in a 45 % reduction in CRC cases and a 53 % reduction in CRC related deaths compared to no screening.

Keywords: Colorectal Cancer, Microsimulation, Cancer Screening, Genetic Algorithm

1. Introduction

Colorectal cancer survival is closely linked to stage of cancer at diagnosis, starting from 92% for early stage diagnosis, stage 1, decreasing to 11% for advanced stage, stage 4. Currently, there are three main methods for CRC screening, endoscopy, stool testing, or computed tomography (CT) scans, and numerous guidelines for CRC screening, e.g., by American College of Gastroenterology (Rex et al., 2009) and by American Cancer Society (Smith et al., 2016). These guidelines, or strategies, are summarized in Fig. 1(A). A screening strategy includes: (1) recommended screening method(s), (2) frequency of screening for each method, and (3) start and potentially end of screening window. The ideal outcome from screening is to disrupt the natural progression pathway to CRC.

An estimated 85% of all CRC cases develop through what is referred to as an adenoma-carcinoma sequence (Gopalappa et al., 2010): A healthy individual develops a precancerous lesion, known as an adenoma within the colon. Not all adenomas will become cancerous, but of the ones that do become cancerous, their probability of transitioning to a cancerous state increases with the size of the adenoma. The remaining 15% of CRC cases occur through a non-visible, or flat, adenoma with no immediate visual signs of an adenoma. The adenoma-carcinoma pathways are demonstrated in Fig. 1(B).

Due to the complexity of CRC and the ethical issues that arise from direct studies of CRC progression, researchers have turned to the use of microsimulations (e.g., Loeve et al., 2000, Frazier et al., 2000, Rutter and Savarino, 2010) that contain a CRC natural development and progression, i.e. natural history model, to conduct epidemiological studies. These microsimulation models have been used primarily to study the cost

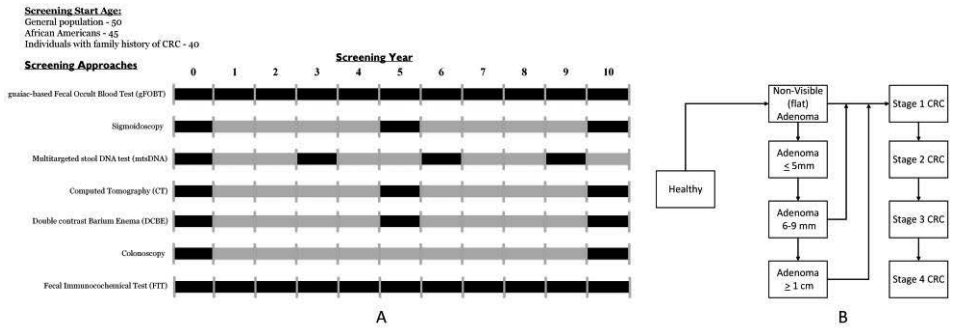

Figure 1. A) Recommended CRC screening strategies. B) Adenoma-carcinoma pathways.

effectiveness of specific screening strategies using what-if analysis. For example, they specify a set of screening strategies, e.g., colonoscopy every 10 years starting at the age of 50 and a FIT every 2 years starting at the age of 45 (Haug et al., 2015), and compare these strategies in terms of their cost-effectiveness and health outcomes. However, the optimum screening strategy may be different from the considered strategies, and it is difficult to efficiently explore all potential screening strategies using what-if-analysis. In this paper, we introduce a simulation-based optimization (SIMOPT) framework to explore the screening strategy space using a CRC microsimulation for efficiently determining the optimum screening strategy for a given cohort.

2. Model Framework

The overall framework can be separated into a CRC natural history model and a screening section, which are implemented in a microsimulation, and an optimization component, which generates various screening strategies that are passed to the microsimulation. For each strategy, the microsimulation constructs a cohort of individuals and their life histories without screening using the CRC natural history model. Then, each individual is screened according to the strategy altering their life history. The microsimulation is repeated multiple times for statistical significance. At completion, the microsimulation computes the cohort's expected gain in life span and expected costs associated with screening and cancer, which are passed to the optimization component for evaluation.

2.1. Natural History

The CRC natural history model assigns each individual a death year and CRC related parameters randomly drawn from distributions constructed by Rutter and Savarino (2010). An individual's death year is stochastically assigned based on the Centers for Disease Control's 2000 life tables (Arias, 2002). The individual's CRC related parameters are used to calculate the development of adenomas, preclinical cancer, clinical cancer, and death due to cancer within their lifetime. These calculations utilize CRC-SPIN's continuous time model (Rutter and Savarino, 2010). The CRC-SPIN's model only incorporates age and gender as CRC related risk factors, and the adenoma-carcinoma pathway, where the probability of transition to cancer is proportional to the adenoma's size. A full description of CRC-SPIN model can be found in Rutter and Savarino (2010).

2.2. Screening

The screening component of the microsimulation takes a screening strategy and an individual's CRC natural history as inputs and outputs an updated life history, where that

individual undergoes screening according to the strategy. The simulation timeline is discretized into one-year increments. The simulation determines when an individual is due for screening, preforms the screening, and takes appropriate action given the screening result. Our model currently assumes a 100 % compliance rate for each individual for every screening strategy and follow-up procedure.

The simulation currently includes three possible screening tests: FIT, sigmoidoscopy, and colonoscopy. For each individual, the screening section determines if an individual has any adenomas or preclinical cancer, as well as location and size of each adenoma at the time of screening. An individual is defined to be at a preclinical cancerous state if the individual has CRC that has not yet been detected or become symptomatic. Detection rate of adenomas and cancers are dependent on the location of the adenoma/cancer, size of the adenoma, how far the testing method reaches within the colon, and the test's sensitivity and specificity (whose values are taken from Aronsson et al., 2017). Each screening test is assumed to have no risk of complications associated with them. Upon positive FIT results, the simulation schedules a diagnostic colonoscopy. Once an adenoma is detected via colonoscopy or sigmoidoscopy it is removed, and the corresponding adenoma progression pathway to CRC is also removed. If the sigmoidoscopy detects any adenomas, a diagnostic colonoscopy is also scheduled. If a sigmoidoscopy or colonoscopy detects preclinical cancer, that individual then transitions into a clinically detected cancer state, where the stage of cancer at diagnosis is potentially less advanced than that of the natural history. Once an individual transitions into a clinically detected CRC state, they are no longer eligible for screening, and instead receive treatment for CRC. The treatment methods are not currently modelled in our simulation but the associated average annual cost of treatment is considered.

2.3. Optimization

The optimization component utilizes genetic algorithm as implemented in the package Distributed Evolutionary Algorithms in Python outlined by Fortin et al (2012). Genetic algorithm was chosen because it is a derivative-free optimization approach and is easy to implement as a wrapper around a microsimulation. In theory, the identification of optimum screening problem can be modelled as a stochastic program, yielding a mixed integer linear program for its deterministic equivalent. However, the sheer size of scenarios (which is the size of microsimulation cohort – 1 million individuals) necessary to represent the population adequately make this approach computationally prohibitive.

The objective is to minimize the total incurred cost due to CRC, which includes screening, diagnostic procedures, and treatment costs, per total quality adjusted life years (QALY) gained due to screening. The decision variables are screening type (w), frequency (x), start age (y), and end age (z). For each decision variable set, the total incurred cost and QALY gained are calculated using the microsimulation.

The objective function is given in Eq. (1), where C_i is the total incurred cost due to CRC and $QYG_{i,n}$ is the QALY gained for individual $i \in I = \{0,1,\dots,|I|\}$ of the simulated cohort for the n^{th} iteration of the microsimulation. Eq. (2) calculates $QYG_{i,n}$ using QALY per cancer stage ($s \in S = \{0,1,2,3,4\}$), $QY_{s,i,t,n}$, based on time of death without screening, $Td_{i,n}$, and time of death with screening, $Td'_{i,n}$. In set S, $s = 0$ represents a cancer free state. In Eq. (3), $C_{i,n}$ is defined as the sum of screening costs, $Cs_{i,t,n}$, and costs due to cancer treatment, $Cc_{s,i,t,n}$, over the individual's lifetime. The values of $Cs_{i,t,n}$, $Cc_{s,i,t,n}$, and $QY_{s,i,t,n}$ are determined by the microsimulation, and these relationships are represented by Eq. (4).

$$min \ \frac{1}{|N|}\sum_{n=1}^{|N|}\frac{\sum_{i=1}^{|I|} C_{i,n}}{\sum_{i=1}^{|I|} QYG_{i,n}} \tag{1}$$

$$C_i = \sum_{t=0}^{Td'} Cs_{i,t} + Cc_{s'_{i,t},i,t} \qquad s'_{i,t} \in S, n \in N \tag{2}$$

$$QYG_i = \sum_{t=0}^{Td'} QY_{s'_{i,t},i,t} - \sum_{t=0}^{Td} QY_{s_{i,t},i,t} \qquad s'_{i,t} \in S, s_{i,t} \in S \tag{3}$$

$$Cs_{i,t,n} = f(w,x,y,z), Cc_{s_{i,t,i,t,n}} = g(w,x,y,z), QY_{s_{i,t,i,t,n}} = h(w,x,y,z) \tag{4}$$

$$w \in W = \{\text{Colonoscopy, Sigmoidoscopy, FIT}\} \quad x \in X = \{1,2,\dots,40\}$$
$$y \in Y = \{20,21,\dots,80\} \qquad z \in Z = \{50,51,\dots,100\} \tag{5}$$

Each gene in the genetic algorithm corresponds to a decision variable, and a unique gene set defines a screening strategy. The algorithm randomly constructs a population of gene sets, evaluates the fitness value of each set as defined by Eq. (1), and induces random changes amongst the initial population to create a new generation of child gene sets. The changes are the random mutations of genes and crossover. The algorithm keeps track of the best preforming set of genes, and continues the generation of child gene sets for a predetermined number of iterations. At termination, it outputs the best three and worst three sets of genes, or screening strategies.

3. Results

The framework was used to determine the optimum screening strategies for both a male cohort and a female cohort. The initial population of gene sets included current screening guidelines for each screening type (three gene sets) and seven randomly constructed screening strategies. The gene sets were then allowed to evolve for ten generations. The probabilities of gene crossover and mutation were 20 % and 50 %, respectively. For each set of genes, the microsimulation's cohort size was one million individuals to coincide with previous screening studies (e.g. Roberts et al., 2007, Loeve et al., 2000). Each individual in the cohort is assumed to be born at time zero. The simulation was run for one hundred iterations, where each iteration had its random number generator seeded by the iteration number to maintain consistency over the comparison of screening strategies. The associated costs were discounted at a rate of 3 % each year after the start of the simulation to account for the time value of money.

Table 1 summarizes the three best and worst screening strategies identified by the framework. Strategies BF and CM (Table 1) closely resemble current recommended screening strategies (Fig. 1(A)). Identification of the accepted screening strategies can be interpreted as a validation of the framework. The results suggest that starting screening later in life (65+ years) yields the highest costs per QALY gained as adenomas developed early in life might have already progressed to CRC. The best strategies favor the use of colonoscopy, which visually inspects the entire colon for adenomas and CRC.

The best strategy identified for the male cohort (AM – Table 1) suggests screening with colonoscopy once every 40 years, at ages 32 and 72. This result demonstrates the importance of early screening. When comparing strategy AM with a similar screening strategy, only starting later in life, it is clear that the early screening has a large effect (e.g. a colonoscopy every 40 years starting at age 64 and ending at 96 yields a cost per QALY gained of $ 12,226.10). A plot comparing the number of clinical CRC cases with and

without screening for the male cohort reveals a small reduction in total number CRC cases due to the initial screening at age 32. However, screening at age 32 deceases the maximum total adenomas in the cohort by 18 %.

Table 1. The three best and worst gender specific screening strategies suggested by the framework

	Female			Male		
	Strategy Name	Screening type, Frequency (y), Start age (y), End age (y)	Cost per QALY gained ($/y)	Strategy Name	Screening type, Frequency (y), Start age (y), End age (y)	Cost per QALY gained ($/y)
Best 3 strategies	AF)	FIT, 17, 49, 100	$ 2,167.41	AM)	Colonoscopy, 40, 32, 96	$ 1,396.25
	BF)	Colonoscopy, 10, 50, 100	$ 2,201.99	BM)	Colonoscopy, 27, 38, 100	$ 1,498.53
	CF)	Colonoscopy, 22, 38, 82	$ 2,626.69	CM)	Colonoscopy, 13, 44, 100	$ 2,042.36
Worst 3 strategies	DF)	Sigmoidoscopy, 1, 80, 92	$ 64,136.28	DM)	Colonoscopy, 13, 80, 100	$ 367,638.92
	EF)	Sigmoidoscopy, 17, 80, 95	$ 74,976.68	EM)	Sigmoidoscopy, 11, 80, 88	$ 433,578.40
	FF)	Sigmoidoscopy, 17, 80, 92	$ 74,976.68	FM)	Sigmoidoscopy, 13, 80, 100	$ 453,126.84

The best strategy identified for the female cohort (AF- Table 1) suggests screening with FIT once every 17 years starting at age 47. The large deviation from the recommended FIT screening strategy may be an artifact of employing diagnostic colonoscopy with perfect compliance upon a positive FIT result. The best screening strategies identified for the female cohort have higher costs per QALY gained than the ones for the male cohort. Males have higher risk of developing CRC than females (Rex et al., 2009), which is also reflected in our microsimulation. Data used to determine the model parameters had 33 % more cases of CRC for males than females (Rutter and Savarino, 2010). Hence, screening has a higher impact on QALY gained for a male cohort.

We applied strategies AF and AM (Table 1) to the 1975 US population, a population in which screening for CRC was not prevalent. We assumed 100 % compliance rate and no risk of complications from screening to investigate the impact screening would have had on the population's CRC incidence and death rate. Figure 2(A) reveals that the screening strategies reduced CRC related deaths by an average of 53 % and decreased the clinical CRC incidence rate by an average of 45 %. Figure 2(B) demonstrates an average of 66 % reduction in the total number of adenomas and an average of 51 % reduction in preclinical CRC incidence. The reduction of the adenomas is responsible for the overall reduction in CRC incidence both clinical and preclinical as well as the reduction of death due to CRC by removing the progression pathway to CRC. These drastic reductions were expected because the original 1975 population received no screening. It should be noted that our 100 % compliance rate assumption artificially inflates the reductions observed in CRC incidence and death rates due to screening. The current compliance rate to colonoscopies is 38 % (Aronsson et al., 2017). Assuming a linear relationship (as a back of the envelope estimation), the observed reductions of CRC related deaths and CRC incidence would have been 20 % and 17 % respectively, which are still significant.

4. Conclusion and Future Work

In this paper, we present a framework to identify a potentially optimal screening strategy for CRC. The framework employs a microsimulation to model the natural progression of CRC within an individual, and to alter the CRC progression using a screening strategy. A genetic algorithm was chosen to determine the optimal screening strategies for male and female cohorts. We applied the best screening strategies identified to the 1975 US population to investigate the effect screening would have had on that population. It was shown that the framework identified screening strategies that are similar to the current guidelines. It should be noted that the current guidelines only consider gender and CRC

history as their risk factors, and hence the similarity of our results to current guidelines increases the confidence in our framework. Future work will focus on incorporating imperfect compliance rates for screening and a diverse set of CRC risk factors within our natural history section, to further describe our investigated cohort creating a more personalized screening strategy.

Abstract

This work presents a model-based economic evaluation of batch and continuous manufacturing technologies for the solid drug products. The intended phase of applications is during clinical development where process/technology needs to be specified along with the development of formulation. The research was conducted in the three steps: (I) generation of alternatives and recognition of uncertainty, (II) creation of the evaluation models, and (III) interpretation of the evaluation results. As a case study, net present values of the process alternatives using either batch or continuous technology were calculated using industrial data, which were compared considering process uncertainty. Monte Carlo simulation was applied to obtain the difference of net present value between the two alternatives as a probability distribution, which could support more informed decision-making.

Keywords: Continuous manufacturing, Monte Carlo simulation, Economic evaluation, Uncertainty analysis, Decision-making.

1. Introduction

In the pharmaceutical industry, processes and products are designed in conjunction with clinical development. Generally, the results of clinical trials determine the necessary amount of active pharmaceutical ingredients (APIs) per product, and the manufacturing processes are designed accordingly. Continuous manufacturing is a novel technology that is being intensively developed both in the academia and in the industry, especially for the manufacturing of solid drug products (Ierapetritou et al., 2016). The choice between batch and continuous technologies affects the clinical development as well as the commercial production largely regarding the economy, quality, safety, and other technical aspects.

Various kinds of studies have been conducted on continuous manufacturing. Case studies were presented which compared two technologies regarding economic performance (Schaber et al., 2011), and product quality (Järvinen et al., 2015). Sundaramoorthy et al (2012) proposed a framework of capacity planning in drug product manufacturing by considering the uncertainty of clinical trials using continuous manufacturing; Walther et al (2015) compared the economic performance of batch and

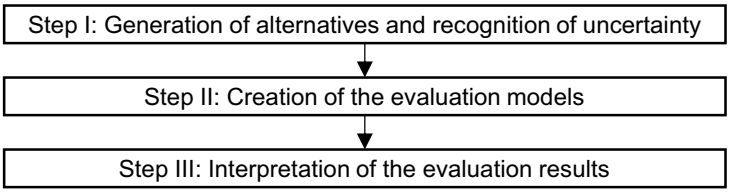

Figure 1 Research strategy for economic evaluation of solid drug products

continuous technologies in biopharmaceutical manufacturing considering uncertainty in technical transfer, product failure during development, and product demand profile. However, general evaluation tools are still to develop, which can support the choice of the batch and continuous technologies with incorporating uncertainty at both clinical development and production stages. To this end, we present an uncertainty-conscious economic evaluation of the two technologies for solid drug product manufacturing, using net present value (NPV) from clinical development to production as the indicator.

2. Research strategy for economic evaluation

Figure 1 shows the three steps of this study: (I) generation of alternatives and recognition of uncertainty, (II) creation of the evaluation models, and (III) interpretation of the evaluation results.

2.1. Generation of alternatives and recognition of uncertainty

In the first step, design alternatives and possible uncertainties at the stages of clinical development and commercial production are listed in order to identify the input parameters to be considered. Table 1 shows the overview of the design alternatives regarding tablet products and the manufacturing processes. Regarding the products, formulation needs to be considered because different types of tablets containing different amount of API are often required for clinical trials. In the industry, two strategies are widely recognized, i.e., “same tablet weight” with different API content and “same composition ratio” with different tablet weight. Given the product, different combinations of unit operations are possible, which is summarized in Figure 2 as the superstructure. Generally, there exist three manufacturing methods: wet granulation, dry granulation, and direct compaction methods. Milling and coating processes are optional, which means that the necessity of these processes is judged mainly by the type of the

Table 1 Design alternatives of pharmaceutical tablets and the manufacturing processes

Coating	A.	With	B.	Without
Technologies	A.	Batch technology	B.	Continuous technology
Granulator	A.	Fluidized bed granulator	B.	High shear granulator

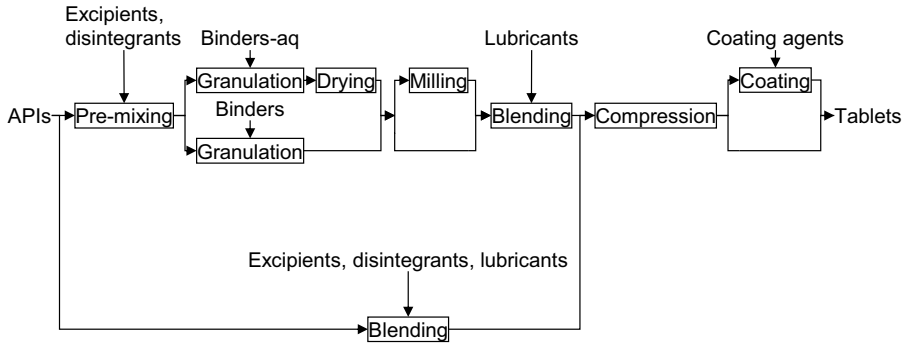

Figure 2 Superstructure of pharmaceutical tablet manufacturing processes

product. After specifying the manufacturing process, the details of unit operations are determined including the choice of batch and continuous technologies and machine types such as fluidized bed and high shear granulation machine. Given the unit operation, there is a range of the process parameters such as blade rotation speed and manufacturing rate. The above mentioned discrete and continuous options need to be specified along with the clinical development towards commercial production, even when some necessary information is unknown. To deal with such decision-making under uncertainty, one powerful approach is Monte Carlo simulation, as Walther et al. (2015) demonstrated in the work of biopharmaceutical process design. We also adopted this simulation technic to incorporate parameter uncertainty in the evaluation result in order to assist more informed decision-making.

2.2. Creation of evaluation models

In the second step, economic evaluation models are developed that can reflect the characteristics of each process and the effect of parameter uncertainty into the result. The objective function is determined as NPV [\$] where the costs for both clinical development and commercial production are considered. In this study, NPV is defined by Eq.(1):

$$NPV = -\sum_{i=0}^{\tau_{\mathrm{dev}}} \frac{C_{\mathrm{dev}}(i)}{(1+r)^i} - \frac{C_{\mathrm{invest}}}{(1+r)^{\tau_{\mathrm{dev}}}} + \sum_{i=\tau_{\mathrm{dev}}}^{\tau_{\mathrm{dev}}+\tau_{\mathrm{sales}}} \frac{C_{\mathrm{sales}}(i) - C_{\mathrm{op}}(i)}{(1+r)^i} \tag{1}$$

where τ_{dev} [y] and τ_{sales} [y] represent the estimated time required for launch and the selling period from launch, respectively. The parameters $C_{\mathrm{dev}}(i)$ [\$ y^{-1}], C_{invest} [\$], $C_{\mathrm{sales}}(i)$ [\$ y^{-1}] and $C_{\mathrm{op}}(i)$ [\$ y^{-1}] represent the annual clinical development cost in the ith year, investment cost, annual sales, and annual operating cost, respectively. The parameter r [–] represents the interest rate.

There are two types of uncertainty in the above mentioned NPV, i.e., one at the clinical development stage, and the other at the commercial production stage. The former contains success/failure of the clinical trials or strategy of formulation development, whereas the latter includes the choice of process technologies and parameters. By combining discrete scenarios and parameter distributions, NPV can be obtained as probability distribution using Monte Carlo simulation.

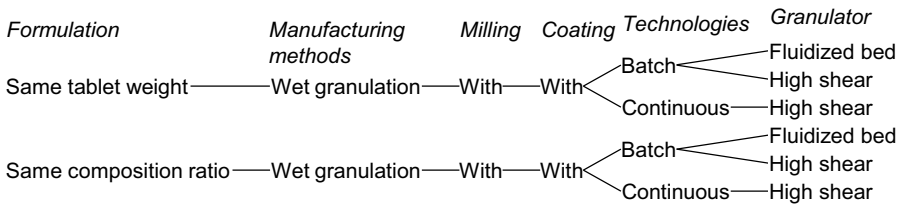

Figure 3 Alternatives of manufacturing processes considered in the case study (details of alternatives are also mentioned in Table 1)

2.3. Interpretation of evaluation results

The evaluation results that are produced as probability distribution are interpreted in order to make decisions on the alternatives (see Table 1). In case of comparing batch and continuous technologies, one approach would be to calculate the difference of NPV between the two technologies in each iteration of Monte Carlo simulation. Sensitivity analysis can be performed between the input and the output distributions in order to identify most contributing parameters.

3. Case study

A case study was conducted along with the steps mentioned above. Based on the actual drug development in the industry, the following situation was assumed. A drug producer has a new tablet product in clinical development. The producer wants to decide which technology to apply for the commercial manufacturing, batch or continuous, both of which are present in the plant. The decision is to be made considering the net present value from the time point of the development until commercial production. Evaluation models were created on the assumption that the products obtained by all alternatives are pharmacologically equivalent for the patient needs.

3.1. Generation of alternatives and recognition of uncertainty

An overview of the product and process alternative was created as shown in Figure 3. The property of the new drug was set as follows: mass fraction of API is high, and the tablet needs to be coated due to the color of API. These product properties reduced the number of alternatives shown in the superstructure in Figure 2 down to the six combinations in Figure 3. More specifically, direct compaction method had to be avoided; milling, granulation, and coating processes were needed.

In this paper, we focus on the choice between batch and continuous for the manufacturing technology with treating other alternatives on, e.g., formulation, as given. Uncertainty for the parameters such as manufacturing rate in continuous manufacturing or numbers of campaign manufacturing lots was considered as relevant, which are to be incorporated in the evaluation.

3.2. Creation of evaluation models

For simplification, the forth cost item of Eq.(1), i.e., operating cost, was selected as the relevant factor, and the economic evaluation model was defined as shown in Eq.(2). Operating cost consists of material, disposal, labor, and utility cost, and the detail of Eq.(2) was presented in our previous research (Sugiyama et al., 2017).

$$NPV = -\sum_{i=0}^{\tau_{\text{sales}}} \frac{C_{\text{op}}(i)}{(1+r)^i} \tag{2}$$

For around 80 parameters contained Eq.(2), probability distributions were determined; for a demonstration purpose, triangular distribution was used, as shown in Eq.(3):

$$f(x) = \begin{cases} \dfrac{2(x - x_{\min})}{(x_{\max} - x_{\min})(x_{\text{std}} - x_{\min})} \,|\, x_{\min} \le x \le x_{\text{std}} \\ \dfrac{2(x_{\max} - x)}{(x_{\max} - x_{\min})(x_{\max} - x_{\text{std}})} \,|\, x_{\text{std}} \le x \le x_{\max} \\ 0 \,|\, x < x_{\min}, x > x_{\max} \end{cases} \tag{3}$$

where $f(x)$ stands for the probability density function of the triangular distribution, x_{std} [–] for the estimated standard value, $x_{\min}$ [–] and $x_{\max}$ [–] for the minimum and the maximum values, respectively. The values of x were provided by the industrial co-authors, where typical manufacturing data was set as x_{std}. For $x_{\min}$ and $x_{\max}$, relatively large margin was assumed to avoid underestimate the effects of parameters. The expected ranges of NPV in batch (NPV^{batch}) and continuous (NPV^{cont}), and the difference ($NPV^{\text{cont}} - NPV^{\text{batch}}$) were calculated by Monte Carlo simulation (10,000 iterations). Figure 4 (a), (b), and (c) shows simulation results of NPV^{batch}, NPV^{cont}, and $NPV^{\text{cont}} - NPV^{\text{batch}}$, respectively, where the last was calculated at each iteration.

3.3. Interpretation of evaluation results

The result in Figure 4 suggests that the probability that NPV^{cont} is smaller than NPV^{batch} is 67 %. If all values of the input parameters are set to $x_{\text{std.}}$, $NPV^{\text{cont}} -$

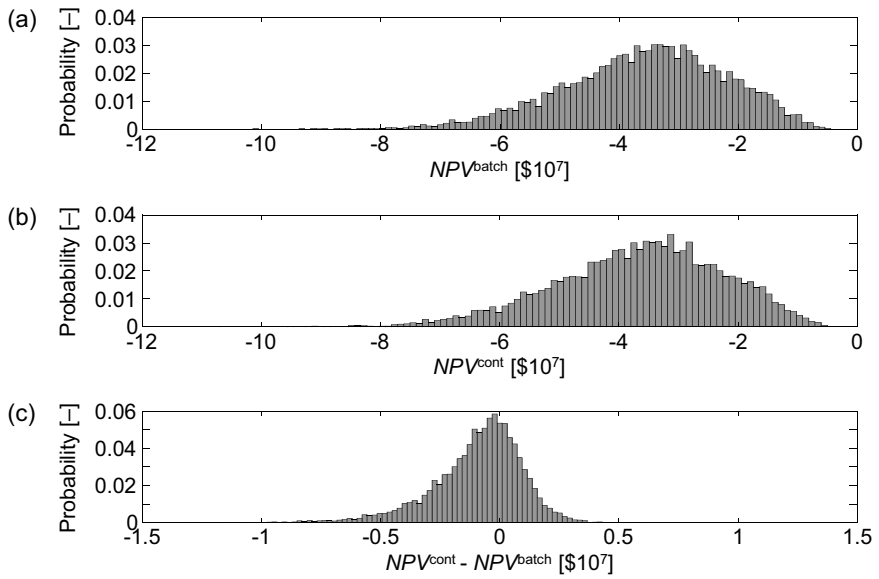

Figure 4 Simulation results of NPV. (a) NPV of batch manufacturing technology, (b) NPV of continuous manufacturing technology, (c) Difference amount of NPV

NPV^{batch} was calculated to be \$6.5×10^5, i.e., if everything is as expected, continuous manufacturing technology is economically beneficial. However, there is 67 % probability that batch manufacturing technology becomes economically more beneficial, i.e., the conclusion could differ when uncertainty was considered.

The ranges of the obtained probability distributions are strongly influenced by the input distributions set, more specifically, by the distribution type as well as the parameters x_{min} and x_{max}. In this case study, a large margin was set for x_{min} and x_{max}; the values should be revised in case more accurate estimation is needed. Sensitivity analysis would quantify the contribution of the input parameters on the output result, which would support the parameter updates and finally decision-makings.

4. Conclusions and outlook

We presented an economic evaluation of batch and continuous technologies for solid drug products as the decision support information during clinical development. An overview of product and process alternatives was shown that are possible to be chosen and are under uncertainty during the stage of development. A case study was conducted using industrial information, where the uncertainty of the process parameters was incorporated in the calculation using Monte Carlo simulation. The NPV using the standard input values was larger for continuous, however, there is 67 % probability that batch becomes more beneficial, i.e., a different conclusion was obtained by considering uncertainty. These findings will be incorporated in our future development of the general tools, which can support the choice of the batch and continuous technologies comprehensively.

Abstract

Following the FDA's historic approval of the first cell-based, autologous, cancer therapy in 2017, there has been an increasing growth in the personalized cell therapy market. Both the personalized character as well as the sensitive nature of these therapies, has increased the complexity of their supply chain design and optimisation. In this work, we have addressed key issues in the cyclic supply chain for simultaneous design of the supply chain and the manufacturing plan. A comprehensive optimisation based methodology through both deterministic and stochastic programming is presented and applied to study the Chimeric Antigen Receptor (CAR) T cell therapies. Multiple objectives including maximisation of the overall net present value (NPV) and minimisation of the average response time of all patients are evaluated, while accounting the uncertainties in patients' demand distribution. Results indicate that the total benefits from the optimized supply chain management are significant compared with the current global market.

Keywords: Precision healthcare, supply chain, optimisation, economic.

1. Introduction

Precision healthcare and medicines, especially cell and gene therapies, are progressing rapidly in clinical trials (Wang and Shah, 2017). As a breakthrough, Chimeric Antigen Receptor (CAR) T-cell therapies have proved to be an effective approach to the treatment of hematological malignancies, such as B-cell leukemia and lymphoma. In August 2017, the U.S. Food and Drug Administration (FDA) made the historic approval of Novartis' Kymriah; an autologous CAR T-cell therapy for B-cell acute lymphoblastic leukemia (ALL), opening the road to novel, cell-based, autologous cancer therapies. Currently, Kymriah's cost is estimated to be $475,000 per patient (Bach et al., 2017), making autologous therapies not only very expensive for patients to afford, but also very challenging to be reimbursed by health insurance schemes (Malik and Durdy, 2016). Due to their sensitive nature, such products are coupled with stringent handling requirements (e.g. temperature hold times, storage times) during transportation and manufacturing. As a result, mapping and then optimizing the supply chain of such products is a challenging task, as one needs to consider multiple factors, ranging from the availability of raw materials to transportation costs that usually, highly affect the total cost (Rafiq et al., 2017). Given their immaturity in the market, such therapies are currently using suboptimal manufacturing and delivery routes. Due to market growth, the latter will soon prove to be insufficient, driving the pharmaceutical industry towards novel solutions that will assist a smooth scale out in process development. The optimisation of the supply chain in cell-based, autologous therapies, is of key importance as it can effectively decrease therapy cost and delivery time and bring such therapies to a much larger group of patients. An

innovative supply chain from laboratory inventions to full-scale commercialization is desired to maximize healthcare and economic benefits (Shah, 2004).

Multi-objective stochastic programming has been effectively adopted to optimize supply chains of various products (Hugo and Pistikopoulos, 2005; Liu and Papageorgiou, 2012; Nikolopoulou and Ierapetritou, 2012; You and Grossmann, 2008). To address the challenges in precision healthcare and medicine supply, here, we establish a stochastic model that can capture the uncertainties in patients' treatment needs, while evaluates objectives including maximizing the overall net present value (NPV) and minimizing the average response time of all patients. Compared with classical supply chain problems that mainly address costs or NPV, the additional objectives of patients' treatment delivery and quality control are equally or even more important for the biomedical industry. Following that, the decision variables such as number of manufacturing modules and distribution centres to be constructed and locations of modification for each sample can be determined under the supply chain constraints (e.g. processing capacities of hospitals and manufacturing sites).

This work first provides a qualitative analysis of the current supply chain in CAR T-cell therapies in Section 2, touching upon main bottlenecks/challenges that are reported in the open literature and/or indicated by the pharmaceutical industry. A mathematical model is formulated in Section 3 and solutions using a deterministic scenario and scenarios in which the demand uncertainty evaluated are presented in Section 4. Conclusions and future work are discussed in Section 5.

2. Qualitative analysis of the CAR T-cell supply chain

We first focus on a qualitative analysis of the current supply chain of CAR T-cells, collecting information both from the open literature, as well as from interviews with industrial project partners.

2.1. Current state-of-the-art

Figure 1 presents the current supply chain of CAR T-cells that begins from the collection of the cells from the patient at a specialized clinical site (*leukapheresis & cell separation/enrichment*). At this point (point (1), Figure 1), the patient sample can be frozen and stored, until a larger batch of patient samples is created. Optimal shipment schedules are defined by the capacity of the manufacturing site, as current facilities can handle a finite number of samples.

During manufacturing, samples undergo a series of modifications (*activation, genetic modification, expansion, formulation, and cryopreservation*) until the final product is ready to be shipped back to the patient. The majority of the manufacturing steps are based on the supply of common raw materials, such as medium, cell washing accessory sets, selection reagents etc. Nevertheless, during *genetic modification* (point (2), Figure 2), patient cells are transduced by viral vectors carrying the genetic material required for the CAR expression. Unlike other materials used in the manufacturing process, viral vector products are highly sensitive, with relatively short shelf-life and strict stability windows, with respect to temperature. Moreover, they are characterized by a complex, lengthy manufacturing process. Therefore, there is an evident interdependence between the two supply chains (CAR T-cells & viral vectors), that stresses the need for the design of optimal planning and coordination, in order to avoid product losses and/or shortages. In particular, the demand in the CAR T-cell space automatically indicates the respective demand of viral vectors.

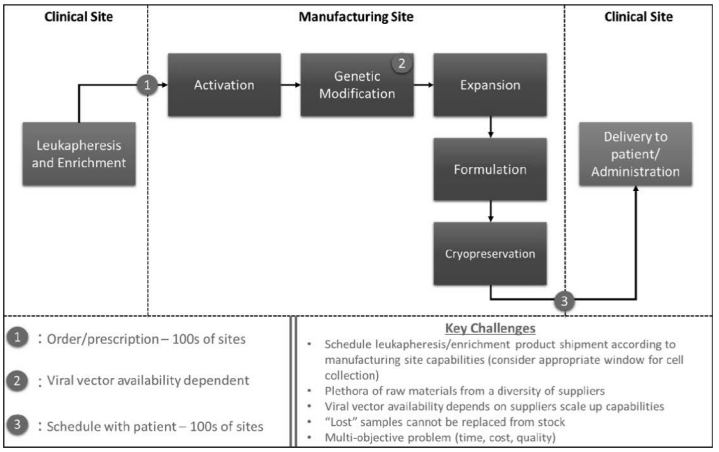

Figure 1. Current CAR T-cell process/distribution steps along with key bottlenecks and challenges (Levine et al., 2017).

Following their manufacturing, CAR T-cells need to be transferred back to the clinical site where they will be administered to the patient. That can often be translated into airfreight shipping, as sites might be located not only in different countries, but also in different continents (Griffiths, 2016). Therefore there are significant transport costs involved, but also challenging cross-border regulations to consider. Moreover, treatment administration must be scheduled based on patient condition; thus posing additional challenges in defining the optimal task scheduling profile.

2.2. Process bottlenecks/challenges

It is observed that commercialisation of CAR T-cell therapies is a challenging, multi-factorial task. Firstly, such therapies introduce 1-to-1 business models, making the patient part of the supply chain. Moreover, due to their autologous nature and specificity, they restrict the possibility of product losses to be replaced from stock, thus stressing the need for minimisation of failure rates. Reflecting the sensitive nature of the studied therapies, *temperature and time excursions* are reported to be amongst the most important challenges. Meanwhile, *sample identification* is at high risk at all times as in this case the patient becomes his/her own donor. Therefore it is essential that samples are not only tracked from the collection point to the manufacturing center, but also and most importantly during their delivery back to the patient, ensuring that the right therapy is administered to the right patient. Other barriers/challenges to commercialisation may arise from: manufacturing (e.g. insufficient facilities), current business models (e.g. one-to-many), reimbursement & clinical adoption procedures.

3. Problem formulation and methodology

3.1. Problem statement

Given a set of hospitals j and the number of patients i that go through cell-therapy cancer treatment at each hospital in a given time period T, the objective is to establish a number of cell manufacturing facilities k and distribution (storage) centres m among the potential available sites with an optimal economic goal meeting the treatment demand while keeping the responsive time of each patient below a certain value and maximising utilisation of existing assets. Different transportation modes l are considered depending

on feasible connections between two sites.The clinical treatment data obtained from ClinicalTrials.gov is used as the foundation to estimate global demand. Time series analysis and regression is first conducted as the most basic methodology for future demand forecasting. The predicted treatment needs follow a certain type of curves for each individual region, mainly in the U.S. (nearly linear growth) and China (exponential growth).

3.2. Supply optimisation

Decision making in the network modelling is formulated as a mixed-integer linear programming (MILP) model, as the objective functions and part of constraints listed in Table 1. The interactive method is used to evaluate the preferences of multiple objectives, which is adapted from the weighting and ε-constraint methods and solved using CPLEX.

Table 1. Mathematical model formulation as designed for the optimisation problem

Index	Mathematical Formulation	Description
Objective functions		
(1)	$Z_1\,(NPV) = Revenue - C_{invest} - C_{operate} - C_{manufacture} - C_{transport} - C_{store} - C_{R\&D}$	Total NPV
(2)	$Z_2\,(Response\ Time) = T_{transport} + T_{manufacturing} + T_{storage}$	Maximisation of patients' satisfaction
Constraints		
(3)	$MCP \times N_k^M - \sum_i S_{i,k}^{MT} \geq 0$ $SCP \times N_m^D - \sum_i MS_{i,m}^{DT} \geq 0$	Manufacturing & distribution capacity constraints
(4)	$\sum_k Y_k^M \leq \alpha\,,\ \ \sum_m Y_m^D \leq \beta$	Total number of manufacturing sites and distribution centres
(5)	$n_i Y_{i,j}^H = \sum_{k,l} S_{i,j,k,l}^H\,,\ \ S_{i,k}^{MT} = \sum_{j,l} S_{i,j,k,l}^M\,,\ \ MS_{i,m}^{DTS} = \sum_{j,l} MS_{i,j,m,l}^{DH}$	Sample balance at each node (hospital, manufacturing and distribution centre)

The multi-objective programing aims to maximize the total NPV (Eq. (1), Table 1). The economic cost structure of cell therapies supply chain includes capital investments, nominal operating costs, manufacturing, transportation and storage costs, as well as potential research and development costs. While the maximisation of patients' satisfaction is represented by the response time of the total supply chain (Eq. (2), Table 1). The two objectives are evaluated in a weighed sum manner, or by converting one to a constraint. In this paper, we will pose an upper bound to the response time while mainly aiming to maximize the NPV of the value chain.

The optimisation constraints mainly include capacity constraints, material and sample balance, and other logistics constraints (Eq. (3)-(5), Table 1). As discussed in Section 2, a key feature of the precision healthcare is that each patient is treated and manufactured individually, while tracked with a label through the whole life cycle and back to the patient in a loop. The sample balance and cell tracking are incorporated into the optimization program as a set of binary constraints.

4. Case study and results

Following the framework proposed, a case study of the CAR-T supply chain is presented in this section. The output provides a whole seamless supply chain with distribution, logistics, and storage capacity for cell and gene therapies in order to accelerate advanced therapy development and commercialisation.

4.1. Deterministic case

In the base case, we consider four types of hospitals are accepting patients at fixed cohort size. The real distance and transportation time are used as input to characterize multiple

routes through each manner (e.g. air and road). The deterministic case is characterized by the absence of uncertain variables, which treats the total patients distributed to be treated worldwide are aggregated to groups. The problem is formulated as a multi-objective MILP optimisation model with the assumption that each batch of patients pass through the same supply chain route as Figure 1. An estimated size of the total patients group is 9,364, which is consistent with the clinical statistics. The 11 considered hospitals that accept patients are located in London, Paris, California, New York, Texas, Florida, Washington (Seattle), China North (Beijing), China South (Shanghai), Singapore and Australia. Another 6 candidate locations can build cGMP manufacturing centres.

The results of the selected sites to for CAR-T manufacturing are shown in Figure 2. The desired responsive time plays a key role in deciding the optimal supply chain strategies. When relaxing the time constraint, the NPV can increase by 64.7% compared with the base case (normal demand level) shown in Table 2.

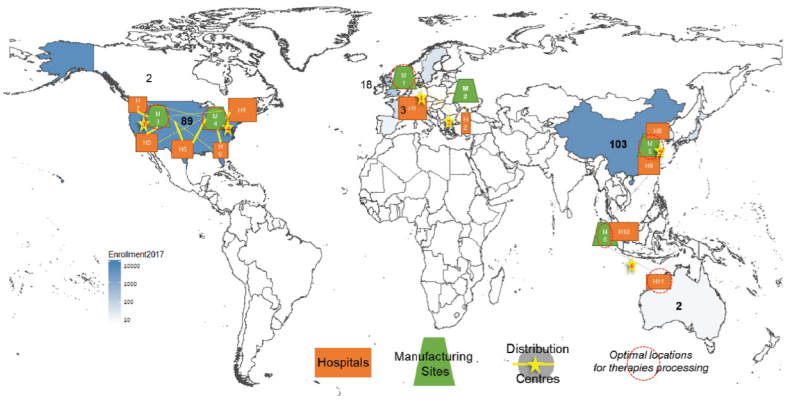

Figure 2. Graphical representation of the results from the deterministic scenario.

4.2. Stochastic case

The operation problem becomes more complex when probabilities are evaluated through stochastic programing approaches. In this stochastic case, the model can be adjusted to accommodate operational issues such as uncertainties in end-point treatment needs, manufactory inventory, and quality of samples. Here we only demonstrate the simplified results from the scenario-based uncertainty analysis, by evaluating each demand stage, e.g., low, medium and high levels. There is a trade-off between total responsive time and economies of scale. Large-scale centralised manufacturing centres are optimal under deterministic conditions, while distributed small-scale flexible plan are more cost-effective under stochastic conditions.

Table 2. Optimisation results of scenarios considering demand uncertainty.

Demand of treatment globally	NPV (billion USD)	Response time (days)	Total manufacturing modules
Low level (121 each month)	1.103	15.31	45 (at 6 manufacture centres)
Normal (242 each month)	1.636	15.31	85 (at 1 hospital and 5 manufacture centres)
High level (484 each month)	0.738 if no time constraint, otherwise infeasible	15.46	167 (at 6 manufacture centres)

5. Conclusions and future work

An illustrative example has been presented to describe the global supply chain optimisation problem for cell therapies for precision healthcare. A commercial cryogenic storage, distribution and logistics solution consisting of configurable, modular components is demonstrated. Through the proposed supply chain optimisation, the NPV increases while the response time is much shortened, compared with the current situation where all therapies are manufactured on site in a completely decentralised manner. In the current discussion, we only consider a single-stage planning using a "snap-shot" description of the supply chain. Future work will also discuss dynamic supply chain operational problems with the development of manufacturing capability through robust, repeatable and scalable routes. Machine learning techniques and data-driven approaches will also be applied to forecast the number of patients and expansion of treatment capacities, associated with multiple factors such as the morbidity, costs, technology advances and clinician provisions, to obtain effective supply chain management solutions.

Abstract

How cholera toxin subunit B (CTB) binds to its receptor in host cell membrane is still not fully understood due to its complex nature. In this study, a kinetic Monte Carlo (kMC) model is proposed to describe the binding kinetics between CTB and its receptor on lipid membrane. The proposed kMC model considers receptor migration, CTB attachment and detachment, and surface forward and backward reactions as discrete microscopic events. At every moment, an event to be executed is selected randomly based on the rates of all possible events, and this procedure continues till the end of simulation. By accounting for these events, the predictions from the proposed kMC model qualitatively agree with the experimental measurements.

Keywords: kinetic Monte Carlo, multivalent protein-glycan interaction, cholera toxin

1. Introduction

In the intestinal lumen, *Vibrio Cholerae*, the main culprit of cholera, secrets cholera toxin (CTx), which is responsible for acute symptoms of cholera once CTx enters cytoplasm. In order for a CTx to move into cytoplasm, its pentameric CTx subunit B (CTB) must bind with its receptor, ganglioside, on host cell membrane that initiates the CTx internalization process. Without the CTB-ganglioside binding, a CTx is unable to cross the host cell membrane as a cell membrane is impermeable to a CTx. Consequently, an effective inhibition of the CTB-ganglioside binding can prevent the cholera infection even in the presence of the bacteria.

Role and structure of CTB have been extensively studied, but the binding dynamics between CTB and ganglioside still remains elusive, particularly at the microscopic level, since its nature is intrinsically complex. First, a CTB can bind up to five ganglioside receptors in host cell membrane; second, multiple types of receptors present in cell membrane can bind with CTB with different affinities (Krishnan et al., 2017); last, the low number of ganglioside receptors in host cell membrane renders the binding process stochastic (Wilkinson, 2009).

Motived by these considerations, this work aims to implement kinetic Monte Carlo (kMC) methodology (Nayhouse et al., 2013) to model the binding kinetics between CTB and GM1 receptors on the surface, which will help us enhance our understanding of the underlying physics of the CTB-ganglioside binding mechanisms at the microscopic level. The kMC is chosen since it is a powerful tool to simulate microscopic reactions on a surface and can track the temporal evolution of the surface

configuration (Nayhouse et al., 2013). Specifically, the dynamic model incorporates four microscopic phenomena of the CTB-receptor binding mechanisms: 1) diffusion of a CTB to surface and attachment to a receptor in host cell membrane, 2) dissociation of a CTB-receptor complex, 3) association between a CTB-receptor complex and a free receptor, 4) migration of free receptors. By accounting for these events, the predictions from the proposed kMC model qualitatively agree with the experimental measurements. In the future, the proposed methodology can be extended to study the binding kinetics between CTB and lipid membrane containing more than one type of receptors to investigate the roles of different receptors.

2. Methodology

This study aims to model the binding kinetics between CTB proteins and their receptors in a cell membrane mimicking environment, where CTB proteins are in the solution and receptors are localized on surfaces of spherical lipid bilayers. The solid-to-solid model and kMC algorithm are implemented to simulate the CTB-receptor binding kinetics (Nayhouse et al. 2013; Fallahi-Sichani and Linderman, 200). In this model, the surface of lipid bilayer is modeled as a square lattice with a periodic boundary condition, and receptors are randomly distributed on the surface. Description of microscopic phenomena

Here, the CTB-receptor binding kinetics are described by five microscopic phenomena as follows

- Receptors and CTB-receptor complexes migration on a lipid bilayer surface.
- CTB proteins diffuse within the solution.
- If a CTB is sufficiently close to a receptor on the surface, CTB can attach to the surface by binding to the receptor.
- A membrane-bound CTB binds to an additional receptor if the CTB has an unfilled binding spot and a receptor is sufficiently close to the CTB.
- A receptor can dissociate from a membrane-bound CTB, and the CTB will detach from the lipid bilayer after all receptors dissociate from it.

For the purpose of this study, the above descriptions are simplified with the following two assumptions. First, the simulation domain is restricted to two-dimensional as our main interest is the dynamics on the membrane. By assuming the solution is well-mixed, the transport of CTB proteins to and from the surface via diffusion is considered implicitly by introducing effective association and dissociation rate constants, which are defined as follows (Lauer et al., 2002):

$$k_f = \frac{k_0}{1 + \frac{5k_0R}{4\pi Da}}, \qquad k_r = \frac{k_{-1}}{1 + \frac{5k_0R}{4\pi Da}} \tag{1}$$

where k_f and k_r are effective association and dissociation rate constants, k_0 and k_{-1} are intrinsic association and dissociation rate constants, R is the number of receptors available for binding, D is a diffusivity coefficient of CTB in the solution, and a is the radius of lipid bilayers. Please note this simplification is derived based on the steady-state diffusion equation and has been experimentally verified (Erickson et al. 1987).

Second, we assume CTB-receptor complexes on the surface is immobile. With these simplification, only the following five events on the surface are considered during the kMC simulation.

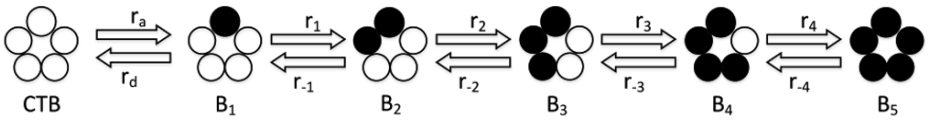

Figure 1. The schematic diagram for the CTB-receptor binding kinetics. B_i is a CTB bound to i number of receptors. Empty and filled spheres represent CTB binding spots without and with bound receptors, respectively.

2.1. Surface kinetics

Description of the CTB-receptor binding kinetics is adapted from that of Lauer et al. (2002) as illustrated in Fig. 1. As a CTB has five binding spots, a CTB will bind to or dissociate from receptors in a step-wise manner, which results in ten reactions to be considered in the kMC (Fig. 1). It should be noted that the steps from CTB to B_1 and B_1 to CTB should be treated separately since the effective rate constants k_f and k_r need to be used to account for the transport of CTB to the membrane implicitly as described above. First, the attachment and detachment rates are defined as

$$r_a = 5k_f CR, \qquad r_d = k_r B_1 \tag{2}$$

where r_a is the attachment rate from solution to the surface, C is the CTB concentration in solution, r_d is the CTB detachment rate from the membrane to solution, and B_1 is the number of CTB-receptor complex with one bound receptor. Here, a factor of five is multiplied because a CTB protein is symmetric molecule with five identical binding spots for receptors (Lauer et al., 2002).

Since a CTB can take up to five receptors, a membrane-bound CTB can associate with or dissociate from additional receptors, which are termed as forward and backward reactions, respectively, hereafter (Fig. 1). The reaction rates of these two events on the membrane are computed as follows

$$r_i = (5-i)k_1 B_{i-1} R, \qquad r_{-i} = (i+1)k_{-1} B_{i+1}, \qquad \forall\, i = 1, \ldots, 4 \tag{3}$$

where r_i is the forward reaction rate from B_i to B_{i+1}, B_i is the number of CTB bound to i number of receptors, k_1 is the forward reaction rate, and r_{-i} is the backward reaction rate from B_{i+1} to B_i.

Finally, the receptor migration rate is defined as (Nayhouse et al., 2013; Fallahi-Sichani and Linderman, 2009)

$$r_m = R\frac{k_m}{l^2}, \tag{4}$$

where k_m is the receptor migration rate constant, and l is the distance between two lattice sites. Nominal parameters for the kinetic parameters and diffusivity are taken from the literature and listed in Table. 1 (Lauer et al. 2002; Krishan et al. 2017).

2.2. Kinetic Monte Carlo Implementation

An event is selected based on a random number and the total reaction rate, r_t, which is defined as

$$r_t = r_a + r_d + \sum_{i=1}^{4} (r_i + r_{-i}) + r_m \tag{5}$$

In order to execute an event, a uniform random number, $\xi_1 \in [0,1)$, is sampled. If $\xi_1 \leq r_a/r_t$, the attachment event is selected. If $r_a/r_t < \xi_1 \leq (r_a + r_d)/r_t$, the detachment event is selected. If $(r_a + r_d + \sum_{i=1}^{j-1} r_i)/r_t < \xi_1 \leq (r_a + r_d + \sum_{i=1}^{j} r_i)/r_t$, the forward reaction from B_j to B_{j+1} is selected. If $(r_a + r_d + \sum_{i=1}^{4} r_i + \sum_{i=1}^{j-1} r_{-i})/r_t < \xi_1 \leq (r_a + r_d + \sum_{i=1}^{4} r_i + \sum_{i=1}^{j} r_{-i})$, backward reaction from B_{j+1} to B_j is selected to occur; if $\xi_1 > (r_a + r_d + \sum_{i=1}^{4} r_i + \sum_{i=1}^{4} r_{-i})/r_t$, the migration event is selected.

When an attachment event is selected, a free receptor is randomly selected to associate with an incoming CTB protein. After a receptor for binding is selected, it is required to check whether there is enough free space around the selected receptor for a CTB without overlapping with other CTB molecules that are already bound to the host cell membrane. If there is no enough space for an incoming CTB, the attachment will be rejected. As the membrane becomes more crowded with the increasing number of membrane-bound CTB molecules, the available space for an additional CTB to attach to the host cell membrane decreases significantly; hence, the rejection rate will increase accordingly.

When a detachment event is selected, one CTB bound to one receptor, which is denoted as B_1 (Fig. 1), is randomly selected and dissociates with the receptor, leaving it on the host cell membrane. Whenever the attachment or detachment event occurs, the concentration of CTB in solution is updated via mass balance by counting the number of proteins undergoing attachment and detachment process

When a forward reaction event from B_i to B_{i+1} is selected, whose rate is denoted as r_i, one CTB bound to i number receptors is randomly selected, and another free receptor will be bound to it. Here, it is required to check whether there are any free receptors sufficiently close to the selected binding spot, which is determined by the distance between the binding spot to free receptors on the host cell membrane. If the distance is smaller than the threshold distance (l_c), the corresponding receptor is classified as a free receptor that can bind with the CTB. If there is no receptor close to the selected binding spot, the forward reaction will not occur; if there is at least one such receptor, one receptor is randomly selected and bind to the binding spot.

Similarly, when a backward reaction event from B_{i+1} to B_i is selected, one CTB bound to $i+1$ number receptors is randomly selected, and one of its bound receptors is randomly selected for dissociation.

Table 1. Nominal parameter values for the CTB-GM1 binding kinetics

$k_0\ (M \cdot s^{-1})$	$k_{-1}\ (s^{-1})$	$k_1\ (cm^2 s^{-1})$	$D\ (m^2/s)$	$k_m\ (m^2/s)$
2.8×10^4	3.2×10^{-3}	3.5×10^{-15}	9.8×10^{-11}	8.25×10^{-12}

When a migration event is selected, one free receptor is randomly selected and move to one of its neighbouring empty site.

After one event is selected and proceeds as described above, the time increment for the selected event is calculated by generating a new random number $\xi_2 \in [0,1)$, and the time increment is computed as follows (Nayhouse et al., 2015)

$$\tau = -\ln \xi_2 / r_t \tag{6}$$

And the simulation will proceed by $t + \tau$ seconds. The kMC simulation is written in C#, and a few realizations are computed to calculate the average kinetics.

3. Results & Discussion

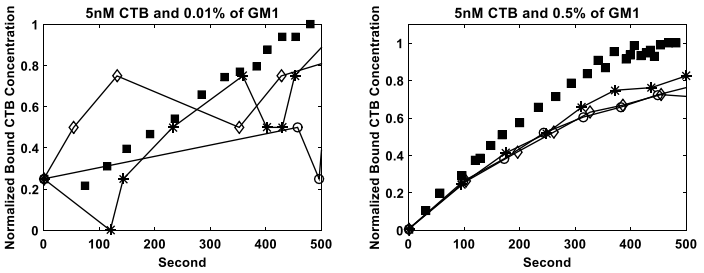

Figure 2. Simulated profiles of total number of bound CTB on membrane with different surface densities of GM1. On each figure, each line represents a different realization of the kMC simulation while filled square points are experimental measurements from Lauer et al. (2002).

The proposed kMC model was applied to describe the number of CTB bound to receptors on lipid membrane. Specifically, the initial CTB concentration was 5nM, and lipid membrane contained two different amounts of GM1 receptors. Here, 0.01% and 0.5% GM1 lipid membranes were considered for the kMC simulations. In Fig. 2, three different realizations of the kMC simulation for each GM1 surface density were presented. Predicted kinetics qualitatively agreed with the experimental measurements (Lauer et al., 2002), which validated the predictive capability of the proposed kMC simulation.

At low GM1 concentration such as 0.01% GM1 membrane, three realizations showed distinct dynamic behaviors due to the dominance of stochasticity in the kinetics caused by low copy number of receptors (Wilkinson, 2009). On the other hand, three realizations of the binding kinetics at 0.5% GM1 surface concentration showed a very consistent behavior with each other, which indicated that stochasticity was minimal under the higher GM1 surface concentration. Two contrasting kMC simulation results under two different receptor surface densities indicated that one of the main sources of stochasticity in the ligand-receptor binding kinetics is the initial amount of receptor available.

The other important feature of this kMC simulation is that it can take into account surface configurations such as hindrance effect of neighboring bound proteins and receptor aggregations. As Fig. 3 demonstrates, the surface containing 2% GM1 became more crowded, which increases the likelihood to reject the attachment event. The consideration of the surface configuration is a desirable feature of the proposed kMC simulation framework since there should be a maximum amount of CTB proteins that

can be bound to the membrane in reality. Previous deterministic models to predict the CTB-GM1 binding kinetics (Lauer et al., 2002) did not account for this issue, and this model would erroneously predict the CTB-receptor binding would occur even when there was no space to accommodate an additional CTB on the membrane. Moreover, it would be difficult to incorporate the surface configuration in a deterministic model. Hence, the kMC modelling approach is a more natural tool to simulate the CTB-receptor binding kinetics.

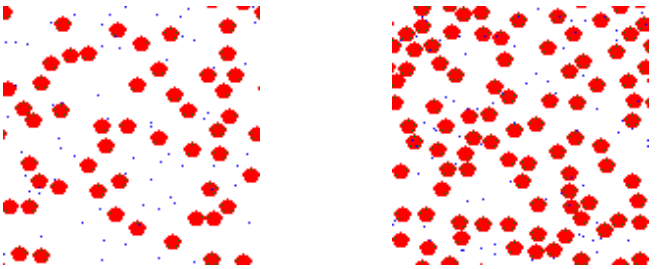

Figure 3. Schematic diagram of CTB surface coverages after 2000 seconds of binding with 1% (left) and 2% (right) GM1-containing membranes under 50 nM CTB. Pentagon-like shapes are membrane-bound CTB, and small dots are GM1 receptors

4. Conclusions

In this study, the kMC simulation framework was applied to model the binding kinetics between CTB and lipid membrane containing one type of ganglioside receptor by considering several important microscopic events as well as the surface configuration. Specifically, the proposed kMC model considered receptor migration, CTB attachment and detachment, and surface forward and backward reactions. The predicted CTB binding kinetics were qualitatively consistent with the experimental observations in the literature. In future, after rigorous parameter estimation of the proposed kMC model against available experimental measurements, it can be applied to study the CTB binding kinetics in the presence of multiple types of ganglioside receptors.

Abstract

The progress in the mechanistic understanding of the unit operations and the availability of multiple sensor technologies enable the inline implementation of data reconciliation and gross error detection methods in continuous pharmaceutical manufacturing. In this work, we demonstrate the benefits of accurate real-time monitoring of the process state in a continuous tableting process, with case studies representative of common situations in pilot-plant or manufacturing line implementation.

Keywords: Pharmaceutical Tableting, Continuous Manufacturing, Process Analytical Technology, Sensor Network, Data Reconciliation.

1. Introduction

Developing robust process operations for continuous production and real-time release testing in pharmaceutical manufacturing is progressing in earnest with the encouragement from regulatory agencies and prominent companies. The Process Analytical Technology (PAT) guidance set the foundation for modernizing pharmaceutical manufacturing by proposing an integration of subject matter expertise in pharmaceutics, powder technology and real-time process management. Accurate real-time measurements of Critical Quality Attributes (CQAs) and Critical Process Parameters (CPPs) are crucial. Some of these variables can be measured directly in real-time, while others require soft sensors, mainly using spectroscopic methods for inline measurements. Ierapetritou et al. (2016) discuss the process and technical challenges for continuous tableting.

In this work, we describe our progress in developing a reliable monitoring system for continuous pharmaceutical tableting**.** We limit this discussion to the application of data reconciliation (DR) and gross error detection (GED) for accurate inline measurements of the process state by using data from individual sensors. The paper illustrates the application of DR and GED in a subsystem of a continuous tableting line which uses dry granulation.

2. Continuous Tableting Process Description

Loss-in-weight (LIW) feeders are used for feeding the active pharmaceutical ingredient, excipients, inert additives, etc. into the continuous blenders. Then the blend is compacted into tablets. Depending on material properties, the blends may require granulation, milling, etc. before tableting. The sensor network is comprised of built-in equipment sensors for CPPs and external sensors for CQAs. The communication framework for

connecting equipment and sensors to a distributed control system (DCS) is crucial to effective network utilization (Singh et al. 2015). Our pilot-plant (Fig. 1) includes an Alexanderwerk WP120 roller compaction unit, two Schenck Accurate AP-300 LIW feeders for metered feed of API (acetaminophen) and excipient (microcrystalline cellulose PH-102), and a Gericke GCM 250 continuous blender. The blend is granulated and blended with a lubricant (0.5 wt% Magnesium Stearate) or glidant (0.2% Silicon Dioxide) using a Schenck DP-4 LIW feeder in another Gericke blender. The final blend is compacted in a Natoli BLP-16 tablet press. As shown in Fig. 1, the sensor network consists of load cell measurements from all the LIW feeders, NIR sensors at locations 2, 3 and 5, microwave sensor (Gupta et al., 2015) at 3; an InnopharmaLabs Eyecon camera at 4, x-ray sensor (Ganesh et al., 2017a) at location 3 and a Sotax AT4 automatic tablet tester at location 6. Additional details of our system are available in Moreno et al. (2017).

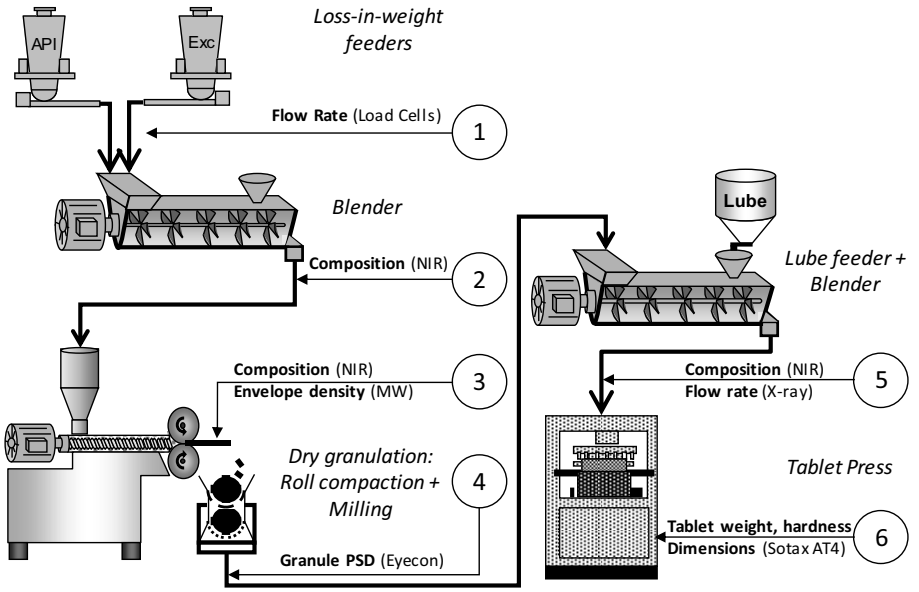

Figure 1. Schematic of pilot plant and available sensor network at Purdue University

3. Systematic approach to measurement accuracy

Real-time release testing in continuous tableting requires accurate and reliable inline measurements. However, there exist several operational challenges. Spectroscopic sensors, such as NIR and microwave, require data pre-processing and analysis before recording in the DCS. Calibration of such sensors is material and sensor location specific. Due to a lack of well-established communication protocols in the industry, tasks such as data acquisition, filtering and processing are performed in separate software. Software issues can result in possible communication failures, rendering the measurement unavailable for specific periods during the process. Handling particulate streams can be subject to frequent fouling of sensor interfaces, leading to biased measurements. Further, tablet properties such as hardness, weight and dimension are measured at set time intervals minutes apart by destructive testing of the samples drawn. Moreover, measurements are always subject to random errors arising from sources such as power supply fluctuations, network transmission delays, changes in ambient conditions, etc.

Data reconciliation (DR), gross error detection (GED) and sensor network design (SND) have been demonstrated to address such challenges for improved measurement accuracy (Narasimhan and Jordache, 1999). DR and GED require direct simultaneous measurement of a number of variables which is larger than the process degrees of freedom to permit the estimation of all variables in the sensor network. Multiple measurements of the same process variable can improve the reliability of that measured variable; however, it does not affect the observability of the unmeasured variables. Besides, sensors using the same technology can miss certain process features which can only be seen via measurements utilizing a palette of alternative technologies. Thus, though the blend uniformity is the primary concern for a continuous tableting process, integrating available mechanistic understanding with sufficient measurements to maintain network redundancy and observability of unmeasured variables is essential for reliable continuous operations.

4. Case Study

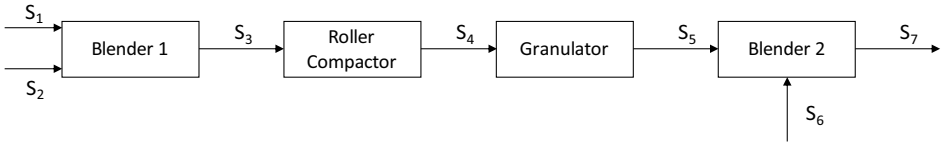

Figure 2. Block diagram for subsystem case study

In this study, the improvements in the accuracy of estimating the process state achieved using DR and GED for a subsystem of the continuous tableting line are demonstrated using three case studies representing situations commonly encountered in experimental implementation. We only consider the feeding, blending and granulating operations in the continuous manufacturing process, leading to the block diagram shown in Figure 2. There are seven material streams, and we assume there is no loss of material. The process variables are summarized in Table 1.

The measurement technologies, if applicable, are indicated in the 'Tool' column. The corresponding expected true values, and relative standard deviations ('RSD' column) of measurements obtained from experimental data under steady-state operations are as indicated. All the unit operations are represented using overall material balances and

Table 1. Process variables with measurements, NOC mean and standard deviations

	Variable	Tool	True Value (units)	RSD
F_1	API Flow	Load Cell	1.00 kg/h	2%
F_2	Excipient Flow	Load Cell	9.00 kg/h	2%
F_3	Blender1 Flow	-	-	-
x_3	Blender1 CU	NIR	10.00 wt%	6%
F_4	Ribbon Flow	-	-	-
S	Roll Gap	RC equipment	1.960×10^{-3} m	3%
ρ_R	Ribbon Density	NIR	0.963 kg/m^3	6%
x_4	Ribbon CU	NIR	10.00 wt%	6%
F_5	Granule Flow	-	-	-
x_5	Granule CU	-	-	-
F_6	Lubricant/Glidant Flow	LIW Load Cell	0.055 kg/h	15%
F_7	TP Inlet Flow	X-ray	10.00 kg/h	3%
x_7	TP Inlet CU	NIR	10.00 wt%	6%

component balance for the API across each node. Thus, there are eight material balance equations. Further, the flow rate from the roller compactor can be calculated using measured values for ribbon density and roll gap as shown in the equation (1). Also, mechanistic understanding of the roll compaction as shown in Equation (2) can be integrated in to the framework. Details of the model, notations and parametric values can be referred to Ganesh et al. (2017b). The roll speed (N_R) and hydraulic pressure (P_H) are treated as fixed parameters, given the low standard deviations of their measurements.

$$F_4 = \pi \rho_R N_R W D S \tag{1}$$

$$\rho_R = \rho_0 P_0^{1/K} \tag{2}$$

Where $1/2\ P_0(1 + \sin \delta_E) W D F\ =\ P_H * A$

and $F = \int_{\theta=0}^{\theta=\alpha} \left[1 + \frac{1-f_0}{f_0}\left(\frac{\theta}{\alpha}\right)^n\right]^K \left[\frac{S/D}{(1+S/D-\cos\theta)\cos\theta}\right]^K \cos\theta\, d\theta$

The set of equations has 3 degrees of freedom for the process, which means the process has a minimum requirement of four gross error free measurements for data reconciliation. Table 1 shows the availability of nine inline measurements, leading to six degrees of redundancy (DoR) in the system for the GED tests. However, given the frequency of fouling, communication errors, requirement of feeder refilling, etc., consistent availability of gross error free measurements from these sensors is challenging. Moreover, LIW tuning parameters are material bulk density specific, which can vary for the raw materials. Also, calibration models for all the spectroscopic sensors are material, location and probe position specific. Hence, the redundancy is crucial to achieving robustness of this system.

The model based DR and GED problems are solved in MATLAB using the approach reported in Moreno et al. (2017). The GED involves solving the global test (GT) and measurement test (MT). MT requires linearization of constraints. The bilinear component balances and Equation (1) are linearized using Taylor series expansion. Equation (2) is highly nonlinear and is linearized as a linear function of roll gap at the corresponding operating conditions. A total of 1000 random normal measurements using the mean and standard deviations given in Table 1 are simulated. Average values of these noisy measurements are compared with the corresponding reconciled values to demonstrate the improvement in measurement accuracy and are presented in Table 2, with units same as those given in Table 1.

Table 2. Measured variable estimates after data reconciliation and gross error detection

Var	NOC		Case 1		Case 2		Case 3	
	Mean	RSD	Mean	RSD	Mean	RSD	Mean	RSD
F_1	1.000	1.79	1.001	1.92	1.003	1.87	1.001	1.80
F_2	8.997	1.57	9.005	1.55	8.997	1.95	9.004	1.55
x_3	10.002	2.04	10.003	2.13	10.032	2.38	10.004	2.03
S	1.929	1.68	1.931	1.66	1.929	2.06	1.930	1.66
ρ_R	0.955	0.24	0.955	0.24	0.955	0.30	0.955	0.24

F_6	0.055	15.20	0.055	15.04	0.055	15.14	0.055	14.77
F_7	10.051	1.43	10.060	1.41	10.056	1.76	10.060	1.42
x_7	9.948	2.04	9.949	2.12	9.977	2.38	9.949	2.03

4.1 Normal operating conditions (NOC)

At NOC, all the nine measurements are expected to be active with true values and RSD as shown in Table 1. DR and GED for the system of equations result in improved accuracy for most process variables, particularly for the CU at all locations, as shown in Table 2 ('NOC' column), while ensuring material balance closure across all units and the process.

4.2 Case 1: Biased measurement from the NIR sensor

Suppose the NIR sensor reports the CU for x_3 as 15 wt%, while the measurements from the rest of the sensors are normal. In such situation, a bias resulting from fouling might be expected. By performing GED and DR, this faulty measurement can be rectified. The reconciled estimate for the CU at Location 3 is closer to the NOC conditions. The reconciled measurement for a shorter duration of gross errors in x_3 is shown in Fig.3 (left). The results of the case study are in Table 2 ('Case 1' column).

4.3 Case 2: Biased measurement from X-ray sensor

During steady-state plant operations, the X-ray sensor at Location 3 (F_7) reports a reduced flow rate of 8 kg/h. With a granulation process, material losses or ratholing in hoppers are always a possibility. However, if both cases are dismissed, the measurement must simply be biased. For the X-ray sensor, faulty measurements arising from communication failure or calibration error resulting from corrective actions for mitigating fouling are possible. In this case, the GED and DR use the existing redundancy in the sensor network to confirm that the process state remains within bounds and thus, a shutdown of the process is avoided. The reconciled measurement for a shorter duration of gross errors in F_7 is shown in Fig. 3 (right) and the results are presented in Table 2 ('Case 2' column).

4.4 Case 3: Unavailability of ribbon density sensor

Calibration of sensors for providing inline measurements of physical properties such as ribbon density is challenging. Moreover, installation of such sensors within the compactor at the ribbon location may require modifications to the equipment and plant setup. The decision to avoid these complexities will result in the unavailability of a direct density measurement. In this case study, we assume ρ_R is an unmeasured variable, reducing the DoR to five. However, an estimate of the ribbon density is important for downstream tableting. DR can accommodate sensor unavailability for estimation of CQAs using process models and measurement redundancy. DR can provide accurate state estimates as shown in Table 2 ('Case 3' column), confirming that the process is within bounds.

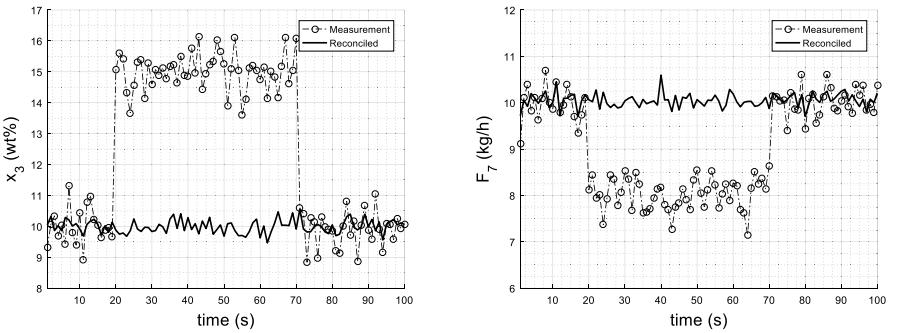

Figure 3. The reconciled values for measurements with gross errors. Bias in x_3 (Case 1, Left figure) and F_7 (Case 2, Right figure)

5. Discussion

For pharmaceutical processes, a measurement of the blend CU inline after every unit operation is essential and is typically achieved using NIR. The measurement RSD for the sensor depends on the material, location, spectra averaging, smoothing, etc. The challenge is to maintain the RSD within regulatory limits. Newer technologies for direct measurement of process variables with simplified calibration are very much desired. However, maintenance action to correct fouling of a sensor could result in bias for the measured variable which is beyond acceptable limits. It would be infeasible to pause a continuous process frequently to check for such errors. Also, ensuring material balance closure is crucial to maintain robust and profitable operations.

6. Conclusions

The case studies in this paper illustrate some of the practical challenges in the implementation of robust inline sensing in continuous pharmaceutical tableting. Specifically, we demonstrate the application of DR and GED to the system of unit operations and sensors using mechanistic models and material balance to obtain reliable and accurate estimates of the process state. Expanding this framework to add the models of other unit operations and measurement technologies is a part of our current research. Moreover, in ongoing work, we show that the application of a DR framework facilitates effective implementation of process control systems (Su et al., 2017). Robust process operations using systematic sensing and control systems are essential for reliable function of a material-tracking framework, leading to real-time release testing in pharmaceutical manufacturing.

Abstract

Healthcare spending in the United States accounts for about 17% of US GDP, making the US the highest healthcare expenditure per capita in the world. There are areas for improvement in the healthcare system and hospital care is one of them, which represents the single largest national health expenditure by the type of services. Because hospital operations and manufacturing processes share some similarities at systems level, we believe that some of the theories and techniques developed for manufacturing processes are also applicable to hospital operations. In this work, we examine whether the so called focused factory theory (i.e., factories that concentrate on narrow range of services or operations produce better products at low costs) is applicable to hospital operations. Specifically, we examine whether the hospitals that are specialized in certain diseases achieve better results in terms of costs and patient outcomes using a national healthcare cost and utilization project (HCUP) dataset. Data analytics tools including multiple linear regression (MLR), principal component regression (PCR), Fisher discriminant analysis (FDA), ordinal regression and logistic regression are used to investigate effects of hospital specialization on the total charge and death of patient during hospitalization.

Keywords: Focused factory theory, hospital performance, specialization,

1. Introduction

The healthcare spending in the United States accounts for about 17% of US GDP, making the US the highest healthcare expenditure per capita in the world. However, the United States has not seen an increase in life expectancy to match its huge outlay on healthcare. Therefore, there are areas for improvement in the healthcare system and hospital care is one of them. This is because hospital care represents the single largest national health expenditure by the type of services, accounting for approximately 31% of total healthcare costs (Hartman et al., 2009). One of many potential routes is through healthcare specialization based on the so called focused factory theory, which states that factories that concentrate on narrow range of services or operations produce better products at low costs. There have been many debates over the subject. Consequently, several studies have been conducted to investigate the effect of specialization on the hospital costs and patient outcomes. However, most of these studies were based on few individual cases, or a limited number of hospitals (Eastaugh, 1992; Herzlinger, 2004). There were studies that have investigated factors associated with high-quality/low-cost hospital performance using national databases such as healthcare cost and utilization project (HCUP). However, specialization was not considered in those studies (Jiang et al., 2006). Because hospital operations and manufacturing processes share some similarities at systems level, we believe that some of the theories and techniques developed for manufacturing processes are also applicable to hospital operations. In this

work, we examine whether the hospitals that are specialized in certain diseases achieve better results in terms of costs and patient outcomes using a national healthcare cost and utilization project (HCUP) dataset. Specifically, multiple linear regression (MLR), principal component regression (PCR), Fisher discriminant analysis (FDA), ordinal and logistic regressions are used to investigate the effects of hospital specialization on the total charge and death of patient during hospitalization. It is worth noting that the effects of specialization on other measures of hospital performance such as efficiencies quantified by data envelopment analysis (DEA)(Ozcan, 2014) require further investigation. The rest of the paper is organized as the follows. Section 2 introduces the dataset used in this study. Section 3 introduces the index used in quantifying hospital specialization and analysis methods to investigate the effect of hospital specialization on costs and patient outcomes. Section 4 presents the results and Section 5 draws the conclusions.

2. The National Inpatient Sample (NIS) dataset

The Healthcare Cost and Utilization Project (HCUP) is a family of healthcare databases and related software tools and products developed through a Federal-State-Industry partnership and sponsored by the Agency for Healthcare Research and Quality (AHRQ). HCUP databases bring together the data collection efforts of State data organizations, hospital associations, private data organizations, and the Federal government to create a national information resource of encounter-level healthcare data (HCUP Partners). HCUP includes the largest collection of longitudinal hospital care data in the United States, with all-payer, encounter-level information beginning in 1988. These databases enable research on a broad range of health policy issues, including cost and quality of health services, medical practice patterns, access to healthcare programs, and outcomes of treatments at the national, State, and local market levels (Steiner et al., 2001).

Table 1. The five most expensive DRG's with at least 5,000 cases in the 2012 NIS-HCUP dataset

DRG	No. cases	Mean TOTCHG	Median TOTCHG	Std. Deviation	Short DRG Description
233	5,506	$207,098	$169,938	$139,804	CORONARY BYPASS W CARDIAC CATH W MCC
25	6,536	$133,707	$101,442	$116,105	CRANIOTOMY & ENDOVASCULAR INTRACRANIAL PROCEDURES W MCC
238	6,847	$99,567	$86,949	$54,958	MAJOR CARDIOVASC PROCEDURES W/O MCC
246	12,337	$97,447	$81,086	$66,060	PERC CARDIOVASC PROC W MCC
470	67,626	$54,210	$47,836	$27,551	MAJOR JOINT REPLACEMENT

MCC: multiple chronic conditions

The National Inpatient Sample (NIS) used in this study is part of HCUP, which covers all patients, including individuals covered by Medicare, Medicaid, or private insurance, as well as those who are uninsured. Overall, NIS covers more than 95 percent of the U.S. population and includes more than 94 percent of discharges from U.S. community hospitals. The 2102 NIS dataset used in this study includes 7,296,968 cases (*i.e.*, inpatient stays). Each case has 481 variables, which include de-identified (*i.e.*, all personally identifiable information has been removed to protect individual identities and privacy) patient data such as age, gender, ethnicity, etc.; disease, diagnosis and procedure data such as disease severity, length of stay (LOS), diagnosis related group

(DRG), cost, total charge (TOTCHG), whether the patient died during the hospitalization, etc. In addition, each case is also linked to hospital related data/information such as bedsize, location, ownership, and teaching status of the hospital, which enable us to evaluate the performance of different hospitals. In this study, we focus on the five most expensive DRG's based on the national average TOTCHG with at least 5,000 cases. Based on this criterion, the five selected DRG's are listed in Table 1.

3. Methods

3.1. Specialization quantification

Farley and Hogan (1990) have proposed an index of specialization based on Information Theory. It has been shown that the index provided intuitively reasonable results in characterizing patterns of specialization across hospitals. In Farley and Hogan (1990), let Φ_i represent the baseline proportion of cases in DRG category i, and let p_{ih} denote proportion of cases in the h^{th} hospital observed in DRG category i. The Information Theory index of specialization (ITI) for hospital h collapses information about differences between the Φ_i's and p_{ih}'s as follows (Farley and Hogan, 1990):

$$ITI_h = \sum_{i=1}^{I}\{p_{ih} \cdot ln(p_{ih}/\Phi_i)\} \quad (1)$$

In our study, because we only focus on the five DRG's listed in Table 1, the specialization index (I_s) of h^{th} hospital is modified based on Eqn. (1) as follows:

$$I_{sh} = \sum_{i=1}^{5}\{w_{ih} \cdot ln(p_{ih}/\Phi_i)\} \quad (2)$$

where $w_{ih} = p_{ih}/\sum_{i=1}^{5} p_{ih}$ such that $\sum_{i=1}^{5} w_{ih} = 1$.

3.2. Multiple linear regression (MLR)

Multiple linear regression (MLR) is performed to investigate the effect of each independent variable on total charge (TOTCHG). Because TOTCHG is strongly right skewed, in order to satisfy the assumption of linearity and constant variance of residual for MLR, the transformed TOTCHG is used. It was found that the 4^{th} root of TOTCHG provide satisfactory performance, which is therefore used as the dependent variable. The independent variables include the following continuous variables: specialization index (I_s), wage index, length of stay (LOS), age, number of chronical conditions, number of diagnosis, number of procedures; as well as the following categorical variables: bed size (small/medium/large), location (rural/urban), teaching status (non-teaching/teaching), ownership (public/private not-for-profit/private for profit), region (northeast/Midwest /south/west), payment (private/Medicare/Medicaid/ others), DRG type (470/233/24/238/ 246), race (white/black/Hispanic/others) and sex (male/female). Dummy variables were introduced for categorical variables and the first variable in each category was used as the reference. The MLR in R was used for the analysis.

3.3. Principal Component Regression (PCR) with mixed variables

The same dependent and independent variables used in MLR were used in principal component regression (PCR). The standard principal component analysis (PCA) cannot be directly applied for this case because of the categorical variables. Therefore, the R package of PCAmixdata was used, which handles a mixture of qualitative and quantitative variables. Because of the large number of independent variables and potential multicollinearity among them, we hope that PCR could address the potential multicollinearity while reducing the impact of noise through dimensionality reduction.

3.4. Principal Component Regression (PCR) with continuous variables only

We also performed standard PCR using the following continuous variables only: specialization index (I_s), wage index, length of stay (LOS), age, number of chronical conditions, number of diagnosis, number of procedures, and total discharge (to represent hospital bed size). The dependent variable is still the 4th root of TOTCHG.

3.5. Fisher discriminant analysis (FDA)

In this analysis, the total charges (TOTCHG's) of all cases were divided into two groups: the lowest TOTCHG group (*i.e.*, the bottom 25%) and the highest TOTCHG group (*i.e.*, the top 25%). Fisher discriminant analysis (FDA) is performed to find which variables highly contribute to the separation of these two groups, and whether specialization index is one of them. The same independent variables used in MLR were used in FDA, which was performed in SPSS.

3.6. Ordinal regression

To reduce the noise in TOTCHG, we categorize TOTCHG for all cases into four groups and use ordinal regression to investigate the effect of specialization. In this study, TOTCHG is divided into four groups based on the quartiles of cases (i.e., dividing all cases into four TOTCHG groups containing an approximately equal number of cases in each group based on TOTCHG). The same independent variables used in MLR were used in the ordinal regression, which was performed in SPSS.

3.7. Logistic regression

Logistic regression is performed to investigate the effect of each independent variable on the death of patients during hospitalization (i.e., one of the patient outcome measures). The dependent variable is the death of patients during the hospitalization (alive/death). For the independent variables, beside the ones used in MLR, the following two variables were included: severity of illness (minor/moderate/major/extreme), risk of mortality (minor/moderate/major/extreme).

3.8. Adjusted R^2

In this study, the adjusted R^2 is used to compare the explanatory power of regression models. The adjusted R^2 is a modified version of R^2 that has been adjusted for the number of predictors in the model. The adjusted R^2, which is always lower than R^2, increases only if the new independent variable improves the model more than by chance. Similarly, the adjusted McFadden's R^2 was used for logistic regression.

4. Results

To visually inspect the effect of specialization on the total charge, in Figure 1 (a), we plot TOTCHG vs. I_s for all cases of the five expensive DRG's listed in Table 1. Because TOTCHG is strongly right skewed, it can be seen from Figure 1 (a) that some of the positive residual of a linear fit line are rather large. In contrast, we also plot $(TOTCHG)^{1/4}$ vs. I_s as shown in Figure 1 (b), which shows more balanced residual of a linear fitting between $(TOTCHG)^{1/4}$ and I_s, supporting our choice of $(TOTCHG)^{1/4}$ as the dependent variable in all regression analyses rather than the original TOTCHG. We have also performed PCA on the combination of dependent variable $(TOTCHG)^{1/4}$ and all independent variables excluding I_s. In the score plot of the first and the third principal components, we use different colors for different ranges of I_s as shown in Figure 2. Although the scores were generated without the inclusion of I_s, they are

clustered for the same range of I_s, indicating the underlying correlation between I_s and other variables.

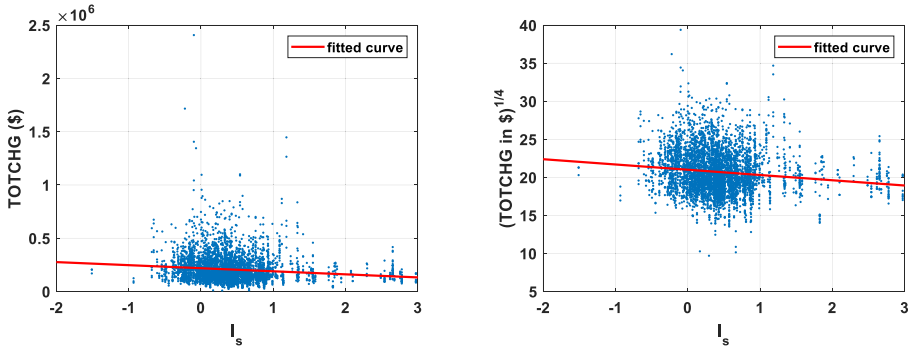

Figure 1. (left) Scatter plot of TOTCHG vs. I_s (dots) with linear fitting (solid line); (right) Scatter plot of $(TOTCHG)^{1/4}$ vs. I_s (dots) with linear fitting (solid line).

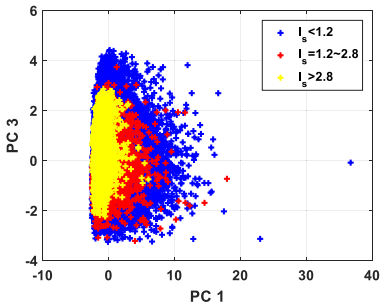

Figure 2. Score plot of the 1st and 3rd principal components of PCA on all variables other than I_s

Next, different regression and discriminant analysis methods discussed in Section 3 are used to model the relationship between $(TOTCHG)^{1/4}$ and various independent variables and the results are listed in Table 2. The second column of Table 2 shows that I_s has a negative effect on $(TOTCHG)^{1/4}$ in all analyses, indicating that higher hospital specialization leads to lower TOTCHG and the p-values of I_s coefficients listed in the last column indicate that the effects are statistically significant in all regression models.

Table 2. The results of regression and discriminant analyses on TOTCHG

Method	**Effect of I_s on $(TOTCHG)^{1/4}$**	**Adj. R^2**	**p-value of I_s coefficient**
MLR	(-)	0.5871	<0.0001
PCR (mixed variables)	(-)	0.5151	<0.0001
PCR (continuous variables)	(-)	0.4009	<0.0001
FDA	(-)	-	-
Ordinal regression	(-)	-	<0.0001

Finally we perform logistic regression to investigate the effect of various factors, including I_s, on the death of patients during hospitalization as one of the patient outcome measures. In the original NIS data, the proportion of patient is severely imbalanced between alive (98.0%) and death (2.0%) cases during hospitalization. One

approach to improve the classification performance for imbalanced data is to either oversample the minority class and/or under-sample the majority class. In this study, balanced dataset is obtained using synthetic minority over-sampling technique (SMOTE) (Chawla et al., 2002). As a result, the fraction of dead patients increases to 17.65% from 2% and prediction ability of model is improved based on the adjusted McFadden's R^2 as shown in Table 3. Table 3 also shows that I_s has a negative effect on the death of patient during hospitalization, indicating higher hospital specialization leads to fewer patient deaths during hospitalization, or better patient outcomes.

Table 3. The logistic regression on the death of patient during hospitalization

Data	The effect of I_s on death during hospitalization	Adj. McFadden's R^2	p-value of I_s coefficient
Orig. imbalanced data	(-)	0.403	<0.0001
Balanced data	(-)	0.575	<0.0001

5. Conclusions

We investigate the effect of hospital specialization on healthcare cost (total charge) and patient outcome (death during hospitalization). This is the first time that a nation-wide dataset of over seven million cases is used for such a study. Various regression methods (including MLR, PCR and ordinal regression) and a linear discriminant analysis method (*i.e.*, FDA) are used to study the effect of hospital specialization on the total charge and the findings are consistent among different methods: higher hospital specialization leads to lower total charge. In addition, logistic regression is used to investigate the effect of I_s on the death of patients during hospitalization as one of the patient outcome measures. Logistic regressions are performed on the original imbalanced data and the balanced data through synthetic minority over-sampling technique (SMOTE). Both results indicate that higher hospital specialization leads to fewer patient deaths during hospitalization or better patient outcomes. This work provides evidence for supporting hospital specialization to achieve low-cost and high-quality hospital care.

Abstract

Stroke is a medical condition, under which poor blood flow to the brain results in cell death. Electroencephalography, EEG, is an electrophysiological monitoring method to record electrical activity of the brain. If EEG signal is processed properly, the feature of each individual stroke case can be analysed to indicate location and severity, which could be used for the diagnosis and continuous monitoring of the treatment process in clinic. In this work, EEG signals from 11 patients with ischemic stroke and 1 healthy person are analysed by Short-time Fourier Transformation (STFT). All patients have malignant middle cerebral artery infarction or received reperfusion therapy. EEG data from ten of them are investigated, which indicates that the delta frequency band energy percentage (DFBEP) in the ipsilateral hemisphere is always higher than the contralateral side, while the alpha frequency band energy percentage (AFBEP) and alpha/delta (AD) are the opposite. Based on this feature, one EEG signal collected along 15 hours from the 11th patient is further analysed by STFT. Compared to the medical record of this patient, the energy of each frequency content changes with the progress of treatment and recovery of patient accordingly, which could be used to monitor the patient condition during the treatment.

Keywords: STFT, Continuous monitoring, Non-invasive diagnosis, Feature extraction

1. Introduction

Stroke is an acute cerebrovascular disease caused by a sudden rupture of the blood vessels in the brain or the inability of blood to flow into the brain due to the occlusion of blood vessels, including ischemic and hemorrhagic stroke.

There are many detection methods available currently, including transcranial Doppler (TCD), magnetic resonance imaging (MRI), computed tomography (CT) and digital subtraction angiography (DSA), etc. Most of them are structural examination, snapshot, and cannot be performed bedside.

As a wide applied and non-invasive detection method, Electroencephalography (EEG) is the general reflection of the electrophysiological activity of brain cells on the surface of

the cerebral cortex or scalp at real time. EEG contains a large number of physiological and functional information.

Delta/alpha power ratio (DAR) was proposed for discriminating between acute ischaemic Stroke (IS) patients and control groups, as DAR from IS patients is significantly higher than that from control groups (Finnigan et al., 2016). Their work reveals that DAR can be an index to recognize the IS symptom, which inspires people that the lesion location could be identified also if sufficient number of montages along scalp are placed, while their analysis is based on Fourier Transform(FFT), and no frequency information is extracted along time. The short-time Fourier transform (STFT) and wavelet transform (WT) was applied to analyse EEG signals for the identification of a child having an epileptic seizure (Kıymık et al., 2015). Both STFT and WT can provide time-frequency information, and STFT is more straightforward to give frequency information along time. Putten and Tavy (2004) introduced brain symmetry index (BSI) for the characterize EEG signals from both hemispheres. However, BSI is calculated within the frequency range up to 25HZ, which fails to differentiate the EEG contribution corresponding to various cerebral conditions, as it is reported that dominant frequency will change for different brain activities.

The aim of this work is to extract more corresponding information from EEG signal regarding to the stroke symptom, not only the frequency content and also the time-frequency content, so as to facilitate the diagnosis and treatment in clinic practice. The rest of this paper is organized as follows: The data is described in Section 2; Methods are shown in Section 3; Result and discussion are included in the Section 4; Conclusion is given in Section 5.

2. Data

2.1. Data acquisition

EEG data acquisition were performed in Beijing Tiantan Hospital of Capital Medical University. We included patients with malignant middle cerebral artery infarction, Tomographic evidence of early hypodensity involving cortico-subcortical topography > 50% of the MCA territory, National Institutes of Health Stroke Scale (NIHSS) > 15, and age ≥ 18 years, or patients who received reperfusion therapy. Patients who received decompressive craniotomy therapy before EEG monitoring were excluded. The EEG examination was performed within 72 hours of symptom onset and more than 30min. The placement of electrodes were based on the international 10-20 system. The electrocardiogram signals collected synchronously. Acquisition frequency was 500Hz. The montage of EEG data is Fp1-C3, C3-O1, Fp1-T3, T3-O1, Fp2-C4, C4-O2, Fp2-T4, T4-O2. All the data saved as ASCII format.

2.2. Details of data

Eleven patients (Patient 1-11) who have infarcts in the hemisphere and a healthy person are analyzed in this paper. Ten short pieces of data taken from the healthy person with total monitoring time of 35.38min are used as references. The details are shown in Table 1.

Table 1. Details of the data

Patient Number	Time	Lesion Location	Reference episode	Time
1	5.33min	Left	1	69s
3	9min	Left	2	45s
4	5min	Left	3	56s
6	5.28min	Left	4	119s
7	3.15min	Left	5	85s
9	1.15min	Left	6	146s
2	5min	Right	7	84s
5	2.77min	Right	8	161s
8	1.2min	Right	9	81s
10	8.63min	Right	10	45s
11	15h	Left		

3. Methodology

3.1. Fourier transform and Short-time Fourier transform

The Fourier transform (FT) decomposes a function of time into the frequencies. Discrete Fourier transform (DFT) is actual used in the processing, can be conducted by Eq.(1).

$$X[k] = \sum_{n=0}^{N-1} x[n] e^{-i \cdot 2\pi k n / N} \tag{1}$$

where $X[k]$ is the frequency domain , $x[n]$ is the time domain and N is the number of the sampling points.However, the Fourier analysis is performed based on the whole signal across the time domain, which only gives the frequency component for the overall signal, and fails to reveal the local information of a signal in time domain. For this purpose, STFT is proposed as in Eq.(2), which involves representing the signal in the time-frequency domain to show the changes in its frequency components with respect to time.

$$STFT\{x[n]\}(m, \omega) \equiv X(m, \omega) = \sum_{-\infty}^{\infty} x[n] \omega[n - m] e^{-jwn} \tag{2}$$

In Eq.(2), $\omega[n]$ is the window function which is a Hamming window and $x[n]$ is the signal to be transformed.

3.2. Frequency band energy

Frequency changes over time can be obtained through STFT, and then the energy is calculated through Eq.(3).

$$\varepsilon = |X(m, \omega)|^2 \tag{3}$$

The frequency band in clinic practice is defined in Table 2.

Table 2. The frequency band adopted in clinic practice

Frequency band	Name
0.5-4Hz	Delta
4-8Hz	Theta
8-13Hz	Alpha
13-30Hz	Beta
30-35Hz[#]	Gamma

[#]30-35Hz: The frequency range which is considered is 0-35Hz in this paper.

The definition of frequency band refers to the guideline (Deuschl and Eisen, 1999). The energy of each frequency band is calculated by integration in Eq.(4).

$$E_i = \int_{f_1}^{f_2} \varepsilon \, df \tag{4}$$

where ε is the transform results of window whose length is N. Each frequency band energy percentage is a more important indicator as defined in Eq.(5).

$$E_{norm} = \frac{E_i}{\sum E_i} \tag{5}$$

where E_{norm} is the normalized frequency band energy.In this paper, delta frequency band energy percentage (DFBEP), alpha frequency band energy percentage (AFBEP) and alpha/delta (AD) are used as main indicators. AD is the ratio of the AFBEP to the DFBEP.

3.3. Processing of data

The procedure of data process is shown in Figure 1.

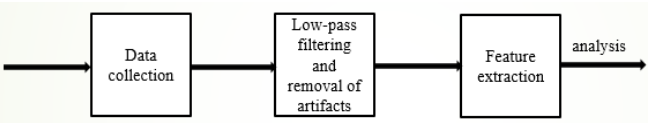

Figure 1. Procedures for data processing.

Frequency range of the low-pass filtering is 0-35Hz. STFT is used in feature extraction in every step of analysis. The energy percentage of each frequency band is calculated.

4. Results and Analysis

4.1. STFT analysis result relative to the lesion location

A comparison of Patient 1 and the reference is shown in Figure 2. Columns with odd numbers correspond to left cerebral hemisphere, otherwise to the right side.

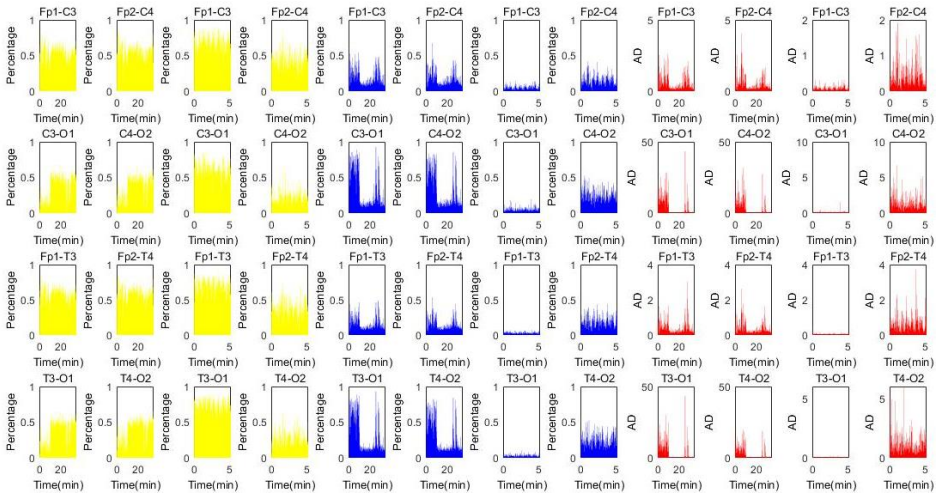

Figure 2. Frequency band energy percentage of the data of patient 1 and the reference. The first and the second columns are DFBEP, the fifth and the sixth columns are AFBEP, and the ninth and the tenth columns are AD. The two columns following each of them are the reference.

As it can be seen from Figure 2, the DFBEP, the AFBEP and the AD of the healthy person are generally symmetrical between left and right cerebral hemisphere. However, the DFBEP of left cerebral hemisphere is higher than that of the right side, while the AFBEP and the AD are opposite to it with respect to the patient 1. AD is a better indicator than AFBEP when compared the frequency band energy percentage of left and right cerebral hemisphere.

Then the average values of the DFBEP, the AFBEP and the AD of left and right cerebral hemisphere of patient 1-10 are calculated respectively. The results are shown in Table 3. Figure 3 depicting symmetry between left and right cerebral hemisphere are drawn according to the data of Table 3

Table 3. The average values of the DFBEP, the AFBEP and the AD of left and right cerebral hemisphere

No: Patient number; L(R): Left (Right) cerebral hemisphere; Re: Refence episode.

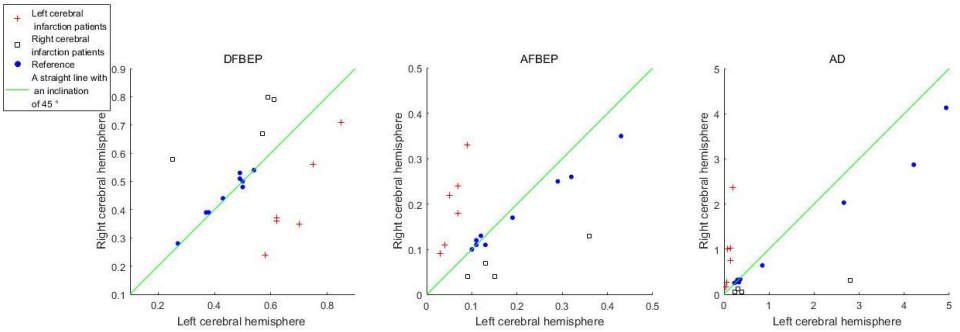

Figure 3. The symmetry between left and right cerebral hemisphere

As it can be seen from Figure 3, the average of the DFBEP, the AFBEP and the AD of the healthy person are generally symmetrical between left and right cerebral hemisphere. However, with respect to the left cerebral infarction patients, the average of the DFBEP of left cerebral hemisphere is higher than that of the right side, while average of the AFBEP and the AD are the other way around. The same results are observed with respect to the right cerebral infarction patients.

To summarize the results obtained from first ten patients, it can be seen that DFBEP is relatively higher, AFBEP and AD are relatively lower when the lesion exists in corresponding cerebral area, thus, DFBEP, AFBEP and AD can be used as indicators to monitor patient condition.

4.2. Monitoring the patient condition

Patient 11 suffered the left-sided cerebral infarction, and was getting better during clinic treatment. His EEG data related to the left cerebral area within the first 15 hours was analysed. DFBEP, AFBEP and AD are illustrated in Figure 4.

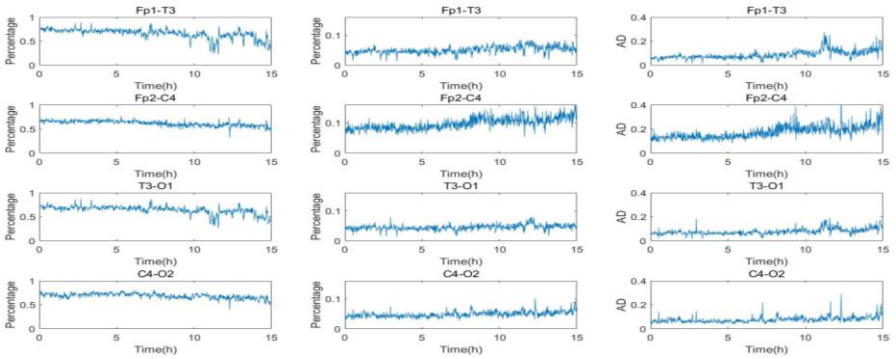

Figure 4. Frequency band energy percentage of patient 11 in the left cerebral hemisphere. The first to the third columns are DFBEP, AFBEP and AD in turn.

It can be seen that that the DFBEP is decreasing, the AFBEP and the AD are increasing along time, indicating that the patient's condition is getting better, which is highly consistent with the clinic record.

5. **Conclusions**

In this paper, EEG signal is analysed by STFT, from which the frequency band energy is obtained. The lesion location of patients with ischemic stroke can be identified by comparing DFBEP, AFBEP and AD among each pair of montages. The preliminary results indicate that DFBEP, AFBEP and AD can be used as indicators for stroke evolution and patient recovery. With further analysis on EEGs it can be employed for more sophisticate clinical applications, e.g. early diagnosis, treatment decision, outcome prediction, and clinical monitoring.

Abstract

Motivated by the need for fast design approaches for sustainable chemical processes, this work focuses on the combination of a quantum chemistry based screening method for the selection of suitable ionic liquids (ILs) as separating agents in chemical gas phase processes and the analysis of the overall process with the help of process simulations. By close integration of the systematic screening procedure for suitable ionic liquids based on constraints defined by the overall process and the flowsheet simulation, the proposed methodology allows for an environmentally and economically feasible process development. The approach was applied to an industrial example process, namely the electrochemical oxidation of hydrogen chloride to chlorine, which is a crucial part of the polyurethane and polycarbonate production. The most efficient industrially realized electrochemical process was developed by Bayer and UHDENORA. It uses aqueous hydrochloric acid as feed stock. As an alternative, our group has shown recently that the electrolysis of gaseous hydrogen chloride is much more efficient and leads to exergy savings of 36% on the reactor level alone. In the present work the separation of unreacted hydrogen chloride from chlorine in the reactor effluent stream by means of selective HCl absorption in ILs is investigated in order to determine whether the exergetic advantage of the novel gas phase reactor can be maintained on the overall process level when the necessary separation steps are included. For this purpose, an extensive screening procedure of ILs available in the COSMOtherm IL database is carried out in order to find the most suitable candidates. Hereby, key properties like the chemical stability in the harsh chlorine environment as well as important physical and thermodynamic properties of the ILs are tailored to the demand of this specific gas phase process. Subsequently, the overall process is simulated with Aspen Plus and a detailed exergy analysis of all process units is performed. Additionally, the results are compared to simulations of the Bayer UHDENORA process. The analysis shows that not only the electrochemical reactor but also the separation steps in the proposed gas phase process display a significantly lower exergy demand than the industrial Bayer UHDENORA liquid phase variant. This demonstrates that the proposed integrated design methodology efficiently supports the development of sustainable, yet profitable chemical processes.

Keywords: Ionic Liquids, Process Design, Process Simulation, Process Integration

1. Introduction

In order to reduce the impact of chemical processes on the environment and society while still preserving economic competitiveness, a more sustainable process design in the chemical industry is imperative. This can be understood as the development of a process that leads to lower values of a set of targeted performance criteria, like costs or environmental impact, in comparison to a reference process (Segovia-Hernandez and Bonilla-Petriciolet 2016). In most chemical processes a complete conversion of the reactant is not achievable so that the feasibility of purifying the reaction product is oftentimes decisive for the overall energetic efficiency and profitability of the chemical process. In the last two decades ionic liquids have gained significant attention in various fields, such as separating agents for the absorption of gases like CO_2 (Zhang 2012). Due to their green and designer properties, they are often regarded as environmental friendly, less hazardous and sustainable alternatives to organic solvents (Rogers and Seddon 2012). However, owing to the vast variety of possible cation-anion combinations, a systematic screening approach for finding the best suited candidate for each specific chemical process is absolutely essential (Song 2017). In addition, the screening process must consider constraints imposed by the particular chemical process, such as the inertness and stability of ILs under the given conditions, the overall process performance in terms of energy consumption and many more. Therefore, it is critical to combine a quantum chemical based IL screening method with a process flowsheet simulation in order to find a the best suited IL for the product purification and at the same optimal process conditions that lead to a more energy efficient and sustainable overall process. In the present work, this combined approach is exemplified by an important process in the chemical industry, the electrolysis of hydrogen chloride to chlorine. Up to now, the most efficient industrially employed process for the HCl electrolysis is the Bayer UHDENORA process, in which aqueous hydrochloric acid is fed into an electrochemical reactor, the emerging chlorine is separated and the depleted hydrochloric acid stream is recycled. More detailed information about this process can be found in our recent publication (Bechtel 2017). This process has the major disadvantage of a significant energy demand on the reactor level as well as in the separation step. Recently, our group has investigated an electrochemical reactor in which gaseous hydrogen chloride is oxidized to chlorine so that the reactor outlet stream consists only of anhydrous hydrogen chloride and chlorine. This reactor concept leads to significant exergy saving on the reactor level (Bechtel 2017). However, in this previous work we have not investigated the use and the advantages of ILs as separating agents to obtain the pure chlorine.

Based on the methodology described above, the goal of this contribution is to determine, whether the use of ionic liquids as a solvent allows for an energy efficient purification of the product and a more economically feasible and sustainable overall process in comparison to the Bayer UHDENORA reference method. For this reason a suitable IL is determined based on the screening procedure explained in chapter 2 and a flow sheeting simulation of the overall process is carried out. Contrary to many other absorption processes reported in literature (Farahipour 2016), the gas mixture consisting of chlorine and hydrogen chloride is very reactive which strongly influences and restricts the selection process of possible ionic liquids. Finally, based on the process simulation a detailed exergy analysis was carried out and the overall exergy demand of the novel proposed IL process was compared to the reference process.

2. Screening procedure and set up of the Process simulation

Although the computer-aided molecular design (CAMD) method has been extended to guide the selection of IL solvents for different separation problems, the state-of-the-art IL screening process mainly concentrates on the estimation of thermodynamic and physical properties due to the unavailability of predictive models for other IL properties (Austin 2016). Considering the highly reactive nature of HCl and Cl_2, a modified IL screening background is proposed for this particular case as depicted in Figure 1.

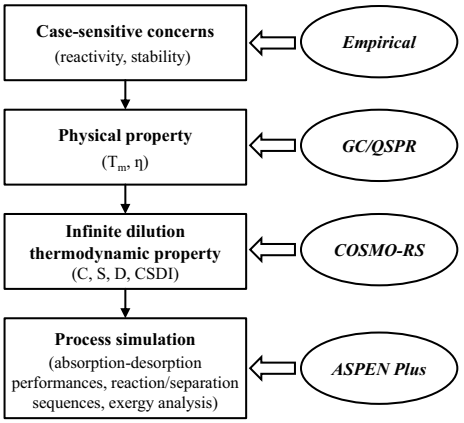

Figure 1, Process design methodology consisting of a three step IL screening procedure and the flowsheet simulation.

In the first step, ILs with functional groups that are prone to react with either chlorine, hydrogen chloride or traces of water that can be present in the gas stream due to crossover in the membrane of the electrochemical reactor are excluded. Therefore, amines and ammonium cations have to be excluded in order to avoid the formation of chloramines. Furthermore, no aromatic systems or allyl groups are allowed, since they are prone to electrophilic substitution with chlorine. This is especially critical, if the aromatic system or the allyl group is substituted with functional groups that increase the electron density in the π-bond. Additionally, no carbonyl, carboxyl, imine or amide group should be present since they can be halogenated in alpha position (Hauptmann 1991). Moreover, metal salts that are prone to hydrolysis in the presence of water like tetrachloroaluminiate have to be discarded in this first screening step (Huheey 2006). In addition cyanides or related groups are also prone to react with halogens (Weyl 2005). Finally, highly fluorinated molecules were disregarded for environmental and economic reasons.

In the second step the melting temperatures T_m of the remaining ILs are estimated using the GC method developed by Lazzús *et al.* (2012) and the viscosities η are calculated with the GC feed-forward artificial neural network (FFANN) method developed by Paduszyń and Domańska (2014) by group contribution (GC) or quantitative structure-property relationship (QSPR) methods. Only ILs with a melting temperature below 298.15 K and a viscosity smaller than 150 mPa s are considered for the following screening step in which the infinite dilution thermodynamic properties are investigated. The higher the viscosity the more difficult and energy intensive is the circulation of the ionic liquid within the process and its units, which is the reason for the imposed maximum value. Here, the absorption capacity *C*, the absorption selectivity towards

hydrogen chloride *S*, the desorption ability *D* and the overall *CSDI* value are calculated with the help of COSMO-RS (Farahipour 2016, Zhao 2017):

$$C = \frac{1}{H_{HCl}^{25}} \times \frac{MW_{HCl}}{MW_{IL}} \tag{1}$$

$$S = \frac{H_{Cl2}^{25}}{H_{HCl}^{25}} \times \frac{MW_{HCl}}{MW_{Cl2}} \tag{2}$$

$$D = H_{HCl}^{55} / H_{HCl}^{25} \tag{3}$$

$$CSDI = C \times S \times D = \frac{H_{HCl}^{25} \times H_{HCl}^{55}}{\left(H_{HCl}^{25}\right)^3} \times \frac{\left(MW_{HCl}\right)}{MW_{Cl2} \times MW_{IL}} \tag{4}$$

In these equations H_i stands for the Henry constant of the substance *i* in the IL and MW_i for the molar mass of the according substance. The most promising candidate of this screening procedure was then chosen for a process simulation in Aspen Plus 8.8. For the process simulation, the IL was treated as a user-defined component for which the molecular structure as well as the boiling point, the density, the critical properties and the acentric factor was manually entered. These properties were determined using the fragment contribution-corresponding states method proposed by Huang *et al.* (Huang 2013). The temperature dependence of the Henry constants of chlorine and hydrogen chloride in the IL was fitted with the method of least squares based on values determined with COSMO RS in a temperature range from 298.15 K – 483.15 K with an interval of 20 K. As a property method COSMO-SAC was chosen and the screening charge density profile as well as the molecular volume were calculated with COSMO-RS and implemented into the flowsheet simulation. The corresponding properties for chlorine and HCl are already implemented in the Aspen Plus databases. In order to allow for a comparison with the simulation of the Bayer UHDENORA process in (Bechtel 2017) the conversion in the electrochemical reactor was set to be 80 % and the remaining 20 % of not converted hydrogen chloride was absorbed in water forming 37 wt% hydrochloric acid, which leaves the process as an additional product. For more information please see (Bechtel 2017). The process flowsheet is shown in Figure 2.

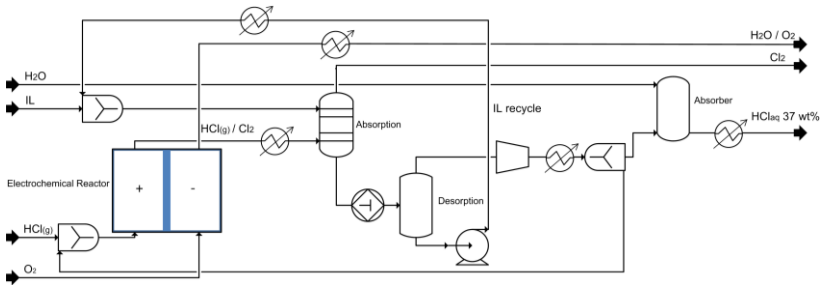

Figure 2, Flow chart of the IL process. The hydrogen chloride in the anode outlet stream in the reactor is absorbed in the IL leaving pure chlorine in the gas stream leaving the absorption unit. Afterwards, the absorbed hydrogen chloride is desorbed at a pressure of 50 mbar and a temperature of 483.15 K. Subsequently the IL is compressed to atmospheric pressure and recycled into the process again. The hydrogen chloride leaving the desorption unit is compressed in 4 steps with intermediate cooling towards atmospheric pressure. Subsequently, the hydrogen chloride can be recycled back to the electrochemical reactor or absorbed in water forming concentrated hydrochloric acid.

It should be mentioned that the proposed multi-step IL screening essentially follows the main idea of the state-of-the-art of IL design method (Song 2017, Farahipour 2016). However, it is interesting to see that only very few ILs out of a large number of possible candidates remain after the first three steps, which makes it possible to perform the detailed process simulation and evaluation in the fourth step. Due to this, and the complex considerations regarding the reactivity, such an approach appears to be very purposeful in this specific case and comparable gas phase processes. Finally, the exergy analysis of the overall process was carried out based on the equations described in (Bechtel 2017).

3. Results

As a result of the second screening step, only 39 ILs remained for which the C, S, D and the CSDI values were calculated and depicted in Figure 3:

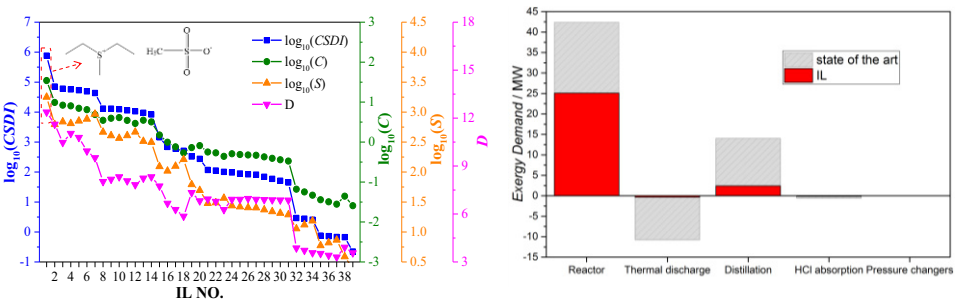

Figure 3, (a) Infinite dilution thermodynamic properties calculated according to Eq. (1-4) for the remaining 39 ILs. (b) Contributions of the different unit operations to the exergy demand of the state-of-the-art process (Bechtel 2017) (shaded) and the novel IL process (filled).

The IL with the highest values in all four categories is diethyl-methylsulfonium methanesulfonate ([S221][MeSO3]). The chemical structure is included in Figure 3. Since it furthermore has a comparatively low heat capacity of only 310 J mol^{-1} K^{-1} at room temperature, it was chosen for the process simulation in Aspen Plus. It is worth noting that the heat capacity of the IL turned out to also significantly influence the exergetic efficiency of the process and should therefore be directly included into the screening process in future investigations. In Figure 3b the exergy demand of the IL-based process is compared with the state of the art process from Bayer UHDENORA. The overall exergy demand of the newly proposed process is 36 % lower compared to the Bayer UHDENORA state of the art process. Additionally, less apparatus are needed for the IL based process. Furthermore, the size of the apparatus can be reduced, since the large water containing recycle streams of the Bayer UHDENORA process (see Bechtel 2017) can be avoided. Finally, it can also be expected that the material costs will be lower in the IL process, since the hydrogen chloride only comes into contact with water at the very end of the process when parts of it are facultatively absorbed in water to generate concentrated hydrogen chloride as a byproduct. Contrary to that, in the Bayer UHDENORA process the hydrogen chloride is absorbed in water right at the beginning of the process which leads to the need of more corrosion resistant and therefore more expensive material throughout the whole process. In future work, a comparison of the capital and production cost between both processes should be carried out to also further quantify the financial profitability. Additionally, the VLE data used for the process simulation could be experimentally validated in future investigations.

4. Conclusions

In the present work, a combination of quantum chemical screening methods for ILs was combined with flowsheet simulations in order to develop an energy efficient and sustainable alternative to a state-of-the-art reference process. This methodology was tested on an industrially important example process, the electrochemical recycling of hydrogen chloride to chlorine. During the screening process, not only physical and thermodynamic properties of the ILs were taken into account but also restrictions arising from the specific process like the chemical stability of the IL. Based on a detailed exergy analysis, it was possible to show that the newly proposed process based on the above explained methodology leads to exergy savings of 36 % compared to the Bayer UHDENORA reference process. Furthermore, significant savings in material costs can be expected which leads to an overall more sustainable and profitable process.

Multiscale scheme for the optimal use of residues for the production of biogas

Manuel R. Taifouris, Mariano Martín[a*]

[a]*Departamento de Ingeniería Química. Universidad de Salamanca, Salamanca, 37008, Spain*

Abstract

This work evaluates the use of four different types of waste such as sludge, manure, municipal solid wastes (MSW) and lignocellulosic residues for the production of biogas and fertilizer using a feedback multiscale analysis. Waste yield to both products is determined and the digestion kinetics is computed using a parameter estimation approach with experimental data. Hydrolysis is the limiting stage. Next, a techno-economic evaluation of a processing facility is carried out. Finally, a supply network model is developed to evaluate the optimal use of the residues over a region in Spain. The network is formulated as a mixed integer linear programming problem selecting the type of residue, the number and size of the digesters and the location of the plants across 59 shires of a particular region in Spain for the available budget. MSW is the selected waste due to its wide availability and large yield to fertilizer. Lignocellulosic residues are the second best option. Only intrashire transport is suggested. The shires selected for its processing are rather scattered as a function of the resources available and the already installed facilities. However, the amount of residues available can provide more than three times the region demand for natural gas, but the investment required adds up to more than 4.4 B€.

Keywords: Waste, Anaerobic digestion, Biogas, Power, Multiscale analysis.

1. Introduction

Developed societies generate large amounts of waste. In the European Union, 5 t of waste are produced per person and year (ec.europa.eu). Not only the volume but also the composition becomes a challenge. Processing the waste requires large and costly facilities but it is required to avoid dangerous effects on the environment. One single technology that is capable of both, processing and generating added value out of waste, is anaerobic digestion. It produces biogas, a mixture of methane and CO_2, and digestate, that can be used as fertilizer. This kind of facilities can be considered as part of the so-called circular economy aiming at the reuse of waste to bring value again to residues extending their lifespan (Lieder and Rashid, 2016). However, the evaluation of the potential of the use of waste requires a multiscale evaluation scheme, from the digestor analysis, kinetics and yield (Weinrich and Nelles, 2015), to the supply chain (Santibañez-Aguilar, 2013), including the techno-economic analysis of the process.

2. Methodology

The design and operation of waste to power systems based on anaerobic digestion have to be evaluated in a multiscale framework, from the process to the supply chain. Due to

the strong link between the various scales, a retrofit analysis is required. High level decisions are made at macroscopic scale, but detail information on the lower levels, process and unit performance and economics, are essential for informed decisions. Thus, we first evaluate the operation of the plant for each of the residues, namely, sludge, lignocellulosic residues, MSW and manure. Detail kinetics for each one is required because the residence time at the reactor is a direct function of the residues physical structure. Therefore, for the same reactor size, typically standardized, the yield is different as a function of the kinetics. Next, a techno-economic evaluation of the production is carried out to determine the investment and production costs. The processing plants allocation depends on the residue availability and its yield to valuable products. A supply chain study is developed to evaluate the use of waste and the size and number of facilities to be installed, considering residue availability per region and type, presence of other transformation plants and transportation costs. A two-level supply chain is formulated considering residues production and transformation layers. Economic or sustainability metrics can be added as objective function.

2.1. Process description

The process consists of the preparation of the feed to the digester to operate at 37ºC and with up to 10% by weight in solids. The reaction is endothermic; therefore an external heating system is in place. The yield depends on the kinetics. We assume a residence time corresponding with 95% of the maximum methane production per residue. Biogas is cleaned from NH_3, using a scrubber, H_2S, using an iron based fixed bed, and CO_2, followed by a pressure swing adsorption (PSA) system. The digestate is filtered. The cake is stored to be sold, and the water, after treatment, reused. The number of standard digesters depends on the processed waste. The economic evaluation is carried out using the factorial method (Sinnot, 1999) based on ‘equipment sizing and costing, Figure 1.

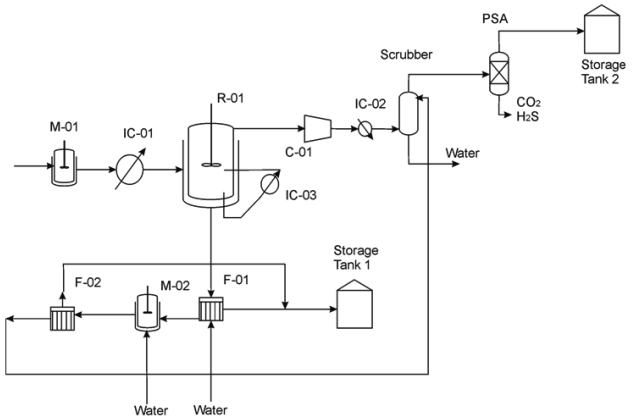

Figure 1.- Scheme of a one digestor process for waste to power.

2.2. Reactor Kinetics

Anaerobic digestion consists of four stages, hydrolysis, acetogenesis, metanogenesis. Detailed models allow simulation but they are too complex to evaluate the effect of waste type on the kinetics. We consider the fact that, for the residues used and the operating conditions, the limiting stage is the hydrolysis. Therefore, we use a hydrolytic kinetics that assumes first order with respect to lipids, carbohydrates and protein based on the work by Weinrich and Nelles (2015) to fit the experimental results in the

literature for four different waste types: manure, lignocellulosic, sludge and MSW. To come up with the model, eq. (1), we consider an average composition for the lipids, carbohydrates and protein within the biomass. However, the use of an average composition results in the fact that a correction parameter, α, is needed to match experimental data. The model requires three input values, X_{CH0}, X_{Pr0}, X_{Li0}. However, only the biodegradable part of the residue will produce biogas (Montañés et al., 2015). This value is experimental for each waste according to its structure. Thus, biodegradability is averaged from different sources for each type of waste to come up with the values used in our mode. Thus, the biodegradability for manure is 46% (Kalamaras and Kotsopoulos, 2014), for MSW 50% (Rao and Singh, 2004), for sludge 55% (Park et al., 2016) and for lignocellulosic residues 74% (Bouallagui et al., 2004).

$$\begin{aligned}
\frac{dX_{Ch}}{dt} &= -k_{Ch}\cdot X_{Ch} + 0.18\cdot k_{DEC}\cdot X_{BAT}\\
\frac{dX_{\Pr}}{dt} &= -k_{Pr}\cdot X_{Pr} + 0.82\cdot k_{DEC}\cdot X_{BAT}\\
\frac{dX_{Li}}{dt} &= -k_{Li}\cdot X_{Li}\\
\frac{dX_{BAT}}{dt} &= (1+\alpha)\cdot(0.1509\cdot k_{Ch}\cdot X_{Ch} + 0.1241\cdot k_{Pr}\cdot X_{Pr} + 0.1857 k_{Li}\cdot X_{Li})\\
\frac{dS_{CH_4}}{dt} &= (1+\alpha)\cdot(0.2433\cdot k_{Ch}\cdot X_{Ch} + 0.2383\cdot k_{Pr}\cdot X_{Pr} + 0.6588 k_{Li}\cdot X_{Li})\\
\frac{dS_{CO_2}}{dt} &= (1+\alpha)\cdot(0.6675\cdot k_{Ch}\cdot X_{Ch} + 0.6822\cdot k_{Pr}\cdot X_{Pr} + 0.6644\cdot k_{Li}\cdot X_{Li})\\
\frac{dS_{H_2O}}{dt} &= (1+\alpha)\cdot(-0.039\cdot k_{CH}\cdot X_{ch} - 0.2047\cdot k_{Pr}\cdot X_{Pr} - 0.4810\cdot k_{Li}\cdot X_{Li})\\
\frac{dS_{H_2S}}{dt} &= (1+\alpha)\cdot(0.0012\cdot k_{Pr}\cdot X_{Pr})\\
\frac{dS_{NH_3}}{dt} &= (1+\alpha)\cdot(-0.0227\cdot k_{Ch}\cdot X_{Ch} + 0.1645\cdot k_{Pr}\cdot X_{Pr} - 0.0280\cdot k_{Li}\cdot X_{Li})
\end{aligned} \tag{1}$$

2.3. Supply chain

This work focuses its attention on a particular agricultural area in the South of Europe. We divide Castile and Leon into the official 59 shires. Each of the shires is characterized by its position, computed using the latitude and longitude of the centre, and the availability of the four waste types considered. (Medioambiente JCYL, 2016). The presence of waste processing facilities is considered by including a penalty that reduces the market of digestate and the profit obtained from it as well as the waste availability in the region and its souroundings. The objective function is given by eq. (2)

$$OF = \sum_i \sum_j TInc(i,j)) - \sum_i \sum_j TotalC(i,j)) \tag{2}$$

The total cost, eq. (3), (TotalC) involves transportation (TC), amortization (FC), raw materials (RM), labour (LB) and utilities (Util). The reference for all computations is the anaerobic digesters used per plant. Three standard sizes are considered, 1,000, 3,000 and 6,000 m^3. The maximum size recommended is based on the difficulties in mixing https://mediathek.fnr.de/. Any plant at a shire consists of a number of digesters of each size. For the transportation a two level supply chain is developed, one for the waste production another one for processing. Only the waste in the processing level will be used in the plants. Transportation takes place at the production layer and from there it is sent to the processing plants. Raw materials only consider water, since waste is obtained at zero cost. Utilities accounts for 15% of the total annual cost. Labour is computed as

per plant size, small, medium or large plant. Finally, amortization is computed using as reference the digester size, the number of them used per plant and its lifetime. A correction factor based on the contribution of the reactor to the total cost of the plant is computed from the detailed process design. Raw material availability is limited in regions where waste to energy plants are already available.

$$\mathrm{TotalC}(i,j) = \mathrm{FC}(i,j) + \mathrm{VC}(i,j) = \frac{\left(\mathrm{FC}(i,j) + \mathrm{TC}(i,j) + \mathrm{RMs}\ (i,j) + \mathrm{Lb}(i,j)\right)}{Util} \tag{3}$$

The benefit, eq. (4) (Tinc), from the operation comes from the production of biogas (Ibio) and digestate (Id). Each digester size generates a certain amount of biogas and digestate as a function of the waste processed and its size. The yield is computed from the reactor modelling stage. Only a fraction of the digestate can be sold in the market the rest generates no benefit.

$$TInc = \sum_i \sum_j (\mathrm{Ibio}(i,j) + \mathrm{Id}(i,j)) \tag{4}$$

The model is formualted as and MILP consisting of 16,500 continuous variables, 708 binary variables and 2,373 equations written in GAMS® and solved in a Windows 10, intel core i7 machine with CPLEX 12.6.

3. Results

3.1. Yields and reactor operation.

It turns out that k_{Ch}, k_{Pr} and k_{Li} are similar for each waste, k_i in Table 1, since there are no recording of the generation of CO_2 , biomass or H_2S that will allow full validation of the model. Next, we fix the residence time for the time that it takes to reach 95% of the maximum methane yield. Thus, the residence time is 15 days for sludge, 30 days for MSW, 24 days for manure and 32 days for lignocellulosic residues. Next, the yield per unit volume of the reactor and day is computed, see Table 2.

Table 1.- Kinetic parameters for various waste types (37 ºC)

Residue	$k_i(d^{-1})$	$X_{ch}(g_{Ch}/g_{vs})$	X_{Pr} (g_{Pr}/g_{vs})	X_{li} (g_{Li}/g_{vs})	Degradability (%)
Sludge	0.21	0.44	0.182	0.309	55
MSW	0.07	0.367	0.268	0.013	50
Manure	0.11	0.83	0.1	0.03	46
Ligno	0.1	0.672	0.125	0.05	74

Table 2.- Yield per residue type.

	CH_4 $(kg/m^3 \cdot d)$	CO_2 $(kg/m^3 \cdot d)$	H_2S $(kg/m^3 \cdot d)$	Biogas $(kg/m^3 \cdot d)$	Biomass $(kg/m^3 \cdot d)$	Digestate $(kg/m^3 \cdot d)$
Sludge	1.057	1.862	0.000653	2.919	0.437	58.721
MSW	0.241	0.650	0.000317	0.891	0136	71.182
Manure	0.359	0.940	0.000176	1.300	0.210	65.070
Ligno	0.502	1.258	0.000219	1.760	0.280	40.149

3.2. Techno-economic analysis of the process.

The use of MSW as reference is based on a previous run of the supply chain model to see which is the most promising residue. This is another feedback required within the multiscale analysis. We consider the flowsheet presented in Figure 1 to identify the units involved. For a facility of 1 single reactor and a production capacity of a reactor of

6,000 m^3, the total cost of the units adds up to 1.5 M€. The cost of IC-03 is included in the reactor cost. Based on the factorial method, factors of 3.4 and 1.45 for a plant dealing mainly with fluids (Sinnot, 1999) and considering that the working capital is 10% of the fixed capital we compute the investment cost of the facility. However, for the supply chain model we need to compute the ratio between digester cost and plant investment, γ. We assume that we can scale the system using a digester as reference unit. Thus, the ratio between the total investment cost and the reactor cost, γ turned out to be equal to 0.10.

3.3. Infrastructure for waste processing.

The regional government has a budget for infrastructure development that accounts for 80% of the total budget for the environmental department. Using a fraction of that budget, from 25% to 100% (88 M€ to 351 M€, JCYL, (2017)), we evaluate the network that can be operated, see Figure 2. Only intrashire transportation is recommended. Thus, sources and sinks coincide. We see that with the entire annual budget, we reach the exploitation of 8.95 % of the biogas potential in the residues. Even if there is a large difference in the fraction processed, the mass of lignocellulosic residue processed is the same as that of MSW when investing 351 M€. That means that 50% of the budget goes to MSW and when it is not economical to continue exploiting MSW, lignocellulosic residues are used due to its larger yield to biogas. No manure is recommended to be used, due to the scattered availability and low yield to digestate, see Table 3.

Table 3.- Waste processing capabilities as a function of the budget

Investment (M€)	88	175	263	351
% Total Waste processing	2.14	4.32	6.71	8.95
% waste processing	22% MSW	43% MSW	48% MSW 2.62% Ligno	70.83% MSW 2.29% Ligno
Biogas cost (€/MMBTU)	59	57	56	51

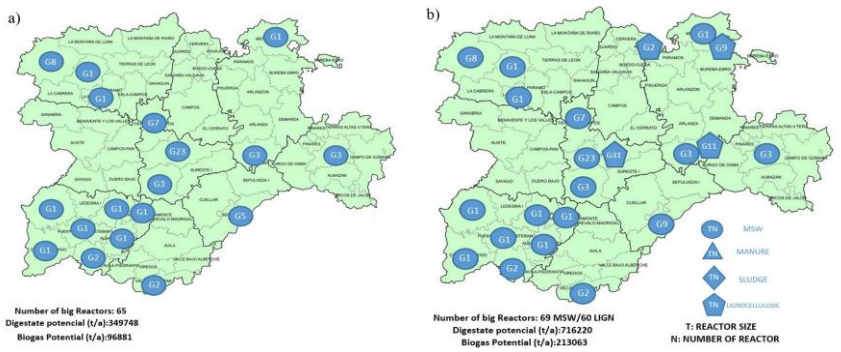

Figure 2.- Waste selection and plant size for a) 175M€ and b), 351 M€

However, this is a one year program. A multiperiod investment plan may allow increasing the processing capacity of residues and the production of biogas. The biogas potential out of the residues in the region reaches $2.09 \cdot 10^9$ m^3 (at 60% methane). The total budget to process this much residue adds up to 4,426 M€, requiring the installation of 1,389 big reactors, 44 medium size and 14 small size reactors. The methane potential from residues can provide 3 times the natural gas demand in Castile and Leon (http://www.cescyl.es) and it can provide 5.1% of the total natural gas consumption in Spain (http://www.cores.es). The production cost of the gas is 10 times higher than

current prices, and 5 times the cost of methane produced from solar and wind (Davis and Martín, 2014) see Table 3. Spain, does not have major sources of natural gas, therefore, the use of residues is an interesting alternative to evaluate.

4. Conclusions

A multiscale approach, from digester analysis to supply chain design, has been developed to evaluate the use of four different types of waste for the production of biogas and digestate. The reactor is characterized using a parameter estimation scheme assuming first order kinetics to evaluate the yield to biogas and digestate of the various waste fractions. Based on this, a techno-economic study of a plant is developed. The macroeconomic scale determines the potential and the location of the processing plants. A supply chain network is developed to evaluate the potential of residues, the type of residue, reactor size and the best location to install the processing facilities.

MSW is the selected waste due to its wide availability and large yield to fertilizer. Lignocellulosic residues are the second best option. Only intrashire transport is suggested. The shires selected for its processing are rather scattered as a function of the resources available and the already installed facilities. However, the amount of residues available can provide more than three times the region demand for natural gas, but the investment required adds up to more than 4.4 B€. Therefore, a multiyear investment program is to be put in place.

Abstract

CO_2 capture from enclosed environments such as commercial buildings can result in reduced ventilation, thereby leading to decreased energy loads on the HVAC systems. We propose a model which regulates the air quality inside the room by adsorption of CO_2 on monoliths coated with zeolite 13X, and water adsorption on packed beds with silica gel. We perform a modeling study and energy assessment by simulating a multi-component, multi-bed system which controls carbon dioxide level inside the room on a 24 hr basis. The results obtained indicate a 75% reduction in energy load with the CO_2 capture system as compared to the conventional ventilation system. We have identified areas of uncertainty in the model and compared non-intrusive polynomial chaos method with Monte Carlo simulations to quantify the model uncertainties. The results show improvement in computational efficiency with non-intrusive methods as compared to Monte Carlo simulations. We conclude that the CO_2 capture system can lead to improvement in building energy performance and application of polynomial chaos methods can result in reduction of computational time.

Keywords: CO_2 capture, Concentration Swing Adsorption, Zeolite 13X, Monoliths

1. Introduction

In enclosed environments such as commercial buildings, temperature and air quality are two important factors which are controlled to maintain a comfortable and workable environment. Air conditioning controls temperature, often at the expense of humidity, and particulate filters reduce suspended matter, but other quality factors, particularly CO_2 concentration, have remained unaddressed. There are health risks associated with high CO_2 concentration (>0.5%) (Fisk, 2000). Occupants may suffer headaches, nausea, fatigue and listlessness when exposed to high CO_2 concentration for prolonged durations. Hence, removal of CO_2 from enclosed environment is essential for improving human productivity.

There have been recent studies on minimizing energy inside buildings (Prívara et al., 2011; Salsbury et al., 2013). However most of them focus on controlling the thermal standards inside buildings (Aktacir et al., 2010; Videla and Lie, 2006). The conventional method of regulating the air quality is through ventilation (Seppänen et al., 1999).

However, such techniques are not energy efficient in case of large and enclosed space because air has to be conditioned to lower concentrations of air pollutants such as CO_2 or air-borne volatile organic compounds (VOCs). An alternate route to lower CO_2 level is to capture the CO_2 from indoor air and recirculate the CO_2 depleted air. The major challenge to implement such a strategy is the small driving force for CO_2 removal due to the low concentration. Recently a 3D monolith coated with zeolite was developed (Thakkar et al., 2016) which shows a promising pathway for dilute CO_2 capture.

In this study, we design and model a modified air conditioning system which regulates temperature as well as air quality, as quantified by CO_2 and H_2O concentrations, inside an enclosed environment. The model includes human occupancy of the room which is time dependent. Human respiration and perspiration dynamics have been taken into consideration while modeling the complex multi-bed system. 13X zeolite adsorbent is considered to capture the CO_2 adsorption dynamics within the 3D monoliths and silica gel packed beds are used to regulate the humidity within the system. Finally, the polynomial chaos expansion (PCE) method (Sanzida and Nagy, 2014; Najm, 2009) is used to quantify uncertainty in the model.

2. Method

2.1. System Design

In the current study, we propose a CO_2 capture system which removes CO_2 from the inside air through concentration swing adsorption cyclic process. The adsorbent used for this study is 3D monoliths coated with zeolite 13X which have shown a significantly large equilibrium capacity (~1 mol/kg) at the CO_2 concentration of 5000 ppm (Thakkar et al., 2016). However, zeolite 13X would show reduction in CO_2 uptake on exposure to humid conditions (Ahn and Lee, 2004) since water molecules compete for the active adsorption sites. To avoid this problem, the indoor air is passed through a dehumidification unit prior to passage through monoliths.

Figure 1 depicts the schematic of the air capture process. The CO_2 rich humid air is directed to the dehumidifier which consists of two packed beds silica gels. One of the packed beds adsorbs water molecules from the indoor air while the other packed bed is regenerated by heating it and re-humidifies the air inside the enclosed space. This ensures the humidity inside the room is within a certain interval (30 – 60 %) as suggested by A.S.H.R.A.E standards (A.S.H.R.A.E, 2004). The dry air rich in CO_2 then passes through the CO_2 capture system which consists of parallel honeycomb like 3D zeolite monoliths (Figure 1). Most recently, 3D printing technique has been applied to manufacture adsorbent monoliths with high adsorbent loading (ca. 90 wt%) and good mechanical strength with comparable adsorption performance to their powder analogues (Thakkar et al., 2016).

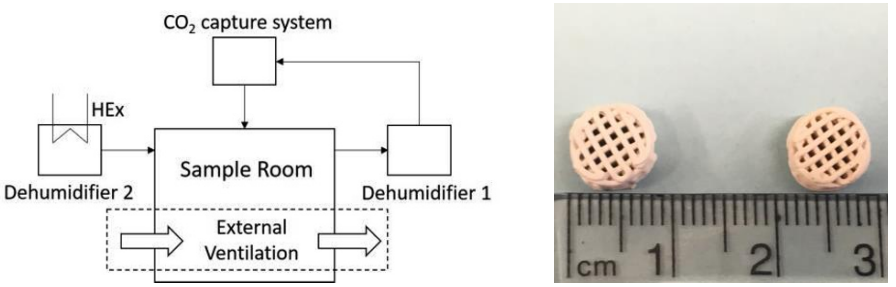

Figure 1: Schematic of the air capture process (left) and 3D zeolite 13X monolith (right)

Coupled heat and mass transfer partial algebraic differential equations are developed for monoliths (Sinha et al., 2017) and packed bed (Bollini et al., 2012). A sample room measuring 5×5×2.5 m^3 is considered to model the gas dynamics inside an enclosed space. It is assumed that the air inside the room is well mixed. It is also assumed that the room is occupied with five healthy adults during regular office hours (9 AM to 5 PM) and the respiration and perspiration dynamics is the same for each of these adults. The gas concentration dynamics inside the room is modelled by the following equation:

$$V_1 \frac{dC_{i,R}}{dt} = k_i + F_R C_{i,in} - F_R C_{i,R} + F_M C_{i,\mathrm{M}} - F_M C_{i,D} \tag{1}$$

where, V_1 is the room volume (m^3), k is the perspiration/respiration rate of healthy adult (mol/s), C is the concentration of i^{th} gas component (mol/m^3) and F is the gas flow rate (m^3/s). The subscripts R, M and D represent the room, monolith and dehumidifier respectively. The multi-bed model is implemented in gPROMS, which is a commercial dynamic process modeling and optimization software.

2.2. Uncertainty Quantification

The assumption regarding the fixed number of people inside the room with constant respiration and perspiration dynamics may not hold true in real life situations. Hence, it is essential is quantify the uncertainty caused due to such variable parameters. In this study, the PCE method is used to quantify model uncertainty in the number of room occupants. In particular, we have used non-intrusive polynomial chaos (NIPC) as described by Eq. 2.

$$\arg\min \sum_{i=0}^{n} \left(y^{(i)} - \sum_{k=0}^{P} y_k \psi_k(\xi^{(i)}) \right)^2 = 0 \tag{2}$$

where, y_k are output PCE coefficient, ξ is standard normal vector, ψ_k are basis functions and y^i are outputs of input data sampled using the Latin Hypercube Sampling scheme. Further details on implementation of non-intrusive polynomial chaos can be found in Najm (2009).

3. Results and Discussion

The multi bed model is simulated for a cycle of 24 hr. Table 1 lists the physical parameters used in the model. The number of monolith channels is selected according to channel adsorption capacity, sample room size and number of people such that CO_2 concentration

inside the room remain below 0.5% at all times. The size of dehumidifier packed bed is determined such that its capacity is sufficient to adsorb water during an entire day of operation of the CO_2 capture system; after which it is replaced by the second dehumidifier for the following day.

Table 1: Physical parameters of the Enclosed Air Capture system

Parameter	Value	Unit
Monolith cell density	400	cpsi
Number of channels	30,000	-
Monolith dimension	0.60×0.25	m^2
Packed bed dimension	0.60×0.30	m^2

The system is designed to constrain the CO_2 concentration inside room below 5000 ppm at all times. Figure 2 shows the CO_2 concentration inside room (Figure 2a) and at monolith exit (Figure 2b) on a 24 hr time basis. It can be seen from Figure 2a that CO_2 concentration rises from 9 AM – 5 PM. This is because it is assumed that the room is occupied by people during that time. However, the rise of CO_2 concentration during that time is not linear and is accompanied by periodic drops in the concentration. This happens because CO_2 is removed from the room by adsorption on monoliths at periodic intervals from 9 AM – 5 PM as can be seen from Figure 2b.

The cyclic nature of this system can be exploited to minimize the energy cost and deal with uncertainty. From 5 PM – 3 AM, the room is assumed empty. However, the CO_2 capture system remains active to lower the room CO_2 concentration back to the initial level. This can be seen from Figure 2a, where the CO_2 concentration inside the room can be seen to drop until 2 AM. The CO_2 capture system during that time can be seen from Figure 2b, where the cyclic adsorption – desorption continues until 2 AM. From 3 AM – 9 AM, the CO_2 concentration in the room stabilizes at the lower bound (Figure 2a) and we stop the CO_2 capture system, as seen from Figure 2b. The current design provides flexibility during this period (3 AM – 9 AM) should there be need for uncertainty quantification due to variations in input parameters such as variable respiration or perspiration rates, variation in number of people inside the room, etc.

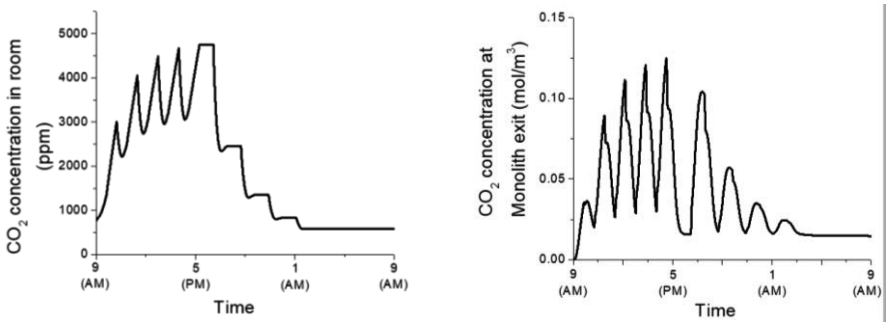

Figure 2: CO_2 concentration dynamics a) inside room and b) at monolith exit

The CO_2 capture system results in reduction of external ventilation rate since the external air flow is now governed by O_2 depletion rate inside the room instead of increase in CO_2 concentration. This results in improvement in energy performance of the overall system

as compared with the conventional ventilation methods. Figure 3 compares the energy performance of both the systems on an hourly basis. It can be seen from the figure that the CO_2 capture system consumes 75% less energy during working hours as compared to the conventional ventilation methods. After working hours (after 5 PM), the energy consumption is negligible for both systems. This is because after 5 PM, it is assumed that the external ventilation is turned off. The only source of energy consumption for CO_2 capture system after 5 PM is because of 3D monolith adsorption–desorption operation which turns out to be negligible as compared to the energy consumption for external ventilation.

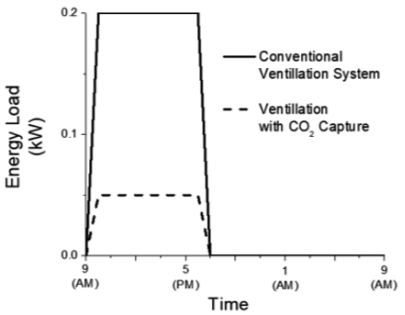

Figure 3: Comparison of energy performance on an hourly basis

Using the mathematical model, we look into quantification of model uncertainty. In order to quantify the uncertainty in respiration dynamics and number of people, we have assumed that the respiration rate varies on a daily basis with a normal distribution, $N(2.64\times10^{-4}$ mol/h, 0.25×10^{-4} $mol^2/h^2)$. Figure 4 shows the performance of NIPC as compared to Monte Carlo simulations. It can be seen from the Figure 4a, that the output CO_2 concentration inside the room converges with the results obtained through Monte Carlo Simulations (MCS). However, NIPC simulations required only 4 input sampling data as compared to 200 sample points required for MCS. This has direct implication on computational performance. Figure 4b provides the computational time incurred due to NIPC as well as Monte Carlo simulation. It can be seen from the figure that NIPC takes less computation time as compared to Monte Carlo simulation. Thus using NIPC, similar convergence in model output can be realized at lower computation cost.

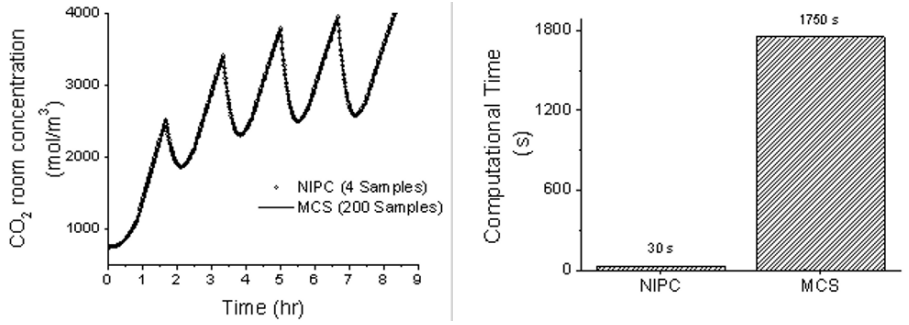

Figure 4: a) Output convergence with NIPC and Monte Carlo, b) Computational time analysis

4. Conclusion

This study proposes a novel strategy to capture CO_2 from enclosed environments. A numerical model is developed with CO_2 adsorption on zeolite 13X 3D monoliths. The optimized results control the CO_2 level inside the room within 5000 ppm at all times. Further, enclosed CO_2 capture system shows improved energy performance compared to conventional ventilation methods. The uncertainty due to variability in respiration and perspiration dynamics is quantified through non-intrusive polynomial chaos and compared to Monte Carlo simulations. It is found that non-intrusive polynomial chaos shows improvement in computational time compared to Monte Carlo simulation. This study establishes direct air capture of CO_2 as feasible strategy for reduction of energy requirements from enclosed environments. Better adsorbents with higher equilibrium capacity for CO_2 will result in better performance. Further, quantification of additional uncertainty such as room size, number of people etc. and design under uncertainty can result in risk minimization and better prediction of system output performance.

Abstract

Flaring is a necessary measure for plant safety in oil & gas industries. However, the industrial flaring generates large amounts of VOC and NO_x, which could transiently aggravate regional ozone concentrations that could affect on human health and the environment. Currently, the national standard value of 98% or 99% for destruction and removal efficiency (DRE) is regulated and presumed for industrial flaring operations. However, the DRE value could be lower than the national standard under various atmospheric and operating conditions, such as the high cross-wind speed and flare jet velocity. Thus, it is important to know the quantity and sensitivity of the regional ozone impact due to lower DREs in oil & gas industries. In this paper, a systematic study on industrial ozone pollution impacts due to the lower flaring DREs caused by cross-wind speed and flare jet velocity has been performed. First, the DRE formulas considering crosswind speed and jet velocity were derived based on available references. Second, the emission inventory assisted by the DRE formulas was updated in a certified episode of air-quality model from Texas Commission on Environmental Quality (TCEQ), where compressive information of meteorology (e.g., solar radiation intensity, wind speed, temperature, pressure and humidity), geography (e.g., population densities and land use) and emission inventory (e.g., point source emissions, area emissions, on-road emissions and biological emissions) were modeled. After that, comprehensive air quality model with extensions (CAMx) based air-quality modelling was conducted to simulate the regional ozone formation and transformation, as well as to study the ozone increments due to effects on DRE changes. This study could provide valuable and quantitative support for all relevant stakeholders, including environmental agencies, regional plants, and local communities.

Keywords: Flare emissions; Air quality; DRE; Cross-wind speed; Jet velocity

1. Introduction

Flaring is the practice of burning unusable or unwanted flammable gas which might otherwise be vented directly to the atmosphere. The oil & gas industry processes millions of cubic feet of hydrocarbon gases every day so that a slight decrease in flaring performance means a release of tens of thousands of cubic feet of emissions into the atmosphere (Baukal and Schwartz, 2001; Ge et al., 2018). It should be noted that flaring is crucial to plant safety in oil & gas industries. However, flaring generates emissions such as CO_2, CO, NO_x (nitrogen oxides), VOCs (volatile organic compounds) due to the incomplete flaring combustion. Given the 98 % flaring efficiency (TCEQ, 2015), the

resultant air emissions include at least 15.4 million pounds of CO_2, 40.0 Klbs CO, 7.4 Klbs NO_x, 15.1 Klbs hydrocarbons, and 100.0 Klbs HRVOC (Xu et.al, 2009). These emissions may cause highly localized and transient air pollution events and negative societal impacts (Ge et al., 2016; Ge et al., 2017a; Ge et al., 2017b). It should be noted that under certain conditions (e.g., strong crosswind, jet velocity, low combustion heating value and stoichiometric ratio), the flare destruction and removal efficiency (DRE) can be reduced and the portion of unburned species can increase (Singh et al., 2014). The main concern is the potential release of unburned VOCs, which is potent to transiently aggravate ground-level ozone concentration locally. The reason is that ozone is formed by the photochemical reaction between NO_x and VOCs (i.e., ozone precursors) in the presence of sunlight.

Ozone is detrimental to humans and many other living organisms (Kampa, 2008). Ozone is one of six common pollutants regulated by the Federal Clean Air Act. U.S. EPA (Environmental Protection Agency) set the National Ambient Air Quality Standard (NAAQS) for ground-level ozone since July 1997. Starting from Oct 1st, 2015, a more stringent ozone standard (70 ppb) has been issued to further enhance protection for public health (EPA, 2016). To improve air quality in nonattainment areas and meet the requirements of, each state was required to issue the State Implementation Plan (SIP) for their future air quality controls. According to EPA regulations, a 98% DRE or higher can be achieved if the flare is operated according to 40 CFR Section 60.18 (McDaniel, 1983). However, flare operations outside of these parameters DRE may be lower than 98% due to the crosswind, jet velocity and others. Very recently, Ge et al. (2016) has studied the ozone impact due to lower DREs via the optimal scheduling of multiple ethylene plant start-ups through virtual case studies, where the 8-h ozone increment under DREs of 95%, 96%, 97% and 98% are 10.1, 8.5, 6.7 and 3.2 ppb, respectively. In general, plant start-up operations generate larger amounts of flare emissions than the normal operating conditions. The study on air quality impact under normal flare situations with lower DREs in oil & gas industries is still lacking.

Thus, it is environmentally important to know the regional ozone impact due to the excess VOCs and NO_x released from oil & gas industries when the DRE value is lower than the national standard. In this paper, a systematic study on ozone pollution impacts due to the lower flaring DREs caused by cross-wind speed and flare jet velocity has been performed. The case study indicates that the maximum ozone impact from the crosswind speed and jet velocity is 0.18 ppb. This study could provide valuable and quantitative support for all relevant stakeholders, including environmental agencies, regional plants, and local communities.

2. Problem statement

This study first utilizes results from computational fluid dynamics (CFD) simulations to obtain DRE profile changed with the cross-wind speed and jet velocity. Next, the emission inventory files for flaring emissions are modified based on the adjusted DRE. For each flare source of oil & gas industries in the studied domain, adjusted DRE is calculated based on its cross-wind speed and jet velocity. After that, emissions of VOC and NO_x are adjusted. Finally, the new emission inventory can be generated then used for the air quality model simulation to ozone impacts due to the cross-wind speed and jet velocity. In this study, the comprehensive air quality model with extensions (CAMx) is employed to simulate the spatial and temporal distribution of ozone concentrations (CAMx User's Guide, 2015). Detailed ozone episodes including emission inventories

and meteorological data used as the base for the air-quality modelling can be obtained from the website of Texas Commission on Environmental Quality (TCEQ).

3. General methodology

3.1 Methodology framework

Figure 1 summarizes the general methodology framework of this study. The computational fluid dynamics (CFD) simulations are firstly employed to obtain DRE profile changed with the cross-wind speed and jet velocity. After that, flaring emissions (i.e., VOC and NO_x) are adjusted by DREs for each elevated point source from the ozone episode. Finally, the new emission inventory can be generated then used for the air quality model simulation to obtain ozone impacts due to flare DREs changed with the cross-wind speed and jet velocity. In the following Sections of 3.2 and 3.3, major technical methods involved in this methodology framework will be elaborated.

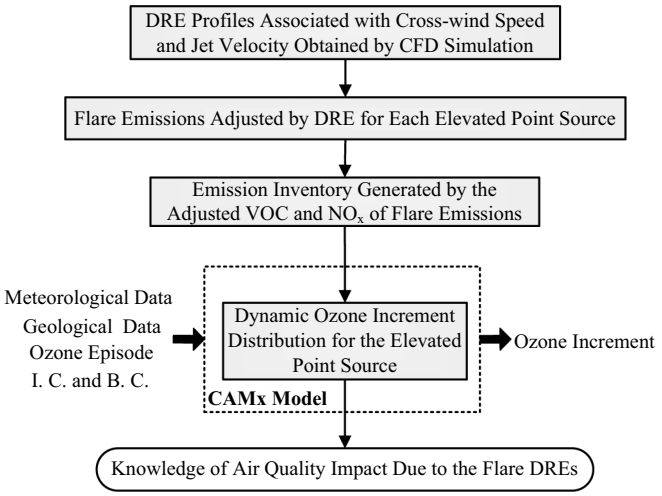

Figure 1. General methodology framework.

3.2 Model descriptions

CAMx is employed in this study to simulate the spatial and temporal distribution of ozone concentration. CAMx is a Eulerian photochemical dispersion model that allows for integrated "one-atmosphere" assessments of tropospheric air pollutants (i.e. ozone, particulates, air toxics, and mercury) over spatial scales ranging from neighborhoods to continents (CAMx User's Guide, 2014). An ozone episode with the completed meteorological and emission inventories data from May 31, 2006 to June 15, 2006 established by TCEQ is selected as the base case model simulation. All the CAMx simulations were run on a Dell computer with four 3.6 GHz CPUs and 8 GB memories. The used CAMx model is a nested regional-to-urban scale with four different grid resolutions (Ge et al., 2016).

3.3 Calculation methods

The amount of flare emissions is calculated based on both the flow rate and chemical species of the vent gases and the appropriate DRE value. The emission inventory files for elevated point sources (i.e., oil & gas industrial flare emissions) were modified

based on the adjusted DREs. For each flare source, the adjusted DRE value is calculated based on its jet velocity and crosswind speed. Next, emissions of VOC and NO_x can be calculated. After all flare emissions are obtained, new elevated point emission files for CAMx will be generated. Given that the original flare emissions data are based on 98 % DRE, the adjusted emissions of VOC and NO_x are as follows:

$$f_{VOC} = f_{0,VOC} \frac{1-\eta(U,V)}{1-0.98} \tag{1}$$

$$f_{NO_x} = f_{0,NO_x} \frac{\eta(U,V)}{0.98} \tag{2}$$

where f_{0,NO_x} and $f_{0,VOC}$ are original emissions of VOC and NO_x from the elevated point sources in the studied domain; the DRE value η is a function of the cross-wind speed of U and the jet velocity of V; f_{VOC} and f_{NO_X} are adjusted VOC and NO_x emissions by the crosswind speed and jet velocity. The units of all emissions are mol/h.

To quantitatively study the ozone concentration impacted from the adjusted DREs, the amount of ozone difference between adjusted DRE case and the base case is defined by the following equation.

$$\Delta C_n^{O_3}(d,h,\mathbf{x}) = C_n^{O_3}(d,h,\mathbf{x}) - C_0^{O_3}(d,h,\mathbf{x}), \quad h = 0, 1, \ldots, 23 \tag{3}$$

where $\Delta C_n^{O_3}(d,h,\mathbf{x})$ represents the hourly ozone difference due to the adjusted $\eta(U,V)$ at hour h on day d in grid x, ppb. $C_n^{O_3}(d,h,\mathbf{x})$ represents the hourly ozone concentration of the n^{th} simulation case at hour h on day d in grid **x.** $C_0^{O_3}(d,h,\mathbf{x})$ represents the background ozone concentration of the base case at hour h on day d in grid x. Note that $C_0^{O_3}(d,h,\mathbf{x})$ are obtained by the CAMx simulation based on the standard 98 % DRE value of flare emissions. Based on the results of $\Delta C_n^{O_3}(d,h,\mathbf{x})$, the significance of ozone impact from adjusted flare DREs due to the cross-wind speed and jet velocity will be obtained to provide quantitative technical support for relevant decision makers.

4. Case studies

4.1 DRE Formula Obtained based on CFD Simulations

CFD simulations show that four variables affect the DRE of industrial flares: crosswind speed, jet velocity of flare vent gas, combustion zone heating value (CZHV), and stoichiometric ratio. Due to limited data sources, only the crosswind speed and jet velocity are considered to adjust DREs in this study. The crosswind speed data can be obtained from meteorological data of the studied ozone episode, while the jet velocity can be obtained from the emission inventory. Based on CFD simulation results from Singh et al. (2014) with practical amendment and mathematic interpolations, the complete relation of DRE with respect to U and V can be generated as shown in Figure 2. It is a 3-D plot of DRE with changes of crosswind speed and jet velocity. It can be seen that the DRE keep the standard value of 98 % when jet velocity is less than 15 m/s. When the jet velocity is larger than 30 m/s and the crosswind speed is larger than 5 m/s, DREs are dropped lower than 80 %.

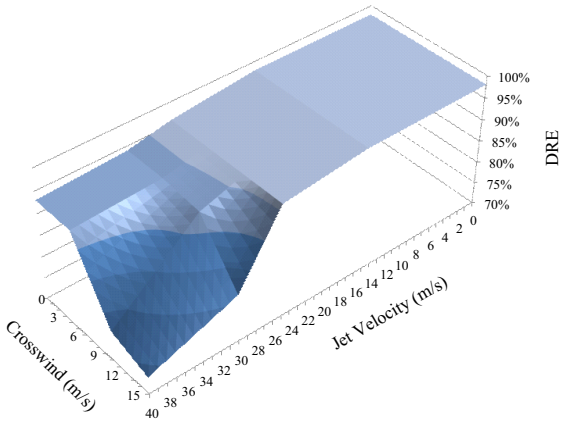

Figure 2. 3D plot of DREs with changes of crosswind speed and jet velocity.

4.2 Simulation Results based on CAMx Simulations

The modified emission inventory files are imported to CAMx model for air quality simulations. The episode of Houston-Galveston-Brazoria May 31-June 15, 2006 (base case) is chosen for the air quality modelling. First, the modelling was run once as the base case to get the background ozone concentrations. Second, the modified emission inventory files were employed, and the air quality model was run again to calculate ozone concentrations under the adjustment of crosswind speed and jet velocity. After that, results from two runs were compared to estimate the effect of cross-wind speed and jet velocity. It can be seen that the maximum hourly ozone increment fluctuates between 0.002 and 0.18 ppb. The maximum hourly ozone decrement fluctuates between 0 and 0.03 ppb. The maximum ozone increment occurred on June 11, 2006.

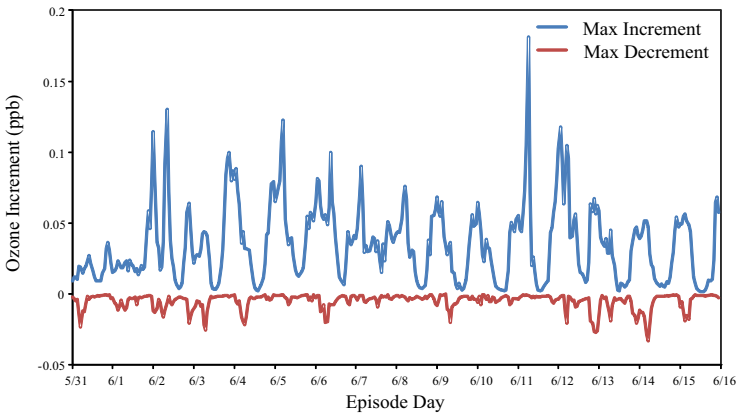

Figure 3. Maximum ozone increment and decrement after the DRE adjustment.

Based on the case studies, it shows that although the individual DREs could be significantly changed by the crosswind speed and jet velocity (e.g., the adjusted DREs can be as low as 74 % at the jet velocity of 40 m/s and the crosswind speed of 15 m/s.), the regional ozone impact will not be affected much (the maximum hourly ozone increment is only 0.18 ppb). It should also be highlighted that the DRE impact factors of combustion zone heating value (CZHV) and stoichiometric ratio are set as fixed values

as normal values in our study. Thus, their impacts on DREs as well as the regional air quality are neglected. Meanwhile, this is the initial study coupling process DRE estimation and regional air impacts. All the results listed in the paper should be treated as preliminary and subject to a variety of risks, uncertainties, and assumptions.

Conclusions

By coupling flare DREs from oil & gas industries with the air-quality model based CAMx simulation together, the ozone impacts generated from the lower DREs due to the meteorological condition (i.e., cross-wind speed) and the process operating condition (i.e., jet velocity) has been investigated in this paper. The CFD based DRE correlations are employed to adjust DREs. Through case studies, it shows that although the individual DREs could be significantly changed by the crosswind speed and jet velocity (e.g., the adjusted DREs can be as low as 74 % at a jet velocity of 40 m/s and a crosswind speed of 15 m/s.), the regional ozone impact will not be affected much (the maximum hourly ozone increment is only 0.18 ppb). This study could provide valuable and quantitative support for all relevant stakeholders, including environmental agencies, regional plants, and local communities.

Abstract

In this article, we present an application of our smart sampling algorithm (SSA) for designing real complex physico-chemical experiments. SSA consists of a novel strategy to select sample points systematically in an adaptive and optimized manner. It ascertains the placement of points in the most unexplored regions of the domain with complex/nonlinear behaviour by solving a series of placement optimization problems. To this end, we employ SSA to design experiments for butanol separation using multicomponent adsorption. Our numerical evaluation shows that the experimental design of SSA requires fewer experimental runs compared to the conventional designs. Overall, SSA is a novel modern experimental design technique that reduces experimental expenses through smart placement.

Keywords: Adaptive sampling, Intelligent placement, Surrogates, Experimental design

1. Introduction

First principles-based or physics-based modelling approach is typically used to model, study, and analyse complex nonlinear physicochemical systems. However, evaluation of such models is generally computationally intensive, thus, prohibiting their repeated evaluations in an analysis procedure. Often, these models are treated as black-box, hence no system information is available to the users without evaluating an instance of their costly simulation. Furthermore, such models are typically validated by conducting real-physical experiments which are obviously expensive. Therefore, it is beneficial to convert such high-fidelity models and corresponding physical experiments into their computationally inexpensive counterparts, *viz.* surrogate models that capture the essential features with prescribed numerical accuracy. In other words, surrogate modelling approach generates a mathematical or numerical representation of the underlying complex system using some sampled input-output data. The literature is replete with a variety of surrogate modelling techniques and their applications. For a given modelling technique, the quality of the surrogate model depends on the input-output data set used for its construction. Since this input-output data set is gathered by evaluating high-fidelity models or by performing rigorous physical experiments, sampling paradigm is the most expensive task in surrogate construction.

Commonly used sampling techniques employ uniform, quasi-random, or systematic distributions. Typically, these one-shot techniques can result in under/oversampling and

thus, poor system approximation. To tackle these issues, a dynamic class of DoE called adaptive sampling (sequential sampling) has attracted attention of the research community (Eason & Cremaschi, 2014). Adaptive sampling has two major advantages over the one-shot techniques namely low computational expenses and better approximations. In this work, we present a practical application of our adaptive sampling technique namely smart sampling algorithm (SSA) for intelligently designing real physical experiments using surrogate models. This article is organized as follows. Section 2 gives the overview of SSA and section 3 presents an application of SSA for designing multi-component adsorption experiments. Finally, we draw our conclusions in section 4.

2. Overview of SSA

Let $y = f(x)$; $f: \mathbb{R}^N \rightarrow \mathbb{R}^M$ for $\mathcal{D}: x^L \leq x \leq x^U$ describe the behaviour of a unit/process/system whose experimental or computational quantification is complex and computationally expensive. We need an analytical or numerical surrogate model $S(x)$ to replace $f(x)$ so that $y \approx S(x)$. Hence, SSA solves a problem of generating K_{max} sample points that can give the best S. In other words, experiments can be conducted at these sample points to extract maximum information from the underlying system. Our thought-process behind the development of SSA considers two fundamental concepts *viz.* exploration and exploitation. To this end, we quantify the exploration of $\mathcal{D}$ using crowding distance metric (CDM). It is based on the Euclidean distance of a point from all the other sample points as given in Eq. (1).

$$\boldsymbol{CDM(x)} = \sum_{\boldsymbol{i=1}}^{\boldsymbol{I}} \left(\left\|\boldsymbol{x} - \boldsymbol{x^{(i)}}\right\|\right)^{\boldsymbol{2}} \tag{1}$$

where $\|.\|$ is the Euclidean norm.

We quantify the exploitation using the departure function defined as follows. Let $S^{(I)}(x)$ denote a surrogate constructed using sample set $X_N^{(I)} = \{x^{(i)} | i = 1, 2, \cdots, I\}$ and its corresponding response set. Let $x^{(j)}$ be a sample point in $X_N^{(I)}$, and let $S^{(I/j)}(x)$ be the surrogate constructed using $X_N^{(I/j)} = \{x^{(i)} | i = 1, 2, \cdots, I, i \neq j\}$ and its corresponding sample set. Then, the departure function is given by Eq. (2).

$$\Delta^{(\boldsymbol{I/j})}(\boldsymbol{x}) = \boldsymbol{S^{(I)}(x) - S^{(I/j)}(x)} \;\; \boldsymbol{j = 1, 2, \cdots, I} \tag{2}$$

Qualitatively, it determines the impact of locating a sample point in the neighbourhood of $x^{(j)}$ on $S^{(I)}$. The larger the values of the departure function, the greater the placement impact; hence, the more plausible the region for sample placement. A single objective that combines the above discussed two concepts can yield the best new sample point. This is achieved by formulating a point placement optimization problem as follows. Given a sample set $X_N^{(I)}$, its corresponding response set, and the surrogate $S^{(I)}(x)$ constructed using them, we aim to place the new point as far away from existing points as possible, and the new point should have the highest impact on $S^{(I)}(x)$. To this end, we formulate a series of NLPs given in Eq. (3). These NLPs are iteratively solved to generate new samples which are in turn used to update the surrogate.

$$\boldsymbol{NLP(j)}: \max_{\boldsymbol{\mathcal{D}}} \left(\Delta^{(I/j)}(\boldsymbol{x})\right)^2 \times \boldsymbol{CDM}(\boldsymbol{x}) \quad \boldsymbol{j = 1, 2, \cdots, I} \tag{3}$$

The optimal solution to the above NLP in Eq. (3) can be a suitable candidate for the new sample point. SSA iteratively solves these NLPs using the multi-start Hooke-Jeeves algorithm for adaptive sample placement as discussed by Garud et al. (2018).

For prespecified $K(< K_{max})$ initial sample points and a chosen surrogate model type S, SSA proceeds as follows:

1. Generate a sample set $X_N^{(I)} = \{x^{(i)} | i = 1, 2, \cdots, K\}$ using any modern DoE technique like Sobol sampling (QS).
2. Compute $Y_M^{(I)} = \{y^{(i)} | i = 1, 2, \cdots, K\}$ using a sample set $X_N^{(I)}$. Note that throughout our discussion $M = 1$. Thus, it is dropped from the subscript here onwards for the sake of convenience.
3. Set $k = K$.
4. Construct $S^{(k)}(x)$ using $X_N^{(k)}$ and $Y^{(k)}$.
5. If $k = K_{max}$, then $S(x) = S^{(k)}(x)$ and STOP. Otherwise, proceed to step 6.
6. Compute $CDM^{(j)} = CDM\left(x^{(j)}\right) \forall\, x^{(j)} \in X_N^{(k)}$ and $j = 1,2, \cdots, k$ using Eq. (1). Arrange $CDM^{(j)} (j = 1, 2, \cdots, k)$ in descending order and define the order as $p = 1, 2, \cdots, k$.
    a. Set $p = 1$.
    b. Construct $S^{(k/p)}(x)$ using data from Steps 1, 2, and $i \neq p$.
    c. Construct and solve $NLP(p)$ given in Eq. (3). Let x^* be the optimal solution. If $\left\|x^* - x^{(i)}\right\| \leq \varepsilon$ for any $i = 1, 2, \cdots, k$, then set $p = p + 1$ and go to Step 6b. Otherwise, $k = k + 1$ and $x^{(k+1)} = x^*$. Evaluate $y^{(k+1)}$, go to Step 4 and update the input-output data set. Note that if p exceeds k, then perform pure exploration-based (space-filling based) sample placement and proceed to Step 4.

Note that this is a brief overview of SSA and the detailed algorithm can be found in Garud et al. (2018).

3. Case Study

In our previous works, we have successfully employed SSA for constructing surrogate approximations of analytical test functions as well as process simulations. Here, we illustrate its application for designing multicomponent adsorption experiments to separate butanol from ABE (acetone, butanol, ethanol) solution.

3.1. Multicomponent adsorption system

Biobutanol has gained significant attention over the last few years as one of the promising biofuels. Its production involves fermentation process which produces broth containing acetone, butanol, ethanol, butyric acid, acetic acid, glucose, and xylose. Moreover, concentration of butanol in the broth is relatively lower due to the presence of inhibiting bacteria. Therefore, the major challenge in biobutanol production is its separation from the broth with high recovery.

Abdehagh et al. (2016) have modelled the multicomponent adsorption (MCA) of ABE for separating butanol. Their aim is to develop an isotherm model for MCA system. For

this, they perform extensive physical experiments and use the experimental data to construct isotherms. These isotherms essentially show the amount of particular component adsorbed, say butanol as a function of component equilibrium concentration. Their study considers both Langmuir and Freundlich isotherm models and concludes that Freundlich isotherm appears to emulate the experimental data very well. However, the number of parameters of Freundlich isotherm increases with increasing number of components, thus increasing the required experimental data set size. Therefore, the classical experimental design approaches may not be efficient for such systems.

To this end, we employ SSA to design experiments for the above discussed system using surrogates. While designing the experiments with SSA, one needs to perform these experimental runs sequentially as SSA generates samples adaptively. However, in this work, we do not perform any physical experiments, rather we rely on the exhaustive isotherm built by Abdehagh et al. (2016) to emulate those experiments. Henceforth, an evaluation of this isotherm serves as performing the real physical experiment.

3.2. Evaluation plan

We build surrogate approximation of MCA system using SSA which guides the generation of new sample points as discussed earlier in Section 2. For this, we consider 7 input variables (experimental conditions or factors) given in Table 1 and equilibrium adsorption capacity (q) as the output/response variable. We generate initial sample points $(K = 20)$ via Sobol sampling and use second order polynomial response surface (PRSM) as a surrogate. We then use this sample set to evaluate experiments and generate input-output data set which is then used to construct the initial PRSM surrogate. SSA adaptively updates the initial input-output data set, in turn the initial surrogate, by generating new sample points and using them to perform new experiments. We consider the following three scenarios for SSA: $K_{max} = \{42, 50, 80\}$. Abdehagh et al. (2016), on the other hand, conduct 42 experiments for multicomponent system and 38 experiments for pure component system, amounting to total 80 experiments. This is necessary since the complete representation of Freundlich isotherm for 7 component system requires estimation of 42 competitive adsorption coefficients and 14 pure component coefficients, resulting in total of 56 parameters.

Besides, we also compute the quality of PRSM approximation using three error-based metrics given in Eqs. (4)-(6) *viz.* average absolute error (AAE) and root mean squared error (RMSE), and pooled error (PE). These metrics quantify the performance of SSA in constructing PRSM approximation.

Table 1: Experimental settings for evaluation of SSA.

Input variables	Description of variables	Lower bounds	Upper bounds
x_1	Butanol concentration (g/L)	0.09	25.00
x_2	Acetone concentration (g/L)	0.17	15.00
x_3	Ethanol concentration (g/L)	0.05	5.00
x_4	Butyric acid concentration (g/L)	0.09	11.00
x_5	Acetic acid concentration (g/L)	0.06	12.00
x_6	Glucose concentration (g/L)	0.09	15.00
x_7	Xylose concentration (g/L)	0.05	10.00

$$\mathbf{AAE} = \frac{\sum_{q=1}^{Q}\left|\boldsymbol{y}^{(q)} - \boldsymbol{S}\left(\boldsymbol{x}^{(q)}\right)\right|}{\boldsymbol{Q}} \tag{4}$$

$$\mathbf{RMSE} = \sqrt{\frac{\sum_{q=1}^{Q}\left(\boldsymbol{y}^{(q)} - \boldsymbol{S}(\boldsymbol{x}^{(q)})\right)^{2}}{\boldsymbol{Q}}} \tag{5}$$

$$\mathbf{PE} = \sqrt{\mathbf{AAE} \times \mathbf{RMSE}} \tag{6}$$

3.3. Results and discussion

We now compare the performance of our SSA-based surrogates with the Freundlich isotherms constructed by Abdehagh et al. (2016). They consider two relatively extreme scenarios of multi-component broths *viz.* low-level and high-level to ascertain that the developed model performs well over the ranges of concentrations. The interested readers may refer to Abdehagh et al. (2016) for mixture compositions for low and high-level scenarios. Figures 1 and 2 show the trends of SSA surrogates and the real isotherms for low and high-level scenarios respectively. Clearly, SSA performs very well in emulating the real isotherm with fewer experimental runs. Freundlich isotherm is constructed using 80 experimental runs while SSA-based surrogate requires only 50 runs to emulate the real isotherm with 3% average error. Overall, we can reduce the total experimental runs by 37.5% to achieve the performance with prescribed numerical accuracy.

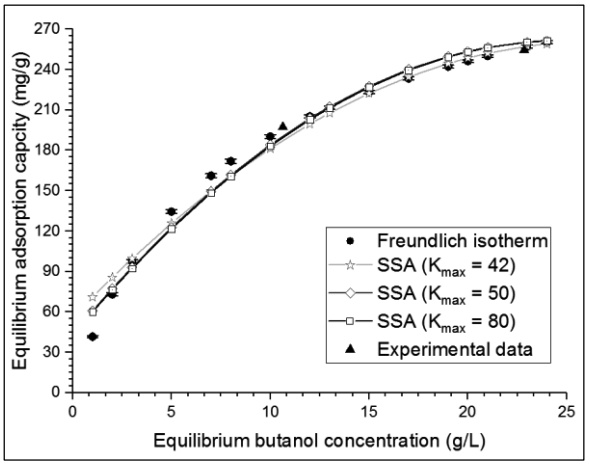

Figure 1: Comparison of SSA surrogates with Freundlich isotherms for low-level scenario.

Additionally, we assess the quality of the surrogates using error-based metrics discussed earlier. Table 2 shows these metrics for three cases. AAE quantifies the average error in surrogate prediction while RMSE captures its sense of distribution. PE combines these two metrics to give an overall performance measure. The lower the values of these metrics, the better the surrogate prediction. SSA shows significant improvement in the performance for $K_{max} = 50$ compared to $K_{max} = 42$. However, the improvement stagnates after $K_{max} = 50$.

Table 2: Performance metrics for surrogates constructed using SSA.

Legend	AAE	RMSE	PE
SSA ($K_{max} = 42$)	8.59	12.14	10.21
SSA ($K_{max} = 50$)	6.31	8.83	7.46
SSA ($K_{max} = 80$)	5.67	7.89	6.69

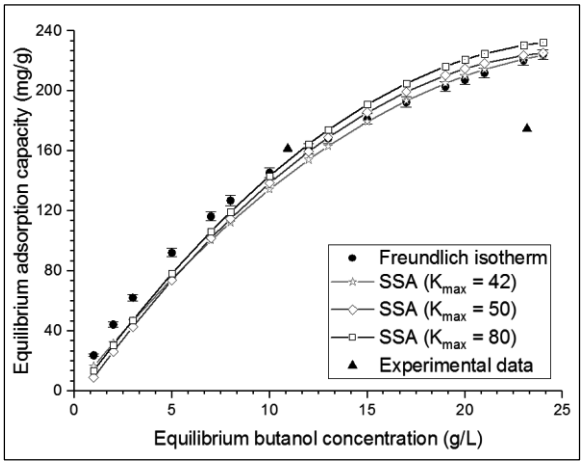

Figure 2: Comparison of SSA surrogates with Freundlich isotherms for high-level scenario.

4. Conclusions

In this work, we show the application of our novel sampling algorithm for designing physical experiments of multicomponent adsorption system. Our numerical evaluation shows that SSA reduces experimental expenses by approximately 37.5% while maintaining 3% average error. Additionally, we compare our SSA-based models with the literature data and it shows that our models perform well over ranges of component concentrations. Overall, SSA is a novel modern experimental design technique that reduces experimental expenses through smart placement.

Visual Modelling with Networks

Heinz A Preisig*, Arne Tobias Elve, Sigve Karolius

Chem Eng, Norwegian Uni. of Sci. & Tech., 7491 Trondheim, Norway
Heinz.Preisig@chemeng.ntnu.no

Abstract

Visual modelling serves the purpose of designing process models, discussing them on the back of an envelope, a serviette, the meeting-room board and define & edit them in the graphical user interface *ModelComposer,* which is a component of our ontology-based simulation environment. Models that spread over large range of time-scales do not connect straightforwardly as the fast time-scale usually is computationally intensive to the extent where on the large time-scale one uses surrogate models derived from the detailed models. The network-of-network approach extends readily to multi-scale system – from quantum to mechanical properties.

Keywords: Ontology-base modelling, process simulation, multi-scale.

1. Background

It is not an exaggeration if one states that process systems engineering is completely dependent on the availability of models, even being driven by models. Recognising the fact that models are so central, we put them right into the centre and make them the main object of activities. It is our goal to enable a more creative interaction with models, allowing people who model processes, which we refer to as ‘’modellers’’, to operate on a high level using primitive building blocks to construct their process models. The primitive building blocks must be fundamental, thus simple without any whistles and bells, but they must also be rich enough to construct process models with all their whistles and bells. Thus, the term primitive or simple.

At this point we have developed our ontology-based modelling environment to the level, where we feel confident to capture the majority of macroscopic processes in mostly mechanistic models; mostly because kinetics is not strictly mechanistic in our view.

The ontology is built in stages, firstly defining the main components of the model, which consecutively is used to define the mathematical representation of all model components expanding to alternative mathematical representations of the same phenomena. It is also used to define two plug-ins for the *ModelComposer* that implements “visual modelling” through a graphical user interface. One of the plug-ins is an automaton, implementing the rules for the generation of the graphs and the other is the graphical appearance of the simple and composite object being available through the graphical interface.

Here we will expand on the visual modelling, the graphical language to define and modify models. Whilst the *ModelComposer* generates mainly index files, which together with the ontology augmented with the equations are put into a model factory that generates code for different simulation environments (Elve and Preisig 2017), we shall attempt to demonstrate the power of the visual modelling approach for model design, thus as an enabling tool for discussions and model representations on a conceptional level and the natural extension to multi-scale problems and the generation of workflows.

2. The basic concepts

A good story starts at the beginning, here with the basic concepts:
Concept Systems -- can be represented as a super network of context-dependent networks of nodes and arcs, namely directed graphs, with the nodes representing the capacities and the arcs the interactions.
Concept Tokens -- live in the nodes and are transported through the arcs. Thus, nodes are capacities for the tokens and arcs transport tokens. The direction is the reference coordinate system for the transport of the tokens.
Concept Typing -- allows for refinement. Typed graphs reflect the different contexts, typed nodes are used to reflect the dynamic and distribution nature, typed arcs reflect the transport mechanisms, whilst typed tokens detail tokens all in each context.
Concept Frame -- generalised from the frame of reference used in physics. It usually includes time, and in physics extends with the spatial coordinates.
Concept Behaviour -- provides the components for the mathematical description, like *state, constant, state time derivative,* and in the context of physical/chemical/biological systems, *transport,* and *conversion.*
These elements are used to define the equations in a lower triagonal form (context-free definition space) given the states and the constants as a starting point. This ensures that any model "extruded" from the ontology via the *Model Composer* is of zero degree of freedom and with zero-order differential index.
For the graphical representation of physical systems, we typically use: 0-3 dimensional distributed systems (0D shown as circles,1-3D as ellipses), point systems (small circles) and reservoirs (half open circles).
For illustrating the concepts and their application we define two contexts, physical systems and control systems, whereby the physical systems may be detailed into the states of aggregation.

3. Illustration of generating alternatives

As an example, we choose a bioprocess consisting of a tank reactor and a tubular reactor with an immobilised culture (Figure 1).

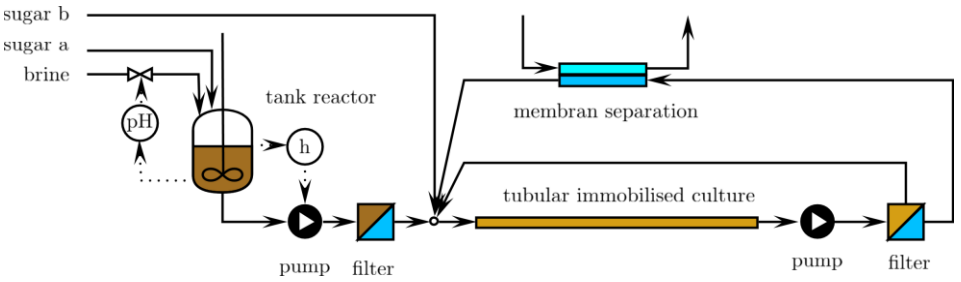

Figure 1. Example bio process

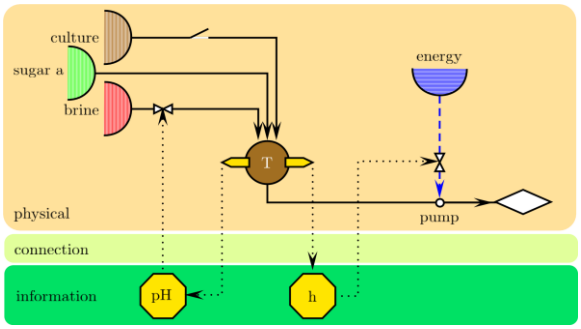

Figure 2. The controlled tank -- three connected networks

We pick a couple of elements from the bio process to show topologies of alternative representations. The first example is the stirred tank reactor and its control. It defines three networks, namely a physical network, and the control network connected with each other over the connection network. For the **physical network**, the tank is represented as a single lump, thus mixing is neglected. In the actual plant, there is a gas washing extracting some of the volatile components, which is also neglected. The collective reservoirs form the environment. Their intensive quantities are assumed constant and available as the reservoir is an infinite-size capacity and cannot be balanced. The rhomboid indicates a connection to the next section of the plant.

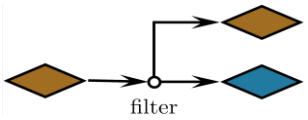

Figure 3. Very simple

Next, we have a look at a **filter**. Many possibilities: we start with a very simple model, namely just a splitter (Figure 3).

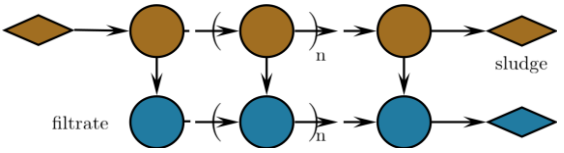

Figure 4. In slices

We can model it as a series of slices each of which has three elements, namely a lump for the sludge, a lump for the filtrate and a transfer through the filter plate, whereby the filter plate itself does not appear as a separate object. Rather it is hidden in the transfer as a resistant. Also, no build-up of the filter cake is included.

The next version considers the distribution effect along the filter from the entrance to the exit as relevant (Figure 6). The simplest version then models the two liquid bodies as each distributed in one direction, namely along the main flow coordinate.

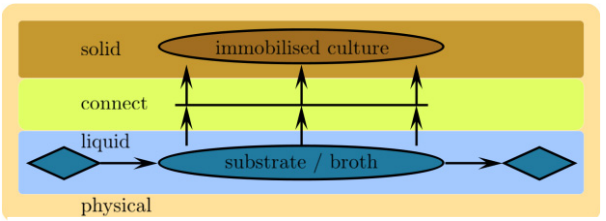

Figure 5. 1D distributed

The tubular reactor is of similar nature.

The difference is in the immobilised culture being also 1D distributed but has no inflow or outflow of the culture. It merrily exchanges material with the liquid phase.

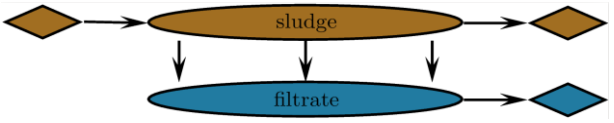

Figure 6. Simple distributed

We now have a solid phase network linked via a connection network representing the interface to the liquid phase network. In all cases, the networks have only one member node.
Considering that the culture is immobilised on fix-bed mixer elements, one can suggest a more complex model (Figure 7). Here we do not show the networks or the interfaces simply because complexity. Their presence is though apparent.
The filter and the tubular reactor case demonstrate a refinement. An interesting expansion into more detail is the culture in the broth or immobilised on the support. In this

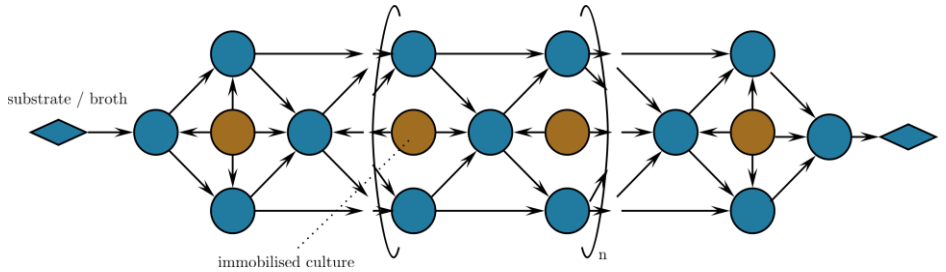

Figure 7. Fix-bed, mixing elements considered

case it is meaningful to add a new branch to the ontology (Preisig, 2016), which captures the metabolism of the cell.
The elements in the topology are linked to elements in the ontology. For example, a lumped system containing species mass is linked to an equation object representing the species mass balance, or a convective mass transport links to an equation like concentration times volumetric flow, where the latter is related to the pressure difference. In these physical systems one always handles materials, the properties of which determine the behaviour of the system. The material properties are thus an essential part of the description.
Today, most modellers would use a thermodynamic properties library to fetch the required properties for the computation of capacity and transport system's behaviours. The generation of these data has been, and still is, a costly affair and very much limited by the experimental work involved. Further, it is data points that are the basis and an interpolation is superimposed to compute the data required by the user software. If one considers multi-component systems, it is apparent that covering the experiments is infeasible given the space being spanned by the common variables temperature, pressure and concentrations. Approximate block-component type of methods like the group contribution method (Joback, 1987) offer some solutions, but are not universal applicable, though certainly useful. New alternatives are opening with the increasingly availability of particle-based computations on the molecular level (Rosso 2012). The Framework7 project MoDeNa (MoDeNa 2017) demonstrates that the integration of scales from quantum to mechanical properties is indeed feasible.

4. Down the scales and up again

With the mathematical model composed from the physical topology of the modelled system, the need is defined for the computation of material properties replacing empirical or idealised mathematical approximations. These "properties" depend on the state, primarily the intensities temperature, pressure and composition. The macroscopic system operating on a much longer time scale than the molecular simulations. The differ-

ence is several orders of magnitude -- picoseconds in contrast to minutes and hours. Taking those a macroscopic system and a molecular system as an extreme and views them from the abstract level of network modelling, the linking of two times scale may be visualised as shown in Figure 8.

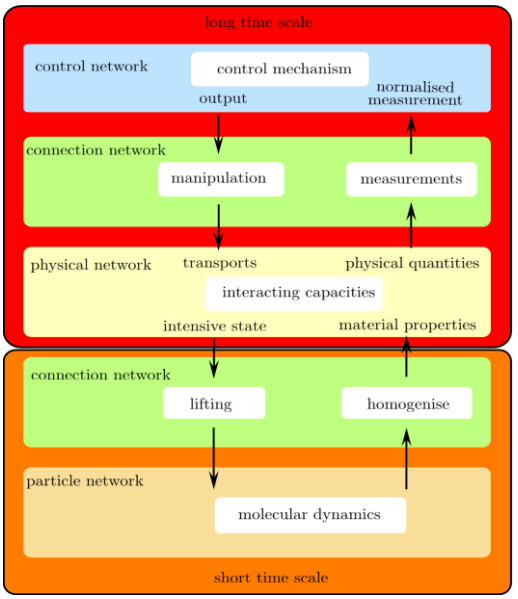

Figure 8. Coupling framework

The downwards information transfer inserts a *lifting* operation, which maps the low-dimensional state of the macroscopic system onto a large dimensional state on the molecular level, usually in the form of Boltzmann distributions for velocity of the molecules. The opposite happens on the way up, a large-dimensional state is mapped into a low dimensional one often called *homogenisation*.

4.1. Network view on molecular simulations

Considering a molecular simulation being approached by representing the molecules as a network of atoms and the material as a network of molecules, one can either view it as a hierarchical network or as a global network with different connections, where the connections represent the intra and inter molecular forces. In all cases, to get reasonable results, one must operate on very large networks, which renders any straight forward setup of the numerical problem infeasible. Methods must and have been developed to approach the super-imposed large-scale optimisation problem requiring a very large number of simulations. As a result, there exist now a zoo of highly specialised simulation environments of such systems.

4.2. Linking and Coupling Scale-Specific Software

The ontology-based modelling environment implements a super-network of context-dependent networks. Whilst the representation of the behaviour of the components can be defined in the form of a context-free, super-bi-partite graph of equations and variable one can also provide a "black box" representing an input/output representation of a complete network. The idea is to allow for the compilation of different context-dependent networks, or groups thereof, as separate computational tasks, which later are combined into a workflow management program handling the interaction and logical linking of the different tasks. Thus, in this context, a mathematical representation network like an atom/molecule & interacting forces network can be either compiled and linked with a solver for a stand-alone task or one inserts a prefabricated program. The *ModelComposer* then generates a workflow for a multi-scale system which then is passed on to a *ModelOrchestrator* for execution thereby combining the different time-scale related programs. This typically involves the on-line generation of surrogate models as explicated in Karolius (2016). The self-contained computational task can be sup-

plied with strategies for adapting the workflow depending on the quality of the surrogate models.

The *ModelOrchestrator* can perform the computational task in a distributed manner, on a high-performance cluster or a dedicated server. As long as the individual computational tasks are self-contained the simulations can be rerun; thus, facilitating a possible avenue of producing simulations that are truly reproducible. The latter is a particularly pressing issue when discussing multi-scale modelling, which typically involves multiple software tools that have a large number of version-specific dependencies. This does not ease the burden of the modeller to provide the strategies for the execution of the scale-specific models. However, the advent of web-based marketplaces for sharing of simulation models, such as nanoHUB (Klimeck and Zentner et al. 2011), can potentially remedy this as well.

5. Conclusions

Visual modelling is a powerful tool for the discussion and generation of alternative model structures. Top down, bottom up and inside outside designs are all possible. The idea of using networks of context-dependent networks provides the necessary richness to capture controlled chemical and biological processes and extends readily for to the representation of multi-scale systems and naturally to the generation of a multi-program environment supervised by a model orchestrator, a platform to handle dynamic workflows.

Abstract

The operation of multiproduct/multipurpose processes involves decisions at different time scales; such as short-term for control, medium-term for scheduling, and long(er)-term for design. In this work, we present a methodology towards the unification of these decisions via multiparametric programming. Based on our previously introduced PARametric Optimization and Control (PAROC) framework, we derive (i) design dependent and scheduling aware control strategies, and (ii) scheduling strategies that are design dependent and control aware. We utilize the proposed methodology to simultaneously determine (i) the distributed control schemes for different operating policies and a range of different designs, and (ii) the coordination of operations in a network of two cogeneration of heat and power (CHP) units as a function of the constituent designs.

Keywords: process design, model based control, scheduling, multiparametric programming.

1. Introduction

Sequential assessment of process design and multi-scale operational activities often leads to suboptimal solutions as each individual problem dictates different, and sometimes conflicting, objectives. A unified formulation of the process design, scheduling, and control problems addresses the inherent interactions among these constituent decision making mechanisms. A general representation of such an integrated problem is presented in Eq. (1).

$$\begin{aligned} \min_{u,S,D,Y} \quad & J = \int_0^\tau P(x,y,u,S,De,Y,d,t)dt \\ s.t. \quad & \frac{d}{dt}x = f(x,u,S,De,Y,d,t) \\ & y_{min} \le y = g(x,u,S,De,Y,d,t) \le y_{max} \\ & u_{min} \le u = h(x,u,y,S,De,Y,d,t) \le u_{max} \\ & S_{min} \le S = m(x,y,S,De,Y,d,t) \le S_{max} \\ & Y \in \{0,1\} \\ & [x_{min}^T, De_{min}^T, d_{min}^T]^T \le [x^T, De^T, d^T]^T \le [x_{max}^T, De_{max}^T, d_{max}^T]^T \end{aligned} \tag{1}$$

where x are the states of the system, y are the system outputs, u are the manipulated variables, S are the scheduling decisions, De are the design variables, Y are the binary

decision variables, d is the system uncertainty, P is the objective function of the system accounting for the short term (control), medium term (scheduling), and longer term (design) costs, f and g are first principle equations, h and m are generic expressions that define the control and scheduling actions, respectively. Eq. (1) is a mixed integer dynamic optimization (MIDO) problem, which is usually highly nonlinear and large scale for chemical processing plants. The interactions between (i) process design and control variables, and (ii) control and scheduling variables in Eq. (1), and the efforts towards integration of these problems are reviewed and discussed in Vega et al. (2014) and Baldea and Harjunkoski (2014). Recent efforts are focusing on the integration of all constituent parts of Eq. (1) (Koller and Ricardez-Sandoval, 2017).

In this work, we extend our previous efforts towards the integration of process design, scheduling, and control (Diangelakis and Pistikopoulos, 2017) to a network of heat and power systems comprising two cogeneration of heat and power (CHP) units operating in parallel, accounting for their start-up and shut down costs. We utilize the PARametric Optimization and Control (PAROC) framework introduced by Pistikopoulos et al. (2015), and the dynamic high fidelity model of the CHP described by Diangelakis et al. (2014).

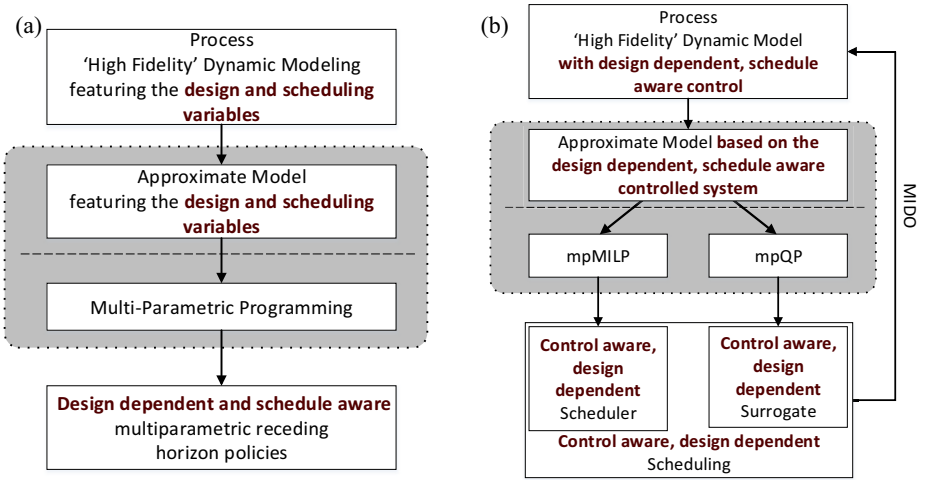

Figure 1. (a) Phase I: Methodology to build design dependent, schedule aware controller, (b) Phase II: Methodology to build design dependent, control aware scheduler. Actions within the gray area happen once and offline.

2. Integrated Design, Scheduling, and Control via the PAROC Framework

The PAROC framework allows for the design of advanced control strategies based on high fidelity models benefiting from the most recent advances in the field of multiparametric programming (Pistikopoulos et al., 2015). In this study, we utilize the PAROC framework to decompose the unified problem formulation in Eq. (1) into two phases, as depicted in Figure 1. The first phase, described in Figure 1a, focuses on the derivation of a control strategy that explicitly accounts for a range of design and scheduling options. The multiparametric solution to this problem allows for an offline optimal control strategy that can be embedded in the system of interest as described in Figure 1b. Accordingly, the Phase II focuses on building the control aware, design dependent scheduler, based on the optimal control strategies derived in the Phase I. Note

that the explicit solutions of the optimal control and scheduling problems are piecewise affine functions of the design De.

2.1. Phase I: Design dependent, schedule aware control strategy

Phase I consists of the following steps described in Figure 1a.

Step 1: "High fidelity" dynamic modelling – A first principle model for the CHP network is developed in the form of Differential Algebraic Equations (DAE) based on Diangelakis et al. (2014). The high fidelity model features the design and scheduling decisions as degrees of freedom of the overall problem. In this work, we use the gPROMS® environment to construct the model and simulate the dynamics of the system.

Step 2: Model approximation – The high fidelity model developed in the first step is highly nonlinear and nonconvex in most applications, and renders the practice of advanced control algorithms quite challenging. Therefore, we appeal to model reduction or system identification techniques to approximate the high fidelity model with a discrete time affine state space representation as presented in Eq. (2).

$$\begin{aligned} x_{t+1} &= A_c \cdot x_t + B_c \cdot u_t + C_c \cdot [De^T, S_t^T, d^T]^T \\ \hat{y}_t &= D_c \cdot x_t + E_c \cdot u_t + F_c \cdot [De^T, S_t^T, d^T]^T \end{aligned} \tag{2}$$

where index t indicates the discrete time steps, and $\hat{y}$ is the output of the system predicted by the approximate model. Note that Eq. (2) explicitly features the design and scheduling variables. In this work, model approximation is performed via the MATLAB® System Identification Toolbox™ using the N4SID algorithm, hence the states x may not preserve the physical meanings of the original states in Eq. (1).

Step 3: Design of the multiparametric model predictive controller (mpMPC) – The approximate model given in Eq. (2) is used to formulate an mpMPC based on the control scheme described in Diangelakis et al. (2016). We further treat the design and scheduling decisions (De and S) as bounded uncertain parameters. The solution of the mpMPC formulation yields an offline map of optimal control actions as affine functions of the design and scheduling decisions, as described by Diangelakis et al. (2017).

Step 4: Closed loop validation – The control strategy is validated via closed loop implementation against the high fidelity model derived in Step 1. The assessment of the closed loop performance, including set point tracking, fast adaptation to changes in the operational level, applicability on a range of different designs, constraint violation, and operational stability dictates whether a new approximate model is necessary.

2.2. Phase II: Design dependent, control aware scheduler

Production scheduling problem can be represented by a state space model as presented by Subramanian et al. (2012), and the derivation of its multiparametric counterpart is presented in Kopanos and Pistikopoulos (2014). Diangelakis and Pistikopoulos (2017) introduces a methodology to integrate the design and control into the schedule on a continuously operating CHP unit. In this work, we consider a network of two CHP units operating parallel, accounting for their start-up and shut-down costs in the schedule.

Step 1: High fidelity model with the closed loop dynamics – The design dependent, schedule aware control strategy is embedded in the high fidelity model.

Step 2: Model approximation – A discrete time affine state space model is derived based on the closed loop behavior of the high fidelity model via system

identification, the N4SID algorithm in this case. Note that the discretization step of the identified model is several orders of magnitude larger than the controller. The identified model is also resampled (via built-in MATLAB function `d2d`) in the time steps of the controller in order to formulate a surrogate model that bridges the time gap between the controller and the scheduler. The identified models in both discretization times are aware of the closed loop dynamics.

Step 3: Scheduling formulation and solution – Based on the approximate model derived in Step 2, we formulate an mpMILP problem accounting for the economic considerations and operational feasibility of the CHP network, as described in Kopanos and Pistikopoulos (2014). The scheduling formulation treats the disruptive scheduling events and the design of the CHP network as parameters. The start-up and shut-down time restrictions are taken into consideration by including lifting variables, as described by Subramanian et al. (2012). Design dependence of the approximate model imposes parametric bounds on the operation. Furthermore, in addition to our previous studies, the cost coefficients on the states of the system, and the start-up and shut-down decisions are affine functions of the design of the CHP network, which is treated as an uncertain parameter. The scheduling formulation yields explicit expressions of operational set point decisions as affine functions of the design, to be passed down to the controller. However, due to the approximation of the scheduling model and the large discretization time, there exists a plant-model mismatch. This discrepancy is addressed via implementing the surrogate model derived in Step 2 into a mpQP problem that recalculates corrective scheduling actions at the control time steps.

Step 4: Closed loop validation – The control strategy, surrogate model formulation, and the scheduler are operated simultaneously in a rolling horizon fashion against the original high fidelity model.

3. Design, scheduling, and control of a CHP network

The problem statement of this study is defined as follows:

Given: A high fidelity model of the CHP, described by Diangelakis et al. (2014), unit costs for (i) energy production, (ii) start-up and shut-down, (iii) purchasing, selling, and disposing of heat and power, and (iv) heat storage, and a residential demand profile for heat and power.

Determine: Operating levels and on/off switching times of the CHPs, quantity of heat to purchase/dispose, quantity of power to purchase/sell, and optimal control actions to achieve the target operating levels.

Objective: Minimize the total cost of operation.

For the methodology to acquire design dependent control strategies, the reader is referred to Diangelakis et al. (2017). In this work, we utilize these strategies to be embedded in the CHP network and the operating schedule.

The integrated control and scheduling strategies are cross validated against different CHP networks with different designs and operated simultaneously in a rolling horizon fashion. Figure 2 shows the Gantt chart of the schedule for a network with two CHPs with internal combustion engines (ICE) of sizes 1.5 L and 4.5 L, respectively. The schedule is given a residential heat and power demand to determine the optimal operating levels of the CHP network.

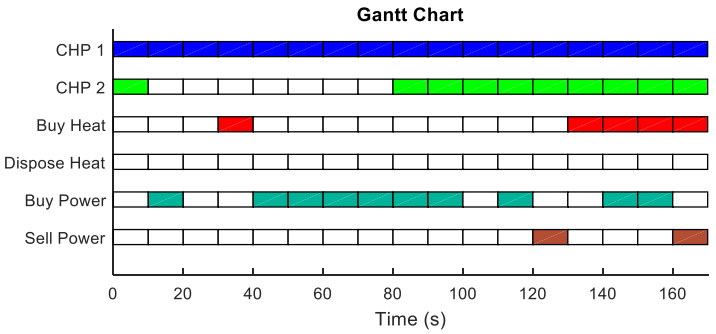

Figure 2. Gantt chart including CHP 1 ($V_{ICE} = 1.5\ L$), CHP 2 ($V_{ICE} = 4.5\ L$).

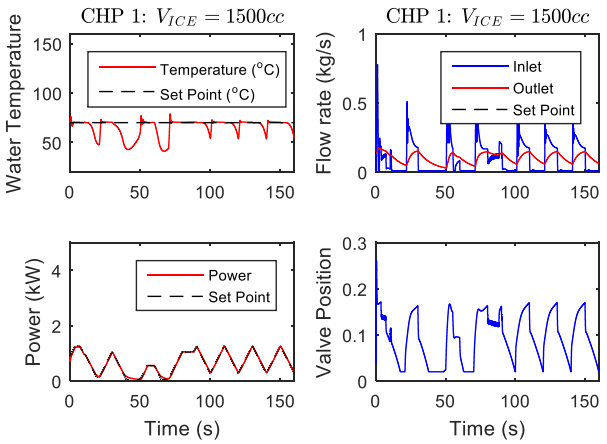

Figure 3. Closed loop response of the integrated schedule and control for CHP 1 ($V_{ICE} = 1.5\ L$).

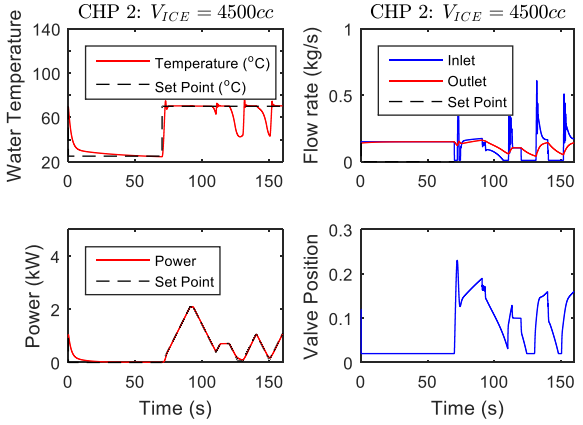

Figure 4. Closed loop response of the integrated schedule and control for CHP 1 ($V_{ICE} = 4.5\ L$).

Figures 3 and 4 show the closed loop response of the CHP units based on the scheduling decisions demonstrated in Figure 2. The responses of both CHP units show that design dependent controllers are able to track the set points provided by the scheduling level. The scheduler allocates different loads on the CHP units recognizing their closed loop behaviour, and their operating costs. For instance, the large CHP unit is switched off

during the early operation due to relatively low demand rate. However, it is switched back on and assigned a higher load than the small CHP unit as the demand increases.

4. Conclusions

In this work, we extended our previous study on simultaneous design, scheduling, and control on a single CHP unit to a network of CHP units, accounting for the start-up and shut-down times and costs. The design, scheduler, and the controller were built based on a single high fidelity model. The complete map of optimal operation in the short and medium term were derived offline via model based multiparametric programming. The frequently encountered time scale gap between the economic scheduler and the controller was bridged via a surrogate model. This work presents a framework to implement CHP network systems on an ensemble of residential units on a larger scale.

Abstract

The IDAES PSE framework represents a new approach for the design and optimization of innovative steady state and dynamic processes by integrating an extensible, equation-oriented process model library with the Pyomo algebraic modeling language. Built specifically to enable rigorous large-scale mathematical optimization, the framework includes capabilities for conceptual design, steady state and dynamic optimization, multi-scale modeling, uncertainty quantification, and the automated development of thermodynamic, physical property, and kinetic submodels from experimental data.

Keywords: Multiscale modeling, conceptual design, process optimization, dynamic optimization, parameter estimation

1. Introduction

The U.S. Department of Energy's Institute for the Design of Advanced Energy Systems (IDAES) was formed in 2016 to develop new advanced process systems engineering (PSE) capabilities to support the design and optimization of innovative new processes that go beyond current equipment/process constraints. Engineers currently rely on state-of-the-art simulation packages to synthesize, model, and optimize process flowsheets with sufficiently detailed models. However, commercial simulation tools struggle with flowsheet optimization and typically limit consideration of nonlinear optimization problems to less than 100 degrees of freedom. As a result, process optimization with large-scale solvers is rarely performed by industry. On the other hand, many of the capabilities for large-scale optimization are available in general algebraic modeling languages (AMLs), which generally require fully open, equation-oriented (EO) models with exact first and second derivatives. Large-scale NLP algorithms routinely solve optimization problems with thousands of variables and degrees of freedom. Moreover, the extension of these optimization models for MINLP, global optimization, and optimization under uncertainty (OUU) requires a flexible and open optimization modeling environment.

The open-source IDAES process systems engineering framework addresses the capability gap between state-of-the-art simulation packages and AMLs by integrating an extensible, equation-oriented process model library with the Pyomo AML (Hart et al, 2011, 2017), which enables formulating, manipulating, and solving large, complex, structured optimization problems. The IDAES framework includes tools for: (1) process synthesis and conceptual design, including process intensification, (2) process design and optimization, including process integration, (3) process control and dynamic optimization, (4) using advanced solvers and computer architectures, (5) automated development of thermodynamic, physical property, and kinetic submodels from experimental data, (6) integration of multi-scale models, (7) comprehensive, end-to-end uncertainty quantification (UQ) and model validation, (8) maintaining complete provenance information, and (9) the ability to support multiple time and length scales, from materials to process to market.

2. IDAES PSE Framework

The IDAES framework consists of multiple components as shown in Figure 1. The core of the IDAES framework is the customizable process model library, built on the Pyomo AML. The core models can be combined to capture the hierarchical structure of sub-processes and complex unit models. In addition, the process model library can be used to support conceptual design via a superstructure formulation, process design, optimization, and integration, and dynamic optimization and control. A suite of machine learning techniques based on ALAMO (Cozad et al., 2014) enables the development of submodels for physical properties, thermodynamics and kinetics directly from experimental data, enabling more effective tracking of uncertainty. To enable the solution of large-scale parameter estimation problems, the machine learning tools can utilize a variety of high performance computing (HPC) capabilities, include GPUs and the National Energy Research Scientific Computing Center (NERSC). Finally, the framework utilizes PySP (Watson et al., 2012) to incorporate and assess uncertainty across models and scales as well as to enable simultaneous, multiscale parameter estimation. All components are developed using open-source best practices on the Github collaborative coding platform.

2.1. Pyomo Algebraic Modeling Language

The IDAES PSE Framework leverages the open source, DOE-funded platform, Pyomo (Hart et al., 2011, 2017), which addresses challenges in formulating, manipulating, and solving large complex structured optimization problems. Pyomo is an extensible algebraic

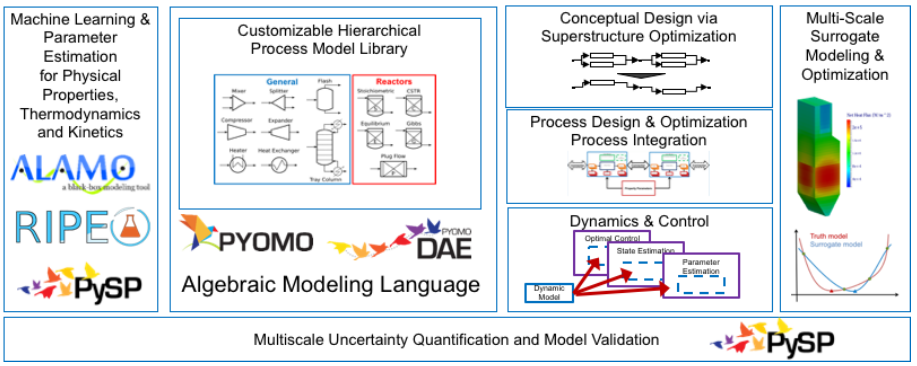

Figure 1. The major components and connection of the IDAES PSE Framework to support conceptual design, process design & optimization, process integration, dynamic optimization, and control while incorporating multi-scale surrogate models.

modeling environment written in the Python® programming language. It allows users to formulate, initialize, solve, and manipulate large-scale optimization problems with concise notation all within the Python ecosystem. Pyomo provides interfaces to dozens of optimization solvers, both open source and commercial, and supports executing solvers both locally and in distributed environments. Most importantly, Pyomo is extensible beyond "standard" algebraic optimization models. In particular, Pyomo provides extensions for block-oriented modeling and Generalized Disjunctive Programming (Friedman, et al., 2013), stochastic programming (Watson, et al., 2012), and dynamic systems containing (partial) differential-algebraic equations (Nicholson, et al., 2017). This enables modeling flexibility and the consideration of constraints and objective functions in non-standard forms not easily handled by other modeling frameworks. Further, Pyomo enables complex analyses by combining these extensions and capabilities with the ability to script custom algorithms and solution processes.

2.2. Hierarchical Equation Oriented Process Models

A major strength of commercial simulation packages is their library of unit models and thermo-physical properties. Such simulation packages, however, often have limited support for incorporating non-standard, dynamic unit models, and they do not directly support UQ. AMLs, on the other hand, are eminently flexible and readily support large-scale optimization, but considerable work is required to construct process models, which are often not easily reused. To overcome this issue, the IDAES framework extends Pyomo's block-based hierarchical modeling constructs to create a library of models for common process unit operations and a framework for rapid development of process flowsheets. Rather than developing highly detailed, but rigidly structured models, the IDAES model library consists of simpler, but extensible, models for each unit operation (Lee et al., 2018). The model library contains an internally consistent suite of interoperable models at different levels of complexity and accuracy for both steady-state and dynamic analysis. Models within the library can be extended with additional detail or rigor as needed, allowing full control of the complexity and accuracy of the models. This focus on adaptability and extensibility enables them to be used for novel processes and configurations.

2.3. Machine Learning and Parameter Estimation

Although commercial simulation tools have extensive databases and pre-regressed models for thermo-physical properties, when investigating innovative, new processes with new materials, such databases are of limited use. In addition, it is not always straightforward to assess the uncertainty inherent in these models. Thus, tools for modeling physical property and reaction kinetics have been developed based on ALAMO, which builds algebraic models that work well in an optimization framework. Building these models directly from data (either from literature or experiments) ensures they address the right range of conditions and enable tight coupling of uncertainty estimates that allow end to end UQ. In addition, through the data management framework, provenance can be more clearly established enabling tracking through the development of a new technology.

The Reaction Identification and Parameter Estimation (RIPE) tool can estimate kinetic reaction parameters from data describing the time evolution of concentrations of chemicals in a reaction system that may include reversible and irreversible reactions as well as homogeneous and heterogeneous catalytic mechanisms. ALAMO is first used to obtain algebraic models of concentration profiles in terms of polynomial, exponential, and logarithmic basis functions, then the constrained regression features of ALAMO are used for

data reconciliation by requiring the time profiles to satisfy physical bounds on concentrations – even over time domains for which concentration measurements do not exist (Wilson and Sahinidis, 2017). Finally, RIPE utilizes integer programming techniques to obtain explicit mathematical representations of the dynamics of the system.

More broadly, parameter estimation for multi-scale systems is a significant challenge since only a subset of parameters can be estimated from data at a given scale. Complex interactions among the parameters can lead to biased estimates unless they are estimated simultaneously. This can lead to a large-scale optimization problem with data that span multiple scales and contain inherent noise. Traditional modeling approaches are often not amenable to such a simultaneous approach since process models and physical property/thermodynamic models are often developed separately. In the IDAES framework, all models and sub-models are implemented in a common platform allowing access to all model parameters, enabling formulation of the complete, simultaneous multiscale problem. The problem can then be readily solved using the capabilities of the PySP module (Watson et al., 2011). The IDAES framework can also be used to develop optimal design of experiments for minimizing the variance of the parameter estimates.

2.4. Process synthesis and conceptual design

The major goal in process synthesis and conceptual design is to optimize, reliably and efficiently, superstructures of process systems to help identify novel process configurations and enable process intensification. These remain major research challenges (Chen and Grossmann, 2017). The approach relies on Generalized Disjunctive Programming (GDP) (Grossmann and Trespalacios, 2013) in which a model consisting of equations, disjunctions, and logic statements is used instead of formulating and solving a single monolithic MINLP model. Thus, only NLP subproblems corresponding to fixed flowsheet structures need to be solved, which greatly increases the robustness of the nonlinear optimization. Furthermore, the conceptual design algorithms in IDAES directly leverage the native support of Generalized Disjunctive Programming in Pyomo. Several test problems have been solved successfully with this approach, including a simplified version of the chemical looping process.

2.5. Process design and optimization

The IDAES framework enables large-scale system-wide optimization using rigorous models of process equipment and thermophysical properties. Complex interactions between multiple process systems can be explored simultaneously without the need for extensive simplifying assumptions that render the problems tractable at the risk of compromising the results. For example, both traditional and advanced combustion technologies such as oxycombustion or chemical looping combustion can be optimized together with their power islands and pollution control systems without relying on fixed steam cycle designs, the use of overly simplistic “Gibbs reactors” that cannot capture key nonlinear responses to operating conditions, or fixed design points from CFD simulations that overlook critical decision variables. Methods for enabling optimization over broad ranges of operation have also been developed that can handle non-smooth features such as vapor/liquid or sub/supercritical phase transitions as well as vanishing phases. The process design and optimization capabilities developed within IDAES are applicable not only to the energy sector but also to several other industries (e.g., chemicals, petrochemicals, pharmaceuticals) where tight integration is desired.

2.6. Dynamics and control

The dynamic process simulation and optimization capability builds on Pyomo's support for expressing ordinary and partial differential equations as large-scale systems of nonlinear equations. The IDAES process model library includes both steady-state and dynamic versions of common unit models allowing users to switch between steady-state and dynamic analysis with minimal changes to their flowsheet implementation. In addition, the IDAES framework includes capabilities for state estimation and control which enable the rapid deployment of approaches such as moving horizon estimation (MHE) and nonlinear model predictive control (NMPC) to arbitrary process flowsheets.

2.7. Multi-scale surrogate modeling and optimization

Even within a powerful equation-oriented platform for process optimization, complex, black box models that resist a direct equation-based description must often be included. These include CFD models for advanced combustors, reactors and separators as well as complex physical property models. When incorporating simplified, surrogate models of such complex models, optimizers often exploit the weaknesses of surrogate models and fail to find the true optimum. To guarantee convergence to the optimal solution, we have developed a trust region filter algorithm, which monitors and controls the errors in the reduced model and guarantees convergence to first order critical points of the complex model. The trust region filter algorithm, based on the SQP filter method along with concepts of Derivative Free Optimization, is developed, analyzed and demonstrated on challenging power plant models in Eason and Biegler (2016). Now implemented in Pyomo, it enhances a powerful optimization capability to include complex black box models.

2.8. Data management

The IDAES Data Management Framework (DMF) is responsible for managing the knowledge and provenance required for the synthesis, design, optimization, and scale up of innovative new processes. The DMF stores property data, inputs, model parameters, model codes, and results in an easily searchable form. Standard representations of provenance (e.g., journal publications and websites) support validation of results. The DMF's Python API can be used within scripts or for interactive analyses in Jupyter Notebooks. The Jupyter Notebooks are themselves stored in the DMF, providing a self-contained reproducible unit of analysis. The API also enables efficient access to large scale data sets for parameter estimation to other components of the IDAES PSE framework.

2.9. Other applications

The core approach of using data to develop submodels, which can then be utilized to formulate larger-scoped optimization problems, has also be applied to materials design (Hanselman and Gounaris, 2017) and multi-scale infrastructure planning (Lara et al., 2017). In the case of designing crystalline materials, for example, computational chemistry data is used to develop simplified structure-function relationships linking atomic neighborhood descriptors to the reactivity of atomic sites. These relationships can then be incorporated into an optimization model that seeks to identify the overall material structure that performs best in the context of the process of interest. In the case of infrastructure planning, the IDAES framework has been used to determine representative dispatch days and growth forecast for an electricity grid, which forms the basis for determining what types of power plants should be built to most economically meet all the expected demand.

3. Conclusions

In conclusion, this paper has described a comprehensive, open source framework to enable large scale process optimization of complex, innovative processes spanning conceptual design and process synthesis to dynamic optimization. The capabilities of this framework are applicable at the process scale as well as for materials design and infrastructure planning.

A framework for multi-network modelling

Arne Tobias Elve*, Heinz A. Preisig

Department of Chemical Engineering; NTNU; Trondheim, Norway
arne.t.elve@ntnu.no

Abstract

We present a new modelling framework called the ModelComposer. This framework combines well-known concepts such as equation-based modelling, graph-based modelling and code generation to produce simulation models automatically. Moreover, the framework uses ontologies as the bases, which means that interoperability of models produced by the modelling framework is high. The model information is stored in JSON-files, and code generation for different programming languages is used to transform the defined models into executable simulation. A result is a modelling tool that promotes the reuse of models and interoperability between networks of models of different domains. This paper will present the overall layout of the ModelComposer and how the framework handles internal conversions within a network and how different networks communicates. This is exemplified by a case study presenting the model construction of a dynamic mixing tank and the simulation of the resulting model.

Keywords: Graph-based Modelling, Automatic Code Generation, Model-Based Simulation, Customized Modelling, Multi-Scale Modelling

1. Introduction

Complex networks are present in many chemical and biochemical systems. In addition to the complexity of networks, there is also the possibility of reaction networks, such as combustions and cell metabolism. These reaction networks are of particular interest because of the emergence of new chemistry, for example, the conversion of biomass to fuels. There exist a variety of mathematical models to describe specific parts, but the challenge is to facilitate the interaction between these networks (Bogusch et al., 2001), especially when the networks operate on different scales.

The motivation for the development of our modelling framework is founded upon the objectives of generating proper and consistent models based on the principles described in (Preisig, 2010), automatically. We also want a minimization of the modelling errors and absolutely no code implementation errors in the desired output language. This also implies that we remove the hand coding of models and focus on the model formulation and not wasting time on programming technicalities.

This approach to modelling is closely related to MOSAIC (Kraus et al., 2014) and (Fedorova, 2015), which both populate model templates. We separate from their work since we extract our model knowledge from an ontology and then unite the knowledge into code based on context instead of using templates designed for special model units. Hence, we are conceptually closer related to (Brandt et al., 2008) and (Koo et al., 2017) that uses ontologies for knowledge management. We combine the equation template approach with the knowledge from the ontology to generate secure and correct models automatically.

2. The ModelComposer

The ModelComposer is a new modelling tool implementing a visual modelling language described in (Elve and Preisig, 2017) to a multi-network modelling environment, with the concepts described in (Preisig et al. 2018). The workflow used in the ModelComposer is illustrated in figure (1).

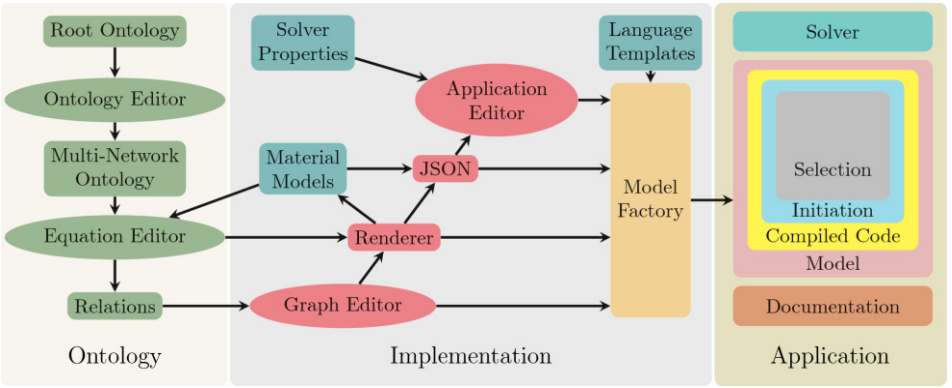

Figure 1. Illustration of the essential workflow for generating executable model code in the ModelComposer. The boxes are tasks required in the modelling procedure, the ellipses are editors that are controlled by a user and the arrows indicate a flow of information.

The framework consists of three parts that that are grouped under the terms ontology, computer implementation and the produced application containing the generated model, which is the output of the tool. We define an ontology to be a naming and definition of "things", properties and relations that exist for a particular domain. Molecules, phases, tanks and energy are examples of such "things" in the context of chemical engineering. The properties are attributes that provide the metric for the "things", and the relations describe how properties and different "things" are related. The relations are what we usually term equations and is how the relations are implemented in the produced model. For the ModelComposer, we have chosen to use a directed graph for the representation of the model topology. This means that the ontologies we construct are tailored for abstraction of a model into a topology. The construction of the ontologies was covered in (Preisig and Elve, 2016). For the ModelComposer, we start off with a root ontology, which we specialise so that we describe the domain in which the model lives. In the next step, we feed the ontology to an equation editor that aids the user in defining the relations of the ontology with structural and unit consistency checking.

The implementation part is where "things" from the ontology are used and connected such that the "things" interact with each other in a structure. This structure represents a network model, which we implement as a directed graph. The nodes of this graph represent the capacities, and the arcs represent interactions of quantities that characterise the capacities. A special graph editor is made for constructing these network structures. The resulting directed graph is then analysed, and the pieces of the graph stored as JSON files maintaining the object structure of the graph. The user then has to choose which application and what solver with properties that also should be implemented. All this information is given over to a compiler that use some language templates described in (Elve and Preisig, 2017) to transform the structure into code in the output language.

The generated model code consists of an initiation procedure, which requires that the user provide constants and initial conditions for the state description. If any alternative calculation method exists for a property, the user also has to select what method the code should use for the calculation. The compiled code are equations that describe the dynamic behaviour of the model. This model is coded into a selected application (typically simulation) that contains model documentation, the executable model code and solver packages required for solving the model. The product is a standalone application written in essentially any output language, but for now, limited to Python.

3. Ontologies and the network view

The modelling methodology involves capturing the behaviour of a set of characterizing quantities that interact with each other in a structure. For a physical system are these characterising quantities the conserved quantities. To have an understanding across different scales, we refer to these quantities as tokens. The term token comes from the analogy of Petri-nets where tokens are contained and move around within in the nets.

To capture the behaviour of multi-network models, we associate attributes of a network to specific layers in our ontology. When constructing the ontology, we start off with defining a root definition and then sequentially refine layers to form a tree of sequentially refined ontology branches. Within a leaf network in the model, all nodes and arcs are described within that refined branch in the ontology. Figure 2 illustrates the hierarchical decomposition of our ontology. Interactions between the networks are then defined on the latest shared leaf in the branch between the two networks. The illustration in figure 2 is an example of a decomposition of an ontology for chemical processes. The structure can be modified to the required specifications.

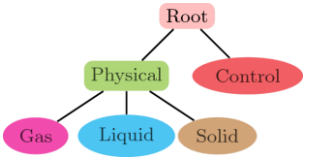

Figure 2. Network based decomposition of an ontology.

3.1. Tokens and typed tokens

We must describe the conversion of species for the modelling method to apply to chemical and biological processes. Mass, which is a conserved quantity and thus a token, consists of species, with species representing a type of mass. We consequently introduce typed tokens, which structurally can capture modelling entities such as species. The associated dynamic equations are then balances, in contrast to conservation. For species the link between them is well defined, namely the molecular-mass weighted sum of the molar species yields the total mass, described in equation (1).

$$m = \lambda^T n \tag{1}$$

The mass, m, is a scalar property in the node, while the molar mass, lambda, and species, n, are vector properties based on the amount of species in the node, which reduces in the multiplication. Nodes and arcs are already implemented as vectors, and by introducing typed tokens as a vector within a node or an arc, we get a vector of vectors structure in the mathematical implementation. This vector of vectors representation is very suitable for reaction networks (Horn et al., 1972). For example, we can use equation (2) when calculating the internal conversion of the entire network.

$$\tilde{n} = VN^T g(\mu) \tag{2}$$

$\tilde{n}$ represents the change rate of amount of moles due to chemical reaction. V is the volume, g(mu) is the extent of reaction in the node based on the chemical potential, and the N matrix captures a complete reaction network mapped into the physical network. The dimensions of the matrix are stacked reactions in nodes and stacked species in nodes. This capturing of the reaction network also applies to metabolic networks.

3.2. *Token and typed token propagation*

The objective of the modelling framework is to generate executable program code for a model. For the instantiation, we first have to calculate the propagation of tokens, which describes how the tokens are spread throughout the multi-network graph. This propagation is calculated before any compiling of code. The rules we have implemented in the ModelComposer is that tokens have to be introduced through reservoirs. Reservoirs are particular nodes where the numerical value of quantities is constant for the dynamic scale of the simulation model. From the reservoir, tokens propagate through the arcs describing the interaction of a particular token between two nodes. This procedure is recursively repeated until the graph is properly instantiated. Some rules are describing what tokens are propagated. For examples does mass also carry energy, whilst energy transport does not imply mass transport. The typed tokens follow the token. For the chemical species, a species can appear in a node if a chemical reaction is defined and all the reactants are present in the node. This node is now the origin of that species, and a new recursive token propagation procedure is initiated from this node. From the species distribution, we can also determine possible reaction networks.

When a token propagates from a network to another, the token has to be translated from token in a network to a token that is defined for the network on the other side of the boundary. We do this by selecting an already defined translation from one side to the other. This now generates an algebraic link that describes the translated token in the scales of the present network. The newly propagated token on the other side then initiates a new propagation routine.

3.3. *Scale coupling networks: Property transaction via ports*

The tokens determine the network definitions and tokens can only be present if they are defined for a particular network. Sometimes there are in some properties of a different network that determine how a token behaves in the other network. An example is temperature measurements, which are transmitted to a control system. A temperature is not described in a signal processing network. Thus it has to transacted as a measurement from the physical system over to a signal in the control system. We, therefore, introduce ports that are the connection point to other networks. The ports with the transactions between them are responsible for handling the broadcasting of variables from one network to the other. For example, the current example illustrated in figure (3). The measurement of a property is to be transacted from a network, denoted by α, of a physical nature defined in a continuous time frame. The transaction translates the measurement over to a signal, which is valid in the connected

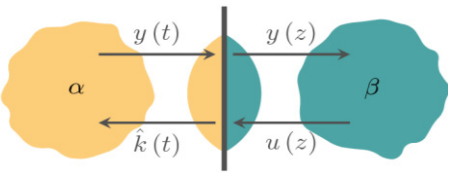

Figure 3. Illustration of transaction of a property between two networks. They are connected with a transaction system containing a algebraic link of a property between two

control network, denoted by β, described in discrete time. The control output from the discrete control network is transacted over to the physical network to a number that represents an updated value for a valve position. For a typed token, we use the same approach, but the link between them is defined in the tokens propagation. This also allows the user to inhibit transaction of some species, which reduce the mathematical space and then simplifies the model. For a scale connection between a physical network on a macroscale, state information can be broadcasted over to a network described on microscale doing molecular calculations. All variables are then available for that network due to the heritance.

4. Case study: Dynamic model of a mixing tank

The following case study highlights the concepts of the modelling framework. The simulation results are from the automatically generated code from the ModelComposer.

4.1. Model implementation

The tank consists of a liquid phase and a gas phase open to the surroundings. The feeds into the tank, illustrated in figure 4, are one acidic with pH 4 and one basic of pH 10, where the compositions of the solutions were set into the reservoirs denoted by A (acid) and B (basic). The reactions are assumed to be equilibrium reactions, which takes place in the liquid (L). The level in the tank is controlled by a level controller, that measures the level and calculates the new position of the valve opening of the outflow, following the same methodology presented in figure 3. We assume perfect mixing in the liquid (L), so we can use a lumped node for the representation. The two inflows are determined by the user, and the flow out from the tank is pressure driven and controlled.

The topology was constructed in the graph editor and the token propagation was carried

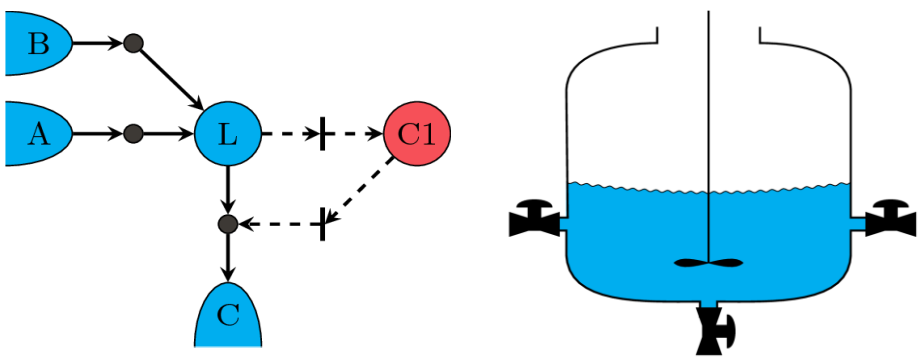

Figure 4. Illustration of the modelled mixing tank and the corresponding topology generated.

out and based on this the reaction systems were selected. Initial conditions were given to the states and constants. The initial volume of the tank was set to 0.5 m^3.

We used the same automatically generated model with three different initial conditions. For the first simulation, we set the initial composition of the tank to be of pH = 10 and only have an inflow of acid. For the second simulation, we set the initial composition of the tank to be of pH = 4 and just add basic solution. For the final simulation we kept the initial composition of the tank to be of pH = 4, but now we added equal amounts of the two solutions. We simulated the tank for 100 seconds and used the Runge-Kutta method as integrator and a root solver for obtaining the equilibrium conditions in the reactions. The results from these simulations are displayed in figure 5. Where the pH in the tank is plotted over time for the three different initial conditions.

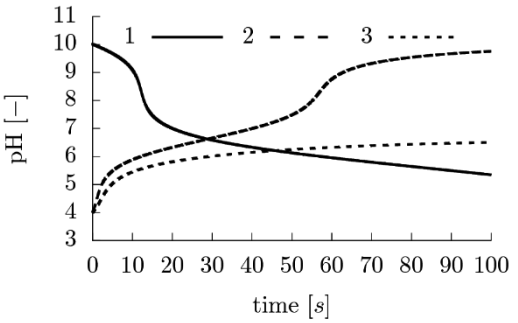

Figure 5. Results from the three simulations.

5. Conclusions

This paper presents the basic concepts in which a modelling tool named the ModelComposer is built upon. The modelling tool utilize an ontology that captures the system knowledge for formulation of models. Interactions between networks are handled in transaction systems containing an algebraic link that defines the transacted property with scaling on both sides in the network boundary. These concepts were used in the study of reactive mixing tank. The code for this system was automatically generated with the ModelComposer.

Approaches to Multi-Scale Modeling from Systems Engineering

Sigve Karolius*, Heinz A. Preisig

Norwegian University of Science and Technology, Sem Sælandsveg 4, Trondheim 7491, Norway
sigve.karolius@ntnu.no

Abstract

The concept of multi-scale modeling has been embraced for different purposes in various branches of science and engineering. In this context, the importance of process-systems engineering is self-evident considering that the overall goals remain to improve or invent novel products and processes through optimization and simulation-guided studies. This paper aims at presenting an overview of past and current approaches to categorize multi-scale models according to scale-integration strategies.

Keywords: multi-scale modelling, surrogate modelling.

1. Introduction

The classic approach to modeling, particularly in engineering, focuses on developing deterministic models based on conservation principles for the purpose of design and optimization of equipment and entire processes. The emphasis in Process-Systems Engineering (PSE) on establishing a diverse and solid foundation has enabled control- and systems-engineers to cover the entire range from model development to computer implementation and optimization.

However, in the domain of multi-scale modeling, this approach quickly becomes impractical. The reason is twofold: firstly, the inherent complexity of the physics and modeling paradigms themselves; secondly, the modeling frameworks required to perform efficient simulations are naturally developed for domain-specific use in a variety of programming languages and are computationally expensive. Therefore, approaches to integrating multi-scale models into optimization frameworks is based on replacing the detailed models with simplified surrogates as presented in (Biegler and Lang et al. 2014).

The purpose of this work is to present current approaches to multi-scale modeling and simulations, as well as reviewing the conceptual work that the PSE community has contributed to the domain. This is relevant for PSE as the material science community is currently focusing major efforts into formalizing documentation, reproducibility of simulation and defining an ontology for materials-modeling as discussed in (Rosso and de Baas 2012).

2. Multi-Scale Perspectives

The multi-scale nature of the physical world has been recognized and utilized as solution strategies in science and engineering. The fundamental idea is that the dynamics for a model on scale "i" are slow compared to the scale below and fast

compared to the one above. Consequently, the apparent dynamics of the lower level is that of an "event", and the scale above is a constant reservoir.

Figure 1: Illustration of models that are scale-separated.

The multi-scale modeling paradigm attempts either to utilize this scale separation or remedy the lack thereof. The work of formalizing categories for multi-scale models has been approached by the PSE community, such as in Pantelides (2001) and later by Ingram and Cameron (2004). Moreover, the review paper of Vlachos (2005) presents concepts and examples from Chemical Engineering. The later also emphasizes the need for systems engineers to facilitate optimization and control for effective utilization of these models in making business and design decisions.

2.1. Coupling and Linking Scales

All of the aforementioned references emphasize that multi-scale modeling poses some additional challenges and that the refinement strategy depends on not only the perspective and desired level of detail, but how models on different scales are intertwined. This will guide the choice of what Pantelides called the "scale-integration" strategy employed.

Ingram states the coupling can be performed from the following perspectives: top-down, bottom-up, concurrent and middle-out. Regardless of perspective, the relationship between two adjacent scale-specific models can be illustrated as shown in Figure 2. The scale coupling from the top-down involves homogenizing the state of the macroscopic scale and subsequently lifting the output from the microscale model.

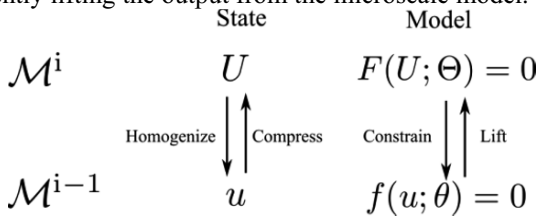

Figure 2: Illustration of the relationships between two coupled scale-specific models.

From a simulation perspective, the homogenization/lifting could be the result of sequential simulations, or the result of processing happening on-the-fly between concurrent simulations. In (Rosso and de Baas 2012), sequentially coupled models are referred to as "linked", whereas the term "coupled" is reserved for concurrently coupled models.

2.2. Model Construction

Constructing a multi-scale model requires at least one person that is familiar with both the overall process and the sub-processes that make up the inter-scale connections. However, there are methodologies that aim at formalizing the construction of different types of scale-connections. For engineering applications, the details of the microscale models are often not of interest and a "top-down" approach can be used. The heterogeneous multi-scale method (HMM) from (Weinan and Engquist et al. 2003), is a methodology for coupling macro- and microscopic models by homogenizing the macroscopic state and lifting the result of the microscopic model at regular intervals.

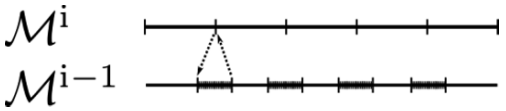

Figure 3: Illustration of the hierarchical multi-scale method (HMM). The model on the macroscopic scale employs the microscopic model, re-instantiating it at every time-step.

In HMM, Weinan and Engquist differentiate between models where the multi-scale nature is due to localized events, e.g. cracks, and those where constitutive information is missing globally and supplied by microscale models. Either way, the microscale model is initialized and averaged around each sampling point. Alternatively, the "top-down" connection can be constructed by scaling the time-step of the adjacent models in order for the simulations to run concurrently. This is the approach of the "seamless" multi-scale method presented in (Weinan and Ren et al. 2009).

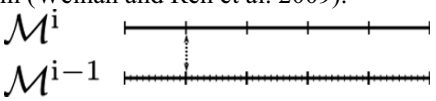

Figure 4: Illustration of the "seamless" multi-scale method. Simulations run concurrent using different time-steps allowing for information exchange at regular points throughout the interval.

At the other end of the spectrum there is the "bottom-up", or simultanious coupling, perspective, which aims at reconstructing the macroscopic model in its entirety using microscale simulations. The so-called "equation-free" approach from (Kevrekidis and Gear et al. 2003) is a formal way of achieving such a coupling by only using the macroscale model to supply information that in unobtainable from the lower scale. The bottom-up approach has the advantage of retaining details of the microscopic scale that would be lost in the HMM. There are also specialized forms of "bottom-up" approaches focusing on course-graining, e.g. modeling a solvent as a bulk-phase rather than molecules.

2.3. Model Formalization

The approach of categorizing scale connections is a useful start for constructing a multi-scale model, but a general approach requires further abstraction. The work of (Yang and Marquardt 2009) takes an even more generic approach, aiming at a formal framework for conceptualizing all multi-scale models. Yang and Marquardt address scale-integration rigorously and is recommended for anyone entering the domain.

Transistivity implies that the properties of a thing "x" contains the set of its constituent parts, here: "y" and "z". Alternatively, the ontology can incorporate the hierarchical relationship "direct parthood", meaning that a thing "y" can be a direct part of "x" without implying that "z" is a part of "x".

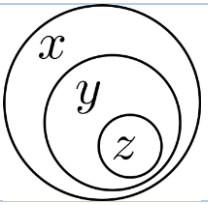

Figure 5: Illustration of the notion of transistivity and direct parthood.

However, there is a potential for conflict between the approach of Yang (2009) and that of Rossi (2012). It arises with the composition of a "thing". In material science the assumption of transistivity, illustrated in Figure 5, is not necessarily valid. In the terminology of Yang, this means that the composition of a thing "x" does not contain all the constituent parts of another thing "y", even though the latter is a subset of the former. For example, if a model based on molecular dynamics (MD) is coupled with a

model based on quantum mechanics (QM) this does not imply that the MD model contains the notion of electrons.Since the model formalization has a direct implication on software design it is imperative that the definitions are coherent between interdisciplinary groups.

3. Multi-Scale Simulation Types

Developing generalized software for the purpose of multi-scale modeling boils down to the question of generalizing different types of scale-integration.

3.1. Concurrent Simulations

The "seamless" coupling of models is a typical example of model construction requiring simulations to run concurrently. This is challenging to address in a generic way but there are examples, such as (Borg and Lockerby 2015), that achieve this by inter linking the low-level simulation models directly into the simulation tool for the macro-scale, e.g. OpenFOAM. The main reason why this is necessary is that there is no standard for passing data between scientific software. Recently there has been approaches, such as semantic interoperability (Hagelien and Chesnokov et al. 2017), that are aimed specifically at providing a generic framework within which meta-data can be defined and subsequently extracted using simple software-specific adaptors.

3.2. Sequential Simulations

Multi-scale models generally require adaptive workflows and distributed computing resources. Consequently, the workflow "orchestrator" is an integral part of any sequential simulation framework. However, the framework can be designed such that any orchestrator in principle can be used. The requirement is that model definitions can contain pre-defined strategies that the framework can employ to resolve errors occurring during a simulation. The added benefit of a sequential framework is that the workflow can be re-run; thus, providing a potential method of documenting reproducible simulations.

4. The MoDeNa Simulation Framework

The software framework Morphology Development of Micro and Nanostructures (MoDeNa), outlined in (Karolius and Preisig 2016), was designed specifically to interlink models sequentially as parts of a larger workflow. It uses adaptive surrogate models and on-the-fly parameter estimation, performing micro-scale simulations as necessary in order to satisfy a given error criteria.

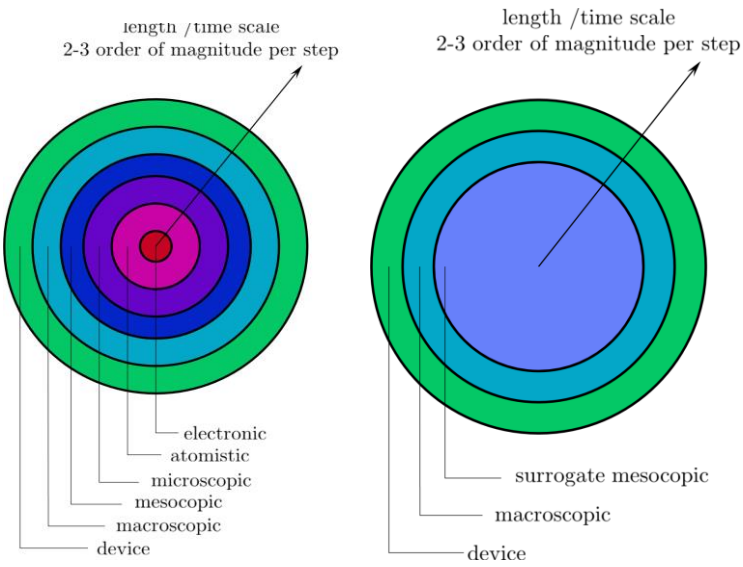

Figure 6: Onion-type multi-scale model employing a surrogate model for the mesoscopic scale.

This was a particularly challenging project as the scale-specific detailed models were developed in parallel with the software framework. It quickly became clear that it is desirable for the framework: 1) attain loose coupling between the models and 2) enforce high cohesion within each model. This is due to the practical need of maintaining the code-base of a large project where each member is familiar with only a small fraction of the complete project. The implication of loose coupling between models is that the API must be well designed such that it can handle all special cases without employing hacks. High cohesion, on the other hand, was enforced by defining that every detailed model was an atomic computational task performing homogenization, simulation and lifting. Consequently, all implementation details related to a scale-specific model is confined is the definition of a single computational task.The design on which the MoDeNa framework was based will obviously not apply to all types of multi-scale models as there is an inherent assumption of scale-separation. However, it does represent one approach for abstracting the scale-integration such that it can be defined outside of the implementation of the detailed models. The challenge of writing an ontology-based software framework capable of handling multiple types of scale-integration has been tackled by (Zhao and Jiang 2012). By extending such a tool to be capable of translating between multiple ontologies one would provide a significant contribution to the domain of multi-scale modelling.

5. Conclusions

The multi-scale modeling paradigm is continuously maturing and there is a need for development of formal conceptualization and generic software solutions. Part of the challenge for the PSE community is to become familiar with software and design concepts that are readily available. This paper presented an overview of current and past approaches to the challenge of tackling coupling of models across scales with a particular focus on the top-down strategy known as hierarchical multi-scale modeling (HMM). It was highlighted that supporting information exchange between simulations running concurrently and sequentially poses significantly different requirements on

software frameworks. The MoDeNa software framework was used as an example of how design principles from software engineering can be enforced in the development process whilst complementing the logical structure of the models that are intertwined.

Abstract

The spillage of hydrocarbons associated with the fuel production chain, have generated irremediable environmental damages to the Colombian geography. The present study presents the analysis of the phenomenology of dispersion of a hydrocarbon in a body of fresh water, using as basis the mathematical modeling presented in the literature. The growth of the stain is studied from experimental tests established by a design of experiments to a determined time. The established criterion was developed for a controlled environment based on the model of dispersion of Fay, comparing the results of the model with the experimental data.

Keywords: Spillage, hydrocarbons, fresh water, dispersion.

1. Introduction

Due to the quantity of products and by-products derived from the processing of oil, this hydrocarbon has been one of the most demanded fuels in the world. The places of exploitation and production of crude oil are diverse in relation to the geography that contains them. This fact generates conditions of variable exploitation and transport (Parra & Haenao 2015, Alexopoulos *et al*, 2013). The effects of spillage are not exclusively associated with the extraction of crude oil (drilling), also, the terrestrial transport operations are (pipelines and tankers) and maritime (ships and offshore stations), which are vulnerable to technical failures and attacks which cause spillages and generate immense affects on natural resources.

Colombia has presented a gradual increase in the production of hydrocarbons, a precipitous increase in production that does not go to the same rhythm of the increase in the structures of fast transportation of the oil (pipelines). In the Colombian hydrocarbons production chain, ground transportation is one of the activities that has been most positioned as an alternative over time, moving crude oil and its by-products through national geography to refineries, processing units and Ports for exportation. With the increase of these transport activities, also, the risk of spillage that significantly impact the natural resources and communities close to the transport routes, increase. In 2014, the Department of Putumayo was affected by large spillages caused by actions of illegal groups, which resulted in the spillage of 5,100 barrels of crude that were transported from the Department of Putumayo to Ecuador. The attack affected 106

families, and the ravine La Canoa which flows into the Putumayo and Guamuez rivers, which supply the municipalities of Puerto Asís and Puerto Leguízamo. The environmental impact caused by hydrocarbon spillage mostly leaves irreversible damages.

This fact makes the study of phenomenology, once the spillage occurs and the provision of tools allows to predict the behavior of occurrences for timely attention, it is of great importance to the world. The present study finds results related to the dispersion of crude oil in freshwater bodies, generating knowledge for the development of spillage control techniques and, in this way, minimizing the negative effects on the ecosystems that are affected in this type of emergencies.

2. Methodology

The criteria established for the selection of the mathematical model (for the dispersion phenomenology) took into account that the variables considered were directly or indirectly measurable by means of an experimental approach, in addition to systems where the changes in the densities were not taken into account and viscosities of fluids due to changes in temperature over time, will not consider the influence of wind currents or mechanical disturbances. The experimental development that was carried out evaluated the growth of the oil stains generated by spillage of four volumes: 20 mL, 25 mL, 30 mL and 40 mL. The volumes used for experimental development were based on the experiment carried out by Cohen et al. (1980), Charbeneau et al., (1995), Qiao et al., (2014) the monitoring times were established through a pre-experimental process, by means of which it was determined that they would take records of the stains at the zero time of the spill, which corresponds to the moment at which the spillage is produced, from then on, we study the growth of the stain hourly. The hydrocarbon spillage present different phenomenologies, which are needed to be understood if the intention is to control a spillage in a timely manner, and to minimize the environmental impacts generated by it.

It is possible to see that the phenomena of dissolution and dispersion occur in all directions, for the purposes of the present study, the complexity of the movements in a two-dimensional sense will be reduced. Figure 2 shows the factors that affect the behavior of the stain over time. This way, it is possible to observe that environmental variables and boundary conditions can accelerate the phenomenologies of dispersion of hydrocarbon spillage in freshwater bodies.

3. Analysis of spillage factors and phenomenologies

The phenomena that are developed in a spillage of crude oil in bodies of water are physical, chemical, biological, and their evolution is related to the time that elapses between the beginning of the spillage and the attention of the same. The focus of study of this work centers on the behavior of the system from the dispersion phenomenon.

Natural dispersion

If a certain amount of hydrocarbon is spilled on a body of calm water, in which there is no interaction with the wind, nor streams of water, nor tides, this volume of oil would be dispersed evenly by the equilibrium of the forces associated with its weight initially, of immediately viscosity and finally by the surface tension. This phenomenon of occurrence in ideal conditions under any of the following names: runoff, mechanical dispersion, expansion or horizontal dispersion Betancourt (2014), Calderon (2007).

Vertical dispersión

The turbulence in large bodies of water is mainly caused by the wind, whereas in rivers it is mainly caused by the banks and the bottom of the channel in greater proportion, this arrangement causes part or all of the rupture of the stain, dividing it into fragments and drops of different sizes. These small droplets can become mixed at different levels of the water column. The small droplets have a greater tendency to remain dispersed in suspension when their diameter is less than 70 μm, whereas for those of larger diameter, the cohesive forces rejoin them, forming a new stain that is spread in thin films (NOAA - National Oceanic and Atmospheric Administration, 1995). The dispersion increases the surface area of the stain, favoring dissolution, biodegradation and sedimentation.

Characteristics and implications of water-oil spill systems

The different characteristics and implications that occur in hydrocarbon spillage are described in Table 1, which describes the time of action and the description of the phenomenon described in the spillage system.

Table 1. Characteristics of the processes involved in an oil spillage

PROCESS	DESCRIPTION	MASS LOSS	ACTION TIME
Mechanical dispersion	Mechanical dispersion determines the growth of the petroleum stain by the balance of gravitational, viscous and surface tension forces.	None	It depends on the initial volume shed, varying from approximately one day to three weeks
Vertical dispersion	The vertical dispersion takes place by the action of the agitation of the body in water, which separates the oil in small drops that are suspended in the water column. The permanence of the hydrocarbon drops in the water column depends on its turbulence	The percentage of mass lost may reach 20% or more depending on the environmental conditions. In the vicinity of a cliff the vertical dispersion can become total.	Vertical dispersion occurs a few hours after the spill has occurred.
Dissolution	The solution is presented by the solubilization of the hydrocarbon fractions present in the petroleum. Generally the same soluble fractions are those that first evaporate.	The amount of dissolved oil is about 1% which depends on the characteristics of the oil and the environmental conditions.	The dissolution as well as the vertical dispersion occurs a few hours after the spill has occurred.
Emulsification	Emulsification occurs by suspending water droplets in the oil, increasing its viscosity, density and environmental impact. The stability of an emulsion depends directly on the content of asphaltenes.	The water content in the oil can be up to 80% in turbulent waters. However a stable emulsion is generally 55 to 70%	The formation of emulsions takes place after a few hours, but begins to be of interest after the first 8 or 15 hours.
Sedimentation	Sedimentation occurs when the oil droplets suspended in the water column are adhered organic material or particles in suspension, causing precipitation.	The amount of settled oil does not reach large proportions and is very variable.	Sedimentation occurs after the first week of the spill.

Mathematical Model: Fay's Model (1971)

It performs an analysis of the forces acting on the interfaces formed when a spillage occurs (water-air, oil-water and oil-air) which accelerate or delay the dispersion of the oil stain once the spillage occurs. In equations 1, 2, 3, 4 and 5 are presented the four forces acting on a spillage:

a. Gravity force:

$$F_P = \Delta\rho g h\left(\frac{dh}{dX}\right) \quad (1)$$

b. Surface tension: Determines the coefficient of dispersion as the net difference between the surface tension of the water-air interface and the sum of the surface tensions of the oil-water and oil-air interfaces

$$\sigma = \sigma_{wa} - (\sigma_{oa} + \sigma_{ow}) \quad (2)$$

c. Inertia:

$$F_I = \rho h \frac{du}{dt} \quad (3)$$

d. Friction:

$$\mu \frac{u}{\delta} = \rho \delta \frac{du}{dt} \quad (4)$$

$$\delta = \sqrt{vt} \quad (5)$$

Where:

ρ = Density of the fluid
h = Height of the stain
g = gravity, X = distance
σ_{wa} = Surface tension
σ_{oa} = Surface tension raw air
σ_{ow} = Surface tension
μ = viscosity
δ = Losses by friction

From the four forces analyzed, Fay (1971) establishes three important regimes to measure the dispersion of the stain (linear or radial) as a function of time. These regimes are known as the Fay dispersion laws and were designed to measure one-dimensional or two-dimensional (axial symmetry) spills.

4. Experiment and discussions

According to the selective criteria presented above, the base model used was Fay's (1971). It performs an analysis of the forces acting on the interfaces formed when a spillage occurs (water-air, oil-water and oil-air). The properties of the crude oil and water used are shown in Tables 2 and 3 below.

Table 2. Properties of water used

Characteristics	Units	Value
Kinematic viscosity at 15 ° C	m^2/s	1.007.10-6-6
Density at 15 ° C	kg/m^3	999.1
Surface tension (water-air)	N/m	$72.08.10^{-3}$

Table 3. Characteristics of crude sales

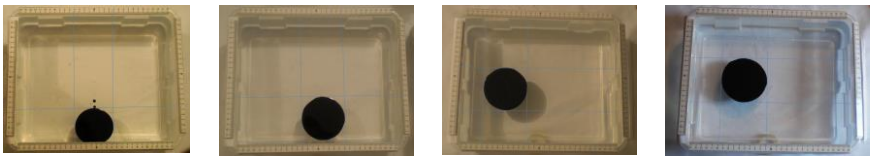
Characteristic	Units	Value
Gravity API @ 60 °F	°API	33,3
Sulphides	%W	0,144
Dissolved solids	%W	0,02
Nickel	Ppm	6
Salt content	PTB	4
Viscosity at 100 ° C	cP	9,1
Paraffins	%W	0,05
BSW	%	0,1019

Source: *Parex Resources Company*

Table 4. Dissolution of the oil stains in 24 hours

20 mL ≈ 17,6 g		
Run No.	**Dissolution (g / h) 24 hours**	**Dissolution %**
Run 1	4,507E-05	2,626E-04
Run 2	7,571E-05	4,412E-04

The analysis compared the amount of spilled crude mass with dissolved mass during each of the time periods monitored in the experimental development.



Time: 0 hours **Time:** 1 hour **Time:** 10 hours **Time:** 15 hours

Figure 1. Experiments

The pre-experimental and experimental development was carried out in a closed room, with artificial light, at temperatures between 10 ° C and 19 ° C. The spillage was manually performed at water level, the oil was measured in precipitated vessels and manually poured into the water, without controlling the speed of the spillage. To determine the growth of the stain, two diameters of the stain were measured, one called the H-diameter, which corresponds to the diameter of the stain on the horizontal axis of the container, and a diameter V corresponding to the vertical axis. The results obtained are presented in Table 5, these were established for a time of 20 mL.

Table 5. Experiment results

Picture No.	Elapsed time (h)	Diameter H (D_1) (mm)	Diameter V (D_2) (mm)
1	0	74	55
2	1	82	85
3	5	82	85
4	10	83	89

They were carried out with the same volumes of experimentation to be able to compare the behavior of the size of the oil stain spilled at different time intervals. These intervals were randomly selected in order to generate a prediction of spillage behavior from a time t = 0.5 hours to t = 48 hours, with intermediate values associated with the experimentation to compare the experimental and theoretical data..

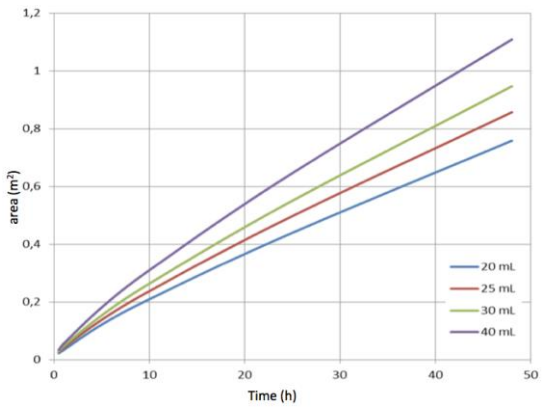


Figure 2. Increase in area over time - Numerical model

As it can be seen in Figure 3 the change of area with respect to time, the growth of the stain is gradual and constant, in conclusion the relationship or trend of the data thrown

is that the greater the volume, the greater the radius of the oil stain in wáter, and the longer the elapsed time the longer the radius. Then, it is concluded that the results generated by the simulator are in line with what was expected and could represent the growth of a crude stain at a steady state, at defined times and volumes.

5. Conclusions

The Fay Dispersion Model evidences a low correlation with the experimental behavior of spillage at laboratory scale, this is due to the sensitivity with the data field and environmental conditions going from a steady state to a dynamic behavior. It is possible to identify that as time increases by the nature of the equilibrium between fluids, the hydrocarbon area on the body of fresh water increases proportionally and without any tendency to equilibrium, this way, the dispersion of the stain is directly proportional to the time and amount of fluid spilled. The generation of more robust models that allow to have external considerations such as wind and mechanical factors are fundamental for the representation of the real phenomenology, the impact of these are significant in the speed of surface dispersion of the stain, as well as the speed in which it produces the spillage. The impact of the wind on the spillage was evidenced by the experimental results of runs one and two of the corresponding spillage to the volume of 30 mL

Abstract

The steel industry is committed to improving product quality and productivity with low production cost. To achieve these objectives, reducing product defects is of utmost importance. There is an increasing interest in developing a model to predict the occurrence of defects online. However, traditional statistical models such as multiple linear regression and Poisson model are not adequate enough to describe the observed defect count data due to the unique characteristics of non-negative integers, over-dispersion, high skewed distribution, and excess zeros in the data. This study develops an online quality monitoring system based on the zero-inflated regression modeling. Zero-inflated models are two-component mixture models that combine a count component and a point mass at zero. Intuitively, a mass of zeros observed in defect data can be attributed to two states: a safe (perfect) state, where no defect occurs, and a non-safe (imperfect) state, in which defects are possible but not inevitable. Zero-inflated models are suitable for modeling discrete and non-negative integers data and can handle both over-dispersion and excess zeros. The effectiveness of the zero-inflated models was verified through their application to the real defect data of a steelmaking plant. The application results demonstrated that the prediction accuracy of the zero-inflated models is superior to the PLS, Poisson, and negative binomial models.

Keywords: Defect data; count data; casting-rolling process; quality prediction; zero-inflated models.

1. Introduction

To keep the advantage in the fierce market competition, the steel industry is committed to improving product quality and yield with low production cost. However, manufacturing processes always suffer from various variations, including equipment malfunctions, process perturbations, improper operations, and so on. These variations may result in different types of defects, which not only degrade product quality but also increase production cost, energy consumption, and lead time. During the continuous casting-rolling process, defects are generally inspected after cold rolling. Because defects cannot be detected during the continuous casting-rolling process, many defective products will be formed. Therefore, developing an online quality monitoring system that can predict the occurrence of defects is vital to improve product quality and yield.

Virtual sensing or soft-sensor is a key technology for predicting product quality or other key variables in real time, and has been successfully applied to many industrial processes (Kano and Nakagawa, 2008; Kadlec et al., 2009). The basic idea of soft-sensor is to construct an inference model that relates product quality (response) to process operating conditions (predictors). Multiple linear regression (MLR) and partial least square (PLS) regression are the most commonly used methods (Kano and Fujiwara, 2013). However, they may not be suitable for modeling defect count data. This is because MLR and PLS depend on assumptions of normality and homoscedasticity of the dependent variable, but the observed defect count data exhibits highly skewed distribution and overdispersion. Furthermore, MLR and PLS could produce negative values for the dependent variable, although the defect count data is nonnegative integers.

Poisson regression is a basic tool for modeling count data (Cameron and Trivedi, 2013). However, it has limitations in its application to the overdispersed data due to its assumption that the variance of the dependent variable is equal to its mean, i.e., "equidispersion". This assumption is often violated by most of the data such as the defect data observed in this study. A remedy for this problem is to implement a negative binomial (NB) regression model, which could be viewed as a Poisson-gamma mixture model (Hilbe, 2011). The NB regression model has a free dispersion parameter, thus it is more flexible than the Poisson regression model in handling overdispersed data. However, the NB model is not adequate enough to account for the excess of zeros.

To account for the unique characteristics of non-negative integers, overdispersion, high skewed distribution, and excess zeros in the observed defect count data, the present work develops an online quality monitoring system based on the zero-inflated model, which is a two-component mixture model that combines a count component and a point mass at zero. Compared to the standard Poisson and NB models, zero-inflated models are not only suitable for modeling discrete and non-negative integers data, but also sufficient for handling both overdispersion and excess zeros. This research is motivated to verify the potential application of zero-inflated modeling technique to the defect data in a steel manufacturing process.

The remainder of this paper is organized as follows. In section 2, the basic theory of the Poisson regression and the NB regression is briefly introduced. Then the zero-inflated modeling technique is explained in section 3. In section 4, the performance of the zero-inflated model is evaluated through its application to the real defect data of a steelmaking plant. Section 5 gives the conclusions of this work.

2. Preliminaries

2.1. Poisson regression

Poisson regression is a basic tool for modeling count data. Given the input-output pairs $\{(\boldsymbol{x}_i, y_i)\}_{i=1}^{N}$, where $\boldsymbol{x}_i^T \in \Re^K$ is an observation of the predictor variables, and y_i is the response, which is a non-negative integer. The Poisson probability density is

$$f(y_i|\boldsymbol{x}_i) = \frac{e^{-u_i} u_i^{y_i}}{y_i!} \tag{1}$$

where $y_i!$ is a factorial, e is the base of the natural logarithm, and u_i is the average number of events. The conditional mean and the conditional variance are given by

$$\mathrm{E}(y_i|\boldsymbol{x}_i) = \mathrm{Var}(y_i|\boldsymbol{x}_i) = u_i. \tag{2}$$

The Poisson regression model can be obtained through parameterizing the conditional mean of y_i as an exponential function of the predictor variables $\boldsymbol{x}_i$:

$$u_i = \exp(\boldsymbol{x}_i^T \boldsymbol{\beta}) \tag{3}$$

where $\boldsymbol{\beta}$ denotes a vector of regression coefficients. Using exponential parameterization ensures the non-negativity of u_i. In general, the parameter estimates of Poisson regression can be obtained by using the maximum likelihood technique (Fox, 2015).

Since Poisson regression assumes that the conditional mean equals the conditional variance, it cannot describe overdispersed data. One way to relax this assumption is to implement the NB model.

2.2. Negative binomial regression

The NB model is a generalization of the Poisson model by allowing the Poisson parameter u_i to vary randomly following a gamma distribution (Hilbe, 2011). The NB probability density takes the form of

$$f(y_i|\boldsymbol{x}_i) = \frac{\Gamma(y_i + \tau)}{y_i!\,\Gamma(\tau)}\left(\frac{\tau}{\tau + u_i}\right)^{\tau}\left(\frac{u_i}{\tau + u_i}\right)^{y_i} \tag{4}$$

where $\tau > 0$ is a shape parameter or dispersion parameter, and $\Gamma(\cdot)$ is a gamma function. The conditional mean and the conditional variance are given by

$$\mathrm{E}(y_i|\boldsymbol{x}_i) = u_i = \exp(\boldsymbol{x}_i^T \boldsymbol{\beta}),\ \mathrm{Var}(y_i|\boldsymbol{x}_i) = u_i\left(1 + \frac{1}{\tau}u_i\right). \tag{5}$$

It is clear that the variance is larger than the mean, so the NB model allows for overdispersion. Furthermore, as $\tau \to \infty$, the NB distribution converges to the Poisson distribution. The maximum likelihood technique is used to estimate the parameters of NB regression (Hilbe, 2011).

3. Zero-inflated modeling for defect data with excess zeros

To monitor the defects online in the casting-rolling process, a quality monitoring system based on the zero-inflated modeling was proposed. Compared to the standard Poisson and NB models, zero-inflated regression models are more powerful in dealing with both the excess zeros and overdispersion in the observed defect data.

Zero-inflated regression models assume there are two underling data generating processes (Cheung, 2002; Zuur et al., 2009). For an observation, the probability that it is generated from process 1 is p_i, and the probability that it is generated from process 2 is $1 - p_i$. A binary model is used to determine which process is used. Process 1 is usually referred to as a point mass at zero, which generates only zero counts, whereas process 2 generates counts from either a Poisson or a NB model. Thus, zero counts may come from two processes. The zero-inflated probability density is given by

$$f(y_i|\boldsymbol{x}_i) = \begin{cases} p_i + \{1-p_i\}g(0|\boldsymbol{x}_i), & \text{if } y_i = 0 \\ \{1-p_i\}g(y_i|\boldsymbol{x}_i), & \text{if } y_i > 0 \end{cases} \tag{6}$$

where $g(\cdot)$ denotes a Poisson or NB probability density function.

In the zero-inflated regression, the parameters u_i and p_i are modelled as the function of the predictor variables $\boldsymbol{x}_i$ and $\boldsymbol{z}_i$:

$$u_i = \exp(\boldsymbol{x}_i^T\boldsymbol{\beta}), \quad \text{logit}(p_i) = \log\left(\frac{p_i}{1-p_i}\right) = \boldsymbol{z}_i^T\boldsymbol{\gamma} \tag{7}$$

where $\boldsymbol{z}_i$ is the vector of zero-inflated predictor variables, $\boldsymbol{\gamma}$ denotes the vector of zero-inflated coefficients, and $\text{logit}(\cdot)$ denotes the logistic regression. Generally, the regressors $\boldsymbol{x}_i$ and $\boldsymbol{z}_i$ could be different.

More formally, when $g(\cdot)$ is specified as the Poisson distribution, zero-inflated Poisson (ZIP) probability density is obtained as

$$f_{ZIP}(y_i|\boldsymbol{x}_i, \boldsymbol{z}_i) = \begin{cases} p_i + (1-p_i)e^{-u_i}, & \text{if } y_i = 0 \\ (1-p_i)\dfrac{e^{-u_i}u_i^{y_i}}{y_i!}, & \text{if } y_i > 0 \end{cases} \tag{8}$$

When $g(\cdot)$ is specified as the NB distribution, the zero-inflated NB (ZINB) probability density is obtained as

$$f_{ZINB}(y_i|\boldsymbol{x}_i, \boldsymbol{z}_i) = \begin{cases} p_i + (1-p_i)\left(1+\dfrac{u_i}{\tau}\right)^{-\tau}, & \text{if } y_i = 0 \\ (1-p_i)\dfrac{\Gamma(y_i+\tau)}{y_i!\,\Gamma(\tau)}\left(1+\dfrac{u_i}{\tau}\right)^{-\tau}\left(1+\dfrac{\tau}{u_i}\right)^{-y_i}, & \text{if } y_i > 0 \end{cases} \tag{9}$$

The conditional mean and the conditional variance of the ZIP model are

$$\text{E}_{ZIP}(y_i|\boldsymbol{x}_i, \boldsymbol{z}_i) = u_i(1-p_i) \tag{10}$$

$$\text{Var}_{ZIP}(y_i|\boldsymbol{x}_i, \boldsymbol{z}_i) = u_i(1-p_i)(1+u_ip_i). \tag{11}$$

The conditional mean and the conditional variance of the ZINB model are

$$\text{E}_{ZINB}(y_i|\boldsymbol{x}_i, \boldsymbol{z}_i) = u_i(1-p_i) \tag{12}$$

$$\text{Var}_{ZINB}(y_i|\boldsymbol{x}_i, \boldsymbol{z}_i) = u_i(1-p_i)\big(1+u_i(p_i+\alpha)\big). \tag{13}$$

Note that the variance is larger than its corresponding mean in both ZIP and ZINB models. This indicates that they are capable of accounting for overdispersion. The parameter estimates of ZIP and ZINB models can be obtained by using maximum likelihood estimation (Cheung, 2002; Zuur et al., 2009).

4. Case study

In this section, the effectiveness of ZIP and ZINB models is validated through their application to the real defect data of a steelmaking plant. The prediction performance is compared with that of PLS, Poisson, and NB models.

The defect dataset was recorded from a continuous casting-rolling process of the steelmaking plant. It consists of 3600 samples and 71 input variables. The objective is to predict the number of defects online. To construct the predictive model, the entire dataset was partitioned into two subsets: a training set with 3000 samples and a testing set with 600 samples. Figure 1 shows the frequency distribution of the defects, which is characterized by a large number of zeros and high skewness. The percentage of no defect is around 70%. Furthermore, its variance is much larger than its mean; that is, overdispersion exists in the data.

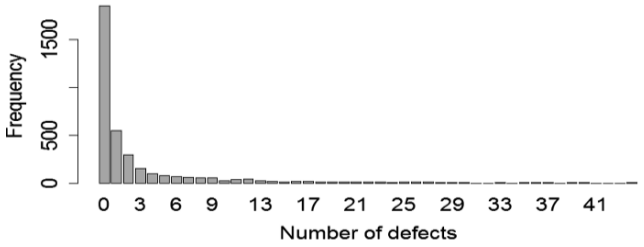

Figure 1. Distribution of the number of defects.

The prediction results of Poisson, NB, ZIP, and ZINB models for the testing data were evaluated in terms of the root mean squared error (RMSE) and correlation coefficient (R^2) criteria. In addition, the PLS model was built as a reference model. 15 variables were selected as the input variables on the basis of the nonlinear feature selection technique of ℓ_1−LSMI (Jitkrittum, 2013). The number of latent variables used in PLS was 5, which was determined by cross-validation. Table 1 presents the RMSEP (RMSE of Prediction) and R^2 of five methods. The PLS model did not perform well and provided a large RMSEP and a small correlation coefficient. As compared to PLS, the Poisson and NB models produced better performances. In contrast with the standard Poisson and NB models, the ZIP and ZINB models achieved significantly better results. The ZIP model yielded the best prediction performance among the five methods. Figure 2 shows the detailed comparison of the PLS and ZIP models. Note that some predicted values of the PLS model are below zero, although the number of defects is nonnegative. In comparison, the ZIP model ensures nonnegative predicted values. All of the above results have demonstrated that the ZIP model is preferred for modeling and analyzing the defect data.

Table 1. Prediction results of five models for the defect data.

Methods	RMSEP	R^2
PLS	4.2065	0.3843
Poisson	4.1723	0.3959
NB	4.1615	0.3775
ZIP	3.9858	0.4307
ZINB	4.0000	0.4258

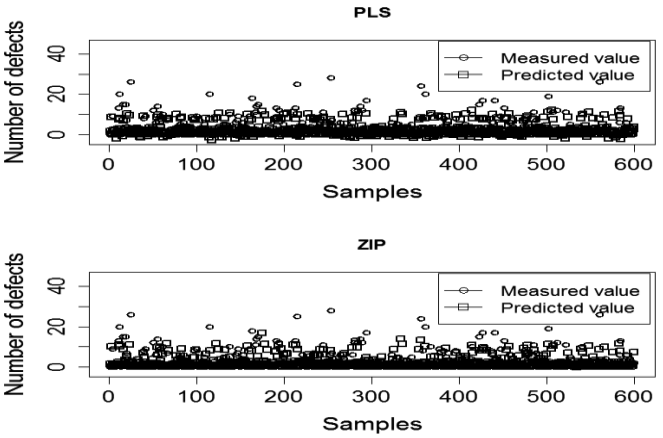

Figure 2. Prediction results of PLS and ZIP models for the defect data.

5. Conclusions

In this research, we focused on the defect data in the steel manufacturing process to predict the number of defects. To account for the unique characteristics of non-negative integers, high skewed distribution, overdispersion, and excess zeros in the observed defect data, an online quality monitoring system based on the zero-inflated model was proposed. The effectiveness of the zero-inflated Poisson (ZIP) and zero-inflated NB (ZINB) models was verified through their application to the real defect data of a steelmaking plant. The results have demonstrated that the ZIP and ZINB models are superior to the PLS, Poisson, and NB models in the prediction performance.

Abstract

States identification is an important step of process safety management, and it can be an individual part or a precursor step of fault detection and diagnosis (FDD). Research on FDD have made good progress, but most of them are carried out on labelled data, which is hard to collect in real situation. In this paper, an unsupervised learning based state identification model is proposed to deal with unlabelled data.

Feature extraction or dimensionality reduction, and clustering are two main steps of the model. t-SNE is an outstanding tool to visualize high-dimensional data, and a deep auto-encoder network is used to reduce the dimensionality to a reasonable amount before t-SNE is implemented. Different clustering algorithm are tested on features to determine which one is better. The unlabeled data are divided into different clusters by this model. In the final part of this paper, the benchmarked Tennessee Eastman process is utilized to illustrate the performance of this unsupervised learning based model.

Keywords: states identification, TE process, deep auto-encoder network, t-SNE, cluster

1. Introduction

With rapid development of modern chemical industry, people are paying more attention to process safety management. In this big data era, data driven process monitoring is used extensively to control risk of chemical process and prevent it from accident.

As a central step of process monitoring, process fault detection and diagnosis (FDD) can be classified into three categories among which process history based methods are more promising when applying in chemical process (Venkatasubramanian et al., 2003). One set of data driven methods are multivariate statistical methods such as principal component analysis (Cho et al. 2005) and partial least squares. Methods based on artificial neural network are also studied widely. Zhang conducted a model based on deep belief network (DBN) for FDD and reached an average 82.1% fault diagnosis rate of all 20 faults of the Tennessee Eastman (TE) process (Zhang et al., 2017).

The research mentioned above have achieved good results, but most of them are carried out on labelled data, which is hard to get in real situation. Methods based on unsupervised learning can work on unlabeled data, identify different states and accordingly divide data into several clusters. This will enable experts to label the data effectively.

The rest of this paper is organized as follows: Section 2 introduces the unsupervised learning model, which consists of t-SNE, deep auto-encoder network based on restricted

Boltzmann machine and clustering algorithms. The model is applied to benchmarked TE process and the result is shown in Section 3. Finally, conclusions are drawn in Section 4.

2. Unsupervised learning based state identification model

With unlabelled data, the amount of clusters or the number of different states is also unknown. t-SNE can be used to visualize high-dimensional data to show how many clusters the data should be distributed in, and meanwhile export 2-dimensional or 3-dimensional features. It is highly recommended to use another dimensionality reduction method, which is deep auto-encoder network in this study, to reduce the number of dimensionality to a reasonable amount (e.g. 50), if the number of features is very high. This will suppress noise. Clustering algorithms are then used to divide extracted features into different groups and lead to the states identification result.

2.1. t-SNE algorithm

t-SNE is a variation of Stochastic Neighbor Embedding (Hinton and Roweis 2002). The algorithm converts the distance between two points into conditional probability and uses Kullback-Leibler divergence to describe similarity of two probability distribution, which is shown as Eq. (1) (Van Der Maaten and Hinton 2008):

$$C = \sum_i KL(P_i||Q_i) = \sum_i \sum_j p_{j|i} log \frac{p_{j|i}}{q_{j|i}} \tag{1}$$

where P_i represents the conditional probability distribution of point *i* in high-dimensional space and Q_i represents the one in low-dimensional space. The algorithm aims at minimization of cost function *C*, which means probability distribution in low-dimensional space fits the real distribution well.

2.2. RBM based deep auto-encoder network

Deep belief network (DBN) is a network consists of several middle layers of Restricted Boltzmann machine (RBM) and the last layer as a classifier. In unsupervised dimensionality reduction, the classifier is removed and a deep auto-encoder network only consisting of RBMs is used. When running the deep auto-encoder network, two steps including pre-training and fine-tuning is executed.

In pre-training stage, each layer with its previous layer is considered an RBM and trained. Low-dimensional features are extracted from input data by pre-training without losing much significant information. Wake-sleep algorithm is introduced for fine-tuning of weights to avoid training process falling into gradient diffusion and accelerate the convergence of feature extraction (Hinton 2006). In fine-tuning stage, the encoder is unrolled to a decoder, and the weights of decoder are transposed from encoder. In wake state, the weights of decoder are adjusted by errors between input data and reconstructed data. In sleep state, the weights of encoder are adjusted by errors between features extracted from input data and reconstructed data respectively. Reconstruction error (RE) shows how well the feature can represent original data.

2.3. Clustering

2.3.1. Typical clustering algorithms

Clustering aims to excavate the internal nature of unlabelled data and divide data into different groups according to their similarity. Clustering algorithms can be broadly

classified as partitioning-based, hierarchical-based, density-based, grid-based and model-based methods (Fahad et al. 2014). BIRCH is a kind of hierarchical-based algorithm, and Affinity Propagation and K-Means belong to partitioning-based algorithms. Mini-batch K-Means is a variation of K-Means. It randomly extracts a small batch of samples to do K-Means algorithm in each iteration and can accelerate the convergence.

2.3.2. Cluster validity index

Cluster validity index is the judging criteria of clustering result, and it can be classified as external index and internal index. External index is calculated by comparing the result with true division, which cannot be obtained in unsupervised learning. And for internal index, true division is not necessary. Silhouette coefficient (SC) is a kind of internal index and it is calculated as follows (Rousseeuw 1987):

$$\mathrm{SC(i)} = \frac{b(i) - a(i)}{\max\{a(i), b(i)\}} \tag{2}$$

where $a(i)$ represents the average distance between sample i and other samples in its cluster, and $b(i)$ represents the minimum average distance between sample i and samples in other clusters. The value of SC ranges from -1 to 1, and SC getting closer to 1 indicates that the cluster algorithm works better.

2.4. States identification model

With the knowledge introduced above, the flow diagram of states identification model is shown in Figure 1.

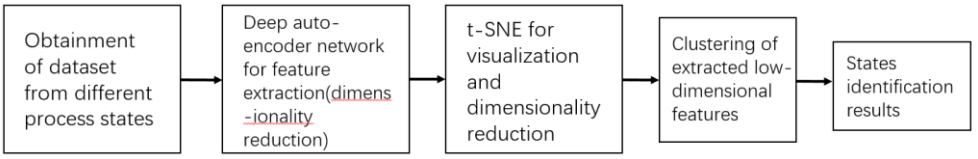

Figure 1. Flow diagram of state identification model

3. Application in the TE process

The unsupervised learning based model introduced in Section 2 is applied in Tennessee Eastman (TE) process in this section.

3.1. TE process and obtainment of dataset

TE process was proposed in 1993 with 53 process variables (Downs and Vogel 1993), but 3 of them never change value and thus can be seen as constants. There are 20 kinds of faults in TE process, and the study in this paper focuses on states identification of step-type faults, so data of Fault 1,2,3,4,5,6,7 and Normal state are sampled.

In each simulation, a kind of fault disturbance is introduced after process running normally for 10 hours, and the fault will run for 65 hours. The data is sampled from the 25th hour to 75th hour of running process with 3-minute sampling period.

TE process is a complex dynamic process, so data sampled at single time point cannot represent the process state precisely. Therefore, data sampled during certain time period are spliced together chronologically. The time window is set by 15,30,45 and 60 minutes, and one-hour-long time window appears to the best option according to cluster results.

There are 20 pieces of data sampled in one hour and they are spliced into a 1,000-dimensional sample, and 490 such samples are obtained for each state.

In conclusion, the dataset used for further study contains 3,920 1,000-dimensional samples.

3.2. Dimensionality reduction by deep auto-encoder network

The structure of deep auto-encoder network including the layer counts and the neurons counts in each layer has great influence on training result. It is assumed that numbers of neurons in hidden layers are determined by the number of layer and the number of neurons in input layer and output layer, At first, 30 different network structures are tested with the number of layer set by 3,4 and 5 and number of neurons in output layer set by 10, 20, … ,100 respectively. The structure is adjusted and optimization range is narrowed gradually on reference to REs. The test results of last optimization are shown in Table 1, and the best structure is a network with 6 layers and 1000, 346, 135, 58, 27, 12 neurons in Layer-1, Layer-2, Layer-3, Layer-4, Layer-5 and Layer-6 respectively.

Table 1. The network structures and REs in last optimization

Structure	Layer counts	Neuron counts in each layer	RE
1	5	1000-278-84-28-7	0.2360
2	5	1000-298-99-37-12	0.1857
3	6	1000-306-105-40-17-7	0.2295
4	6	1000-346-135-58-27-12	0.1734

There are some parameters that influence training progress of single RBM, such as momentum and weight-decay. The momentum is usually valued from 0.5 to 0.9, and the weight-decay is valued near 0.0001 (G. Hinton, 2010). The model is run with different values of momentum and weight-decay as shown in Table 2 and the last combination of values is chosen.

Table 2. Different values of momentum and weight-decay and corresponding REs

Momentum	Weight-decay	RE
0.7	0.0001	0.1803
0.7	0.0002	0.1766
0.8	0.0001	0.1735
0.8	0.0002	0.1698

3.3. Visualization and 2-dimensional features extraction by t-SNE

The deep auto-encoder network as optimized above is run to reduce data dimensionality to 12 for implement of t-SNE. t-SNE extracts 2-dimensional features and makes the visualization with them, which is shown as Fig 2.

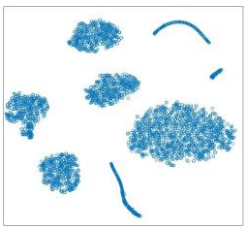

Figure 2. Visualization of the data

3.4. Clustering

The 2-dimensional features are then clustered by Affinity Propagation, BIRCH, K-Means and Mini-batch K-Means algorithm with clusters number set by 8, if needed, which can be seen from Fig 2. The results are shown in Table 3. K-Means and Mini-batch K-Means algorithm work better than the other two, and Mini-batch K-means algorithm is chosen for shorter running time.

Table 3. Comparison of different cluster algorithms

Algorithm	SC
Affinity Propagation	0.6229
BIRCH	0.6362
K-Means	0.6805
Mini-batch K-Means	0.6796

Mini-batch K-Means algorithm is run on the 2-dimensional features and the result is shown as Table 4 and Fig 3.

Table 4. Final clustering result

Cluster	1	2	3	4	5	6	7	8	total
Normal	0	253	0	0	0	0	237	0	490
Fault-1	0	0	0	490	0	0	0	0	490
Fault-2	0	0	0	0	0	490	0	0	490
Fault-3	0	270	0	0	0	0	220	0	490
Fault-4	0	0	490	0	0	0	0	0	490
Fault-5	0	207	0	0	0	0	283	0	490
Fault-6	0	0	0	0	266	0	0	224	490
Fault-7	490	0	0	0	0	0	0	0	490

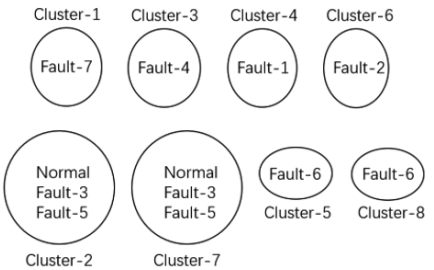

Figure 3. Schematic of clustering result

3.5. Discussion of the result

It can be seen from the result that Cluster-1,3,4,5,6,8 have pure components, which means they consist of data of a single state respectively, and data of Fault-1,2,4,6,7 only appear in these clusters. This cluster result enables experts to label all data of Fault-1,2,4,6,7 precisely and effectively with their expertise, because they only need to identify the state of cluster centres.

Data sampled from Fault-3,5 and Normal state are not separated and they gather to Cluster-2,7. Take Fault-3 for example, the process disturbance of Fault-3 is feed

temperature of Stream 2, and the variable influenced most is temperature of reactor cold water. But it only deviates from Normal state slightly and thus cannot be distinguished from Normal state. Many previous FDD research on TE process based on supervised learning also indicate that some faults are difficult to diagnose correctly since the data do not have obvious features, such as Fault-3,5,8,9,12,13,14.

4. Conclusions and outlooks

In this paper, an unsupervised learning based states identification model is proposed. Deep auto-encoder network and t-SNE algorithm are used to extract features and visualize data. Extracted 2-dimensional features are clustered by Mini-batch K-Means algorithm.

Application of the model on step-type faults of TE process leads to meaningful result. Data of Fault-1,2,4,6,7 are distributed to clusters which only consist of data of their own types respectively, therefore the identification rate of Fault-1,2,4,6,7 can reach 100%.

But the model cannot distinguish data of Fault-3,5 and Normal state currently. In the near future, research will be focused on unsupervised states identification of these states by improving the feature extraction network and cluster algorithm.

Abstract

In this work, we proposed a data-driven soft sensor based on deep learning techniques, namely the convolutional neural network (CNN). In the proposed soft sensor, instead of only building time-independent correlations among the key variable with other measurements, the moving window method is utilized to describe the most recent process dynamics, where the time-dependent correlation can be located. Beyond on that, a signal recovery scheme is developed to improve the model robustness when confronting common sensor faults. The proposed soft sensoring technique was tested on the composition data of gas-phase components from an ethylene pyrolysis reactor. The model was also verified through the manually introduced sensor faults.

Keywords: Soft sensor; Deep learning; Data-Driven; Big data

1. Introduction

In recent decades, increased accessibility of process measurement has boosted the development of data-driven approaches for process monitoring. The quality and quantity of the measurements are of the paramount importance for chemical processes. While in practice, some key variables can be difficult to measure in real-time due to physical or technical limitations. Therefore, soft sensoring techniques haven been developed for the supplement of real measurements. Generally speaking, soft sensor techniques are predictive models that can find correlations among key measurements with other variables. Two types of models that are commonly used as soft sensors are model-based models and data-driven models. Model-based approaches are designed based on physical features of the dynamical systems, while in data-driven approaches, features are obtained from process data solely through machine-learning. Although model-based approach contains physical meanings of the system, it is generally labour-intensive and difficult as it requires experienced researchers to develop the mathematical encoding, while it also requires massive experimental validations. On the contrary, machine learning algorithms are able to extract optimal features directly from raw data. Through such machine-learned features, feature selection algorithms are trained in order to select the most meaningful subset of the features to represent the system. The combination of feature learning and feature selection is the core of machine learning algorithms to learn the system through data.

Recent development in deep learning techniques (LeCun, 2015) has huge potential as a feature learner. Deep learning methods stack multiple layers of nonlinear estimators (neurons) to represent features in different levels from shallow to deep. Such architecture is able to represent complicated functions and correlations, and it has already been used to process images and natural languages as a state-of-the-art approach. Though deep learning methods have achieved huge success, training the deep learner is still challenging. In a typical deep network, there are always thousands of parameters that need tuning, which requires huge amount of training data. Moreover, activation functions e.g. sigmoid function that are used to enhance the nonlinearity expression in each layer can cause gradient vanishing or exploding problems, leading the gradient-based back propagation unable to tune the earlier layers in the network. The problem can then be solved by the development of the restricted Boltzmann machine (RBM) (Hinton G. E., 2006, 2010) and its application of greedy layer-wise training. Shang et al. (2014) proposed a deep learning based soft sensor based on RBM. They found that the deep soft sensor outperforms over many conventional methods with shallow architectures. Yan et al. (2017) applied stacked denoising autoencoders (SDAEs) to train the network, which estimated the oxygen content in flue gasses. Another approach using hierarchical extreme learning machine was proposed by Yao (2017).

However, finding time-correlation information remains a challenge in all above approaches. Hence, in our work, we proposed a soft sensor that is able to extract time-correlation information of the process as well as correlations among other measurements, so the dynamics of the system can be well established. Convolutional neural network (CNN) is used to obtain the process information from a moving window at each time point. Not only CNN has shown improved performance over traditional recurrent neural network (RNN) (Zhang, 2015), but it also reduces the training time over RNN (Baidu-Research, 2017). Besides, we also developed a signal recovery scheme in order to confront short-time sensor faults that happen in real processes.

2. Background

2.1. Rectified linear unit (Relu)

Relu is a bilinear activation function used in neural network, which is defined as:

$$f(x) = \max(0, x) \tag{1}$$

Where x is the input. Due to the simple nonlinear expression, the gradient computation is much more efficient than many other activation functions such as sigmoid. Besides, relu can effectively reduce the gradient vanishing problem since the derivative is independent of input domain. As of 2017, relu is widely used in deep learning for multiple types of tasks.

2.2. Convolutional neural network (CNN)

CNN is a deep neural network originally designed for image analysis. Recently, it was discovered that the CNN also has an excellent capacity in sequent data analysis such as natural language processing (Zhang, 2015). CNN always contains two basic operations, namely convolution and pooling. The convolution operation using multiple filters is able to extract features (feature map) from the data set, through which their corresponding spatial information can be preserved. The pooling operation, also called subsampling, is used to reduce the dimensionality of feature maps from the convolution

operation. Max pooling and average pooling are the most common pooling operations used in the CNN. Due to the complicity of CNN, relu is the common choice for the activation function to transfer gradient in training by backpropagation.

3. Methods

3.1. CNN soft sensor

Based on the recent success of the CNN in sequence data analysis (Zhang, 2015), we proposed a soft sensor using the similar idea. In the proposed soft sensor, convolutional filters with multiple region sizes are used to extract features at various granularities from moving windows. Hence, influence from different past time periods can be counted into future steps. Based on the extracted features, target measurement at the next time point can be estimated. The scheme of the proposed soft sensor is illustrated in Figure 1.

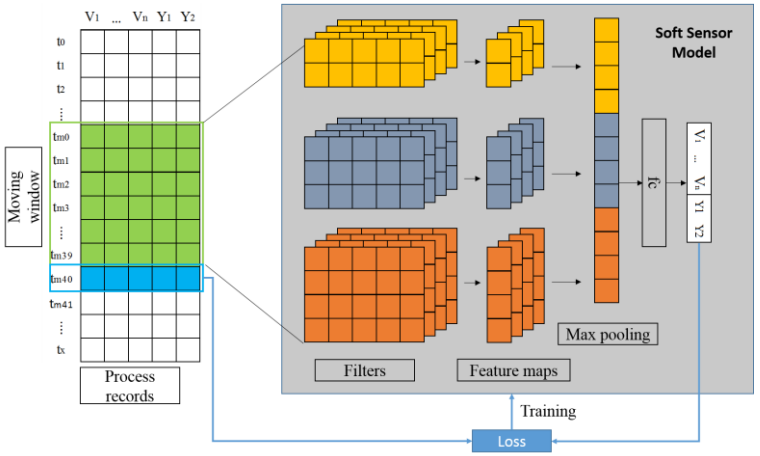

Figure 1. Illustration of overall architecture of the proposed soft sensor. *V* denotes the related variables to key variables *Y*. Their historical records are extracted by moving windows that are the model input. Feature maps are generated by convolutional 1D filters with multiple length. For the feature maps, max pooling and layer flatten operation (the fc layer) are used before final prediction.

3.2. Loss function

Since datasets from industrial processes are born with noise from measurements, conventional loss functions such as mean squared error (MSE) are not ideal, because such loss functions would just duplicate the noise into the model. Inspired by Salas's work (2017), we utilized the following loss function in order to reduce measurement noises for each variable.

$$\sum_{i=1}^{n}(y_i - \overline{y}_i)R^{-1}(y_i - \overline{y}_i)^T \tag{2}$$

where y_i is the predicted value, $\overline{y}_i$ is the target value, and R is the covariance matrix for measurements error which is estimated as $diag(\sigma_1, \sigma_2, \cdots, \sigma_i)$. It should be noted that the standard deviation used here should be taken from steady state, so the measurement errors can be properly estimated (Chen, 1997).

3.3. Implementation

Sensor faults are common in process operation. In practice, soft sensors still take data from real process measurements, and hence, faulty data can still downgrade the soft sensor performance. To improve the robustness of the soft sensor, we integrated the fault detection step with the soft sensor. In our work, we utilize a simple fault detection method that detect faults based on the mean and standard deviation values of the moving window. Besides, any proper fault detection methods can be replaced including any knowledge based methods to multivariable statistic methods (PCA T^2). By such method, the model can be robust for the sensor fault for a short time period.

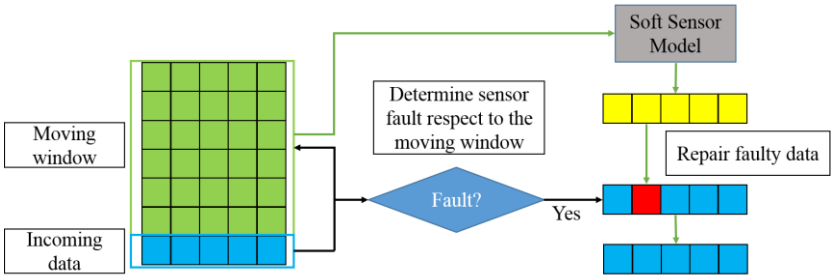

Figure 2. The scheme of integration of fault detection method with the soft sensor. The incoming data is tested with the current widow. Any faulty variables are replaced with the value generated from the sensor model.

4. Case Study

In this work, the proposed method is tested on an industrial pyrolysis reactor which is used to crack naphtha to ethylene. In the process, the naphtha is first mixed with steam before cracking in the furnace. In practice, due to the physical limitation, compositions of the gas-phase components in the outlet flow of reactor are unable to be measured in real time. The measurement takes about 16 minutes for each sample from the stream. Hence, the proposed soft sensor is applied in this process and the performance is tested on the historical data of the process.

Total 21 variables are selected, including 5 key variables (volume percentage measurements of methane, ethylene, ethane, propylene and propane) that require real-time prediction, and 16 related variables (e.g. feedstock compositions, feed flow rate, pressure, and temperature in different coils) that could provide extra process information to the model. Sensor faults are manually created into the dataset to verify the effectiveness of the proposed method.

5. Result and Discussion

5.1. Test result

The proposed model was trained with 9k data from an operation cycle whose recording interval is 1 minute. The model is validated by 1k data from the same operation cycle, and 500 data from another operation cycle was used for testing. Besides, sensor faults were introduced in the test data to verify the robustness of the proposed method. The overall test result is summarized in Figure 3, where the result was also compared with the partial least squares (PLS) model that did not account time-correlation information.

The result demonstrates the capability of the proposed soft sensor for key variables' prediction, and even for the drifting condition (Fig 3e), the proposed model can still trace the process trend. Additionally, when confronting sensor faults manually introduced into the dataset from time 190 to 210, the proposed signal recovery scheme proves its effectiveness. The comparison with the PLS model also indicates the superiority of the proposed model that outperforms the conventional linear and time-independent methods.

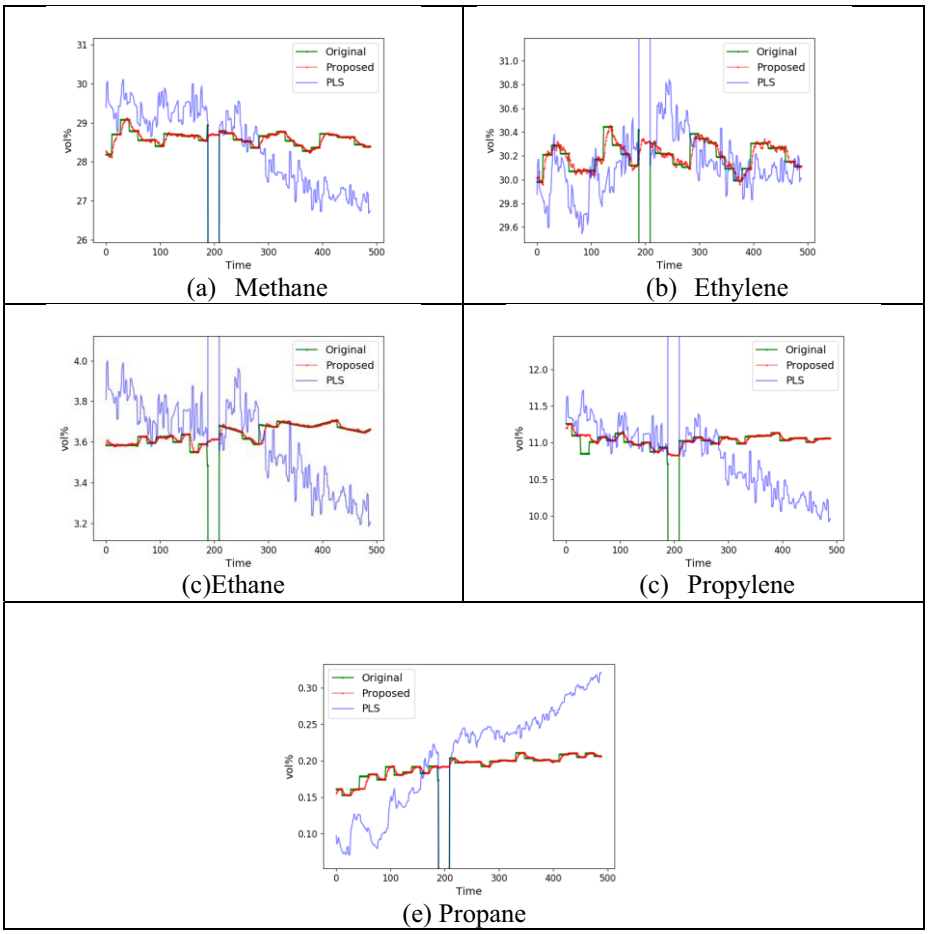

Figure 3. Composition prediction of gas-phase components under the condition of sensor faults that are introduced from time 190 to 210. The moving window size for the model is 10, and 60 filters for two filter region size of 5 and 10 are used in the convolutional layer.

5.2. Parameter selection

In the proposed soft sensor, the window size and filter configurations are important parameters that affect the ultimate performance. Hence, their effects are analysed (see Table 1). From the experimental results, a relative small window size is recommended. A large window length can lead the model less sensitive to the process changes and drifting, and hence an obvious delay can be observed, while a small length makes the model oversensitive to any fluctuations in the data including potential noises. Regarding the filter size selection, large filter size that covers the whole moving window seems

very necessary, since in all parallel experiments for different window lengths, such filter size setting can achieve better performance than others. Besides, multiple filters that can provide multi-granularity features can improve the model performance.

Table 1. Effect of window sizes and filter combinations to the model.

Window size	5		10				40			60		
Filter combination	2, 3	2, 5	3, 5	5, 10	3, 5, 10	10	20, 30	30, 40	20, 30, 40	20, 30	20, 30, 40	40, 50, 60
Loss	0.008	0.01	0.01	**0.004**	0.006	0.014	0.04	0.04	0.03	0.08	0.09	0.07

6. Conclusions

In this work, a soft sensor was proposed using the convolutional neural network, which predicts the measurements at next time step by extracting time-dependent correlations from a moving window. The proposed method was verified on the dataset from an industrial pyrolysis reactor. The model shows a remarkable performance on predicting the composition values of five gas-phase components. Additionally, through the experiment on manually introduced sensor faults, the proposed method proves its robustness to short-time sensor faults.

Abstract

Historical data from thirteen monitored and controlled process variables (PVs) is used to build a Partial Least Square (PLS) model to estimate the content of methylacetylene and propadiene (MAPD) on the product of a propene production plant in Brazil. A technique called Variable Importance in Projection (VIP) is used to select the important PVs and the performances of the PLS-VIP models for two trickle bed reactors are compared with the performance of the PLS models for the same beds. An F test did not provide evidence for significant difference between the PLS and the PLS-VIP models in neither bed. The coefficient of determination of both PLS-VIP models were above 0.80 (0.81 and 0.87), an acceptable value given the industrial nature of the data. The developed models show are adequate for implementation as empirical models for virtual analysers that can estimate the content of MAPD contaminants in case on-line analysers fail to provide such.

Keywords: PLS, VIP, Virtual Analyser, MAPD content

1. Introduction

The petrochemical industry is constantly innovating its methods and searching for processes that are safer and more efficient. Strong competition among different companies calls for technology that can guarantee both the product specification and a solid yield on the invested capital. Such technological devices include on-line analysers such as gas chromatographers, which grant a faster answer on the composition of products when compared with laboratory analysis. However, the cost of such instrumentation is still high (thousands of dollars) and the constant monitoring of the material flow requires frequent skilled maintenance (Musaev, 2003). During those, the loss of vital information could lead to a halt in production, unless another device allows for such information to be carefully estimated. As such, virtual analysers claim a strategic position in modern industry due to its capacity to replace essential equipment, such as on-line analysers, for mathematical models when the former is unavailable.
On-line analysers are commonly used in the petrochemical industry. During the production of propene in a usual petrochemical plant, the removal of contaminants through catalytic hydrogenation employs gas chromatographers to evaluate catalytic conversion, selectivity and the content of contaminants, in order to guarantee product specification and process efficiency (Cohn, 2006). Other devices, such as temperature

probes and flow meters, may gather an immense amount of data about the process over the course of a campaign, which usually lasts between four to six months.
Such data can be used to predict the content of methylacetylene and propadiene (MAPD) contaminants in case the on-line analysers fail to provide information about the former, preventing a halt in production and a subsequent loss in capital. The prediction can be done through Partial Least Square (PLS) regression, which has been widely used in the monitoring of industrial processes, since it usually provides empirical models with reasonable prediction capacity (Indahl, 2014). However, as reported by Galindo-Prieto et al. (2015), highly computerized analytical instrumentation can produce datasets with a large amount of predicting variables. Reducing the dimensionality of the model can lead to easier interpretations and more robust predictions. One method to achieve such reduction is the Variable Importance in Projection (VIP), commonly used for selecting the important predicting variables in PLS models. (Liu and Chan, 2014).
Hence, the aim of this paper is to develop a virtual analyser to estimate the methylacetylene and propadiene (MAPD) content in the outlet of a trickle bed reactor on a propene production plant in Brazil. Such analyzer will use a PLS regression model in which the predicting variables are selected from thirteen process variables (PVs), currently used for monitoring the production process, through the Variable Importance in Projection (VIP) technique.

2. Catalytic Hydrogenation System

The hydrogenation reaction happens in a heterogeneous bed reactor, either bed A or bed B on Figure 01, which alternate as the primary reactor. If bed A is doing the conversion, bed B is bypassed. As the catalytic campaign of bed A ends, bed B starts its catalytic campaign and bed A is bypassed. As bed B ends its campaign, bed A starts a new one and the cycle repeats. The reactor feed is high on MAPD contaminants (up to 7% mol), which is out of market specification. The contaminants need to be converted to propene through the hydrogenation of MAPD. Concentration in the outlet of the bed reactor needs to reach a level lower than 0.35% mol before it goes into the next reactor (bed C), where the levels of MAPD drop to parts per million in mol. Levels of MAPD on the product are monitored by on-line gas chromatographers.

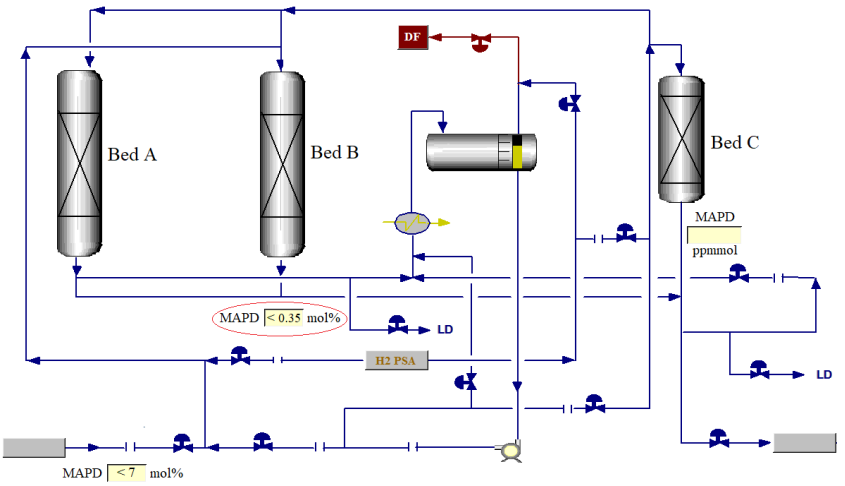

Figure 1. MAPD converter

Table 1. Process Variables

Process Variable	Symbol	Description
Fresh Feed Flow (C)	V1	Fresh propene flow, in ton/h
Recycle Flow (C)	V2	Recycle flow, from primary reactor, in ton/h
Fed H_2 flow (C)	V3	H2 fed into primary reactor, in ton/h
Bed Pressure (M)	V4	Primary reactor pressure, in bar
Combined Feed Temp. (M)	V5	Temperature of the combination of V1 (colder) and V2 (hotter), in ^oC
Bed Temp. (6 points) (M)	V6 to V11	Temperature of primary reactor across 6 different points, in ^oC
Outflow Temp. (M)	V12	Temperature of reactor outlet, in ^oC
MAPD in feed (M)	V13	MAPD content in feed flow, in % mol

The virtual analyser that is the focus of this paper will be monitoring the levels of MAPD currently monitored by the gas chromatographer circled on Figure 1. The thirteen monitored (M) and controlled (C) process variables of the trickle bed reactors are described in Table 1.

3. PLS-VIP Regression Model

The available dataset for modelling is divided into training (80%) and testing (20%) sets using the KenStone algorithm (Kennard and Stone, 1969). This algorithm starts selecting the testing set by choosing the two observations that have the largest geometric distance from one another. Among the remaining ones, it selects the observation with largest geometric distance from the closest observation already selected. This process is repeated until the testing set reaches 20% of the observations in the original dataset.

As reported by Indahl (2014), PLS regression has been widely used for empirical modelling where predicting variables are highly correlated. The predicting variables are organized in a data matrix X and the response variables in a data matrix Y. Both datasets can be decomposed respectively as $X = TP^T + E$ and $Y = TQ^T + F$ where T represents the score vectors of original dataset according to the first k terms of the Latent Variables (LVs), P and Q are the loading vectors of the data matrices X and Y, and E and F are residuals. (Liu and Chan, 2014). As such, a dataset $\hat{Y}$ can be predicted from a set of new observations X through Equation (1, where B is the pseudo-inverse of T.

$$\hat{Y} = \mathrm{X}P^T B Q^T \tag{1}$$

VIP scores provide the influence of each predicting variable j on the data matrix X_{IJ} on the PLS model of a given response vector $\hat{Y}$according to Equations (2, (3) and (4.

$$VIP_j = \sqrt{d \sum_{k=1}^{h} v_k \left(w_{kj}\right)^2 / \sum_{k=1}^{h} v_k} \tag{2}$$

$$\text{where } v_k = c_k^2 t_k' t_k \text{ and } c_k = \frac{t_k' y(k)}{t_k' t_k} \tag{3) and (4}$$

Where d is the number of variables and h the number of latent variables on the PLS model. The proportion of the fraction of the explained variance of X_{IJ}, for each variable j over all latent variables is expressed by v_k, which is weighted by the term w_{kj} that

represents the covariance between X and Y. The term c_k is calculated for each column of the PLS scores matrix T and for the predicted response Y.
As suggested by Akarachantachote et al. (2014), a threshold value for VIP of 1 is adopted as the criterion to define an important variable. After processes variables were selected, the same training and testing subsets used to develop the PLS model are used to develop a PLS-VIP model, where only the PVs selected by VIP are used.

4. Model Development

Data from one catalytic campaign of each bed was used to generate a PLS model for each bed after outlier removal using Principal Component Analysis (PCA). The VIP scores of each process variable from Table 1 is shown on Figure 2, where the threshold value of one is highlighted. For bed A, the selected PVs were the recycle flow (V2), the hydrogen fed flow (V3), bed pressure (V4), three temperature points across the bed (V8 to V11) and MAPD content in feed (V13). For bed B, the selected variables were recycle flow (V2), bed pressure (V4) and five temperatures points across the bed (V7 to V11). Although the fed hydrogen flow (V3) did not reach the threshold value of one for bed B, its importance to the conversion process along with the proximity of its VIP score (0.985) to the threshold (one) prevented its exclusion from the PLS-VIP model for bed B. The difference between the VIP scores for the same PVs on beds A and B suggests that, although there must be some similarities of the overall process behavior on both beds, a single empirical model describing both is not adequate.
Figure 3 displays the predicted MAPD content against the observed MAPD content (measured by the gas chromatographer) for bed A for the PLS and PLS-VIP models. Both show an adequate distribution of points around the support line, suggesting the models perform well when predicting MAPD content for bed A. The points are more dispersed around the support line for the PLS-VIP model and there is a drop of R^2 (from 0.84 to 0.81) and an increase in the Root Mean Square Error of Prediction, RMSEP, (from 1125 to 1207 ppm), when compared with the PLS model, as seen on Table 2. However, an F test did not show any significant difference between the RMSEP of the models, with an F_{cal} of 1.07. At $\alpha = 5\%$, the critical F for the dataset is 1.30. There is no significance difference between the biases of the models neither, and their low absolute values (23 and 28 ppm) suggest the lack of systematic errors.
A similar behavior is seen on Figure 4, where the predicted MAPD content against the observed MAPD content for bed B is shown. The points are still well distributed along the support line and the performance of the PLS and PLS-VIP models are even more suitable than on bed A, with an R^2 of 0.92 and 0.87, respectively.

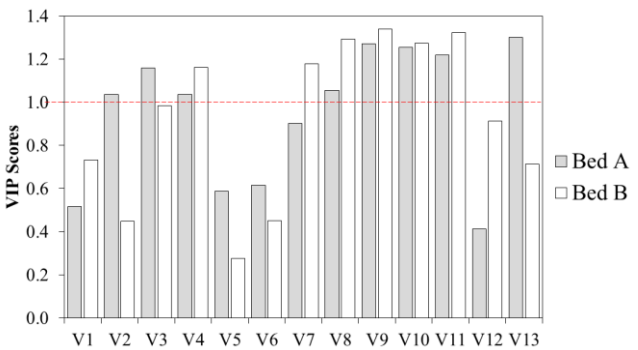

Figure 2. VIP Scores for beds A and B

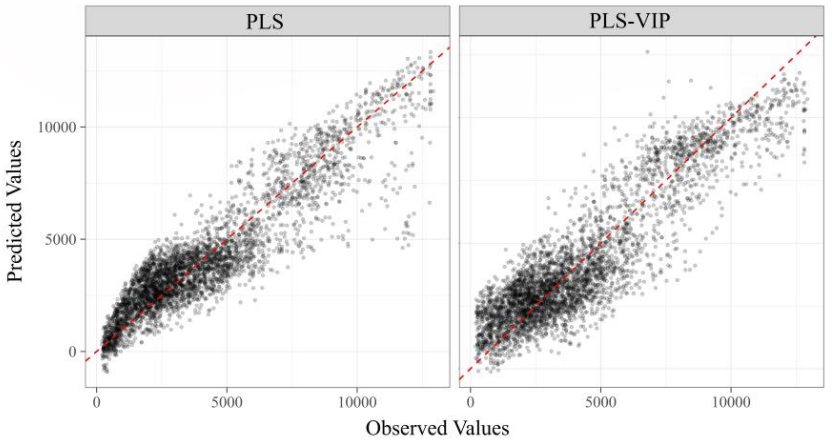

Figure 3. Predicted vs. Observed MAPD content - bed A

There is also an increase in the dispersion of points around the support line from the PLS to PLS-VIP model for bed B. There is a more noticeable increase in RMSEP (from 878 to 1131 ppm) and BIAS (from 1.38 to 32 ppm). Yet, an F test with $\alpha = 5\%$ did not support a significant difference of the models, with the F_{calc} at 1.28 and $F_{critical}$ at 1.30.
Table 2 compares the performances of the models before and after variable selection by VIP for both beds. All models have adequate performances and there is no evidence supporting significant difference between the PLS and the PLS-VIP models for neither bed. A reduction in the number of process variables required to estimate the MAPD content is important not only because it lowers the costs associated with the model, but also because it makes the model more robust. In case there is a failure of the on-line analyser, the virtual analyser is only able to guarantee the product is within specification if data for the input variables is available on real time. A model that requires less input implies that a less number of devices are required to keep the prediction running. As a result, in a case where both the gas chromatographer and the fresh feed flow meter fail, the PLS-VIP model would be able to predict the MAPD content whereas the PLS model would not. Hence, there is a much lower chance of there being a halt in production due to the lack of information on the concentration of MAPD on the product.

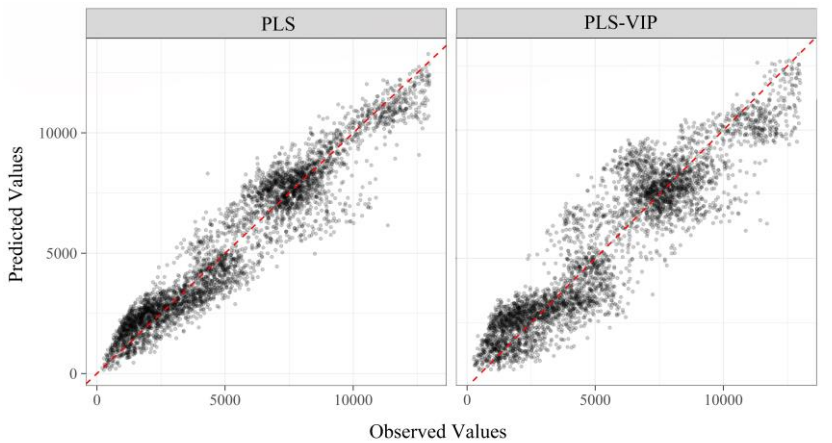

Figure 4. Predicted vs. Observed MAPD content - bed B

Table 2. Figures of Merit for PLS before and after VIP

	Before Variable Selection				After Variable Selection			
Bed	PVs	R^2	RMSEP / ppm	BIAS / ppm	PVs	R^2	RMSEP / ppm	BIAS / ppm
A	13	0.84	1125	23	9	0.81	1207	28
B	13	0.92	878	1.8	8	0.87	1131	32

5. Conclusions

The developed PLS-VIP models on this paper show that it is possible to achieve a reliable virtual analyser that predicts the MAPD content in the outflow of a trickle-bed reactor based on collected data from available process variables. Comparison between PLS and PLS-VIP models indicate that it is possible to reduce the number of required process variables as input on the model while still keeping suitable prediction capacity. The implementation of the established models does not require effort as there is already a control system in place, onto which the model could be adapted. Hence, the virtual analyser could be easily used in case the current on-line analyser fail to provide information on MAPD content of the product, which could potentially halt production of propene and cause an enormous loss in invested capital. Moreover, the methodology applied to arrive at the mathematical model for this virtual analyser can be easily replicated in other important reactors of the same plant, potentially making different processes more efficient and robust.

Abstract

In many industrial processes, soft-sensors have been used for estimating a product quality or other key variables. Many kinds of modeling methods have been researched to deal with the problems such as small number of samples, the nonlinearity, and the changes in process characteristics. Because no modeling methods is perfect to all industrial processes, it is difficult to select the best modeling method and to appropriately tune parameters at the early stage of soft-sensor design. Thus, the estimation error of soft-sensors often becomes unacceptable. In such a case, another modeling method should be used, however, there is no systematic way to classify the root cause of bad estimation performance and select the alternative method. In this research, we focus on main two root causes, the shortage of samples and the process nonlinearity, and propose a method for evaluating the effect of each root cause. The proposed method provides important information to improve the estimation performance of soft-sensors. The usefulness of the proposed method is demonstrated through case studies of twelve actual process data.

Keywords: soft-sensor, root cause analysis, small number of samples, process nonlinearity

1. Introduction

In many industrial processes, on-line measurements of the quality variables are not always available because of the unacceptable cost of the measurement equipment, and the measurement delay. To solve this problem, statistical soft-sensors, which estimate difficult-to-measure variables from easy-to-measure ones, have been widely used. Various modeling methods such as partial least squares (PLS), support vector regression (SVR), and artificial neural network (ANN) have been developed to improve the estimation accuracy of soft-sensors. When the estimation accuracy of such modeling methods is poor, however, its reason is difficult to clarify. Generally, building a high performance soft-sensor is very laborious, because the input variables and the samples for model construction have to be carefully selected and parameters have to be tuned appropriately (Ogawa et al., 2008). From the practical viewpoint, time-saving for building a good soft-sensor is very important, and it is useful to clarify the root causes of the estimation error. In this research, we propose a method for evaluating effect of the number of model construction samples and the strength of the process nonlinearity on the estimation performance. In the proposed method, the estimation errors obtained by different number of model construction samples are used to evaluate the effect of number

of samples on the estimation performance, using PLS and locally weighted PLS (LW-PLS) (Kim et al., 2011) as modeling methods. Additionally, the strength of process nonlinearity estimated by these methods is used to judge whether the introduction of a nonlinear modeling method is appropriate for improving the estimation error or not. The usefulness of the proposed method is demonstrated through applying the proposed method to twelve process data.

2. Analysis methods for root causes of soft-sensors' estimation error

In industrial processes, main causes associated with soft-sensors' estimation error are as follows:

- Insufficient number of samples for model construction
- Strong process nonlinearity
- Inappropriate selection of the input variables
- Inappropriate selection of the samples for model construction
- Changes in process characteristics

In this research, we focus on "number of samples for model construction" and "process nonlinearity".

2.1. Analysis method for the effect of the number of samples and process nonlinearity on the estimation error

In the proposed method, the estimation error is calculated by using different number of samples and two modeling methods to evaluate the effect of the number of samples and the process nonlinearity on the estimation error. PLS and LW-PLS are used as the modeling methods. In LW-PLS, the localization parameter φ is used to adjust the weight of each sample. When φ is larger, smaller samples are prioritized, and when φ is zero the LW-PLS becomes the same as the conventional PLS (Kim et al., 2011). The proposed method consists of the following steps:

1. Set the localization parameter φ of LW-PLS to 0.
2. Set the ratio of samples used for model construction p to 0.4.
3. Set the iteration number r to 1.
4. Divide the samples of a process are randomly at a ratio of 7:3, and set 100p % of the former data as model construction samples and the latter data as model verification samples.
5. Construct an LW-PLS model by using the model construction data. The number of latent variables is selected by leave-one-out cross validation.
6. Apply the LW-PLS model is to the model verification samples, and calculate the root mean square error of prediction RMSEP:

$$\mathrm{RMSEP}_{p,r}^{\varphi} = \sqrt{\frac{1}{N_{\mathrm{v}}}\sum_{n=1}^{N_{\mathrm{v}}}\left(\hat{y}_{\mathrm{v},n}^{\varphi} - y_{\mathrm{v},n}\right)^2} \tag{1}$$

   where, N_{v} is the number of model verification samples, $y_{\mathrm{v},n}$ is the output of the n-th model verification sample, and $\hat{y}_{\mathrm{v},n}^{\varphi}$ is the estimated value of $y_{\mathrm{v},n}$ by LW-PLS model.
7. Update r to $r + 1$. If r is smaller than or equal to the maximum iteration number R, return to step 4. In this research, R is set to 50.
8. Calculate the average value of RMSEP MRMSEP, by

$$\mathrm{MRMSEP}_{p}^{\varphi} = \frac{1}{R}\sum_{r=1}^{R}\mathrm{RMSEP}_{p,r}^{\varphi} \tag{2}$$

9. Change the ratio of samples used for model construction p, and return to step 3 until all candidates of p are selected. In this study, the candidates of p are 0.4, 0.6, 0.8, and 1.
10. Change the localization parameter φ and return to step 3 until all candidates of φ are selected. In this study, the candidates of φ are 0, 0.5, 1, 1.5, 2, 2.5, and 3.

2.2. The evaluation of the effect of the number of samples

Using obtained $\mathrm{MRMSEP}_p^{\varphi}$, it is possible to evaluate whether the given number of samples is sufficient or not. The value of p corresponds to the number of samples used for model construction. Thus, it is expected that $\mathrm{MRMSEP}_p^{\varphi}$ with the same φ decreases with the increase of p. From the gradient of the $\mathrm{MRMSEP}_p^{\varphi}$, it is possible to estimate the number of the additional samples which are necessary to make the estimation performance acceptable.

2.3. The evaluation for the effect of process nonlinearity

Generally, when the process is close to linear, a smaller value of φ shows a better performance, and the nonlinearity of the process becomes stronger a larger value of φ shows a better performance. When φ is extremely large, a small number of samples are used to construct the model. Thus, usually $\mathrm{MRMSEP}_p^{\varphi}$ with the same p becomes convex with φ. By using this feature of the localization parameter φ, the degree of process nonlinearity is evaluated. The degree of process nonlinearity can be evaluated from the gradient of the $\mathrm{MRMSEP}_p^{\varphi}$. For example, if the $\mathrm{MRMSEP}_p^{\varphi}$ decreases with φ at the wide range of φ, the nonlinearity of the process should be strong. For such a process, we can expect that the performance of a soft-sensor will improve if we use a nonlinear model. On the other hand, if the gradient of $\mathrm{MRMSEP}_p^{\varphi}$ is almost zero or positive, it is expected that the nonlinearity of the process should be weak. In such a case, it can be stated that application of various nonlinear models will not greatly contribute to the improvement of accuracy of soft-sensor.

3. Application to actual process data

In this section, we describe the results of applying the cause analysis methods shown in the previous section to actual process data.

3.1. Overview of actual p*rocess data*

In this research, 12 actual process data from as chemical, pharmaceutical, and food processes are used. Table 1 outlines the data. The detailed information of datasets of processes 1 – 9 is confidential since the datasets are from private companies. Those of processes 10 – 12 are opened to public and located at the following URL: http://www.eigenvector.com/data/.

Table 1: Contents of data in each process

No.	Number of the samples	Number of the inputs	Estimation target
1	284	114	API content in a tablet
2	113	91	The amount of MgSt after cleaning
3	93	377	The amount of Ibuprofen after cleaning
4	776	40	The residual amount of NaOH after cleaning acid gas
5	634	9	Aroma concentration in the product of distillation column 1
6	606	70	95% boiling point of the product of distillation column 1
7	122	16	Impurity (chloride) amount in the the product of distillation column 2
8	405	23	Impurity (water) amount in the the product of distillation column 2
9	157	18	Impurity (water) amount in the the product of distillation column 3
10	460	650	A quality attribute of a tables
11	395	401	90% boiling point of diesel fuel
12	80	700	A quality attribute of a corn

Results and discussion

The results of applying the analysis method described in section 2 to each process data shown in Table 1 are illustrated in Figures 1 and 2.

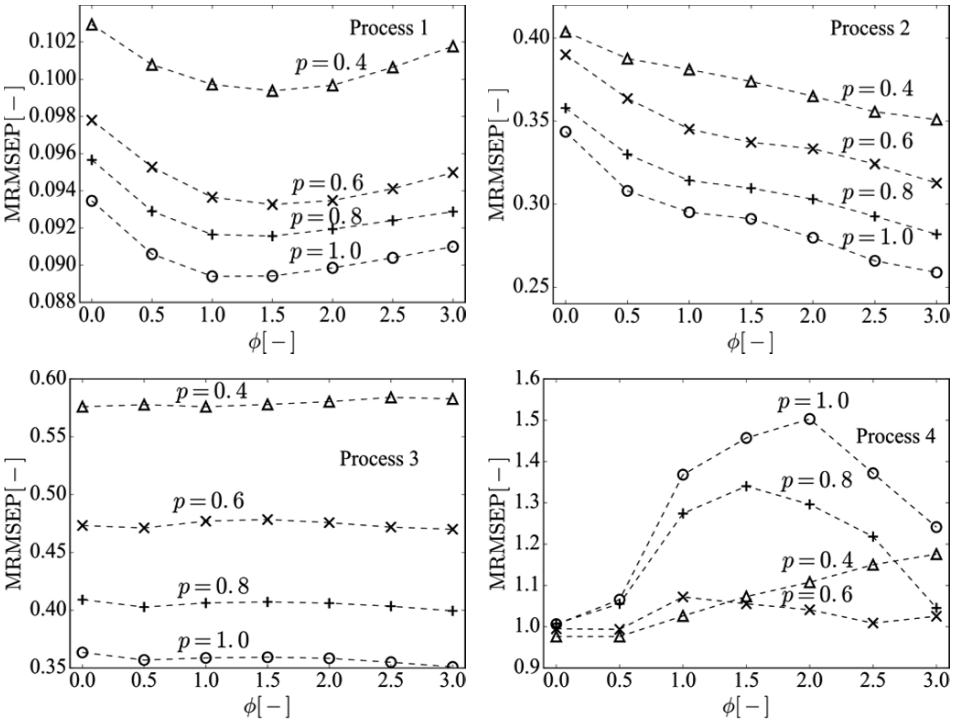

Figure 1: Estimation error in each process (Process 1-4)

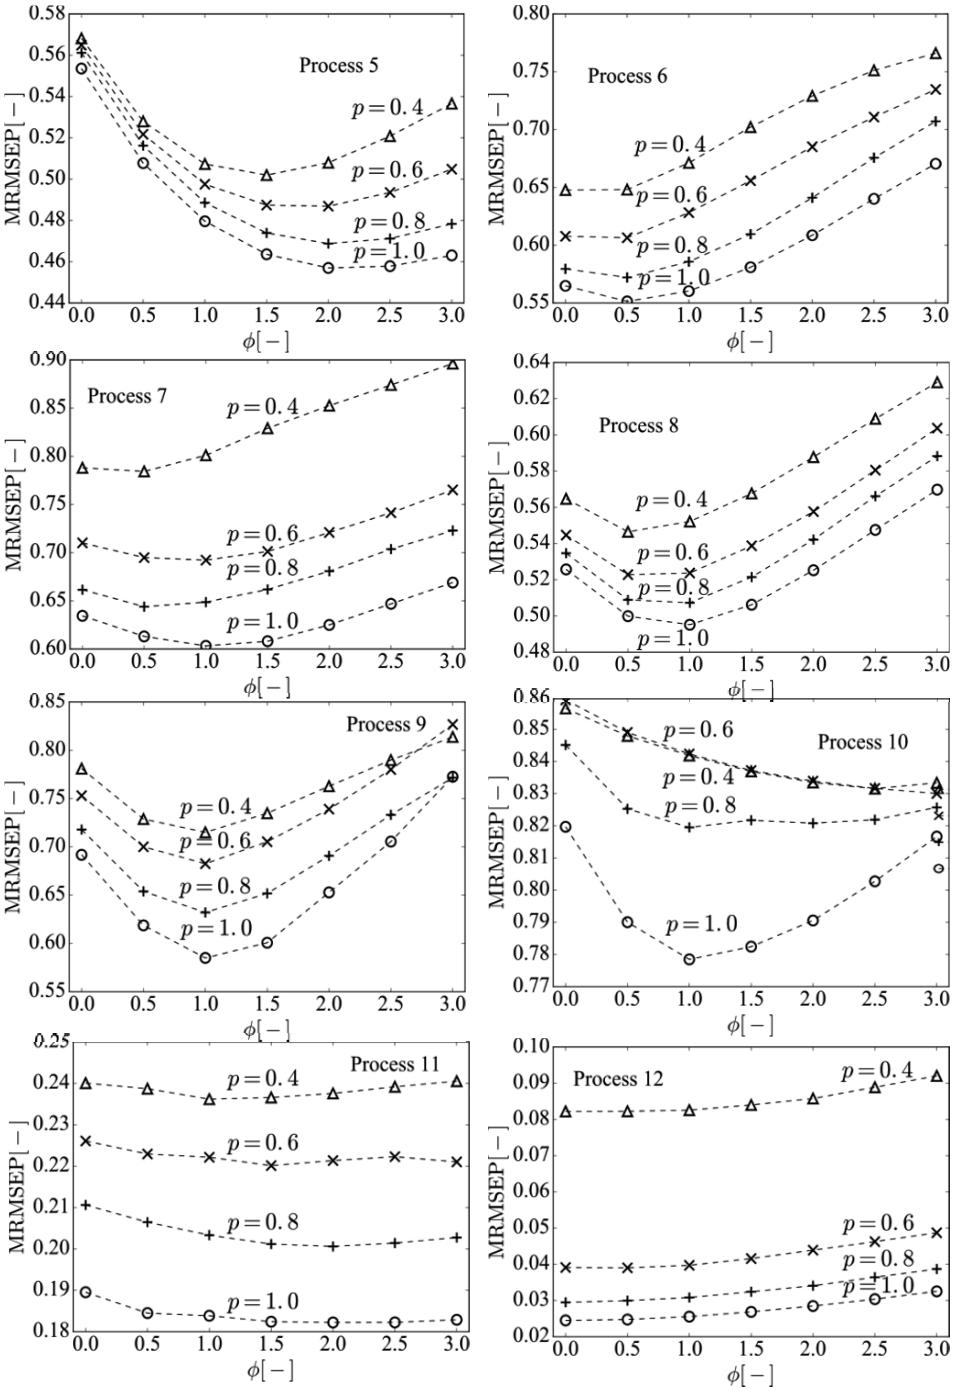

Figure 2: Estimation error in each process (Process 5-12)

3.1.1. Evaluation result of the effect of the number of model construction samples

In Figures 1 and 2, the estimation error decreases with the number of samples for model construction except for process 4. From this result, the estimation error when the number of model construction samples is increased can be estimated. For example, in process 1, it is expected that MRMSEP of linear PLS (φ = 0) will be 0.091 when the number of samples is increased by 20% (p = 1.2). By using this information, the number of samples required to reach an allowable estimation error is estimated, and engineers can make decisions as to whether or not to actually increase the number of samples. Moreover, since the same tendency is shown not only in PLS but also in LW-PLS, it can be expected that this method can be useful regardless of the modeling method.

3.1.2. Evaluation result of the effect of degree of p*rocess nonlinearity*

In process 2, the gradient of $\mathrm{MRMSEP}_p^{\varphi}$ with the same p has the tendency of decrease in wide range. In processes 1, 5, 8, 9, and 10, the $\mathrm{MRMSEP}_p^{\varphi}$ clearly has convexity with φ. In other words, the $\mathrm{MRMSEP}_p^{\varphi}$ decreases when φ is small, while the $\mathrm{MRMSEP}_p^{\varphi}$ increases when φ is large. This is because a small number of samples are used to construct the model. For these processes, we can judge that nonlinear modeling methods are effective to improve estimation accuracy because these processes can be regarded as highly nonlinear ones. On the other hand, in processes 3, 4, 6, 7, 11, and 12, the gradient of $\mathrm{MRMSEP}_p^{\varphi}$ is almost zero or positive. In such a case, it can be said that applying various nonlinear models will not greatly contribute to the improvement of the accuracy of soft-sensors since the nonlinearity of the process is expected to be weak.

4. Conclusions

In this research, we proposed a method for evaluating the root causes of the estimation error of the soft-sensor. The effectiveness of the proposed methods about insufficient number of samples for model construction and the degree of process nonlinearity was demonstrated through applying it to 12 process data. By using the proposed method, it becomes easier to decide whether to increase the number of samples for construction or whether to apply another nonlinear model as a model construction method. It is expected that the proposed method can contribute to efficient soft-sensor design at various industrial processes.

Abstract

In this work, a data mining-based algorithm is presented for the pre-processing—e.g., noise removal, batch isolation—of continuously measured historical records of biopharmaceutical manufacturing. The algorithm applies approximate string match and decision tree classifiers to remove noise from commercial production data automatically. Single batches are isolated using k-means clustering, after which algebraic semantic is used to characterize whether the data points within a batch describe the normal process execution or failures. The algorithm was applied to a dataset containing two months of manufacturing data in a cleaning and sterilization process. The performance of the algorithm was evaluated, resulting in a yield of 95 %, a mean time deviation of 1.3±4.6 %, and a rate of misclassification of 1.5 %, which showed a high performance of the algorithm. This study supports the introduction of data-driven automation approaches as well as smart manufacturing in pharmaceutical manufacturing.

Keywords: GMP, Natural language recognition, Supervised machine learning, Unsupervised machine learning.

1. Introduction

Pharmaceutical companies are facing an increasing competition and cost pressure on the market. In fact, the cost and time necessary to discover and develop new drugs are increasing with time (DiMasi et al., 2016), and for this reason, “big” companies are asked to contrast the increasing offer of generics—i.e., biosimilars and small molecule generics—in the market.

The optimization of processes and operations is of primary importance to ensure competitiveness while maintaining the high-quality standards and the compliance to good manufacturing practice (GMP). Process system engineering (PSE) approaches such as computational process design and retrofitting have been applied to achieve optimal design through Quality by Design (QbD) in the synthesis of pharmaceutical processes. In a review work, Rantanen and Khinast (2015) emphasized the importance of QbD-based thinking in the industry, and showed various technics and methods that are essential for the process modeling and design in the manufacturing science. While first-principle approaches tackle process design, synthesis, and optimization, data science approaches, such as data mining, can be used in the improvement of operations (Köksal et al., 2011).

In the same study, Köksal et al. (2011), showed that the quality of mining activities strongly depended on the quality of the data; data quality, in this study, is defined as integrity and noisiness—i.e., how much noise is comprised of the data. Before applying any intelligent algorithm, the data usually requires a preliminary "cleaning"; hence, in this study, the translation of raw data—e.g., timestamp, ID, and text—into systematized and noise-free numerical data is reviewed. Recently, in a proof-of-concept study, Meneghetti et al. (2016) presented a data mining-based algorithm for recognizing batches and process phases using data historians in drug product manufacturing of pharmaceuticals. However, as it was also pointed out in the study, challenges, such as the presence of noise in the data, could encumber the reliable translation of information into real knowledge, which is often the case in the pharmaceutical industry. Kemppainen (2017) discusses the challenges and opportunities in transforming the pharmaceutical manufacturing industry by increasing digitalization and introducing smart manufacturing concepts.

In this work, we present a data mining-based algorithm for pre-processing the continuously measured manufacturing records of biopharmaceutical batch processes in a robust manner. The algorithm combines natural language recognition and supervised machine learning approaches to classify and remove noise from commercial production data efficiently. Unsupervised machine learning as well as algebraic semantic are then applied to isolate single batches and characterize uncertainty, such as process failures. The application of the algorithm delivers data that can be utilized for the improvement of the operations—e.g., process runtime reduction—through the current industrial practices without manual interactions with the original records. The process that is the object of the study, where the records are to be pre-processed, is the so-called cleaning-in-place and sterilizing-in-place (CIP/SIP) process. Such a process consists of a sequence of independent tasks and is one of the change-over operations that contribute to producing high-quality drugs the most.

2. Pre-processing algorithm

The algorithm consists of six steps: import raw data, sequence raw data, train noise classifier, filter noise, cluster data by batch, and characterize batch. The algorithm shown in Figure 1 is used to identify noise and isolate single batches in a continuously recorded dataset while considering for process failures.

2.1. Import raw data (step 1)

The analysis timeframe—i.e., from initial to final time—and the resulting number of data points N_0 $[-]$ (with n as the counter) are selected to retrieve the correspondent data from the manufacturing database $\boldsymbol{M}$. The step imports all the time stamps, here defined as data tuples consisting of the time of execution t_n $[h]$, the task identity document (ID) id_n $[-]$, and a binary variable called process-noise (PN) class. The PN class classifies the timestamp as "process"—i.e., $PN = 0$—or "noise"—i.e., $PN = 1$—and is used in the steps 4 and 5. The resulting dataset is hereafter referred to as the raw dataset $\boldsymbol{D_1}$.

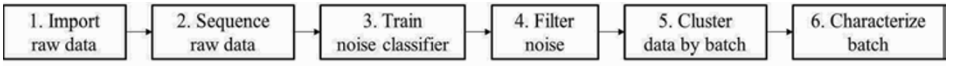

Figure 1 Sequence of steps necessary to pre-process manufacturing records.

2.2. Sequence raw data (step 2)

The sequencing step consists of four main sub-steps: (2.1) find extremity task sequence (ETS), (2.2) calculate primer size, (2.3) calculate heterogeneity coefficient H_n.

2.2.1. Find extremity task sequence (ETS) (step 2.1)

In this step, $\boldsymbol{D_1}$ is screened to locate the position of the ETSs ($p^{\mathrm{ETS}}[-]$). Start-ETSs (sETS) and end-ETSs (eETS) are the sequences of s-number of tasks located at the start and end of the process recipe. The positions p^{ETS} is found when the Wagner-Fischer distance $D_{n,n+s}^{\mathrm{ETS}}\ [-]$ (Ukkonen, 1985) between the id_n of an ETS and that of a same-size sequence of tasks belonging to $\boldsymbol{D_1}$ and starting from p_n is equal to zero. The step is concluded by gathering the execution times of the task relative to p^{EST} of each ETS in the set T^{ETS}.

2.2.2. Calculate primer size s_n^p (step 2.2)

The primer size $s_n^{\mathrm{p}}[-]$ is calculated dynamically for each point of $\boldsymbol{D_1}$ depending on three conditions, here shown by Eq. (1):

$$\begin{cases} s_n^{\mathrm{p}} = 1 & if\, d_n^{\mathrm{ETS}} \le s \\ s_n^{\mathrm{p}} = |d_n^{\mathrm{ETS}}| + 1 & if\, \mathrm{d}_n^{\mathrm{ETS}} > s\ s.t.\ p_n > p^{\mathrm{ETS}} \\ s_n^{\mathrm{p}} = \left(1 - e^{\frac{-d_n^{\mathrm{ETS}}}{h}}\right) s^{\mathrm{p,max}} & else \end{cases} \tag{1}$$

The parameters $d_n^{\mathrm{ETS}}\ [-]$, $s^{\mathrm{p,max}}\ [-]$, and $h[-]$ are distance between p_n and the nearest p^{ETS}, the maximal primer size, and a size-change velocity factor, respectively.

2.2.3. Calculate heterogeneity coefficient H_n (step 2.3)

First, the primer of size s_n^{p} at position p_n is defined as the fragment of the process recipe from k to $k + s_n^{\mathrm{p}} - 1$, where $k \in [1, K]$ is the counter of the tasks and K is total number of tasks in the recipe. Second, the minimum WF distance $D_n^{\mathrm{WF}}[-]$ between the primer and the fragment of $\boldsymbol{D_1}$ is calculated following Eq. (2).

$$D_n^{\mathrm{WF}} = \min_k D_{n,k}^{\mathrm{WF}}\left(s_n^p\right) \tag{2}$$

The distance $D_{n,k}^{\mathrm{WF}}[-]$ is the k-depedent distance, and is a function of s_n^{p}. Third, the heterogeneity coefficient $H_n\ [-]$ is calculated. H_n is defined in Eq. (3) and quantifies the degree of difference between the primer and the fragment of $\boldsymbol{D_1}$.

$$H_n = \frac{D_n^{\mathrm{WF}}}{s_n^{\mathrm{p}}} \tag{3}$$

2.3. Train noise classifier (step 3)

Supervised machine learning is used to classify noise; here, noise is defined as the recorded tasks that are not executed within a commercial batch—i.e., a task that does not follow the process recipe. Because of the industry—i.e., the industry is the final user of the algorithm—decision tree classifier was chosen for its simplicity and flexibility. The classifier was trained using the parameters H_n and s_n^{p}, and PN as predictors and response, respectively; the class PN of the data points contained in the training and the validation datasets is evaluated manually.

2.4. Filter noise (step 4)

In this step, the data points classified as noise—i.e., $PN = 1$—are removed from the dataset $\boldsymbol{D_1}$, resulting in a smaller and noise-free dataset, hereafter named as $\boldsymbol{D_2}$.

2.5. Cluster data by batch (step 5)

The data from $\boldsymbol{D_2}$ is clustered; the k-means algorithm is applied to isolate the clusters, data in which are then re-ordered to enforce a clear split between batches. The algorithm iteratively identifies the number of clusters, namely the number of batches, by evaluating how many batches are comprised in each cluster, and whether there are empty clusters. The clustering dimensions are defined as the process coordinate π_n $[-]$ and t_n; the parameter π_n locates the task id_n inside the process recipe with respect to the end of the process, where $\pi_n = 0$ and $\pi_n = 1$ stand for the beginning and the end of the process, respectively. The re-ordering algorithm, which moves data points within the clusters, uses the execution time t_n of the sETS stored in T^{ETS} as criteria; in practice, it enforces each cluster to start with an sETS. After determining the clusters, the time extrema of each cluster, which determine the beginning and the end of each batch, are used to summon all the data points contained in each batch from $\boldsymbol{D_1}$.

2.6. Characterize batch (step 6)

The data within one batch is analyzed to identify the presence of failures. Because GMP dictates the actions to be taken in case of failure, the failure-related data points are isolated by means of algebraic semantics. As an outcome, failure-related data points are labeled as *failure*, whereas the others are labeled as *normal*.

3. Implementation of the algorithm on commercial records

The algorithm was applied to a raw dataset containing two months of commercial records of a CIP/SIP process in a drug product manufacturing plant of F. Hoffmann-La Roche Ltd., Switzerland.

3.1. Preliminary studies

The design of the algorithm was analyzed by performing a multi-objective evaluation. As a preliminary study, an analysis was performed on the influence of the parameters s and $s^{\mathrm{p,max}}$ on the total execution time and prediction F-score of the algorithm. Another study was performed regarding the stability over time of the classifier. From Figure 2 (left), which shows a cumulative cost function—i.e., normalized weighted sum of the execution time and F-score— as function of s and $s^{\mathrm{p,max}}$, the first study could identify $s = 4$ and $s^{\mathrm{p,max}} = 20$ as the best constellation of the parameters. From Figure 2 (right), which represents the stability over time, the algorithm could deliver stable results for 1,500 h, after which the variance of the F-score started the increase. Because of the increasing instability of the classifier, the model was re-trained every 1,500 h.

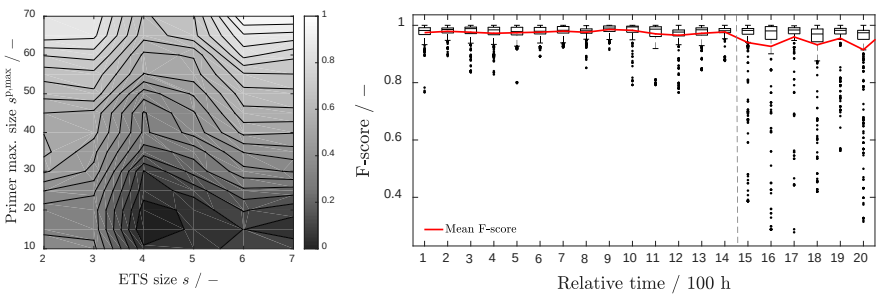

Figure 2 Results of the sensitivity analysis (left) and stability over time analysis (right).

3.2. Implementation

First, in step 1, manufacturing records of the CIP/SIP process were exported from the database, the dataset of which represented 1,451 h of the production data, and was defined as the raw dataset $\boldsymbol{D_1}$. The raw dataset consisted of the time series of $N_0 =$ 8,762 triplets of the variables t_n, id_n and PN.

Second, in step 2, the raw dataset was sequenced. After finding the sETS and eETS, 43 and 35 counts, respectively, the size of the primer s_n^{p} (see Eq. 1) and the heterogeneity coefficients H_n (see Eq. 3) were calculated. Sequencing, in a practical sense, was a transformation of dimension, namely, a translation from natural language in the id_n to a dimension describing the difference between the recorded data points from the process recipe.

Third, the decision tree classifier (max. number of split = 10, cost matrix $\begin{bmatrix} 0 & 1 \\ 10 & 0 \end{bmatrix}$) was trained and cross-validated (10-fold), where the parameters s_n^{p} and H_n were used as the predictors and the class PN as response. The classifier showed high prediction quality, yielding an F-score of 99.52 %; the result of the training, namely, the decision boundary, is highlighted in Figure 3 (left). In Figure 3, the decision boundary divides the combination of predictors in the two classes: noise (crosses) and process (circles).

Fourth, the classifier was used to evaluate the PN classes of the dataset $\boldsymbol{D_1}$; the data points that were classified as noise were eliminated. The filtering of the noise resulted in the noise-free dataset $\boldsymbol{D_2}$, containing 6,596 data points; hence, the 39% of the recorded points did not contain essential information, namely, was potentially hampering the coming steps of the algorithm.

Fifth, the two-dimensional k-means algorithm was used to identify, inside the dataset $\boldsymbol{D_2}$, the number and the domains of the clusters, which corresponded to a CIP/SIP batch. The iterative procedure, which was initiated by setting the initial guess to 43—i.e., the number of sETS—identified 40 different clusters. The result of the clustering can be seen in Figure 3 (right), where each grey zone represents a cluster, namely one batch. The points located within each cluster belong to the same batch.

Sixth, failures within each cluster were identified by isolating the failure specific task and alarms using semantic. The result of this step, namely the points categorized as *failure*, is highlighted in red (Figure 3, right); these data points can be used to evaluate the relative impact of uncertainty on the total time invested in the CIP/SIP. Because CIP/SIP is a support process—i.e., process which does not produce products—, the shorter the runtime is, the higher the production capacity of the manufacturing plant becomes, resulting in potentially higher revenues.

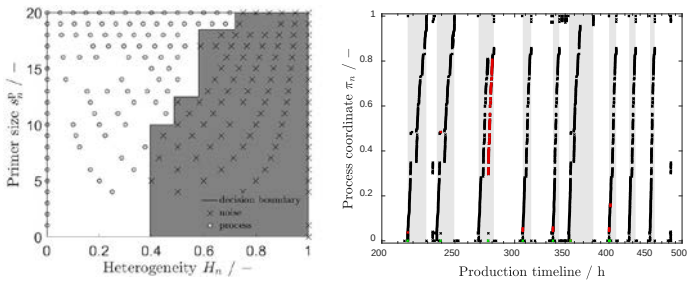

Figure 3 Results of the noise-classification (left) and batch-clustering (right) operations

The performance of the algorithm was evaluated by comparing the outcome of the algorithm with the manual pre-processing using three indicators: yield, mean time deviation and misclassification rate. The evaluation resulted in a yield of 95 %, a mean time deviation of 1.3±4.6 %, and a rate of misclassification of 1.5 %, which showed the high performance of the algorithm.

4. Conclusion and outlook

In this study, we presented an algorithmic approach for the pre-processing of biopharmaceutical manufacturing records considering the presence of uncertainty. The algorithm is used to automate the isolation of batches within a continuously measured historical record. DNA-like sequencing technics, an example of which is the approximate string matching algorithm, were used to transform natural language data into quantitative data. Such data was subsequently used for the classification of noise by decision tree models. After clustering and filtering the dataset into single batches, the impact of uncertainty was characterized. The outcome of characterization was the isolation of the data points describing operations that are not expected in the normal operational framework, and that can be attributed to the presence of failures in the process. A limitation is the relatively high algorithm execution time, which was attributed to the sequencing step dealing with text-recognition algorithms. Another limitation is the fact that the heterogeneity coefficients can only be calculated in the presence of a significant amount of the data, rendering online applications difficult. In future works, the algorithm and the resulting data will be applied in a framework for implementing predictive maintenance in biopharmaceutical drug product manufacturing. The current and the future study support the introduction of data-driven automation approaches as well as industry 4.0 and smart manufacturing in pharmaceutical manufacturing.

Abstract

Data-driven soft-sensors are statistical models constructed from historical data, and expected to perform well both in normal and novel process conditions. Numerous adaptive mechanisms for soft-sensors have been developed, but more work is required to develop appropriate statistical modeling tools for chemical processes, which yield highly collinear measurements in changing operating conditions. In the current study, numerous predictor subset selection and statistical learning tools are employed on 12 different data sets from a crude distillation unit simulated in SimSci PROII™, and the generalization capacities of the models are evaluated using the test points inside and outside the operating regions of the training sets. Relevance vector machine is found to be promising for adaptive modeling, with accuracies close to those of neural network models.

Keywords: adaptive modeling, cross-validation, predictive modeling, predictor selection.

1. Introduction

Data driven soft-sensors for chemical processes are usually constructed using global modeling methods, such as partial least squares (PLS), artificial neural networks (NNs), support vector machines, or adaptive local models (Yan et al., 2004, Kadlec et al., 2011). Proper tuning of parameters in these statistical models is essential for achieving a high generalization capacity, for which cross-validation (CV) is commonly used. The current CV practice involves partitioning the training data into k (usually taken to be between 5-20) folds, each of which is predicted using models constructed from the concatenation of the remaining folds (Kohavi, 1995). Online automatic sampling of processes, producing tens to a few hundred collinear process variables, creates a large number of redundant predictors, inflating the variance of the quality variable predictions. Predictor subset selection algorithms may be used to improve the accuracy and reduce the computational complexity of the statistical models (Hastie, et al., 2011), and to determine a convenient dimension of the neighborhood space, i.e. the subspace in which nearest neighbor search is performed, in order to combat "curse of dimensionality". It should, however, be noted that predictor selection, a form of parameter tuning itself, must be performed in an "outer" loop in CV to prevent biased prediction error (PE) estimates (Reunanen, 2003).

In the chemical process literature, various tools, such as mutual information or NNs, are used to reduce the dimension of predictors (Sun et al., 2016, Jin et al., 2014), yet

experience-based subset selection is still not uncommon, bringing doubt on the generalizability of the suggested modeling techniques. Additionally, abrupt changes in operational conditions necessitates availability of modeling methods, which, trained on small samples, can make accurate predictions outside the operating region; hence, statistical learning algorithms convenient for soft sensors in chemical/biochemical industries are to be developed. The current study aims to (i) construct "automated" unbiased statistical learning methods using various model building tools (Section 2.1), (ii) implement predictor selection methods (Section 2.2), and (iii) assess their performances in predicting T95 (distillation temperature of 95% vol. of oil) measurements from a crude distillation unit (CDU), simulated by SimSci ProII^{TM} (Section 2.3), under small/large sizes of training data and interpolation/extrapolation test data. The promising learning methods for adaptive soft-sensing are discussed Section 3.

2. Statistical Learning Methods

2.1. Linear and Nonlinear Modeling Approaches

A linear statistical model can be represented by, $y_i = \mathbf{x_i}\boldsymbol{\beta} + \epsilon_i$; response and predictor variables are denoted with the mean centered $y_i \in \mathbb{R}$, and $\mathbf{x_i} \in \mathbb{R}^p$ for $i = 1, \ldots N$ samples, respectively, and ϵ_i is the uncorrelated random error. Here, $\boldsymbol{\beta} \in \mathbb{R}^p$ is estimated using training data $\mathbf{X} = [\mathbf{x_1} \ \ldots \ \mathbf{x_N}]^T$. Since least squares (LS) estimates have high variance in the presence of highly redundant predictors, PLS extracts orthogonal components, which yield the maximum covariance between the response and the predictor variables, and linear inner relations are built between each score ($\mathbf{t_j}$) and unexplained (residual) response ($\mathbf{y_j}$) vector in a stepwise manner (Wold et al., 2001). Ridge regression (RR) and Lasso minimize the sum of squared residuals subject to a constraint on the norm of $\boldsymbol{\beta}$, equivalently stated as $\min_{\boldsymbol{\beta}} \left\{ \frac{1}{2} \sum_{i=1}^{N} (y_i - \mathbf{x_i}\boldsymbol{\beta})^2 + \lambda \sum_{j=1}^{p} \|\beta_j\|^q \right\}$; the amount of shrinkage (λ) of the LS parameter estimates, is equal to 1 for Lasso, and 2 for RR (Hastie, et al., 2011). In Bayesian linear regression (BLR), assigning a zero mean Gaussian prior on the weight parameter yields a posterior distribution with mean values equivalent to the ridge estimates, while defining hyperparameters for each weight in relevance vector machine (RVM) yields sparsity due to narrow zero-mean posterior distribution of most of the weights (Tipping, 2001).

A nonlinear statistical model can be represented by $y_i = f(\mathbf{x_i}) + \epsilon_i$, in which $f(x)$ can be approximated with either linear functions, as discussed above, or nonlinear modeling methods, such as nonparametric models, and NN. Kernel PLS may be used to construct a non-linear PLS model, in which a nonlinear mapping is performed from the original data space to the feature space using a kernel function, while the inner relation remains linear (Rosipal and Trejo, 2001). Nonlinear PLS modeling (PLS_{QI}) may also be performed via replacing the linear inner relation between $\mathbf{t_j}$ and $\mathbf{y_j}$ with a quadratic function (Wold, et al., 1989). NN is a collection of interconnected artificial neurons, which pass the weighted input signals through threshold transfer functions, and a NN model with at least one hidden layer may be used to approximate any continuous function (Cybenko, 1989).

2.2. Predictor Selection

The simplest alternative to exhaustive search is sequentially adding or removing predictors, based on correlation coefficient ($\hat{\rho}_i$) and mutual information (I_i) between the

i^{th} predictor and the response variable. At each step of forward selection (FS), predictor improving the fit the most significantly is added to the model (Hastie, et al., 2011). In jack-knife estimation scheme on PLS, PLS(JK), backward selection is employed in eliminating insignificant predictors (Martens and Martens, 2000). In minimum redundancy-maximum relevance (MRMR) method, predictor yielding the maximum ratio of relevance to redundancy is selected in stepwise fashion (Ding and Peng, 2005). In the current study, relevance and redundancy are measured via $\hat{\rho}$, as in $RC_i = \widehat{\rho_i}/VIF_i^{0.75}$, or $\hat{I}$, as in $RM_i = I_i/VIF_i^{0.75}$, and variance inflation factor (VIF), respectively.

3. Model Construction and Assessment using Synthetic CDU Data

SimSci PROII™ is used to model a CDU, to which crude oil (API gravity 29.5) at 390°C and 2 atm enters at a flowrate of 13.5 m^3/min (Figure 1A). Approximate fractional factorial design and perturbations on eigenvectors around the nominal conditions were employed on 16 inputs, such as crude flowrate (F_c) and reflux ratio (R), to represent two different operational modes, from which various datasets were produced at steady state. Columns of the predictor matrix (**X**) consist of the measured values of 70 process variables, such as inputs, column and side-stripper tray temperatures (T_i), condenser duty (C_D) (dashed lines in Figure 1), and T95 values of kerosene (y_1), diesel (y_2) and atmospheric gas oil (y_3) outlet streams are the response variables, to which uncorrelated measurement noise ~$\mathcal{N}$(0°C, 2.5^2°C^2) was added. Test Sets were formed in two different simulation settings: interpolation data (D_{int}) was collected from the same operating region sampled during the training set, while perturbations in input variables covered a wider range and different subspaces for producing extrapolation test data (D_{ext}). σ_1^2/σ_2^2 and σ_1^2/σ_{10}^2 (σ_i is the i^{th} singular value of **X** matrix) lie between 4-8 and 25-400, respectively, showing the high redundancy of the predictors.

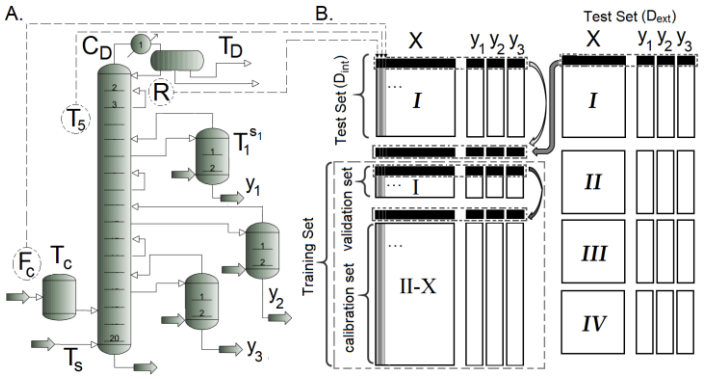

Figure 1. Schematic representation of (A) the CDU; (B) model training/testing algorithm. Construction of the predictor matrix is demonstrated using representative process variables (dashed arrows). Solid arrows (between the blocks of data) represent the inclusion of validation/test data to calibration/training data in stepwise manner for the adaptive local RVM method.

For each response variable, 37 predictive models (P) (Table 1) were trained on D_{int} for N=225 and 50 (Training Set in dashed lines in Figure 1B), and tested using repeated double CV (Krstajic, et al., 2014). Linear models were trained also on data including

squares of predictors (SP). The inner loop, consisting of 10 partitions of validation-calibration sets (normal Roman numbers in Figure 1B) and 20 random repetitions, was used for tuning model parameters and determining number of predictors in 1 to 3-D grid searches. The tuned parameters were then used in fitting the suggested model structure to the whole Training Set and predicting the Test Set. Additionally, models obtained for each calibration set was used to form an ensemble of predictive models (crogging) for PLS and NN models (Barrow, 2013). The outer loop was partitioned into four folds, each consisting of a Test Set of 75 observations (italic Roman numbers in Figure 1B), to determine unbiased PE estimates ($\widehat{\text{PE}}$), computed by root mean square error: $\text{RMSE}_k = \left(\frac{1}{75}\sum_{i=1}^{75}\left(y_{k,i} - \hat{y}_{k,i}\right)^2\right)^{0.5}$, k = 1, 2, 3. In both inner and outer loops, calibration sets and training sets were autoscaled (except for PLS/Sc), and validation and test sets were scaled accordingly. Repeating the outer loop 10-15 times yields 50 $\widehat{\text{PE}}$ values, which were averaged ($\text{avg}\widehat{\text{PE}}$). D_{ext} was not used during parameter tuning and training; a similar four-fold outer loop architecture was also used on D_{ext} (the second column in Figure 1B) to decrease sampling variability in comparing the prediction performances on D_{int} and D_{ext}. While batch training was used for the first 36 methods, an adaptive learning framework was adopted in local RVM (RVM_{L}); optimum dimension of neighborhood space and number of nearest neighbors, measured by Euclidean norm, were determined by CV on calibration sets, with stepwise inclusion of each validation sample to calibration set and each test sample to Training Set (shown with solid arrows between blocks in Figure 1B).

Learning and predictor selection methods are labeled with the name of the former method followed by the latter in parentheses, while crogging and predictor scaling based on PLS **X** residuals are denoted by /Cr and /Sc, respectively, e.g. $\text{PLS}_{\text{SP}}(Red_{cor})$ uses Red_{cor} for predictor selection on **X** including the quadratic terms and PLS for parameter estimation. Predictive accuracies of models are assessed using the following efficiency metric on P:

$$\text{Eff}_i(k,l) = \frac{\min_{j\in P}\left(\text{avg}\widehat{\text{PE}}_j(k,\{N=225,\text{Dint}\})\right)}{\text{avg}\widehat{\text{PE}}_j(k,l)},\ k \in K \text{ and } l \in L \quad (1)$$

Here, K represents three T95 measurements and two modes of data production, and L consists of D_{int} and D_{ext} for N=50, 225. $\text{Eff}_i(k,l)$ taking a value close to unity shows that accuracy of the i^{th} method is close to that of the best predictor on D_{int} for N=225. $\text{Eff}_i(k,l)$ values are averaged and minimized over K to obtain $\text{avgEff}_i(l)$ and $\text{minEff}_i(l)$, respectively, which are indicators of the relative generalization capacities of the models.

Table 1. Predictor selection and statistical learning methods used in the current study.

LS, RR, RR_{SP}, BLR, BLR_{SP}, PLS, PLS_{SP}, PLS/Sc, PLS_{SP}/Sc, PLS/Cr, PLS_{SP}/Cr, PLS (FS), PLS_{SP}(FS), PLS(FS_{val}), PLS(Red_{cor}), $\text{PLS}_{\text{SP}}(\text{Red}_{\text{cor}})$, PLS(JK), PLS_{SP}(JK) PLS(JK)/Cr, PLS_{SP}(JK)/Cr, RVM, RVM_{SP}, Lasso, Lasso_{SP}, PLS_{QI}, PLS_{QI}(FS), $\text{PLS}_{\text{QI}}(\text{Red}_{\text{MI}})$, Kernel PLS, NN, NN/Cr, NN(FS), NN(FS)/Cr, $\text{NN}(\text{Red}_{\text{cor}})$, $\text{NN}(\text{Red}_{\text{cor}})$/Cr, $\text{NN}(\text{Red}_{\text{MI}})$, $\text{NN}(\text{Red}_{\text{MI}})$/Cr, RVM_{L}(FS)

4. Results & Discussion

Representative examples of the prediction methods are placed in Figure 2A with respect to avgEff and minEff values. For NN(FS-MRMR)/Crogging and RVM_{L}(FS) models,

minEff on D_{int} is > ~95%, followed by NN(FS), $PLS_{QI}(Red_{MI})$, PLS(FS), PLS_{SP}(FS), RVM, PLS(Red_{cor}) methods, while minEff drops down to < ~90% for Lasso, PLS, PLS_{SP} and NN. Extrapolation efficiencies (Figure 2B) reveal a clearer picture of the relative performances: the lowest prediction accuracy of local RVM_L(FS) method on extrapolation set can reach 70% of the highest prediction accuracy by a global method on interpolation test set.

Extrapolation efficiency of the global RVM exceeds 50%, followed by NN(FS/MRMR)/Crogging methods. PLS(Red_{cor}) has the highest efficiency among the remaining predictors, while PLS(FS) and PLS_{SP}(FS), contrary to their small PEs for D_{int}, show low extrapolation efficiencies (too small to display in Figure 2). Average efficiency of Kernel PLS is unacceptably low (Table 2), and occasional high PEs prevent Lasso from being a reliable estimator. Efficiencies of PLS, RR, BLR and NN lag significantly behind those of the estimators discussed above, and including quadratic term does not generally improve efficiency. PLS(FS_{val}), in which predictor selection is guided by the inner CV loop, yields worse efficiency compared to that of PLS(FS).

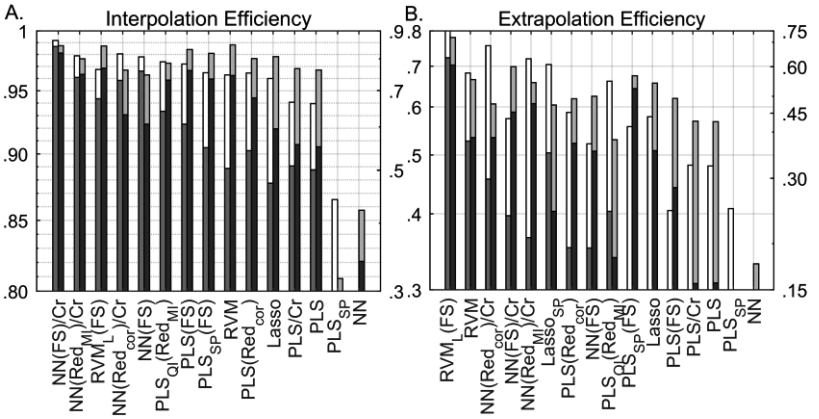

Figure 2. Prediction efficiencies of the best and benchmark methods for (A) D_{int} (B) D_{ext} data: Bars on the left and right side of each tick corresponds to N=225 (left axis) and 50 (right axis), respectively; the light and dark colored bars correspond to avgEff and minEff values, respectively.

FS-based methods yield marginally better predictions for N=225 on both D_{int} and D_{ext}, while predictions using MRMR are highly superior on D_{ext} with N=50. Number of predictors selected by MRMR is found to exceed that by FS, particularly for N=50, hence resulting models are likely to possess a higher amount of information on the predictor-response relation, possibly improving extrapolation predictions.

Table 2. RMSE values of selected prediction methods, averaged over datasets.

Name	RMSE (°C)	Name	RMSE (°C)
RVM_L(FS)	2.66, 3.06, 3.19, 3.60*	Lasso	2.68, 3.24, 8.14, 5.10
NN(Red_{MI})/Cr	2.62, 3.22, 3.91, 4.80	PLS	2.74, 3.44, 6.61, 7.66
RVM	2.67, 3.04, 3.90, 4.80	Kernel PLS	3.13, 4.34, 7.33, 8.70
PLS(Red_{cor})	2.67, 3.23, 4.98, 5.43	NN	3.41, 6.17, 47.0, 17.0

*: Numbers separated by comma are PEs for N=225 and 50 on D_{int} and N=225 and 50 on D_{ext}, respectively.

5. Conclusions

Raw industrial data usually consists of large but redundant set of predictors, so an automated predictor selection and model construction method is required for unbiased predictions. In the current study, a large number of predictor selection and modeling methods, mostly tuned by repeated k-fold CV, are tested on various synthetic data, sampled both from the interior and exterior regions of operation history. The modeling methods are coupled with statistical tests when necessary to prevent inflation of variance in an automated modeling setting. Relatively low prediction efficiencies are encountered for LS, PLS, RR; BLR, Kernel PLS, NN and Lasso. Predictor selection has significant benefit in linear/nonlinear PLS and NN models, particularly with crogging. PLS(Red_{cor}) carries potential for adaptive modeling, and the only non-linear PLS model with moderate extrapolation efficiency is constructed via Red_{MI}. RVM, being >10 times faster than NN, has a high generalization capacity, and using RVM in an adaptive local frame improves the prediction accuracy significantly. Future study aims to implement the best methods in the current study to chemical/biochemical processes in dynamic adaptive frameworks.

Abstract

Uncertainty presented in pipeline erosion predictions may limit the field application of these models. Especially when the to-be-tested regions highly extrapolate the prediction model, large prediction uncertainties can be witnessed. We previously developed a Gaussian process (GP) model based framework to estimate the erosion prediction uncertainty. There are two major goals in the quantification of erosion prediction uncertainty. The first is to minimize the prediction discrepancy of the model uncertainty. The second is to enhance the reliability of the predicted model uncertainty. GP modeling, as a kernel-based approach, relies on the proper selection of hyperparameters. The hyperparameters are generally optimized by maximum marginal likelihood (MLE) using conjugated gradient approach. However, using MLE as the objective function may not satisfy both goals. Furthermore, for non-convex marginal likelihood functions, optimization approaches like conjugated gradient is sensitive to the selection of initial values, and may lead to local optima. Here, we present a bi-objective optimization approach for training the GP model of erosion prediction uncertainty. GP models trained using bi-objective optimization outperform the GP model trained using the MLE based approach in terms precision and reliability for the prediction of erosion model uncertainty.

Keywords: ε-constrained approach; Bayesian optimization; Gaussian process modeling

1. Introduction

The unplanned extraction of solids in oil and gas production leads to erosion in the pipeline, especially under gas-dominated conditions. The formulation of erosion is a complex process and depends on many factors. Several empirical or semi-empirical models have been developed to predict erosion rate as a guideline for equipment design, repair, and replacement. Due to the complexity of the erosion process and the extreme cost in collecting field data, the discrepancies between erosion models' predictions and actual erosion rates can be very significant, e.g., several orders of magnitude for some operation conditions (Dai and Cremaschi, 2015). We hypothesize that most of the discrepancy can be explained by the uncertainty of the model predictions. We used Gaussian process method (Rasmussen and Williams, 2006) to quantify the model uncertainty and the prediction variance of erosion-rate models (Dai and Cremaschi, 2015). Gaussian process method, as a machine learning approach, is able to provide the underlying distribution of the prediction uncertainty. The Gaussian process (GP) model estimations of erosion-rate prediction uncertainty can be evaluated using two criteria: (1) the mean prediction of GP model, which quantifies the prediction accuracy and is generally defined by the squared residual between the mean prediction of GP model and

the target; and (2) the confidence on the GP model predictions, which is indicated by the covariance function and can be quantified using the overall prediction variance. An accurate GP model should yield the minimum mean squared error (MSE) and the minimum prediction variance (VAR). In our previous work (Dai and Cremaschi, 2015), the hyperparameters of GP models were obtained by maximizing the marginal likelihood function using the Maximum Likelihood Estimation approach (MLE, Giunta et al., 2006). Although MLE is considered the gold standard for statistical parameter estimation, it cannot guarantee that the two aforementioned objectives are satisfied at the same time. Here, we train GP models using a bi-objective optimization approach that minimizes MSE and VAR, and apply ε-constrained approach for generating the Pareto optimal set. Bayesian optimization algorithm is used to solve the resulting optimization problems. Spectral mixture kernel with a special initiation scheme is found to be the best kernel for the GP model to estimate model uncertainty of erosion-rate predictions. The results reveal that the GP model trained using MLE yields a solution that is not Pareto dominant.

2. Methodology: quantification of erosion-rate uncertainty

For uncertainty quantification of erosion rate, the experimental response, $\mathrm{y^e}$, can be expressed as the summation of erosion model's prediction of erosion rate, $\mathrm{y^m}$, erosion model bias, α, and the experimental error, ε (Kennedy and O'Hagan, 2001). The model bias includes the uncertainties associated with estimated model parameters in erosion model, the numerical errors and the model form discrepancies, and can be expressed as a Gaussian random process (Jiang et al., 2013). The experimental variability is shown to follow a normal distribution (Dai et al., 2016). Therefore, the model bias and the experimental variability are combined into one term that defines the erosion model uncertainty, and is referred to as model discrepancy (δ) for the remainder of the paper.

2.1. Gaussian Process Modeling (GPM)

In Gaussian process modeling, the distribution of a function is determined by a Gaussian process, which is composed of a set of random variables, where any finite number of random variables from the set follows a joint probability distribution (Rasmussen and Williams, 2006). Therefore, we can express the function using a multivariate Gaussian distribution with its mean and covariance functions (Eq. (1)).

$$f(x) \sim GP(m(x), K(x, x')) \tag{1}$$

where $x, x' \in R^d$, $m(x) = \mathrm{E}[f(x)]$, $K(x, x') = \mathrm{E}\left[\left(f(x) - m(x)\right)\left(f(x') - m(x')\right)^T\right]$ for measurements taken at $D = \{(x_i, f_i), i = 1, \ldots N\}$, and $f_i = f(x_i)$. The function values f_* at N_* untested locations (x^*) are predicted using $f_* \sim N\left(m_*, K(x_*, x_*)\right)$. The joint distribution of the observed f and the to-be-predicted f_* is

$$\begin{bmatrix} f \\ f_* \end{bmatrix} \sim GP\left(\begin{pmatrix} m(x) \\ m(x_*) \end{pmatrix}, \begin{bmatrix} K & K_* \\ K_*^T & K_{**} \end{bmatrix}\right) \tag{2}$$

where $K = \{k_{ij}\}$ is an $N \times N$ symmetric positive definite covariance matrix, K_* is an $N \times 1$ covariance matrix, and K_{**} is an $N_* \times N_*$ matrix. The elements $k_{ij} = k(x_i, x_j)$ measure the correlation between variables x_i and x_j. The posterior distribution of f_* is:

$$P(f_*|x_*, x, f) = N(\mu_*, \Sigma_*) \tag{3}$$

where $\mu_* = m(x_*) + K_*^T K^{-1}\big(f - m(x)\big), \Sigma_* = K_{**} - K_*^T K^{-1} K_*$.

Since the covariance function is a positive definite matrix satisfying the Mercer Theorem, it is also a kernel function. The performance of GP prediction relies on the selection of the kernel function (Wilson and Adams, 2013) (Eq. (3)). Squared exponential, Matern and rational quadratic kernels are among the commonly used kernel functions (Rasmussen and Williams, 2006). The kernel function should be selected based on knowledge of the underlying function and characteristic of the data. Once it is set, its hyperparameters are optimized using maximum marginal likelihood. However, optimization approaches like conjugated gradient rely on choice of initial values and are prone to be trapped in local minima. In this paper, to obtain the optimum set of hyperparameters, a global optimization approach, Bayesian optimization, is used.

2.2. Bayesian optimization

Bayesian optimization, a method used with black-box models with moderate dimensions, is well-suited for the optimization of hyperparameters in machine learning approaches (Shahriari et al., 2016), and provides the global solution without multiple random initializations (Bull, 2011). Bayesian optimization approach sequentially evaluates the objective function as a black-box deterministic function. The approach uses acquisition function (α_n) to search for new data points to evaluate the objective function. Acquisition function provides a balanced sampling between exploration and exploitation. In this paper, the objective function is approximated using a Gaussian process model. In Figure 1, the GP model used as the objective function in the Bayesian optimization is referred as GP2 to differentiate it from the GP model used for estimating erosion model discrepancy. The posterior distribution of GP2 reveals areas not modeled well (with large uncertainty) and the objective function values at sampled points reveal the region where the minimum value lies. The algorithm starts by training GP2 given initial n sample points. A new sample point with the maximum α_k is selected. The new sample and its corresponding objective function value are then used to update the distribution of GP2. The acquisition function based on $n+1$ data points is calculated and utilized to determine the next sampling point. The whole process is repeated until the difference of the objective function values at the latest two samples is smaller than a threshold ϵ (Fig. 1).

2.3. Kernel function used in the GPM

Spectral Mixture (SM) kernel (Eq.(4)) is used for the erosion model discrepancy GP model. It contains Q scaled mixture of Gaussian distributions. It can cover a wide range of spectral density and can approximate any stationary kernels with high accuracy.

$$k_{SM}(x, x') = \sum_{q=1}^{Q} w_q cos\,(2\pi(x - x')\mu_q) \prod_{d=1}^{D} exp\big(-2\pi^2(x - x')^2 v_q^{(d)}\big) \tag{4}$$

where w_q's are weights indicating the relative importance of mixture components, inverse means, $1/\mu_q$, are the periods of components, and inverse standard deviation, $1/\sqrt{v_q}$, is the length scale that controls the influence of each input dimension. The hyperparameters (w_q, $1/\mu_q$, $1/\sqrt{v_q}$) are initialized via data-dominated priors (Wilson

and Adams, 2013). The hyperparameters in the kernel function for the covariance and the constant value used in the mean function are the set of hyperparameters (θ) that are optimized based on the data for training the GP model.

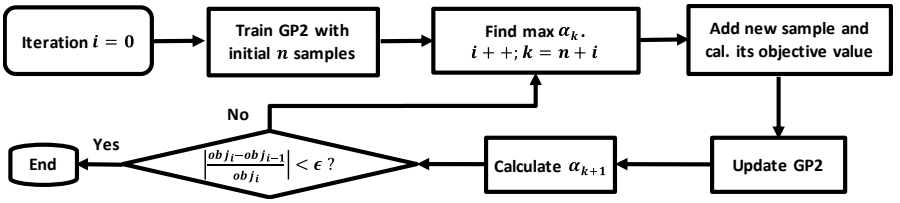

Figure 1. Bayesian optimization algorithm used to determine the hyperparameters

3. Optimization objectives for determining GPM hyperparameters

Here, the commonly used objective formulation to optimize the GPM hyperparameters is introduced in addition to two other formulations, which represent the two major goals in the quantification of erosion prediction uncertainty.

3.1. The Maximum Likelihood Estimation (MLE)

From Section 2.1, the measurements can be expressed using Eq. (5), which is also called the marginal likelihood function. The log marginal likelihood is given in Eq. (6).

$$p(f|x,\theta) = N(m(x), K) \tag{5}$$

$$\log\big(p(f|x,\theta)\big) = -\frac{1}{2}f^T K^{-1} f - \frac{1}{2}log\det|K| - \frac{n}{2}log2\pi \tag{6}$$

Optimal set of hyperparameters are obtained when the log marginal likelihood function is maximized. The conjugated gradient approach is commonly used to solve the partial derivatives of the log marginal likelihood with respect to hyperparameters (Rasmussen and Williams, 2006). This is the traditional approach for constructing GPMs.

3.2. Minimization of mean squared error (MSE)

The GP model hyperparameters can be estimated by minimizing mean squared error (MSE) using Eq.(7), where δ_i and $\hat{\delta}_i$ are the calculated and estimated model discrepancies for the i^{th} data point (in unit of mils/lb), and N is number of data points.

$$\min_{\theta} \frac{\sum_{i=1}^{N}\left(\delta_i - \hat{\delta}_i\right)^2}{N} \tag{7}$$

3.3. Minimization of prediction variance (VAR)

Performance of GPM is also assessed using prediction reliability. A smaller prediction variance represents a more reliable estimation. Equation (8) can be used to estimate the GPM hyperparameters by minimizing the total prediction variance (VAR), where $\hat{\sigma}_i^2$ stands for the estimated variance of the model discrepancy for the i^{th} data point.

$$\min_{\theta} \frac{\sum_{i=1}^{N}\hat{\sigma}_i^2}{N} \tag{8}$$

3.4. Bi-Objective Optimization for GPM Training: ε-constrained approach

In this paper, MSE and VAR are used as two objectives for estimating GPM hyperparameters. The Pareto optimal set for the bi-objective optimization problem is obtained using the ε-constrained approach (Miettinen, 1999).

4. Results

The data used for training and testing the GPM contains 585 samples (erosion rate measurements) with 10 dimensions with a large input space. A MATLAB® based toolbox, Gaussian Process for Machine Learning – GPML (Rasmussen and Nickisch, 2010), is used to train the GP models and make predictions based on the GP models. The function `bayesopt` in MATLAB is used to develop the Bayesian optimization approach. Cross validation is used to evaluate the generality of the developed GPMs. The optimization problem is solved using training data set constructed by a 4-fold cross validation. The hyperparameter values obtained with the highest marginal likelihood from the Spectral mixture kernel initialization (based on data-dominated priors) are used as the initial values for the θ to be optimized by Bayesian optimization approach. To evaluate the objective function efficiently in Bayesian optimization process, expected improvement with time-weighting is used as the acquisition function (Snoek, Larochelle, and Adams, 2012). The Bayesian optimization process is continued until the difference of the objective function values at the latest two evaluations is smaller than 1×10^{-3}. The minimum MSE (Eq. (7)) and the corresponding VAR are 6.03×10^{-7} $(\text{mils/lb})^2$ and 1.41×10^{-1} $(\text{mils/lb})^2$. The minimum VAR (Eq. (8)) and the corresponding MSE are 1.74×10^{-8} $(\text{mils/lb})^2$ and 3.48×10^{-6} $(\text{mils/lb})^2$. The minimization of MSE with VAR as the ε-constraint yields the Pareto front shown in Figure 2.

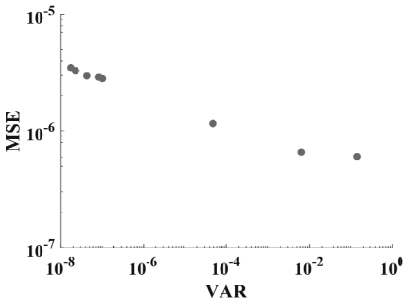

Figure 2. Pareto front of the bi-objective problem

The corresponding MSE and VAR values obtained when hyperparameters are estimated using MLE are also calculated for comparison, and they are 8.66×10^{-4} $(\text{mils/lb})^2$ and 3.40×10^{-3} $(\text{mils/lb})^2$. These values sit far above the Pareto front, revealing the advantage of constructing the problem as a bi-objective one and a potential disadvantage of using MLE to achieve both precision and reliability for prediction of erosion model discrepancy. The root mean square error (RMSE) of erosion model discrepancy for the database is 3.32 mils/lb, indicating for per pound of sand particles transported in the pipeline, there are 3.32 mils (thousandth of an inch) length loss of pipe inner wall incorrectly predicted by the erosion prediction model. Considering the case with natural gas transported at a rate of 3.0×10^{8} standard cubic feet per day (a very typical production rate in oil and gas transportation), the yearly thickness loss calculated is less

than 20 mils. According to ANSI/ASME Standard B31.3 (applies to major facilities onshore and offshore worldwide), the minimum design wall thickness is 0.11 inch (110 mils) (ANSI/ASME 2002). Therefore, this miscalculation is significant, and it will increase for predicting thickness loss for longer periods. Thus, we utilized the bi-objective framework to develop GP models for estimating erosion model discrepancy. The RMSEs of the erosion model discrepancy using the optimum GP models range from 7.76×10^{-4} to 1.86×10^{-3} mils/lb. Therefore, for unit sand particles transported, the uncertainty of erosion rate is at most off by 1.86×10^{-3} mils on average. It can be concluded the estimations obtained from the GP trained using the bi-objective optimization approach have small prediction biases.

5. Conclusions

In this paper, Gaussian process modeling is adopted to estimate the uncertainty of erosion-rate model predictions, which is defined by model discrepancy. To reduce the variance of model discrepancy estimates while maintaining precision, a bi-objective optimization problem is formulated using mean squared error and total variance. Bayesian optimization, as a global optimization algorithm, is implemented to solve the bi-objective problem using ε-constraint approach. The results reveal that the Pareto front solutions dominate the traditional approach, Maximum Likelihood Estimation.

Information Entropy based Indices for Variable Selection Performance Assessment

Q. Peter He*

Department of Chemical Engineering, Auburn University, Auburn AL 36849, USA
qhe@auburn.edu

Abstract

Variable selection plays an important role in data-driven modeling and other applications, and becomes increasingly important as big data become ubiquitous. In the last a few years, many different variable selection methods have been reported. However, how to directly evaluate the performance of variable selection methods has received limited attention. The common criteria used to assess variable selection performance either indirectly measure the effects of variable selection, such as through prediction performance of a model, or require ground truth of variable relevancy, which is usually unavailable, incomplete, or unverified in industrial applications. To address this limitation, two information entropy based consistency indices are proposed to directly evaluate the performance of variable selection methods: one does not require ground truth of variable relevancy, the other can make use of such information if available. A simulated case study (with ground truth) and an industrial case study (without ground truth) are provide to compare the proposed indices with the existing methods.

Keywords: variable selection, soft sensor, consistency index, information entropy.

1. Introduction

With ever-accelerating advancement of information, communication, sensing and characterization technologies, tremendous amount of data are generated and stored every day. Those so called “Big Data” are often extremely high-dimensional, contaminated by noise, and interspersed with a large number of irrelevant or redundant features, making it a challenging task to retrieve useful information from the data (Comminges and Dalalyan, 2011; Ting et al., 2010). Variable selection has been one of the practical approaches to reducing data dimensionality prior to data interpretation or modeling. Even for projection-based dimension reduction methods such as principal component analysis (PCA) and partial least squares (PLS), variable selection is often applied as a pre-processing step to further improve the modeling performance. Among various applications where variable selection is applied, soft sensor development is arguably the one that saw the largest impact from variable selection – it has been shown that the performance of soft sensor can be tremendously improved if only vital variables are included in model development (Andersen and Bro, 2010; Reunanen, 2003).

In the past few decades, many different variable selection approaches have been reported for various applications. However, how to directly evaluate their performance has received limited attention. Currently, variable selection performance is evaluated through prediction performance with indirect metrics such as the average mean absolute percentage error ($MAPE$), coefficient of determination (R^2). It can also be evaluated

directly with metrics such as the geometric mean of selection sensitivity and specificity (G). Their definitions are given below:

$$MAPE = \frac{1}{N}\sum_{i=1}^{N}\left|\frac{y_i-\hat{y}_i}{y_i}\right| \times 100\% \quad (1)$$

where y_i is the measurement and $\hat{y}_i$ is the prediction.

$$R^2 = 1 - \frac{SSR}{SST} \quad (2)$$

where $SSR = \sum_{i=1}^{N}(y_i - \hat{y}_i)^2$ is the sum of squared residual, and $SSR = \sum_{i=1}^{N}(y_i - \bar{y})^2$ is the total sum of squares, with $\bar{y}$ being the average of y. R^2 measures how well the data fits the model.

$$G = (Sensitivity \times Specificity)^{1/2} \quad (3)$$

where sensitivity and specificity are the true positive (*i.e.*, relevant variables selected) and true negative (*i.e.*, irrelevant variables not selected) rates, respectively. The value of G ranges from 0 to 1. $G = 1$ indicates that all the predictors are classified correctly.

Among these three commonly used criteria, $MAPE$ and R^2 can only indirectly measure the effects of variable selection through the prediction performance of a model. Although G directly measures the accuracy of variable selection, it is only applicable when the ground truth of the variable relevancy is known, such as in the simulated case studies. For most industrial applications, the information on the true relevant variables could be unavailable, incomplete, or unverified. In these cases, G cannot be computed.

In order to address these limitations, in this work we propose two information entropy based consistency indices to directly evaluate the performance of different variable selection methods. Based on the assumption that the underlying process model of a given data set stays the same, it is expected that the variables being selected using different training data set (such as through performing Monte Carlo (MC) runs) should be consistent if truly relevant variables are being selected every time. On the other hand, if a variable selection method is not capable of identifying truly relevant variables, different training data sets (containing different disturbances and noises) will likely result in different variables being selected. Therefore, the consistency indices proposed in this work evaluate the performance of a variable selection method by quantifying the consistency of the variable selection results among different MC runs.

2. Information Entropy and Variable Selection Consistency Indices

2.1. Shannon's information entropy

In the physical sciences, or thermodynamics and statistical mechanics, the entropy is a measure of the degree of randomness – the higher entropy means the choices are made more randomly, or less consistently. According to Shannon, information is a measure of one's freedom of choice. The amount of information is defined to be measured by the logarithm of the number of available choices:

$$H_s = -\sum_{i=1}^{n} p_i log_b(p_i) \quad (4)$$

where p_i is the probability of occurrence of event i and the base b can be 2, e, or 10. H_s plays a central role in information theory as measures of information, choice and uncertainty (Shannon and Weaver, 2015).

2.2. The proposed information entropy based consistency indices

For a random variable in the case of two possibilities with probability p and $q = 1 - p$, the Shannon's information entropy can be defined as

$$H_s = -(plog_2 p + qlog_2 q) \tag{5}$$

H_s is plotted in Figure 1 (a) as a function of p, which shows that $H_s = 0$ if and only if $p = 0$ or $p = 1$. In other words, H_s vanishes if we are certain of the outcome. H_s equals the maximum of 1 if $p = 0.5$, which is the most uncertain situation.

To propose a variable selection consistency index, namely I_c, it is desired that I_c is at the maximum if the outcome is certain, or the selection is the most consistent, *i.e.*, either $p = 0$ or $p = 1$. On the other hand, it is desired that I_c is at the minimum if the outcome is the least certain, or the selection is the least consistent (*i.e.*, $p = 0.5$, 50% chance being selected, 50% chance being not selected).

Based on the above considerations, we propose a variable selection consistency index I_c based on Shannon's information entropy (H_s) of two possibilities (which is true for variable selection – either selected or not selected). Specifically, I_c is defined as

$$I_c = 1 - H_s, \text{ or } I_c = 1 + plog_2 p + qlog_2 q \tag{6}$$

I_c is plotted in Figure 1 (b) as a function of p, and it can be seen that I_c has the desired properties discussed above. For the general case of multiple variables, I_c is the average consistency indices of all variables:

$$I_c = \frac{\sum_{i=1}^{n}(1+p_i log_2 p_i + q_i log_2 q_i)}{n} \tag{7}$$

where p_i is the probability of variable i being selected, $q_i = 1 - p_i$, the probability of variable i not being selected, n the total number of variables. It can be seen that $I_c \in [0,1]$. Eqs. (6) and (7) are defined based on the assumption that the true relevance of the variable(s) is unknown. Therefore the consistency index is solely based on the certainty or predictability of a variable being selected in the future events.

When the true relevance of a variable is available, this knowledge should be taken into account. In order to do so, let us consider a truly relevant variable. If the variable is not selected at all, *i.e.*, $p = 0$, it is the most consistent case so $I_c = 1$ based on Eq.(6). However, it is consistently wrong as it is not selected, so its corresponding I_c should be penalized. Similarly for all cases of $p < 0.5$, I_c should be smaller than that for cases of $p > 0.5$. Because of the symmetry of Eqn. (10) at $p = 0.5$, $I_c(p) = I_c(1 - p)$.

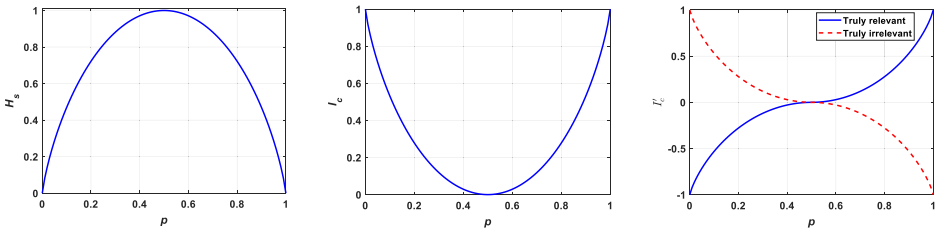

Figure 1. (a) H_s as a function of p; (b) I_c as a function of p; (c) $I_c^{'}$ as a function of p.

Therefore, it makes sense to flip the left half of the curve (*i.e.*, $p < 0.5$) in Figure 1 (b) down around the x-axis, which will result in the modified consistency index (I_c') with penalty, *i.e.* $I_c' = -1$ for $p = 0$. Similarly, for a truly irrelevant variable, the right half of the curve (*i.e.*, $p > 0.5$) in Figure 1 (b) should be flipped down around the x-axis.

$$I_c' = r \cdot \rho \cdot I_c, \text{ or } I_c' = r \cdot \rho \cdot (1 + plog_2 p + qlog_2 q) \tag{8}$$

where $r = 1$ if the variable is truly relevant, otherwise $r = -1$; $\rho = 1$ if $p \leq 0.5$, otherwise $\rho = -1$. It can be seen that I_c' ranges from -1 to 1.

Figure 1 (c) plots I_c' for a truly relevant variable (solid line) and for a truly irrelevant variable (dashed line) as a function of p. As can be seen from Figure 1 (c), if a truly relevant variable mistakenly never gets selected (*i.e.*, $p = 0$), $I_c' = -1$; if it correctly always gets selected (*i.e.*, $p = 1$), $I_c' = 1$. On the other hand, if a truly irrelevant variable correctly never gets selected (*i.e.*, $p = 0$), $I_c' = 1$; if it mistakenly always gets selected (*i.e.*, $p = 1$), $I_c' = -1$. It is worth noting that I_c' applies equal penalties on wrongly omitted truly relevant variable and wrongly selected irrelevant variable. However, the definitions of I_c' can be adapted to provide asymmetric penalties.

For the general multivariate case, I_c' is defined as the average of the consistency indices of all variables, which will still guarantee that $I_c' \in [-1,1]$:

$$I_c' = \frac{\sum_{i=1}^{n}\{r \cdot \rho \cdot (1 + p_i log_2 p_i + q_i log_2 q_i)\}}{n} \tag{9}$$

It is worth noting that we previously proposed a consistency index based on Shannon's information entropy (Wang et al., 2015). Due to the limited space, it is not discussed in this work. However, there is a serious flaw in that the index is not symmetric at $p = 0.5$. The $\mathrm{I_c}$ proposed in this work is completely different from it.

3. A Simulated Case Study

In this section, we will use a simulated case where the ground truth of variable relevancy is known to compare the variable selection consistency indices proposed in this work (*i.e.*, $\mathrm{I_c}$ and I_c') with the traditional index G. The simulation case study was introduced in (Chong and Jun, 2005) and was used in our previous work (Wang et al., 2015). There are totally 40 variables but only 10 variables are true relevant variables. Details can be found in (Wang et al., 2015). In one case study, the variable selection results of two methods, PLS with variable importance in projection (PLS-VIP) (Wold et al., 2001) and competitive adaptive reweighted sampling with PLS (CARS-PLS) (Li et al., 2009), are shown in Figure 2 as the frequencies of all variables being selected. The frequencies are based on 100 Monte Carlo (MC) runs of each method where the training data were randomly selected for each MC run. In Figure 2 the frequencies of the true relevant variables (*i.e.*, variables 1-5 and 36-40) are shown as the black bars, while those of the irrelevant variables (*i.e.*, variables 6-35) are shown as cyan (or gray in monochrome). Various indices discussed previously are calculated and listed in Table 1.

As can be seen from Table 1, all indices show that PLS-VIP is better than CARS-PLS in this case, which agrees with our intuition. For CARS-PLS, I_c' is significantly lower than $\mathrm{I_c}$ because $\mathrm{I_c}$ does not make use of the ground truth of variable relevancy while I_c' penalizes the wrongly selected irrelevant variables.

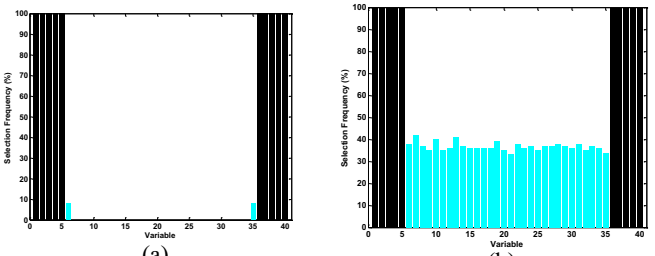

Figure 2. Frequencies of variables being selected by two methods: (a) PLS-VIP; (b) CARS-PLS

Table 1. Comparison of variable selection indices

Method	G	I_c	I_c'
PLS-VIP	.997	.990	.980
CARS-PLS	.795	.645	.289

The evaluation from the $\boldsymbol{G}$ value is the highest, which seems overly optimistic: a closer look at the differences between Figure 2 (a) and (b) suggests that (b) performs much worse than (a), as all irrelevant variables were selected around 40% of the time.

4. An Industrial Case Study

The industrial case study is the production of polyester resin using in the manufacturing of coatings via batch poly-condensation between a diol and a long-chain dicarboxylic acid. Thirty-four variables are routinely measured and recorded. There is no information on the true relevance of the variables to the final product quality, which is assessed by acidity number and viscosity (Facco et al., 2009). Due to limited space, only PLS-VIP and genetic algorithm with PLS (GA-PLS) are discussed in this work. Variables are selected based on their relevance to acidity number, as shown in Figure 3 (a) and (b), and to viscosity, Figure 3 (c) and (d). The two methods are compared in Table 2. Neither G nor I_c' is applicable in this case because the ground truth of variable relevancy is unknown. It can been seen from Figure 3 and Table 2 that the two variable selection methods perform drastically differently in terms of variable selection consistency. PLS-VIP has significantly more consistent variable section for both acidity number and viscosity than GA-PLS.

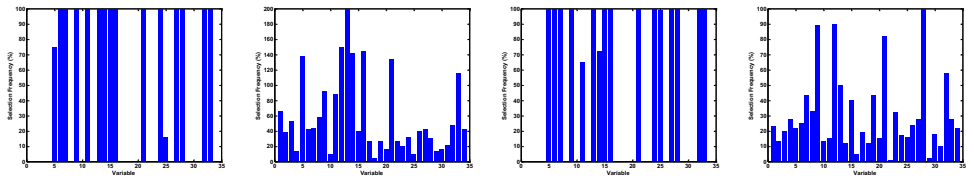

Figure 3. Industrial case study: frequencies of variables being selected by PLS-VIP and GA-PLS for acidity number – (a) and (b); and for viscosity – (c) and (d).

Table 2 also shows that I_c is in good agreement with other performance indices, including percentage improvement in $MAPE$ compared to full model without variable selection (%Imp), R^2, and prediction bias. This case study shows that variable selection consistency is highly correlated with the performance of the resulted soft sensor, validating the need and benefits of directly assessing variable selection consistency.

Table 2.Variable selection and other performance indices: industrial case study

Property	Method	I_c	%Imp	R^2	Bias
Acidity number	PLS-VIP	.958	28.4	.95	-.03
	GA-PLS	.354	21.9	.45	.07
Viscosity	PLS-VIP	.945	30.5	.92	-.01
	GA-PLS	.334	19.9	.87	-.13

5. Conclusions

In this work two variable selection consistency indices, I_c and I_c', are proposed to directly assess the performance of different variable selection methods. I_c' is used when the ground truth of variable relevancy is known, such as in the simulated cases. I_c is used when the knowledge of variable relevancy is unavailable, such as in most industrial cases. I_c and I_c' overcome some of the limitations of existing indices such as G. The simulated case study in this work shows that I_c and I_c' give more objective assessments than G. The industrial case study shows that I_c is highly correlated with the performance of the resulted soft sensors, validating the need and benefits of directly assessing variable selection consistency. More cases are needed to validate the consistency between I_c (I_c') and resulted soft sensor prediction performance and whether it is application dependent.

Abstract

Virtual Analysers are used in industrial processes due to its capacity to replace essential equipment by mathematical models. In order to guarantee the precision of the model output, one has to assure the model input will be available and reliable, implying greater efforts to sustain a high maintainability of the measuring devices used to generate model input. Thus, there is a significant trade-off between model costs and output reliability. This work introduces a new index, called *Ana-Braga-Barbosa-Adelmo* (ABBA), which embodies such economic trait when selecting an empirical model for virtual analysers. Associated costs of different Partial-Least-Square (PLS) models used to estimate the content of contaminants in a trickle bed reactor are simulated through Monte Carlo assuming a Poisson distribution for instrument failure. The performance of different PLS models are analysed in light of the new proposed index, which indicates the most adequate one. Such is different from the PLS model developed based on selection of variables through Variable Importance in Projection (VIP) as the latter relies on a greater number of input variables for similar performance.

Keywords: PLS, Virtual Analysers, VIP, Model Costs

1. Introduction

The petrochemical industry is constantly innovating its methods and searching for processes that are safer and more efficient. Strong competition among different companies calls for technology that can guarantee both the product specification and a solid yield on the invested capital. Such technological devices include on-line analysers such as gas chromatographers, which grant a faster answer on the composition of products when compared with laboratory analysis. However, the cost of such instrumentation is still high (thousands of dollars) and the constant monitoring of the material flow requires frequent skilled maintenance (Musaev, 2003). During those, the loss of vital information could lead to a halt in production, unless another device allows for such information to be carefully estimated. As such, virtual analysers claim a strategic position in modern industry due to its capacity to replace essential equipment, such as on-line analysers, for mathematical models when the former is unavailable.
As described by Bakhtadze (2003), virtual analysers are also used as the algorithmic basis of on-line control systems. Such could be done in one of two ways: either the system only monitors process variables (PVs) and supports the decision making by the operator to guarantee product specification, or the system does not only monitor the

process variables but also offers correction actions. Recent papers by Nogueira *et al.* (2017) and Yadykin (2016) highlight such functionalities. The former monitors the quality of a polymerization process to support the decision making on the operational level in a process plant. The latter evaluates power system stability and suggests the threat of a cascading failure.

Although developing a process representative model for a virtual analyser is not trivial, once it is established, its implementation and integration do not demand much energy. Yet, in order to guarantee the precision of the model output, it is necessary to ensure that data for the model input will be available and reliable. Such imply greater efforts in sustaining a high maintainability of the measuring devices which are used to generate the model input data. As such, there is a significant trade-off between the costs associated with the virtual analyser model and the precision of its output, an economic feature that is often disregarded in a usual purely statistical model development. Hence, the aim of this paper is to introduce a new index, called *Ana-Braga-Barbosa-Adelmo* (ABBA), which attaches an economic trait when deciding the mathematical model used on the development of virtual analysers. In a case study, such index will support the decision of the most adequate Partial-Least-Square (PLS) model of a virtual analyser which estimates the content of methylacetylene and propadiene (MAPD) contaminants in the outlet stream of a trickle bed reactor on a propene plant located in Brazil.

2. The proposed index

This section describes the parameters used to define the new proposed index. Subsections 2.1 to 2.3 describe such parameters and subsection 2.4 defines the index.

2.1. The coefficient of determination

A figure of merit used for characterizing the output reliability of empirical models is the coefficient of determination (R^2), which represents how much of the variability of the output variable is predicted by the input variables based on sample values. It can be defined by Equation (1).

$$R^2 = 1 - \frac{\sum_i^n (y_i - \hat{y}_i)^2}{\sum_i^n (y_i - \acute{y})^2} \tag{1}$$

Where n is the number of observations on the dataset, y_i is the measured output variable at time$i$, $\hat{y}_i$ is the model estimated values of the output variable and $\acute{y}_i$ is the mean of the observed values of the output variable.

2.2. Implementation Costs

The total implementation costs associated with an empirical model over the course of t years is defined in this paper by Equation (2).

$$C_t = \sum_{j=1}^{j} \left(C_{sj} \acute{k}_j \right) \tag{2}$$

Where j is the number of input variables, C_{sj} is the cost of replacing the device responsible for providing the numerical value of input j and $\acute{k}_j$ is the number of failures of such device over the course of t years.

The number of failures of each device is assumed to follow a Poisson distribution, which is often used to describe counting processes associated with failure in industries (Ross, 2014). Equation (3) describes the probability mass function of such distribution.

$$P(k) = \frac{\lambda^k e^{-\lambda}}{k!} \tag{3}$$

Where k is the number of events in a given time interval, λ is the average number of events per interval (also known as failure rate) and e is Euler's number.

2.3. The definition of model complexity

For data collected from an m number of process variables, a PLS model can be developed with j of those variables, where$j \leq m$. Among the available techniques to select the process variables that will be part a model, Chongc and Jun (2005) suggest VIP, which provides a score related to the importance of each input variable on a PLS model built with all m variables. The technique develops a new PLS model with all input variables that have a VIP score greater than one. Besides that, the VIP technique allows the input variables to be ranked from least important to most important.
The model complexity (h) is defined in this paper as the difference between the number of input variables used on the development of any PLS model (j) and the number of input variables selected by the VIP technique (j_{VIP}), as shown by Equation (4).

$$h = j - j_{VIP} \tag{4}$$

2.4. The definition of ABBA

The *ABBA* index for a model of complexity h is defined by Equation (5)

$$ABBA_h = \frac{{R^2}_h - {R^2}_{h-1}}{{c_T}_h - {c_T}_{h-1}} \tag{5}$$

Where ${c_T}_h$ is the standardized cost of a model with complexity h. The standard used is the model with maximum cost, where $h = m$.

2.5. Employing ABBA

ABBA will be employed on the selection of the most adequate mathematical model through the computation of the VIP scores for each PV used as a predicting variable. For an m number of available PVs, there are m potential PLS models. The first PLS model is developed with v latent variables, where all PVs are used. Their respective VIP scores are determined and the variables are organized by increasing order of VIP. The lowest score variable is removed and a new PLS model (with complexity $h = m - 1$) is developed with the same number of latent variables as before. This process continues until a PLS model with only one PV ($h = j_{VIP} - m$) is finally developed. For every developed PLS model there is a respective value of model complexity (h), coefficient of determination R^2 and standardized cost c_T. As both R^2 and c_T tend to increase with h, the model with the best trade-off between implementation costs and output reliability will be represented by a peak in an *ABBA* vs. h graph.

3. Case study

The introduced ABBA index will be applied to support the decision of the most adequate PLS model used on a virtual analyser that estimates the concentration of MAPD contaminants in a trickle-bed reactor at a propene production plant in Brazil. Such concentration is currently estimated by a gas chromatographer (on-line analyser) that requires frequent skilled maintenance. During those, there is no real-time monitoring of the MAPD content on the product, since laboratory analysis does not

provide an answer at the same rate of production. This could potentially halt the output of propene, as product specification is not guaranteed, and cause an enormous loss in invested capital.

Table 1 - Devices used for monitoring PVs - Costs and Failure Rate

Model ID	PV	Monitoring Device	Cost / U$	λ
V1	Fresh feed flow	Orifice plate	300	0.20

V5	Bed Pressure	Manometer	100	0.50
V6-V11	Bed Temperature Across 6 points	Thermocouple	2500	0.20
V12	Outflow temperature	Thermocouple	2500	0.20
V13	MAPD content in feed	Chromatographic column	4000	0.30
		Thermal Detector	6000	0.25

Historical data from thirteen monitored and controlled process variables (PVs) is available as input for modelling. The measuring devices of the PVs are described together with their respective implementation cost and failure rate (λ), for a time spam of 5 years, on Table 1. Implementation costs include both the cost of new equipment, since it is assumed that when a device fails it is not repaired but replaced, and costs associated with the failing of transmitters, since the measured values of the process variables need to reach the control room in order to be monitored.

4. Results and Discussion

The VIP scores of the PLS model with all thirteen process variables ($j = 13$) are presented on Figure 1. There are six PVs with greater scores than the threshold of one ($j_{VIP} = 6$). Hence, the maximum model complexity is $h = 7$ and the minimum is $h = -4$. A purely statistical approach would develop a PLS model with the six selected variables. However, the way the model performance (measured by R^2) is changing as a function of the number of selected PVs (measured by c_T) would be completely disregarded. The coefficient of determination is plotted against the standardized cost (where the standard is the median of the full model) for all developed PLS models (from $h = -4$ to $h = 7$). The model complexity is displayed over the data points on Figure 2.

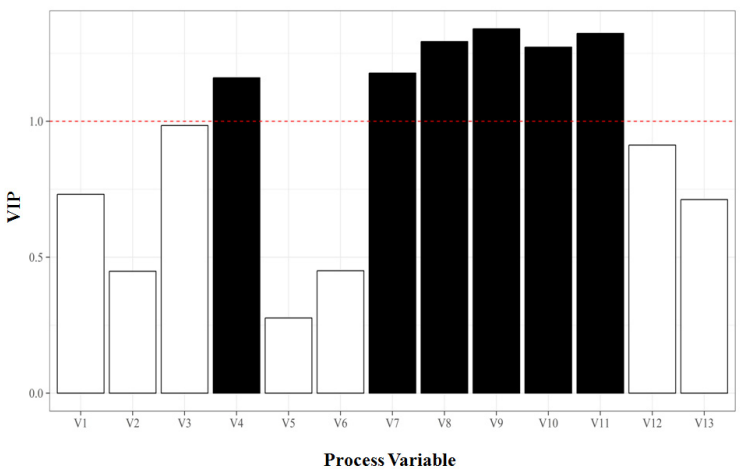

Figure 1 – VIP scores for Process Variables.

It is important to notice that there could be a model where no PV is used as input and the model output is estimated as the historical average MAPD content. Such model performs extremely poorly since the process is dynamic, and it is not a suitable candidate for the virtual analyser. Thus, it has been removed from this analysis.

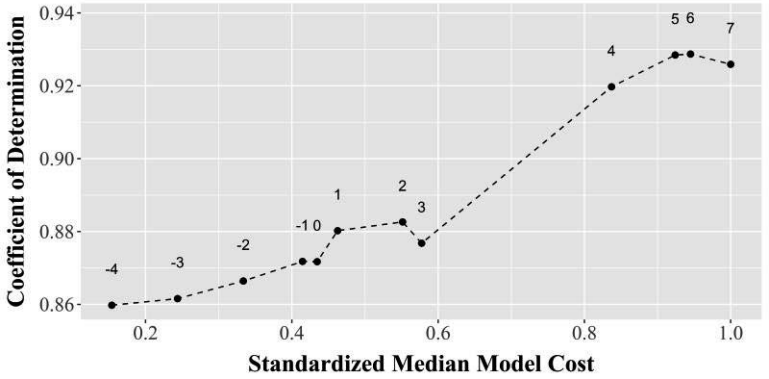

Figure 2 – Evaluation of model R^2 versus standardized model cost.

On a simple multiple linear regression, an increase in the coefficient of determination is expected when a predicting variable is added to the mathematical model. In case the addition of such variable causes a drop in performance, its coefficient would be zero and R^2 would, at the least, remain the same. However, such relationship is not always seen on PLS regression models. As see on Figure 2, an increase in model complexity does not always cause an increase in R^2. Going from $h = 2$ to $h = 3$, there is actually a decrease in R^2. This can be explained by the fact that PLS models maximize the covariance between the latent variables and the response variable. As such, the addition of a predicting variable could cause a lower model prediction capacity while covariance is being maximized. Such has been previously reported by Brereton (2009). Besides that, Figure 2 also indicates that the suggested threshold of one for VIP scores is not valid for all datasets. In fact, the drop in performance observed with PLS models of lower complexity ($h < 0$) does not seem to be significant and, although no statistical test was performed, such has been reported before by Akarachantachote *et al*. (2014). The trade-off between implantation costs and output estimate is evaluated through ABBA scores on Figure 3.

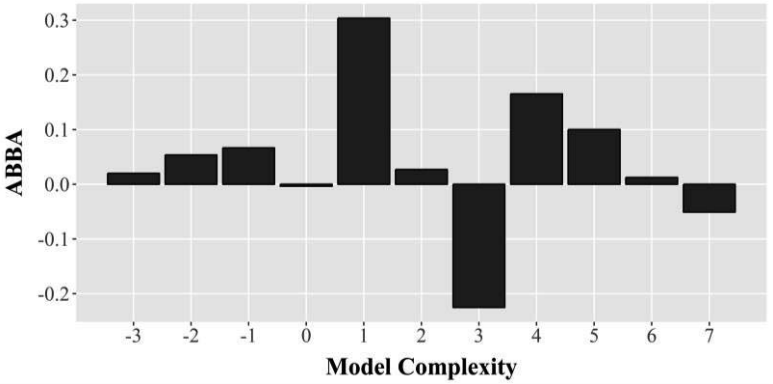

Figure 3 – ABBA index versus model complexity.

The trade-off between the associated cost and model fitting presented by the ABBA index (Figure 2) indicates the model with complexity $h = 1$ as the most adequate one for implementation on a virtual analyzer. Its peak in 0.3 can be translated as the maximum gain in output reliability due to an increase in the associated model cost. It is important to note that models where ABBA is negative must be avoided, since an investment in said models mean a reduction in output reliability.
In some cases, there may be a need to define a minimum value for the model reliability (R^2) or a maximum value for its cost. As the ABBA index provides a relative measure of the impact on output reliability due to an increase in model complexity, regions of acceptance might need to be defined if restrictions are in place. As an example, for an investment restriction of up to 0.6 the maximum cost, the model with complexity $h = 1$ should be implemented. If the restriction is on a R^2 higher than 0.9, Figure 2 indicates a region of acceptance which includes models with complexity higher than $h = 5$. The ABBA index on Figure 3 suggests that the model with $h = 4$ is the most adequate, as investment on more complex model do not generate any higher gains.

5. Conclusions

This paper shows that the analysis of the trade-off between implementation costs and model output reliability when deciding the most adequate model for a virtual analyser is an asset for the success of its implementation. Models of higher complexity require higher maintainability of the measuring devices that provide numerical values for input variables, meaning higher associated costs. Purely statistical techniques, such as VIP, do not consider the economics involved on the decision of the most adequate model and might lead to virtual analysers where the associated costs are not translated into model reliability. The use of ABBA in the case studied provided evidence to justify the implementation of a model that, albeit its higher complexity, possesses economic foundations for its selection, indicating the high potential of the new proposed index.

Abstract

This work looks at the application of big data in the milk powder processing industry, where the focus is on improving product quality and preventing off-specification product. This results in an increased focus on the quality attributes, which may be infrequently measured, and have low repeatability, thus resulting in challenges to the veracity of the data. Combined with the low frequency of failures, the data set is also 'unbalanced', making it difficult to analyse using normal black-box big data techniques. However, these can be addressed using tailored algorithms for elucidating the effects of specific parts of the process on the quality attributes of interest, and by using techniques such as bootstrapping with up- and down-sampling of data to address the issue of an unbalanced dataset.

Keywords: big data, dairy, processing, modelling

1. Introduction

The term "Big Data", characterised by volume, velocity, variety and veracity (White, 2016), is rapidly gaining attention, both by vendors providing novel IT solutions, and manufacturers wondering how best to take advantage of these new offerings. While the application of big data is not unusual in the dairy industry, to date it has been primarily restricted to farm management (Wolfert 2017), the management of the dairy herds using genetics to increase milk production (Cole, 2012), and machine learning for establishing culling rules for herd management (McQueen, 1995). The application of big data mining techniques and analytics to dairy processing at the factory is still relatively new.

Milk powder is a complex powdered product with a wide range of chemical, microbiological, physical and functional properties set down by the customer (Sharma, 2012). Functional attributes, such as different attributes of rehydration and solubility performance, are important quality parameters for end use. However, they are not well understood as they are defined by individually tailored testing procedures, with often complex links to the physical and chemical properties of the powder. This means that the effect of processing conditions on these properties is not well understood. At first glance this is precisely the type of applications that big data analysis is suited for.

Big data approaches are many and varied, including principal component analysis, partial least squares regression, neural networks, random forests, and machine learning (Chiang, 2017). These can be linear or non-linear, and are all black box in nature, and therefore ignore any pre-existing knowledge of the process. However, a crucial distinction between herd and farm management and processing is that personnel in the latter domain wish to know "why" a particular phenomenon occurs. A 'pure' black-box model approach is unlikely to articulate this, and is one reason why traditionally engineers have been uneasy to embrace such approaches. In our case, it is important to know why the milk powder is occasionally off-specification for particular attributes, and therefore how to subsequently correct this.

This paper explores the specific challenges for big data analytics in milk powder processing and presents two case studies for overcoming some of the challenges.

2. Challenges in the Milk Powder Industry

Of the four characteristic "V"s mentioned above, we argue that veracity and velocity are the key concerns for large scale powder production processes. For example in our application what we really want to know is how the powder performs in terms of rehydration, such as how it disperses, wets and produces any sediment. As mentioned earlier, these attributes are measured using individually tailored tests, such as the ISO/TS 17758:2014 standard (IDF 87:2014) for the determination of the dispersibility and wettability of instant dried milk, and are often laborious. Therefore, unlike standard process measurements such as pressure, flow or temperature, this quality data is infrequent, somewhat subjective, and often measured with a significant time lag and is difficult to trace through the process.

This means that although the velocity of the process data is high, the quality of the data is low. In carrying out the work presented in Section 3, this resulted in the need for laborious data reconciliation, to be able to apply `big data analytics' in this area. This is not unusual in the process industry – for example Cauvin et al. (2008) created a unified database for information management for a petrochemical site as the data storage within the institute was found to be highly heterogeneous and unsuitable for data mining.

This is especially important for short, infrequent processing events, such as line swaps during continuous operation, which rely on accurate traceability, something not handled well by the standard statistical algorithms. In Section 3.1 we describe the effect of powder re-blend on product quality, an infrequent operation when powder manufactured during start-up is held back, and then subsequently blended into powder made during stable production periods. This required a purpose-built, bespoke, algorithm in order to isolate these periods. This bespoke algorithm approach was also successfully used for analysing ingredient addition variation and off-spec results by Boiarkina (2017).

This introduces the second challenge in the dairy industry: veracity. Powders are notoriously difficult to sample reliably and many of the functional tests have poor repeatability. The quality tests are designed with grading in mind, not for diagnosing the effect of process parameters. For example, the functional properties of dispersibility and slowly dissolving particles are quantised into single digit numbers of discrete levels, seven and five levels respectively. This means the quality test results are not suitable for standard modern analytical algorithms to tease out any useful underlying correlations. Coupled with the fact that specification failures are rare means that even the large data set is information poor, and therefore makes it difficult to generate accurate models for

these rare, but important events. This means that techniques, such as up-sampling of off-spec data (Section 3.2), during model building become important in overcoming these limitations, as standard application of techniques, such as PLS, did not work.

3. Case Studies

3.1. Bespoke Algorithms for Process Data Analysis

The quality of milk powder produced cannot be guaranteed during start up, shut down and transitory periods (such as equipment line swaps). During this time, the milk powder is diverted into specific "start-stop" hoppers from which the powder can be re-blended at a low rate into the powder to be packed out or packed out as a lower grade powder. However, the effect of re-blend on the powder quality produced at an industrial plant was unknown.

Although a dataset suitable for multivariate analysis had been created previously, this dataset could not be used for this analysis as reblend events were not demarcated. Furthermore, due to mixing in the powder storage hoppers, two start-stop hoppers and different rates of re-blend being used, there was a fuzzy boundary around whether a quality sample was definitively associated with a specific re-blend event. For example, two bins could be used for packing out powder, but only one of them used for re-blending into, and information around which bin the quality sample came from was not available. This was a big data veracity challenge.

A bespoke algorithm was created to scan through a season worth of powder hopper weight data and identify periods of 're-blending' and 'packing out' taking place. This was based on the rate of change in the bin level, with a cut-off for what is considered a re-blend event versus packing out being set visually, and by discussions with plant operators. It was verified manually. The gradient detection algorithm had to be able to handle noisy data, so using straight differencing methods alone for the change in bin level was ineffective, and erroneously picked up a significant number of non-events. An example of the re-blend data is shown in Figure 1.

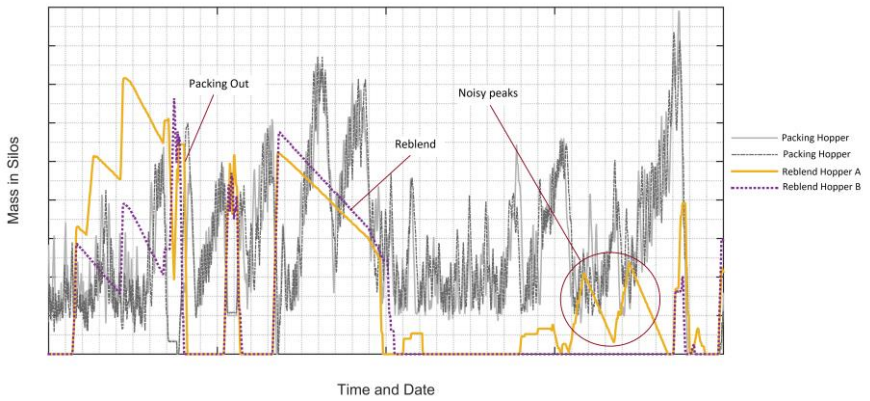

Figure 1 - An example of hopper weight fluctuations during a production run showing re-blend, packing out and noise in the data that makes it difficult to extract events.

In this case, the interest was to determine if the quality of the powder produced during re-blend was lower than the quality of the powder produced without re-blend. An analysis of variance (ANOVA) was used to compare the means of the two groups (with and

without re-blend), as well as to evaluate if there was a difference in the quality of the powder produced with a low and high rates of re-blend. A statistical difference was only found for two quality parameters, the sifter bulk density and a wettability test (shown in Figure 2). However, the difference was very small, and it was confirmed that the plant could continue to re-blend powder safely at a low rate without impacting the quality parameters studied.

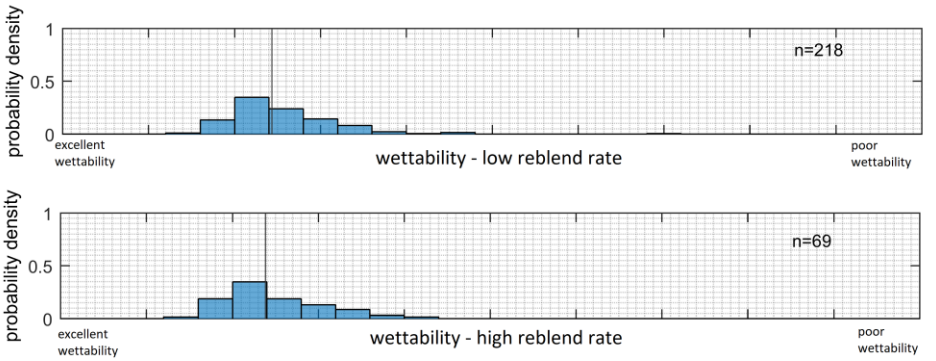

Figure 2 - Effect of re-blend rate on the wettability of instant whole milk powder, with the number of samples analysed shown in the top right hand corner.

3.2. Down-sampling and Up-sampling for Information Poor Data

In many cases in industrial data, no matter how big the volume, there may be very little information in the key areas of interest, such as times when product quality is poor. In the case of a well-controlled process, there may be so few occurrences of product failure that it is difficult or impossible to find predictive relationships by statistical regression, in order to avoid operational regions causing product failure in future. This is particularly important in the case of milk powder, where the production rate is very high, and quality tests are delayed, such that even the rare occurrences result in a high cost of quality failure.

A key functional property studied involved a proprietary test, where rehydrated powders were visually manually graded on a scale where a rating of 5 or higher constitutes a quality failure. The scale was such that some powders received a 3 rating, almost all powders received a 4 rating, and very few (off spec powders) were rated 5. Furthermore, this is an integer scale, where fractional values cannot exist, and hence categorical modelling was used, rather than linear regression. The training data included no values of 1 or 2, or greater than 5, and hence they can never be predicted from this data, but obviously it is ideal if the plant can avoid process operations likely leading to a score of 5.

Random forest models (James, 2013) were used to predict functional properties, from a big data set covering a full season of production, spanning approximately 30 plant process variables including temperatures, pressures and differential pressures, and flowrates around key unit operations, utilising expert domain knowledge to create this subset from the hundreds of measurements available. This process data is available at 30-second intervals from the plant historian, but it must be aligned against physical property measurements of fat, protein, moisture, and bulk density which are sampled hourly, and then against the desired functional tests which occur 3-5 times per day. This results in significant reduction of the original dataset, where several hundred thousand rows of process data result in only 392 samples, of the correct product type.

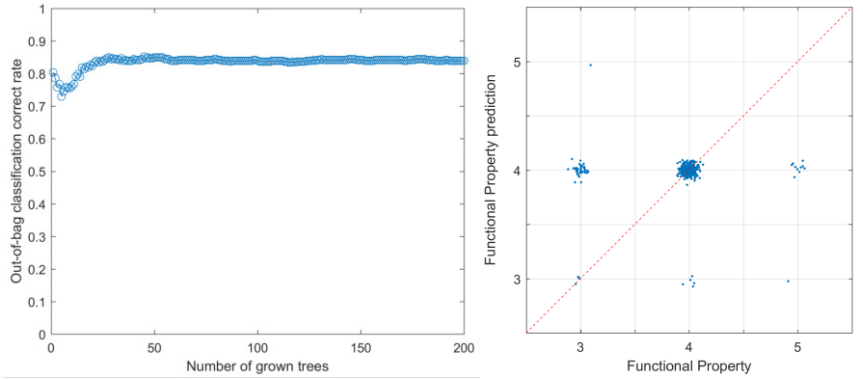

Figure 3 - Random forest prediction without resampling (points jittered for visibility)

Bootstrapping is used in the Random Forest modelling to improve the model fit (R^2), where the dataset is repeatedly randomly sampled, and a new tree grown each time, to see how the model fit improves as more trees are used. The initial model results shown in Figure 3 appear very promising, with R^2 well over 0.8, with only a few trees needed. On closer inspection however, it was clear that the model need only ever predict a (constant) value of 4, and it will be correct over 80% of the time due to the distribution of input data. The number of predictions of any other value were few, with only 3 out of 50 values of 3 predicted correctly, and 0 out of 11 values of 5. This clearly illustrates the potential downfall of modelling where the good/bad data distribution is unbalanced.

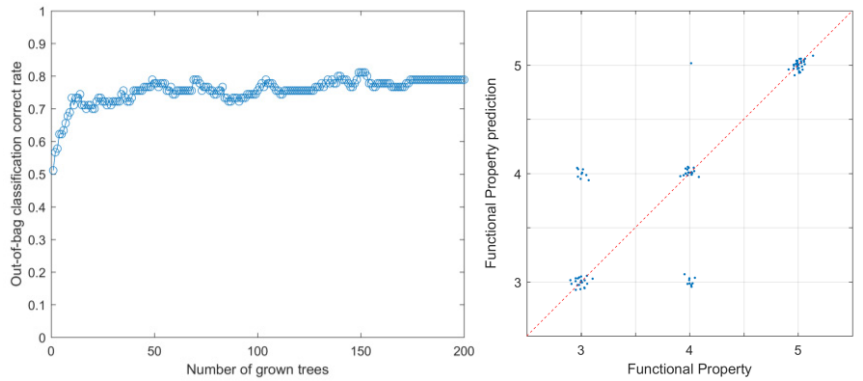

Figure 4 - Random forest prediction with resampling (points jittered for visibility)

Resampling was a key approach to improve the model in this case, where both down-sampling and up-sampling were used, to reduce the class imbalances (Kuhn, 2013). The 50 existing samples of 3, and 331 samples of 4 were randomly selected to form a sample size of 30 each, and the 11 existing values of 5 were randomly up-sampled with replacement, until it also had 30 occurrences. The model results in Figure 4 show a lower R^2 of around 0.75 after a similar number of trees, however the prediction is significantly improved in practice. In this case, around 70% of each of the 3 & 4 values were correctly predicted, with some 3's predicted as 4's and 4's predicted as 3's, but more importantly for the application of preventing off-specification powder, all 30 values of 5 were

predicted correctly, and only 1 of all 90 points was incorrectly predicted as a 5 i.e. there were no missed-alarms, and only one false-alarm.

4. Conclusions

The utilisation of big data in the milk powder processing industry, or indeed any processing industry, has a very different purpose compared to many other big data applications. The focus in processing is on the 'why' something is off-specification. This results in a larger focus on the quality attributes, rather than the process data. Given that quality attributes are collected at a lower rate than process data, and the tests themselves are often complex, with poor repeatability and coarse quantized results the veracity and velocity of this data becomes paramount. Furthermore, the data is often information poor, with few results of interest, partly of course because industries primarily produce on-spec product. This means that bespoke algorithms and techniques such as bootstrapping and up- and down-sampling during modelling become critical to extract useful information.

5. Acknowledgements

The authors would like to acknowledge the Primary Growth Partnership program from the New Zealand Ministry of Primary Industries for funding the project and would also like to thank Fonterra staff, specifically Richard Croy, James Winchester, Nigel Russell and Steve Holroyd for providing resources and support throughout the project.

Abstract

Helmets are an important piece of personal protective equipment on many worksites. In spite that wearing a safety helmet is mandatory for each worker, some do not always obey the regulation. In order to ensure the safety of workers and promote the automation of safety management, in this paper, an automated visual helmet identification method based on deep convolutional neural networks (CNN) is proposed. First, motion detection is applied to capture the segments of moving objects from videos. Then pedestrian detection based on deep CNN is utilized to detect whether there are humans or not in the image segments. Next the head regions are captured from human images. Finally, with red, yellow, blue, white and non-helmet image samples, helmet identification based on deep CNN is used to detect whether humans are wearing helmets or not and to identify the colors of helmets if helmets exist.

Keywords: Accident Prevention; helmet identification; work safety; deep convolutional neural networks.

1. Introduction

Caused by slips, falls, collisions and struck by falling objects, many high-risk industries are suffering from high injury and fatality rate. In order to protect workers from the danger, safety helmet is an important piece of personal protective equipment on many worksites, such as construction, chemical engineering, manufacturing, mining industries. In spite that wearing a safety helmet is mandatory for each worker, some do not always obey the regulation. Presently, most worksites already deployed video surveillance systems to supervise behaviors of workers for work safety. However, considering a large number of surveillance screens for safety helmet supervision, it is a tough task for humans to detect violators during long periods of time. It was proved that as the duration of monitoring of videos increases, the errors made by humans also increase (Hu et al., 2004).

With the advent of the era of smart manufacturing, the automation of safety management has equal importance with manufacturing process. To make factories more intelligent and automated, it is necessary to replace humans to supervise the behaviors of workers through machines like video surveillance systems. Based on computer vision, automated visual approaches develop rapidly in the manufacturing industry. Over the recent years, some approaches have been proposed for motorcycle helmet identification. Chiverton et al. (2012) used Histogram of Oriented Gradients (HOG) to extract features of motorcyclists and their heads and Support Vector Machines (SVM) for feature classification, which achieved 85 % accuracy. Waranusast et al. (2013)

studied color based features for the helmet identification task. However, the aforementioned approaches only used one descriptor for feature extraction. Silva et al. (2013) developed a hybrid descriptor, combined with Circle Hough Transform (CHT), HOG and Local Binary Patterns (LBP). By using Random Forest as the classifier, the accuracy for helmet identification reached 94.23 %. This result showed that the combination of different types of descriptors could achieve better performance than a single one. Recently, Dahiya et al. (2016) proposed a helmet identification system for bike-riders. It compared the performances of three widely used feature descriptors, HOG, Scale-Invariant Feature Transform (SIFT) and LBP using SVM classifier.

The above helmet identification methods all used hand engineered features, which suffer from challenges such as occlusion of objects and illumination effects, which cause the difficulty to accurately classify workers between wearing a helmet and not wearing a helmet. To achieve higher accuracy of motorcycle helmet identification, Vishnu et al. (2017) used deep convolutional neural network (CNN) to extract discriminative features of helmets. This study showed that using features extracted by deep CNN is better than using hand engineered features. CNN was first proposed in the late 1980s (LeCun et al., 1989), and brought about a revolution in computer vision and pattern recognition with the emergence of deep CNN in 2012 (Krizhevsky et al., 2012). Over the past few years, deep CNN has become the dominant algorithm in the computer vision and pattern recognition tasks. Vishnu et al. (2017) used the AlexNet architecture (Krizhevsky et al., 2012) for two classification tasks, one is for classification between motorcyclists and non-motorcyclists and the other is for classification between helmets and heads.

In spite that many motorcycle helmet identification methods with the satisfactory performance were developed, the helmet identification task for workers have been paid less attention. Different from motorcycle helmets covering the entire head, safety helmets for workers only cover the upper part of the head. Besides, helmet colors have different meanings in different industries. For example, in chemical engineering, workers wearing red safety helmets are operators while supervisors wear yellow safety helmets. Therefore, it is also useful to identify the helmet colors of workers. Park et al. (2012) developed an approach based on color histograms for construction workers. A recent work was conducted by Rubaiyat et al. (2017). They combined color-based and CHT for automatic helmet detection in the construction industry. However, they both used hand engineered features for feature extraction.

In this paper, we present an automated visual method based on deep CNN to improve the accuracy of helmet identification for workers in industries. First, motion detection is applied to capture the segments of moving objects from videos. Then, we collect human images as positive dataset and non-human images as negative dataset. Here pedestrian detection based on deep CNN is utilized to detect whether there are humans or not in the image segments. Next the head regions are captured from human images. Finally, with red, yellow, blue, white and non-helmet image samples, helmet identification based on deep CNN is used to detect whether humans are wearing helmets or not and to identify the colors of helmets if helmets exist.

The rest of this paper is organized as follows: Section 2 describes the proposed automated visual helmet identification method. Section 3 presents the experimental evaluation and finally section 4 summaries this paper.

2. The proposed method

Figure 1 shows the flowsheet of the proposed method. This method contains four steps: motion detection, pedestrian detection, head location and helmet identification.

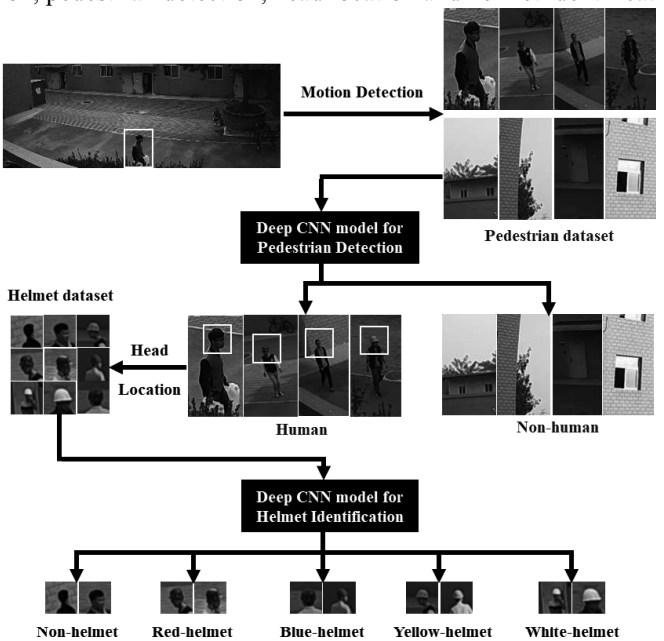

Figure 1-Flowsheet of the automated visual helmet identification method.

2.1. Motion detection

The dataset is collected from cameras and the frame size is 1920 × 1080 pixels. First, we apply K-Nearest Neighbors (KNN) background subtraction method (Zivkovic and Van Der Heijden, 2006) to capture the regions of moving objects from the static background. The moving objects include humans and non-human objects including shaking trees, moving clouds, opening or closing doors. If the area of the moving object is over 1000 pixels, it will be regarded as human-like objects and resized to 320 × 160 pixels.

2.2. Pedestrian detection

To distinguish human images from non-human images, the human-like image segments are classified by a deep CNN model. CNN is a stack of several convolutional layers and pooling layers, which is aimed to extract features from images. Following the part of feature extraction, fully connected layers are used to classify the human-like image segments into human class and non-human class. In this way, human image segments are detected from videos.

2.3. Head location

Before the helmet identification, the head position should be located in the corresponding human image segment. To solve this problem, we need to use the results of the background subtraction. Figure 2(a) is the human image segment and Figure 2(b) is the corresponding image after the process of the background subtraction. The point

(x, y) is the top pixel of the human and the point (x, y+5) is set as the center pixel of the head region (see Figure 2(c)). The head region is then located with a fixed size, 50× 50 pixels (see Figure 2(d)).

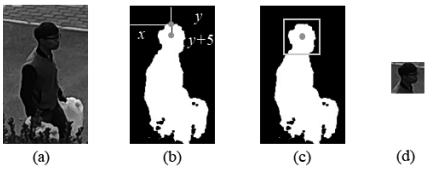

Figure 2-Process of the head location.

2.4. Helmet identification

To detect whether humans are wearing safety helmets or not and to identify the colors of helmets if helmets exist, the head image segments are classified by a deep CNN model. Different from the pedestrian detection, the last fully connected layer of the model for helmet identification is aimed to classify the head image segments into five classes (red, yellow, blue, white and non-helmet).

3. Experimental evaluation

3.1. Dataset

Pedestrian dataset : Using the motion detection to handle the videos, we collect 20504 human-like image segments (320 × 160 pixels) including 4646 human samples and 15858 non-human samples.

Helmet dataset : Using the head location to handle the human image segments, we collect 4648 head image segments (50 × 50 pixels) including 720 red-helmet, 706 yellow-helmet, 700 blue-helmet, 451 white-helmet and 2071 non-helmet samples.

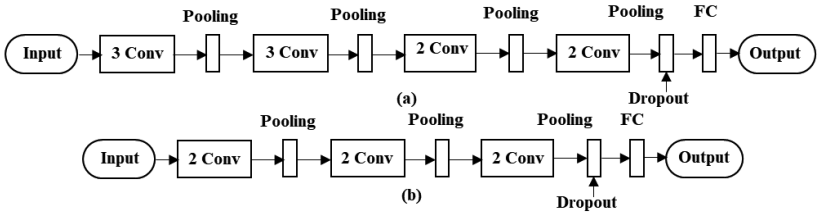

Figure 3-Deep CNN models: (a) For pedestrian detection; (b) For helmet identification.

3.2. Pedestrian detection

A deep CNN model is built for the pedestrian detection, which consists of 10 convolutional layers, 4 max pooling layers, and 1 fully connected layer for classification (see Figure 3(a)). The dropout is utilized for the last max pooling layer, which is aimed to avoid "overfitting". Based on the pedestrian dataset, 5-fold cross validation is implemented to train and test the model. The accuracy (ACC) results of the classification task is listed in Table 1. Figure 4 illustrates the 2D visualization of sample distributions of the input and output using t-SNE. Here "0" represents non-human images and "1" represents human images. The output t-SNE map shows that the deep CNN model has great performance for distinguishing the human and non-human image samples.

Table 1-Results of pedestrian detection.

	1	2	3	4	5	Average
Train ACC (%)	99.8	99.8	99.8	99.8	99.8	99.8
Test ACC (%)	99.6	99.6	99.5	99.4	99.7	99.6

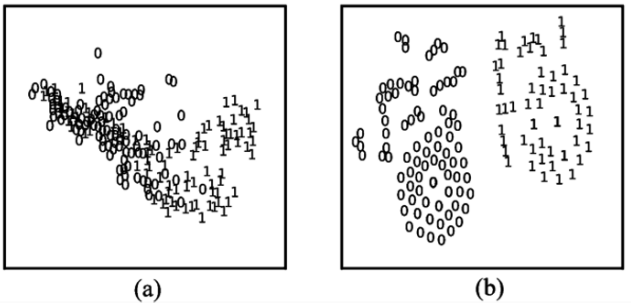

Figure 4-2D visualization of sample distributions for pedestrian detection using t-SNE.

3.3. Helmet identification

A deep CNN model is built for the helmet identification, which consists of 6 convolutional layers, 3 max pooling layers, and 1 fully connected layer for classification (see Figure 3(b)). The dropout is utilized for the last max pooling layer. Based on the helmet dataset, 5-fold cross validation is implemented to train and test the model. The accuracy results of the classification task is listed in Table 2. Figure 5 illustrates the 2D visualization of sample distributions of the input and the output using t-distributed stochastic neighbor embedding (t-SNE) (Maaten and Hinton, 2008). Here "1" represents "red", "2" represents "yellow", "3" represents "blue", "4" represents "white" and "0" represents "non" helmet image samples. In the input t-SNE map, the samples of 5 classes are mixed up. After the calculation of the deep CNN model, the output t-SNE map shows clear clustering of samples, which demonstrates the validation of our proposed method.

Table 2-Results of pedestrian detection.

	1	2	3	4	5	Average
Train ACC (%)	99.2	99.1	99.1	99.2	99.0	99.1
Test ACC (%)	98.9	99.0	99.3	98.9	98.1	98.8

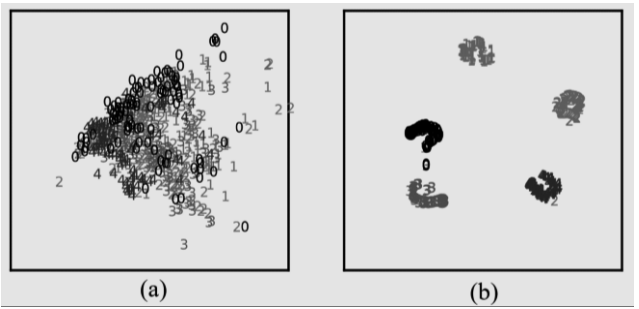

Figure 5-2D visualization of sample distributions for helmet identification using t-SNE.

4. Conclusions

In this paper, we present an automated visual helmet identification method based on deep convolutional neural networks. The deep CNN models show outstanding performances on the pedestrian detection and helmet identification tasks. The average accuracy for pedestrian detection reaches 99.6 % and for helmet identification reaches 98.8 %. This method can be applied on many high-risk work sites, which will help reduce the risk of casualties and promote the automation of safety management for smart factories.

Abstract

European large stationary sources are currently emitting more than 1.4 Gtons of CO_2 every year. A significant decrease in greenhouse gases generation cannot be achieved without relying on carbon capture and sequestration technologies. However, although being practiced for over 30 years, CO_2 transportation is intrinsically characterised by the risk of leakage. To assess and tackle this issue, this study proposes a spatially mixed-integer linear programming approach for the economic optimisation of a European supply chain for carbon capture, transport and geological storage, in which a risk analysis is carried out and incorporated within the modelling framework. Post-combustion, oxy-fuel combustion and pre-combustion are considered as technological options for CO_2 capture, whereas both pipelines (inshore and offshore) and ships are taken into account as transport means. Societal risk assessment and risk mitigation measures are included in the design of the transport network. The overall supply chain is economically optimised, in such a way as to guarantee that the local level of risk complies with a pre-defined threshold.

Keywords: supply chain optimisation, carbon capture and storage, societal risk analysis, risk mitigation measures, hazardous CO_2 transport.

1. Introduction

Although being practiced for over 30 years, transport of CO_2 is nowadays still rising public concern, especially when the possibility of leakage is taken into account in the vicinity of densely populated areas. In fact, pipelines corrosion and external sources may affect the transport safety and, when transported for long distances through densely populated regions, CO_2 exposes to risk a number of people that may be significantly greater than the number of those exposed to risk from either capture or storage sites (IPCC, 2005). Although being a non-toxic and non-flammable gas, CO_2 exhibit a greater density than air, and could therefore locally accumulate to highly dangerous concentrations in certain areas. To assess and tackle this issue, the implementation of a carbon capture and sequestration (CCS) network cannot be disjointed from a proper optimisation-driven analysis that aims at risk minimisation, even at early supply chain (SC) design stage (Onyebuchi et al., 2017). Similarly to what is commonly proposed for gas pipelines, some papers deal with risk-constrained CO_2 SC optimisation, but just a few

were focused on hazards related to pipeline transport systems and on the quantification and prevention of their potential loss. Han and Lee (2013) proposed a fuzzy optimisation for the simultaneous techno-economic, environmental and risk assessment of a CCS SC in South Korea, where risk related to transport modes was treated in terms of cost and technical loss. Khan and Tee (2016) described a general mathematical framework for risk-cost optimisation of underground pipelines networks, where both pipeline corrosion and other failure modes were taken into account, so as to define the life-cycle costs and propose a maintenance strategy. Knoope et al. (2014) addressed risk for the appropriate design and routing of a CO_2 pipeline, including geographic features and considering different measures of risk mitigation. In particular, as regard methods for risk reduction, several contributions were specifically focused either on the optimal positioning of safety valves, or on the selection of suitable transportation paths (e.g., Vianello et al., 2016).
As a result, a lack of knowledge can be identified in the field of large-scale CCS SC optimisation, i.e. the case in which risk and safety measures are simultaneously included in the modelling framework along with the description of those economic aspects related to the installation and operation of such complex networks. In particular, given the high-scale of the investigated problem, societal risk appears to be the best option to estimate the measure of incident size, since it represents the risk related to a population located in the effect region of one or more incidents (AIChE, 2000). Therefore, this study proposes a mixed-integer linear programming (MILP) model for the economic optimisation of a European SC for carbon capture, transport and geological storage, in which a risk analysis is carried out and incorporated within the modelling framework.

2. Material and methods

This paper proposes a single objective, multi-echelon, time-static, spatially-explicit MILP model for the strategic design of a risk-constrained CCS SC within the European geographical context. The objective is the total cost minimisation, such that all feasibility and logical constraints for the optimal SC design are satisfied as in the model reported in d'Amore and Bezzo (2017), while simultaneously including societal risk analysis on CO_2 transport modes and implementing the possibility of installing specific risk mitigation measures on the resulting logistic network, according to the locally accepted levels of societal risk. All the SC stages (i.e., capture, transport and sequestration) are simultaneously optimised within the mathematical framework. In order to decrease the computational burden, here the SC is not described as a multi-period time evolving infrastructure, but only the final configuration (defined in terms of capability for CO_2 sequestration) is taken into account. The spatial resolution is achieved as in d'Amore and Bezzo (2017) by means of a grid $g = \{1, 2, 3, \ldots, 122, 123, 124\}$ of European squared cells. Capture technologies are then introduced through a set of options k that includes: (*i*) post-combustion absorption from the flue gasses of coal-fired power plants; (*ii*) post-combustion absorption from the flue gasses of gas-fired power plants; (*iii*) oxy-fuel technology applied to coal-fired power plants, in which a pre-combustion air separation is obtained for a nearly pure oxygen combustion; and (*iv*) pre-combustion, which entails the production of a hydrogen-rich syngas to fuel gas-fired facilities. Transport is described through a set of modes $l = \{$*inshore pipeline*, *offshore pipeline*, *ship*$\}$; flowrates are discretised according to a capacity set p to speed up the problem computing. The risk analysis is characterised by the implementation of different classes of scenarios $h = \{i, ii, iii, iv\}$ according to the magnitude of the hazard, whereas risk mitigation measures, whose selection may affect both societal risk and total cost of specific transportation paths, are included within a set of possible options m.

Societal risk is defined as the risk of health consequences related to the population that may be affected by hazardous incidents *h* in a certain region *g*. Therefore, this work assesses the risk analysis for inshore pipelines only, being the offshore and the ship options clearly practiced far from densely populated areas. Furthermore, risk related to docking operations was not considered in this model. Three options were chosen to describe the damage surface: (*i*) a strong impact (LC50), in which results a toxic dose of 100000ppm for 15 min; (*ii*) an intermediate situation with 60000ppm for 10 min; and (*iii*) an area of irreversible damage (IDLH) generated by a dose of 40000ppm for 30 min (Vianello et al., 2016).

Within the framework of pipeline transport systems, a risk mitigation measure can be defined as either a physical or a planning safety option that, if implemented, produces (*i*) a decrease in the failure frequency or in the quantity of CO_2 released, i.e. a beneficial influence on societal risk, but (*ii*) also an increase in the costs of the transport system, i.e. a disadvantageous effect on economics. Following the indications by Knoope et al. (2014), the following risk mitigation measures were included in this study within the set of options *m*: (*i*) the installation of marker tape above the pipeline; (*ii*) the installation of protective concrete slabs that may prevent an excavator driver from punching a hole in the pipeline; (*iii*) the deep burying of pipelines (at 2.0 m), which may reduce the possibility to hit the pipeline; and (*iv*) the establishment of a weekly surveillance interval to detect illicit excavations and therefore prevent damages. In addition, the "none" mitigation option was included in set *m* as well, in order to consider the "no-action" choice. On the other hand, other mitigation options that are related to the specific flowrate characteristics (e.g., the optimisation of block valves distance, or the choice of the design factor for calculating walls thickness), were not considered in this study, given the large scale of a European SC optimisation and the spatial resolution that is here considered according to the grid *g*.

3. Mathematical formulation

The objective is the minimisation of total costs (*TC* [€]) that occur to install and operate the CCS SC, in such a way as to guarantee that the local level of risk is lower than a pre-set threshold. *TC* is given by the contributions of the cost for capture (*TCC* [€]), the cost for transport (*TTC* [€]), and that for sequestration (*TSC* [€]):

$$TC = TCC + TTC + TSC \tag{1}$$

The capture and the sequestration problems are described as in d'Amore and Bezzo (2017). On the other hand, the transport problem is here modified to introduce the risk analysis on inshore pipeline transport for both inter- and intra-connection system. As regards inter-connection between region *g* and *g'*, the regional societal risk SR_g^{inter} [events] in origin region *g* is given by the sum of local societal risk $SR_{p,g,l,g'}^{inter}$ [people·events]) produced by each flowrate *p* that is transported from region *g* through mean *l* to region *g'* (oppositely, $SR_{g'}^{inter}$ [events] refers to destination region *g'*):

$$SR_g^{inter} = \sum_{p,l,g'} SR_{p,g,l,g'}^{inter} / P_g \qquad SR_{g'}^{inter} = \sum_{p,l,g} SR_{p,g,l,g'}^{inter} / P_{g'} \qquad \forall g, g' \tag{2}$$

where P_g [people] and $P_{g'}$ [people] are the population in region g and g', respectively. $SR^{inter}_{p,g,l,g'}$ can be evaluated according to the optional implementation of a mitigation option:

$$SR^{inter}_{p,g,l,g'} = \sum_m MF_m \cdot \delta^{inter}_{m,p,g,l,g'} \cdot \sum_h \overline{Pd}_{g,g'} \cdot Sh^{inter}_{h,g,g'} \cdot Pf_h \cdot LD_{g,g'} \qquad \forall p,g,l,g' \qquad (3)$$

$\overline{Pd}_{g,g'}$ [people/km^2] represents the average value of population density between region g and g', while $Sh^{inter}_{h,g,g'}$ [km^2] is the surface affected by hazardous case h between region g and g'. Each incident typology h is then weighted according to the probability Pf_h [events/km] that incident h through mode l generates an event (Table 1).

Then, $LD_{g,g'}$ [km] is the distance between region g and g' (i.e., the transportation length). The binary variable $\delta^{inter}_{m,p,g,l,g'}$ of Eq.(3) is a decision variable representing whether a mitigation option m is taken into account on a specific inter-connection path, or not, and it is then coupled with mitigation factors MF_m [%] (Table 2) so as to take into account the applicable measures for risk mitigation. $Sh^{inter}_{h,g,g'}$ is calculated by multiplying the safety distance from pipeline L_h [km] (Table 1) by the overall transport length $LD_{g,g'}$. Eq.(3) therefore defines local societal risk as a result of population, transport modes and incident typology as well as considering the possible implementation of a mitigation option. Conversely, as regards intra-connection within cell g, the regional societal risk SR^{intra}_g [events] in region g is given by the contribution of local societal risk ($SR^{intra}_{g,l}$ [people·events]) generated by mode l, that is then weighted for the local population P_g:

$$SR^{intra}_g = \sum_l SR^{intra}_{g,l} / P_g \qquad \forall g \qquad (4)$$

where $SR^{intra}_{g,l}$ can be estimated according to the possible implementation of mitigation measures (i.e., through a binary variable $\delta^{intra}_{m,g,l}$, representing whether a mitigation option m is implemented in region g for intra-connection mode l, or not), and on the basis of the potential impact surface ($Sh^{intra}_{h,g}$ [km^2]) that may be affected:

$$SR^{intra}_{g,l} = \sum_m MF_m \cdot \delta^{intra}_{m,g,l} \cdot \sum_h Pd_g \cdot Sh^{intra}_{h,g} \cdot Pf_h \cdot LD_g \qquad \forall g,l \qquad (5)$$

Table 1. Probability (Pf_h [events/km]) and liquid release distance (L_h [km]) of hazard h.

		Pf_h			L_h		
h	hazard	LC50	60000ppm	IDLH	LC50	60000ppm	IDLH
i	Rupture	0.002600	0.000780	0.000026	1.800	2.300	2.700
ii	large puncture	0.002600	0.000780	0.000026	0.450	0.587	0.725
iii	med. Puncture	0.007800	0.002340	0.000078	0.108	0.139	0.171
iv	small puncture	0.013000	0.003900	0.000130	0.027	0.035	0.044

Table 2. Mitigation factor (MF_m [%]) and unitary cost (UMC_m [€/km]) of mitigation m.

m	none	marker tape	concrete slab	deep burying	surveillance
MF_m	100.0	59.9	20.0	29.0	70.0
UMC_m	0	220	110000	51500	1337

Pd_g [people/km^2] is the population density in region g, LD_g [km] is the maximum size of cell g, $Sh^{intra}_{h,g}$ is calculated by multiplying the safety distance L_h by LD_g. Finally, the total

regional societal risk SR_g [events] is constrained to be lower than the maximum allowable regional societal risk (SR_g^{max} [events]), that is imposed by national standards:

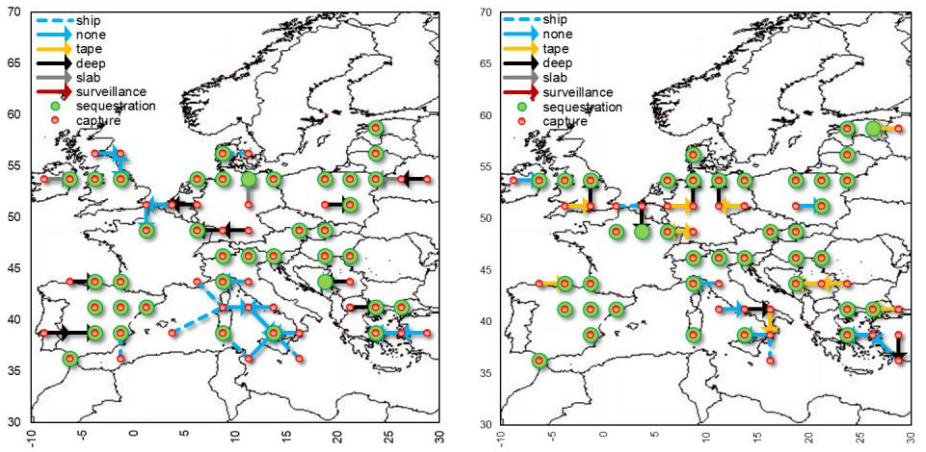
$$SR_g = SR_g^{inter} + SR_{g'}^{inter} + SR_g^{intra} \leq SR_g^{max} \qquad \forall g \tag{6}$$

and the total cost for mitigation TTC^m [€] is evaluated for the selected and installed transport network, according to the unitary cost of mitigation (UMC_m [€/km]) (Table 2):

$$TTC^m = \sum_{m,p,g,l,g'} \delta_{m,p,g,l,g'}^{inter} \cdot UMC_m \cdot LD_{g,g'} + \sum_{m,g,l} \delta_{m,g,l}^{intra} \cdot UMC_m \cdot LD_g \tag{7}$$

4. Results and discussion

The modelling framework was optimised in less then 1 hour by aim of the software GAMS® through the CPLEX solver on a 32 GB RAM laptop. The regional upper bound for societal risk SR_g^{max} calculation was set equal to 0.01 events (i.e., following the indications provided by United Kingdom regulations, AIChE, 2000), whereas the lower bound for minimum European carbon reduction target was imposed equal to 50 % of overall yearly CO_2 emission from large stationary sources (d'Amore and Bezzo, 2017). Furthermore, three scenarios will be here investigated according to the employed methodology for failure evaluation: (*i*) Scenario A - LC50; (*ii*) Scenario B - 60000ppm; and (*iii*) Scenario C - IDLH criteria (Table 3).



(a) (b)

Figure 1. SC configuration for Scenario A (a) and Scenario B (b).

Scenario A exhibits a total cost *TC* of 20.9 G€ (the SC is sequestering more than 600 Mtons of CO_2), of which *TTC* is 1.8 G€ (i.e., the 8.7 % of *TC*). In particular, the SC entails the installation of strong mitigation measures (deep burying and concrete slabs) on the inshore pipeline system (Figure 1a), in order to keep SR_g always lower than SR_g^{max}. This produces a total cost for mitigation TTC^m of 187 M€ (10.3 % of *TTC*). Furthermore, a noteworthy part of the transport infrastructure is developed within offshore areas, in order to exploit the beneficial effect of low population density on societal risk. As regards Scenario B (Figure 1b), the implementation of the 60000 ppm methodology generates a lower mitigation cost (TTC^m is here 89 M€, since mostly marker tape is now installed as mitigation option), which consequently produces a lower value of *TTC* (1.5 G€) and also

a decrease in *TC* (20.5 G€), despite an identical amount of sequestered CO_2 with respect to Scenario A. Within Scenario B, the majority of the transport infrastructure is developed in the mainland, with some deep burying operated in densely populated areas. Conversely, the IDLH approach (Scenario C) is even less cautionary then other scenarios, since it suggests the installation of no mitigation measures, thus producing the best economic performance (*TC* is 20.3 G€), and lower cost for transport (*TTC* is 1.3 G€). Therefore, according to the IDLH methodology for safety distance calculation, it is possible to design an economically optimal European transport network, which already satisfies the regional risk constraints without implementing any mitigation measure on the inshore system.

Table 3. Economic results and computational information for all scenarios.

scenario	criteria	*TTC* [M€]	TTC^m [M€]	sol. time [s]	opt. gap [%]
A	LC50	1814.8	186.6	792	1.9
B	60000ppm	1531.2	89.6	569	1.3
C	IDLH	1292.1	0.0	627	0.4

5. Conclusions

A wide-scale European risk-constrained economic optimisation has been here presented, in which the minimisation of total cost for capturing, transporting and sequestering CO_2 from large stationary sources has been coupled with a societal risk analysis and with the possible implementation of risk mitigation measures on the transport infrastructure. In particular, different system configurations emerged according to the chosen methodology for failure evaluation. In the most conservative scenario (i.e., when the LC50 criteria is employed), mitigation actions represented 10 % of total cost for installing and operating the transport network. For the two additional scenarios being considered, mitigation costs never represented more than 6 % of transport costs.

Alarm Data Analysis for Safe Plant Operations: Case Study of Ethylene Plant

Zhexing Wang and Masaru Noda*

Department of Chemical Engineering, Fukuoka University, Fukuoka 814-0180, Japan
**mnoda@fukuoka-u.ac.jp*

Abstract

Sequential alarms are sets of alarms occurring in succession within a short period of time after triggering an initial warning alarm about an abnormality. These types of alarms reduce the ability of plant operators to cope with operation abnormalities because critical alarms are often lost in numerous other correlated ones. Previously, we proposed an identification method for sequential alarms buried in noisy plant operation data using dot matrix. The dot matrix method is a sequence alignment method for identifying similar regions in DNA or RNA, which may be a consequence of functional, structural, or evolutionary relationships between sequences. In this case study, we use this dot matrix method with operation data from an industrial ethylene plant. The results revealed that sequential alarms in a high volume of operation data from the industrial ethylene plant could effectively be identified using the dot matrix method.

Keywords: Plant Alarm System; Sequential Alarm; Dot Matrix Method; Plant Operation Data, Ethylene Plant

1. Introduction

Advances in distributed control systems (DCS) in the chemical industry have made it possible to inexpensively and easily install numerous alarms in these DCS. While most alarms help operators detect an abnormality and identify its cause, some do not. A poor alarm system might cause sequential alarms, which are a series of alarms that generally occur quickly in specifically-timed succession. These sequential alarms reduce the operators' ability to cope with plant abnormalities because the critical alarms get buried under many unnecessary ones. Therefore, it is very important to identify sequential alarms in plant operation data to ensure safe operations.

Event correlation analysis (Nishiguchi *et al.*, 2010) was first proposed to identify sequential alarms in noisy plant operation data. This method used plant operation data and a cross correlation function to quantify the degree of similarity on the basis of the time lag between two alarms. Sequential alarms were identified by grouping correlated alarms and operations in accordance with their degree of similarity. This event correlation analysis was applied to the operation data of an industrial ethylene plant, previously, and correctly identified similarities between correlated sequential alarms (Higuchi *et al.*, 2010, Takai *et al.*, 2012). However, the event correlation analysis occasionally failed to detect similarities between two physically related sequential alarms when deletions, substitutions, and/or transpositions occurred in the alarm sequence.

A method for evaluating similarities between sequential alarms by using the normalized Levenshtein distance metric was proposed by Akatsuka *et al.* in 2013. The Levenshtein distance (Levenshtein 1966, Yujian and Bo, 2007) is a string metric for measuring the

difference between two sequences defined as the minimum number of edit operations, such as insertion, deletion, and substitution of a single character, needed to transform one string into another.

In our previous study (Wang *et al.*, 2017), we proposed an identification method of sequential alarms by applying a dot matrix method to plant operation data. The Levenshtein distance was applied to the simulation data of an azeotropic distillation column, and the results revealed that the method was able to correctly identify similarities between correlated sequential alarms even when the event correlation analysis failed due to deletions, substitutions, and/or transpositions in the alarm sequence. However, the method was not able to identify sequential alarms hidden in plant operation data. To address this, we applied the dot matrix method to the operation data of an industrial ethylene plant in this study.

2. Dot Matrix Method

A dot matrix method (Mount, 2004) is a sequence alignment method for identifying similar regions in DNA or RNA. Figure 1 shows an example of two DNA sequences. Similar regions in DNA or RNA may be a consequence of functional, structural, or evolutionary relationships between the sequences.

In the dot matrix method, one sequence (S_1) is listed across the bottom of the graph, and the other sequence (S_2) is listed down the left side, as illustrated in Fig. 2. Starting with the first character in S_2, the comparison moves across the graph in the first row and places a dot in any column where the character in S_1 is the same. The second character in S_2 is then compared to the entire S_1 sequence, and a dot is placed in row 2 wherever a match occurs. This process is continued until the graph is filled with dots representing all the matches of S_2 characters with S_1 characters. A diagonal row of dots reveals the similarity between these two sequences. Dots not on a diagonal row represent random matches that are probably not related to any significant alignment.

Fig.1 Dot matrix comparison of two DNA sequences

The major advantage of the dot matrix analysis for finding sequence alignments is that all possible matches between two sequences are found, leaving the engineers the choice of identifying the most significant matches through an examination of the dot matrix for long runs of matches, which appear as diagonals.

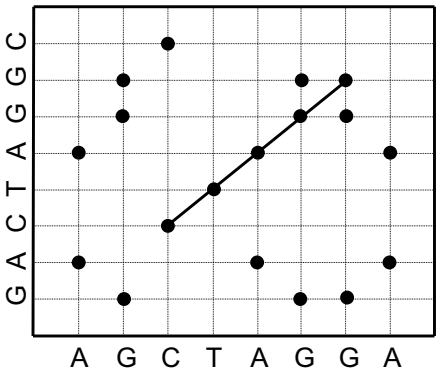

Fig.2 Dot matrix comparison of two DNA sequences

3. Identification Method for Sequential Alarms

The plant operation data recorded in DCS generally consisted of the alarm timings and their tag names, as listed in Table 1. Plant operation data was first converted into a single alarm sequence by putting them in order of the time the alarm occurred. Then, similar regions in the alarm sequences were identified by comparing the alarm alignment with the converted sequence. Figure 3 shows an example of the plant operation data dot matrix analysis. Finally, the identified similar regions, which were assumed to be sequential alarms, were classified into smaller sets of similar sequential alarms in accordance with the similarities between them.

Table 1 Example of plant operation data

Date/Time	Alarm tag name
2013/01/01 00:08:53	A_1
2013/01/01 00:09:36	A_4
2013/01/01 00:11:42	A_2

4. Case Study of Ethylene Plant

We focused our study on an Idemitsu Kosan Co. Ltd. ethylene plant in Chiba, which started operations in 1985. Figure 4 is a process flow diagram for the ethylene plant, which has two board operators using DCS. The plant IDs in Fig. 4 indicate the unit identification number, which are summarized in Table 2.

The total number of alarms in the DCS was 3236 for process control and monitoring. When an alarm occurred, the alarm name and time were recorded in the operation log data.

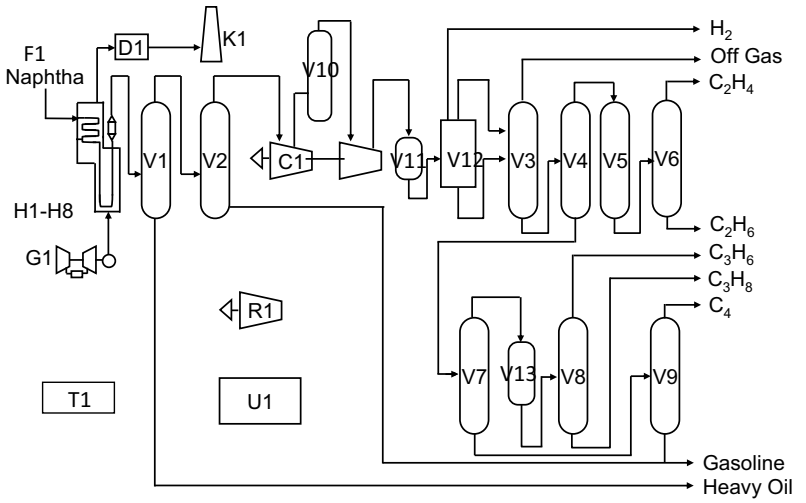

Fig. 4 Process flow diagram for ethylene plant (Higuchi *et al.*, 2010)

Table 2 Units in ethylene plant

No.	Unit name	No.	Unit name
C1	Cracked gas compressor	V2	Quench water tower
D1	DeNOx section	V3	Demethanizer
F1	Feed	V4	Deethanizer
G1	Gas turbine	V5	Acetylene absorber
H1–H8	Cracking furnaces 1–8	V6	Ethylene fractionator
K1	Exhaust gas stack	V7	Depropanizer
P1	Product processing unit	V8	Propylene fractionator
R1	Refrigeration compressor	V9	Debutanizer
T1	Tank	V11	Dryer
U1	Utility section	V12	Chill train
V1	Primary fractionator	V13	Hydrogenation Reactor

The plant log data gathered in one month included 914 different types of alarms. A total of 16803 alarms were generated. Figure 5 shows the times at which the 914 types of

alarms and operation events occurred. It was difficult to identify sequential alarms from just the data shown in Fig. 5.

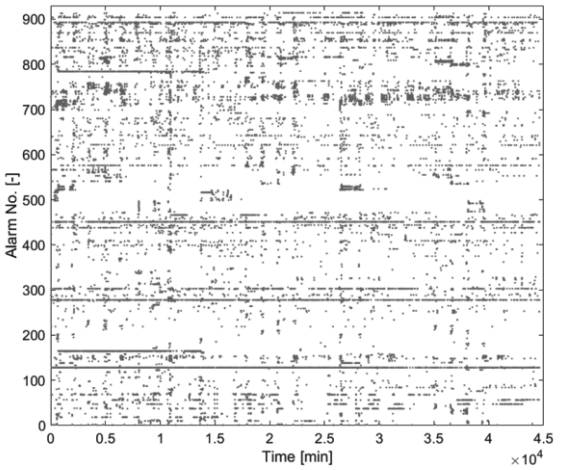

Fig. 5 Plant operation data of ethylene plant (Higuchi *et al.*, 2010)

Figure 6 shows the result of a dot matrix analysis of the plant operation data. A large number of sequential alarms in the plant operation data can be inferred from the multiple diagonal lines represented in black. Table 3 lists the top 10 longest sequential alarms identified by our method. The results revealed that our method is able to correctly identify similar sequential alarms in plant operation data.

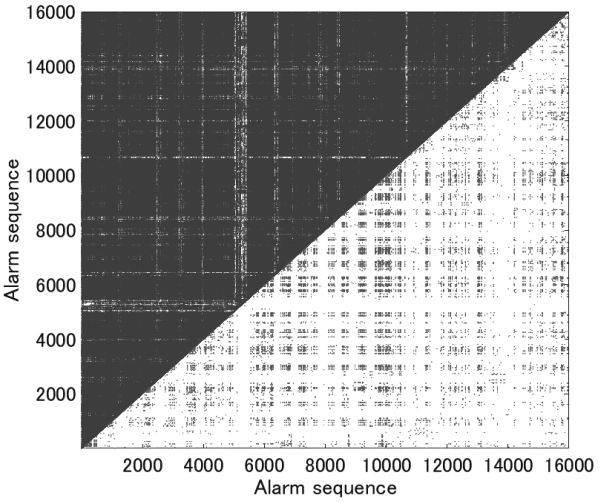

Fig. 6 Results of dot matrix analysis

Table 3 Top 10 longest sequential alarms

Rank	Fre.	Len.	Alarm sequence	Related units
1	2	8	$A_{451}\rightarrow A_{128}\rightarrow A_{451}\rightarrow A_{278}\rightarrow A_{451}\rightarrow A_{128}\rightarrow A_{451}\rightarrow A_{128}$	V2, U1
2	2	7	$A_{450}\rightarrow A_{451}\rightarrow A_{128}\rightarrow A_{516}\rightarrow A_{450}\rightarrow A_{451}\rightarrow A_{128}$	H2, U1
3	2	7	$A_{128}\rightarrow A_{451}\rightarrow A_{128}\rightarrow A_{451}\rightarrow A_{128}\rightarrow A_{165}\rightarrow A_{784}$	H2, U1
4	2	6	$A_{893}\rightarrow A_{128}\rightarrow A_{812}\rightarrow A_{813}\rightarrow A_{814}\rightarrow A_{815}$	H6
5	2	6	$A_{826}\rightarrow A_{164}\rightarrow A_{165}\rightarrow A_{784}\rightarrow A_{451}\rightarrow A_{128}$	H2, U1
6	2	6	$A_{516}\rightarrow A_{451}\rightarrow A_{128}\rightarrow A_{451}\rightarrow A_{516}\rightarrow A_{128}$	H2, U1
7	2	6	$A_{451}\rightarrow A_{816}\rightarrow A_{451}\rightarrow A_{816}\rightarrow A_{128}\rightarrow A_{816}$	H6, U1
8	2	6	$A_{451}\rightarrow A_{812}\rightarrow A_{813}\rightarrow A_{814}\rightarrow A_{815}\rightarrow A_{128}$	H6, U1
9	2	6	$A_{165}\rightarrow A_{784}\rightarrow A_{278}\rightarrow A_{451}\rightarrow A_{128}\rightarrow A_{893}$	U1, U2
10	2	6	$A_{128}\rightarrow A_{451}\rightarrow A_{128}\rightarrow A_{278}\rightarrow A_{451}\rightarrow A_{128}$	U1

5. Conclusions

A dot matrix method using the Levenshtein distance metric was applied to an ethylene plant operation data. The results revealed that the method was able to correctly identify similar sequential alarms in the data. By classifying sequential alarms into smaller groups, a dot matrix method using the Levenshtein distance metric effectively identified similar types of alarms. These results revealed that this method can correctly identify similarities, despite changes to sequences, in plant operation data to ensure safer operations at an industrial chemical plant.

Comparison of Fire Extinguishing Approaches in Engine Control Rooms

Julian Enrique Mendez Alvarez*, Felipe Muñoz Giraldo

Product and Process Design Group Chemical Engineering Department, Universidad de Los Andes, Bogotá 111711, Colombia
je.mendez188@uniandes.edu.co

Abstract

Electric cabinets are a major contributor to electrical fire hazards, with an occurrence of more than 10% of all fire events. This project addresses the comparison of various fire suppression approaches in engine control rooms, using Fire Dynamics Simulator as support tool. The project studies three different scenarios, one of them without a protection system, a second one with a clean agent as extinguishing tool and a final one, which implements an inherently safer design. For the first case, the gas temperature in the room reached a limit of 620 °C. This condition may cause structural damages to the room, as well as injuries to the personnel in charge of fire extinction. For the second scenario, it was determined that the extinguishing agent may decrease the negative effects of the fire, although it may not protect other important structures. Finally, the inherently safer design limits the negative effects to the cabinet where the fire occurs, protecting the structure of the remaining cubicles, as well as the personnel.

Keywords: Compartment fire, Inherently Safer Design, Computational Fluid Dynamics, Process Safety, Fire Dynamics Simulator

1. Introduction

The study of electrical fires is a major concern for fire safety in the industry, particularly for oil industry. In petrochemical facilities, the fire hazard may cause severe consequences on safety functions inside the fire compartment and may lead to the loss of one or several compartments (room for electrical control equipment, battery room, etc.), as just as structural damage on the facilities. From the OECD Fire Database the majority of the fire ignition is due to electrical sources (close to 50%) (W. Werner et al, 2011; W. Werner et al. 2009).

Electric fires mean economic losses for companies because they cause partial or full stops of the processes, economic sanctions and several injuries or fatalities (mainly related with severe burns and exposure to toxic combustion products) (Department for Communities and Local Government, 2013; Society of Fire Protection Engineers, 2002). Considering the possible consequences, it is necessary to implement systems or strategies that reduce the likelihood or mitigate the above-mentioned consequences. These strategies are usually implemented following either a prescriptive approach or a performance-based approach (International Maritime Organization, 2009). Prescriptive methods include the compliance of international preventive standards which may mitigate the consequences, yet they use correction factors that can overestimate the system specifications (creating extra costs) or underestimate those requirements (worsening the consequences). On the other hand, performance-based approaches rely on the simulation of the combustion

dynamics in order to estimate the effects of the fire over the structure. The combustion dynamics can be simulated using different computational fluid dynamics tools, considering its great accuracy. One of the most used computational tools is Fire Dynamics Simulator (FDS, developed by the National Institute of Standards and Technology). The simulation of fire protection techniques allows to compare several performance-based techniques such as the active technologies (use of a clean extinguishing agent), as well as a passive technique (inherently safer design).

2. Methodology

Three different scenarios were defined for the comparison of different fire extinguishing approaches. The three scenarios share the cubicles distribution, based on NFPA 70 (National Fire Protection Association, 2014). However, the compartments have frontal and on top ventilation for the first and second scenarios, while the inherently safer system suppresses this element because of its incompatibility with the standards used in the design of this kind of applications (Striebel & John GmbH & Co. KG, 2007). Moreover, for the unprotected scenario (based on an existing industrial facility), an equivalent ventilation area of 15% was defined for the room. These vents were suppressed for the protected scenarios in order to avoid the loss of extinguishing material and a flashback scenario in the inherently safer scheme.

A heat release ratio of 1600 kW/m^2 was imposed, considering typical fires in industrial facilities. The combustion material was assumed as a mix of typical materials present in cubicles, such as cellulose, polyester, polyurethane and PVC. This fictional fuel was defined with the lumped species model proposed by FDS, using the properties reported in Table 1 .

Table 1. Fuel properties

Fuel properties	
Heat of Combustion [J/kg]	29,850,000
Molecular Formula [-]	$C_1 H_{1.6} O_{0.285} N_{0.03}$
CO yield [mol/mol]	0.505
Soot yield [mol/mol]	0.159

Table 2. Fire suppression technologies

Fuel properties		
Material	Clean Agent	Fireproof coating
Molecular Formula [-]	$C_6 F_{12} O$	N/A
Specific Heat [J/kg.K]	987	1,200
Conductivity [W/kg.K]	0.00035	0.15
Emissivity [W/m^2K^4]	N/A	0.7

A clean extinguishing agent was selected for the second scenario. Several sprinkler systems were installed in the room, in order to inject the extinguisher. A volumetric concentration of 5% was considered for a 10 *s* injection time (considering the technology requirement). On the other hand, a fireproof coating was selected for the inherently safer design case. The material was selected according to the DIN 4102-1 code (Striebel &

John GmbH & Co. KG, 2007). Both clean agent and coating properties are reported in Table 2.

A span of one minute was imposed for the simulations, considering the time that takes to the different technologies to mitigate the fire. Furthermore, the grid size was set at 0.20 m for every direction, considering the characteristic diameter criteria, proposed by FDS, depicted in (1). This approach considers the heat release ratio of the fire and the density, specific heat and temperature of the environment.

$$D^* = \left(\frac{HRR}{\rho_\infty Cp T_\infty \sqrt{g}}\right)^{\frac{2}{3}} \tag{1}$$

Additionally, in order to accurately predict the flame extinction, the adiabatic flame temperature of a lower flammability limit mixture was considered. The software algorithm determined if enough heat was transferred to every cell in order to generate a combustion reaction. This temperature is determined as it follows.

$$T_{CFT} = T_0 + \left(\frac{LFL}{100}\right)\frac{\Delta H_c}{nCp} \tag{2}$$

In order to determine the walls' temperature, as well as the cubicle temperature, some temperature recording devices were installed. However, the tool estimates the adiabatic wall temperature that must be corrected in order to obtain temperatures in the same magnitude order of the experiments (Ulf Wickström, Dat Duthinh, & McGrattan, 2009). Hence, the following models were implemented in the post processing stage for the unprotected scenario and the clean agent scenario.

$$\frac{dT}{dt} = \frac{1}{\rho C_p l}\left(h(T_A - T) + \sigma\epsilon(T_A^4 - T^4)\right) \tag{3}$$

As for the surfaces receiving a heat flux as a product of conduction, convection and radiation mechanisms, the proposed model in (3) turns into the following set of equations.

$$\frac{dT_1}{dt} = \frac{h\left(T_{A_1} - T_1\right) + \sigma\epsilon\left(T_{A_1}^4 - T_1^4\right)}{\rho C_p l} + \frac{\alpha}{2l^2}(T_2 - T_1) \tag{4}$$

$$\frac{dT_2}{dt} = \frac{h\left(T_{A_2} - T_2\right) + \sigma\epsilon\left(T_{A_2}^4 - T_2^4\right)}{\rho C_p l} + \frac{\alpha}{2l^2}(T_1 - T_2) \tag{5}$$

where the sub index "1" stands for the cubicle where the fire occurs and the sub index "2" corresponds to the adjacent cubicle. Finally, for the third case, the fireproof coating must be considered. Thus, the model is modified as it follows.

$$\frac{dT_1}{dt} = \frac{1}{\rho C_p l}\left(h\left(T_{A_1} - T_1\right) + \sigma\epsilon\left(T_{A_1}^4 - T_1^4\right) + \frac{kk_r}{2(k_r l + kl_r)}(T_2 - T_1)\right) \tag{6}$$

$$\frac{dT_2}{dt} = \frac{1}{\rho C_p l}\left(h\left(T_{A_2} - T_2\right) + \sigma\epsilon\left(T_{A_2}^4 - T_1^4\right) + \frac{kk_r}{2(k_r l + kl_r)}(T_1 - T_2)\right) \tag{7}$$

3. Results

After implementing the post-processing algorithm, cubicle wall temperatures were obtained. The temperature profiles are depicted in Figure 1.

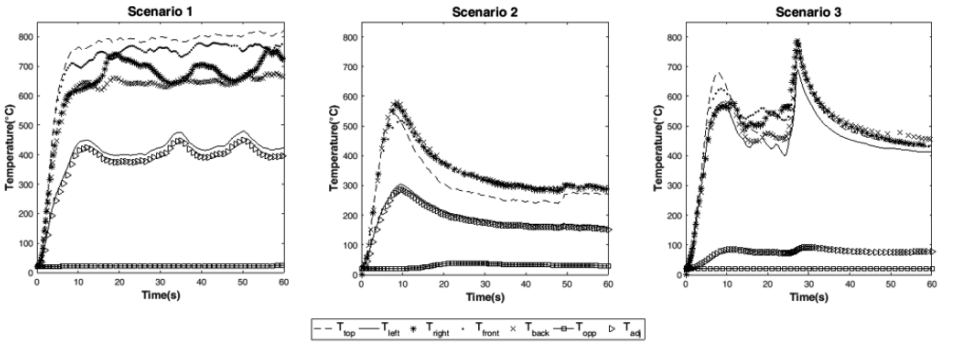

Figure 1. Cubicle Temperature Profile

For the scenario with no fire protection technique, the compartment reached a peak of approximately 820°C at the top of the cubicle, and temperatures close to 800°C for the left, right, frontal and rear walls. This temperature magnitude represents potential risks for the wiring and mechanical integrity of the cubicle where the fire is present and the adjacent one. However, it does not affect the cubicle located in front, given that its temperature does not rise above 50°, which indicates that the prescriptive approach (NFPA70) distribution is effective. In the second scenario, the extinguishing agent lowers the temperature inside the burning cabinet. However, the agent injection spreads the heat of the fire to the adjacent cubicle and may cause potential affectations. The inherently safer design scenario confines the fire to the original cubicle so it prevents potential risk for other cabinets in the room.

In addition, the evolution of the temperature profiles are correlated to the oxygen concentration inside the cubicle. In the first case, there is a constant oxygen feed because of the top and frontal ventilation, that causes the re ignition of the fire and all the peaks depicted for Scenario 1. In the second case, the extinguishing agent displaces the available oxygen in the compartment which causes the combustion process to stop and contributes to a lower temperature. The third case presents a particular behavior; two different temperature peaks can be recognized around 8 *s* and 30 *s*. The second peak corresponds to a re-ignition of the flame due to the entrance of extra oxygen via the frontal ventilation. This shows that a frontal ventilation might not be suitable for an inherently safer design application.

Moreover, net incident radiation was analyzed in order to perform a consequence calculation. As displayed in Figure 2, the first scenario reaches a value of 3.7 kW/m^2 for the surroundings of the cubicle. This incident heat flux could cause first degree burns in 70% of the exposed personnel for an exposure period of 60 *s* and even, second degree burns (in 27% of the exposed personnel). For the protected scenarios, the incident heat flux does not reach a value that may constitute a risk for human health. For a 60 *s* period of exposure, an incident heat flux of 1.5 kW/m^2 or 1 kW/m^2 does not cause any burn to the attending personnel.

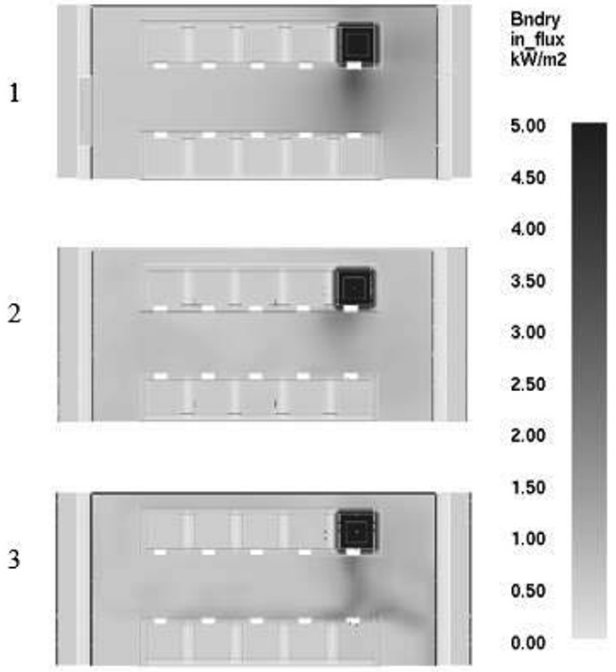

Figure 2 Incident Heat flux

4. Conclusions and future work

The comparison of the scenarios and techniques using FDS was successful. It was determined that even though the use of a clean agent extinguishes the fire, it may propagate the consequences of the conflagration to other compartments. On the other hand, an inherently safer design approach gives up the mechanical and electrical integrity of the affected cubicle but saves the mechanical integrity of the remaining compartments. An inherently safer design implementation is recommended when the heat release ratio is so high that an active system (such as a sprinkler system) cannot guarantee the mechanical integrity of a facility. However, if the forecasted heat release ratio is low, an extinguisher injection system should be implemented, only if it is linked to a smoke detection system. This allows an early detection of the incident and an effective mitigation of the consequences.

Although valuable conclusions were drawn from this comparison, different factors should be considered in order to perform deeper and more valuable analysis. For instance, the cabinets' distribution should be considered in a sensitivity analysis, as well as the ventilation of the room and the compartments. Likewise, the studied technologies should be varied in order to have a wider panorama (different wetting agent, different coating material with varying thickness). Furthermore, economic and technical assessment parameters could be included (cubicle replacement cost, capital cost of the alternatives, economic losses).

Additionally, it is suggested to implement a performance-based analysis for the inherently safer design case, removing the frontal vent in order to determine its suitability for this

kind of approach. Finally, it is recommended to perform an "after simulation" analysis of the grid, in order to determine a balance between computational resources demand and results accuracy.

A novel method for real-time alarm root cause analysis

Feifan Cheng, Jinsong Zhao*

Department of Chemical Engineering, Tsinghua University, Beijing 100084, China
chengff15@mails.tsinghua.edu.cn

Abstract

With complexities in the control systems, it is natural that the chemical plants may become vulnerable to faults in practice. Alarm systems were designed to raise an alarm when a fault is detected. But modern alarm systems often produce large amounts of false or nuisance alarms which leads to alarm floods. Operators receive far more alarms than they can handle. To reduce the alarm floods, we developed a novel method which combined the Time-delayed Convergent Cross Mapping (TCCM) and Bayesian Network (BN). In this paper, the BN is constructed with application of TCCM to process data and expert knowledge. The alarm data is used to estimate the conditional probability among the nodes of the BN. The BN is used to find the alarms propagation paths and root cause at real-time. Finally, the method is applied to the Tennessee Eastman model to illustrate the applicability.

Keywords: Root Cause; Alarms; Bayesian network;

1. Introduction

Process control has made a great contribution to the production efficiency, product quality, process safety and environmental protection in the modern chemical process industry (Shu and Zhao 2015). With complexities in the control systems, it is natural that the chemical plants may become vulnerable to faults in practice. Alarm systems were designed to raise an alarm when a fault is detected. As a process consists of a large amount of different process devices that provide an alert when the process shows an abnormal operating situation, most of the alarms are not meaningful and can be ignored by the operators (Rodrigo, Chioua et al. 2016). The operators are distracted and might ignore critical alarms. So it is necessary to develop a methodology to select the most meaningful alarms and bring the operator's attention to the root cause of the alarms.

A lot of research are focused on the alarm management. A large number of unimportant alarms fall within three categories: standing alarms, repetitive alarms, and consequence alarms. For standing and repetitive alarms, such widely implemented techniques as delay-timer, deadband and shelving are suggested. These methods were successfully implemented on the chemical process. Compared with standing and repetitive alarms, consequence alarms are more complicated and more difficult to handle. To handle the consequence alarms, it is important to obtain the correlations of different alarms. For example, a modified Smith–Waterman algorithm was used for alarm flood pattern matching (Cheng, Izadi et al. 2013). But these methods have the limitation that only alarm data is used for analysis. The BN can be used for root cause analysis of alarms. However, the BN built by expert experience is time-consuming (Wang, Khan et al. 2015). And the root cause detected by the BN may be not the true root cause. Because the BN detects the root cause by the probability of variables at abnormal state. In

present work, these drawbacks are overcome. The BN is constructed with application of TCCM to process data and expert knowledge. The alarm data is used to estimate the conditional probability among the nodes of the BN. After an important variable generates an alarm, the BN is used to find all the possible alarm propagation paths to the important variable. A root cause variable can be found at each path. TCCM is applied to find the causality between these root cause variables. Finally, a true root cause variable is found.

Our research aims to develop a comprehensive method that can precisely find the root cause of alarms. In the following section, we first introduce the basics of TCCM and BN. In Section 3, the proposed method is presented. In section 4, the proposed method is applied to the Tennessee Eastman model to illustrate the applicability. Finally, a conclusion is made.

2. TCCM and BN

2.1. Time-delayed Convergent Cross mapping

At first, the mathematical mechanism of Convergent Cross Mapping (CCM) is described. CCM is a powerful new methodological approach that can help distinguish causality from spurious correlation in time series from dynamical systems (Sugihara, May et al. 2012). The technique is based on the idea that causation can be established if states of the causal variable can be recovered from time series of the affected variable. CCM uses Takens' idea to detect if two variables belong to the same dynamical system.

CCM appears to be limited by the fact that it may not be able to distinguish between bidirectional causality and strong unidirectional causality that leads to synchrony. TCCM makes an extension to CCM that can resolve this problem: by explicitly considering different lags for cross mapping, it is possible to determine whether a driving variable acts with some time delay on a response variable (Ye, Deyle et al. 2015). The main idea is showed as Figure 1. The model is (1). The parameter embedding dimension E and time lag τ are important for TCCM. The value E is estimated by applying simplex projection to the individual time series and choosing the optimal E. Time lag τ is estimated by average mutual information.

$$\begin{cases} x_t = 0.1 * x_{t-1} + rnorm(0,1) \\ y_t = 2 * \mathrm{x}_{t-lag}{}^2 \end{cases} \tag{1}$$

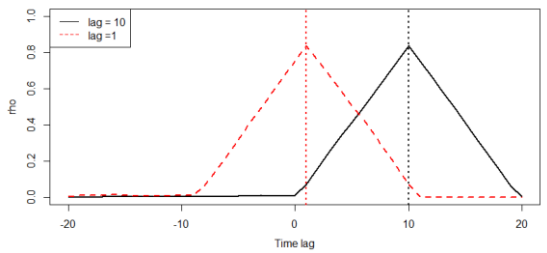

Figure 1: Calculate the correlation coefficient rho by shifting the lag between x and y. To the simple system, the time delay lag is the time lag at which the rho is maximum.

2.2. Bayesian network

A BN graphically shows the relationship among variables of a probability distribution. The BN contains two parts, a graphical structure that defines the qualitative representation and the conditional probabilities that define the quantitative representation. The BN is a directed acyclic graph (DAG). But there may be some loops at chemical plants. Cyclic networks are dealt with by transformation of cyclic networks to acyclic networks using dummy nodes.

3. Method

The overall picture of the methodology is in Figure 2. TCCM is applied for detecting causal relationship between variables and for construction of network. Knowledge of process is used to verify the constructed network. If the network contains a loop, a dummy node is created for one of the variables involved in the loop. Conditional probabilities among different nodes are the quantitative part of the network which is calculated using maximum likelihood method. More details on each part is presented in the application.

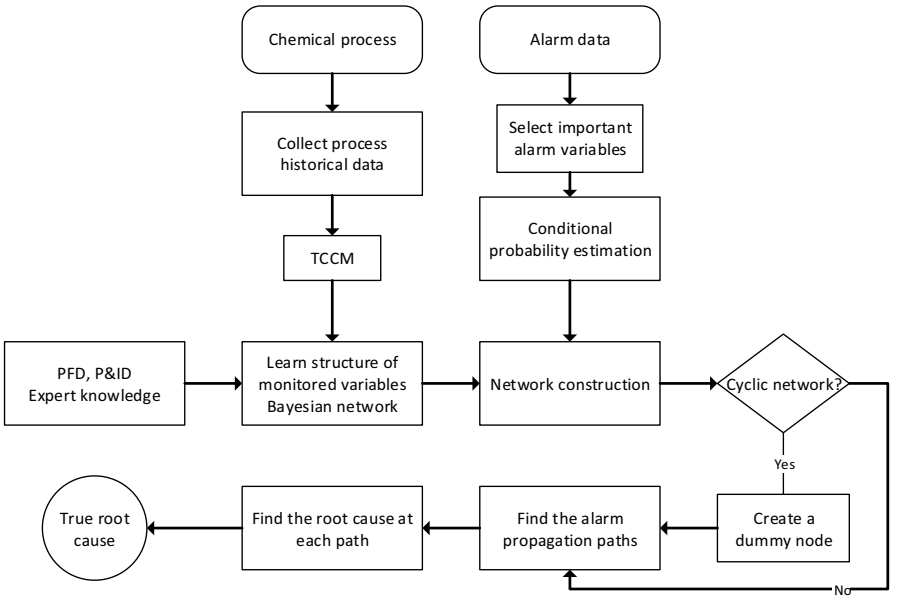

Figure 2: Proposed method for the root cause analysis of alarms

4. Application

To illustrate the applicability of the proposed method, the method is applied to the Tennessee Eastman model. The model consists of five major units: a reactor, condenser, compressor, separator, and stripper; and, it contains eight streams: A, B, C, D, E, F, G, and H. The flow diagram of this process is shown in Figure 3. It consists 41 measured variables and 12 manipulated variables. Among measured variables, 22 variables are continuous process variables and 19 variables are related to composition measurements. The 22 continuous process variables are shown in Table 1 that are the main focus of the

research (Ricker 1996). There are 20 potential faults in this model, a fault scenarios is studied at this paper.

The faulty scenario is a loss in feed A at 20 h. The sample interval is 0.01 h. This variation may change the process parameters in downstream units. The simulation stopped at 27.19 h. The data set consists of 2000 samples from normal data and 719 samples from the abnormal data.

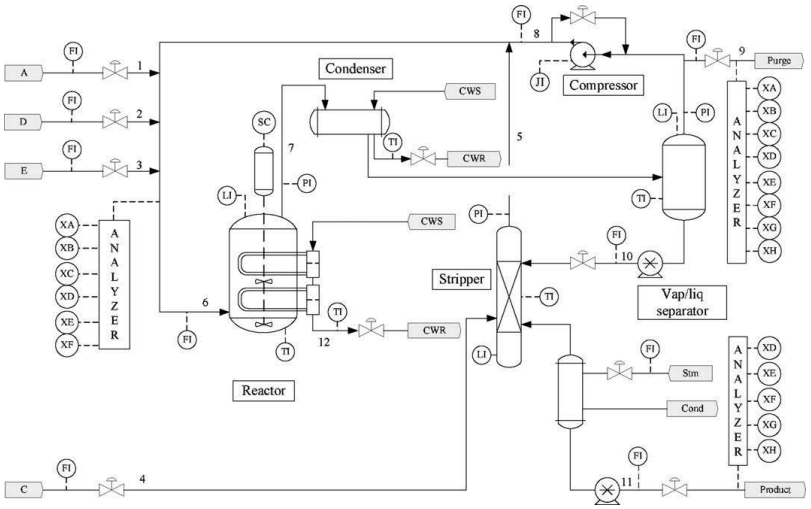

Figure 3: Schematic diagram of Tennessee Eastman model

Table1: Measured Variables in Tennessee Eastman model

Variable	Description	Variable	Description
XMEAS1	A Feed (stream 1)	**XMEAS12**	Separator level
XMEAS2	D Feed (Stream2)	**XMEAS13**	Separator pressure
XMEAS3	E Feed (Stream 3)	**XMEAS14**	Separator Underflow (Stream 10)
XMEAS4	Total Feed (Stream 4)	**XMEAS15**	Stripper Level
XMEAS5	Recycle Flow (Stream 8)	**XMEAS16**	Stripper Pressure
XMEAS6	Reactor Feed Rate (Stream6)	**XMEAS17**	Stripper Underflow (Stream 11)
XMEAS7	Reactor Pressure	**XMEAS18**	Stripper Temperature
XMEAS8	Reactor Level	**XMEAS19**	Stripper Steam Flow
XMEAS9	Reactor Temperature	**XMEAS20**	Compressor Work
XMEAS10	Purge Rate (Stream 9)	**XMEAS21**	Reactor Cooling Water Outlet Temperature
XMEAS11	Separator temperature	**XMEAS22**	Separator Cooling Water Outlet Temperature

The history process data is used to calculate the structure of BN by TCCM. The high alarm limit of each variable is the mean plus three times standard deviations of normal data. The low alarm limit of each variable is the mean minus three times standard deviations of normal data. The process variable can be transferred into three levels: low, normal and high. Reactor Temperature (XMEAS9) is selected as the important alarm variable. The samples when XMEAS9 is at abnormal state are used to estimate the conditional probability of BN. Tennessee Eastman model contains a loop. To deal with this issue, a dummy node is designed for the Recycle Flow (XMEAS5) involved in the

loop. GeNIe software is used to display and update the BN. The constructed network is showed in Figure 4. In this fault scenario, the XMEAS9 is at low level. So the probability of XMEA9 at low level is set 100%. Two alarm propagation paths found at BN is showed at Figure 5. A feed (XMEAS1) and Compress Work (XMEAS20) are the root cause at each path. To find the true root cause of alarms, TCCM is used to detect the causality between XMEAS1 and XMEAS20. The result is showed in Figure 6. From the Figure 6, XMEAS1 is the driving variable, and XMEAS20 is the response variable. XMEAS1 at low level is the true root cause of the alarms.

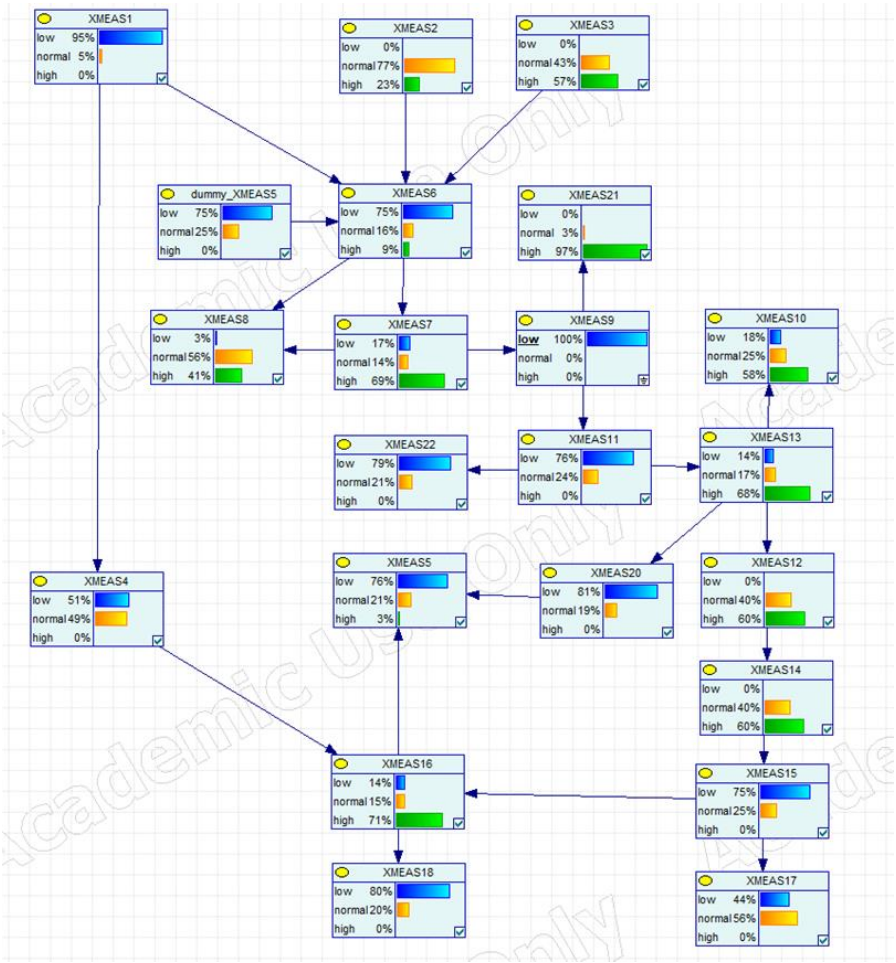

Figure 4: BN for Tennessee Eastman model

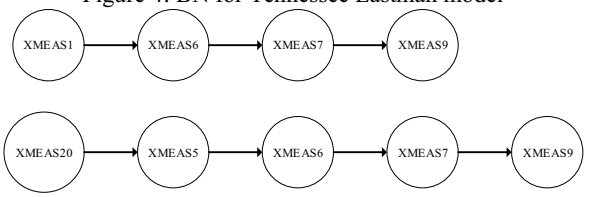

Figure 5: Two alarm propagation paths

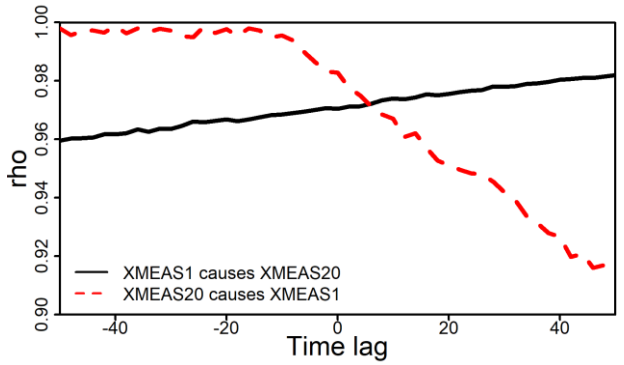

Figure 6: Calculate the correlation coefficient rho by shifting the time lag. In the full line, the time lag maximizing the rho is positive, which means XMEAS1 is the driving variable. In the dotted line, the time lag maximizing the rho is negative, which means XMEAS 20 is the response variable.

5. Conclusion

This paper integrates TCCM and BN to generate a comprehensive method for root cause analysis of alarms. The structure of BN was learned from the process data by TCCM. The proposed method was applied to the Tennessee Eastman model, and it showed a powerful diagnostic capability. The strength of proposed method is that it diagnoses root cause of alarm as well as shows the propagation pathway of the fault. This information will help operators to take correct action and recover the process quickly. However, most of chemical processes are working in dynamic condition. In such cases conditional probability of the BN will shift with time. So the dynamic BN should be implemented to handle this problem. This method needs more test with industrial data sets.

Abstract

As leakage seriously threaten the safety of chemical processes, the technology of image recognition based on Convolutional Neural Network (CNN) is used in this paper to probe the chemical leakage. First, the three-dimensional scenes of chemical process are built under normal working conditions and leakage conditions. Then, a CNN with 15 layers is established, including 3 convolutional layers, 4 activation layers, 3 pooling layers, 2 local response normalization layers, 2 fully connected layers, 1 dropout layer, respectively. After the network performance is optimized by adjusting the parameters and functions in each layer, the experimental results with accuracy of 95.82 % are obtained.

Keywords: convolution neural network; leakage; image recognition.

1. Introduction

During the process of chemical production, the corrosion widely exists in many materials, which will lead to not only the material leakage of production, storage, and transportation equipment in long-period operation, but also environmental pollution and material property losses. In some serious circumstances, it will cause fire, explosion and poisoning, endangering the safety of personnel. In practice, the monitoring equipment of chemical plant is widely used, which provides favorable terms for the identification of leakage condition by using image recognition technology.

Convolutional neural network (CNN) is one of the most effective methods for image recognition. CNN originates from the proposal of BP algorithm. In 1989, LeCun used it in multilayer neural network (LeCun et al., 1989). In 1998, LeCun proposed LeNet-5 model (LeCun et al., 1998) to complete the prototype of neural network. In the following ten years, the related research of CNN tends to stagnate. There are two reasons: the first one is that researchers realized that calculation of multilayer neural network in training BP is too large to complete by the limited computing ability of hardware; the second one is that the shallow machine learning algorithms like support vector machine (SVM) emerge gradually. From 2006, the CNN achieves rapid development again (Hinton and Salakhutdinov, 2006). In 2012, CNN won the ImageNet Championship, so the superior performance of ReLU activation functions in the network attracts people's attention (Krizhevsky and Sutskever, 2012). In 2014, Google developed a 20-layer VGGNet model. In the same year, the DeepFace and DeepID models were proposed, and the correct rate of face recognition and face authentication

on the LFW database was enhanced to 99.75 % (Sun et al., 2014; Sun et al., 2015). In 2015, LeCun, Bengio, and Hinton, who are famous in the field of deep learning, published a review of Deep Learning on "Nature" (LeCun et al., 2015). In 2016 AlphaGo defeated Li Shishi, and in 2017 AlphaGo defeated Ke Jie (Silver et al., 2016).

Due to the outstanding performance of CNN in image feature extraction, this paper applies CNN to identify chemical process leak. We used it to identify leakage in the chemical processes and obtained superior classification accuracy by adjusting its parameters.

2. The architecture of the CNN

CNN is a kind of multilayer neural network specially designed for processing two-dimensional data. CNN is considered to be the first truly successful deep learning method based on a multi-tiered hierarchical network. The close connection and spatial information between layers in CNN make it especially suitable for image processing and understanding. So it can automatically extract rich correlation characteristics from images.

CNN consists of convolutional layer, active layer, pooling layer, fully connected layer, and input-output layer. It owns structural characteristics like local connection, weight sharing, temporal or spatial sub-sampling, which make it superior in image recognition.

In this work, a CNN with 15 layers (except the input layer) is established, including 3 convolution layers, 4 activation layers, 3 pooling layers, 2 local response normalization layers, 2 fully connected layers, 1 dropout layer, and 1 output layer. The architecture of the CNN is shown in Fig. 1.

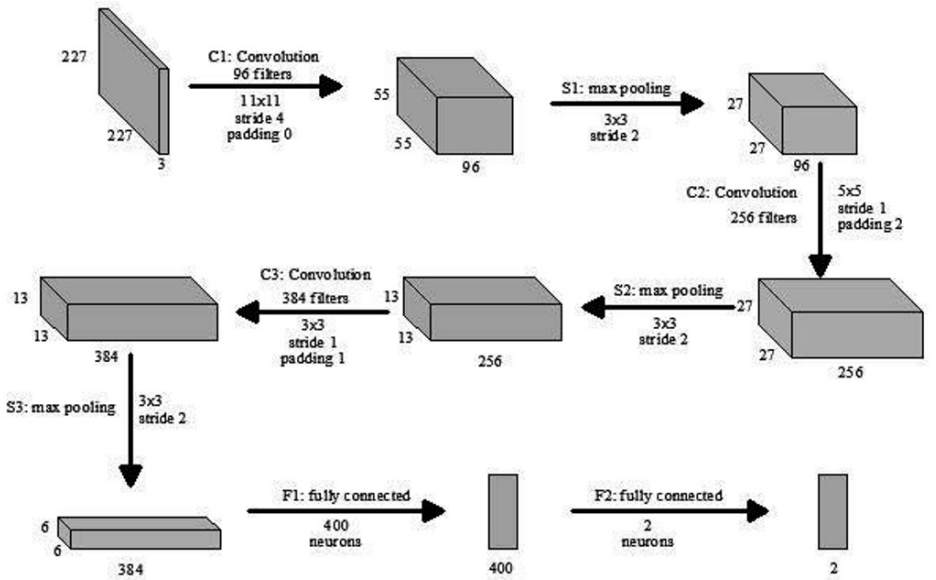

Figure 1. The architecture of the CNN

2.1. The input, output layer and fully connected layer

All the images are normalized into 227×227 pixels. Because the images are RGB images (3 channels), there are 227×227×3 inputs.

In Fig. 1, F1 layer is a fully connected one. It has 400 neurons, which are fully connected with S3 layer.

F2 layer is the output layer, also a fully connected layer. Because there are 2 kinds of images in total, the number of the output neurons amounts to 2. These 2 neurons are used to connect the 400 neurons in F1. We can then get 2 float typed prediction probability through Gauss filter.

2.2. Activation layer

There are four activation layers after C1, C2, C3 and F1, respectively. The activation layer injects nonlinear factors into the neural network to make the data distinguishable under nonlinear conditions (Nair and Hintion, 2010). In order to optimize the training result, we compared the effect of different activation functions on the classification accuracy.

2.3. Pooling layer

There are three pooling layers after the first three activation layers, as shown in Fig. 1. The first one is S1 layer. Its kernel size is 3×3， stride is 2. We get 96 feature maps with a size of 27×27. The second one is S2 layer, which kernel size is 3×3 and stride is 2. We can then get 256 feature maps with a size of 13×13. The third one is S3 layer, which kernel size is 3×3 and stride is 2. We can get 384 feature maps with a size of 6×6. In order to optimize the training result, the effect of different pooling methods on the classification accuracy should be compared.

2.4. Local response normalization layer and dropout layer

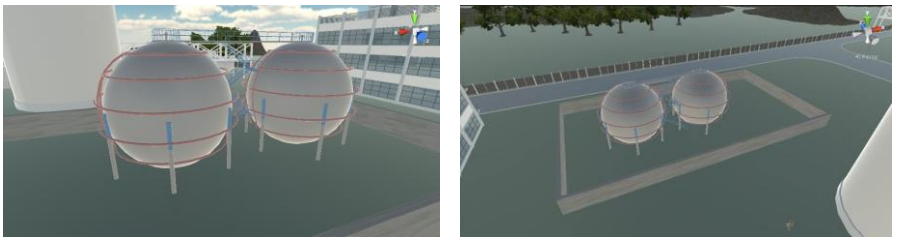
There are two local response normalization layers after S1 and S2, respectively. The role of the local response normalization layer lies in improving the recognition rate and increasing the generalization ability through smooth processing. The dropout layer is added before F2 to prevent the occurrence of over fitting.

3. Experimental results

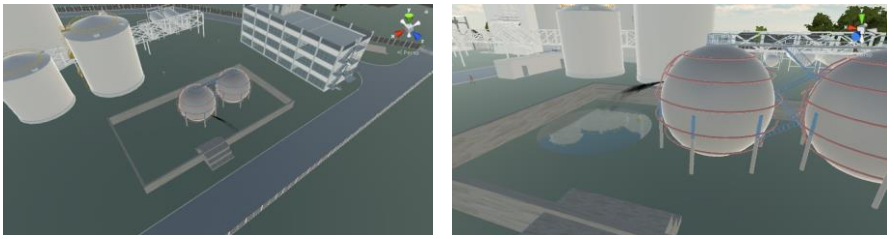
This paper mainly simulates the occurrence of a leakage accident caused by a crack in a liquefied hydrocarbon spherical tank. In practice, the microcrack source in the spherical tank gradually develops into macroscopic crack or penetrating crack, resulting in low-stress brittle fracture of the spherical tank. The leaked liquefied hydrocarbon absorbs the heat around it and vaporizes rapidly. It is easy to be ignited and leads to overpressure explosions at last.

3.1. Dataset

The scene picture of material leakage in chemical process is not easy to obtain, so this paper draws the scene picture in the chemical production process by using a 3D drawing software. We take the image interception from different angles, as shown in Fig. 2. A total of 1,477 pictures were intercepted with 1,190 (595 for normal working conditions and 595 for leakage conditions) as a training set and 287 (141 for normal working conditions and 146 for leakage conditions) as a test set. Then we normalize all the images to 227×227 pixels to enter the input layer.



(a) Normal working conditions



(b) Leakage conditions

Fig. 2 Schematic diagram of normal and leakage conditions

Table 1. The accuracy of the maximum pool method and the mean pool method

The number of iterations	MAX	AVE	The number of iterations	MAX	AVE
100	0.7561	0.7073	1100	0.9268	0.7456
200	0.7666	0.7282	1200	0.9373	0.777
300	0.8014	0.7456	1300	0.9477	0.7561
400	0.8014	0.7317	1400	0.9338	0.7666
500	0.8118	0.7596	1500	0.9477	0.7491
600	0.8676	0.7143	1600	0.9547	0.77
700	0.8293	0.7352	1700	0.9512	0.7735
800	0.885	0.7491	1800	0.9512++	0.7526
900	0.9303	0.7666	1900	0.9547	0.777
1000	0.9443	0.7526	2000	0.9582	0.7909

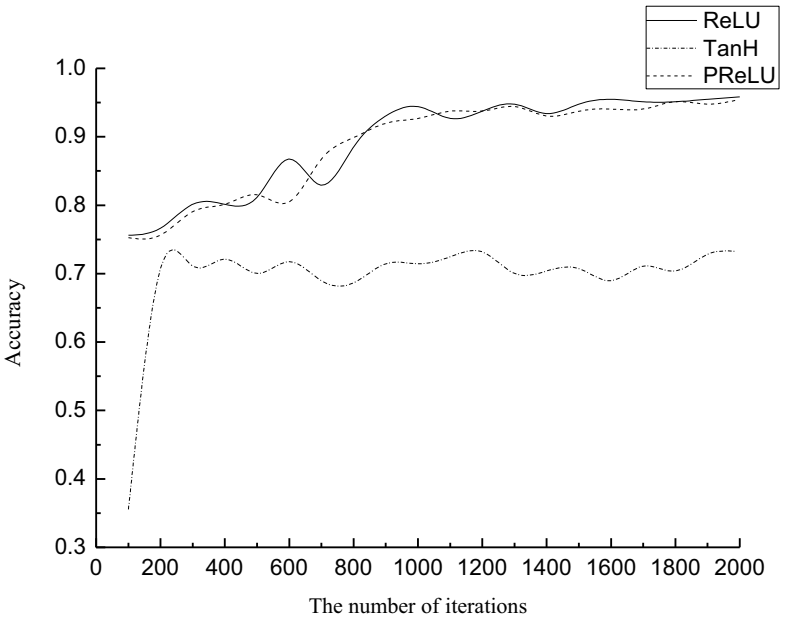


Fig. 3 Comparison between ReLU, PReLU and TanH

3.2. Network optimization

In order to optimize the training result, the effect of different pooling methods and activation functions on the classification accuracy are compared. As shown in Table 1, when the iteration number goes to 2,000 times, the accuracy of the maximum pooling method has reached 95.82 %, and the mean pooling method is only 79.09%. As can be seen from Fig. 3, the final accuracy of ReLU reached 95.82 %, PReLU reached 95.48 %, while TanH is only 73.17 %. With the increase of iteration times, the convergence rate of PReLU and ReLU is almost the same. Consequently, the maximum pooling method and ReLU activation function could make the classification accuracy higher.

4. Conclusions

This paper applies convolution neural network to image recognition of chemical process leakage. A 15 level convolution neural network is constructed. The influence of different pooling methods and activation functions on classification results is studied. The maximum pooling method and ReLU activation function was identified to make the classification accuracy higher. However, the image in this paper obtained by the 3D drawing software, is some different from the locale scene and needs to be further improved.

Abstract

Cyber security is currently a serious problem for not only office automation (OA) systems but also industrial control systems (ICSs). If ICSs are cyber-attacked, serious accidents such as explosions and leakage of harmful substances may occur. Therefore, cyber-security is a very important factor in discussing safety, and should not be considered separately. Risk analyses have been conducted in plant design and operation stage so as to avoid the risk to the operation of ICSs. However, since conventional analysis methods focus on the "equipment" and "products" of a plant, it is difficult to consider the upper layer system. In this paper, we suggest a risk assessment for safety that it is possible to link the physical processes and ICS. We propose a risk analysis method using the Systems Theoretic Accident Model and Processes (STAMP).

Keywords: Risk Analysis, Safety, Cyber Security, STAMP

1. Introduction

Industrial control systems (ICSs) are used for various kinds of social infrastructure, and they play important roles in realizing their control functions and ensuring their safety. ICSs currently use open architectures and they are often connected to external systems such as office systems. Most communication protocols for ICSs are designed without consideration of cyber security. By the appearance of Stuxnet in 2010, physical attacks due to cyber-attacks have become a reality.

Cyber-attacks against ICSs can directly affect physical objects, unlike attacks directed solely against information systems. Therefore, they have a high risk of causing accidents that are directly connected to disasters and that affect human lives. The accidents may occur not only in processes controlled by ICSs but may stop the services provided by them and also supply products that do not meet product requirements. For example, cyber-attacks against chemical plants can cause serious accidents such as explosions. Furthermore, accidents such as a loss of opportunity due to the interruption of the production and shipment of products containing harmful substances may happen. Therefore, to prevent such accidents, strengthening security against cyber-attacks that affect safety is an important issue. Therefore, safety and cyber-security must not be considered separately. Also, cyber-security must be considered based on countermeasure to prevent hazardous situations. To deal with such problem, risk analysis for safety must be expanded for enterprise systems.

2. Risk Analysis for ICSs

Problems that may occur from cyber-attacks against ICSs require consideration and countermeasures; these problems are "Inappropriate settings are given because of the rewriting of target values in automatic control systems," "Information related to automatic control and monitoring is tampered with and concealed by cyber-attackers," "Console operators and field operators cannot take appropriate actions because of falsification and concealment," and "Actions taken to remedy problems inadvertently cause more accidents."

Such problems may be caused by cyber-attacks not only at the site level where operators and field workers are but also at the upper layers of ICSs such as enterprise resource planning (ERP) and manufacturing execution systems (MESs). These problems may also affect other companies and regions through products and services.

In order not to cause the previously mentioned problems, the controlled process must also be protected from cyber-attacks. It is important to improve security by introducing security tools as countermeasures against cyber-attacks. However, we must consider the existence of numerous cyber-attack methods and zero-day vulnerabilities. Even if security tools are introduced, it is impossible to deny that the controlled processes are affected by expected attacks and that the countermeasures for security don't work well.

Therefore, on the premise that ICSs are vulnerable to cyber-attacks, maintaining system functions and business continuity for the whole structure of ICSs including their operation and management (which we call "whole ICS" in this paper) is necessary. It is also important to construct a whole ICS that can stop safely even when production is stopped for any reason. In order to construct such a structure, risk assessment for safety and security of the whole ICS is necessary.

3. Risk Analysis using STAMP

From the design stage to the operation stage in the plant life cycle, risk analysis methods such as hazard and operability (HAZOP) study and fault tree analysis (FTA) are used to analyze the latent risks in the plant. However, these risk analysis methods focus on "products" and "equipment" in the plants, it is difficult to expand the analysis targets to human systems and organizations with these methods. For example, in HAZOP study, due to characteristic that many experts analyze over a long period of time using P&ID, the discussion of countermeasures often ends with "Sound an alarm when detecting an abnormality." However, such countermeasures are scarce in terms of business continuity such as what is an alarm indicating what to do and who to respond. Therefore, it is insufficient to discuss business continuity when ICS is cyber-attacked.

To solve the problems described in Section 2, we consider the Systems Theoretic Accident Model and Processes (STAMP), which is the accident model proposed by Nancy G. Leveson et al., is useful for the purpose [1]. In STAMP, a system has components called a controller and its target process (controlled process). An instruction (control action) is sent from the controller to the controlled process, and reports (feedback data) from the controlled process to the controller are transmitted; thereby, a control loop is formed by the relationship. The control structure of a contemporary system whose control loop has accumulated many layers is described in the diagram. Furthermore, it is said that human systems and organizations can also be analyzed by dividing them into controllers and controlled processes.

When expressing whole ICS using STAMP, factories and plants are located at the lowest level of the control structure diagram. The control system and the production planning system are located at the higher level; furthermore, the management layer and regulations for the company are located at the higher level. With such a description, it is possible to hierarchically represent the mechanism of the entire system. In the conventional risk analysis methods, accidents are assumed to occur because of simple component problems such as a component failure or a single malfunction. On the other hand, STAMP extends the conventional analysis methods in which accidents can occur even if the behavior of components and mutual interference between components violate the safety constraints of the system.

However, detailed description of the component is not set in the original STAMP. Therefore, it is difficult to express clearly the concrete control structure of ICSs and relationship between physical processes, such as process flow. Also, it is difficult to make concrete discussions when considering the scenario leading up to the accident and measures to prevent it. We propose to express control structure by assigning "Possible Actions," "Accessible Information", "Prepared Information" as a role to each component. Possible Actions means a control actions that the component can do. Possible Actions is based on Accessible Information requested from other components and Prepared Information keeping itself. This proposal makes it possible to track interactions between components.

In this paper, we apply STAMP in order to improve the business continuity ability of the whole system including many hierarchies from the control site to management. We propose the following procedure for risk analysis using the extended STAMP which is previously mentioned.

Step 1: Identify risks that can occur in the control system to be analyzed

Step 2: Express the target control system using STAMP

Step 3: Assign "Possible Actions," "Accessible Information," "Prepared Information" as role to each component

Step 4: Derivation of scenarios leading up to accident and planning countermeasures

In Step 1, the analysts identify the risk of causing undesired events in the ICS to be analyzed. The result of the conventional risk analyses may be available. In Step 2, the structure of the entire system including management and operation of the control system to be analyzed is represented by the STAMP. Subsequently, the role is described in the diagram and the control structure is expressed in more detail. In Step 4, discuss scenarios leading to accidents from detailed diagrams and consider countermeasures. After that, the analyst adds countermeasures to the diagram.

We set the analysis target as a batch plant on the premise of flexible operation and organize the analysis procedure in the next section.

4. Case Study with Batch Plant

Even if the batch plant to be analyzed is connected by piping, it is possible to manufacture multiple products at the same time by using different tanks and transfer paths. However, by performing such flexible operation, a risk of contamination due to the mixing of different raw materials for manufacturing into tanks and transfer paths that are under different manufacturing process may happen. Also, contamination occurs even if the

material passes through tanks and transfer paths that are insufficiently cleaned. These contaminations not only cause problems for the quality of manufactured products, but also generate hazardous substances such as toxic gases because of mixing. In addition, the multipurpose batch plant is also required to realize new production by mastering general purpose equipment. On the basis of the above preconditions, we proceed with the procedure proposed in Section 3.

Step 1: Identify risks that can occur in the control system to be analyzed

In this step, analysts identify potential risks. For example, the risk of contamination can be considered as follows.

A) Contamination due to insufficient cleaning inside of tanks and piping

B) Contamination due to incomplete blocking between processes

Step 2: Express the target control system using STAMP

In Step 2, analysts represent the batch plant and the control structure of the whole system that uses it in the STAMP. In this paper, with reference to the S95 standard [2] [3], we created a diagram of the whole system of a batch plant including management (as shown in Figure 1).

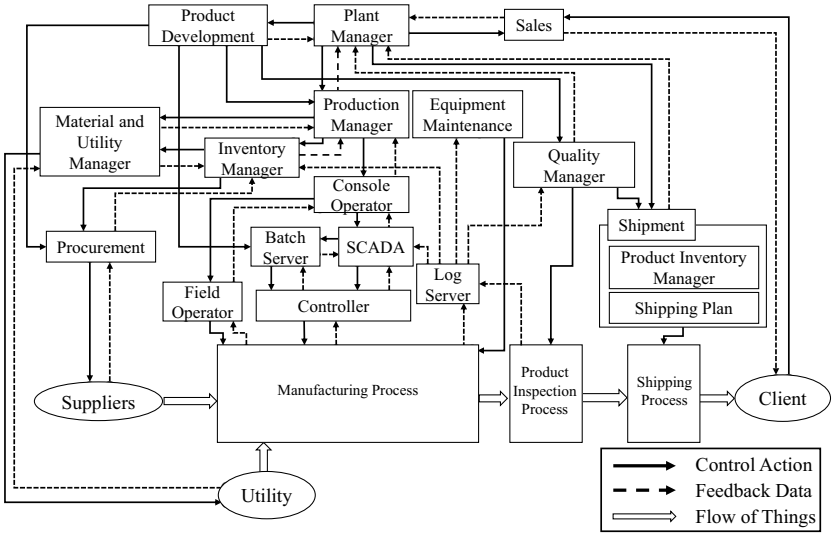

Figure 1: Control Structure Diagram of Batch Plant

Step 3: Assign "Possible Actions," "Accessible Information," "Prepared Information" as role to each component

In this paper, we focus on the range shown in Figure 3 among the control structure and discuss it. However, we thought that a more detailed diagram is necessary for analyzing a batch plant controlled based on recipe, and described the components of the Controller and the Batch Server in more detail (as shown in Figure 2).

Step 4: Derivation of scenarios leading up to accident and planning countermeasures

With reference to Figure 2, we explain the derivation of the scenarios leading up to the

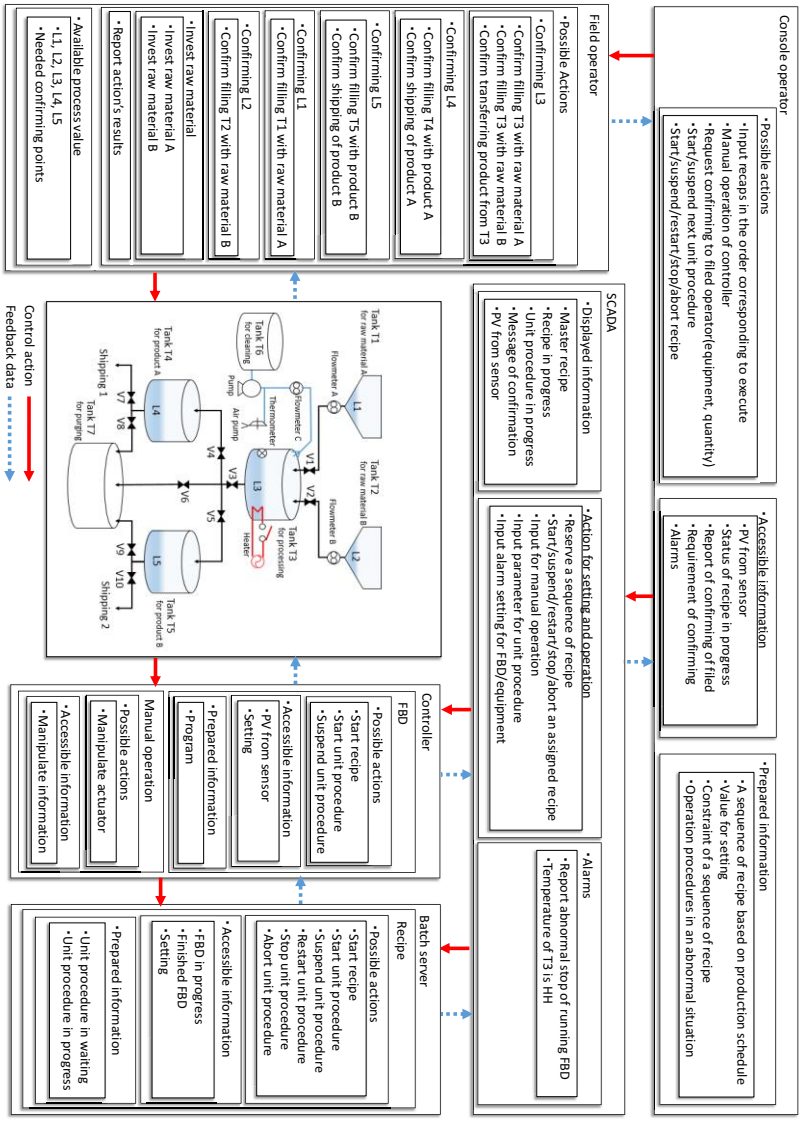

Figure 2: Control Structure Diagram Assigning Roles to Components

accident and countermeasures using “A) Contamination due to insufficient cleaning inside of tanks and piping” as an example. If there is an inadequacy in the execution of the recipe to be cleaned, the Controller recognizes it and the report it to the Batch Server. The Batch Server compares the report with “Unit procedure in progress” as Prepared Information, and reports it to SCADA. SCADA, which is the monitoring screen, alarms the Console Operator for inaccuracies. The Console Operator can execute “Manual Operation of controller” as Possible Action by comparing “alarm” and “recipe execution state” as Accessible Information, and furthermore, “emergency response operation procedure” which is Prepared Information. Therefore, from Figure 2 and the scenario, it can be interpreted that an accident will occur if any one of these interactions fails. In this way, by implementing the suggested expression of roles, it is possible to discuss the

scenarios that the operation for safety is performed and the ones leading to accidents. After that, countermeasures are planned from the scenario. In this case, it is effective to monitor the behavior by comparing the execution status of the cleaning recipe with the sensor's value, in consideration of the situation where the cleaning incomplete alarm does not function properly. This countermeasure builds a system that console operators can notice abnormality and respond.

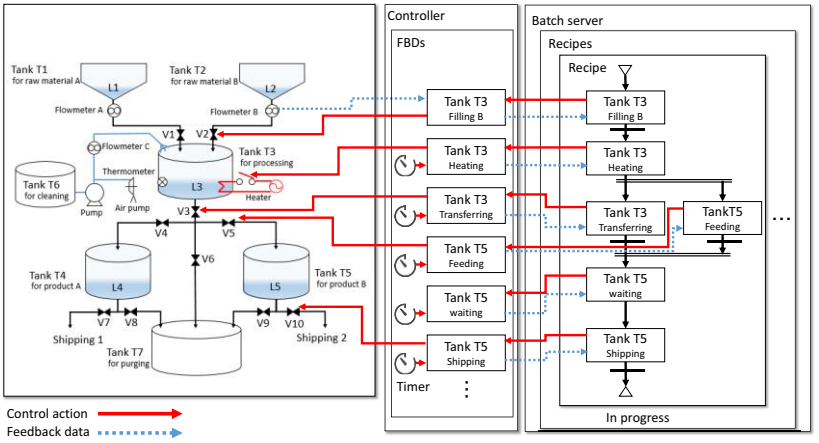

Figure 3: Control Structure Diagram in More Detail

5. Conclusion

In this paper, we suggest that risk assessment for safety and business continuity is important on the premise that ICS systems are threatened by and vulnerable to cyber-attacks. It is necessary to extend the conventional risk analysis methods so that upper layers of management and operation can be analysed. We proposed a procedure for creating a diagram and discussing it by using the STAMP. Also, we are expecting that it is possible to discuss cyber-security by extending this method. If we use the diagram where physical process and ICS are linked like this, we should be able to discuss appropriate network division against cyber-attacks [4].

Parameters determination of Convergent Cross Mapping for causal analysis of chemical variables

Si Meng Li, Tong Qiu*

Department of Chemical Engineering, Tsinghua University, 100084 Beijing, China
** qiutong@tsinghua.edu.cn*

Abstract

Causal analysis of chemical variables is important for safe and efficient operation of chemical processes. Convergent cross mapping (CCM) proposed recently is suitable for nonlinear systems and can calculate the time delay and causal relationship between variables accurately. However, CCM has not been directly applied for causal analysis of chemical variables, because it does not have an algorithm for calculating phase space reconstruction parameters. In this paper, the optimal parameter algorithms are selected to improve CCM, greatly expanding CCM for analyzing causal relationship of chemical variables. Finally, using Tennessee Eastman model, it's proved that CCM with optimized parameters can basically get the causal relationship network more efficient than the original CCM and transfer entropy method.

Keywords: Convergent Cross Mapping; Phase space reconstruction; Takens theory; Embedded dimension; Time delay interval

1. Introduction

Causality inference and root cause analysis are important for fault diagnosis in the chemical industry. Many methods have been discussed to resolve causal analysis between variables, such as Directed Transfer Function (DTF), Bayesian Nets (BN), Transfer Entropy, Granger Test and etc.-DTF proposed in 1991 only applies to linear systems. BN has high stability requirements for the data at the same time, limiting the scope of application in engineering. Granger Test requires a linear relationship between variables. Transfer Entropy relative to these algorithms can be used for nonlinear system data analysis, but it is computationally expensive, inefficient and highly dependent on the probability distribution density of data (Luo L et al., 2017). Chemical processes are non-linear, multivariate processes, so above methods are not suitable enough.

Convergent cross mapping (CCM) (G. Sugihara et al., 2012) introduced by Sugihara et al. is a technique for computing specific kinds of correlations between sets of time series and is reported to be "a necessary condition for causation" capable of distinguishing causality from standard correlation, intended to be useful in situations where Granger causality is known to be invalid (Luo L et al., 2017). However, it cannot be directly applied to chemical processes. Causal relationship between chemical variables is mostly non-linear because chemical process system is a multi-dimensional and nonlinear causal system. And data sampling intervals of different chemical plants are different, resulting in the diversity of chemical data. These two characteristics limit CCM applied to the chemical industry variables.

The main principle of CCM algorithm is to reconstruct the phase space of the time series according to Takens reconstruction manifold affine theorem, and then make a predictive

analysis of the causal relationship between the time series. In this paper, it'll be shown that the selection of phase space reconstruction parameters which are embedding dimension-E and time delay interval-τ has a great influence on the prediction effect of CCM, and it's important to specify the method for determining these parameters.

2. The reconstruction parameters of CCM

Takens reconstruction theorem is a delay reconstruction (Takens F, 1981). The principle of time delay reconstruction is to project each column $X(t), Y(t)$ in the original manifold $M = [X(t), Y(t)]$ to a one-dimensional space, and then take out the individual element at τ intervals and form the E-dimensional matrix to reconstruct the shadow manifold. E and τ mentioned here are two important parameters. The expression for reconstructing the vector is as follows:

$$M_x = [X(t), X(t+\tau), X(t+2\tau), \cdots, X(t+(E-1)\tau)] \tag{1}$$

$$M_y = [Y(t), Y(t+\tau), Y(t+2\tau), \cdots, Y(t+(E-1)\tau)] \tag{2}$$

Taking the Lorenz equation as an example, take the parameters $b = \frac{8}{3}, r = 28, \sigma = 10$,

$$\frac{dx}{dt} = -\sigma(x-y) \quad \frac{dy}{dt} = rx - y - xz \quad \frac{dz}{dt} = xy - bz \tag{3}$$

The following figure is the original manifold and shadow manifold. It's shown that the original manifold and shadow manifolds are diffeomorphisms. There is a continuous injective relationship between the shadow manifolds M_x and M_y. If all $x_{t,i}(i = 1 \cdots k)$ converge on a particular $x_{t,0}$, then $y_{t,i}(i = 1 \cdots k)$ also converge on the corresponding $y_{t,o}$.

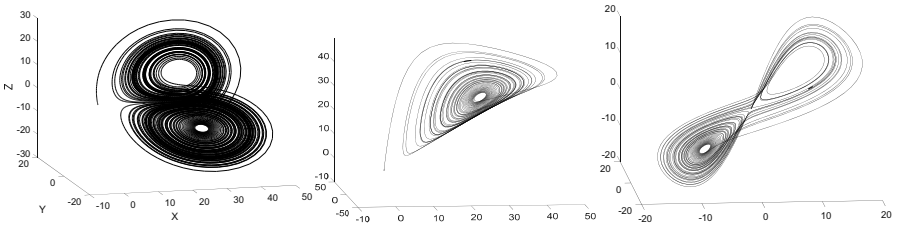

Figure 1. The original manifold and shadow manifold

CCM predicts causality by measuring points on the shadow manifold (G. Sugihara et al., 2012). So the effect of reconstruction phase space directly affects the accuracy and computational efficiency of CCM calculation results. And the effect of reconstructing phase space is related to the parameters E and τ.

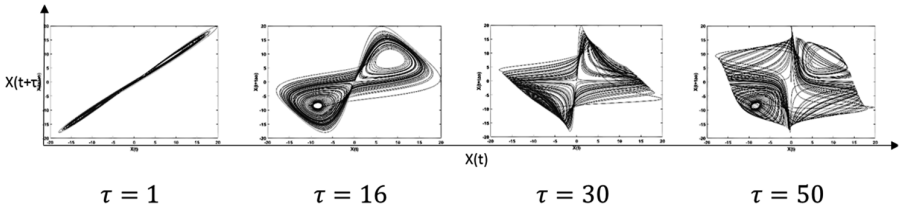

Figure 2. Reconstruction manifold changes with τ

Fig. 2 shows the influence of time delay interval τ on the manifold. As the value of τ increases, the change of the attractor of the reconstructed manifold is as shown. Whether the value of τ is too large or too small, it will make the reconstruction of manifold can't reflect the mutual information of original system well.

As for embedded dimension E, it will increase the amount of computation if the value of E is too much. And it will reduce calculation accuracy if the value of E is too small. As mentioned earlier, the chemical data is multi-dimensional, the data interval varies with the sampling interval. But in the original CCM algorithm, the values of the parameters are fixed and do not change with the input data, which are not always the best for each pair of data. The work of this paper is to propose a method to calculate the optimal parameter E and τ.

3. Algorithm to determine the parameters

In this paper, algorithm to determine the parameters of CCM is improved to make them more suitable for calculating chemical variables.

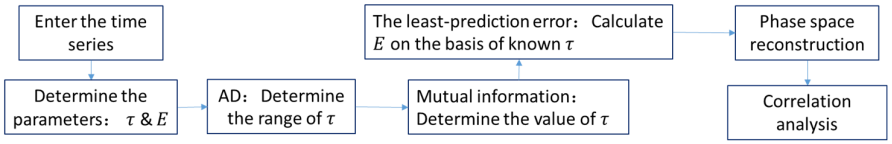

Figure 3. Flow chart of algorithm to determine the parameters

3.1. Average Distance: determine the range of τ

In our approach, Average Distance (AD) is mainly used as the initial treatment of time series (Harman E A et al., 1989). The basic principle of choosing τ is that the original sample sequence $X(t)$ and its delay sequence $X(t+\tau)$ are independent but not irrelevant completely, so that $X(t)$ and $X(t+\tau)$ can be treated as independent coordinates in phase space reconstruction. By measuring the degree to which the trajectory of the reconstruction state space opens from the main diagonal of the state space, quantitative reduction of the redundancy error as τ increases is quantitatively described, ie, the change of the average displacement

$$S(E,\tau) = \frac{1}{N}\sum_{E,n=1}^{N_E}\sqrt{\sum_{l=1}^{E-1}\left(x(n+l\tau)-x(n)\right)^2} \tag{4}$$

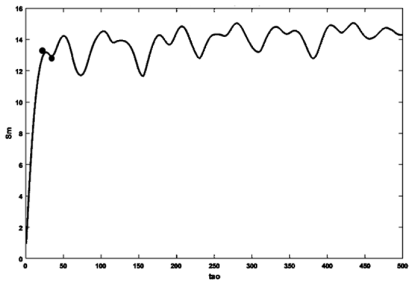

Figure 4. The average displacement curve.

Take the first extremal interval where the slope of $S(E,\tau)$ changing with τ as the feasible interval of delay time, that is, the τ value is in this interval. Fig. 4 is the average

displacement curve made using Lorenz system data, which is the feasible interval between two circles.

3.2. Mutual Information: Determine the value of τ

The related entropy between two random variables is called mutual information (Fraser A M, 1986), which is a measure of the randomness of Y when X is known, or a measure of the randomness of X when Y is known. Mutual information function:

$$I(X,Y) = H(X) + H(Y) - H(X,Y) \tag{5}$$

After reconstructing the phase space, the mutual information curve with the change of τ between the adjacent vectors is made. When the curve is reduced to the minimum for the first time, τ is the best result.

We only need to calculate the mutual information corresponding to the value of τ in the extremal interval determined by AD method, so as to improve the calculation computational efficiency and accuracy.

3.3. Least-prediction Error : Calculate E on the basis of known τ

The algorithm that is chosen to determine E is the Least-prediction Error method (Cao L, 1997), which is selected by comparing the results of various algorithms in our study (Simeng Li, 2017). The principle of the algorithm is to avoid the intersection of the orbit of the phase space and itself when reconstructing. The algorithm is more computationally efficient than the other methods [6]. It can be used to calculated E after knowing time delay interval τ, the specific calculation process reference literature (Cao L, 1997).

The parameters of the reconstructed phase space have all been determined, and phase space reconstruction and correlation analysis can be performed. In this paper, the CCM using the parameters calculated by above algorithm to reconstruct the phase space is called the improved CCM.

4. Example systems

This paper uses Tennessee Eastman (TE) model to verify the improved CCM. TE simulation process characterizes the condition by 41 measured variables, detailed description of the process and model establishment can be found in Tian et al (1993).

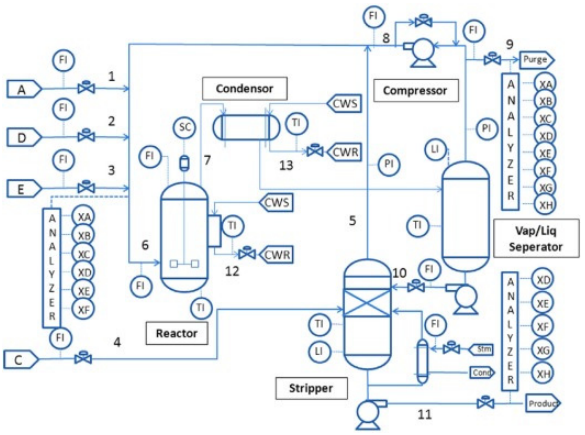

Figure 5. Flowchart of the Tennessee Eastman process

Measurements 1 to 22, which are process variables such as flowrates, the temperature, the pressure, and the liquid level, are considered in this case. In the steady state, a normal-distribution random number is added to the steady-state data to simulate the noise in the actual working condition. The figure below is the outputs of the data in steady state, each variable output by the TE model has its own weak fluctuations because of the added noise. The existence of these fluctuations makes the causal relationship between each other can be detected by the improved CCM algorithm. The algorithm can obtain the causality between variables in TE model according to the steady-state data with noise, which shows the sensitivity of the improved CCM algorithm.

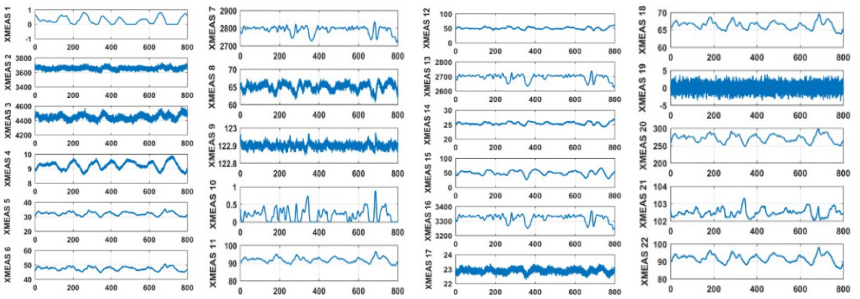

Figure 6. Outputs of the Tennessee Eastman process

We performed a correlation test on steady-state data and compared the results with those of the original CCM program. The data named causality in the table show the existence and strength of causality between variable A and variable B. The causality shows the correlation calculation results, the larger the value of causality, the stronger the correlation. And the causality is over 0.5 indicating that there is a correlation between this two variables (G. Sugihara et al, 2012). As for results of the improved CCM, there are 231 results of the calculation, of which 189 are over 0.5, indicating there are causal relations in 189 pairs of data.

Table 1. Causal relations calculated in TE process

Variable $\boldsymbol{A}$	Variable $\boldsymbol{B}$	$\boldsymbol{E}$	$\boldsymbol{\tau}$	Causality $\boldsymbol{A \rightarrow B}$	Causality $\boldsymbol{B \rightarrow A}$	Causality (the original CCM)
A feed (stream 1)	Reactor feed rate (steam 6)	6	13	0.875	0.349	0.021
D feed (stream 2)	Reactor feed rate (steam 6)	6	13	0.819	0.425	0.037
E feed (stream 3)	Reactor feed rate (steam 6)	6	21	0.833	0.695	0.101
Reactor feed rate (steam 6)	Reactor feed rate (steam 6)	6	25	0.546	0.255	0.002
Reactor feed rate (steam 6)	Reactor level	5	13	0.734	0.352	0.009
Reactor temperature	Reactor cooling water outlet temperature	5	20	0.632	0.655	0.013
Product separator under flow (stream 10)	Stripper level	6	19	0.726	0.407	0.243
Stripper underflow (stream 11)	Stripper level	5	23	0.652	0.294	0.044
Stripper steam flow	Stripper temperature	6	30	0.622	0.388	0.000

Table 1 are part of results calculated by the improved CCM and the original CCM. The original CCM takes $E = 3, \tau = 1$. Shu (2013) points out that the causal relations list in

table 1 should exist according to inference but have not been captured by Transfer Entropy. The method proposed in this paper successfully solves this problem. All of these relationships can be calculated by the improved CCM algorithm from Table 1.

And compared with the calculation results of the original program, it can be seen that the causality calculated by the original CCM program is nearly 0, which is that the correlation is not detected at all. It indicates the improvement of the original CCM in this paper is successful and meaningful.

The improved CCM algorithm in this paper is more suitable for the chemical system than both the original CCM program and the transfer entropy algorithm. What's more, it is worth mentioning that the computational efficiency of the original CCM program is roughly 6 times that of the improved program.

5. Conclusions

As a correlation detection algorithm, CCM has been widely used in many fields. Chemical process is a time-lag and non-linear system and can't directly use the CCM program. The innovation of this paper lies in the combination of AD algorithm, mutual information and the least-prediction error to calculate the parameters of reconstructed phase space. The CCM algorithm is optimized to improve the accuracy and efficiency of the calculation, so that the correlation between chemical variables can be measured. Finally, an example of TE process verifies the effectiveness of this method, which shows that this method can calculate the correlations of steady-state data which can't calculate by the original CCM and Transfer entropy.

Abstract

Human operator performance is a key factor for proper operation of safety critical industries like process control, nuclear power plant and aviation. Several incident reports identify human error as one of the causes responsible for accidents. One way to reduce human error is to impart proper operator training which requires understanding how operators learn during training. Traditionally, learning is evaluated on the basis of subjective assessments and outcomes of the task execution. It obscures the cognitive aspect of the learning process like understanding how operator gives attention to various information sources and develops the process of decision making during the training program. In this study, we use pupil size measurement from eye tracking system to study and understand learning as participants undergo repetitive trials of simulated flight operations tasks. A derived measure based on time-frequency analysis of pupil size variation is observed to be sensitive to the process of learning during task repetition. We observe improvement in the task performance accompanied by the decrease in the proposed measure.

Keywords: Eye tracking, training, learning, pupillometry

1. Introduction

Safety has been one of the prime areas of interest for industries like process control, nuclear power plant and aviation as they are aggravated persistently by large-scale accidents despite many interventions. For instance, on a statistical basis, of the 20 accidents that have led to the largest property damage losses in the hydrocarbon industry in the 40 year period from 1974 - 2013, 25% have occurred in the last 5 years from 2009 (Marsh, 2014). Flight businesses relating to the UK fixed-wing general avionics reported 1007 incidents in the years from 2005 to 2011. The analysis of which revealed 49.7% resulted from the loss of control (LOC), 69.2% of these occurring during the landing phase (Taylor et al., 2014). A detailed analysis of various incidents reveals that human error is one of the principal causes for failure to control the situation during abnormal condition.

Human operator's ability to successfully handle an abnormal scenario plays a significant role in deciding the magnitude of such industrial accidents. Hence, the decision making and the cognitive information processing skills of an operator needs to be advanced to reduce or eliminate effects of such incidents. Experts in safety critical domains suggest the need for appropriate training for operating personnel to manage the abnormal situation (Bullemer and Nimmo, 1994). It is therefore important to develop training programs with an emphasis on the cognitive abilities of the operator, and tailor

training tasks for the operators so as to impart an adequate mental model of the situation that can help in their decision-making process. Traditionally, operator training simulators (OTS) provide the trainee operator to understand and be acquainted with the simulated environment that mimics the "look and feel" of the situation. Research attention has been focused on developing comprehensive training simulators that can mimic plant behavior in different operating conditions and abnormalities (Patle et al., 2014). However, there are hardly few approaches that focus on understanding their learning process, identified as crucial to enhancing operators' skills and abilities (Bullemer and Nimmo, 1994). The conventional approach to evaluate learning is through means of subjective assessment of the imparted knowledge about the task and scenario. The process lacks understanding of how operator gives attention to various information sources and develops the process of decision making during the training program. Recent studies emphasize that use of virtual reality for training operators has been claimed to improve operator's cognitive readiness (Manca et al, 2013).

Much like control room operators in process plants, pilots in aviation industry are required to continuously monitor the state of the system, analyze the information and take necessary control actions. In both the settings, the operator/pilot processes information acquired from the HMI, assesses the situation and decides on the appropriate future actions. Similar issues of improper cognitive processing and resulting human error are also found in pilots (Miller and Parasuraman, 2007). The pilot error (also known as cockpit error), usually defined as the error caused due decision, action or inaction by the pilot is determined to be the major cause for loss of control during flight operation (Belcastro and Fostar, 2010). Sarter et al. (2007) have used eye tracking to understand shortcomings in pilot's automation monitoring strategies and corresponding performance. They confirm that monitoring failures are one major contributor to breakdowns in pilot-automation interaction. Di Nocera et al. (2000) used the distribution of fixation on HMI to evaluate pilot's mental workload during the different phase of flight. The study reveals landing phase of the flight operation requires high mental workload demand which may prone to error during these phases. Kilingaru et al. (2013) analyzed the visual scanning behavior using gaze attentional strategies for the expert and novice pilot. The study indicates the existence of the difference in visual attention behavior for novice and expert pilots. The experts (highly trained) tend to focus on the more relevant instrument with frequent and small dwell compared to the novice (less trained) failing to give proper attention to the relevant instrument. Many other studies have utilized eye tracking to understand the cognitive behavior of the pilots. However, less effort has invested to understand the learning process as the novice pilot repeatedly undergo the flight operation. In this study, we used the derived measure from time-frequency analysis of pupil size variations to understand the pilot's learning behavior with the repetition of the experimental trials. The magnitude of power in the low-frequency spectrum corresponds to workload and various affective states like stress, anxiety, fatigue which potentially affects the human operator's performance. (Yamanaka and Kawakami, 2009). The high power level in the lower spectrum (0-0.7 Hz) corresponds to higher workload and presence of affect states (Lüdtke et al.,1998). The repetition of trials reduces the workload as the participants learn and adapt to the situation present in the scenario (Foroughy C., 2017). We analyze the power level in the low frequency spectrum of pupil size variation

as the participant performs the repeated trials of landing procedures with varying level of difficulties.

2. Experimental methodology and data analysis

We conducted an experiment with two participants who voluntarily participated in the study and played the role of a pilot for the flight simulator. Participants are the graduate students who have no prior experience of the flight simulator and its operations. The simulator consists of one training task followed by actual experimental tasks. Participants can repeat the training tasks until they become ready to perform the actual experimental tasks. The experimental tasks involve take-off phase, cruise phase and landing phase with varying level of difficulties. The difficult tasks involve landing in the hilly region (task 2 and task 3) or urban region with a sheer position of runways (task 4) whereas easies task contains the landing in the coastal area with relatively less requirement of proper altitude control (task 1). Each participant has performed all the four tasks five times with eye tracking. Standard nine-point calibration is presented before the start of the experimental tasks in order to ensure the proper quality of gaze and pupil data collection. The eye gaze data and pupil data are collected at 120 Hz with the use of Tobii TX300 eye tracking system.

The pupil diameter collected as a time series is first processed to remove the blink artifacts. The consecutive invalid entries of the pupil size for more than 100ms are treated as the blinks and removed for further analysis. This is followed by the calculation of spectrogram of the valid entries of the pupil data using Matlab. Moving window of 720 samples with an overlap of 700 samples is selected to calculate the spectrogram. The values of the power levels at different frequency components in each time window are considered to calculate the area under the power spectral density. The power levels in the frequency bands between 0-0.7 Hz are added to manipulate the value of the measure for each window. The measure is then normalized with respect to its maximum and minimum values across all the tasks performed by a particular participant. The measure of normalized area under the power spectral density (APSDn| f=0-0.7 Hz) is considered to evaluate the learning in this experiment.

3. Illustrative Example

Figure 1(a) shows the spectrogram for a typical task containing take-off phase, cruise phase and the landing phase. It contains the majority of the power level within 0-0.7 Hz for all the windows. The normalized area under the power spectral density ($APSDn_{| f=0\text{-}0.7\ Hz}$) of the first participant while carrying out the first trial of task 2 is shown in figure 1(b). The maximum value of the measure (1.00) is observed to occur during the landing phase between t=100 s and t =110 s. The participant would have faced high workload demand since they were not aware of the situation present in task 2 during the first trial which has resulted in the failure. Figure 2 shows the values of the measure with time for the same participant performing the same task during fifth trial. The participant succeeds in the fifth trial of task 2 and the corresponding maximum value of the measure reduces to 0.78 between t=80 s and t=90 s. It is expected that the participant would have learned how to handle the scenario of task 2 with repetitive trials culminating in successful completion in the fifth trial accompanied by the reduction in the maximum by 22%. However, single task of success and failure are not sufficient to indicate the process of learning hence all the task performed by both the participants are analyzed in detail in the next section.

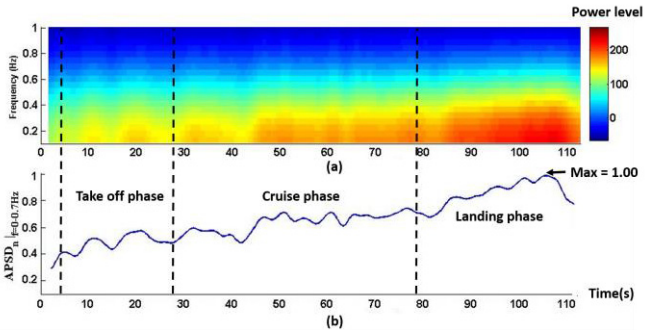

Figure 1:(a) A typical spectrogram of the pupil size variations during task execution (b) Normalized area under the power spectral density during trial 1 of task 2 for participant 1

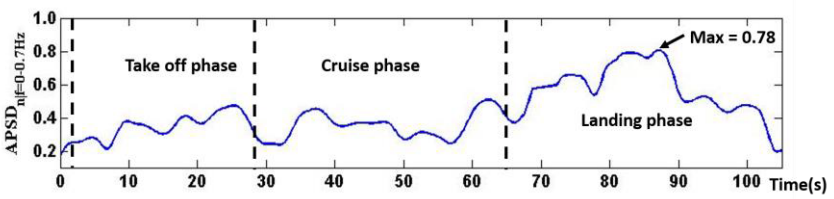

Figure 2: Normalized area under power spectral density during trial 5 of task 2 for participant 1

4. Analysis of all tasks

In this study, the landing phase is considered and the maximum value of the measure during this phase is analyzed to observe the effect of learning through task repetition. The maximum value of the measure represents the peak demand exhibited by the participant during the course of task execution. The peak demand decreases as individual learns through repetition of the same task. It leads to decrease in the maximum value of the measure during the task execution. Foroughy C. et al (2017) have observed the decrease in the maximum value of the pupil size to analyze the learning through repetition in case of target identification task with the unmanned aerial vehicle.

Figure 3(a) and figure 3(b) show the bar graph representing the maximum of the measure in each of the trials for participant 1 and participant 2 respectively. The character "S" and "F" on the top of each bar represent the success and failure of the task respectively. The improved success rate in consecutive trials of a particular task has been considered as an indication of learning. The success rate is compared with the maximum of the measure to verify the sensitivity of the measure in the evaluation of learning process.

Analysis for participant 1:

Participant 1 has not succeeded in any of the tasks during the first trial and correspondingly the maximum value of the measure is also observed to be the highest during these trials. However, task 3 does not exhibit this pattern. This participant has succeeded in the subsequent trials of task 1 and task 4 and this is reflected as a reduction in the maximum value of the measure during these tasks. The trend of the proposed measure, therefore, provides an indication of the participant's learning to handle the scenario for these two tasks. The maximum value of the measure is observed to fall from 0.85 in the first trial to 0.58 in the fifth trial of task 1. Likewise, the maximum value of the measure has reduced from 1.00 in the first trial to 0.81 in the last trial of task 4. The maximum is observed to increase for the third trial of task 2 which can be attributed to

the difficulty faced by the participant in learning and handling the scenario. The participant has succeeded in the subsequent trials which are accompanied by the fall in the maximum values. For task 3, the participant has failed in the first three trials and the highest has occurred at trial 3. Though the participant has succeeded in handling the task 3 in fourth and fifth trials, the maximum of the measure does not observe to reduce which may indicate high workload demand for him to handle the scenario of task 3. This indicates the sensitivity of the measure for the participant's ability to adapt to the scenario which may not be revealed directly through the final outcome of success or failure.

(a) (b)

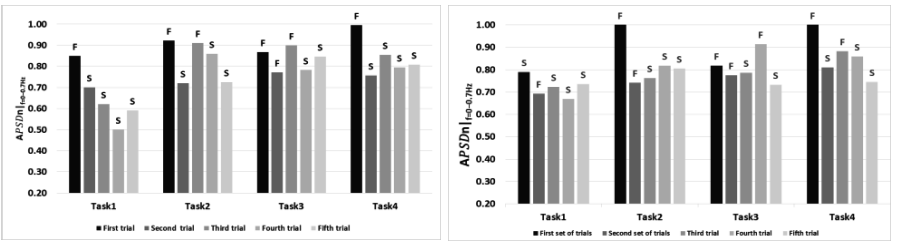

Figure 3: Maximum of the measure during each task for participant 2

Analysis for participant 2:

The maximum of the measure exhibits similar behavior for participant 2 for the first trial tasks. For task 1, the participant has succeeded in 4 out of 5 trials and the corresponding maximum value has also reduced from 0.79 in trial 1 to 0.74 in trial 5. The maximum of the measure in task 2 has also observed to be reduced from 1.00 during trial 1 to 0.80 in trial 5. Similarly, for task 4, the participant has succeeded in last two trials and the corresponding maximum value has reduced to 0.74 during trial 5 compared to 1.00 during trial 1. Like participant 1, task 3 has also more failures (3 out of 5 tasks) and correspondingly the maximums of the measure do not contain the consistency with the performance in successive trails.

Due to the small sample size, a paired t-test is performed to compare the mean difference between the first and the last trial of each task ($t=4.79$, $DOF = 7$, $p<0.01$). The decrease in the mean value (Mean $APSD_n$ during the first trials = 0.90, Mean $APSD_n$ during the last trials = 0.74) of $APSD_n$ during the last trial indicative of the effectiveness of the technique to evaluate learning.

5. Conclusion

The effectiveness of operator training is a crucial aspect of safer operation in safety critical domains. Traditional techniques to evaluate learning process involve subjective measures based on the knowledge and ability to perform the certain task successfully which obscures the cognitive aspect of the task performance. Use of eye tracking measures provide the almost real-time window of operator cognition and hence reveal the dynamics of the learning process. In this study, we analyzed the pilot's ability to learn with repetitive trial and observed the corresponding change in the derived measure of pupillometry. The maximum value of the measure is observed to decrease with repetition accompanied by the increase in the success rate. However, further investigation with relatively large population is required in order to claim the statistical significance on sensitivity and validity of the measure.

The present study can be expanded in several directions. The proposed measure can be combined with gaze position to get more insight into the process of learning. An increased value of the measure while visual attention on a specific information source

during repeated trials may indicate difficulty in comprehending the information from a particular source. The similar analysis in other safety critical fields like process control and nuclear power plant may provide insight for developing the more effective training scenarios or learning strategies for the operators.

Abstract

Safety and sustainability are commonly considered once the conceptual design of a process has been carried out. As an effect, modifications to the process to address safety and sustainability issues are more expensive and difficult to make. Several efforts to include safety and sustainability criteria during the process conceptual design have been made. The main challenge is to find a systematic way to reconcile these criteria with the economic objectives to provide an outcome easy to interpret by decision makers. The objective of this paper is to introduce a new safety and sustainability weighted return on investment metric, a tool that is intended to achieve such reconciliation. A case study dealing with the production of methanol from shale gas is presented. The results show how a design with suitable operating conditions that reconcile economic, environmental and safety criteria can be identified with the use of the new metric.

Keywords: safety, sustainability, process design.

1. Introduction

Typically, the decision making process in the chemical industry relies on technical and economic analysis. Safety and sustainability are usually considered after the conceptual design has been carried out. The effect is that changes in the design due to such factors become more difficult to make at that point in time.

Recently, some approaches have been proposed to include safety in addition to economic considerations during process design, such as the one by Martinez-Gomez et al. (2017) in which the optimization of the production of syngas using economic and safety considerations was developed. El-Halwagi et al. (2013) introduced an approach to incorporate safety objectives in the selection, location and sizing of a biorefinery.

The environmental impact is another criterion to be considered during the design stage of the process. Gong et al. (2014) introduced an optimization model for the sustainable design and synthesis of an algae production network with economic and environmental criteria. Julián-Durán et al. (2014) analyzed the economic and environmental impact of different reforming technologies for methanol production.

Recently, El-Halwagi (2017) presented a metric that includes sustainability criteria in the conventional return on investment (ROI) analysis, called the sustainable weighted return on investment metric (SWROIM). The SWROIM includes sustainability indicators that are compared with target values using a weighted factor, determined by the decision maker. The targets represent the best performance that a process can have for a given indicator; such targets can be determined for instance from the effect of mass and energy integration.

The SWROIM serves as the basis for a new metric presented in this work, called safety and sustainability weighted return on investment metric (SASWROIM). When safety is to be included in the metric, it is not possible to use the target comparison because there is not such a thing as the safest process, a process can only be made safer. Then, the objective of this new metric is to include safety and sustainability criteria in the conventional ROI concept and to apply the metric to a case study to illustrate its potential use as part of the conceptual process design.

2. Description of the metric

The SASWROIM is based on the conventional ROI,

$$ROI = \frac{AEP}{TCI} \tag{1}$$

where AEP is the annual after-tax economic profit and TCI is the total capital investment. A set of design alternatives is to be considered, and the index P is used to indicate each project. The projects are assessed using safety and sustainability indicators given by the index $\{i|i=1,2,\ldots,N_{Indicators}\}$. To perform the comparison, target and base-case values for the indicators should be determined. The target is the best possible value of an indicator in the range studied; the base-case is the actual state of the process that must be included in the range. The importance of each indicator is considered through a weighted factor w_i, which represents the relative significance of a given safety or sustainability indicator compared with the economic profit; the values for the factors are established based on company objectives, consequence analysis or government restrictions.

The SASWROIM is calculated using Eq.(2) and Eq.(3) where ASSP is the annual safety and sustainability profit.

$$SASWROIM = \frac{ASSP}{TCI} \tag{2}$$

$$ASSP_P = AEP_P \left[1 + \sum_{i=1}^{N} w_i \left(\frac{indicator_{Base,i} - indicator_{P,i}}{indicator_{Base,i} - indicator_i^{Target}} \right) \right] \tag{3}$$

In the ratio $\frac{indicator_{Base,i} - indicator_{P,i}}{indicator_{Base,i} - indicator_i^{Target}}$ the denominator indicates the maximum possible improvement and the numerator indicates the improvement or deterioration of project P for the indicator i.

The SASWROIM is especially useful when the value of the ROI is close to the threshold value established by the company. In such cases, the new metric can promote projects that are, apparently, not sufficiently profitable, but that are safer or have a positive impact on the environment. Conversely, projects that are just a little over the threshold value, but that are more pollutant or hazardous than the base-case, may show a level below the threshold value based on the new metric. Therefore, this metric provides an easy and systematic approach to reconcile safety and sustainability criteria with the profitability objectives of the company.

3. Case study

The discovery of shale gas reserves has promoted the development of gas-to-liquid technologies; one of the most attractive applications for the chemical industry is the production of methanol. The production of methanol from shale gas has been analyzed by some authors (Julián-Durán et al., 2014, Ortiz-Espinoza et al., 2017a, Ortiz-Espinoza et al., 2017b), who have found conflicts when evaluating the environmental and safety aspects of the process. In this work, we take a process reported in Ortiz-Espinoza et al. (2017a) to expand the analysis and solve the conflicts among economic, environmental and safety criteria with the use of the SASWROIM.

The production process for methanol involves three main stages, reforming, methanol synthesis and purification. There are different reforming technologies, such as partial oxidation, steam methane reforming, auto thermal reforming, and combined reforming (Julián-Durán et al., 2014). For this case study, only the partial oxidation (POX) reforming method is considered. Partial oxidation is used to produce syngas from hydrocarbons and oxygen. The advantage of this technology is the low amount of carbon dioxide, which has to be removed before the methanol synthesis step. (Julián-Durán et al., 2014). Figure 1 shows the flowsheet of the process.

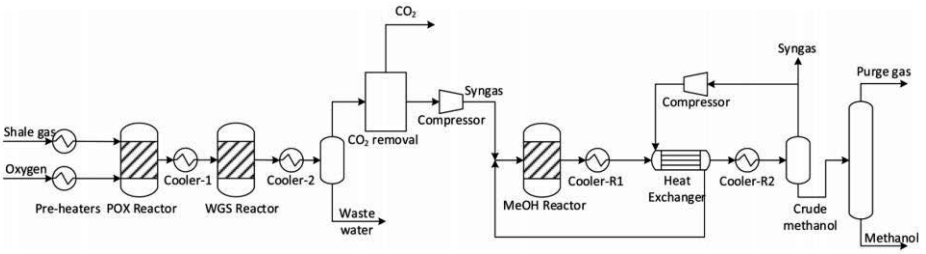

Figure 1. Methanol production flowsheet using POX (Julián-Durán et al., 2014)

3.1. Safety indicator

The process route index (PRI) is used to evaluate safety; this index quantifies the inherent safety level for each process route according to its level of explosiveness. One of the most important criteria for the quantification of the level of explosiveness is the combustibility (ΔFL_{mix}), which is calculated from the difference between the lower (LFL) and upper flammability limits (UFL),

$$LFL_T = LFL_{25}\left[1 - \frac{0.75(T-25)}{\Delta H_C}\right] \tag{4}$$

$$UFL_T = UFL_{25}\left[1 - \frac{0.75(T-25)}{\Delta H_C}\right] \quad (5)$$

The objective of the PRI is to represent the overall process inherent safety level by accounting for the average value of stream parameters such as density, pressure, energy and combustibility; the process with the lowest PRI value in the range is considered inherently safer (Leong and Shariff, 2009). Eq.(6) shows how to calculate the PRI index.

$$PRI = \frac{[(average\ mass\ heating\ value) \times (average\ fluid\ density) \times (average\ pressure) \times (average\ \Delta FL_{mix})]}{10^8} \quad (6)$$

3.2. Sustainability indicator

The environmental impact of the process is assessed through GHG emissions. The estimation of emissions was made in a life cycle basis, considering the acquisition and processing of shale gas, the electricity consumption, the fuel for the heating utilities and emissions due to the outlet streams. A combination of emissions factors (Laurenzi and Jersey, 2013; EPA, 2015; EPA, 2008) and Aspen Plus simulations were used to determine the total emissions of the different process configurations. The results are reported as CO_2 equivalents (CO_2-e).

4. Results

The methanol process has two main drawbacks, namely its high CO_2 emissions and its rather adverse inherent safety levels. A way to decrease the emissions of CO_2 is to increase the recycling fraction of the unreacted syngas in the methanol synthesis loop. On the other hand, the main hazard in this process is the high pressure in the methanol synthesis reactor; hence, a way to reduce the hazard is to reduce the operating pressure of the reactor. For this case study the recycling fraction and the pressure of the reactor were varied from 0.5 to 0.9 and from 50 to 83 bar, respectively.

The first step is to calculate the conventional ROI and the values of the indicators. The results are shown in Table 1.

Table 1. ROI, safety and sustainability indicators for the different process configurations

R / P (bar)	0.5			0.6			0.7			0.8			0.9		
	ROI	CO_2-e	PRI	ROI	CO_2-e	PRI	ROI	CO_2-e	PRI	ROI	CO_2-e	PRI	ROI	CO_2-e	PRI
83	46.90	14.90	17.56	50.04	14.06	17.56	53.62	13.27	17.51	57.42	12.49	17.35	61.62	11.71	17.08
70	43.06	15.89	13.51	46.81	14.85	13.49	50.95	13.87	13.47	55.53	12.88	13.42	60.63	11.89	13.27
60	38.97	17.07	10.72	43.21	15.85	10.64	47.94	14.63	10.61	53.26	13.40	10.57	59.35	12.16	10.47
50	33.03	19.02	8.11	37.87	17.41	8.10	43.37	15.80	8.09	49.71	14.19	8.07	57.20	12.56	8.00

Before applying the SASWROIM, we need to determine the base-case and the target values. For this case, the targets for CO_2-e and PRI are 11.71 and 8.00 respectively, and the base-case is at 60 bar with a recycling fraction of 0.7. The values of the weight factors for this case study were taken as 0.1. The metric was then applied, and the

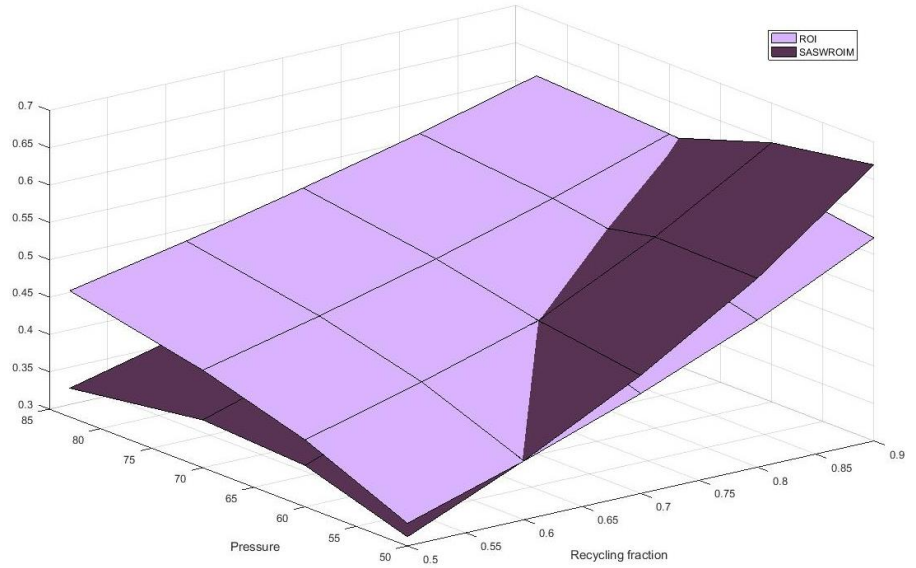

Figure 2. Comparison between SASWROIM and ROI

values of ROI and SASWROIM are plotted in Figure 2. It can be observed that, while the highest ROI was found at a pressure of 90 bar and a recycling fraction of 0.9, the highest SASWROIM resulted at 50 bar and a recycling fraction of 0.9.

The values of the metric can change depending on the weight factors for each indicator. Different factors can be considered to select the weight factors such as the company's core values, penalties due to regulations or consequence analysis. A sensitivity analysis of the impact of the weight factors in the metric can help to select the right values for the factors.

5. Conclusions

The SASWROIM metric provides a systematic method to reconcile safety and sustainability criteria with the economic objectives during the conceptual process design, and it gives an outcome easy to interpret by decision makers. This new metric has been applied to a case study dealing with the production of methanol from shale gas, using a partial oxidation reforming technique. The main hazard was identified as the high pressure of the methanol synthesis reactor. As for the environmental implications of the design, the synthesis gas recycling ratio was found to be the most critical part of the process. Different projects were considered and evaluated using the new metric, and a configuration that reconciles safety, sustainability and economic criteria was found with the reactor operating at 50 bar, and with the design based on a recycling ratio of 0.9.

Abstract

Leak accidents of chemical plant belong to a major industrial accident that can cause huge damage to human and facilities. Accurate detection and prompt response to leaks, earlier in the event of accidents, is crucial to alleviate damage. This research presents an approach to predict the location of leak source in real-time, by using the measured data from a sensor network as an input data to a pre-trained deep neural network. Computational Fluid Dynamics (CFD) simulations for various leak scenarios are conducted for a real plant geometry, and the massive data derived from the simulations are used for training and verification of the neural networks. Proposed deep neural network models perform well as a solution to the problem of leak-source tracking, one of the challenging inverse problems in chemical process safety.

Keywords: chemical leak, source tracking, deep-learning, big data, process safety.

1. Introduction

Leak accidents of chemical plants are serious industrial accidents that cause enormous human and material damage. The extent of the damage depends on whether the initial response is appropriate or not. To reduce the scale of the damage, it is necessary to establish a system that can identify the leak source(s) precisely at the beginning of the accident. It makes it possible to respond promptly and systematically.

For this reason, several attempts have been made to develop a methodology to identify the source of chemical leak(s). In the robotics field, behavior-based algorithms are embedded in mobile robot(s), and the location of leak source is tracked by executing a pre-input unit action according to the situation that robots are to be encountered in the tracking process (Holland and Melhuish, 1996; Russell, 2004). These methods require expensive mobile sensors and a long time demand for tracking. On the other hand, the approach of predicting the leak point through the data analysis, based on the information collected from a sensor network using only the fixed sensors, can overcome the above-mentioned disadvantages; lower cost of the sensor and reduced tracking time.

In this study, we tried to develop a model that can predict leak location(s) using an artificial neural network when leak substances are detected in the sensors located in plant fence. CFD simulations were conducted on a real chemical plant geometry to generate data for training and verification of neural networks. The concentration data of simulation were extracted at the sensor installation points and the neural networks were trained with the data of concentration, wind speed, and wind direction.

2. Design of leak-source tracking system

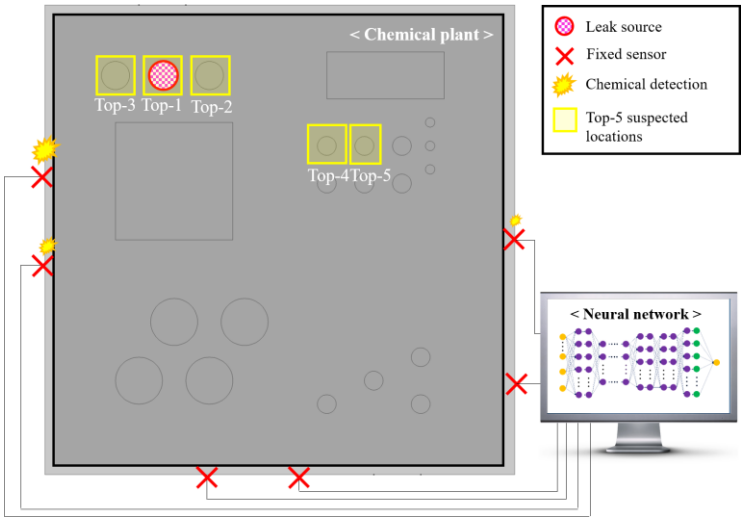

Fig. 1 Schematic diagram of the leak-source tracking system using fence-monitoring data.

The leak-source tracking model inputs the data to the neural network and propagates the data through the complex network. The computed values at the last hidden layer are transformed into the likelihood of each storage tank as potential leak points through softmax function. Fig. 1 shows the schematic concept of proposed model. The model outputs the top five points with high likelihood.

In order to train and validate neural networks, sensor detection database for various leak accident scenarios is needed. However, safety and cost problems are too huge to conduct experiments on various leak accident scenarios for real chemical plants. For this reason, CFD simulations for a real chemical plant geometry were conducted to generate data. However, the detection errors of the data measured by the sensor are not considered, and it is necessary to assume that the CFD and the actual phenomenon coincide very closely. The development of the predictive model was done as follows:

a. Select target: the target chemical plant should be selected first because the leak flow pattern varies greatly depending on the geometry.

b. Generate scenarios of chemical leak accident: the representative scenarios of potential leak accidents should be generated.

c. Conduct CFD simulation and extract data from the sensor installation points.

d. Preprocess and split the data: the extracted data must be preprocessed and split into training data and test data.

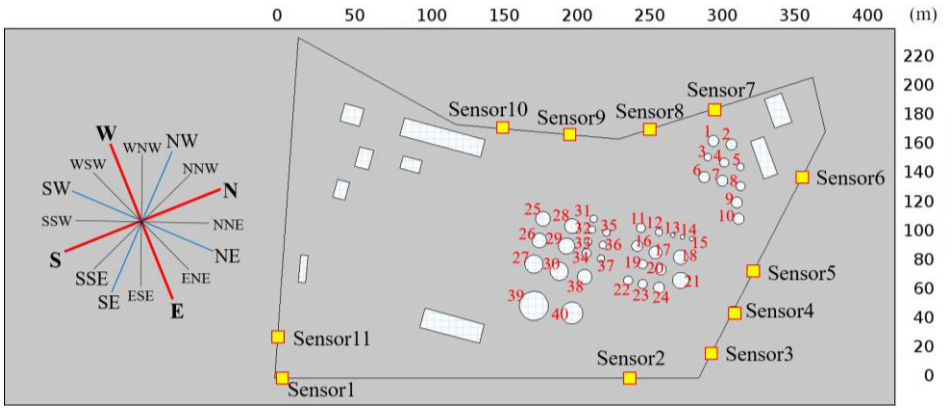
e. Train the networks and check the performance: the performance of the trained models should be verified using test data.

f. Derive the best model: it is needed to experiment with several structures and experimentally and empirically determine the optimal model because no clear methodology for network structure optimization has been presented yet.

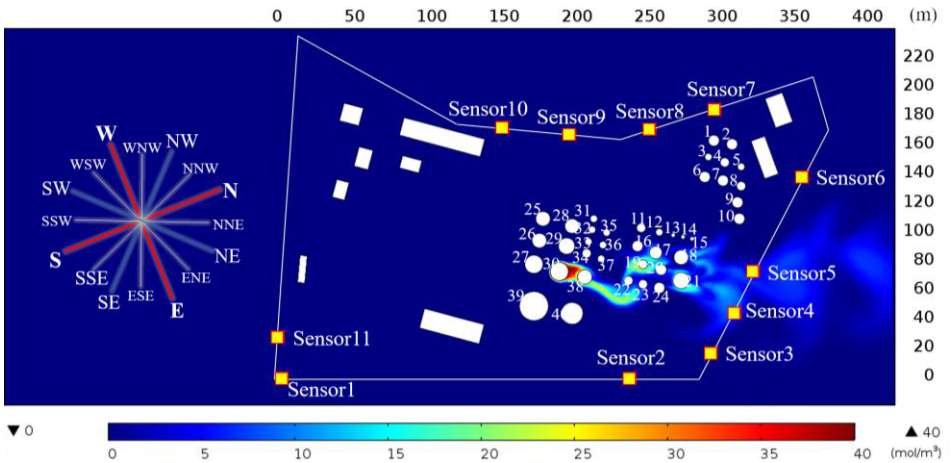
3. CFD simulations for database generation

Originally, CFD simulations were conducted to optimize the sensor-placement, using COMSOL Multiphysics 5.0 for "D" chemical plant in Yeosu, Korea by Cho (2017). Toluene was applied as a leak substance. Fig. 2a shows the information of target and considered wind fields. 40 storage tanks inside the chemical plant were set as potential leak candidates and 16 wind fields are applied to each tank; a total of 640 scenarios. The storage tanks are numbered from 1 to 40. For all accident scenarios, real-time simulations were performed from 0 to 750 seconds in the 2D-horizontal plane. Fig. 2b is an example of the simulation result.

After conducting CFD simulation, concentration data of leak material were extracted at the corresponding points in second. The collected concentration data were saved in the database including the wind speed and direction data used in each accident scenario. The wind direction was converted into the degrees rotated clockwise from the north and saved in the database.



(a) Schematic diagram of "D" chemical plant in Yeosu, Korea.



(b) An example of CFD simulation result: NNE wind, leakage of the 30-storage tank.

Fig. 2 Schematic diagram for the target and toluene dispersion simulations.

4. Modeling of neural network

4.1. Experiment for designing input layer structure

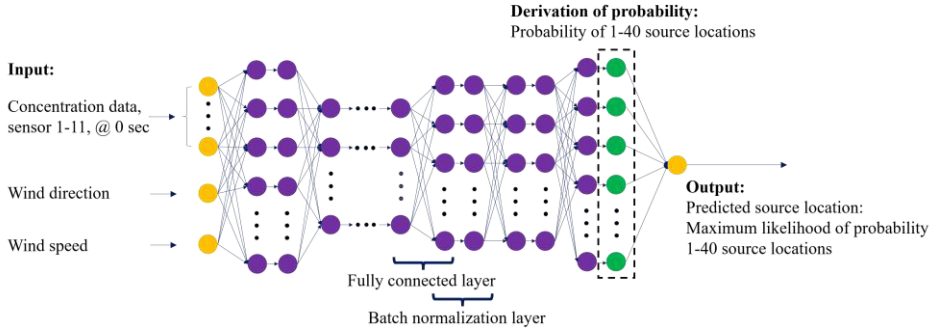


Fig. 3 Feed-forward neural network using the current time point data as inputs.

A simple approach when solving the leak-source tracking problem using the artificial neural network is to train the network using datasets that consist of the concentration, wind direction, and wind speed data collected in one-second. Fig. 3 shows a schematic diagram of the network structure.

Each data is labeled as the corresponding storage tank number if the maximum value of concentration measured by 11 sensors exceeds ERPG-2. Here, ERPG-2 refers to the maximum concentration in the air where almost everyone is exposed for an hour, causing irreparable injury, irreparable or without serious health effects.

A Feed-forward Neural Network (FNN) of 13-15*b*-20*b*-25*b*-20*b*-25*b*-30*b*-35*b*-40 was used to check the approximate performance, but there is no mathematical base on the hidden layer structure. Where *b* is the layer where batch normalization (Ioffe and Szegedy, 2015) is used. Softmax activation function was used for the last hidden layer and ReLU activation function (Nair and Hinton, 2010) was used for the other hidden layers. Adam optimizer (Kingma and Ba, 2014) was used for training.

As a result, low accuracy was obtained; the training accuracy and the test accuracy were 37.8% and 37.2%, respectively. This is because the amount of information was insufficient to predict the location.

In general, the leaking material forms a plume along the wind and is dispersed. The wind fields which move the plume are fluctuated by the complex geometry. Therefore, the concentration graphs measured on the fixed sensors also show the fluctuating patterns according to time. These phenomena have been found in most scenarios. Considering these facts, it was judged that it is better to create a dataset with continuous time series data with a certain sequence length, not only one-second length data. Fig. 4 shows the network structure.

The data were reshaped in a sequence length of 60 seconds. The length of 60 seconds is an amount that would allow a sufficient amount of data to be taken into account in the predictive model, even though it is a short time to predict the leak location with a human perception

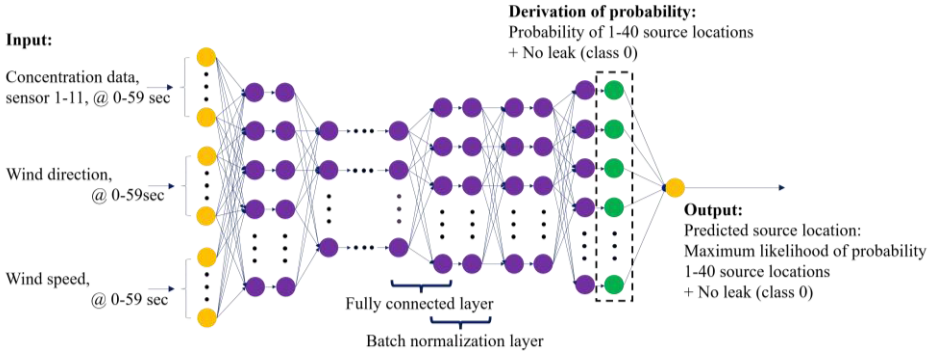

Fig. 4 Feed-forward neural network using 60-second time series data.

In this case, the concentration data, wind direction and wind speed measured from 11 sensors are composed of 60-sequence columns; a total of 780 variables constitute one dataset. It means that each dataset includes 660 variables of concentration. If 10 or more of them were above the ERPG-2 concentration, we labeled the datasets with the storage tank number of the corresponding scenario. For datasets that did not meet these criteria, they were labeled as class 0 (no leak).

4.2. Experiment for designing hidden layer structure

There are four models used in the experiment. As shown in Table 1, the number of parameters is increased by 2, 3, and 4 times based on FNN 1. In all four models, the number of neurons in the input layer, output layer, and the last hidden layer are the same. The batch size, the position that batch normalization applied, activation function, and optimizer are all the same. Through this, we tried to find the proper network size to solve the problem by observing the performance according to the size of the network rather than the structural difference.

As shown in Fig. 5, the greater the number of parameters, the wider the gap between the test loss and the training loss. It means that overfitting problem is getting worse because test loss does not decrease, even though training loss decreases continuously as the number of parameters increases. This means that it is no longer meaningful to increase the number of training epochs or network capacity.

Table 1. Summary of results obtained

	Network structure	Epoch	Number of parameters	Maximum accuracy training/test
FNN 1	780-25*b*-28*b*-28*b*-28*b*-28*b*-28*b*-41	5,000	25,020	71.2 % / 71.1 %
FNN 2	780-50*b*-48*b*-45*b*-42*b*-37*b*-28*b*-41	5,000	49,979	81.5 % / 78.7 %
FNN 3	780-75*b*-67*b*-57*b*-47*b*-38*b*-28*b*-41	5,000	74,998	87.0 % / 82.4 %
FNN 4	780-100*b*-82*b*-65*b*-50*b*-38*b*-28*b*-41	5,000	100,022	89.5 % / 84.1 %

where b: batch normalization is used

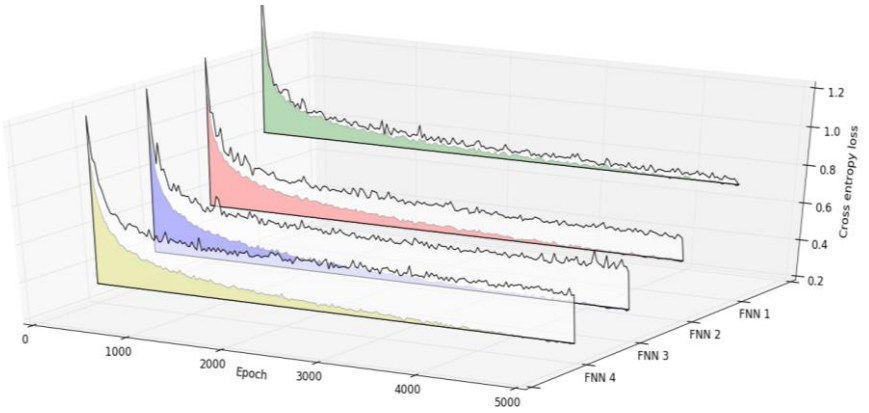

Fig. 5 Cross entropy loss of feed-forward neural networks for training data and test data.

As shown in Fig. 5, the greater the number of parameters, the wider the gap between the test loss and the training loss. It means that overfitting problem is getting worse because test loss does not decrease, even though training loss decreases continuously as the number of parameters increases. This means that it is no longer meaningful to increase the number of training epochs or network capacity.

Conclusions

In this study, for big-data based source tracking, CFD simulations were performed for leak accident scenarios in a real chemical plant, and leak-source tracking models were developed by training the leak dispersion data in FNNs. It was found that constructing input data to have a certain sequence length is suitable for the nature of leak-source tracking problem of chemical plants, a challenging safety inverse problem. For the testbed problem, the actual leak points were predicted with the test accuracy of 84.1% for 40 leak candidates. Considering the high-prediction performance of the proposed leak-source tracking method based on the deep neural net, it is expected to be deployed as a solution to the problems of identifying the leak source(s) out of chemical plants.

Optimal design of a COEX process for spent nuclear fuel reprocessing using small channels

Davide Bascone[a*], Panagiota Angeli[a], Eric S. Fraga[a]

[a]*CPSE, University College London, London WC1E 6BT, UK*
davide.bascone.14@ucl.ac.uk

Abstract

The use of small channels for liquid-liquid extraction seems to be promising, since hydrodynamics are more easily controlled and mass transfer is enhanced. The use of small scale contactors may be particularly beneficial for spent nuclear fuel (SNF) reprocessing, due to the small size and consequent safety improvements. In this paper, a mathematical model for the intensified liquid-liquid extraction in small channels has been developed. A multi-component system is considered, including most of the components in the SNF. The resulting model is a large scale mixed integer nonlinear optimisation problem. A novel design of the COEX (co-extraction of uranium and plutonium) process, employing small channels, is presented. Results show that several improvements are obtained, compared to traditional technologies, in terms of safety and solvent degradation.

Keywords: Liquid-liquid extraction; small channels; spent nuclear fuel reprocessing; optimisation; process design.

1. Introduction

Current commercial plants for Spent Nuclear Fuel (SNF) reprocessing use the PUREX (Plutonium URanium EXtraction) process. The aim is to recover U and Pu, which can be reused as MOX (Mixed OXide) fuel in appropriate nuclear reactors. These components are approximately the 97% of the SNF, and can be recovered by Liquid-Liquid Extraction (LLE) by a selective organic solvent, the Tributyl Phosphate (TBP), after dissolution of SNF in nitric acid, according to the reactions:

$$UO_2^{+2} + 2NO_3^- + 2TBP \leftrightharpoons [UO_2(NO_3)_2] \cdot 2TBP \quad (1)$$

$$Pu^{4+} + 4NO_3^- + 2TBP \leftrightharpoons [Pu(NO_3)_4] \cdot 2TBP \quad (2)$$

This LLE is mostly carried out in pulsed columns and mixer settlers. However, both conventional process and technologies have several disadvantages. For instance, pulsed columns and mixer-settlers require long residence time of the aqueous-organic mixture, which inevitably leads to solvent degradation. A promising alternative to these traditional technologies may be the intensified LLE in small channels, exploiting the advantages of improved mass transfer in small scale contactors. The concept of decreasing plant size but not performance, which is in fact improved in small scale contactors, is known as process intensification. This technology may be particularly interesting for nuclear applications. Some benefits may be improvements in safety, due to the small volume of

hazardous materials involved, reduced solvent degradation due to short residence time, easy control of hydrodynamics to improve mass transfer and low pressure drop.

The PUREX process delivers a pure Pu stream, implying nuclear proliferation risk. Several alternatives to this process have been proposed, such as UREX, UREX+2, NPEX, COEX (Nash and Lumetta, 2011). The latter flowsheet may be the most promising, since it reduces extraction steps. It also improves proliferation resistance: a mixed U/Pu is achieved, providing a better homogeneity of U/Pu distribution within the MOX fuel, compared to the current approaches.

The COEX process has the same first section of PUREX process, i.e. the codecontamination section, where U and Pu are separated from most of the SNF. The product stream of the codecontamination section, which is an organic phase containing U, Pu, HNO_3 and very small amounts of Tc, Np, Zr and Ru undergoes a first stripping step. This step is called "co-strip" (step 5 in Figure 1), the goal is to strip (or back extract) simultaneously U and Pu from the organic stream. However, the Pu/U ratio in the organic stream outgoing the codecontamination section is too low to produce MOX fuel from this stream. Hence, the idea is to strip all Pu and only part of U to achieve an adequate Pu/U ratio for MOX fabrication, which is around 10%. To back extract Pu and only part of U, the oxidation states must be changed to exploit their different equilibrium behaviour. Pu is originally present in the mixture as Pu(IV), U as U(VI). A reducing agent is used to reduce Pu(IV) to Pu(III). Pu(III) is not very extractable, contrarily to Pu(IV) and U(VI), therefore is it simple to strip. Reductants used in nuclear industry for plutonium stripping are hydroxylamine nitrate (HAN) and U(IV). Also, a scavenger agent is used to reduce re-oxidation from Pu(III) to Pu(IV) and improve Pu stripping. Typically, hydrazine nitrate $N2H4{\cdot}HNO_3$ is used for this purpose.

In this paper, a mathematical model for intensified extractions in small channels, suitable for SNF reprocessing, has been developed. A differential equation has been used to describe the mass balance of each component. The model involves a 12-component LLE. Attempts to model LLE with "nonlinear equilibrium", i.e. when the distribution coefficient is estimated as function of the concentration of components, for a large number of components and using differential mass balances are limited in the literature. The most complex and detailed model for SNF reprocessing available is the model developed by Gonda and Matsuda (1986). They have modelled a 5-component LLE, with U(VI), U(IV), Pu(IV), Pu(III) and HNO_3, using a partial differential equation to describe the dynamic behaviour in pulsed columns, which also included six chemical reactions.

Uranium extraction in small channels for nuclear application has been investigated by Tsaoulidis and Angeli (2015). Empirical correlations for mass transfer and hydrodynamic parameters have been obtained from experimental data. They have also investigated mass transfer through CFD simulations, but no models for optimisation and design of

intensified LLE in small channels have been developed, and no multi-component LLE has been investigated.

2. Mathematical modelling

The segmented two-phase flow pattern obtained in small channels, i.e. dispersed phase plugs separated by continuous phase slugs, has been approximated in this work with a simple ideal plug flow model to describe mass balance of the *i* component in the *k* phase:

$$-v_k \frac{dC_{i,k}}{dL} - K_L a\left(C_{i,k} - C_{i,k}^{eq}\right) + \Sigma R_{i,k}\varphi = 0 \tag{3}$$

Ideal plug flow conditions are typically used in the literature to estimate mass transfer coefficients in small channels. Steady state conditions have been considered. The mass transfer coefficient has been calculated according to Kashid *et al*. (2010):

$$K_L a = 0.88 \frac{v_{mix}}{L} Ca^{-0.09} Re^{-0.09} \left(\frac{D}{L}\right)^{-0.1} \tag{4}$$

Kashid *et al.* used a Y-junction to mix the two phases. Eq. (4) was developed for the system acid acetic solution-kerosene, similar to the one investigated in this work, which is nitric acid solution – TBP/kerosene (30% v/v). A correction factor, function of the dispersed to continuous phase flow ratio and based on experimental data reported in the literature (Tsaoulidis *et al.*, 2013), has been included in the calculations to take into account the effect of the flow ratio on the interfacial area. Crucial in the model is the estimation of the distribution coefficients, i.e. the ratio between concentrations in the organic and the aqueous phases for each component at equilibrium conditions; the coefficients describe the driving force for the mass transfer. For these calculations, expressions from the literature have been included in the model. Distribution coefficients of U(VI), Pu(IV) and HNO_3 have been calculated according to Richardson and Swanson (1975). Coefficients for U(IV) and Pu(III) have been estimated as suggested by Kumar and Koganti (1998, 2003), whilst for Zr and Ru the correlations developed by Natarajan *et al.* (2012) have been used. Distribution coefficients of Np(IV) and Np(VI) have been estimated according to Kumar *et al.* (2001). Finally, distribution coefficients of HNO_2 and Tc have been calculated as suggested by, respectively, Hongyan *et al.* (2013) and Asakura *et al.* (2005). For Np(V), almost inextractable, a nominal value of 0.01 has been used (Hongyan *et al.*, 2013). In addition to the redox reactions between Np(IV), Np(V) and Np(VI), modelled according to Hongyan *et al.* (2013), many chemical reactions are involved if a reductant is introduced in the system to reduce plutonium from Pu(IV) to Pu(III). U(IV) has been used as reducing agent, and kinetics were estimated according to Tachimori (1994). Pu(III) can reoxidise to Pu(IV) (Tachimori, 1994) hence, to prevent it, $N2H4{\cdot}HNO_3$ is used as nitrite scavenger (Gonda and Matsuda, 1986). $N2H4{\cdot}HNO_3$ also acts as reductant (Tachimori, 1994). Furthermore, U(IV) can oxidise to U(VI) (Gonda and Matsuda, 1986).

The design of a scale out manifold that ensures acceptable flow distribution in the many small channels is essential to process high throughput with small scale devices.

Commenge *et al.* (2011) have proposed a methodology for the design of a comb-like flow network. Pressure drop calculations have been included in the model. Multi-stage counter-current design has been considered, to achieve high extraction efficiency and meet industrial requirements.

The resulting model, posed as an optimisation problem, is a mixed-integer nonlinear problem, implemented in GAMS. The model is large, due to the 50 grid points used to numerically solve Eq. (3) by the 4th order Runge-Kutta method.

3. Case study

To demonstrate the applicability of the model, the COEX process has been investigated. This flowsheet reduced the number of unit operations required, compared to the current PUREX process. In this paper, a further reduction of unit operations has been considered: no second cycle for U purification has been used, significantly reducing the plant cost. This could be achieved if small channels are used, where separations can be improved (in particular, of Np) and further U purification may be not required (U purity of about 99.99% could be achieved, according to the model). Also, no organic recycle stream between steps 8 and 5 is needed. The flowsheet is shown in Figure 1. The aim is to minimise the total annualised cost, which includes operating and capital expenses. Several constraints have been included in the model, to meet industrial requirements in terms of typical decontamination factors (DF): minimum 10,000 for Ru and Zr. DF of Tc is typically around 10, but in this work it has been increased to 50 to avoid further U purification. Recovery of U and Pu in the flowsheet must be higher than 99%, concentration of U in the aqueous phase outgoing step 1 must be ≤ 1.68 mol m^{-3}, ratio Pu/U in the aqueous stream leaving step 8 must be 9.5%.

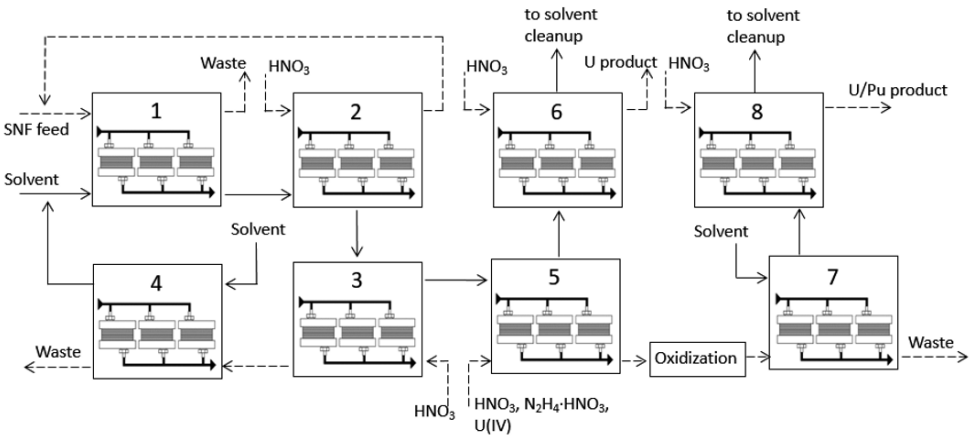

Figure 1: Diagram of COEX process. Continuous line refers to organic stream, dashed line refers to aqueous stream. Flow rate of SNF feed is approximately 200 L h^{-1}.

Design variables are operating variables (flow rates, HNO_3 concentrations), diameter and length of channels (equally sized), number of stages, geometry of manifold (number of elements, width and length of distributors/collectors). Also, concentration of HNO_3, U(IV) and N2H4·HNO_3 in the aqueous streams are free variables.

Table 1: Optimal design. Diameter and length of small channels are, respectively, 2 mm and 100 mm for all steps. No. of channels expressed as: (no. of elements of scale 1) x (no. of elements of scale 2) x (no. of elements of scale 3) x (no. of elements of scale 4).

Step	No. of stage	Aq. to org. flow ratio	No. of channels in manifold
1	4	0.84	67 x 15 x 11 x 1
2	3	0.52	70 x 8 x 8 x 1
3	2	0.24	67 x 12 x 7 x 1
4	1	0.50	70 x 6 x 5 x 1
5	4	0.20	66 x 9 x 6 x 1
6	4	2.17	67 x 14 x 10 x 1
7	4	0.89	70 x 6 x 6 x 1
8	3	3.38	69 x 7 x 6 x 1

3.1. Results

The results of the optimisation are shown in Table 1. Very short residence times, in the order of seconds, are involved using this novel technology. This may represent an important benefit if compared with the residence times of pulsed columns and mixer-settlers, which are in the order of minutes and inevitably cause solvent degradation. High extraction efficiency can be achieved by the high K_La obtained in the small-scale contactors. The values of K_La achieved are, in all steps of the flowsheet, between 0.2 and 0.3 s^{-1}. Roizard *et al.* (1997) listed typical K_La in a stirred tank between 0.03 and 0.8 s^{-1}, and K_La of approximately one order of magnitude lower in columns. For uranium extraction in small channels with same diameter, length and superficial velocity of the mixture, a K_La of approximately 0.1 s^{-1} was reported (Tsaoulidis and Angeli, 2015), using significantly more viscous organic diluents (ionic liquids). The difference between this experimental value and the one used in this work could be explained by two reasons: the lower viscosity, which increases the mass transfer coefficient, and the increased interfacial area, as result of the lower aqueous (dispersed) to organic flow ratio. Another advantage is related to the small size of the channels. In this case study, the average volume of each step is around 120 L. The typical total liquid volume for mixer-settlers is 60,000 L, 800 L for pulsed columns (K. Nash and G. Lumetta, 2011). Smaller volumes lead to safety improvements and a better control of nuclear criticality: neutrons have a greater possibility of escaping with higher surface area to volume ratio.

3.2. Comments on mathematical model

The mathematical model is large, around 700,000 equations, and nonlinear. A sequential modular approach has been first used to solve the flowsheet and provide initialisation. Then, all the unit operations are optimised simultaneously. The mass transfer model, Eq.(4), and its parameters have been derived from experiments in small (< 1 mm) channels. However, Eq.(4) has been used in the literature to fit experimental data of liquid-liquid extraction of uranium in small channels, with diameters up to 2 mm

(Tsaoulidis and Angeli, 2015). The latter value has been assumed as upper bound for the diameter. For larger channels, more data would be required. The current model has been implemented for SNF application, but it may be potentially used for any other LLE applications in small channels.

4. Conclusions

An optimisation model for intensified extraction in small channels has been developed, formulated as MINLP problem. A novel COEX process has been investigated to demonstrate the applicability of the model. Results have confirmed many potential advantages of this novel technology, in terms of performance and size. The mathematical model developed suitable for nuclear application, can be applied to other separation processes involving extractions, by integrating the model with new components and the appropriate equations for thermodynamic calculations.

An MILP-based Operability Approach for Process Intensification and Design of Modular Energy Systems

Vitor Gazzaneo, Juan C. Carrasco, Fernando V. Lima*

Department of Chemical and Biomedical Engineering, West Virginia University, Morgantown, WV 25606, P.O. Box 6102, USA

Abstract

A mixed-integer linear programming (MILP) operability approach is developed for the design of high-dimensional and nonlinear systems. For the approach formulation, classical operability concepts are extended to attain process intensification towards system modularity. Motivated by natural gas utilization processes, a catalytic membrane reactor for the direct methane aromatization (DMA-MR) conversion to hydrogen and benzene is chosen as case study. The DMA-MR is described by a system whose design is challenged by complexity, including nonlinearities and a highly-constrained environment. A DMA-MR subsystem is addressed, for which 80% reduction in membrane area and 78% reduction in reactor volume is obtained when compared to a base case with equivalent performance. The proposed approach presents a computational time reduction greater than 3 orders of magnitude compared with previously introduced nonlinear programming-based operability approaches. These results indicate that the proposed approach is computationally efficient and thus can be extended to address higher dimensional cases.

Keywords: Operability, Process Intensification, Modular Systems, Energy Systems, Optimization.

1. Introduction

Modular systems are promising technologies characterized by versatility. They provide an alternative for the traditional industry by considering small modules of higher efficiency. As these modules can be shipped and assembled, the exploitation of resources in remote and originally untapped areas becomes feasible. A DMA-MR for methane conversion to hydrogen and benzene can be considered as a potential candidate system for modular natural gas utilization that could be transported to stranded gas fields. In this case, the concept of process intensification characterized by the enhanced reaction and separation phenomena in the membrane reactor may enable high efficiency units for modular system applications. Additionally, a substantial decrease in cost and environmental footprint are key outcomes of system modularity that are also associated with process intensification. The design of a modular energy system, however, is challenged by its complexity, including nonlinearities, system dimensionality and a highly-constrained environment. An MILP-based operability approach is proposed here to overcome these challenges. Operability was first described as a mapping between inputs and outputs of a system that was established to measure the ability of a design to achieve specified desired operating states. The aim in the new formulation is to extend

classical operability concepts and tools to attain process intensification targets and ensure system modularity in a computationally efficient manner.

Process operability was initially used for the assessment of low-dimensional nonlinear systems. The expansion to high-dimensional nonlinear systems was successfully addressed by employing optimization algorithms based on nonlinear programming (NLP) [1,2]. However, previously proposed approaches were challenged by the system dimensionality in terms of high computational expense. The novelty in this work consists of the fully utilization of MILP tools to tackle systems of similar complexity, with the advantage of computational time reduction.

2. Process Operability Concepts

In traditional process operability concepts, inputs (u) and outputs (y) are respectively represented by the Available Input Set (AIS) and Achievable Output Set (AOS). The desired operating region for the outputs and the corresponding region for the inputs in order to achieve such outputs are called Desired Output Set (DOS) and Desired Input Set (DIS), respectively. For a given set of inputs, the calculation of the corresponding outputs is performed by direct mapping employing a first-principles process model, M. Conversely, the inverse model, M^{-1}, represents the pathway from the outputs to inputs. For an m x n dimensional input-output system, the operability sets are generically represented by:

$$AIS = \left\{u | u_i^{min} \leq u_i \leq u_i^{max};\ 1 \leq i \leq m\right\};\ DIS = \{u | u = M^{-1}(y); y \in DOS\};$$

$$AOS = \{y | y = M(u);\ u \in AIS\};\qquad DOS = \left\{y | y_i^{min} \leq y_i \leq y_i^{max}; 1 \leq i \leq n\right\};$$

Nonlinear systems require a nonlinear model M. The derivation of M^{-1} may be complex and sometimes not straightforward. One contribution of this work is the numerical computation of M^{-1} employing computational geometry tools, overcoming the challenges associated with the analytical calculation of M^{-1}. The description of such computation can be found in section 3 below, along with the proposed approach.

3. MILP-Based Operability Approach

In the developed framework, the operability mapping accounts for design variables (physical dimensions, feed and operating conditions) as inputs and measures of production (production rates and efficiency) as outputs. Such mapping is established by dividing the original nonlinear space into several linear subspaces described by linearized models. This task is performed with the utilization of computational geometry techniques such as Delaunay-triangulation. The properties of the obtained subsets are then analyzed to find the minimum number of divisions that is needed to adequately represent the original system. Using such divisions, an optimization algorithm based on MILP concepts is formulated, considering all process constraints and specific targets associated with process intensification. The steps of the developed framework can be summarized as follows:

1) The nonlinear system is simulated, generating input-output data points. First-principles models for the application of interest are considered for this task.

2) Using a computational geometry-based technique, e.g., Delaunay-triangulation, sets of triangles are obtained. Each triangle in the AIS has a counterpart in the AOS. This step can be repeated, with gradual reduction in number of considered data points,

until the triangulation is still possible for the minimum number of points. Once executed, this gradual reduction results in the minimum number of triangles needed to adequately represent the original nonlinear system. Alternatively, if needed, this step can be performed using only the points of the operating envelope, i.e., points of the boundary of AIS and AOS.

3) The DOS is selected and its intersection with the AOS is calculated by employing computational geometry tools. The input counterpart of the calculated region is the feasible DIS. This pathway from outputs to inputs is the inverse model calculation performed using linearized models represented by triangles.

4) An MILP minimization problem is formulated to reduce footprint in terms of physical size and ensure the compliance of process constraints and intensification targets. Here, the MILP formulation considers the regions of input/output delimited by the DIS/DOS in step 3. This formulation is mathematically defined as:

$$\Phi = \underset{u}{\text{minimize}}\ (footprint)$$

Subject to: $u \in DIS$, $y \in DOS$
Linearized process model and constraints
Process intensification targets

The mixed-integer nature is necessary due to the existence of the discrete regions represented by triangles. For each triangle, a binary value is assigned and the sum of all assigned values have to be 1. Interpolations are allowed by using weights related to the vertices of existing triangles. The outcome of the optimization is an optimal design inside a unique triangle.

4. Results: DMA-MR Case Study

In this section, each step of the framework described above is applied to a 2x2 DMA-MR subsystem, in which each step is in a separate subsection.

4.1. Simulation of the DMA-MR System

The feed for the shell and tube MR configuration considered is natural gas (methane) in the tube side, and a sweep gas (a laboratory inert gas, e.g., helium) in the shell side. The methane is converted into benzene and hydrogen following a two-step reaction mechanism. Hydrogen is selectively permeated through the membrane, yielding a hydrogen-rich permeate and a benzene-rich retentate. Figure 1 shows the adopted configuration along with reactions.

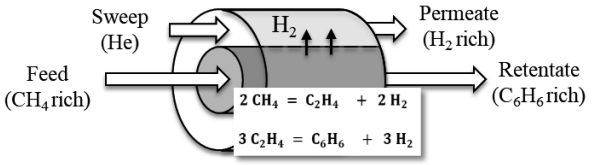

Figure 1. DMA-MR cocurrent configuration scheme.

For the performed operability analysis, the inputs are the reactor dimensions (length and diameter) and the outputs are benzene production and methane conversion. Other variables such as reactor temperature, pressure, feed, etc., are assumed

constant/controlled for this analysis. A nonlinear model is developed, which is characterized by a set of ordinary differential equations (ODEs) obtained from molar balances inside tube and shell (refer to [2] for model details and assumptions). An initial simulation is carried out considering 10,000 combinations of reactor dimensions, with the reactor length range from 10 to 100 cm and tube diameter range from 0.5 to 2.0 cm. Such simulation is performed in MATLAB, employing a stiff ODE solver, "ode15s", due to the nature of the ODE system.

4.2. Triangulation of AIS and AOS

The obtained data points from the input-output simulation are used for the triangulation task. The AIS is constrained to the given rectangular mesh and the AOS is constrained to its original hull. Figures 2 and 3 show the initial triangulation and the one obtained with minimum number of triangles, respectively.

For an evenly spaced AIS grid, the configuration with the minimum number of triangles employing the approach described above is a 38 x 38 grid. To produce a system representation with an even lower number of triangles, an alternative triangulation using only the outside operating envelope has to be performed. In such case, an unconstrained Delaunay-triangulation is applied to the AOS envelope points, resulting in a set of triangles that connect the edges of the original shape. As a lower number of triangles is used to represent the system, an error increase is expected in such representation. The trade-off between computational time and relative error is further addressed in section 5.

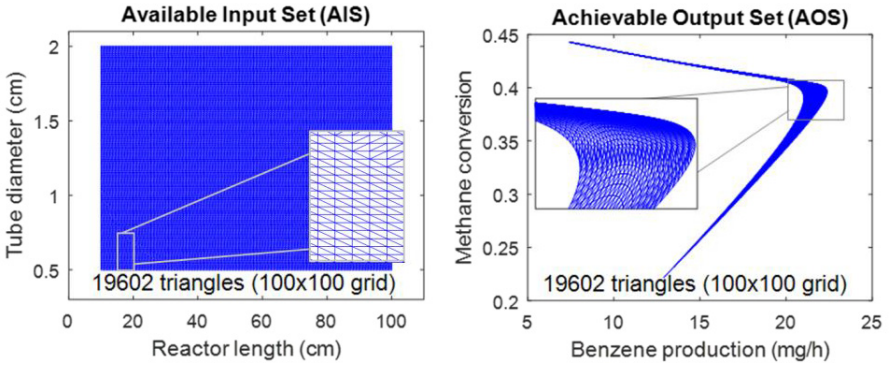

Figure 2. Constrained triangulation of AIS and AOS for initial case.

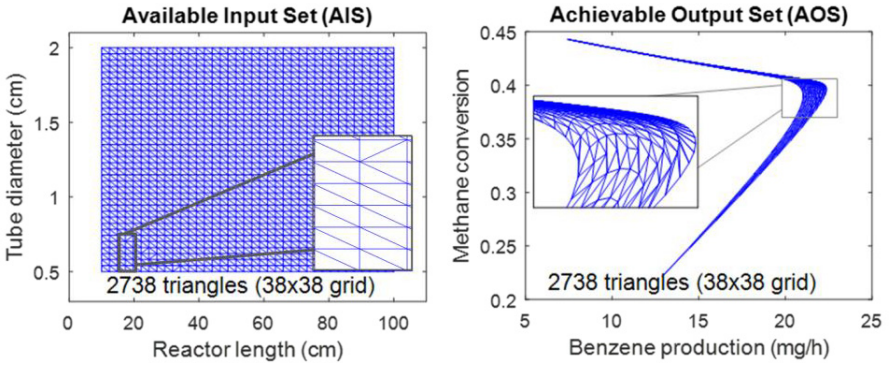

Figure 3. Constrained triangulation of AIS and AOS for case with minimum number of triangles.

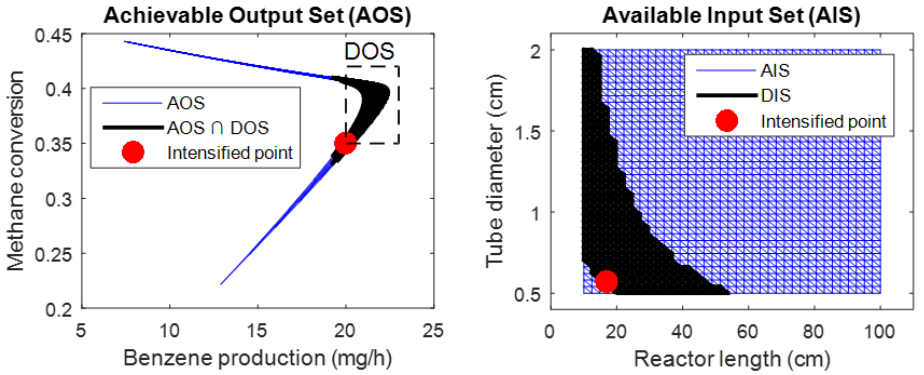

Figure 4. DOS selection, DIS calculation and MILP solution for minimum number of triangles.

4.3. Quantification of Linearized Spaces and DOS Selection

For this application, the DOS region is defined as benzene production ranging from 20 to 23 mg/h and methane conversion from 0.35 to 0.42 as shown in Figure 4. The intersection of this region with the AOS is calculated using the function "isOverlapping" in the MPT toolbox [3] in MATLAB. The inverse mapping step employing the triangles results in the region of desired inputs, the DIS. Figure 4 also illustrates the DIS calculation for the case with minimum number of triangles.

4.4. MILP Formulation and Optimal Design

The reduction of the MR footprint is defined as the MILP objective function. The model for the optimization task corresponds to a set of linearized multi-models. As constraints, the ratio $L/D \geq 30$ is considered here for plug flow, where L is the reactor length and D the tube diameter. An additional performance target is set for a benzene production of at least 20 mg/h. The MATLAB subroutine "intlinprog" is used for this task.

Figure 4 shows the intensified point given by $(L, D) = (17.0, 0.57)\ cm$, obtained using the proposed MILP formulation. A comparison with a base case from literature [2] is established, where $(L, D) = (100, 0.50)\ cm$. The obtained design shows equivalent reactor performance for an 80% reduction in membrane area and 78% reduction in reactor volume.

5. Computational Results

The developed approach is executed for a different number of initial points and the trade-off between computational cost and relative error is analyzed. For such activity, NLP-based approaches [2,4] are also run for similar number of initial points. The NLP result for the case with the largest number of initial points is considered as the benchmark result, given the detailed exploration of the input-output spaces performed in this case using the nonlinear model. Table 1 summarizes the obtained comparison.

From the results in Table 1, note that the proposed approach performs faster in all scenarios for the same number of initial points. When compared to the NLP-based approach benchmark case considering the same number of initial points, it shows a computational time improvement greater than 3 orders of magnitude with a relative error less than 2%. Such improvement indicates the computational efficiency of the developed approach and thus its feasibility to address high-dimensional calculations.

Table 1. Trade-off performed between computational time and relative error for proposed approach when compared to NLP-approaches.

Approach	CPU Time (h:min:s)	# Initial Points	Reactor Length (cm)	Tube Diameter (cm)	Relative Error (w.r.t. membrane area) (%)	Gain in CPU Speed (times) **
NLP-based Approach [2,4]	00: 06: 30.60	25	18.00	0.600	10.23	-
	00: 25: 21.15	100	17.38	0.577	2.31	-
	06: 11: 04.35	1444	17.26	0.570	0.50	-
	10: 35: 50.21	2500	17.14	0.571	0	-
Proposed MILP-based Approach	00: 00: 00.03*	24	18.02	0.601	10.50	12,844
	00: 00: 00.03*	100	17.63	0.588	5.74	44,773
	00: 00: 07.29	1444	17.03	0.568	1.28	3,051
	00: 00: 32.00	2500	17.00	0.567	1.66	1,191

*Rounded values; ** for the same number of initial points

6. Conclusions

The developed MILP-based operability approach was successfully applied to attain process intensification towards footprint reduction and system modularity. When compared to NLP-based operability approaches, it performed faster at any scenario with minimal errors, especially for a higher number of initial points. As computational cost was not a tractability barrier for the developed approach, this approach will be extended next to address higher dimensional cases.

Abstract

The rotating packed bed (RPB) that is a novel process intensification (PI) reactor has been successfully adopted in the chemical industry in recent decades. Unlike sheer process optimization, PI aims to break the bottleneck of transfer processes at the micro level, like mixing and reaction kinetics, such that the process shifts to be governed by its innate reaction rate rather than by mass transfer. This work demonstrates a superstructure synthesis approach for evaluating PI device through a case study involving an RPB and a packed bed (PB). A multi-scale model links the micro-mechanisms of intensification in the RPB with the macro-level decisions of equipment selection and interconnection. The proposed superstructure considers configurations of an RPB and PB in series, in parallel, and in between, allowing quantification of their synergy. The overall model is formulated as a nonlinear programming problem and is demonstrated with the case of H_2S removal from refinery tail gas. The computational results show that the configuration of both RPB and PB in parallel is optimal under the assumption of linear investment and operating costs. Over a wide range of possible electricity prices, the hybrid system of both units is shown to be more cost-effective than a single RPB or PB. This synergistic effect is uncovered with the integration of process intensification and superstructure optimization, illustrating a new way for both PI and PSE to incorporate.

Keywords: Process intensification, Process synthesis, Rotating packed Bed, Nonlinear programming

1. Introduction

Process intensification, a promising pathway in the development of sustainable and cost-effective chemical process systems(Van Gerven et al., 2009),is defined by Ramshaw(1995) as a methodology for making remarkable reduction in equipment size, energy consumption, or waste generation while achieving a given production goal. PI has become a topic of increased interest(Stankiewicz, Lutze et al. 2000,2010) with its main goal to coordinate different unit operations/processes effectively and to activate synergistic effects during process development(Huang, 2007). Process synthesis—the assembly and interconnection of units for efficient performance and low energy consumption(Weserberg, Grossmann, 1975, 2000) —is an excellent complement to process intensification(Moulijin, 2008). However, both of these areas are distinct to

some extent. Process intensification places greater emphasis on the micro-mechanisms of intensification and experimental validation of transfer phenomena(Moulijin, 2008). In contrast, process synthesis obtains an optimal configuration given a set of potential alternatives topologies for a process system. By reducing the bottleneck of transfer processes at the micro level, like mixing and reaction kinetics, such that process reactions are governed by their inherent rates rather than by transport phenomena(Baldea, 2015), PI can further improve solutions from process synthesis. Therefore, it is meaningful to obtain insight into the connection between process intensification and process synthesis.

2. Outline of integrated optimization approach

The rotating packed bed is a novel and compact PI operating unit(Ramshaw, Bucklin, et al., 1981, 1987) that utilizes centrifugal acceleration to intensify mass transfer. Its low investment cost leads to growing adoption in gas purification, distillation and nano-material preparation applications(Munjal, Kelleher, Chen, el at., 1989, 1996, 2002). Fig.1 shows the difference in size between the RPB and traditional PB for an industrial desulfurization process. Due to the 1-2 orders of magnitude increase in the volumetric mass transfer coefficient for the RPB, its volume is only 9% as large as the PB. This work examines the industrial desulfurization of cracking dry gas at a refinery in China(see Fig.1) as the specific case study to discuss the integration of process intensification and process synthesis. The dry gas contains about 1vol% H_2S, which is not only a hazard to human health and the environment, but also a burden to pipeline upkeep due to its corrosiveness. The RPB stands beside the packed bed. The dry gas enters the RPB and contacts with an absorbing solution of methyl-diethanolamine (MDEA) counter-currently. The sweet gas after desulfurization leaves the RPB, and goes into a clear dry gas pipeline with a maximum H_2S content specification of 20ppm.Most refineries employ a packed bed for desulfurization. However, conventional PBs require large volumes, leading to high investment costs and large absorbing solution circulation flows. The RPB makes up for these deficiencies of the PB, especially increases with limited space, such as the desulfurization of natural gas on an off shore drilling platform, where the RPB realizes its full potential.

Fig. 1 The comparison between RPB and PB within an industry case

On the other hand, the RPB is rotating equipment that requires significant energy input. As shown in Table 1, the RPB has a distinct advantage over the PB on the space it occupies. However, the RPB requires a motor to provide rotation. Therefore, there are several tradeoffs between RPB and PB. Process intensification and process synthesis

can be coupled to search for novel configurations that combine both technologies as shown in Fig. 2.

In this paper, nonlinear programming models are first presented to optimize the RPB and the PB separately. Next, a superstructure optimization model is proposed to synthesize configurations that integrate the advantages of the packed bed, which requires less energy input, and the rotating packed bed, which has high mass transfer efficiency leading to smaller sizes.

In order to synthesize a design involving RPB and PB units, the superstructure shown in Fig. 3(a) is proposed, in which the liquid and gas streams are distributed among potential streams for countercurrent flow. Gas streams and liquid streams are supplied to the two treatment units. After the gas streams are contacted counter-currently with liquid streams in the units, both gas and liquid are recycled to the treatment units or sent to the outlet stream, subject to a limit on the H_2S concentration of the sweet gas.

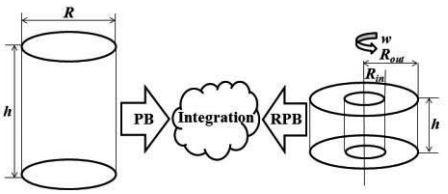

Fig. 2 Processes combining process intensification and synthesis

Table 1 Rotating packed bed vs packed bed

	Rotating Packed Bed	**Packed Bed**
Height	2.89 m	32 m
Equipment volume	3.4 m^3	36 m^3
Motor	37kW	--
H_2S content in sweet gas	<20ppm	<20ppm

The configuration between the RPB and the PB could be in series, as shown in Fig. 3(B), or in parallel, as shown in Fig. 3(C), and even in-between. This is decided by parameters determined from the optimization results. The goal is to minimize the total cost of the integrated system. The synthesis problem is formulated as a nonlinear programming (NLP) model that involves constraints corresponding to the performance of the RPB and the PB, the intensification mechanism of mass transfer, the end-effect quantification of the RPB, and mass balances in the process.

3. Problem statement

The sizes and design parameters of RPB and PB are variables to be determined in the superstructure of Fig 3a so as to meet the gas purifying specification and treatment capacity. The flow rates and concentration of the gas and the liquid in each stream of the superstructure are also variables to be determined. Using mass transfer models for the RPB and the PB, fairly accurate design and operating conditions can be obtained.

The objective is to select the optimal configuration involving the RPB and the PB so as to minimize the total investment and operating costs.

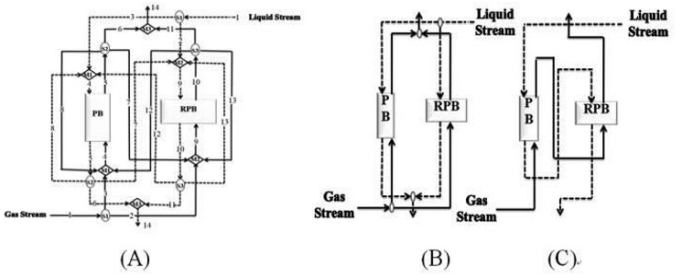

Fig. 3 Superstructure of the integrated RPB and PB processes: (A) overall structure; (B) in parallel configuration; (C) in series configuration. S denotes a splitter and M denotes a mixer, respectively. Gas streams are denoted by solid lines; liquid streams, by dashed lines.

The mathematical model of integrated RPB and PB processes in the superstructure of Fig 3a is NLP model, which consist of mass transfer process intensification mechanisms, fluid flow expressions and mass balance equations.

4.H_2S purification case study

In order to apply the NLP models in the previous section, we consider a case study on a desulfurization process for crack gas at a refinery in China which is shown in Fig.1. The gas contains about 1vol% H_2S and the solvent used is MDEA. This quantity of H_2S is not only a hazard to human health and the environment, but also exacts a high cost for pipeline repair and replacement. The wire mesh packing porosity, ε, is 0.97, and the total specific surface area, a, is 220 m^2/m^3. The liquid jet initial velocity is 6m/s upon entering the rotating bed. Other physical parameters for the H_2S purification case study are presented in Table2. We solve the NLP models for RPB (P1), for PB(P2) and superstructure (P3) using GAMS IPOPT 3.12 and CONOPT 3. The results are presented in Tables3.

Table 2 Parameters for H_2S purification case study

	Rotating Packed Bed	Packed Bed
Content of H_2S	10,000 (ppm)	10,000 (ppm)
Gas flow	10,000 (m^3/hr)	10,000 (m^3/hr)
Liquid film renewal times	90	--
Operating cost scale factor for Rotation,$c_{RPB,1}$	2.2(10,000 CNY/kw)	--
Operating cost factor for RPB volume, $c_{RPB,2}$	121(10,000CNY/m^3)	--
Investment scale factor for PB volume, $c_{PB,1}$	--	5(10,000CNY/m^3)

Operating cost scale factor for RPBliquid pumping, $c_{RPB,3}$	1 (10,000CNY·hr/m^3)	--
Operating cost scale factor for PB liquid pumping, $c_{PB,2}$	--	1.6 (10,000 CNY·hr/m^3)
Diffusion coefficient, D	1.2×10^{-9} (m^2/s)	1.2×10^{-9}(m^2/s)
Reaction rate constant of $H_2S$with MDEA, k_{ov}	1.5×10^{8}(1/s)	1.5×10^{8}(1/s)
H_2S content in exit gas	<100 (ppm)	< 100 (ppm)

Table 3.Comparison between separate reactors and solution from superstructure.

	RPB (Rotating packed bed)	**PB (Packed bed)**	**RPB-PB hybrid**	
			RPB	PB
Height/*m*	0.347	15.275	0.273	7.449

Annual electricity cost for liquid pump /10,000 CNY	5.112	15.926	2.427	8.271
Structure	Individual	Individual	In parallel (b in Fig.3)	
Gross cost /10,000 CNY	69.826	86.928	62.449	

5. Conclusions

This paper investigates the conceptual synthesis of a process involving both conventional and intensified technologies. A superstructure optimization formulation is proposed to consider parallel, series, and in between configurations of the RPB and the PB, with recycle, with the overall goal to minimize the total annual cost while meeting gas capacity and effluent contaminant specifications. To incorporate the micro-mechanisms of intensification into the macro-level superstructure decisions, a multi-scale model was developed that captures the high-level effects of mass transfer in the RPB and the PB, allowing its use in synthesis. The model was applied to a case study involving H_2S removal from refinery tail gas. The computational results shows that the configuration of both RPB and PB in parallel is optimal under the assumption of linear investment and operating costs. Over a wide range of possible electricity prices, the hybrid system of both units is shown to be more cost-effective than a single RPB or PB. This synergistic effect is uncovered with the integration of process intensification and superstructure optimization, illustrating a new way for both PI and PSE to work together.

Abstract

In this work we present an integrated framework to derive intensified designs with guaranteed safety and operability performance. A step-by-step procedure is described featuring: (i) superstructure-based process synthesis using Generalized Modular Representation Framework, (ii) development of advanced multi-parametric control strategies following the PAROC framework and software platform, and (iii) inherent safety analysis at early design stage utilizing quantitative risk assessment. Two case studies with increasing intensification complexity, namely heat exchanger network synthesis and reactive distillation column design, are investigated to demonstrate the capabilities of the proposed framework.

Keywords: Process intensification, Generalized Modular Representation Framework, multi-parametric Model Predictive Control, risk assessment

1. Introduction

Modular process intensification (PI) offers the potential to drastically reduce the energy consumption and processing cost by involving multifunctional phenomena at different time and spatial scales (Van Gerven and Stankiewicz, 2009). In this context, phenomena-based synthesis tools, comparing to their conventional unit-operation-based counterparts, have attracted much interest as a potential means for automated generation of intensified options from a lower aggregation level without a pre-postulation of plausible flowsheets. Recent progress in this field includes, but not limited to, computer-aided software-tool for phenomena-based multiscale and multistage sustainable process synthesis – intensification by Tula et al. (2017), Infinite DimEnsionAl State-space (IDEAS) framework application on energetic intensification of hydrogen production (Pichardo and Manousiouthakis, 2017), and systematic building block approach by Demirel et al. (2017). However, it is worth noting that the afore-derived intensified designs often reduce the degrees of freedom for safe operation and process control due to high integrity, thus arousing concerns from process safety and operability perspective (Baldea, 2015). In this way, further attention is required to simultaneously synthesize intensified but safely operable systems.

The objective of this paper is to introduce a systematic framework to deliver intensified designs through the phenomenological Generalized Modular Representation Framework

(GMF), and at the same time, to guarantee their safety and operability performance by conducting risk assessment and model predictive controller design. The full framework (Figure 1a) and its detailed methodologies (Figure 1b) are described in section 2. In section 3, the framework is applied to heat exchanger network (HEN) synthesis for thermal intensification. A further application on hybrid reaction/separation processes is demonstrated through a reactive distillation case study in section 4.

2. Framework Description

As shown in Figure 1a, the proposed framework consists of three interactive toolboxes (i.e., process intensification/synthesis toolbox, process simulation/optimization toolbox, and process operability/control/safety toolbox) to link steady-state synthesis, dynamic analysis, and operability assessment at the conceptual design stage. Each toolbox can accommodate different techniques implemented in multiple software environments, thus rendering this framework a desirable flexibility. Verifiable and operable process intensification designs are delivered as the outcome. The procedure followed for this purpose and specific techniques for each toolbox in the current work are presented below on a step-by-step basis (Figure 1b).

Step 1: Process Intensification / Synthesis Representation – Generalized Modular Representation Framework (GMF), presented originally in Papalexandri and Pistikopoulos (1996), is utilized for process synthesis from phenomena level. The GMF uses aggregated multifunctional mass/heat exchange modules and pure heat exchange modules to represent chemical processes, conventional or not, by detecting mass and heat transfer feasibilities based on Gibbs free energy (Ismail et al., 2001). Thus, the discovery of intensified pathways can in principle be achieved by optimizing fundamental performance to overcome process bottlenecks, such as improving mass/heat transfer and/or shifting reaction equilibrium.

Step 2: Process Optimization – A superstructure formulation is developed based on GMF to account for the large search space of intensification possibilities. The overall problem is formulated as a mixed integer nonlinear programming (MINLP) problem and solved using GAMS.

Step 3: Process Operability / Safety Assessment – After obtaining the initial optimal design from the aforementioned steps, feasibility test is performed to evaluate its functionality under varying operating conditions. A multiperiod MINLP model is then formulated considering the detected critical operation points. Moreover, risk assessment is incorporated as a constraint into the synthesis model to indicate the inherent safety performance of the resulting design, accounting for consequence severity and equipment failure frequency (Nemet et al., 2017).

Step 4: Optimal Intensified steady-state designs – Up to this point, optimal intensified designs satisfying flexibility and safety targets are derived from steady-state analysis.

Step 5: Dynamic Simulation and Control – "High fidelity" dynamic model of the resulting PI designs determines the validity of dynamic analysis. This modeling task takes place in gPROMS® Process Systems Enterprise (1997-2017). The development of multi-parametric model-based predictive controller (mp-MPC) is performed through the application of the PAROC framework and software platform (Pistikopoulos et al., 2015). Its simultaneous design and control step gives optimal design via the formulation of a (mixed-integer) dynamic optimization problem (Diangelakis et al., 2017).

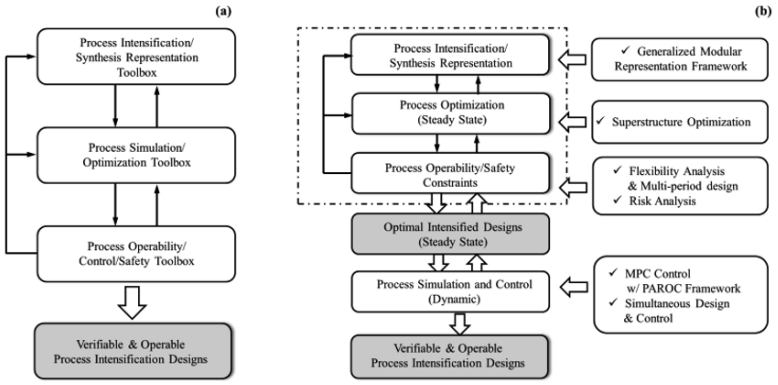

Figure 1. Proposed framework for the synthesis of operable intensification systems (a) The systematic framework, (b) Methodology flow

Step 6: Verifiable and Operable Process Intensification Designs – Closed-loop validation is performed to ensure the consistency throughout the framework, after which verifiable and operable intensification designs will be delivered as the outcome.

3. Heat Exchanger Network Synthesis Example

The afore-described framework is first applied to investigate a heat exchanger network (HEN) synthesis problem for thermal intensification, aiming to demonstrate the steps of the proposed framework as an example from a broader set of intensified systems.

3.1. Problem Description

This case study consists of two hot streams (H1, H2), two cold streams (C1, C2), and one hot utility (HU). Given are: (i) stream flowrate data (Kotjabasakis and Linnhoff, 1987); (ii) uncertain heat transfer coefficient ($U_{H1\text{-}C1}$), for which the flexibility of the network is desired if this stream match is selected; (iii) disturbance and control objective, for which controller design is essential; and (iv) stream toxicity, represented by LC_{50} (i.e., lethal concentration, 50%) of the substance, and equipment data for four types of heat exchanger (HE), namely double pipe HE (DP), plate and frame HE (PF), fixed plate shell and tube HE (SF), and U-tube shell and tube HE (UT), which necessitates inherent safety evaluation (Nemet et al., 2017). The objective is to synthesize a HEN with minimized total annual cost as desired operability performance.

3.2. Steady-state Synthesis with Flexibility and Safety Considerations

The pure heat exchange module of GMF is used here for HEN representation. The superstructure representation accounts for all potential stream matches and their corresponding bypass options. A nominal HEN design without flexibility or safety considerations is first performed to obtain a reference network (Figure 2a). Its risk value is calculated as per introduced in Section 2 Step 3. Two periods of operation are identified by the feasibility test as the extreme values of $U_{H1\text{-}C1}$. To obtain an inherently safer design, risk tolerance is decreased by constraining: (i) overall HEN toxicity risk less than 75% of the nominal risk value, and (ii) individual HE toxicity risk less than 50% of overall risk. Setting the first risk tolerance results in the change of H1-C2 exchanger type from SF to UT (Figure 2b), as the latter one has much higher area density, leading to significant reduction in HE volumes and in the amount of intrinsic

hazards. The risk level is further decreased by confining individual equipment risk so that none of the HEs is particularly risky. In this case, a different network is synthesized to render H1-C2 HE a lower risk level by relieving its heat exchange burden (Figure 2c). These two safely operable HENs separately serve as Candidate 1 and 2 for the next step dynamic analysis.

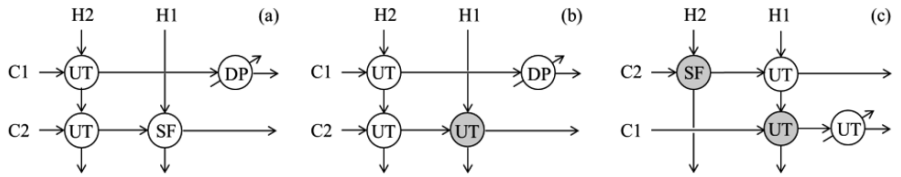

Figure 2. Topology of HEN at different operability level:
(a) Nominal design, (b) Candidate 1, (c) Candidate 2

3.3. Dynamic Modelling and mp-MPC Controller Design

The dynamic HEN is described by a Partial Differential Algebraic Equation (PDAE) model based on gPROMS® Process Model Library for Heat Exchange (PSE, 1997-2017). The network configuration is fixed for each candidate case study as per Figure 3b and 3c, and heat exchanger areas are used as design variables. To ensure the consistency going from steady-state synthesis to dynamic simulation, the dynamic model is validated to match its steady-state synthesis analogue.

In this system, the bypass flowrate and the heat utility duties are the degrees of freedom, and the outlet temperature of stream H1 and C1 are the outputs. The inlet temperature of stream H2 is treated as a disturbance to the operation. The mp-MPC controller design, following PAROC framework (Pistikopoulos et al., 2015), takes place for the two candidates individually. Each mp-MPC problem is formulated using corresponding linear state-space model approximated by the System Identification Toolbox of MATLAB®. Via POP® toolbox in MATLAB®, the problem of Candidate 1 is solved for an output horizon of 2 and a control horizon of 2 resulting in 118 critical regions in solution map, while that of candidate 2 is solved for an output horizon of 2 and a control horizon of 1 resulting in 89 critical regions. Given random disturbances deviating within ±10 K per second, the designed controllers are tested against the "high fidelity" model for closed-loop validation, indicating the agreement between the outputs and setpoints.

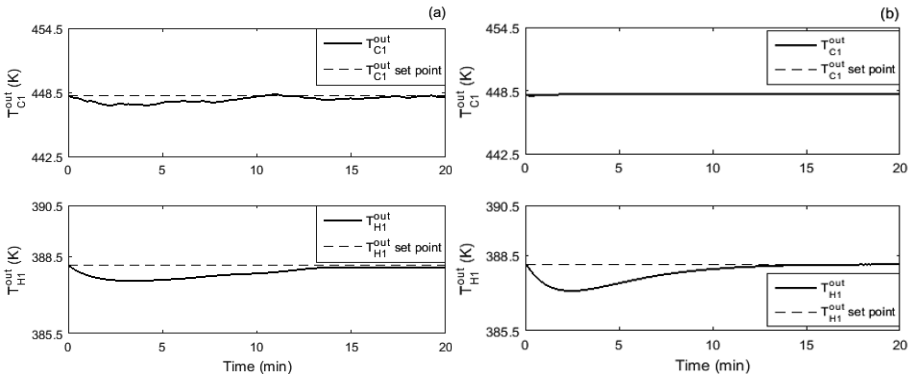

Figure 3. Closed-loop validation of the controller against the high fidelity model:
(a) Candidate 1, (b) Candidate 2

The dynamic optimization problem is then formulated and solved for the minimal total annual cost under each HEN configuration. The obtained results are shown in Table 1. Up to this point, two HENs are designed with different levels of operability, control, and safety. While the final construction decision depends on the trade-off between desired operability behavior and economic performance, this framework demonstrates the potential for comparison of various operable design alternatives.

Table 1. Optimization results for HEN example

	HE Area (m^2)				Investment	Operating Cost
	H1 – C1	H1 – C2	H2 – C1	H2 – C2	Cost (k$)	(k$/yr)
Candidate 1	/	604.4	125.6	99.9	528.4	7357.0
Candidate 2	221.4	522.2	/	165.7	557.4	8593.9

4. Reactive Distillation Example

In this section, the proposed framework is applied on hybrid separation/reaction systems to exploit the synergetic potential of this representative intensification system. The synthesis problem of classical methyl-tertiary-butyl-ether (MTBE) reactive distillation, originally presented in Ismail et al. (2001), is revisited herein for the purpose of demonstration, and to be further investigated for its operability performance.

The design problem aims to produce MTBE bottom product at a rate of 197 mol/s and with the purity higher than 98 mol%. Two types of multifunctional mass/heat exchange modules (i.e., reaction/separation module and pure separation module) and the pure heat exchange modules in GMF are utilized to detect intensification possibilities with respect to the minimal operating and pseudo-capital cost. The optimal design is illustrated in Figure 4. The structure features two hybrid modules for reactive section, one separation module at the bottom separating unreacted methanol back to reactive section, and another separation module at the top transferring n-butene to distillate. This result is consistent while slightly improved comparing to the literature results.

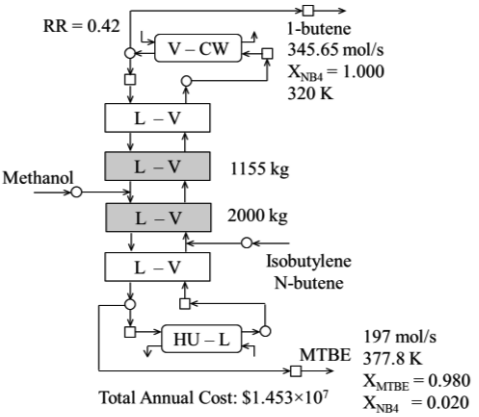

Figure 4. Optimal GMF design of MTBE reactive distillation

In the dynamic analysis, the "high fidelity" dynamic rate-based model of MTBE reactive distillation column is adapted from Schenk et al. (1999), represented by sets of differential algebraic equations (DAE) of index 1. In this system, the design variables include column diameter, reboiler and condenser heat exchange areas. Reflux ratio, steam flow rate, and cooling water flow rate are the three degrees of freedom. Sinusoidal disturbance in the isobutylene inlet composition is introduced while product specification is to be satisfied via the design of mp-MPC controller.

4. Conclusions

In this paper, we present a systematic framework for the design of intensified system with guaranteed operability and safety performance. The framework is applied to two representative intensification systems (i.e., heat integration and reactive distillation). The results indicate that significant improvement can be achieved to exploit intensification opportunities by utilizing phenomena-based Generalized Modular Framework, and to enhance safety and control by performing corresponding assessment at the early design stage. The full framework enables to complete the whole story of synthesizing operable intensification systems. Future work will focus on applying the framework to more intensification systems, as well as zooming in the techniques employed in each toolbox.

Efficiency Analysis of Chemical-looping Fixed Bed Reactors integrated in Combined Cycle Power Plants

Chen Chen, George M. Bollas*

Department of Chemical & Biomolecular Engineering, University of Connecticut, 191 Auditorium Road, Unit 3222, Storrs, CT 06269, USA.
george.bollas@uconn.edu

Abstract

In this work, dynamic modeling is used as a tool to analyze the performance of chemical-looping combustion (CLC) integrated with combined cycle (CC) power plants. Fixed bed CLC reactors are incorporated into CC power plants. Efficiency improvements are achieved by optimizing the process design and managing CLC operating strategies. Specifically, this work presents the effect of operating variables on the performance of CLC-CC. The optimal CLC-CC power plant model has a time-averaged efficiency of 51.84%, power output of 223.6 MW, and CO_2 capture efficiency of 96%. The main factor that limits plant efficiency is the maximum reactor temperature, which is constrained by the materials of oxygen carriers. Moreover, it is shown that the impact of the temperature of air fed to the CLC heat removal stage and the pressure ratio are more significant than other process variables.

Keywords: Chemical-looping combustion, CO_2 capture, power generation.

1. Introduction

Greenhouse gas emissions have been identified as a main cause for detrimental global climate change. Fossil fuel combustion mainly contributes to the increasing emissions of CO_2, the key constituent of greenhouse gases. However, due to the intermittent nature of renewable energy sources, the use of fossil fuel remains necessary to balance the electricity grid and avoid other cascading problems. Greenhouse gas emission mitigation can be also accomplished by reducing fossil fuel consumption or by improving the efficiency of energy generation and utilization. Switching to less carbon intensive fuels also reduces CO_2 emissions. Compared with coal, the combustion of natural gas has a smaller carbon footprint and higher thermal efficiency. Combined cycles (CC), using natural gas, can reach higher efficiencies of up to ~60%, which is by far the highest efficiency in thermal power processes. Moreover, carbon capture and storage (CCS) technologies have the potential to accomplish very low levels of CO_2 emissions. Among CCS technologies, chemical-looping combustion (CLC) is a promising approach to capturing CO_2 with a low energy penalty. In CLC, the fuel and air remain unmixed by using a metal oxide as oxygen carrier (OC) to transport oxygen from the air reactor (where OC is oxidized by air) to the fuel reactor (where OC is reduced by fuel). The produced H_2O and CO_2 are inherently separated from other gases in the process avoiding the need for additional equipment or energy consumption for the separation of CO_2. Therefore, process options should include CC and CLC to reduce CO_2 emissions per unit of energy. Fluidized bed CLC reactors, which were largely the focus of prior work, are not able to

maintain stable solids circulation at the high pressure required for CC power plants. Therefore, fixed bed reactor designs were proposed to circumvent the solids separation and loop sealing problems under high pressure. Moreover, CLC fixed bed reactors are easy to scale to meet requirements for intensification and modularization, pressurize, and can handle relatively large range of particle sizes. Due to their compact design, lower capital cost, better utilization of OC, and smaller process footprint, fixed bed reactors are excellent candidates as process intensification options for CLC-CC plants.

System-level dynamic simulation and optimization play a significant role in exploring the feasibility of integrating CC with CLC. For example, Spallina et al. (2014) simulated a series of CLC-CC power plants showing average efficiencies of 41% at CO_2 capture efficiency of 97%. Chen et al. (2016) presented a dynamic model of CC with CLC fixed bed reactors, and showed that the CC performance is only slightly affected by the intrinsic dynamics of the semi-batch operation of fixed beds. Prior research presented the integration CLC with CC, and the static and dynamic estimation of a CC power plant with semi-batch fixed bed CLC reactor (Chen et al., 2016). The power plant model with a simple control architecture was simulated and validated against full load data reported in the literature. The conventional combustor was replaced by a high-pressure CLC island including fixed bed reactors operating in parallel. This analysis showed that the CC power plant generates relatively stable electricity output despite the intrinsic dynamics of fixed beds. This was accomplished by optimizing the CLC operational strategy for stability and thermal efficiency. The estimated efficiency of CLC fixed beds with CC was estimated at ~48% with a small fluctuation of ~2% around the desired steady state.

The objective of this work is to further improve the overall efficiency of the integrated CLC-CC power plant, wherein the conventional combustor is replaced by a CLC island. In the following, the CLC-CC process is described, and the configuration and arrangement of the power plant studied is presented. Thereafter, the optimal control formulation for CLC operation is discussed. The last section communicates efficiency evaluations of the integrated CLC-CC power plant. The efficiency analyses present the impact of certain variables on the power plant operations and potential efficiency improvements by adjusting selected manipulated variables and plant degrees of freedom.

2. Description of the CLC-CC Process

In a typical CC process, fuel is mixed with compressed air in the combustor to generate high-temperature flue gas, which is then expanded in the gas turbine to generate electricity. The gas turbine exhaust feeds a steam (Rankine-type) cycle to evaporate and superheat water, which is expanded in steam turbines to generate additional electricity. In this work, a natural-gas-fueled CC power plant was used as the reference case. This CC power plant has an efficiency of 57.9% and power output of 250 MW. The pressure ratio used for the gas turbine is 30:1. The temperature of flue gas fed to the gas turbine is 1440 °C. The superheated steam is at 565 ℃ and 160 bar. The model development and validation of this commercial system were presented in prior work (Chen et al., 2016).

Figure 1 presents the key design aspects of a CLC-CC plant, where the conventional combustor is replaced by a CLC island. Air feeds the oxidization reactor, and fuel is fed to the reduction reactor. A heat removal stage is used to extract the heat generated by the oxidation of the metallic oxygen carrier, sending high-pressure/high-temperature gas to be expanded in the gas turbine of the CC plant. The exhaust of the gas turbine is fed to a steam cycle. Two new HRSGs (HRSG3 and HRSG4) are incorporated, as compared to

previous designs presented in Chen et al. (2016). The heat of the purge exhaust is utilized to superheat water in the HRSG3. The oxidation exhaust firstly superheats the steam in the HRSG4, and then the HRSG4 exhaust preheats the compressed air.

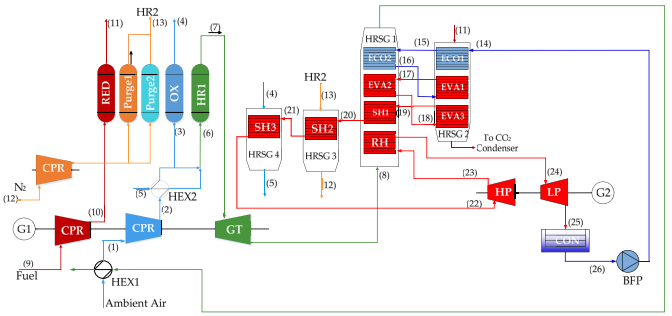

Figure 1. Diagram of the optimal CC power plant with fixed bed CLC reactors.

3. CLC Optimal Control Formulation

The fixed bed CLC reactor was represented with a heterogeneous reactor model (Han et al., 2016a, 2016b) This model includes conservation equations of mass, energy and momentum. Reaction kinetics models were developed on the basis of experimentation and model-based optimal design of experiments. These kinetic models were modified to account for pressure effects with empirical correlations adjusting the atmospheric pressure kinetics, which was verified for accuracy in high-pressure CLC experiments. Overall, the reactor models used in this work are sufficiently accurate to describe the operation of large-scale fixed bed systems, as shown in Zhou et al (2015a, 2015b). The kinetic model is extrapolated in term of temperature range from the developed earlier, to illustrate the benefits of high temperature on CLC-CC efficiency. Using these reactor models an optimal CLC-CC configuration was designed, which included several semi-batch CLC reactors operating in parallel (in different operating mode – reduction, purge, oxidation, heat removal, purge). The integrated CLC island was optimized for thermal efficiency by manipulating the time delay between reactors and operating variables, as discussed in the following section. For a given plant arrangement and oxygen carrier, the optimal control strategy searches for decision variable values that maximize CLC efficiency, while always satisfying plant steady state and dynamic constraints. The system model and optimization were implemented and solved in the commercial software package gPROMS (Process Systems Enterprise, 2014).

Table 1. Control variables in the optimal control problem

Control variables	Notation
Air feed rate Air temperature Fuel feed rate Fuel temperature	$\mathbf{u}_i$
Reduction time interval Oxidation time interval Heat removal time interval	τ_i

As shown in Table 1, the control profile for switching gas streams to the CLC reactor employs piecewise constant functions, represented as $\mathbf{u}(\tau_i)=\mathbf{u}_i$, where $\mathbf{u}$ is the vector of feed rate and temperature of the gas streams and τ_i is the time duration of the i-th CLC

step, i.e., reduction, purge, and oxidation. The set of control variables is summarized in the design vector, represented as $\boldsymbol{\phi}=[\mathbf{u}_i,\boldsymbol{\tau}, \boldsymbol{\omega}]$, which is constrained by upper and lower limits permitted in the design space, $\boldsymbol{\Phi}$.

3.1. Optimization Formulation

Typical targets for CLC-based power plants are ≥ 96% CO_2 capture efficiency and ≥ 98% fuel conversion, as written in Eqs.(1)-(2). Additional constraints defined by power plant considerations included $T_{out}(t)$ (heat removal exhaust gas temperature) stability (within a set tolerance, δ), limits to the pressure drop across the reactor, and maximum allowable internal temperature to ensure material stability, as shown in Eqs.(3)-(5). The overall objective of this optimization was to maximize the CLC power generation capability over the cyclic operation of the fixed bed by varying the control variables shown in Table 1. For the CLC island of the CLC-CC plant, efficiency was represented as the fraction of enthalpy of gas fed to gas turbine. In Eq.(6), T_{out}, $\dot{m}_{out}$, h_{out} are the temperature, mass flow rate, and enthalpy of exhaust streams, τ_{HR} is the heat removal duration, τ_{cycle} is the interval of one complete redox cycle. **f** is the set of differential algebraic equations representing the fixed bed reactor for states **x**, admissible inputs $\mathbf{u}_i$, and cycle duration $\boldsymbol{\tau}_i$. The time horizon for the optimization is at least twice that of the τ_{cycle}, because it takes more than one redox cycle to achieve the cyclic steady state.

$$S_{CO_2}(t)= \frac{\int_{t_0}^{\tau RED} F_{out}(CO_2,t)dt}{\int_{t_0}^{\tau RED} F_{in}(CH_4,t)dt} \geq 96\%, \tag{1}$$

$$X_{fuel}(t)= 1-\frac{\int_{t_0}^{\tau RED} F_{out}(CH_4,t)dt}{\int_{t_0}^{\tau RED} F_{in}(CH_4,t)dt} \geq 98\%, \tag{2}$$

$$TIT-\delta \leq T\_out\ (t) \leq TIT+\delta, \tag{3}$$

$$\left(\frac{\Delta P}{P_{in(t)}}\right) \leq \Delta P^{max}, \tag{4}$$

$$T(t,z)+\delta \leq T^{max}, \tag{5}$$

The control optimization problem was formulated as follows:

$$\max \eta_{HR} = \max \frac{\int_{t_0}^{\tau_{HR}} (\dot{m}_{out}(t)\cdot h_{out}(t))dt}{\int_{t_0}^{\tau_{cycle}} (\dot{m}_{out}(t)\cdot h_{out}(t))dt}$$

subject to: Eq. (1)-(5)

$$\begin{aligned}
&\mathbf{f}(\dot{\mathbf{x}}(t),\mathbf{x}(t),\mathbf{u}(t),\boldsymbol{\theta},t)=0,\\
&\mathbf{f}(\dot{\mathbf{x}}(t_0),\mathbf{x}(t_0),\mathbf{u}(t_0),\boldsymbol{\theta},t_0)=0,\\
&\mathbf{y}(t)=\mathbf{h}(\mathbf{x}(t)),\\
&\mathbf{x}^{\min}\leq\mathbf{x}(t)\leq\mathbf{x}^{\max}\\
&\mathbf{u}_i^{\min}\leq\mathbf{u}_i\leq\mathbf{u}_i^{\max} \qquad \forall \boldsymbol{i}\in[\mathbf{1},\boldsymbol{N_u}]\\
&\tau_i^{\min}\leq\tau_i\leq\tau_i^{\max} \qquad \forall \boldsymbol{i}\in[\mathbf{1},\boldsymbol{N_u}]
\end{aligned} \tag{6}$$

3.2. Case study: Fixed bed CLC with NiO and CH_4

The case study discussed in this section optimizes a Ni-loaded fixed bed CLC reactor with CH_4 as the fuel and the corresponding constraints for optimal control of the CLC-CC power plant. The CLC reactors are designed so that they can handle the same heat input as that of the reference CC power plant. Table 2 shows the specific parameters for a single fixed bed reactor. As shown in Figure 2(a), the oxidation exhaust achieves the

desired set-point with minimal deviations. The heat removal step initiates when the exhaust temperature is within 50 °C from *TIT*. After most of the heat has exited the bed and $T_{out}(t) < TIT\text{-}50$, the reactor is briefly purged and the feed switches to CH_4. The fuel flow rate is much lower than the air feed rate, which explains the sudden drop in exhaust gas enthalpy. In Figure 2(c), there is a sudden drop in O_2 and rise in N_2 when the cycle switches from oxidation (OX) to heat removal (HR), because the OX exhaust was mixed with inlet air during HR, to improve overall energy efficiency.

Table 2. Parameters of the fixed bed CLC reactor

Parameter	Value	Parameter	Value
Weight content of metal oxide	40 wt.% NiO	CH_4 flow rate	8.626 kg/s
Particle diameter	5 mm	Max. reactor temperature	1300 °C
Reactor length	9.4 m	Max. reactor pressure	30 bar
Reactor diameter	4.7 m	Turbine inlet temperature, *TIT*	1250 °C
Max. pressure drop	0.03 bar	Temperature tolerance, δ	50 °C

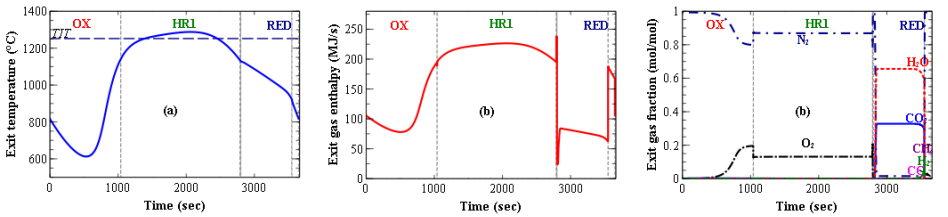

Figure 2. Dynamic profiles of exit gas (a) temperature, (b) enthalpy, and (c) composition.

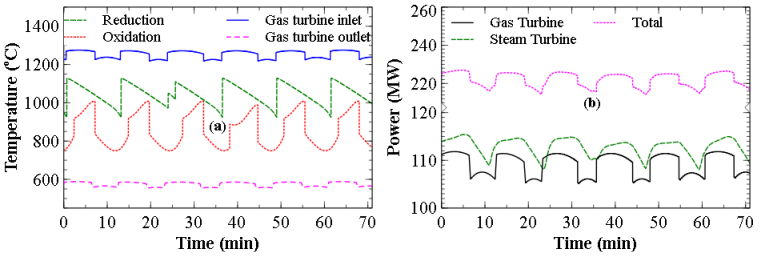

Figure 3. (a) Temperature profiles of the gas streams; (b) dynamic power performance.

3.3. Efficiency Evaluation of CLC-CC

The exhaust gas from each CLC reactor was mixed according to its originating cycle, thus the temperature profiles are less fluctuating than those of the gases from a single reactor, as shown in Figure 3 (a). The exhaust gases can be grouped as: CO_2/H_2O from RED, N_2/O_2 from OX, and air from HR. Here, the CC model was developed in a commercial software Dymola (Elmqvist et al., 1996) and integrated with the CLC model developed in gPROMS. The gPROMS CLC model outputs were brought into the gas turbine in the Dymola CC model as boundary conditions. The stream data of gas fed to the CLC reactor island was matched to those generated by the compressor in the Dymola plant model. The overall plant efficiency was improved by manipulating variables, such as the pressure ratio (*PR*), temperature of the gas compressor feed (T_{CPR}), temperature of the combustor feed (T_{air}), and mass flow of feed water ($\dot{m}_{FW}$). T_{air} is the temperature of air fed to the OX

and HR stages, T_{OX} andT_{HR}, respectively. Table 3 shows the impact of variables on the gas power output (P_{GT}), steam power out (P_{ST}), and total power output (P_{TOT}), and efficiency improvements ($\Delta\eta$).The optimal CLC-CC power plant has a time-averaged efficiency of 51.84%, time-averaged power output of 223.6 MW, and CO_2 capture efficiency of 96%. The efficiency is ~6% points lower than the reference CC power plant, which mainly results from the lower *TIT* reached in CLC (Naqvi and Bolland, 2007).

Table 3. Impact of variables on the power plant performance. *

Variables	Range	P_{GT}	P_{ST}	P_{TOT}	$\Delta\eta$
T_{CPR} [°C]	[23,50]	-	+	-	0.39%
T_{OX} [°C]	[480,550]	+	-	+	0.51%
T_{HR} [°C]	[480,520]	+	-	+	3.83%
PR [-]	[10,30]	-	+	max**	0.7%
$\dot{m}_{FW}$ [kg/s]	[57,76]	/	-	-	0.19%

* "+" means that increasing the variable improves the power generation, while "-" means the opposite; ** PR=20:1, the total power generation reaches the maximum value.

4. Conclusions

The efficiency of an integrated CLC-CC power plant was improved with an optimal CLC control strategy, modification of power plant arrangement and design, and manipulation of the remaining plant degrees of freedom. It was shown that an optimal CLC-CC power plat can reach efficiencies of up to 51.84% at CO_2 capture efficiency of 96%. *PR* and T_{HR} were shown to be more significant than other plant admissible inputs. Higher T_{HR} values originate from higher reactor temperatures, which are only feasible with oxygen carriers that can tolerate these high temperatures. Future oxygen carrier materials research should focus on enabling higher reactor temperatures, which leads to higher CLC-CC power plant efficiency.

Modeling Multistream Heat Exchangers (MHEXs) Using Operational Data

Harsha Nagesh Rao[a] and Iftekhar A. Karimi[a*]

[a]*Dept. of Chemical & Biomolecular Engineering, National University of Singapore, 4 Engineering Drive 4, Singapore 117585*
cheiak@nus.edu.sg

Abstract

Multi stream heat exchangers (MHEXs) allow simultaneous heat exchange among multiple streams. These exchangers are usually used in energy-intensive applications such as natural gas liquefaction, air separation, etc. Minimizing the energy consumption of processes with existing MHEXs is crucial, but reliable system-wide operational optimization requires the knowledge of flow distribution and individual heat-transfer areas of the exchanging streams in MHEXs. However, MHEXs are virtually black boxes due to their proprietary designs and complex geometry. In this work, we present a generic non-linear programming (NLP) model to estimate the flow distribution and heat transfer areas for each pair of exchanging streams in an MHEX based on its historic operational data. We apply the developed geometry-independent model on the main cryogenic heat exchanger (MCHE) from an existing C3MR LNG plant and estimate its heat transfer parameters successfully. These parameters can then be used for the operational optimization of the process.

Keywords: MHEX, NLP, Optimization, LNG

1. Introduction

Multi stream heat exchangers (MHEXs) are individual process units that allow simultaneous exchange of heat among multiple streams. Mainly used in energy-intensive cryogenic processes like natural gas liquefaction, air separation, etc., MHEXs are complex, proprietary and often associated with phase changes of mixtures. An MHEX normally has several sections in series, called bundles (Hasan et al., 2009; Nagesh Rao & Karimi, 2017). These bundles can be viewed as independent MHEXs which may not necessarily have the same exchanging streams.

While numerous studies have addressed the design of processes employing MHEXs (Nagesh Rao & Karimi, 2017; Tsay et al., 2017), very few studies have attempted the operational optimization of processes employing MHEXs. Operational optimization of a process, in the context of this study, primarily involves obtaining optimal operating conditions for various process units (E.g. stream temperatures, pressure ratios for compressors, etc.) given MHEXs with known flow distribution and individual heat-transfer areas between each pair (hot and cold) of exchanging streams.

However, as MHEXs have proprietary designs and complex fluid flow patterns (Hasan et al., 2009; Nagesh Rao & Karimi, 2017), it is difficult to characterize their flow distribution and heat transfer areas. Hence, we need operational models estimate the flow distribution and the individual heat transfer areas for the streams exchanging heat in an MHEX. Furthermore, the estimated parameters can be used to predict the response of the MHEX for process variations in feed conditions, ambient temperature, etc. Without an

accurate predictive model, operators must depend on their qualitative experience and employ heuristics during process variations (Hasan et al., 2009).

When there is limited knowledge about the internals of the MHEX, simpler models which are applicable to all classes of MHEXs are preferable. However, very few generic operational models exist in literature. Hasan et al. (Hasan et al., 2009) modeled MHEX operation using a hypothetical network of two stream heat exchangers. They proposed a novel mixed-integer nonlinear programming (MINLP) formulation using operational data for finding the best equivalent network representing an MHEX. Their formulation incorporated phase change of streams but allowed only one cold stream. Also, they neglected heat leaks and pressure drop prevalent in MHEX operation. Khan et al. (Khan et al., 2012) modeled MHEXs using artificial neural networks. Jiang et al. (Jiang et al., 2015) developed an equation oriented predictive model for an MHEX in air separation units. They used a regression model to correlate the outlet temperatures with the inlet temperatures and flowrates. However, such data-trained models may not predict the performance accurately when the operation is away from training conditions (Hasan et al., 2009). As they have no physical significance, data-trained may not even ensure thermodynamic feasibility. Clearly, there is a need to develop a reliable and simple operational model for MHEXs to address the above shortcomings.

In this work, we propose a geometry-independent model for MHEXs using operational data. MHEX operation is described using a network of two-stream exchangers following Hasan et al. (Hasan et al., 2009). The model presented can handle multiple hot and cold streams, include ambient heat leaks, and consider pressure drops. Our approach enables us to deduce a series of exchangers that best represents the operation of the MHEX without the need for integer programming, making our formulation NLP rather than MINLP.

2. Problem Statement

Consider a bundle in an existing MHEX. $\boldsymbol{I}$ hot streams ($\boldsymbol{i = 1, 2, \dots, I}$) and $\boldsymbol{J}$ cold streams ($\boldsymbol{j = 1, 2, \dots, J}$) of known physical properties pass through this bundle. The properties include compositions, flowrates, inlet and outlet temperatures, and inlet and outlet pressures. These operational data are available for $\boldsymbol{N}$ distinct steady states ($\boldsymbol{n = 1, 2, \dots, N}$) of the bundle. Given these, we aim to estimate the flow distribution and heat transfer areas for each pair of heat-exchanging streams in the bundle that best describes its operation over all $\boldsymbol{N}$ states. We assume that the hot streams supply heat to cold streams only.

3. Model Formulation

The primary idea is to represent the operation of an MHEX bundle by a network of simple two-stream heat exchangers with known flow distribution and heat transfer areas for each pair of exchanging streams. Given the inlet temperatures of the exchanging streams, this network of exchangers must predict the outlet temperatures close to the actual temperatures. We use the single-stage superstructure (Figure 1) presented in our previous work (Nagesh Rao & Karimi, 2017) to derive this network.

We have N sets ($n = 1, 2, \dots, N$) of operational data. We split hot stream i into J substreams and cold stream j into I substreams to allow heat exchange in $I \times J$ parallel series (S_{ij}, $i = 1, 2, \dots, I$; $j = 1, 2, \dots, J$) of two-stream exchangers. Let S_{ijn} denote the series for data set n. Each S_{ijn} can have at most five of the exchangers ($k = 1, 2, \dots, 5$) to allow dedicated phase change intervals in the series (Nagesh Rao & Karimi, 2017). We

use s to denote any stream entering/leaving a bundle, hot (i) or cold (j), and define the following parameters. $F_{sn}, TI_{sn}, TO_{sn}, PI_{sn}, HI_{sn},$ and HO_{sn} be the molar flow, inlet temperature, outlet temperature, inlet pressure, outlet pressure, inlet molar enthalpy (specific), and outlet molar enthalpy (specific) of stream s in data set n. DP_{in} and BP_{in} be the specific molar enthalpy of hot stream i at its dew point and bubble point in data set n respectively. Similarly, DP_{jn} and BP_{jn} be the specific molar enthalpy of cold stream j at its dew point and bubble point in data set n respectively.

3.1. Estimation of flow distribution

Let f_{ij} denote the fraction of hot substream i flowing through S_{ij}, and g_{ij} denote the fraction of cold substream j flowing through S_{ij}. Therefore,

$$\sum_j f_{ij} = 1 \tag{1}$$

$$\sum_i g_{ij} = 1 \tag{2}$$

Consider an exchanger E_k in S_{ijn}, and call it E_{ijkn}. Let us define the following for E_{ijkn} as shown in Figure 1.

$TIN_{ijkn}, TOUT_{ijkn}$ = Inlet and outlet temperatures of the hot stream
$tin_{ijkn}, tout_{ijkn}$= Inlet and outlet temperatures of the cold stream
$PIN_{ijkn}, POUT_{ijkn}$ = Inlet and outlet pressures of the hot stream
$pin_{ijkn}, pout_{ijkn}$= Inlet and outlet pressures of the cold stream
$HIN_{ijkn}, HOUT_{ijkn}$ = Inlet and outlet specific molar enthalpies of the hot stream
$hin_{ijkn}, hout_{ijkn}$= Inlet and outlet specific molar enthalpies of the cold stream
Q_{ijkn}= Heat duty of E_{ijkn}

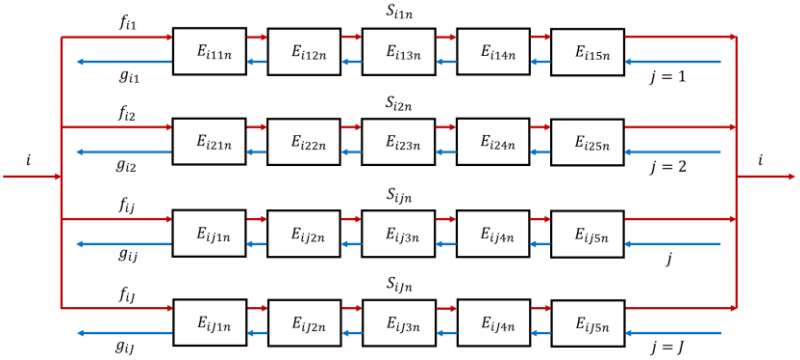

Figure 1. Schematic of our single-stage superstructure with $I \times J$ potential exchanges.

The inlet pressures and molar enthalpies of each series S_{ijk} are specified from the operational data, $HIN_{ij1n} = HI_{in}$, $hin_{ij5n} = HI_{jn}$, $PIN_{ij1n} = PI_{in}$ and $pin_{ij5n} = PI_{jn}$.

Then, in each series S_{ijk} (Figure 1), we have $HIN_{ijkn} = HOUT_{ij(k-1)n}$ and $PIN_{ijkn} = POUT_{ij(k-1)n}$ for $2 \le k \le 5$. Similarly, $hin_{ijkn} = hout_{ij(k+1)n}$ and $pin_{ijkn} = pout_{ij(k+1)n}$ for $1 \le k \le 4$. Next, we write the following related to the energy balance for E_{ijkn}.

$$HIN_{ijkn} \ge HOUT_{ijkn},\ hout_{ijkn} \ge hin_{ijkn} \tag{3}$$

$$Q_{ijkn} = f_{ij}F_{in}\left(HIN_{ijkn} - HOUT_{ijkn}\right) = g_{ij}F_{jn}(hout_{ijkn} - hin_{ijkn}) \tag{4}$$

We distribute the pressure drops across E_{ijkn} in proportions to their heat duties using the following equations.

$$Q_{ijn} = \sum_{k=1}^{5} Q_{ijkn} \quad (5)$$

$$(PIN_{ijkn} - POUT_{ijkn})Q_{ijn} = Q_{ijkn}(PI_{in} - PO_{in}) \quad (6)$$

$$(pin_{ijkn} - pout_{ijkn})Q_{ijn} = Q_{ijkn}(PI_{jn} - PO_{jn}) \quad (7)$$

Next, we prevent phase change in E_{ijkn} to using the following equations.

$$\left[HIN_{ijkn} - DP_{in}\right]\left[HOUT_{ijkn} - DP_{in}\right] \geq 0 \qquad 1 \leq k \leq 5 \quad (8)$$

$$\left[HIN_{ijkn} - BP_{in}\right]\left[HOUT_{ijkn} - BP_{in}\right] \geq 0 \qquad 1 \leq k \leq 5 \quad (9)$$

$$\left[hin_{ijkn} - DP_{jn}\right]\left[hout_{ijkn} - DP_{jn}\right] \geq 0 \qquad 1 \leq k \leq 5 \quad (10)$$

$$\left[hin_{ijkn} - BP_{jn}\right]\left[hout_{ijkn} - BP_{jn}\right] \geq 0 \qquad 1 \leq k \leq 5 \quad (11)$$

Then, the substreams of hot stream i from each series S_{ijn} mix to form the parent stream. The outlet enthalpy of stream i exiting the bundle for data set n is given by

$$\overline{\overline{HOUT}}_{in} = \sum_j f_{ij}.HOUT_{ij5n} \quad (12)$$

As heat leak/gain from the ambient may be prominent in some processes, outlet enthalpy of the cold stream j exiting the bundle for data set n is given by

$$\overline{\overline{hout}}_{jn} = \sum_i\left[g_{ij}.hout_{ij1n} \pm qc_j\left(g_{ij}.hout_{ij1n} - hin_{ij5n}\right)\right] \quad (13)$$

$$0 \leq qc_j \leq 1 \quad (14)$$

where, qc_j is the fraction of the total change in cold stream enthalpy due to heat leak/gain from the ambient. To ensure the minimum approach temperature (MTA_{ij}) in series S_{ij}, we have

$$TIN_{ijkn} \geq tout_{ijkn} + MTA_{ij},\ TOUT_{ij5n} \geq tin_{ij5n} + MTA_{ij} \quad (15)$$

We use the formulation provided in our previous work (Nagesh Rao & Karimi, 2017) to estimate the temperature of the exchanging streams as a function of their specific enthalpy and pressure. Finally, we define the objective function to estimate optimal flow fractions f_{ij} and g_{ij}. Our objective is to minimize the difference between the actual outlet temperatures and the predicted outlet temperature for hot and the cold streams. Hence, we minimize the squared error between the observed and predicted outlet enthalpies summed over the n data sets

$$Min.\ \sqrt{\sum_n\left[\ \sum_i\left[\left(HO_{in} - \overline{\overline{HOUT}}_{in}\right)\right]^2 + \sum_j\left[\left(HO_{jn} - \overline{\overline{hout}}_{jn}\right)\right]^2\ \right]} \quad (16)$$

Let us refer to the above equations as model 1 (M1). The result of M1 provides the optimal flow distribution between each hot stream and cold stream (f_{ij} and g_{ij}), and the duty of each segment in S_{ijn}. In the next section, we develop a separate NLP model M2 to estimate the heat transfer area A_{ij} of the series S_{ij}.

3.2. Areas for two-stream exchanges

Given the duty of each exchanger E_{ijk} in S_{ijn} from the solution of M1, we predict the

heat transfer areas A_{ij} for each series that best describes the operation of the bundle. The log mean temperature difference ($LMTD$) is of the form

$$LMTD_{ijkn} = \begin{cases} \frac{\left(\Delta T^1_{ijkn} - \Delta T^2_{ijkn}\right)}{\left[\ln\left(\Delta T^1_{ijkn}\right) - \ln\left(\Delta T^2_{ijkn}\right)\right]}, & \Delta T^1_{ijkn} \neq \Delta T^2_{ijkn} \\ \frac{\Delta T^1_{ijkn} + \Delta T^2_{ijkn}}{2}, & \Delta T^1_{ijkn} = \Delta T^2_{ijkn} \end{cases} \quad (17)$$

where, $\Delta T^1_{ijknm} = TIN_{ijkn} - tout_{ijkn}$ and $\Delta T^2_{ijkn} = TOUT_{ijkn} - tin_{ijkn}$ are the two temperature approaches. We follow Tsay et al. (Tsay et al., 2017) to estimate the tube side heat transfer coefficient α^{tube}_{ijknm} and the shell side heat transfer coefficient α^{Shell}_{ijknm} of the MHEX. Then, we have the overall heat transfer coefficient U_{ijkn} for E_{ijkn} given by

$$U_{ijkn} = \frac{\alpha^{tube}_{ijkn}.\alpha^{Shell}_{ijkn}}{\alpha^{tube}_{ijkn} + \alpha^{Shell}_{ijkn}} \quad (18)$$

Then, the heat transfer area for E_{ijkn} is given by

$$A_{ijkn} = \frac{Q_{ijkn}}{U_{ijkn} LMTD_{ijkn}} \quad (19)$$

The area A_{ij} of the heat exchangers in series S_{ij} can be predicted by minimizing the following objective function

$$Min. \sqrt{\sum_i \sum_j \sum_n \left(A_{ij} - \sum_k A_{ijkn}\right)^2} \quad (20)$$

4. LNG Case Study

We applied our models M1 and M2 on an existing main cryogenic heat exchanger (MCHE) of an LNG plant in Qatar employing the C3MR liquefaction process. We implemented these M1-M2 in BARON/GAMS 24.6.1 in a 64-bit Windows 7 desktop with a 3.6 GHz Intel Core i7 processor and 16 GB of RAM. As shown in the Figure 2, the MCHE consists of three bundles, viz. hot, mid and cold bundles. The hot and mid bundles have four hot streams viz. Natural gas (NG), mixed refrigerant liquid (MRL), mixed refrigerant vapour (MRV) and liquefied petroleum gas (LPG) being cooled by the mixed refrigerant (MR). LPG mixes with NG post its exit from the mid bundle, and enters the cold bundle along with MRV. MRV exiting the cold bundle returns to the bundle via a Joule-Thomson (J-T) valve as a cold stream.

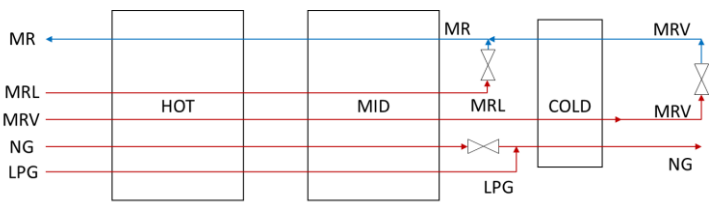

Figure 2. MCHE configuration in the LNG case study

We use the operational data presented in Hasan et al. (Hasan et al., 2009). Furthermore, we pre-processed data to include the J-T valve expansions of the streams exchanging heat in the MCHE. The flow distribution and the heat exchange areas are shown in Figure 3. The areas are given in a scaled unit au to ensure confidentiality.

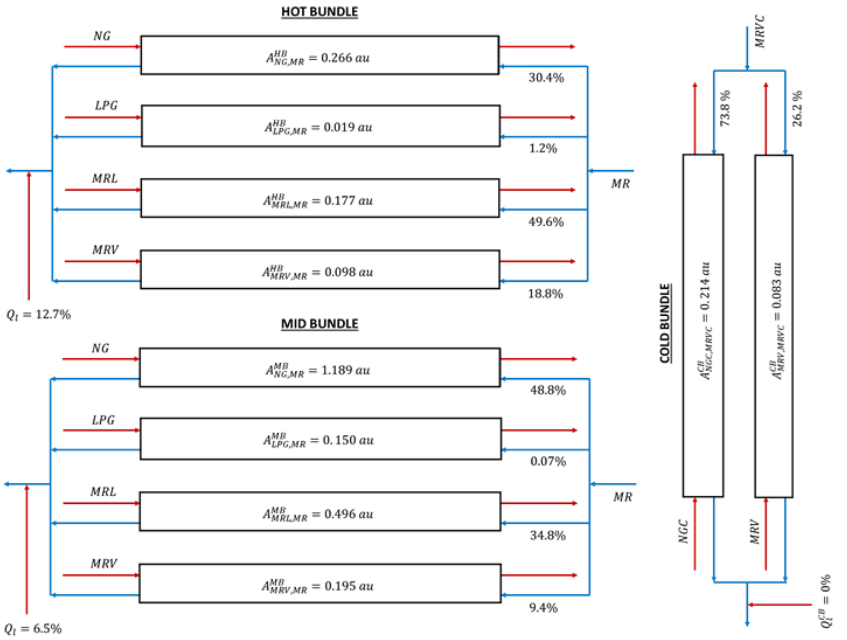

Figure 3. Estimated flow distribution and individual heat transfer areas for the MCHE

5. Conclusions

We presented an operational model for MHEXs to estimate the flow distribution and the individual heat transfer areas of the exchanging streams. This data-driven NLP model is geometry-independent and can be applied to any class of MHEXs. We used a simpler single-stage superstructure to develop the model which can handle multiple hot and cold streams, consider pressure drops and include ambient heat leaks. We then applied our model on a 3-bundle MCHE from an existing LNG plant in Qatar, and estimated the flow fractions and the heat exchange areas between the hot streams and the refrigerant in each bundle. Along with enabling the operational optimization of the process, the estimated parameters can also be used for predicting the response of MHEXs under variations in feed conditions, ambient temperature, etc.

This work was funded under Energy Innovation Research Programme (EIRP) Award NRF2014EWTEIRP003-008, administrated by the Energy Market Authority (EMA).

Simulation and optimization of a combined cycle gas turbine power plant under part-load operation

Zuming Liu, Iftekhar A. Karimi*

Department of Chemical & Biomolecular Engineering, National University of Singapore, 4 Engineering Drive 4, Singapore 117585
cheiak@nus.edu.sg

Abstract

As the electricity demand fluctuates frequently, combined cycle gas turbine (CCGT) power plants often run at part-load conditions. In order to improve the plant performance, a simulation-based optimization approach is proposed to determine an optimal operating strategy that maximizes the plant efficiency. The influence of the optimal strategy is compared with that of fuel flow control (FFC) and inlet guide vane control (IGVC). It is shown that the plant efficiency is increased by as much as 2.63% over FFC and 0.93% over IGVC. Moreover, it seems that FFC tends to prioritize the gas turbine and IGVC tends to prioritize the steam cycle, while the optimal strategy strikes a balance between the two.

Keywords: Simulation, Optimization, Gas turbine, Steam cycle, Part-load operation

1. Introduction

Combined cycle gas turbine (CCGT) power plants fired by natural gas have higher thermal efficiency and lower CO_2 emissions than their coal-fired counterparts. With the rapid increase of energy demand and stricter environmental regulation, CCGT plants are now undergoing widespread installation. However, as the energy demand fluctuates frequently with time, CCGT plants often run at off-design conditions. Under this circumstance, the plant operating strategies have significant influence on the plant performance. Kim and Hwang (2006) analyzed the performance of recuperative gas turbines during off-design operation. Various operating strategies, including fuel flow control (FFC), variable speed control (VSC), and inlet guide vane control (IGVC) for single-shaft configuration, as well as FFC and variable area nozzle control (VANC) for two-shaft configuration, were investigated. Haglind (2011) studied the effects of variable geometry gas turbine on the off-design performance of combined cycles, and found that the plant performance was improved by using IGV and VAN. Jimenez-Espadafor Auilar et al. (2014) considered eight operating strategies for a combined heat and power (CHP) plant, and showed that IGVC offered the best regulation capacity. The above studies simulate the operation of CCGT plants for a given policy, but they cannot optimize the policy. In other words, one must manually test pre-formulated operating strategies to improve part-load operations. Therefore, a comprehensive multi-variable simulation-based optimization approach is necessary to find the best operation strategy for any given part-load.

2. System description

Figure 1 shows the schematic of a typical CCGT power plant. The pressurized ambient air from the air compressor enters the combustor, where a gaseous fuel (natural gas) is burnt. The combustion gas expands in the turbine to produce power. Some air from one or more stages of the compressor is supplied to the turbine blades to keep them cool. The exhaust gas from the turbine then enters a heat recovery steam generator (HRSG) to generate high pressure (HP), intermediate pressure (IP), and low pressure (LP) steam, which drives which drives HP, IP and LP steam turbines to generate extra power. The exhaust steam from LP steam turbine goes to a condenser, and the condensate is finally pumped back to the HRSG.

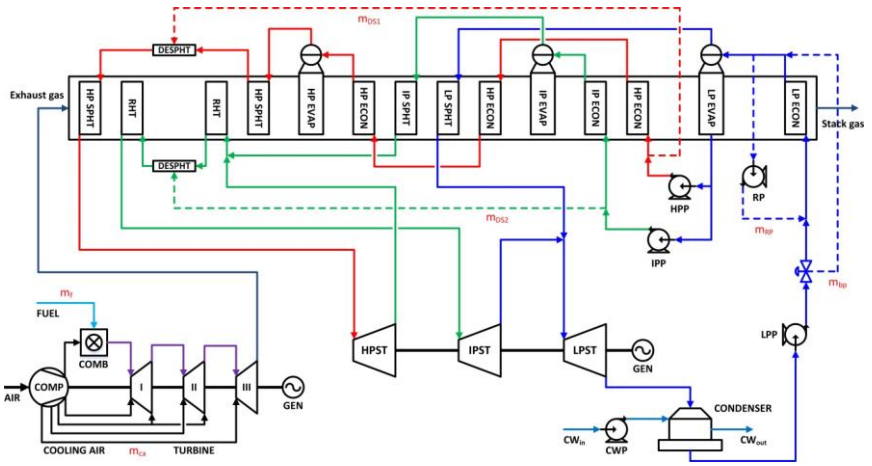

Figure 1 Schematic of a triple-pressure reheat combined cycle power plant.

3. Methodology

3.1 CCGT modeling

The CCGT plant is modeled using a commercial simulator GateCycle. The air compressor is modeled by the compressor map. The turbine is represented by the choking condition. The cooling air from the inter-stages of the compressor to cool the turbine blades is determined using a differential pressure correlation. The turbine efficiency is corrected using a semi-empirical formula. The HRSG is modeled as a series of heat exchangers with off-design correction of overall heat transfer coefficients. The steam turbine is modeled via the modified Stodola's law, and the water pump is modeled by the pump curves. All of these are implemented in GateCycle to form a holistic model for the CCGT plant (Liu and Karimi (2017)).

3.2 Simulation-based optimization

We use IGV angle ($\Delta\alpha$), fuel flow (m_f), cooling airflow to turbine stage t ($m_{ca,t}$), and four water flows [desuperheaters (m_{DS1}, m_{DS2}), recirculation (m_{RP}), and bypass (m_{bp}) as in Fig. 1] in HRSG as the optimization variables to maximize combined cycle efficiency (CCE) at a given part-load in order to find an optimal

operating strategy. Maximizing CCE is same as minimizing the fuel flow for a given part-load.

$$\min m_f\left(\Delta\alpha, m_{ca,t}, m_{DS1}, m_{DS2}, m_{RP}, m_{bp}\right) \tag{1}$$

We enforce the following operational constraints during optimization:

- Each turbine blade metal temperature must not exceed its design metal temperature:

$$T_b \le T_{b,d} \tag{2}$$

- HP steam and reheat steam temperatures must not exceed their design values:

$$T_{\text{HP steam}} \le 565^{\circ}C, T_{\text{Reheat steam}} \le 565^{\circ}C \tag{3}$$

- Stack gas temperature must exceed a lower limit to prevent corrosion:

$$T_{\text{Stack gas}} \ge 99.7^{\circ}C \tag{4}$$

A simulation-based optimization approach (see Fig. 2) is used to optimize the plant performance for any given part-load. The plant is simulated in GateCycle, and the particle swarm optimization (PSO) algorithm is implemented in Matlab for optimization. GateCycle is interfaced with Matlab via Cyclelink.

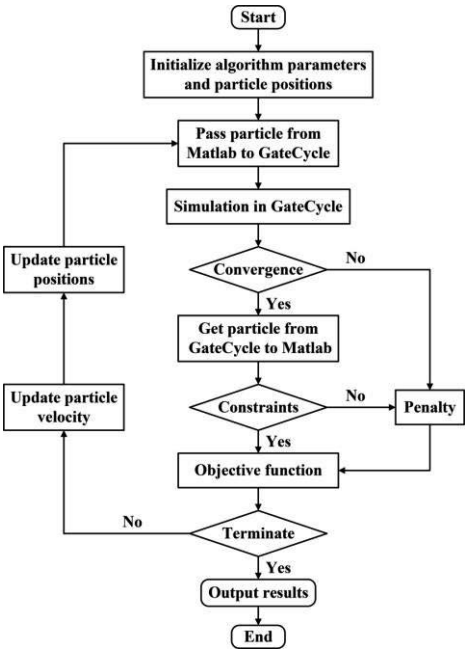

Figure 2 Simulation-based optimization using PSO algorithm.

4. Results and discussion

In CCGT plants, the following two operating strategies are widely used:

- Fuel flow control (FFC): the fuel flow is reduced to achieve the desired part-load.
- Inlet guide vane control (IGVC): IGVs and fuel flow are changed simultaneously to achieve the desired part-load, while maintaining the turbine exhaust temperature (TET) at its design value.

Figure 3 shows the results for FFC. The turbine inlet temperature (TIT) reduces by 26.9% from 100-40%, as FFC manipulates only the fuel flow to change the power output. Because the compressor operating point moves downward along the constant speed line, the pressure ratio reduces by 13.3%. However, the airflow increases by about 1.0%, causing that TIT drops quickly. As the cooling airflows are affected by pressure ratio, the total cooling airflow (summed over all GT stages) reduces by 10.0%. Moreover, both TET and blade metal temperature drop quickly with TIT. Because of these changes, the gas turbine (GT) power and gas turbine efficiency reduce by 62.8% and 11.3%, respectively. As TET drops quickly, the waste heat available for the steam cycle (SC) reduces. As a result, the ST power and steam cycle efficiency (SCE) by decrease by 54.6% and 8.8%. Overall, CCE decreases by 14.3% from 56.3% at 100% load to 42.0% at 40% load. This indicates part-load operation has a huge impact on the plant performance under FFC.

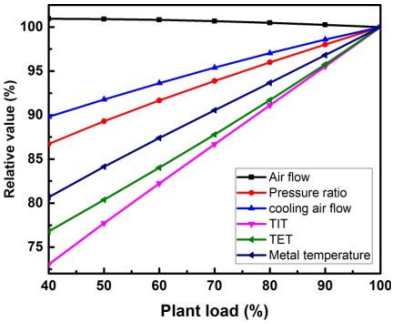

Figure 3 Plant operating variables versus plant load under FFC.

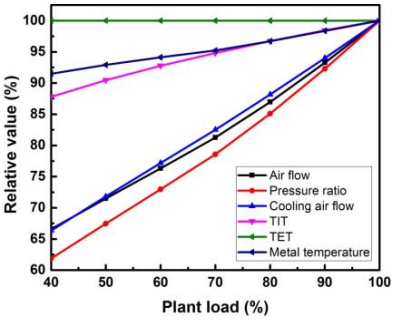

Figure 4 Plant operating variables versus plant load under IGVC.

Figure 4 presents the plant performance under IGVC. The airflow and pressure ratio are reduced by 33.4% and 38.1%, since the IGVs are closed gradually. As a result, the total cooling airflow reduces by 33.6%. Moreover, the drop in TIT is retarded due to the simultaneous reductions in the fuel flow and airflow. Thus, TIT reduces by 12.2% as compared to 26.9% for FFC. As TET remains at its design value, GT and HRSG run much hotter in IGVC than FFC. The drop in TIT reduces the GT power and GTE by 72.9% and 17.5%, respectively. However, the SC performance is improves compared to FFC due to the higher TET. Hence, the ST power decreases by 35.6% versus 54.6% for FFC, and SCE reduces only slightly by 0.6%. Although GTE for IGVC is lower than that for FFC, the higher SC performance improves CCE for IGVC, which decreases by only 12.6% from 56.3% to 43.7%. This clearly suggests that IGVC is more efficient than FFC.

In contrast to FFC and IGVC, the optimal strategy (Figure 5) gives the best CCE via manipulating several variables. The optimizer minimizes the cooling airflows to

keep GT as hot as allowable. As a result, the pressure ratio and total cooling airflow reduce by 30.2% and 81.4%. Moreover, the optimal strategy uses 47.8-71.2% lower total cooling airflow than FCC and IGVC. The optimizer also tends to maximize the blade metal temperature. This leads to a drop in TIT by 17.2%, more than IGVC, but less than FFC. As TET only reduces by 4.0%, the optimal strategy maintains GT at lower average temperatures than IGVC. This results in nil desuperheater flows. Furthermore, the stack gas temperature is kept at its minimum to ensure maximum heat recovery by manipulating the recirculation and bypass flows. Under the optimal strategy, the GT power and GTE reduce by 70.0% and 15.0% respectively, while the SC power and SCE decrease by 41.0% and 1.6% respectively. However, CCE is higher than FFC and IGVC, and reduces by 11.7% from 56.3% to 44.6%, which is the lowest drop among the three operating policies, as shown in Figure 7.

For implementing the optimal strategy for the CCGT plant, IGVs is manipulated to maintain TET variation tendancy. Moreover, cooling air flows are changed to keep blade metal temperatures constant. The recirculation flow is regulated to maintain LP economizer inlet temperature constant, while the by-pass flow is varied to keep the stack gas temperature at its minimum value. Finally, fuel flow is reduced to decrease the plant load.

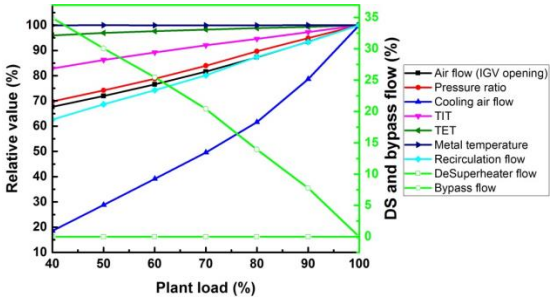

Figure 5 Plant operating variables versus plant load for the optimal strategy.

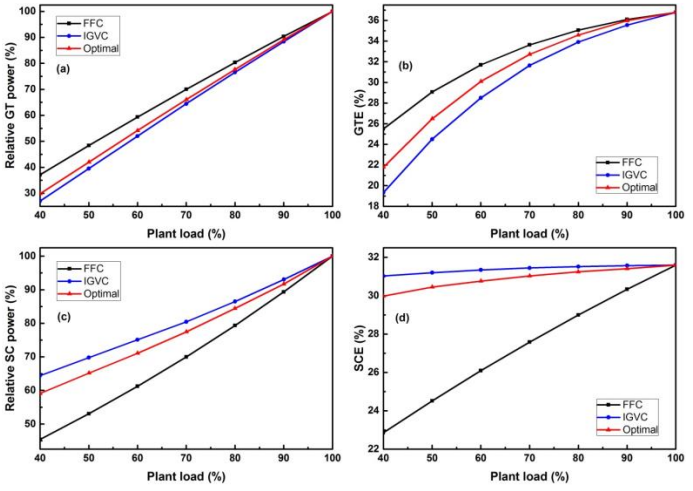

Figure 6 GT power, GTE, SC power, and SCE versus plant load under FFC, IGVC, and optimal strategy.

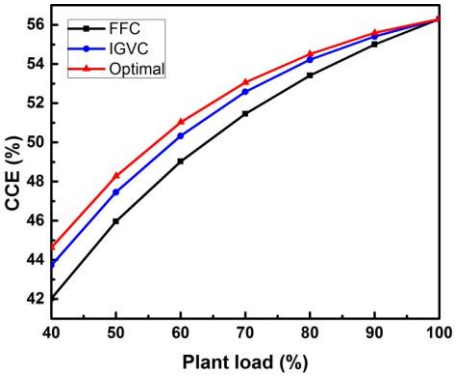

Figure 7 CCE versus plant load under FFC, IGVC, and optimal strategy.

5. Conclusions

In this work, a rigorous multi-variable simulation-based optimization approach is proposed to obtain an operating strategy that maximizes the overall plant efficiency. It is shown that FFC prioritizes GTE, and gives the worst plant performance. IGVC prioritizes SCE, and gives much better performance than FFC. However, it is not the best operation strategy for a CCGT plant. Our optimal strategy achieves the best trade-off between the GT and SC cycles, and gives the best plant performance. It can increase CCE by as much as by 2.63% and 0.93% compared to FFC and IGVC, respectively. Our optimization approach thus provides a basis for evaluating various operating policies.

Optimal Design of Boil-Off Gas Liquefaction in LNG Regasification Terminals

Harsha Nagesh Rao[a], Iftekhar A. Karimi[a*], and Shamsuzzaman Farooq[a]

[a]*Dept. of Chemical & Biomolecular Engineering, National University of Singapore, 4 Engineering Drive 4, Singapore 117585*
cheiak@nus.edu.sg

Abstract

Boil-off gas (BOG) generation is inevitable in LNG regasification terminals, which import and store huge amounts of LNG. The energy and costs required to reliquefy the generated BOG is substantial for a regasification terminal. Consequently, it is important to optimize BOG reliquefaction in regasification terminals. In this work, we develop a novel superstructure for BOG reliquefaction comprising of all the process options discussed in our previous work (Rao et al., 2016) and use a nonlinear programming (NLP) formulation to minimize the total annualized cost (TAC) of the process. We then use a derivative-free optimization approach to solve this simulation-based optimization problem. For a case study terminal (Park et al., 2012), we discuss the optimal configurations for BOG reliquefaction corresponding to varying amounts of BOG in the terminal.

Keywords: LNG, Regasification Terminal, Design.

1. Introduction

Natural gas (NG) is the fastest growing fossil energy resource with its trade poised to increase significantly in the foreseeable future. Liquefied Natural Gas (LNG) is the most common and economical mode of transporting NG over long distances. As LNG is a cryogenic liquid (around –160°C) at atmospheric pressure, heat ingress into LNG throughout its storage and transport is inevitable regardless of heavy insulation. This vaporizes a portion of the LNG to generate boil-off gas (BOG). LNG regasification terminals which import and store huge amounts of LNG are concentrated sources of BOG. Unless reliquefied and/or reused, BOG is an economic loss, and alters LNG composition and quality over time. The power consumption and the costs associated with the reliquefaction of BOG are significant for a regasification terminal, and hence, reducing them is important. Therefore, it is crucial to optimize the configuration of BOG reliquefaction in regasification terminals.

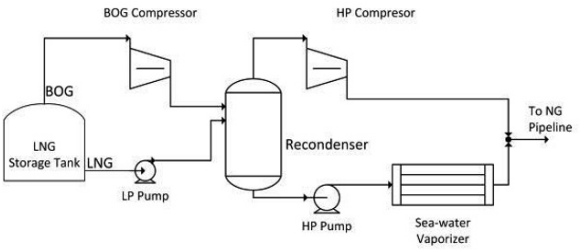

Figure 1: A typical LNG regasification terminal

Consider a typical LNG regasification terminal shown in Figure 1. A regasification terminal stores the incoming LNG in atmospheric tanks, and regasifies it continuously to supply NG to gas distribution grids or customers at high pressures (40-80 bar). BOG from the LNG storage tanks is compressed to a sufficiently high pressure, and recondensed using low-pressure LNG (LP-LNG) pumped from the LNG tanks. Subsequently, the recondensed liquid is pressurized to the send-out pressure of the terminal to form high-pressure LNG (HP-LNG). HP-LNG is then regasified in a seawater vaporizer to form the send-out NG.

Most literature on LNG regasification concerns the utilization of cryogenic energy of LNG to produce power by integrating various cycles such as Organic Rankine, Brayton, etc. Very few studied the retrofit design of a BOG reliquefaction system (Chaowei Liu, 2010; Park et al., 2012). In our previous study (Rao et al., 2016), we evolved reliquefaction schemes to minimize the terminal power consumption based on physical arguments. However, it is not straightforward to synthesize schemes to lower total annualized cost (TAC) due to the trade-offs involved between capital and operating costs. Therefore, we develop a superstructure comprising of several process options and optimize the process systematically.

2. Problem Statement

Consider the seawater-based LNG regasification terminal in Figure 1. On a long-term basis, it receives and gasifies F_{OUT} tonne/h (send-out rate) of LNG on an average, and supplies NG to a local gas distribution grid at specified conditions. Let βF_{OUT} $(0 < \beta < 1)$ tph of BOG exit the tanks at (P_{G1}, T_{G1}), and $(1-\beta)F_{OUT}$ tph of LNG be available for send-out at (P_{L1}, T_{L1}). We allow the user to specify BOG and LNG conditions independently based on real terminal data. With this, we address the following problem in this work.

Given:

1. LNG throughput or gas send-out rate F_{OUT} tonne/h (tph). Composition and conditions (P_{L1}, T_{L1}) of the LNG available for send-out on an average.
2. BOG composition, generation fraction β, and conditions (P_{G1}, T_{G1}) on an average.
3. Desired send-out temperature (T_{OUT}) and pressure (P_{OUT}).
4. Ratio (p_{sw}) of the power required to pump seawater to the rate of heating required for regasification.

Obtain: Configuration, design targets (e.g., heat-transfer areas), and optimal operating conditions for various process units that correspond to the minimum total annualized cost (TAC) of the reliquefaction process for a given β.

3. Novel Superstructure

We concluded from our previous study (Rao et al., 2016) that the indirect cooling of BOG prior to compression using high pressure (HP)- and medium pressure (MP)-LNG are effective process options to reduce the power consumption of the terminal. However, we did not include the impact of direct cooling BOG using LNG at low pressure, called desuperheating. This process option involves spraying low pressure (LP)-LNG at the inlet of a knockout drum to reduce the temperature of BOG. The residue liquid from the knockout drum can be used for BOG recondensation by elevating its pressure. The sprayed LP-LNG vaporizes upon contact with the superheated BOG, resulting in an increase in the BOG flowrate. Consequently, the

decrease in the compression work due to the reduction in BOG temperature is slightly offset by the rise in the compression work due to the increased BOG flowrate. Therefore, desuperheating may not be the best option to precool BOG from an energy perspective. However, desuperheating requires low capital investment as it mainly consists of a drum operated at low pressure. Hence, in this study, we incorporate all plausible combinations (series and/or parallel) to cool BOG before compression using indirect heat exchange with HP- and MP-LNG, and direct heat exchange by LP-LNG (Figure 2). These coolers are placed in the order of increasing potency of the coolants (HP-LNG < MP-LNG < LP-LNG). Let us refer to these components collectively as the cooling unit (Figure 2) for further use.

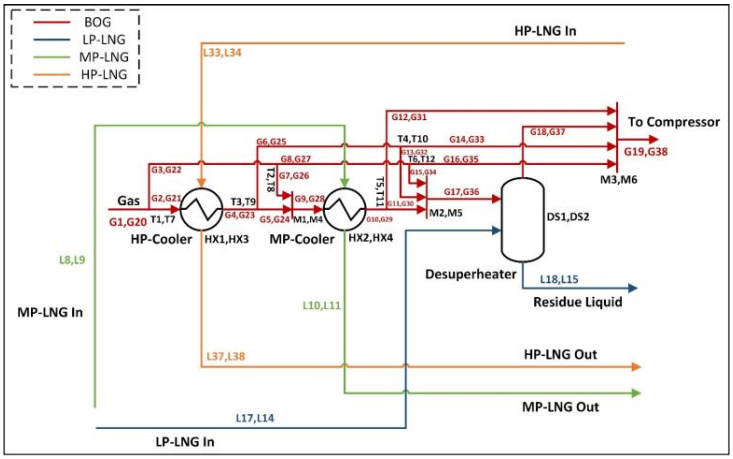

Figure 2: The cooling unit

The overall superstructure for BOG reliquefaction is shown in Figure 3. Derived from schemes presented Rao et al. (Rao et al., 2016), this superstructure can synthesize schemes with either one stage or two stages of recondensation. BOG from storage tanks, shown in red colour, enters the cooling unit-1 (CU-1) prior to compression by C1. If BOG undergoes recondensation in one stage, BOG from C1 enters the cooling unit-2 (CU-2) followed by the second stage of compression (C2). The compressed BOG can be partially or fully cooled by the HP cooler HX5 or even bypass it before entering the recondenser R1, where it is fully reliquefied. If BOG undergoes recondensation in two-stages, BOG from C1 enters the cooling unit-2 (CU-2) that consists only of the HP-LNG cooler HX3 along with the option to partially or fully bypass it. This is because BOG enters the recondenser R1 subsequently. We learnt from the previous work (Rao et al., 2016) that direct heat exchange with LP-LNG is superior to indirect cooling by HP- or MP-LNG. Next, the uncondensed BOG from R1 is fed to the second compressor C2. The output of C2 can be partially/fully cooled by the HP-LNG cooler HX5 before entering the second recondenser R2, where BOG is fully reliquefied. To ensure feasibility, splitters T13 and T15 cannot allow partial splits. In other words, only one of their two outputs can exist. Similarly, M7 and M9 are binary mixers with one of the inlets present.

LNG send-out from the storage tanks, indicated in blue colour, is divided for desuperheating and recondensation purposes. A part of the LNG to be used for desuperheating (at tank pressure) is sent to the desuperheater DS1 of cooling unit-1 (CU-1) at BOG pressure via valve V1. Remaining LNG to be used for desuperheating is

pumped using pump P4 to the BOG pressure at the inlet of the second desuperheater DS2 of CU-2. The residual liquids from DS1 and DS2 are pressurized the recondenser R1 pressure using pumps P3 and P5, and mixed with LP-LNG in M10. LNG to be used for recondensation is pumped to the recondenser R1 pressure using the LP-Pump P1. Subsequently, while most of the LP-LNG is sent to mixer M10 followed by R1, a part of LP-LNG is pumped using MP-pump P2 to form MP-LNG (shown in green colour). MP-LNG is used for cooling BOG in the MP-LNG coolers HX2 of CU-1 and HX4 and CU-2. The MP-LNG streams exiting HX2 and HX4 are mixed in M12. Further, the recondensed liquid exiting R1 is pressurized by P6 and fed to the second recondenser R2, if present. However, a portion of this liquid has an option to partially bypass R2 via pump P7 even in the case of two-stage recondensation to limit the size of R2. In this scenario, P7 is used to elevate its pressure to that of R2. The recondensed liquid from R1 and R2 are pressurized by P8 to be mixed with MP-LNG stream exiting mixer M12, if MP-LNG is at a higher pressure. If MP-LNG (at M12) is at a lower pressure than the recondensed liquid (at M11), pump P9 is used to match pressures. This mixture from M13 is pressurized to the send-out pressure by the high-pressure pump (P10) to form HP-LNG (shown in orange colour). The seawater vaporizer is generally over-designed, and has a complex design with special considerations to avoid ice formation when seawater contacts HP-LNG. Therefore, it has a high capital cost almost insensitive to the scheme of BOG reliquefaction. Hence, we do not include the costs associated with the SW regasifier in this study.

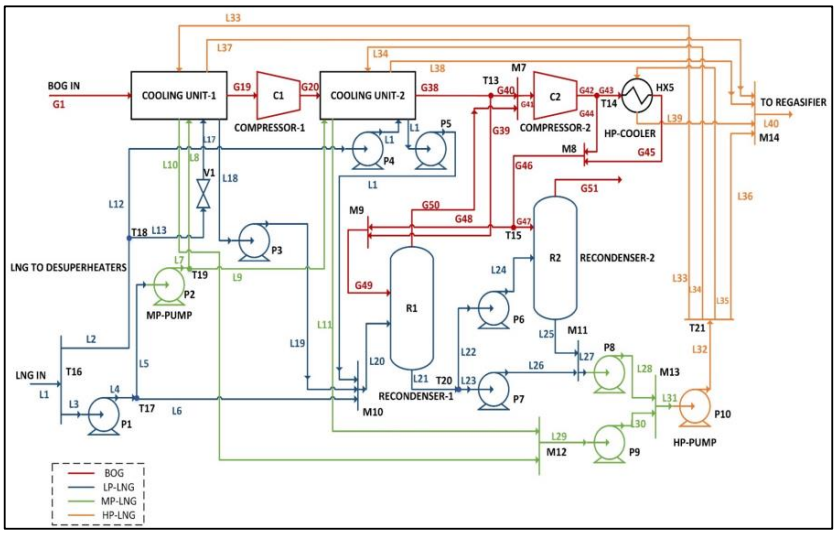

Figure 3: Superstructure for BOG reliquefaction

4. Model Formulation and Solution Strategy

We develop independent modules for the process units of our superstructure such as heat exchangers, pumps, compressors, recondensers, desuperheater, mixers and splitters in a suitable programming platform. We do not use unit modules in commercial simulators as they generally have fixed input-output structures, and offer limited flexibility. This is a medium-scale simulation-based NLP model with 35 independent variables. We implemented the model in MATLAB R2015a while accessing the Peng

Robinson fluid package from Aspen Hysys using the hysyslib toolbar, and used the Nonlinear Optimization by Mesh Adaptive Direct Search (NOMAD) algorithm to solve the problem.

5. Case study

We consider the Pyeongtaek LNG receiving terminal case study discussed in Park et al. (Park et al., 2012). We solved the model for $0.03 \leq \beta \leq 0.15$ to study the effect of varying BOG concentration in the terminal. Figure 4 present the variation of the minimum TAC of the terminal with β.

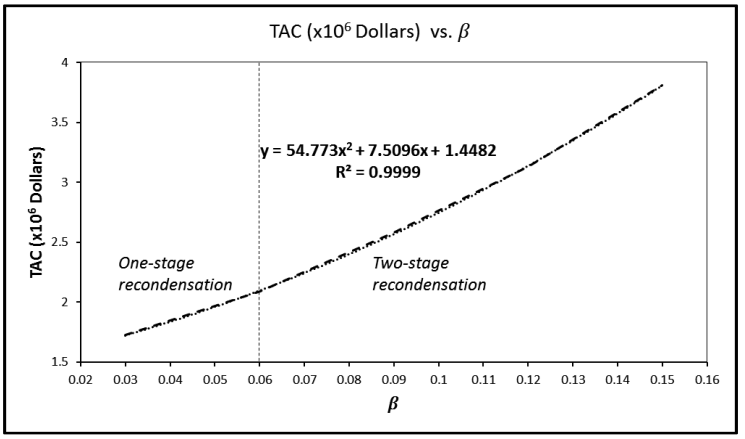

Figure 4: Minimum TAC vs β

We inferred from the Rao et al. (Rao et al., 2016) that recondensation in two-stages is much more energy efficient than recondensation in one stage. This is because BOG flow to the second compressor is reduced due to the partial recondensation in stage I. Besides, BOG entering the second compressor is saturated. Therefore, the feed temperature of BOG and hence the compression work are low. However, the capital investment on the second stage of recondensation is justified only if the there is considerable reduction in the power consumption (or OPEX) of the terminal. As the savings in power consumption of the terminal increases with β, we find that recondensation in two stages is optimal only for $\beta \geq 0.06$.

The optimal terminal configuration for $\beta = 0.03$ with one stage of recondensation is shown in Figure 5a. BOG is slightly precooled in the desuperheater by LP-LNG prior to compression, and subsequently recondensed in R1 completely. Next, the savings in the OPEX is just sufficient to invest on another stage of recondensation for $\beta = 0.06$ (Figure 5b). BOG is compressed to a low pressure and sent to the first recondenser R1 at a low temperature, wherein it is partially reliquefied. The uncondensed gas from R1 is compressed further. As the compressor output is sufficiently cold, it is directly fed to the second recondenser R2 for complete reliquefaction. Then, Figure 5c shows the optimal configuration for the range of $0.09 \leq \beta \leq 0.12$. A desuperheater prior to C1 is added to the configuration from the previous case. Lastly, consider the case of highest BOG concentration ($\beta = 0.15$). The optimal configuration shown in Figure 5d does not have any coolers from cooling unit-1 (CU-2). In this case, HP-LNG has very less precooling potential. However, there is a HP cooler after CU-1.

Overall, we find that two-stage recondensation is optimal for terminals with $\beta \geq 0.06$. Desuperheating provides direct heat exchange with a superior coolant LP-LNG at a low capital cost. Hence, it is often employed to precool BOG in the optimal configurations discussed above. Though HP-LNG and MP-LNG coolers minimize the power consumption of the reliquefaction process, capital investments on them is not justified for low-moderate concentration of BOG in the terminal.

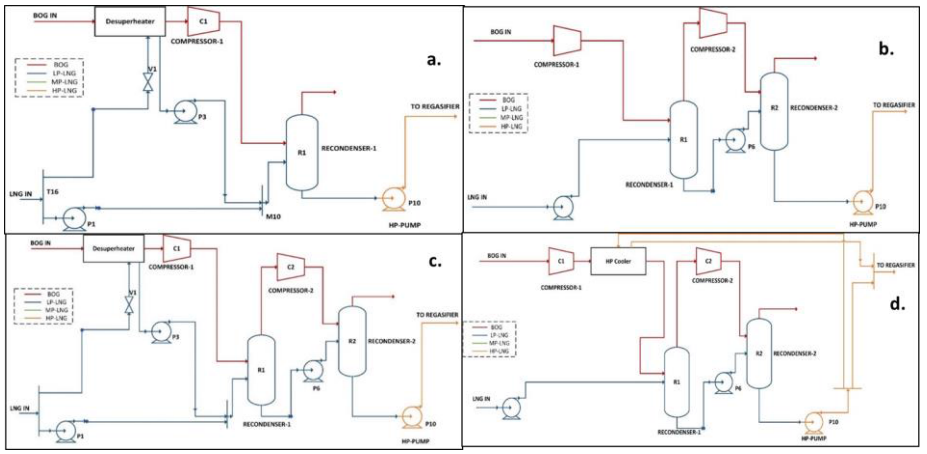

Figure 5a-d: Minimum TAC configurations

6. Conclusions

We developed a novel comprehensive superstructure for BOG reliquefaction. The superstructure allowed up to two stages of recondensation, incorporated three pressure levels of LNG (LP-, MP-, and HP-LNG) and all of their combinations(series and parallel) to cool BOG via direct and indirect heat exchange. We used a modular NLP formulation to minimize the total annualized costs of the reliquefaction process that is suitable for derivative free optimization by NOMAD. For the case study terminal from Park et al. (Park et al., 2012), the optimization results suggest that two-stage recondensation is optimal beyond 6% BOG concentration in the terminal and desuperheating using LP-LNG is a favourable precooling option.

Abstract

Microreactors with two-phase slug flow have an advantage over the conventional batch reactors in mass transfer because of the internal circulation flow within the slugs. The slug flow in the microreactors have to be monitored, because the slug lengths influence mass transfer performance. In this work, an experimental investigation is carried out to analyze the formation of gas-liquid slug flow in a single T-shaped channel. The result shows that the feed pressures oscillate periodically along the formation of a pair of gas and liquid slugs. Based on this result, a feed pressure-based method is developed to monitor whether a slug having the desirable length is generated. By the developed method, the slug flows can be monitored without complicated processing, such as the placement of the windows or electrodes on channels. In addition, the applicability of the developed method to a multi-channel reactor connected to manifold-type flow distributors is investigated. As a result of the investigation, it is proposed that, by using Fourier transform analysis of pressure signals obtained at the inlet of either flow distributor, the number of pressure sensors required for estimating all the pressure oscillation cycles is reduced to just one. The effectiveness of the proposed method is experimentally demonstrated under both normal and abnormal conditions of the process.

Keywords: Process monitoring, Microreactors, Multi-channel reactors, Gas-liquid slug flow, Fourier transform analysis.

1. Introduction

Microreactors can realize short residence time as well as high mass and heat transfer rates. Recently, microreactors with multi-phase flow have attracted researchers' and engineers' attention by their unique flow characteristics. For example, when two mutually immiscible fluids, such as gas and liquid, are simultaneously fed into a microchannel, various flow patterns such as annular, dispersed and slug flows are generated as to the design and operating conditions (Shao et al., 2009). Among these, slug flow, also called Taylor flow or segmented flow, is especially attractive for its small residence time distribution and large interface area per fluid volume (Kreutzer et al., 2008). In addition, rapid mass transfer between two phases is achieved because the liquid interface is constantly renewed by the circulation flow inside the slug (Kashid et al., 2005). As an application example, Takebayashi et al. (2012) reported that the direct carbonylation of nitrobenzene to phenylisocynate was conducted by using a T-shaped microchannel with gas-liquid slug flow, and the isocyanate yield in the microchannel was three to six times higher than that in the batch reactor.

A process monitoring method needs to be developed to realize stable long-term operation of microreactors with gas-liquid slug flow, because the slug lengths, which influence mass transfer performance, are shifted to undesired values under abnormal conditions such as the deposition of solid on the surface of channels. Optical methods (Ide et al., 2009) and electrical methods (Ye et al., 2011) have been proposed as the measuring methods of void fraction in channels. Though these methods are applicable to the monitoring of slug flows, there are some drawbacks. As the optical method requires the placement of the windows on the channels to visualize the slug flow, it is not applicable to microreactors made of opaque materials. The electrical method uses the electrical resistance and capacitance of fluid in the channels to estimate the flow condition in the channel. If the device is made of electrically-conductive materials such as stainless steel, complicated electrically-insulated placement of electrodes is required. Hence, the objective of this research is to develop alternatives to the conventional monitoring methods for slug flows in channels.

The outline of this paper is as follows: In Section 2, a monitoring method for a single T-shaped channel with two-phase slug flow is proposed on the basis of the experimental observation about the relationship between the flow behavior and feed pressure changes of gas and liquid. In Section 3, an experimental study is carried out to investigate the applicability of the developed monitoring method to a multi-channel reactor connected to manifold-type flow distributors. In addition, a method of solving the problem that the number of sensors increases as the number of channels increases is proposed.

2. Slug flow monitoring for a single channel reactor

In this section, the characteristic points of feed pressure profiles that correspond to the formation of gas and liquid slugs in a single T-shaped channel are made clear. In addition, a slug flow monitoring method for the single T-shaped channel is proposed.

2.1. Experimental setup

Figure 1 shows an experimental system used in this study. Pure nitrogen (gas) and distillated water (liquid) are fed into a T-shaped channel from a gas cylinder and a pressure tank, respectively. The gas flow rate is controlled by a mass flow controller (FCST-1005LC, Fujikin). The liquid flow rate is controlled by a mass flow controller (LV-F50PO, Horiba STEC). After gas and liquid are contacted in the mixer, slug flow is formed and goes through a succeeding tube. The end of the tube is immersed in a beaker filled with water. The beaker is open to the atmosphere, and the water level of the beaker is kept constant. The sizes and materials of tubes and mixers are summarized in Table 1. The length between the pressure sensor and the mixer is defined as the length of feeding tube. The mixers are made of polymethyl methacrylate (PMMA). The tubes (JR-T-6806-M10, VICI AG International) are made of fluorinated ethylene propylene (FEP). All of the channels and tubes have circular cross-sections. The slug formation behavior in the mixer is observed by high-speed video camera (VW-6000, KEYENCE), and the gas and liquid feed pressures are measured by pressure sensors (PA-830-101G-10, NIDEC COPAL ELECTRONICS). The digital fiber-optic sensor unit (FU-L51Z, KEYENCE) is installed at near the inlet of FEP tube to measure superficial velocity of slug flow and slug lengths of gas and liquid. The measurements acquired from pressure sensors and digital fiber-optic sensor unit are collected in a computer through a data logger (NR-600, KEYENCE).

2.2. Slug formation and pressure oscillation

The experimental result is explained. Figure 2 shows a photo of gas-liquid slug flow in the succedent FEP tube, where gas and liquid feed flow rates are 1.0 mL/min and 1.0 mL/min, respectively. All of gas slugs in the FEP tube have no liquid film, and the shapes are almost cylindrical. This is because FEP has hydrophobic property. Figure 3 shows the pressures at gas and liquid feed flows. Both pressures oscillate periodically and the oscillation phases of gas and liquid pressures have a half cycle difference. For clearly observing the profile of gas and liquid pressure measurements, smoothed lines obtained by the Savitzky–Golay filter are shown in black lines.

Figure 4 shows the gas-liquid slug formation behavior in the mixer. Photos in Fig. 4 are taken at time A to time E in Fig. 3. The gas and liquid discharge alternately from the confluence part of the mixer into the succeeding tube. The relationship between the periodic pressure fluctuation and the formation of gas and liquid slugs is explained as follows: During the period between Fig. 4(A) and just before Fig. 4(C), the gas penetrates to the confluence part of the mixer, but it is still blocked by liquid flow. Thus, the gas pressure continuously increases because gas is constantly supplied to the confluence part. At the time shown in Fig. 4(C), the gas occupies the confluence part, and the gas starts flowing from the confluence part to the succeeding tube. By the flow, the pressure of the gas feeding section gradually decreases. The flow behavior of liquid during the periods from Fig. 4(C) to (E) is explained in a similar manner as that of gas during the periods from Fig. 4(A) to (C). These phenomena are repeated as far as gas-liquid slugs are formed. The magnitude of liquid pressure oscillation is larger than that of gas pressure oscillation, and the profile of liquid pressure change is clearer than that of gas pressure change. This is due to the difference of the fluid properties between gas and liquid, such as viscosity, compressibility and wettability. Thus, the liquid pressure profile is used in the slug flow monitoring method explained in the next subsection.

2.3. Slug flow monitoring method

Based on the result of Sec. 2.2, a monitoring method for gas and liquid slug lengths in a single T-shaped channel reactor is developed. When the T-shaped channel reactor with gas-liquid slug flow is operated at Q_G and Q_L, feed pressures of gas and liquid are fluctuated periodically with the cycle time t_{GL}, which is equal to the generation cycle time of a pair of gas and liquid slugs. Hence, the estimates of gas and liquid slug lengths

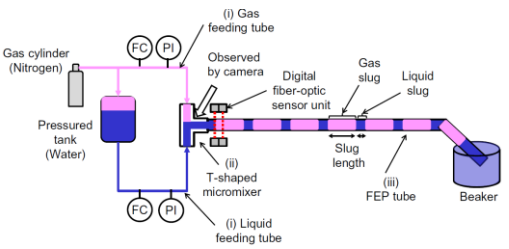

Figure 1 Experimental system of a single T-shaped channel reactor

Table 1 Sizes and materials of tubes and mixers

Location in Fig. 1	I.D. (mm)	Length (mm)	Material
(i) Feeding tube	1.00	100	FEP
(ii) Micromixer	1.30	40 for all branches	PMMA
(iii) Reactor tube	1.00	500	FEP

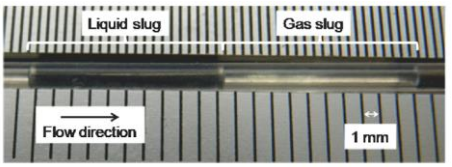

Figure 2 Slug flow in the FEP tube

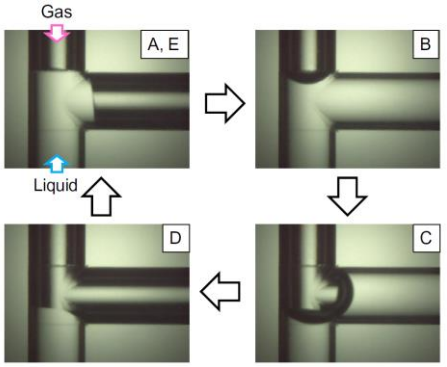

Figure 4 Photos of flow behavior in the mixer

Table 2 Estimates and measurements of gas and liquid slug lengths

	Q_G/Q_L	L_G^*: L_G [mm]	L_L^*: L_L [mm]
Case 1	1.0	11.1:11.0	11.1:11.1
Case 2	2.0	15.2:15.3	7.6:7.6
Case 3	0.5	7.6:7.5	15.1:15.2

are derived by the following equations:

$$L_G^* = Q_G t_{GL} / A \tag{1}$$

$$L_L^* = Q_L t_{GL} / A \tag{2}$$

where A is the cross sectional area of gas and liquid slug flow, and L_G^* and L_L^* are estimated values of gas slug length L_G and liquid slug length L_L, respectively. Accuracy of the developed method was evaluated. The results are summarized in Table 2. It is concluded that slug lengths can be estimated accurately by using the developed method.

3. Slug flow monitoring for a multi-channel reactor

The applicability of the developed method to a multi-channel reactor connected to manifold-type flow distributors is investigated. In addition, a method for reducing the number of installed sensors is proposed.

3.1. Experimental setup

Figure 5 shows a schematic diagram of an experimental system developed in this study. Gas (nitrogen) and liquid (distilled water) are fed by mass flow controller (MFC) at Q_{GT} and Q_{LT}, respectively. The outlets of gas and liquid MFCs are connected to a gas manifold (MG) and a liquid manifold (ML), respectively. The MG and ML distribute gas and liquid to parallelized channels (Ch.1 to Ch.4), respectively. Each channel is composed of a gas barrier channel (BG), a liquid barrier channel (BL), a gas feed channel (FG), a liquid feed channel (FL), a T-shaped union (T) and a reaction channel

(R). The barrier channels, which have high hydraulic resistance, are used to realize equal flow distribution. Pressure sensors (PI1 to PI4) are installed between BLs and FLs of Ch.1 to Ch.4, and a pressure sensor (PI0) is installed at the inlet of the ML. The flow rates of gas and liquid in Ch.1 to Ch.4 (Q_{Gi}, Q_{Li}; i=1, 2, 3, 4), the slug lengths of gas and liquid in Ch.1 to Ch.4 (L_{Gi}, L_{Li}; i=1, 2, 3, 4) and the generation cycle time of a pair of gas and liquid slugs in Ch.1 to Ch.4 (t_{GLMi}; i=1, 2, 3, 4) are measured by using the digital fiber-optic sensors installed on the Rs of Ch.1 to Ch.4.

3.2. Applicability of the developed method to multi-channel reactor

To verify the applicability of the monitoring method developed in the previous section to a multi-channel reactor, the relationship between the generation cycle of a pair of gas and liquid slug in each channel and the fluctuation cycle of feed pressure in each channel is investigated through an experimental case study. Figure 6 shows the profiles of liquid pressure changes acquired from PI1 to PI4 under a normal condition where $Q_{GT} = Q_{LT} = 8.0$ mL/min and gas and liquid are equally distributed to Ch.1 to Ch.4. By comparing one-minute average values of the pressure fluctuation cycles in Ch.1 to Ch.4 (t_{GLi} [s] ; i=1, 2, 3, 4) and those of t_{GLMi} (i=1, 2, 3, 4), it is confirmed that, in every channel, the fluctuation cycle of feed pressure is equal to the generation cycle of a pair of gas and liquid slugs. In addition, the same result is confirmed under an abnormal condition where blockage occurs in Ch.1. Therefore, it is shown that the proposed method for a single T-shaped channel is applicable to the multi-channel reactor.

3.3. Slug flow monitoring method

Figure 7 (a) and (b) show the results of Fourier transform analysis of the pressure data acquired from PI0 to PI4 under the normal and abnormal conditions, respectively. It is shown that, under both conditions, peak frequencies of PI0 are almost equal to those of PI1 to PI4: namely, the pressure fluctuation cycles at PI1 to PI4 can be estimated from PI0. This result opens up the possibility of reducing the number of pressure sensors. In this study, just three measurements, Q_{GT}, Q_{LT} and the pressure at PI0, are used to monitor the gas and liquid slug lengths in all parallelized microreactors. The verification result shows that the estimation error is within 5% of real value.

4. Conclusions

In this study, from the experimental investigation of a single T-shaped channel, it was made clear that the pressures in gas and liquid feeding tubes oscillate periodically along the formation of a pair of slugs. By using this fact, a slug flow monitoring method based on the feed pressure measurements was developed, whose effectiveness was verified through several case studies. In addition, the developed method was applied to the multi-channel reactor connected to manifold-type flow distributors, and it was proposed that, by using Fourier transform analysis of pressure signals obtained at the inlet of the flow distributor, the number of pressure sensors required for estimating the pressure fluctuation periods of every microchannel is reduced to just one. The effectiveness of the proposed method was experimentally demonstrated under both normal and abnormal conditions of the process.

Abstract

Microreactors and micro heat exchangers have very unique characteristics due to the small size of their channels. Our close examination of the properties of microchemical systems has resulted in the finding that microchannel reactor systems have modular structures, a feature which may be exploited to create novel systems. In microreactors, reagents are mixed in a dedicated device while another microchannel is used to exchange heat. For this reason, the chemical reactor, which is conventionally treated as a unit operation, may be decomposed into more elementary operations, thereby enabling the development of new chemical apparatuses by reconfiguring the individual modules. This presentation introduces a conceptual framework for the elementary operation of these chemical apparatuses. An example of the application of these concepts to the development of a new distillation device will be discussed.

Keywords: microreactors, unit operations, elementary operations, distillation.

1. Introduction

Microreaction technology has attracted the attention of chemical engineers for decades. Whereas classical chemical engineering focuses on the use of large vessels to increase processing rates, in micro-scale reactions, small channels are exploited to enhance performance. The challenge of decreased throughput is addressed by using a so-called numbering up in which large scale production is achieved by designing many parallel microchannel reactors. The combination of the remarkable heat transfer and flow controlling properties of microchannels with the development of a unique mass production strategy has enabled microreaction technology to become a promising technology that will be exploited in chemical industries in the near future.

The concept of modularization has existed in the field of microreaction technology for many years, and a set of microchannel modules have been commercialized by several hardware manufacturers. This approach has much in common with that of the process design approach adopted in conventional chemical engineering, where chemical processes are treated as a set of unit operations.

During the early stages of microreactor development, researchers proposed to use the technology to develop small chemical processes for the on-site on-demand production of chemicals. This application required the development of a variety of small unit operations for separation and purification. To meet this need, we began to develop a microchannel distillation device. However, we discovered that it is extremely difficult to achieve countercurrent contact of vapor and liquid in microchannels. After an

extensive examination of the fundamental properties of microchannels and distillation, we came to the conclusion that there are a set of fundamental operations which govern many chemical processes and apparatuses. These elementary principles underpin the established set of unit operations. This concept can be exploited to create new chemical apparatuses.

In this report, we summarize the foundation of the new set of fundamental operations and show an example application of these concepts to the development of a new distillation apparatus.

2. Elementary operation in microchemical processes

In microchemical plants, microchannels are exploited to achieve a variety of unit operations such as reactions, heat exchange, or extraction. With their small characteristic diameters and high surface-to-volume ratios, microchannels are suited to intensify the mixing and heat transfer of fluids. In addition, the nature of flow apparatuses allows for the precise control of residence time. It is even possible to sequentially inject reagents at an interval as short as a few milliseconds. This is extremely useful in applications which include active reaction intermediates that deactivate within milliseconds. These features are rooted to the properties of the microchannels.

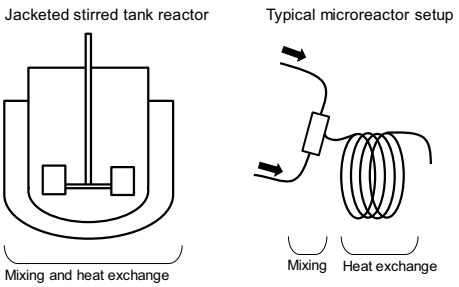

Figure 1. Functions of stirred tank reactor and microreactor setup

Our study of the properties of microreactors revealed that in addition to the utility of fine channels, another aspect of the geometry of microreactors plays an important role. That is, microreactors have intrinsically modular structures. Figure 1 compares a conventional stirred tank reactor and a typical microreactor setup. For a reaction to take place, usually two or more reagents must be mixed well, and the heat of reaction must be added or removed at an appropriate rate. In conventional chemical engineering, all of these operations are carried out in a single reactor unit. In the microreactor setup, although both mixing and heat exchange are necessary for the reaction, they are achieved in a different manner. A dedicated mixing device is employed, and heat exchange is accomplished using a downstream tube, which also ensures an appropriate residence time. This observation tells us that it is necessary to split the function of the reactor into mixing and heat exchange before converting reactions to be performed on microchannel devices. In addition, it is important to note that the reactor is divisible, and mixing and heat exchange are the elementary operations which are common across all chemical reactors.

It is expected that a variety of chemical apparatuses can be decomposed into elementary operations in a similar way. Examination of the configuration of various devices used in

microchemical processes reveal that each is realized by the combination of elementary operations such as liquid–liquid contact, gas–liquid contact, mixing, and heat exchange (Figure 2). This demonstrates that every conventional unit operation can be decomposed into a set of more elementary operations. Once a unit operation is treated as a set of elementary operations, a new device can be created by intensifying and reconfiguring each operation.

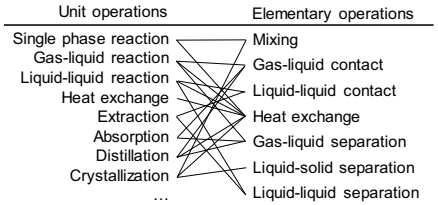

Figure 2. Unit and elementary operations

3. Application to distillation

3.1. Elementary operation of distillation

Distillation is a conventional unit operation. For this reason, it is usually considered one of the smallest units which constitutes a chemical process. In our study, we discussed further the decomposition of distillation from the viewpoint of elementary operations. As a first step, distillation can be seen as a collection of stages. A stage is not an elementary operation: its function can be further split into gas–liquid contact, equilibration, and gas–liquid separation. Any chemical apparatus with these three functions can play the role of a distillation stage. Figure 3 shows a distillation device that was designed using this idea (Sotowa et al., 2003). Experiments showed that it can separate a water–methanol mixture with a tray efficiency of 70%.

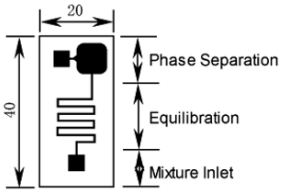

Figure 3. Distillation device consisting of phase separation and equilibration sections (Sotowa et al., 2003)

3.2. Multistage distillation

In theory, multistage distillation can be achieved using interconnecting devices as shown in Figure 3. However, it would be undesirable to simply replace the trays in a conventional distillation column with these devices. Because the tray temperatures vary in conventional distillation, the temperature of each device should be independently controlled. This calls for the development of an alternative strategy to achieve multistage distillation.

Thus, we proposed a new multi-stage distillation configuration in which the entire system is kept at a uniform temperature and the mixture is separated by forming a pressure distribution. Temperature control is easily achieved by using a thermostatic bath or circulating heat medium.

Conventional distillation columns have excellent separation performance but usually consume a high volume of energy. Although a large amount of heat is required to generate a vapor stream at the reboiler, a large portion of it is released from the condenser. Researchers have developed methods of thermal integration within a column, leading to the invention of distillation techniques such as VRC and HIDiC. In the proposed method, the temperature of the entire distillation column is controlled using a single heat medium so that the heat released from the condensing unit is automatically transported to the evaporation unit. Thus, it is expected that the proposed method will enable separation at a much smaller energy cost.

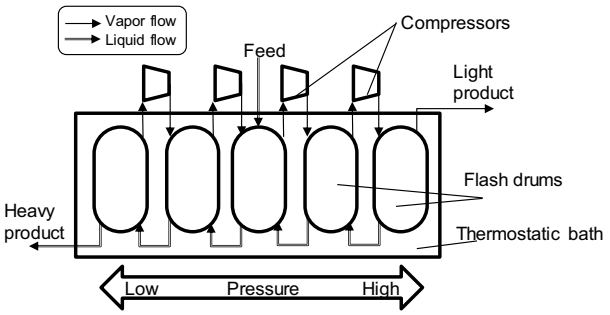

Figure 4. Pressure-driven distillation system (PDDS)

3.3. Scaling up

A distillation apparatus consisting of microchannels can process only small volume of chemicals. To increase the throughput of microchemical devices, parallelization or numbering up is usually employed. It should be noted that the chief advantage of the distillation method proposed in this study is its high energy efficiency, which is brought about by isothermal operation rather than the properties of microchannels. Thus, conventional scale-up (rather than numbering up) is suited for increasing the throughput of the proposed distillation device. Finally, we conceived the distillation system which is shown in Figure 4 and called a pressure-driven distillation system (PDDS) (Asada et al., 2010). The major components of PDDSs are flash drums and compressors. The compressors are necessary to form the pressure distribution required to achieve separation. The drum with the lowest pressure corresponds to the reboiler, from which the high boiling product is obtained. The distillate flows out from the drum with the highest pressure. The reflux ratio is determined by the pressure of the drum of highest pressure, which plays a role similar to the partial condenser in traditional distillation technology.

The highest and lowest pressures in this system are determined by the vapor pressures of the components in the mixture at the operating temperature. For example, when this was applied to a water–methanol separation, the lowest and highest pressures were 1.0 and 3.5 atm, respectively, when the operating temperature was 100 °C. When this mixture was separated using a 20-stage PDDS, the average compression ratio per unit was $10^{(1/20)} = 1.06$. A compression ratio of 1.06 is small; indeed, it is so low that low power compressors or blowers would be sufficient. The distillation system could be designed using the well-known McCabe–Thiele method using the *x-y* relationship in the *P-xy* VLE data. Once the composition of each stage was obtained using the McCabe–Thiele method, the pressure of each stage was determined from *P-xy* data. The resulting

set of pressures could then be directly used in the final design or fine-tuned to minimize the total rate of energy consumption.

The energy efficiency of PDDS was evaluated by conducting a process simulation for a methanol–water system. The feed was assumed to be an equimolar mixture, and the number of stages was 13. The specifications for both the top and bottom products were both 99% and the feed rate was 10 kmol/h. A PDDS was designed using the McCabe–Thiele method. The result of this design was input as the initial condition of an optimization calculation to minimize the total rate of energy consumption. The sum of the electric energy required to operate the compressors was 14.5 kW. The energy consumption rate of the comparable conventional reaction was also calculated. The ratio of the overall reflux ratio to the minimum reflux ratio was 1.01. The reboiler duty was calculated as 67.7 kW. To enable comparison, the electric energy was converted to thermal energy by assuming that a generation efficiency was 0.35. The results of this study suggest that the PDDS could be used to cut the consumption of thermal energy by 39% (Ito et al., 2014)

3.4. Experimental evaluation of separation performance

We are currently conducting an experimental study to validate the PDDS design concept. Our present focus is on the understanding its separation performance because a PDDS large enough to evaluate the rate of energy consumption may not be practical for a laboratory setting.

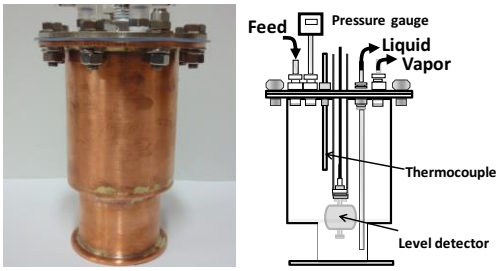

Figure 5. A device for a stage in PDDS

Figure 5 is a small-stage device developed in our laboratory. The body is made of copper to facilitate heat exchange with an external fluid. It is equipped with a pressure sensor, thermocouple, and liquid level sensor. The liquid level was controlled by manipulating a solenoid valve connected downstream of the liquid extraction line. A diaphragm pump within the vapor stream is activated when the pressure exceeds a set point.

A four-stage PDDS (Figure 6 (left)) was constructed in a thermostatic bath. A separation experiment was carried out using a methanol–water mixture. The four devices were connected to achieve a countercurrent flow of vapor and liquid and placed in a thermostatic bath at 80 °C. The pressure set points were 1.15, 1.3, 1.45, and 1.6 atm, respectively. The methanol composition of the feed was 66 mol%. The feed mixture was fed to the second stage from the low-pressure side at a rate of 2.0 mL/min. Samples of the liquid and vapor phases were collected after the system reached a steady state. The composition of each sample was determined by densitometry.

The measured compositions were plotted against *P-xy* data as shown in Figure 6 (right). The compositions of the samples were comparable to those given by the VLE data. A

slight deviation in the sample composition from the equilibrium can be observed at the highest-pressure stage. This is due to the large pressure fluctuation caused by the on–off operation of the diaphragm pump for pressure transport. This fluctuation is expected to be resolved by constructing a large apparatus and employing a more sophisticated control algorithm. Taken together, these observations suggest that the separation performance of PDDS is expected to be comparable to that of a conventional distillation column.

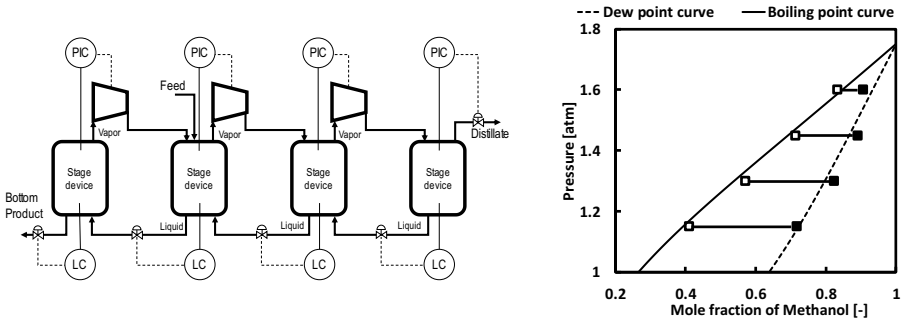

Figure 6. Configuration of 4-stage PDDS (left) and composition distribution (right)

4. Conclusions

Through close examination of the properties of microchemical process technology, the elementary operations in chemical apparatuses were identified. Conventional unit operations can be decomposed into a set of elementary operations, as shown in Figure 2. This framework allows us to create new chemical devices with distinct properties from their conventional analogues.

The development of PDDS was presented as an application of this idea. The proposed PDDS is unique in that a mixture is separated using a pressure distribution. It is expected be highly energy-efficient. Experimental evidence confirms that the PDDS can achieve satisfactory separation performance. Larger scale experimental work is being undertaken to evaluate the energy efficiency of PDDS.

Dynamic Bounds on Stochastic Chemical Kinetic Systems through Semidefinite Programming

Garrett R. Dowdy and Paul I. Barton*

Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, Massachusetts, 02139, United States of America
pib@mit.edu

Abstract

The method of moments has been proposed as a potential means to reduce the dimensionality of the chemical master equation (CME) appearing in stochastic chemical kinetics. However, attempts to apply the method of moments to the CME usually result in the so-called closure problem. Several authors have proposed moment closure schemes, which allow them to obtain approximations of quantities of interest, such as the mean count of molecules of each species. However, these approximations have the dissatisfying feature that they come with no error bounds. This paper presents a fundamentally different approach to the closure problem in stochastic chemical kinetics. Instead of making an approximation to compute a single number for the quantity of interest, we calculate mathematically rigorous bounds on this quantity by solving semidefinite programs (SDPs). These bounds provide a check on the validity of the moment closure approximations, and are in some cases so tight that they effectively provide the desired quantity. This paper extends a previously published method for calculating steady-state bounds to the problem of calculating time-varying bounds.

Keywords: semidefinite programming, chemical master equation, closure problem, stochastic chemical kinetics, moments

1. Introduction

Chemical reactions are often modelled using deterministic rate laws. However, when the number of molecules in a reaction system is relatively small, as in a single biological cell, these deterministic rate laws become unreliable, and the system's time evolution is best viewed as a stochastic process. This stochastic process is governed by the chemical master equation (CME), which describes the time evolution of a probability distribution describing the system. In principle, one could solve the CME to obtain the time evolution of the distribution. However, in any system of practical importance, the number of states is very large, rendering direct solution of the CME impractical (see Higham, 2008).

In an effort to circumvent this problem, instead of modelling the time evolution of the full probability distribution, some have proposed modelling only its moments up to some finite order m. The moments could then be used to calculate quantities of interest such as the mean count of molecules of each chemical species and the variances in these counts. The difficulty with this approach is that the system of ordinary differential equations describing how the moments change over time usually suffers from the so-called "closure problem", in which the time evolution of the moments up to order m depends on the values of higher-order moments.

To deal with this problem, various authors have proposed "closure scheme" approximations. For example, C. S. Gillespie (2009) assumes that the unknown distribution is normal; Smadbeck and Kaznessis (2013) assume it is maximum entropy. With such assumptions, the low-order moments determine the entire distribution (including the high-order moments), and the closure problem is bypassed. One can then approximate both dynamic trajectories and steady-state values for the moments. Unfortunately, these are just approximations, with no bounds on error. The approximation could be good; on the other hand, it could be quite bad. These two scenarios are indistinguishable, unless some second, independent method is applied to the problem.

In this paper, we propose an alternative strategy. Instead of selecting one of the many distributions satisfying prescribed conditions on the low-order moments and calculating some approximation of the quantities of interest, we acknowledge that many distributions satisfying the prescribed conditions exist and calculate rigorous bounds on the quantities of interest. These bounds are computed by solving semidefinite programs (SDPs), convex optimization problems which can be solved efficiently, both in theory and practice (Vandenberghe and Boyd, 1996).

This paper extends a previously published method for calculating steady-state bounds to the problem of calculating time-varying bounds (see Dowdy and Barton, 2018 and the references therein).

2. Mathematical Background

2.1. Notation of Stochastic Chemical Kinetics

Consider a stochastic chemical kinetic system with N distinct chemical species and R reactions. At any point in time, the state of the system is described by a vector $\boldsymbol{x} = (x_1, \ldots, x_N) \in \mathbb{Z}_+^N$, where $x_i \geq 0$ is the count of molecules of species i present.

The state changes with the occurrence of each reaction. For example, if $\boldsymbol{s}_r \in \mathbb{Z}^N$ is the vector of stoichiometric coefficients of reaction r, then an occurrence of reaction r takes the system from state $\boldsymbol{x}$ to $\boldsymbol{x} + \boldsymbol{s}_r$.

2.2. Invariants

In general, given an initial state $\boldsymbol{x}_0 \in \mathbb{Z}_+^N$ and a stoichiometry matrix $\boldsymbol{S} = [\boldsymbol{s}_1 \ \cdots \ \boldsymbol{s}_R] \in \mathbb{Z}^{N \times R}$ not every state $\boldsymbol{x} \in \mathbb{Z}_+^N$ is accessible to the system. The set of possible states X must be contained in the affine subspace $\{\boldsymbol{x}_0 + \boldsymbol{S}\boldsymbol{v} : \boldsymbol{v} \in \mathbb{R}^R\}$. If $\boldsymbol{S}$ has a nontrivial left null space, spanned by the linearly independent basis vectors $\boldsymbol{b}_1, \ldots, \boldsymbol{b}_L \in \mathbb{R}^N$, and we define the matrix $\boldsymbol{B} \equiv [\boldsymbol{b}_1 \ldots \boldsymbol{b}_L]^{\mathrm{T}} \in \mathbb{R}^{L \times N}$, then $\boldsymbol{B}\boldsymbol{x} = \boldsymbol{B}\boldsymbol{x}_0$ for all $\boldsymbol{x} \in X$. That is, certain linear combinations of the components of $\boldsymbol{x}$ are conserved by the reaction system. These linear combinations are the "invariants" of the reaction system.

2.3. The Chemical Master Equation

Because of the stochastic nature of the system, there is some uncertainty as to the state at time t, and we express this uncertainty by assigning a probability $P(\boldsymbol{x}, t)$ to each of the possible states $\boldsymbol{x} \in X$. This probability distribution $P(\cdot, t)$ changes over time according to the chemical master equation (CME):

$$\frac{dP}{dt}(\boldsymbol{x},t) = \sum_{r=1}^{R}[P(\boldsymbol{x}-\boldsymbol{s}_r,t)a_r(\boldsymbol{x}-\boldsymbol{s}_r) - P(\boldsymbol{x},t)a_r(\boldsymbol{x})], \quad \forall \boldsymbol{x} \in X, \tag{1}$$

where a_r is the "propensity function" of reaction r, described by Higham (2008), which is proportional to the rate constant c_r. Note that this equation holds for all possible states $\boldsymbol{x} \in X$.

2.4. Moments in Stochastic Chemical Kinetics

The probability distribution $P(\cdot,t)$ can be characterized by its moments. In particular, for any multi-index $\boldsymbol{j} = (j_1,\ldots,j_N) \in \mathbb{Z}_+^N$ we have a moment $\mu_{\boldsymbol{j}}(t)$ defined as

$$\mu_{\boldsymbol{j}}(t) \equiv \sum_{\boldsymbol{x}\in X} P(\boldsymbol{x},t)\,\boldsymbol{x}^{\boldsymbol{j}}, \tag{2}$$

where the sum is over the set X of all possible states, and $\boldsymbol{x}^{\boldsymbol{j}} = \prod_{k=1}^{N} x_k^{j_k}$ is a monomial. The order of the moment $\mu_{\boldsymbol{j}}$ is defined as the sum $\sum_{k=1}^{N} j_k$.

Some moments have intuitive meanings. For example, the zeroth-order moment $\mu_{\boldsymbol{0}}$ indexed by $\boldsymbol{0} = (0,\ldots,0)$ is simply the sum of probabilities across all possible states, so that $\mu_{\boldsymbol{0}}(t) = 1$ for all times t. More important for our purposes, the first-order moment $\mu_{\boldsymbol{e}_i}$ indexed by $\boldsymbol{e}_i = (0,\ldots,1,\ldots,0)$ is the mean number of molecules of species i.

2.5. The Closure Problem

As described by Smadbeck and Kaznessis (2012) and Gillespie (2009), the CME can be used to derive a system of linear ordinary differential equations describing how the moments of the distribution change over time. In particular, we can write

$$\frac{\mathrm{d}\boldsymbol{\mu}_L}{\mathrm{d}t}(t) = \boldsymbol{A}_L\boldsymbol{\mu}_L(t) + \boldsymbol{A}_H\boldsymbol{\mu}_H(t), \tag{3}$$

where $\boldsymbol{\mu}_L(t)$ is a vector of moments up to arbitrary order m, $\boldsymbol{\mu}_H(t)$ is a vector of finitely many moments with order greater than m, and $\boldsymbol{A}_L$ and $\boldsymbol{A}_H$ are constant matrices, whose sizes depend on m. The fact that the time derivatives of the moments with order up to m depend on higher-order moments is the essence of the closure problem. It is unclear how to solve such a system.

One could apply a closure scheme, assuming that the underlying distribution is normal (C.S. Gillespie, 2009) or maximum entropy (Smadbeck and Kaznessis, 2013). Doing so allows us to express the high-order moments in terms of the low-order moments, and thus "close" the system of equations. However, as noted in the introduction, these closure schemes provide no bound on the error introduced in making their assumptions. In the following section, we propose a different approach.

3. The Bounding Method

3.1. The Paradigm

Instead of trying to calculate the quantity of interest directly, let us calculate rigorous bounds on that quantity. For example, for the mean molecular count of species i at time t, $\langle x_i(t)\rangle$, let us calculate two numbers, $\langle x_i(t)\rangle^L$ and $\langle x_i(t)\rangle^U$, such that

$$\langle x_i(t)\rangle^L \leq \langle x_i(t)\rangle \leq \langle x_i(t)\rangle^U \tag{4}$$

is guaranteed.

How might we calculate these bounds? Suppose that we write down several mathematical constraints that the moment vector $\boldsymbol{\mu}(t)$ at time t must necessarily satisfy. Suppose that we then optimize over the set of vectors $\boldsymbol{\mu}$ satisfying these necessary conditions, searching for the vector $\boldsymbol{\mu}$ with the greatest component $\mu_{\boldsymbol{e}_i}$:

$$\begin{aligned} \mu^*_{\mathbf{e}_i} \equiv \max_{\boldsymbol{\mu}} \; & \mu_{\mathbf{e}_i} \\ \text{s.t.} \; & \boldsymbol{\mu} \text{ satisfies necessary conditions} \end{aligned} \tag{5}$$

Then, because the vector $\boldsymbol{\mu}(t)$ corresponding to true moments at time t satisfies the necessary conditions, it is a feasible point for this optimization problem. It follows that the optimal value $\mu^*_{\boldsymbol{e}_i}$ is an upper bound on $\mu_{\boldsymbol{e}_i}(t) = \langle x_i(t)\rangle$, and we can set $\mu^*_{\boldsymbol{e}_i} \equiv \langle x_i(t)\rangle^U$.

Following the same reasoning, we can calculate at lower bound on $\langle x_i(t)\rangle$ by solving the minimization version of Problem (5).

3.2. Necessary Conditions

What exactly are the necessary conditions appearing in Problem (5)? First, we have some linear equalities implied by the invariants of the reaction system:

$$\sum_{\boldsymbol{x}\in X} P(\boldsymbol{x},\tau)\, \boldsymbol{x}^{\boldsymbol{j}} \boldsymbol{B}(\boldsymbol{x}-\boldsymbol{x}_0) = \mathbf{0}, \tag{6}$$

for finitely many multi-indices $\boldsymbol{j} \in \mathbb{Z}^N_+$. These equations can be written concisely as

$$\widetilde{\boldsymbol{B}}\boldsymbol{\mu}(t) = \mathbf{0}. \tag{7}$$

Next, we have several linear matrix inequalities which reflect the support of the underlying probability distribution $P(\cdot, t)$:

$$\boldsymbol{M}^{\mathbf{0}}_n\big(\boldsymbol{\mu}(t)\big) \succcurlyeq \mathbf{0}, \tag{8}$$

$$\boldsymbol{M}^{\boldsymbol{e}_j}_{n-1}\big(\boldsymbol{\mu}(t)\big) \succcurlyeq \mathbf{0}, \;\; \forall j \in \{1,\dots,N\}. \tag{9}$$

The exact definitions of these matrices are given in our related publication on stochastic chemical systems at steady state (Dowdy and Barton, 2018). However, for now, all that matters is that the matrices are affine functions of the vector $\boldsymbol{\mu}(t)$.

Next, we have a family of equalities which can be derived from Equation (3), which reflect the dynamics of the system, and which tie $\boldsymbol{\mu}(t)$ to the initial moment sequence $\boldsymbol{\mu}(0)$:

$$\boldsymbol{\mu}_L(t) - e^{\rho t}\boldsymbol{\mu}_L(0) = (\boldsymbol{A}_L - \rho \boldsymbol{I})\boldsymbol{z}^{(\rho)}_L + \boldsymbol{A}_H \boldsymbol{z}^{(\rho)}_H, \quad \forall \rho \in \{\rho_1,\dots,\rho_d\}. \tag{10}$$

These equations are valid necessary conditions for any choice of the values of $\rho_1,\dots,\rho_d$. However, roughly speaking, we will try to pick these values to match the eigenvalues of the dominant dynamic modes of the chemical master equation (1).

Equation (10) introduced a set of decision vectors $\boldsymbol{z}^{(\rho)}, \forall \rho \in \{\rho_1,\dots,\rho_d\}$, which are defined by

$$z_{\boldsymbol{j}}(t) \equiv \int_0^t e^{\rho(t-\tau)} \sum_{\boldsymbol{x}\in X} P(\boldsymbol{x},\tau)\, \boldsymbol{x}^{\boldsymbol{j}}\, \mathrm{d}\tau, \qquad \forall \rho \in \{\rho_1, \ldots, \rho_d\},\ \ \forall \boldsymbol{j} \in \mathbb{Z}_+^N, \tag{11}$$

and can be thought of as "generalized moments". As moments, these vectors $\boldsymbol{z}^{(\rho)}$ must satisfy several constraints analogous to Conditions (7)-(9):

$$\widehat{\boldsymbol{B}}\boldsymbol{z}^{(\rho)} = \boldsymbol{0}, \qquad \boldsymbol{M}_n^{(\boldsymbol{0},\boldsymbol{0})}\big(\boldsymbol{z}^{(\rho)}\big) \succcurlyeq \boldsymbol{0}, \tag{12}$$

$$\boldsymbol{M}_{n-1}^{(\boldsymbol{0},\boldsymbol{e}_j)}\big(\boldsymbol{z}^{(\rho)}\big) \succcurlyeq \boldsymbol{0}, \qquad \forall j \in \{1, \ldots, N\}, \tag{13}$$

for all $\rho \in \{\rho_1, \ldots, \rho_d\}$.

3.3. A Semidefinite Program

Substituting Necessary Conditions (7)-(10) and (12)-(13) into Problem (5), we obtain a semidefinite program:

$$\begin{aligned}
\langle x_i(t)\rangle^U \equiv \max_{\boldsymbol{\mu}(t),\boldsymbol{z}^{(\rho_1)},\ldots,\boldsymbol{z}^{(\rho_d)}} \ & \mu_{\boldsymbol{e}_i}(t) \\
\text{s.t.}\ \ & \boldsymbol{\mu}_L(t) - e^{\rho t}\boldsymbol{\mu}_L(0) = (\mathbf{A}_L - \rho\mathbf{I})\mathbf{z}_L^{(\rho)} + \mathbf{A}_H\mathbf{z}_H^{(\rho)}, \\
& \qquad \forall \rho \in \{\rho_1, \ldots, \rho_d\}, \\
& \widehat{\mathbf{B}}\mathbf{z}^{(\rho)} = \mathbf{0},\ \mathbf{M}_n^{(\mathbf{0},\mathbf{0})}(\mathbf{z}^{(\rho)}) \succcurlyeq \mathbf{0},\ \forall \rho \in \{\rho_1, \ldots, \rho_d\}, \\
& \mathbf{M}_n^{(\mathbf{0},\mathbf{e}_j)}(\mathbf{z}^{(\rho)}) \succcurlyeq \mathbf{0},\ \ \forall j \in \{1, \ldots, N\},\ \forall \rho \in \{\rho_1, \ldots, \rho_d\}, \\
& \widehat{\mathbf{B}}\boldsymbol{\mu}(t) = \mathbf{0},\ \mathbf{M}_n^{\mathbf{0}}(\boldsymbol{\mu}(t)) \succcurlyeq \mathbf{0}, \\
& \mathbf{M}_n^{\mathbf{e}_i}(\boldsymbol{\mu}(t)) \succcurlyeq \mathbf{0},\ \ \forall j \in \{1, \ldots, N\},
\end{aligned} \tag{14}$$

Solving this SDP gives us our upper bound on $\langle x_i(t)\rangle$. Solving the corresponding minimization bounding problem gives us our lower bound.

4. Example

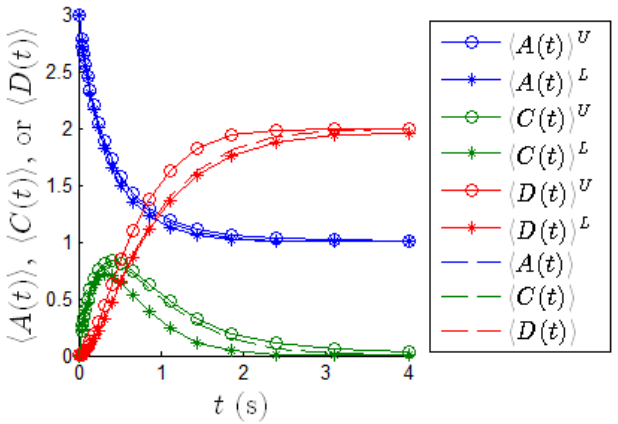

Figure 1 Time-varying bounds on the mean molecular counts of several species appearing in Reaction System (15).

Consider the simple sequential reaction system

$$A + B \xrightarrow{c_1} C \xrightarrow{c_2} D \tag{15}$$

with $c_1 = 1$ s^{-1}, $c_2 = 2$ s^{-1}, and an initial state of $x_A = 3,\ x_B = 2,\ x_C = 0$, and $x_D = 0$. Repeatedly solving SDP (14) and its lower-bounding analogue for this system, using $\{\rho_1, \ldots, \rho_d\} = \{0, -c_1, -c_2\}$ and a range of t values, gives the time-varying bounds on $\langle A \rangle, \langle C \rangle$, and $\langle D \rangle$ shown in Figure 1. All SDPs were solved using SeDuMi (Sturm, 1999).

This system is small enough that we can calculate the exact time-varying means by solving the CME (dashed lines in Figure 1). These exact means lie within the bounds, as predicted by the theory. Also, in this case, the bounds are tight around the exact means. We have chosen an example for which the exact means are available because it supports the theory. However, in general, the exact solution will not be available.

5. Conclusions

The proposed bounding method is a fundamentally different approach to the problem of characterizing time-varying distributions in stochastic chemical kinetic systems. In this paper, it has been applied to calculate bounds on the mean molecular counts. These bounds are theoretically guaranteed to be accurate, in contrast with the results of moment closure schemes. Of course, bounds on a quantity are less useful than the quantity itself, but we've seen that the bounds are sometimes so tight that they effectively give us the desired quantity.

There are several possible extensions and variations of the bounding method. First, one can formulate an SDP for calculating an upper bound on the variance in the count of each molecular species. Second, one can formulate an SDP to calculate bounds on the probability that the count of molecules of each species lies within a particular range. This leads to bounds on a histogram describing the underlying unknown distribution. Finally, there are computational efficiencies to be gained by considering reduced descriptions of the state of the system in which only the "independent components" are considered. These extensions and variations of the bounding method will be detailed in a forthcoming publication.

Abstract
A three-dimensional, multiscale computational fluid dynamics (CFD) model is presented here which aims to capture the deposition of amorphous silicon thin films via plasma-enhanced chemical vapor deposition (PECVD). The two domains which define the multiscale model are linked using a dynamic boundary which is updated at the completion of each time step. A novel parallel processing scheme built around a message passing interface (MPI) structure is applied in order to allow for transient simulations to be conducted using a mesh with greater than 1.5 million cells. Due to thin film thickness non-uniformity present in the *a*-Si:H product, an improved PECVD reactor geometry is proposed. The resulting geometry is shown to reduce the product offset from ~8% to less than 4% using identical deposition parameters.

Keywords: Multiscale modeling, computational fluid dynamics, kinetic Monte-Carlo, thin film growth.

1. Introduction
The past two decades have seen continual development in the multiscale modeling of plasma-enhanced chemical vapor deposition (PECVD) with specific applications to the manufacturing of silicon thin films for use in the photovoltaic and microelectronics industries (da Silva and Morimoto, 2002, and Collins et al., 1994). Accurate modeling of thin film deposition remains a key element in the effort to improve product quality and to cut down on manufacturing costs due to the difficulties associated with continuous and/or in situ measurements during chambered deposition processes. Recently, Crose et al. (Crose et al., 2017) demonstrated a novel multiscale computational fluid dynamics (CFD) model, which combined a macroscopic CFD domain with a microscopic surface domain through a common boundary which lies on the surface of the silicon wafer. Despite the success of this model in capturing the behavior of the PECVD reactor with regard to the non-uniform deposition of a-Si:H films and in providing a basis for future multiscale CFD modeling endeavors, the two-dimensional axisymmetric nature of the model limits the exploration of some phenomena which exist in the three-dimensional in space process. Specifically, two-dimensional (2D) axisymmetric models cannot represent the full geometry of showerhead holes that provide process gas to the plasma region -- a key feature when considering the uniformity of thin film products.

Given the aforementioned motivations, the framework previously developed for use in 2D applications is extended to the three dimensional domain. Using a three-dimensional (3D) render which captures the typical geometry of chambered, parallel-plate PECVD reactors, a CFD model is proposed in the present work which is capable of reproducing both accurate plasma chemistry and fluid flow into the reaction zone through the showerhead region. With regard to the microscopic domain (i.e., the surface of the silicon wafer), a detailed kinetic Monte Carlo (kMC) algorithm developed previously by Crose et al. (Crose et al., 2017) is applied in order to capture both the exchange of mass and energy, as well as the microstructure of the a-Si:H thin-film. Given that the startup and operation of PECVD reactors are inherently dynamic, the proposed simulations cannot derive accurate rector behavior from steady-state solutions; however, the computationally demanding nature of the transient simulations necessitates the use of a parallel computation strategy as well as taking advantage of multiple-time-scale phenomena occurring in the process. In this work, a Message Passing Interface (MPI) structure is adopted which allows for the discretization of both the macroscopic CFD volume and the microscopic kMC algorithm. The outlined multiscale model is applied to the deposition of 300 nm thick a-Si:H films revealing significant non-uniformities in the thickness of the thin-film product. An improved reactor geometry is proposed which utilizes a polar showerhead arrangement and a radially-adjusted showerhead hole diameter. This geometry is shown to reduce thickness non-uniformity in the *a*-Si:H thin film product from ~8% to less than 4%, representing significant product quality improvement and financial savings.

2. Three-dimensional Modeling

Recently, Crose et al. (Crose et al., 2017) demonstrated the need for multiscale modeling in the PECVD process due to the interconnection between the macroscopic, reactor scale and the microscopic, thin film growth domains. Specifically, a two-dimensional (2D) axisymmetric geometry was used in the creation of the reactor mesh and a hybrid kinetic Monte Carlo (kMC) algorithm was applied to capture the growth of amorphous silicon (*a*-Si:H) thin film layers. Although this model has proved useful in designing optimized reactor operational strategies, some features of the PECVD reactor are lost when using 2D representations. In looking at Fig. 1, the difference between showerhead geometries becomes clear: the cylindrical showerhead holes and their associated spatial arrangement of the 3D system cannot be directly translated to 2D models. Given the primary motivation of addressing *a*-Si:H thin film product quality through improved PECVD reactor design, in this work the development of a 3D multiscale CFD model will be discussed including both the macroscopic and microscopic domains, as well as the associated dynamic boundary conditions and parallel computing implementation.

2.1. Macroscopic domain

As discussed previously, we utilize a 3D, cylindrical PECVD reactor geometry (see Fig. 1, right) with dimensions typical of those used in industry. The showerhead holes, visible in Figs. 1 and 2, have a diameter of 1 cm and are evenly spaced in a rectangular array throughout the inlet region. In order to solve the partial differential equations which capture the gas phase mass, momentum and energy balances, the reactor geometry is discretized using an unstructured mesh containing ~1.5 million tetrahedral cells. Although the choice to use an unstructured mesh rather than a simplified

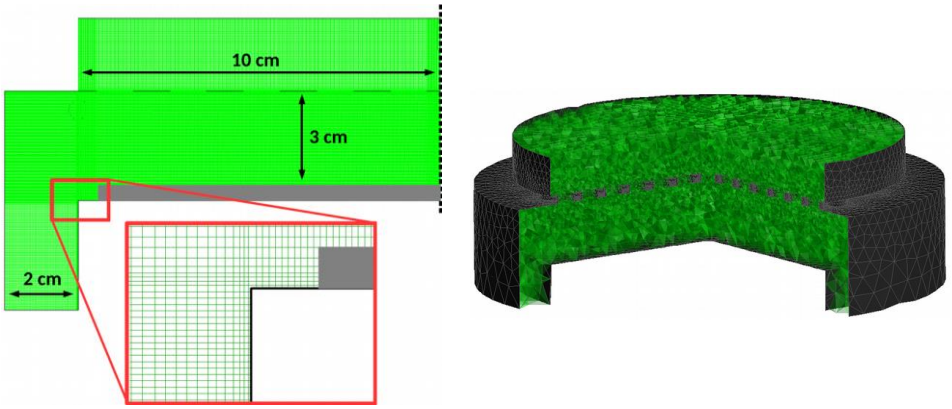

Figure 1. (left) 2D axisymmetric geometry after discretization using a structured mesh containing 120,000 cells. (right) Collection of 1.5 million polygons which define the unstructured, 3D mesh.

structured mesh comes at the cost of computational efficiency, the curvature of the cylindrical reactor shell and showerhead holes favors its use. It is important to note that throughout this work ANSYS software is applied to the creation of the geometric mesh (specifically, ICEM meshing) and as a solver for the PDEs mentioned above.

The ANSYS Fluent software alone cannot yield a multiscale model for the PECVD process of interest; consequently, three user defined functions (UDFs) have been developed to tailor the solver to the deposition of *a*-Si:H thin films. More specifically, the thirty four most dominant gas phase reactions have been accounted for via a volumetric reaction scheme which includes terms for the nine primary plasma reactions which lead to thin film growth. The necessary electron density within the plasma region is calculated using a product of the zero-order Bessel function and a sine function which account for the spatial dependencies within the cylindrical reaction zone. The third UDF necessary to the multiscale nature of the model simulates the growth of *a*-Si:H thin films along the surface of the wafer substrate, and will be touched upon briefly in the following section. The details of these UDFs, in particular the kinetic Monte Carlo (kMC) algorithm which defines the microscopic domain, will not be provided here due to space limitations; however, an in-depth discussion can be found in Crose et al. 2017.

2.2. Microscopic domain

As radicals diffuse from the gas phase down to the substrate surface, they enter the microscopic domain. While tracking of each individual particle remains a computationally infeasible task, growth of *a*-Si:H thin film layers may still be achieved using kinetic Monte Carlo (kMC) algorithms. Specifically, the substrate surface is broken down into discrete regions along the *x*-*y* plane as shown in the right-hand side of Fig. 2, and within each region an independent kMC simulation is executed. Each simulation consists of a lattice of width 1200 particles which captures the growth of a representative *a*-Si:H layer within the associated region. The tetrahedral cells bordering each region are assigned dynamic boundary conditions corresponding to the exchange of mass and energy due to thin film growth at each time step (see Fig. 2, left). Details concerning the development of the kMC algorithm used here may be found in Crose et al. (Crose et al., 2017) and will not be discussed further at this time.

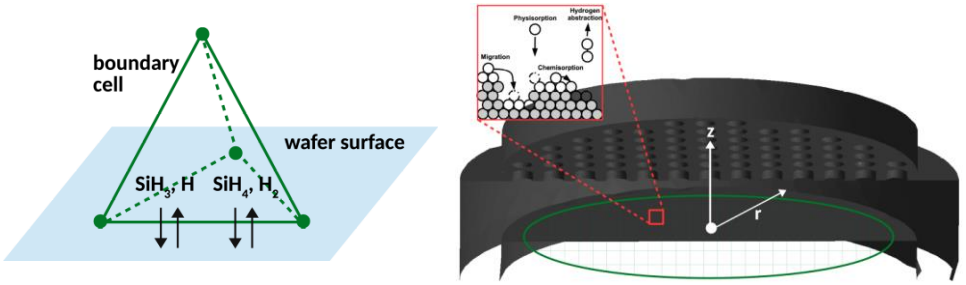

Figure 2. (left) Finite element adjacent to the substrate surface with dynamic boundary condition calculated via microscopic simulation domain. (right) Kinetic Monte Carlo setup within overall multiscale simulation. Wafer substrate discretized in both the *x* and *y* directions forming a 'grid' structure.

2.3. Multiscale workflow

The methodology for connecting the macro- and microscopic domains is of particular importance to the function of the multiscale model; consequently, the simulation workflow must be examined here. At the start of each transient batch simulation, $t = 0$, the first time step for the macroscopic CFD domain is calculated within every cell of the unstructured mesh using ANSYS Fluent as discussed previously. Additionally, the first two UDFs (e.g., the volumetric reaction and electron density scripts) are executed and the results of which are fed into Fluent's PDEs. Once a time step has been completed, $t = t_1$, the species concentration, the temperature and the pressure along the boundary of the wafer substrate are transferred to the microscopic domain (i.e., Fig. 2, left). The discrete kMC simulations discussed above are then initialized using this information allowing for growth of *a*-Si:H thin film layers to begin. Once all of the microscopic simulations have reached t_1, the dynamic boundary conditions for cells bordering the wafer surface are updated based on the mass and energy transfer within the associated region. Again, the macroscopic PDEs are solved such that the time moves forward to t_2 and the cycle continues. In this way, the multiscale model progresses until the end of the batch deposition process is reached (i.e., until $t = t_{batch}$).

2.3.1. Parallel computation

The move from 2D to 3D PECVD reactor models comes at the cost of computational efficiency. In the recent work of Crose et al. (Crose et al., 2017), the 2D axisymmetric CFD simulations required the use of a message passing interface (MPI) structure in order to parallelize the domain and to achieve feasible computation times (e.g., <1 day per batch simulation). In this work, the computational demands are further increased due to the mesh containing ~1.5 million cells (as opposed to 120,000 for the 2D model), tetrahedral cell shape and far more discrete kMC simulations required to span the substrate surface. As a result, parallelization of the multiscale domain remains crucial to operation of transient simulations. Decomposition of the reactor mesh will not be detailed here but may be found in Crose et al. (Crose et al., 2017); however, orchestration of the independent kMC simulations is unique to this work and will be provided below.

As mentioned in previous sections, the substrate surface is broken down into the grid structure shown in the right-hand side of Fig. 2. Given that kMC simulations within this structure are independent (i.e., do not share mass and energy directly), they are potential candidates for distribution amongst the computation nodes. At the start of each batch

simulation, the N_{kMC} wafer regions are assigned evenly among the 128 compute nodes available. The compute nodes then calculate the growth of *a*-Si:H thin film layers for their assigned regions during each microscopic time step. Before the next macroscopic step can begin, growth information from each node is communicated to the host process and the cell boundary conditions are updated.

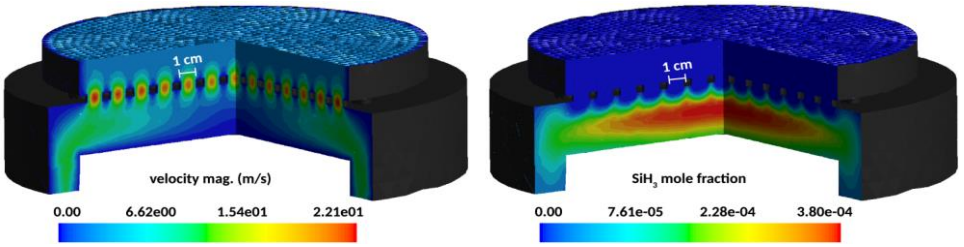

Figure 3. (left) Velocity magnitude within 3D PECVD reactor showing dead-zone near substrate center. (right) Non-uniform, steady-state SiH$_3$ concentration.

3. Results

3.1. Non-uniform deposition

The PECVD reactor cross sections shown in Fig. 3 have been obtained after the brief startup period to give an idea of the gas phase throughout most of the thin film growth (note: the startup period constitutes less than 2% of the deposition time). In looking at the flow field (Fig. 3, left), three distinct regions become apparent: (1) rapid acceleration as the precursor gas passes through the showerhead, (2) increased flow velocity as the unused gas is forced through the narrow outlet regions and (3) a 'dead zone' just above the center of the substrate. The effect of the flow field on product quality can be readily seen in Figs. 3 and 4; the concentration of the primary deposition species, SiH_3, is non-uniform. Not only is there a sharp drop-off in the mole fraction of SiH_3 in the radial, r, direction, but along the azimuthal, θ, direction significant variation exists. The triangular data points in Fig. 5 further highlight this phenomena. In moving radially outward from r = 0 cm to r = 8 cm (the edge of the wafer substrate), the mole fraction of SiH_3 steadily decreases. Additionally, for a fixed radial position (e.g., r = 4 cm) azimuthal variation in x_{SiH3} is worthy of note. In recent years, spatial non-uniformity of deposition species has been shown to contribute to thin film products with thickness offset from the desired set-point (da Silva and Morimoto, 2002, Crose et al., 2016 and Crose et al., 2017), causing device quality issues and poor solar conversion. As such, elimination of 'hot-spots,' or regions defined by significantly different concentrations, is of great interest from a manufacturing perspective.

3.2. Adjusted reactor geometry

By capturing the detailed showerhead geometry, the 3D multiscale CFD model presented here is capable of evaluating alternative PECVD reactor designs. To this end, an adjusted showerhead design is presented here with the goal of reducing spatial non-uniformity in the concentration of SiH_3 such that the *a*-Si:H product is of improved quality. Two key changes have been implemented in the design of the showerhead holes: (1) the rectangular showerhead hole array (e.g., Fig. 4, left) has been altered in favor of the polar array shown in the right-hand side of Fig. 4, and (2) the diameter of the holes are radially dependent. By maintaining larger showerhead holes near the edges of the inlet region with smaller holes at the center, the distribution of SiH_3 is significantly more uniform. In looking at the right of Fig. 4, the hot-spots present in the

original reactor geometry have been eliminated in both the radial and azimuthal directions. In terms of product quality, the circular data points in Fig. 5 demonstrate that the *a*-Si:H thickness offset has been reduced from ~8% to less than 4%.

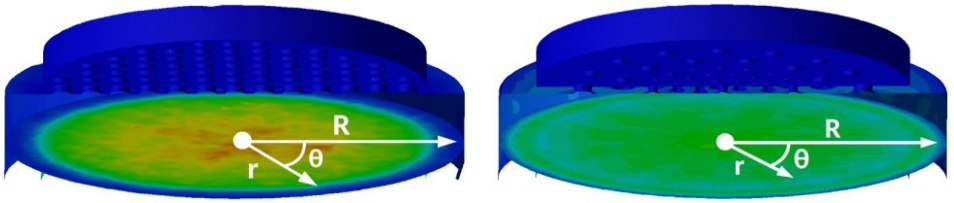

Figure 4. (left) Cross section of SiH_3 concentration taken just above the surface of the wafer substrate (right) SiH_3concentration above the wafer surface for the adjusted reactor geometry.

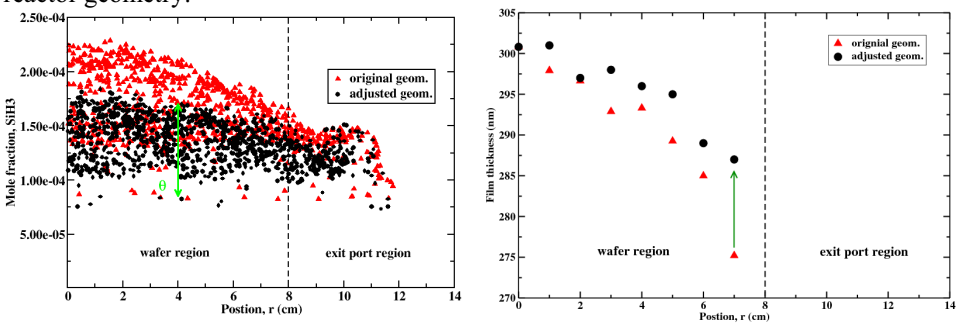

Figure 5. (left) SiH_3 mole fraction as a function of radial position, r, and azimuthal position, θ. (right) Radial *a*-Si:H product thicknesses.

4. Conclusions

An alternative PECVD reactor design has been evaluated using a three-dimensional multiscale CFD model which coordinates communication between the macroscopic reactor scale and the microscopic thin film growth domain. Application of this model to two representative PECVD reactor geometries has shown that thickness non-uniformity in the *a*-Si:H product can be minimized by adjusting the positions and size of the showerhead holes. As a result, the 3D CFD model presented here holds promise for not only improving product quality in PECVD processing, but also for significant savings in time and resources otherwise spent on testing and manufacture of reaction chambers.

Abstract

A hybrid empirical computer-aided methodology to design the solvent for a reaction, incorporating both selectivity and rate, is presented. A small initial set of diverse solvents is used, for which experimental, *in situ* kinetic data are obtained. A surrogate model is utilized to correlate the reaction kinetics with solvent properties and a computer-aided molecular design (CAMD) multi-objective optimization problem is then formulated to identify solvents with improved performance compared with the initial solvent set. This methodology is applied to an S_NAr reaction of 2,4-difluoroacetophenone with pyrrolidine, which demonstrates an interesting effect of solvent on both the selectivity of the *ortho*-:*para*-substitution ratio and the overall rate of the reaction. A set of Pareto optimal solutions is identified, highlighting the trade-off between reaction rate and selectivity.

Keywords: solvent effects, selectivity, optimization, computer-aided molecular design.

1. Introduction

Solvents can have significant effects on liquid-phase chemical reactions, such as on the rate, selectivity and solubility, yet there is no general model for predicting the solvent effects on reactions (Reichardt and Welton, 2010). In the production of pharmaceuticals and fine chemicals, solvents characteristically constitute between 80 and 90 % of the materials used by mass (Constable et al., 2007). Additionally, given that many traditional solvents are volatile organic compounds and account for around half of the greenhouse gas emissions in the production of pharmaceuticals (Jimenez-Gonzalez et al., 2005), the industry is facing increasing pressure to employ more environmentally friendly solvents, ideally without compromising on reaction efficiency and performance.

Consequently, many methods have been developed to aid in the selection of solvents for reactions. When a vast array of experimental data is available chemometrics can be implemented in order to identify promising solvents (Havet et al., 2002). However, this method is not applicable when experimental data is lacking or laborious to acquire. Computer-aided molecular design (CAMD) has thus evolved as a predictive and systematic method for solvent design. Early CAMD work involved using generate-and-test methods whereby target solvent properties were identified and all the possible

solvents that fit these properties were designed using group contribution (GC) methods (Gani and Brignole., 1983). Following from this, optimization-based CAMD was employed and process performance criteria were targeted (Odele and Machietto, 1993). Whilst generate-and-test methods may be efficient for problems with a small design space, as they involve generating all possible combinations, including many that may be infeasible solutions to the problem, for large design space problems, optimization methods are preferable (Austin et al., 2016).

More recently reaction kinetics have been incorporated into a CAMD framework, both experimentally (Folic et al., 2004) and theoretically (Struebing et al., 2013; Austin et al., 2017), where maximizing the rate constant for the reaction was set as the solvent design target. This concept has been extended to reaction selectivity whereby hypothetical experimental data was generated and a surrogate model was derived based on the solvatochromic equation (Folic et al., 2008). The optimization objective was to maximise the difference in concentration between the desired product and a by-product. In our work an empirical-CAMD methodology is developed to maximise both reaction rate and selectivity in the case of competing reaction pathways. Kinetic data are measured experimentally in order to derive the surrogate model, and multi-objective optimization is employed to incorporate both selectivity and rate of the desired reaction as design objectives. The consideration of both selectivity and rate is of great importance given that they respectively affect the amount of waste and the scale of a typical industrial process. Thus, these objectives are important from a green chemistry and an economic perspective.

2. Empirical-CAMD methodology

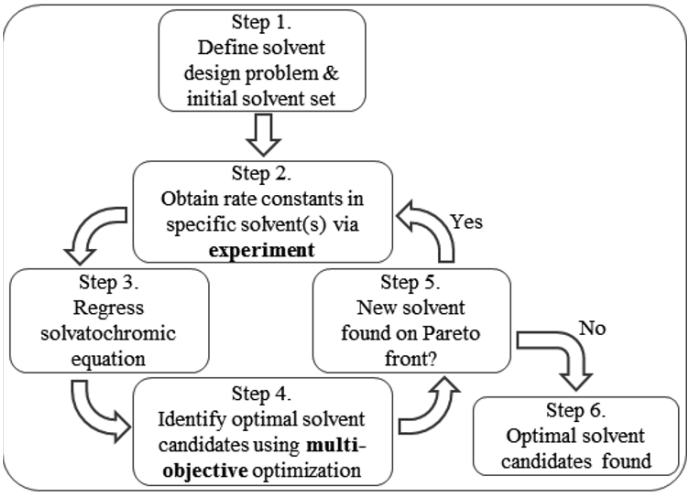

Figure 1: Empirical-CAMD algorithm for identifying optimal solvents for reaction productivity where the solvent influences multiple reaction parameters of interest.

In Step 1 the design objective and constraints are determined as well as the initial solvent set, which should include a diverse range of functional groups and polarity. In Step 2 the rate constants in these solvents are obtained experimentally. A number of possible experimental techniques can be employed, the choice of which is dependent on the specific reaction being studied. In Step 3 a surrogate model is derived from the experimental rate constants. The surrogate model used here is the solvatochromic

equation, which correlates linearly the properties of solvent *i* with the rate constant of a reaction in that solvent (log k_i) using 6 reaction specific coefficients:

$$\log k_i = c_0 + c_A A_i + c_B B_i + c_S S_i + c_\delta \delta_i + c_H(\delta^2_{Hi}/100) \quad (1)$$

where A_i and B_i are hydrogen bonding acidity and basicity of solvent *i* respectively and S_i is its polarisability/polarity (Folic et. al., 2007), δ_i is determined by the number of halogen and aromatic functional groups (Sheldon, et al., 2005) and δ^2_{Hi} is the square of its Hildebrand solubility parameter (Hukkerikar, et al., 2012) all of which are obtained using GC methods. The reaction specific coefficients c_i, i = 0, A, B, S, δ, H are obtained by linear regression of Eq.(1). In Step 4 the solvent design problem is translated into a mathematical optimization problem. A multi-objective optimization (MOO) method is utilised. The ϵ-constraint method (Haimes, et al., 1971) is employed to pose and solve the problem, which transforms one or more of the objectives into a constraint. The general formulation of the problem tackled here is written as follows:

$$\max \quad f_1(\boldsymbol{x}) \quad (2)$$

$$s.t. \quad f_2(\boldsymbol{x}) \geq \epsilon \quad (3)$$

$$\boldsymbol{h}_1(\boldsymbol{x}) \leq Z\boldsymbol{y} \quad (4)$$

$$C\boldsymbol{y} \leq \boldsymbol{d} \quad (5)$$

$$\boldsymbol{x}_i \in \mathbb{R}^m \quad (6)$$

$$\boldsymbol{y}_i \in \{0, 1\}^u \quad i = 1,\ldots,q, \quad (7)$$

where $f_1(\boldsymbol{x})$ is one objective function and $f_2(\boldsymbol{x})$ is the other that is transformed into a constraint using ϵ which is set by the user, $\boldsymbol{h}_1(\boldsymbol{x}) \leq Z\boldsymbol{y}$ is a set of molecular complexity, chemical feasibility and structure-property constraints, $C\boldsymbol{y} \leq \boldsymbol{d}$ is a set of constraints on the binary variables, $\boldsymbol{x}$ is an m-dimensional vector of variables denoting the number of groups as well as the physical properties of the solvent, $\boldsymbol{y}$ is a $q \times u$ matrix of binary variables used to constrain continuous variables such as the number of groups, to integer values and to activate functional groups. The problem is formulated as a mixed-integer linear problem and is solved using the CPLEX solver with the GAMS software, version 24.9.1.

In Step 5 the Pareto-optimal solvents generated in the design step are crosschecked against the solvents used to derive the surrogate model. If at least one of the Pareto-optimal solvents had not been included, the algorithm returns to Step 2; if all the Pareto-optimal solvents were included, the algorithm continues to Step 6, reaching convergence.

3. Case Study - S_NAr Reaction of 2,4-Difluoroacetophenone with Pyrrolidine

Nucleophilic aromatic substitution (S_NAr) reactions are used widely in medicinal chemistry (Brown and Boström, 2016). In addition, where there is the possibility for substitution at more than one site on the aromatic ring, improving the selectivity is important to maximize the reaction productivity and to reduce waste (Wang et al., 2009). Our empirical-CAMD methodology is applied to an S_NAr reaction of 2,4-difluoroacetophenone (A) with pyrrolidine (B) (Fig. 2) where the solvent influences both the rate of the reaction and the selectivity. As shown in Table 1, reactions in solvents with high selectivity values (k_o/k_p), where k_o and k_p are the rate constants for *ortho*- and *para*-substitution respectively, generally result in lower reaction rate constants (k_o). Consequently, both log k_o as a measure of rate and log k_o – log k_p as a measure of selectivity are used as key performance objectives, resulting in a MOO problem.

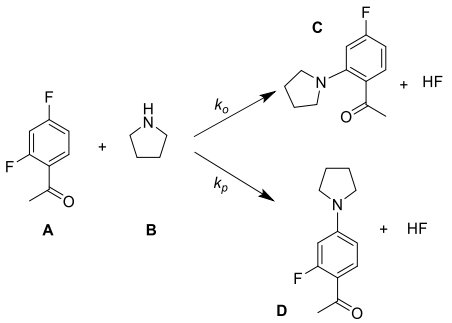

Figure 2: S_NAr reaction that exhibits an effect of solvent on the k_o:k_p selectivity.

In Step 1 the initial solvent set is chosen, as listed in Table 1, with the solvent design objective set to maximize both the rate (f_1=log k_o) and selectivity (f_2=log k_o – log k_p) for *ortho*-substitution. In Step 2 the concentrations of the reaction species in these solvents are monitored using *in situ* ^{1}H NMR experiments at 323 K and ambient pressure. The data is fitted to a kinetic model (one per solvent) to obtain the experimental rate constants k_o and k_p. In Step 3 the solvatochromic equation is regressed with the experimental rate constants k_o and k_p to obtain the surrogate model, the reaction specific coefficients.

Table 1: Experimental *Ortho* to *Para* selectivity of the initial solvent set.

Solvent number	Solvent	k_o x 10^3 (M^{-1} s^{-1})*	Selectivity (k_o/k_p)*	Dielectric constant†
1	1,4-Dioxane	0.44	9.68	2.2
2	Triethylamine	0.20	7.87	2.4
3	Chloroform	0.24	10.80	4.7
4	Chlorobenzene	0.58	14.53	5.7
5	1-butanol	0.13	1.05	17.3
6	Acetonitrile	0.90	1.50	35.7
7	Dimethylformamide	1.12	0.53	37.2
8	Dimethylacetamide	1.14	0.41	37.7
9	Dimethyl sulfoxide	1.97	0.32	46.8

*Experimental rate constants obtained from ^{1}H NMR *in situ* experiments at 323 K and ambient pressure.
†Experimental dielectric constant at 298K (Winget et al., 1999).

A range of algorithms have been proposed to solve MOO problems, specifically the sandwiching algorithm has been applied to mixed-integer problems that have a discontinuous Pareto front (Burger et al., 2015). Here we explore the benefits of MOO without attempting to control computational cost. Instead, we solve problem (2)-(7) repeatedly using integer cuts to generate 50 solutions for each value of ϵ and deduce the Pareto front from this. Constraints are placed on the boiling and melting points to insure that the solvents generated are liquid within the range 298 K to 323 K. Additional environmental and safety constraints are also imposed using GC methods, specifically on

toxicity (LD50) (Hukkerikar, et al., 2012a), the octanol-water partition coefficient at infinite dilution at 298 K (log K_{ow}) and the flash point (Hukkerikar, et al., 2012b).

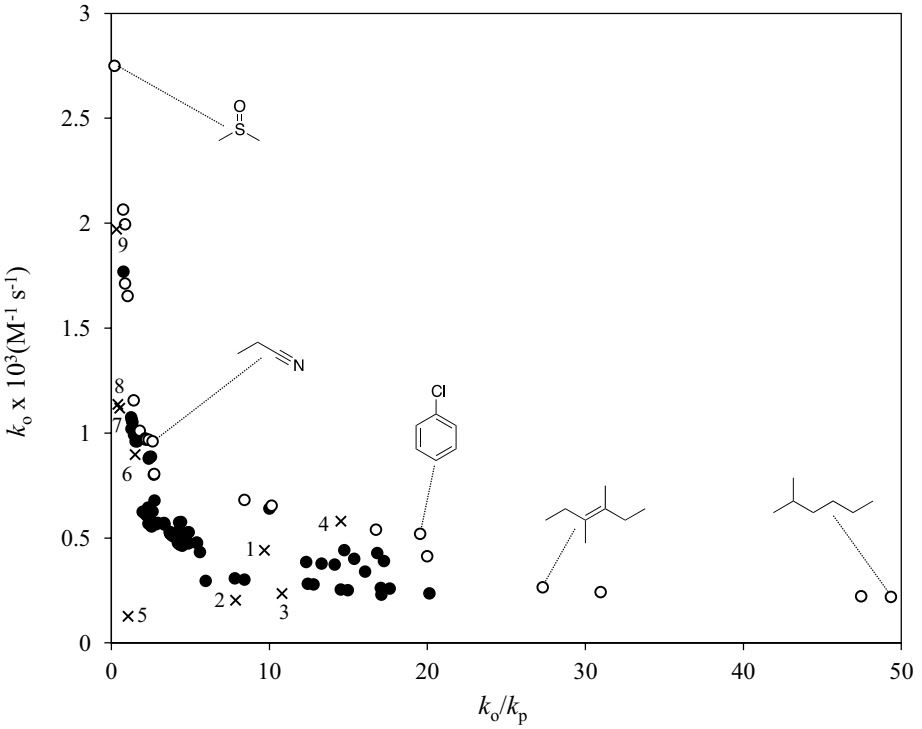

Figure 3: Experimental and CAMD solutions to the MOO problem. Numbered crosses correspond to the experimental values for the solvents in the initial set, closed circles correspond to dominated solutions to the optimization problem, and open circles indicate the Pareto-optimal solutions with example molecules highlighted.

In Fig. 3 solutions to the problem for maximising both rate and selectivity are presented, compared with the experimental values for the initial solvent set and the trade-off between rate and selectivity is evaluated. Propionitrile is generated as a Pareto-optimal solution with a k_o value 65 % lower than for dimethyl sulfoxide, the Pareto-optimal solution with the maximum rate, however an order of magnitude improvement in the selectivity is obtained. Considering the high selectivity region in Fig. 3, the selectivity increases by 81 % from 3,4-dimethyl-3-hexene to 2-methylhexane, the Pareto-optimal solution with maximum selectivity, without a significant negative impact of 17 % on the rate. MOO allows for the trade-off between rate and selectivity to be assessed, enabling a more informed solvent choice for the user, which will ultimately be dictated by considering ease of product separation compared with reactor running costs and logistics.

At this point the solvent design methodology has been implemented for one iteration. However, some of the Pareto-optimal solutions were not included in the initial solvent set and the algorithm will therefore return to Step 2, where in future work the reaction kinetics in these solvents, that are commercially available, will be measured to update the surrogate model. The methodology will then be implemented iteratively until convergence, when all Pareto-optimal solutions are included in the initial solvent set.

4. Conclusions

We have proposed an empirical-CAMD methodology that utilises multi-objective optimization and applied this to identify optimal solvents for an S_NAr reaction. A trade-off between the rate and selectivity is evaluated and a set of Pareto-optimal solutions is identified. Future work involves running the algorithm to convergence in order to obtain the most accurate set of optimal solutions by iteratively improving the surrogate model.

Abstract

Organic Rankine Cycles (ORC) transform low- and medium-temperature heat into mechanical power. One promising application of ORCs is the recovery of exhaust gas heat from heavy-duty vehicles. To utilize the full potential of the transient exhaust gas heat, both, the ORC process and working fluid have to be designed. To integrate the working fluid design into the process design, we developed the so-called 1-stage CoMT-CAMD approach, which allows us to identify the optimal combination of ORC process and working fluid. However, 1-stage CoMT-CAMD is limited to steady-state heat input preventing the consideration of the transient exhaust gas behavior. In this work, we propose an iterative algorithm combining 1-stage CoMT-CAMD with time-series aggregation to tackle the challenge of transient exhaust gas behavior, so-called time-resolved 1-stage CoMT-CAMD. By using time-series aggregation, the transient exhaust gas behavior can be represented with sufficient accuracy by a few time steps serving as quasi-steady-state input for 1-stage CoMT-CAMD. The presented algorithm efficiently identifies the optimal working fluid and ORC process while capturing the transient exhaust gas behavior.

Keywords: 1-stage CoMT-CAMD, PC-SAFT, transient input, time-series aggregation.

1. Introduction

Nearly 30 % of the CO_2 emission in 2014 result from the transportation sector (Muncrief and Sharpe, 2015). The CO_2 emission can be reduced by reducing the fuel consumption of heavy-duty vehicles (HDV). This reduction can be obtained by transforming the exhaust gas waste heat of the engine into mechanical power using Organic Rankine Cycles (ORC). ORCs on HDVs reduce the total cost of ownership and improve the compliance with future CO_2-regulations (Eichler et al., 2015). However, ORCs have high investment and low efficiencies. To ensure an efficient process, tailor-made ORCs are required.

For tailoring an ORC, the working fluid selection has to be integrated into the process design leading to a mixed-integer nonlinear program (MINLP) (Zhang et al., 2016). Solution approaches to this MINLP have been recently reviewed by Linke et al. (2015). In our previous work, we proposed the Continuous-Molecular Targeting−Computer-Aided Molecular Design (CoMT-CAMD) approach for the integrated design of molecules and processes (Bardow et al., 2010; Lampe et al., 2015). Herein, the PC-SAFT equation of state (Gross and Sadowski, 2001) is used as thermodynamic model. In the CoMT stage, a hypothetical optimal fluid is identified by relaxation of the discrete pure component parameters of PC-SAFT. In a second stage, CAMD and a Taylor approximation around

the hypothetical optimum are used to identify real fluids. Recently, the CAMD problem has been directly linked to the CoMT problem in the so-called 1-stage CoMT-CAMD approach enabling us to solve the resulting MINLP in one stage (Schilling et al., 2017a). So far, CoMT-CAMD is limited to a steady-state input. However, for ORCs on HDVs, the exhaust gas heat source shows a transient behavior. Since the optimal working fluid depends on the temperature and mass flow of the heat source, a single design point is not sufficient to capture the transient behavior. However, the consideration of the full transient behavior within the integrated design generally results in large optimization problems, which requires dynamic models and computationally efficient solution methods.

In this work, we therefore propose an iterative algorithm to capture the transient heat input within the 1-stage CoMT-CAMD approach. For this purpose, time-series aggregation techniques are used to transform the transient exhaust gas behavior into quasi-steady-state parameters serving as heat input in 1-stage CoMT-CAMD. An iterative algorithm determines the aggregated time steps required to accurately represent the full time series. The presented algorithm results in an optimal combination of ORC process and working fluid while capturing the full range of the transient exhaust gas behavior.

2. Transient heat source for ORCs on heavy-duty vehicles

For the design of ORCs on heavy-duty vehicles, the full transient driving cycle has to be considered. In this work, the driving cycle is described by the VECTO Long Haul Cycle (LHC) (Dünnebeil et al., 2015). The LHC time series consists of 10656 time steps t for the vehicle velocity and the road slope during $5328\ s$ (Figure 1, left). The LHC time series of the vehicle velocity and road slope are inputs to models for the vehicle and engine of a $40\ t$ HDV with a 6-cylinder $11\ l$ on-road diesel engine with $340\ kW$ at rated power (Bergmann et al., 2017). Thereby, we obtain the time series of the exhaust gas temperature T_t and mass flow rate $\dot{m}_t$ used as input of the ORC (Figure 1, right).

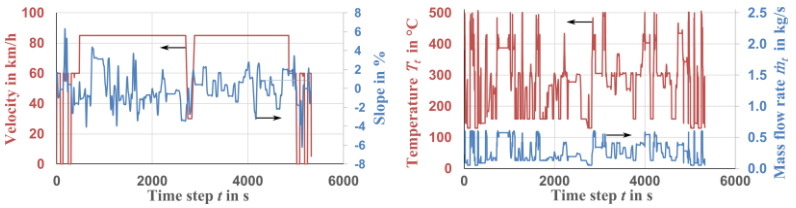

Figure 1: Time series of (left): the velocity and road slope of the VECTO LHC (Dünnebeil et al., 2015) and (right): the temperature and mass flow rate of the exhaust gas (Bergmann et al., 2017).

3. Time-resolved 1-stage CoMT-CAMD

1-stage CoMT-CAMD can be used for the integrated design of ORC process and working fluid considering steady-state heat input (Schilling et al., 2017a). In general, a transient heat source would require a dynamic model leading to optimization problems of prohibitive complexity. Thus, we employ a discrete-time approximation assuming quasi-steady-state behavior. Quasi-steady-state approximation of dynamic ORC models have been successfully used, e.g., by Preißinger et al. (2017). Within the present design context, a quasi-steady-state model allows to capture the full range of the transient exhaust gas, which can be regarded as conservative compared to a dynamic model, which might smoothen peaks of the transient behavior. The resulting time-resolved 1-stage CoMT-CAMD algorithm combines 1-stage CoMT-CAMD with time-series aggregation (Bahl et al., 2017) to efficiently solve the integrated design problem based on quasi-steady-state input.

3.1. Time-resolved 1-stage CoMT-CAMD algorithm

The time-resolved 1-stage CoMT-CAMD algorithm is shown in Figure 2. The input of the process is defined by a time series T. In step 1, we use the k-means algorithm (MacQueen, 1967) to aggregate $t \in T$ time steps to N_k aggregated time steps $k \in K$, where N_k is initialized by the user for the first iteration. Here, we start with a single time step. Each aggregated time step k represents a subset T_k of time steps by one characteristic mass flow rate $\dot{m}_k$ and temperature T_k of the exhaust gas as well as a duration Δt_k. The aggregated time steps serve as heat input to the ORC process. In step 2, we use the aggregated time steps in 1-stage CoMT-CAMD to identify a ranking of working fluids (see section 3.2). In step 3, an individual process optimization of the full time series T is performed for each identified fluid, to validate the quality of the time-series aggregation. The mean relative deviation $\overline{\Delta r}$ is calculated between the objective function with N_k aggregated time steps and the full time series T (step 4). We iteratively increase the number of aggregated time steps N_k, until $\overline{\Delta r}$ satisfies a maximum allowed error ε. The final ranking of working fluids is the result of the time-resolved 1-stage CoMT-CAMD algorithm.

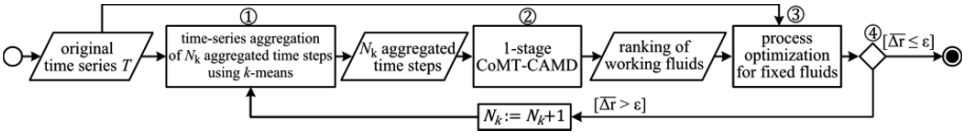

Figure 2: Workflow of the time-resolved 1-stage CoMT-CAMD algorithm.

3.2. Problem definition of time-resolved 1-stage CoMT-CAMD

In time-resolved 1-stage CoMT-CAMD, the N_k aggregated time steps are combined in one overall objective function $\tilde{f}$. The resulting MINLP problem is defined as follows:

$$
\begin{aligned}
\min_{x_k, y^S} \quad & \tilde{f} = \sum_{k=1}^{N_k} \Delta t_k \cdot f_k(x_k, \Theta_k) \\
s.t. \quad & g_{1,k}(x_k, \Theta_k) = 0 && \forall\, k \in K && \text{process model} \\
& g_{2,k}(x_k, \Theta_k) \leq 0 && \forall\, k \in K && \text{process model} \\
& \Theta_k = h(x_k, z, y^S) && \forall\, k \in K && \text{PC-SAFT} \\
& z = GC \cdot y^S && && \text{CAMD and GC method} \\
& F_1 \cdot y^S = 0 && && \text{CAMD and GC method} \\
& F_2 \cdot y^S \leq 0 && && \text{CAMD and GC method} \\
& x_{lb} \leq x_k \leq x_{ub} \in \mathbb{R}^n && \forall\, k \in K \\
& y^S_{lb} \leq y^S \leq y^S_{ub} \in \mathbb{Z}^I.
\end{aligned}
\tag{1}
$$

In this problem, a process-based objective function $\tilde{f}$ (e.g., net power output) is calculated as the sum of N_k objective functions f_k multiplied by the relative duration Δt_k of the aggregated time step k. The objective functions f_k compute the objective for an aggregated time step k and depend on degrees of freedom of the process x_k (e.g., pressure levels) and properties of the working fluid Θ_k (e.g., enthalpies). For each aggregated time step k, equality constraints $g_{1,k}$ (e.g., energy balances) and inequality constraints $g_{2,k}$ (e.g., pressure limits) of the process are considered. The PC-SAFT equation of state (Gross and Sadowski, 2001) is used as consistent thermodynamic model to calculate equilibrium properties Θ_k. In PC-SAFT, a fluid is described by its pure component parameters z. A CAMD formulation enables the design of novel working fluids. Here, a working fluid is represented by the vector y^S, which contains the number of functional groups constituting the molecular structure. In this work, we employ the 20 functional groups presented in Schilling et al. (2017a). Additionally, functional groups for 1-alcohols and

1-amines as well as 16 individual groups for small molecules are considered which cannot be combined with other functional groups (e.g., methane). The molecular structure y^S is linked to the pure component parameters of PC-SAFT using the homosegmented group contribution (GC) method of PC-SAFT (Sauer et al., 2014). Additional constraints F_1 and F_2 ensure the structural feasibility of the molecule taken from Struebing et al. (2011).

The MINLP results in the optimal working fluid y^S and the corresponding optimal process x_k of all aggregated time steps. A ranking of working fluid candidates is calculated using integer-cuts. The MINLP is solved using the local MINLP solver DICOPT (Grossmann et al., 2002); for details see Schilling et al. (2017a).

4. Case study

The time-resolved 1-stage CoMT-CAMD algorithm is applied to the integrated design of a subcritical ORC for waste heat recovery from heavy-duty vehicles (Figure 3). The heat source is characterized by the exhaust gas temperature T_k and mass flow rate $\dot{m}_k$ of aggregated time step k considering the LHC driving cycle as input.

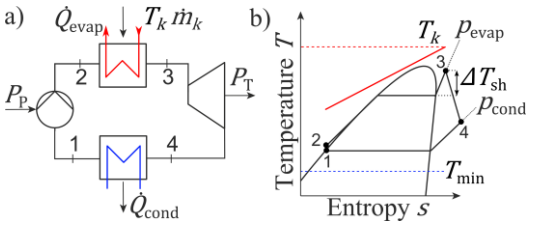

Figure 3: ORC process in (a) flowsheet and (b) qualitative temperature-entropy diagram.

4.1. General specifications of the process

The mean net power output $\bar{P}_{net}$ is considered as objective function $\tilde{f}$ in problem (1):

$$\tilde{f} = \bar{P}_{net} = \sum_{k=1}^{N_k} \Delta t_k \cdot P_{net,k}(x_k, \Theta_k) = \sum_{k=1}^{N_k} \Delta t_k \cdot \left[P_{T,k}(x_k, \Theta_k) - P_{P,k}(x_k, \Theta_k)\right] \quad (2)$$

The degrees of freedom of the process x_k are the mass flowrate of the working fluid $\dot{m}_{wf,k}$, the reduced pressure levels in the condenser p_{cond}^{red} and evaporator $p_{evap,k}^{red}$ and the degree of superheating $\Delta T_{sh,k}$. $\dot{m}_{wf,k}$, $p_{evap,k}^{red}$ and $\Delta T_{sh,k}$ are optimized for aggregated time step k, while p_{cond}^{red} is defined as equal for all aggregated time steps since it is not affected by the transient heat source. In practice, the degree of superheating ΔT_{sh} is not a degree of freedom, but results from the heat transfer in the evaporator, which is not considered in this study. The inequality constraints $g_{2,k}$ of problem (1) specify the minimal approach temperature in the evaporator ($\Delta T_{min} = 20\ K$), the minimal temperature in the condenser ($T_{min} = 80\ °C$), the minimal and maximal pressure levels ($1\ bar \leq p \leq 35\ bar$). We limit the maximal number of functional groups of the molecular structure to $n_{max} = 25$ leading to 126 binary degrees of freedom describing the molecular structure.

4.2. Results and Discussion

In this case study, a ranking of 25 working fluids is calculated for each iteration with N_k aggregated time steps using 1-stage CoMT-CAMD. A maximum allowed error of $\varepsilon = 1\ \%$ is assumed and the proposed algorithm is initialized with $N_k = 1$ aggregated time steps. For a better illustration of the time-resolved 1-stage CoMT-CAMD algorithm, the algorithm is not stopped when $\overline{\Delta r} < \varepsilon$, but continued to $N_k = 8$ and the standard deviation σ of the relative deviation Δr over all working fluids of each ranking is calculated.

For $N_k = 1$ aggregated time step, the mean relative deviation is $\overline{\Delta r} = 37.7\ \%$ with a standard deviation of $\sigma = 5\ ppts$ (percentage points) (Figure 4). The mean relative deviation $\overline{\Delta r}$ decreases quickly and for $N_k = 3$ the time-resolved 1-stage CoMT-CAMD algorithm satisfies the required accuracy of $\varepsilon = 1\ \%$ ($\overline{\Delta r} = 0.98\ \%$ with $\sigma = 0.8\ ppts$). Thus, for the integrated design of process and working fluid, the 10656 time steps of the LHC driving cycle are sufficiently reflected by 3 aggregated time steps. However, the monotony of the algorithm cannot be guaranteed ($N_k = 4$; $\overline{\Delta r} = 2.6\ \%$; $\sigma = 1.4\ ppts$), but 5 to 8 aggregated time steps show again a mean relative deviation of $\overline{\Delta r} < \varepsilon = 1\ \%$ with $\sigma < 0.6\ ppts$. Thus, the mean relative deviation $\overline{\Delta r}$ and standard deviation σ does not steadily decrease with increasing number of aggregated time steps and a systematic validation using the full time series is important (Bahl et al., 2017). The presented time-resolved 1-stage CoMT-CAMD algorithm ensures such a systematic validation.

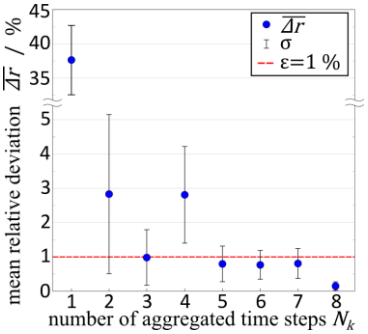

Figure 4: Mean relative deviation $\overline{\Delta r}$ of the objective function value of the 25 working fluids identified with 1-stage CoMT-CAMD using N_k aggregated time steps and the full time series as well as the corresponding standard deviation σ over all working fluids.

Table 1: The top 5 identified working fluids as well as the benchmark ethanol and the corresponding objective function value considering the full time series of the LHC driving cycle.

Rank	Name	P_{net} / kW
1	Butanone	8.15
2	Benzene	8.15
3	n-Butylamine	7.94
4	Butyraldehyde	7.92
5	Acetone	7.91
-	Ethanol	7.45

Due to the local nature of the optimization solver and different inputs, the identified rankings are not necessarily identical between different numbers of aggregated time steps. Only 5 of the 25 working fluids identified with 1 aggregated time step are also identified in the rankings of 2 aggregated time steps, whereas more than 20 of the 25 identified fluids are identical for 2-8 aggregated time steps. The optimal identified working fluid is butanone with $P_{\text{net}} = 8.15\ kW$ (Table 1). Compared to the benchmark ethanol with $P_{\text{net}} = 7.5\ kW$, which is commonly used as working fluid for HDVs, butanone shows a 9.5 % higher objective. Thus, the time-resolved 1-stage CoMT-CAMD algorithm efficiently identifies promising working fluids for ORCs on HDVs while capturing the full transient exhaust gas behavior. In future work, the ranking has to be assessed regarding further criteria, which are not captured within the thermodynamic quasi-steady-state model of the presented case study (e.g., flammability, toxicity, economics or dynamics). Furthermore, the impact of model uncertainties and the local nature of the MINLP solver has to be investigated for the time-resolved 1-stage CoMT-CAMD algorithm (for details on the impact on 1-stage CoMT-CAMD see Schilling et al. (2017a; 2017b)).

5. Conclusions

In this work, we present the time-resolved 1-stage CoMT-CAMD algorithm for the integrated design of process and working fluid for ORCs on heavy-duty vehicles considering the full transient exhaust gas behavior as input of the ORC. For this purpose, we combine

1-stage CoMT-CAMD with time-series aggregation techniques to capture the transient time series of the exhaust gas by aggregated time steps. An accuracy measure is introduced to identify the number of aggregated time steps that are required to reflect the full time series accurately. The resulting algorithm is applied to the design of an ORC on a HDV considering the LHC as driving cycle with 10656 time steps. The results show that the proposed algorithm accurately identifies promising working fluids using 3 aggregated time steps. We identify butanone as the most promising working fluid, which increases the performance by 9.5 % compared to the commonly used working fluid ethanol.

Study on DFT Based Computation for Quantum Chemical Descriptors of Neodymium Carboxylate Molecules

Shuguang Xiang *, Jiye Wang

Institute of Process Systems Engineering，Qingdao University of Science & Technology，Qingdao 266042，China
xsg@qust.edu.cn

Abstract

As a relatively new research domain of Process Systems Engineering (PSE), Computer-aided Molecular Design (CAMD) explores the micro-scale systems, such as compound molecules, to discover the quantitative structure property relationship (QSPR) or the quantitative structure activity relationship (QSAR) of a molecule. One of the approaches to create QSPR or QSAR is to compute quantum chemical descriptors by some commercial quantum chemistry software. In this study, ADF2014, a piece of quantum chemistry computational software based on density functional theory (DFT), was chosen to compute the titled compound molecules and obtained well ballanced accuracy and efficiency of computation. Detailed computation methods were developed, including how to build an initial molecular geometry, how to set the computing parameters, how to simplify the initial geometry, how to deal with the the conformation search, etc. Four descriptors including the HOMO energy, the LUMO energy, the dipole moment and the polarizability of ligand were selected according to the variation percentage and the correlation matrix. The four descriptors of 17 neodymium carboxylates were computed. Results indicate that the repeatability of the computation methods is well and the variation among computed values of a quantum chemical descriptor of different neodymium carboxylates is outstanding, which meets the requirement for QSAR modeling.

Keywords: computation method, quantum chemical descriptor, neodymium carboxylate

1. Introduction

Process Systems Engineering (PSE) is nowadays developing from the traditional meso scale into the macro and the micro scale. In the direction of micro scale, Product Engineering or Computer-aided Molecular Design (CAMD) focuses on studying the quantitative structure property relationship (QSPR) of a molecule (Alexandre et al., 2014). For a catalyst, the quantitative structure activity relationship (QSAR) between its molecular structure and catalytic activity can be studied by computing its quantum chemical descriptors, which is an approach well developed in the pharmaceutical field (Boone et al., 2016; Gubskaya, 2010) for molecular design of medicines or pesticides. However, it is not an easy thing to compute quantum chemical descriptors of a compound molecule, especially for such compound as neodymium carboxylate with a neodymium atom in its molecule, due to the many-body effect, the relativistic effect and the multi-configuration effect (Martelli et al., 2014; Xiang et al., 2016).

The neodymium carboxylate is usually used as a key component of catalyst for coordination polymerization of dienes in the rubber manufacturing industry to produce synthetic rubbers. Impoving its catalytic activity has been an everlasting subject. While the traditional research method is uasually by experiments in the laboratry, the QSAR method that combines quantum chemical computation and experiments has not been reported for the titled compound. But we believe it is a hopeful method to greatly increase the catalytic activity if a proper approach to compute the quantum chemical descriptors is to be created, which attracted us to carry out this study.

The density functional theory (DFT) approach is known as the most popular one in quantum chemical computation. It allows for correlation effects to be included in a computation that takes roughly the same time as a Hartree-Fock computation that does not include correlation effects (Levine, 2013; Yu et al., 2016). The ADF module in ADF2014 used in this study is based on DFT (Baerends et al., 2014). Evenmore, as a semiempirical approach, the MOPAC imbedded in ADF has advantages in geometry preoptimization of neodymium complexes (Stewart, 2012). With all above, the computation efficiency and accuracy are anticipated to be well ballanced.

2. Computations

2.1. Hardware and Software

Three DIY desktop PCs each with a 1T hard disk, a 16G RAM and an Intel Core i7 CPU (3.4 GHz); The ADF module of ADF2014, version ADF2014.07 201505162227 r46825.

2.2. Computation Methods

2.2.1. Development of computation methods

(1) Determination of initial geometry

According to Wang and Xiang (2015), and Zhang et al. (1990), and for computation efficiency, the initial coordination structure for neodymium carboxylate complexes was simplified as a six-coordinated monomeric one and pre-optimized with UFF (Rappe et al., 1992) and MOPAC into a trigonal antiprism or an octahedron, shown in Fig. 1.

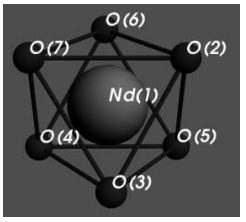

Figure 1. Simplified initial coordination structure of carboxylate (Other atoms are omitted)

(2) About conformation search and the most stable conformer

Geometry optimization usually converges to a local minimum other than a global one. In order to arrive at the global minimum, one should do conformation search and geometry optimization of each conformer, which is a trivial and time-consuming job (Xiang et al., 2016). For simplification, these were omitted in this work, which made the computation efficiency increased by at least 10 times. It is believed that the geometry optimization of neodymium carboxylate complexes initially optimized by MOPAC2012

may reach the global minimum or a nearby local minimum (Dutra et al., 2013). Moreover, with the same meothods, the optimized geometries, though not the global minimums, ought to be comparable, which is enough for computation of descriptors to be used in QSAR modeling.

(3) Computation of quantum chemical descriptors

For QSAR modeling, eight quantum chemical descriptors related to catalytic activity were computated, including the frontier orbital energies, ε_{HOMO} and ε_{LUMO}, the Mullikin charge of Nd, q, the dipole moment, μ, the oil-water partition coefficient, logP, the ligand molecular polarizability, α, the electrophilicity index, ω, and the frontier orbital energy gap, ε_{HOMO}-ε_{LUMO}.

2.2.2. Detailed computation methods

(1) Method to build the initial geometry

In the INPUT module of ADF2014, build an initial geometry as shown in Fig. 1, and optimize with the MOPAC module: Method=PM6， Total charge=0.0， Spin polarization=3，Unrestricted=No，Sparkles=yes.

(2) Precise optimization of geometry

Precise optimization was performed in the ADF module: Total charge =0.0，Spin polarization = 3，Unrestricted = yes，XC potential in SCF = GGA: BLYP，Relativity (ZORA) = Scalar，Basis set = TZP，Frozen core = Large，Numerical Quality = Normal/STO fit; Coordinates used for optimization = Cartesian, Optimization method = AUTO, Number of geometry iterations = 200, Maximum number of SCF cycles = 300, SCF convergence method = A-DIIS, Molecular symmetry = NOSYM.

(3) Stability verification of optimized geometry

Parameter settings for frequency calculation included those in the precise optimization of geometry and, Analytical frequencies = yes, Max number of CPKS iterations = 50.

(4) Computation of quantum chemical descriptors

The HOMO energy, the LUMO energy, the Mulliken charge, the dipole moment and the polarizability of ligand can be obtained directly from the out file of geometry optimization of complex or ligand. The electrophilicity index, ω, was calculated as Eq. (1). The logP was calculated using the solvation model, COSMO-RS, with concentration in mole fraction, solvents of n-hexane and water, and temperature of 298.15 K.

$$\omega = \frac{(\varepsilon_{LUMO}+\varepsilon_{HOMO})^2}{4(\varepsilon_{LUMO}-\varepsilon_{HOMO})} \quad (1)$$

3. Results and discussions

3.1. Verification of computation methods

First, repeated the computation of neodymium n-pentanoate for six times to obtain the eight descriptors related to the catalitic activity. Results are shown in Table 1, in which CV is the coefficient of variation and defined as the ratio of the standard deviation, s, to the absolute average value of a descriptor, |av|, in percentage, as Eq. (2). Results in Table 1 show that the CV values are small, indicating good repetitiveness.

$$CV = s/|av| \times 100 \quad (2)$$

Second, the descriptors and their CV values for five different neodymium carboxylate complexes were computed and listed in Table 2. The descriptors with CV values more than ten times larger as CV_0 include α, logP, μ, ε_{HOMO} and ε_{LUMO}. That is to say, these descriptors differ significantly among different neodymium carboxylate complexes and are thus suitable for building QSAR. Therefore, the computation methods are proved to be suitable for QSAR study.

CV/CV_0	11.5	12.6	4.4	12.8	92.6	111.9	4.0	1.9

3.2. Selection of proper quantum chemical descriptors

As stated in 3.1, some descriptors are suitable for QSAR modelling. But, not all are necessary because they may be correlated to one another and correlation with the molecular structure may not be significant. Therefore, the linear correlation was studied with the correlation matrix and the results show that four quantum chemical descriptors, i.e. ε_{HOMO}, ε_{LUMO}, μ and α, can be chosen as the representative.

3.3. Computation results of descriptors

Seventeen neodymium carboxylate complexes with different ligands from the acetic acid to the n-tetradecanoic acid were selected to compute their quantum chemical descriptors. One sample of the optimized molecular geometries and the computation results of all the seventeen are shown in Fig. 2 and Table 3.

Results in Table 3 show that CV/CV_0 are all larger than 10.0, which means descriptors ε_{HOMO}, ε_{LUMO}, μ and α all have significant variations among the seventeen complexes

compared with the accidental computation error and are thus suitable for QSAR modeling.

4. Conclusions

(1) The ADF module of ADF2014 was chosen to calculate descriptors of neodymium carboxylate molecules, which well ballanced the computation accuracy and efficiency.

(2) Detailed computation methods were developed. Results proved that the developed methods have good repeatability and the selected descriptors have significant enough variation among different neodymium carboxylate complexes, which is required by QSAR modeling.

(3) With the help of the variation coefficient and the correlation matrix, four suitable quantum chemical descriptors were selected, including the energy of the highest occupied molecular orbital, the energy of the lowest unoccupied molecular orbital, the dipole moment and the polarizability of ligand.

(4) The values of the four selected descriptors of seventeen neodymium carboxylate complexes were computed and obtained. The results are suitable for QSAR modeling and further for CAMD.

Experimental validation of scheduled PID control for directed self-assembly of colloidal particles in microfluidic devices

Yu Gao, Richard Lakerveld*

Department of Chemical and Biological Engineering, The Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong S.A.R
kelakerveld@ust.hk

Abstract

Directed self-assembly provides a promising route to assemble small-scale structures for engineering applications. Typically, a local particle density has to be controlled to assemble specific structural features defect-free. The strong non-linearity of self-assembly systems complicates such control. Therefore, in this work, a gain-scheduling approach for automated control of directed self-assembly is developed and experimentally tested. An empirical input-output model is developed from experimental data, which is used to design a scheduling approach for a feedback controller. The controller is tested in a microfluidic cell with patterned electrodes to direct the self-assembly process with electric fields. The experimental results demonstrate a significantly improved dynamic performance over a broad range of operating parameters when gain-scheduling is considered compared to a conventional feedback controller.

Keywords: directed self-assembly, small-scale systems engineering, feedback control, gain scheduling

1. Introduction

Self-assembly is the spontaneous association of small particles into structures, which has great potential for the precise manufacture of advanced materials. Electric fields can be used to direct the self-assembly into a desired direction flexibly due to their tunable strength and direction. Once in-situ observation of the system is available, automated control can be implemented to dynamically shape the electric field to direct the self-assembly process, which is an example of small-scale process control (Ulissi, 2013; Paulson, 2015). Feedback control has been demonstrated to be effective to self-assemble colloidal crystals with low defects (Juárez and Bevan, 2012; Tang et al., 2016) or to position particles along predefined lines to fabricate non-periodic structures with single-particle resolution (Gao and Lakerveld, 2017). Tight control of the local particle density is important for both crystalline structures (Juárez et al., 2012) and individual particle alignment (Gao and Lakerveld, 2017). Furthermore, local particle density control is an important basis for the implementation of hierarchical multi-resolution approaches to self-assemble more complicated non-periodic structures (Lakerveld et al., 2012; Solis et al., 2010). However, such automated control of a local particle density is challenged by the stochastic and highly nonlinear behavior of directed self-assembly systems when external electric fields are used as manipulated variables. The abundance of engineering systems with non-linear behaviour has led to much progress on control

strategies for nonlinear systems such as Linear Parameter-Varying (LPV) control (Apkarian et al., 1995), which includes gain-scheduling (Shamma and Athans, 1992). However, to the best of our knowledge, gain scheduling methods have not been applied for controlling directed self-assembly systems despite their great potential for this new type of application area.

In this work, a gain-scheduling feedback control strategy for directed self-assembly of colloidal particles is developed and validated experimentally. The control objective is to control a local particle density using patterned electrodes in a microfluidic cell over a broad range of operating conditions despite the strong non-linear behaviour of such system. An input-output model describing the particle density as function of both electric field frequency and voltage between electrodes is developed from experimental data. Subsequently, an optimal value for voltage to maximize the range of attainable particle density is identified, which is used to develop an automated control strategy based on scheduled PID control with field frequency as manipulated variable. Finally, the novel particle-density controller is implemented experimentally in the microfluidic device for performance assessment.

2. Input-output model development and controller design

A microfluidic cell with patterned electrodes was used for model development and controller implementation. The details of this experimental setup are described elsewhere (Gao and Lakerveld, 2017). In summary, a suspension with microspheres is placed between two transparent ITO-coated glass slides that act as electrodes, of which one has patterns of photoresist to create a non-uniform field. The glass slides are separated by a thin rubber spacer. A low-voltage AC electric field is induced between both electrodes using a function generator (33500B, Keysight Technologies) to direct the self-assembly process. An optical microscope (Nikon, Ni-U) equipped with a research-grade digital camera (Nikon Digital Slight Qi2) and automated image analysis (Matlab) are used to observe the positions of all particles in real time with a typical time lag of 1s.

The particle density in a specific area of the cell was measured for various voltages in the range of 2-10V and frequencies in the range of 60-300kHz to develop the empirical input-output model. Five sequential images were used to determine the stable particle density for a given pair of voltage and frequency (Figure 1A) once there were no more significant changes in particle density. Illustrative microscopy images corresponding to the various measured particle densities are shown in Figure 2A. It can be seen that the particle density depends approximately linearly on the voltage for the applied frequencies. More data would be needed to reveal any higher-order dependency. Depending on the frequency, particle density will either go up or down when increasing the voltage. This behaviour is likely caused by a switch in dominating physical phenomena of the self-assembly system, i.e., the system behaviour is driven by positive dielectrophoresis (pDEP) at the lower frequencies and negative dielectrophoresis (nDEP) at higher frequencies (Oh et al., 2009). The measured particle densities clearly demonstrate the non-linear behaviour of the system, which motivates the use for a scheduling approach.

To construct the empirical model, linear interpolation between two logarithmic functions that describe the particle density ρ (μm^{-2}) as function of frequency f (kHz) at the lowest and highest voltage tested is used as follows:

$$\rho(f,v) = a_1 \cdot \log_{10}\left(\frac{f}{f_0}\right) + b_1 + \frac{a_2 \cdot \log_{10}\left(\frac{f}{f_0}\right) + b_2 - a_1 \cdot \log_{10}\left(\frac{f}{f_0}\right) - b_1}{v_{max} - v_{min}}\left(v - v_{min}\right) \quad \forall v = \left[v_{min}, v_{max}\right] \quad (1)$$

where a_1, a_2, b_1, b_2 are fitting parameters obtained from the experimental data and v_{max} and v_{min} are the maximum and minimum voltages tested, respectively. Numerical values for the model parameters are given in Table 1. Figure 1B and 1C show that the measured particle density at the lowest and highest voltage can be well described using a logarithmic function with two fitting parameters each.

Figure 2B and Figure 2C show a plot of the density as function of frequency and voltage as described by Eq.(1) with parameters as given in Table 1. The largest range of attainable particle density can be achieved for a voltage of 10V when varying frequency. Therefore, a constant voltage of 10V is used for the design of a PI controller with frequency as the manipulated variable.

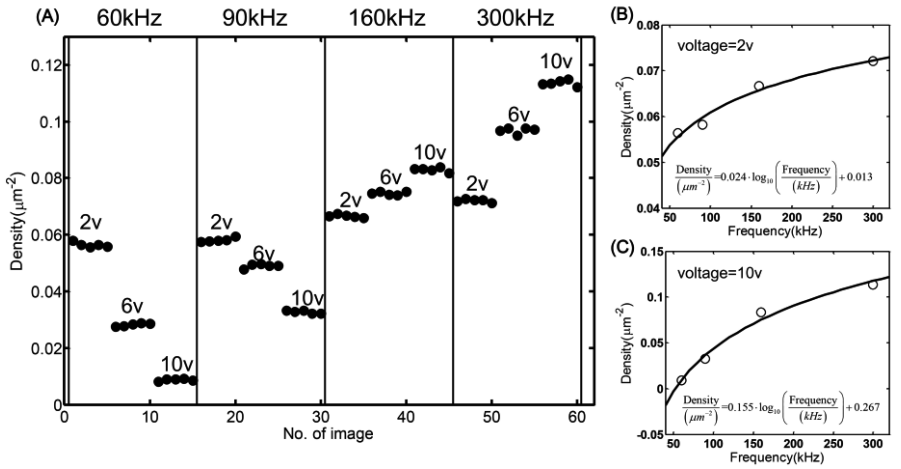

Figure 1. (A) Particle density of self-assembly system as function of frequency and voltage; (B) Empirical model for particle density as function of frequency at a constant voltage of 2V; (C) Empirical model for particle density as function of frequency at a constant voltage of 10V.

Table 1. List of numerical values for the model parameters

a_1/μm^{-2}	b_1/μm^{-2}	a_2/μm^{-2}	b_2/μm^{-2}	v_{min}/V	v_{max}/V	f_0/kHz
0.024	0.013	0.155	0.267	2	10	1

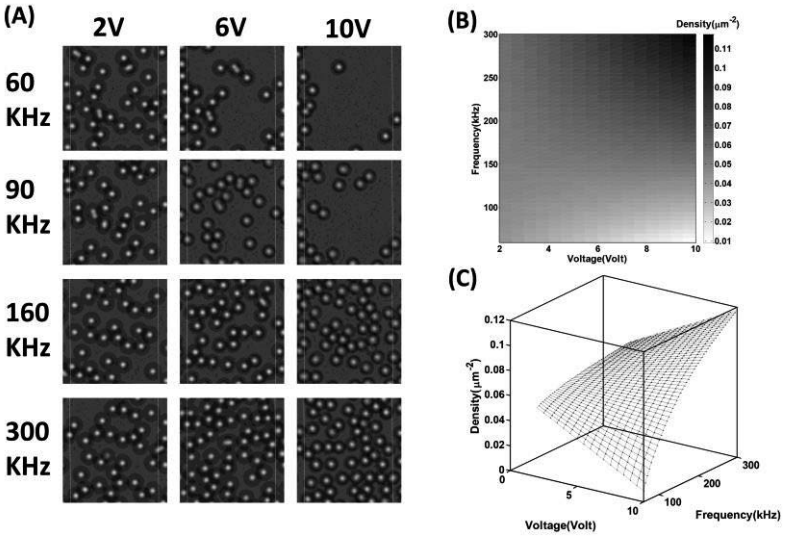

Figure 2. (A)Microscopy images of particle densities at different operating frequencies and voltages. Each image shows a part of the area that is used for measuring the density with image analysis for illustrative purposes; (B) Grayscale mapping of the density with respect to frequency and voltage; (C) Surface plot of the particle density as function of frequency and voltage.

Derivative action is not included in the controller design as it is complicated by measurement noise, which is common for self-assembly systems due to Brownian motion. A gain scheduling procedure is applied to account for the nonlinear dependency of the manipulated variable (frequency) on controlled variable (local particle density). The process gain K can be obtained directly from the empirical model:

$$K=\left.\frac{\partial\rho(f,v)}{\partial f}\right|_{v=10}=\frac{a_2}{\ln 10}\cdot\frac{1}{f}\ , \tag{2}$$

which is used to calculate the tuning parameters for a gain-scheduled PI controller using the Internal Model Control tuning method as follows:

$$K_p=\frac{2\tau+\theta}{2K\lambda},\ \tau_i=\tau+\frac{\theta}{2},\ \lambda\geq 1.7\theta\ , \tag{3}$$

where θ is the system dead time, which is equal to 1s due to the delay from image analysis. τ is the process time constant, which is approximated as 30s by measuring the dynamic response of particle density with respect to a step change in frequency. Finally, λ is obtained as 25s by trial and error.

3. Controller implementation and performance assessment

The designed controller is implemented in MATLAB using the Keysight Command Expert interface between Matlab and the function generator within the experimental setup. Image analysis is used to measure the local particle density with a delay of approximately 1s. The dynamic development of the local particle density with the proposed gain-scheduled controller in closed-loop mode for a set-point tracking experiment is illustrated in Figure 3A. The solid step-wise line represents the set point and the solid and dashed continuous lines represent the measured particle density with and without gain-scheduling, respectively. It can be seen that the density is well controlled around each set point despite the large range over which the set points are varied. Noise is present in the measured density due to the stochastic nature of Brownian motion. Furthermore, it can be seen that the gain-scheduled controller reaches the set point faster compared to a conventional PI controller with essentially no overshoot for both cases. The gain-scheduled controller particularly outperforms the conventional controller for higher set points, which is due to the diverging proportional gain compared to the base case as shown in Figure 3B.

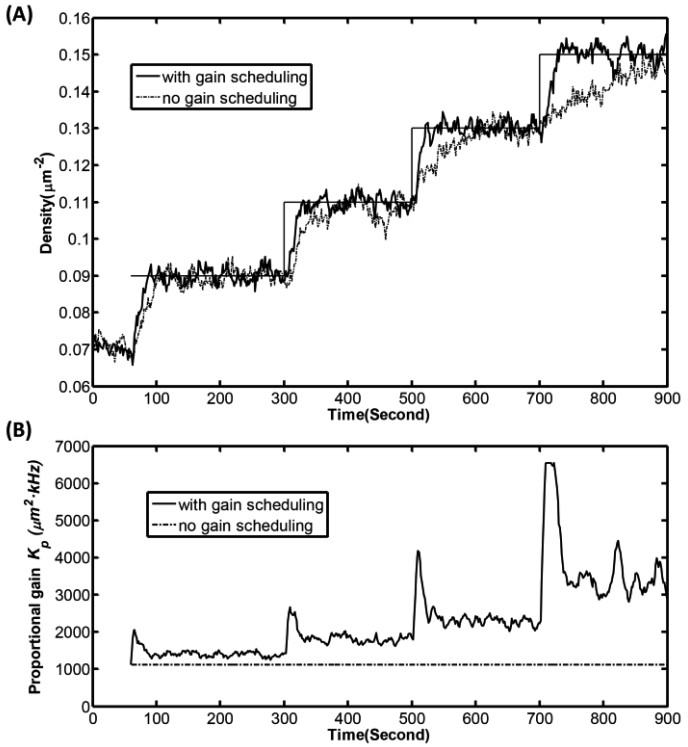

Figure 3. (A) Density and (B) Proportional gain as function of time during a set-point tracking experiment for cases with and without gain scheduling.

4. Conclusions and outlook

A gain-scheduled feedback controller for directed self-assembly has been developed and experimentally tested in this work. An empirical model is used to estimate the process gain online for different operating conditions such that a local particle density can be controlled effectively over a broad range of set points with electric field frequency as the manipulated variable, despite the strong nonlinear behaviour of such system. A conventional controller without gain-scheduling shows a more sloppy behaviour when the set point moves away from the base-case conditions. Future work may involve the extension of the feedback controller for particle density with controllers for particle alignment such that complicated non-periodic structures can be self-assembled, possibly in the framework of a multi-resolution approach (Solis et al. 2010). A more robust model-based control system such as MPC is of interest for future work, which may need a dynamic model rather than the current model. Finally, specific applications such as self-assembly of biological cells are of interest to be investigated.

Abstract

Mathematical optimization can readily support the design of nanostructured materials in areas that are typically explored via design of experiments. The combinatorial nature of possible configurations of nanomaterials leads to a high-dimensional space, which can be efficiently explored by algorithms traditionally developed in process systems engineering. In this work, we demonstrate a mathematical optimization based framework for the design of doped perovskite oxygen carriers. Specifically, we developed an approach for incorporating evaluations from density functional theory into simplified structure-function relationships that can be embedded directly into mathematical models. The material design question was formulated as a mathematical optimization model and solved to identify patterns of dopant that are expected to yield a highly reducible material. The results from the dopant placement optimization model can inform the theoretical bounds of material performance as well as identify structures that can serve as targets for experimental synthesis.

Keywords: mixed-integer linear programming, nanotechnology, oxygen carriers

1. Introduction

Ongoing developments in the synthesis of nanostructured materials are enabling the fabrication of increasingly complex materials. This results in combinatorially-complex design spaces, which in turn require the use process systems engineering techniques to efficiently explore and find optimal structures. We have previously demonstrated a materials design framework that uses mathematical optimization to design nanostructured materials bottom-up from the building blocks of matter (Hanselman and Gounaris, 2016). This optimization framework utilizes a generic modeling approach that can be applied to other material systems to identify novel, high-performance materials. In this work, we adapt the aforementioned materials design framework for the design of doped perovskites. Previous work by Lekse et al. (2014) shows that doped perovskites can achieve rapid and reversible oxygen release, making them promising materials for oxygen carriers for chemical looping. In particular, we consider a $BaFeO_3$ perovskite doped with indium that exhibits tunable oxygen release with respect to dopant content. The addition of indium replaces iron in the lattice at specific sites ("B-sites") in the perovskite material and is expected to strengthen bonds to neighboring oxygen atoms, while weakening bonding to oxygen further away in the lattice. This tradeoff of bond

strengths gives rise to the design question of how to best place the available amount of dopant throughout the crystal lattice. Such an optimal doping pattern could then be the aim of a controlled synthesis effort based on growing the material layer-by-layer or via some other nanostructuring technique. In order to quantitatively study the material properties as a function of specific dopant placements, density functional theory (DFT) can be used to predict the reducibility of the doped perovskite lattice. The relevant quantity in this context is the "oxygen excess energy," defined as the energy of the complete lattice minus the energy of the lattice with a particular oxygen removed. Since Motohashi et al. (2010) showed the perovskite oxygen release process was generally not kinetically limited, we assume that the oxygen excess energy serves as a good indicator of the reducibility of the carrier. For our purposes, a carrier containing a large number of oxygen sites that are easily removed will correspond to a highly reducible material. While DFT is useful for predicting the reducibility of oxygen sites in the perovskite material, it is not tractable to employ directly in conjunction with a mathematical optimization process, where the evaluation of material performance will be frequently required. Instead, we seek to develop a simplified structure-function relationship that uses algebraic constraints to predict the oxygen excess energy as a function of dopant placement in the lattice. In this work, we have identified a set of relevant motifs to characterize the impact of dopant on the oxygen excess energy of a nearby oxygen site. This set of motifs was evaluated using DFT, and then a simplified structure-function relationship was identified using standard model identification tools. This simplified structure-function relationship was then embedded in an optimization model to design the dopant placement in a perovskite lattice.

2. Computational Methods

In order to enumerate relevant motifs, we first proposed a motif definition that was expected to explain the variation in oxygen reducibility with respect to nearby dopant placement around a central oxygen atom. Given the computational cost of DFT calculations, it was deemed important to not define a motif that included too many B-sites which would result in the enumeration of a large list of conformations. It was expected that only the closest neighbours contribute significantly to bonding in the lattice; therefore, we chose to define motifs according to the doping pattern of the 10 closest B-sites to an oxygen on the perovskite lattice. Indium-doped $BaFeO_3$ perovskites are experimentally observed to be stable in the cubic phase with between 10 % and 30 % of the B-sites doped, so we limited our enumeration to only include motifs near that range, with between 0 % and 50 % dopant locally around each oxygen site. More specifically, we identified 74 motifs that included all possible ways to place between 0 and 5 indium atoms in the total 10 B-sites of the motif in a rotationally-unique way.

We performed spin-polarized DFT GGA+U calculations using the Perdew-Burke-Enzerhoff functional and the rotationally invariant formulation as implemented in the VASP code (Kresse and Furthmüller, 1996). Solid solutions with different structural motifs were modelled using a 4x4x4 supercell model containing 320 atoms. This size was chosen to make the calculations tractable without compromising the accuracy of the description of the electronic structure. We found that truncating the plane wave basis set at 520 eV kinetic energy cut-off and using a 4x4x4 k-point mesh yielded converged total energies. For one structure, performing the DFT calculations on an Intel-based High Performance Computing (HPC) system with 128 cores typically took 200 cpu hours.

Given the set of possible motifs, we can propose several geometric descriptors of dopant placement to explain the variation between motifs. These descriptors can include counts of dopant at different distances away from the central oxygen, counts of pairs of dopant in various configurations, as well as imbalances in dopant across the central oxygen. Importantly, these values can all be encoded in an algebraic model using propositional logic with binary variables; therefore, it is possible to express the problem as a mixed-integer linear programming mathematical optimization model.

Together, the DFT evaluations and the set of geometric descriptors for dopant placement can be used to propose simplified structure-function relationships for oxygen excess energy. This process is readily supported by standard model identification tools such as ALAMO, which build simple and predictive regression models by maximizing an information criterion (Cozad et al., 2014). In this way, we were able to identify which geometric descriptors had a significant impact on the evaluation of oxygen excess energy.

This simplified structure-function relationship was later embedded in a mathematical optimization model, which was solved using CPLEX 12.7.1, primarily using default settings (IBM Corp., 2017). While effort was put towards tailoring the formulation of the model to improve its numerical performance and be in position to address larger problem instances, the main goal was to demonstrate the potential of expressing the material design problem in a suitable optimization model.

3. Results

The set of rotationally-unique conformations featuring between 0 and 5 indium atoms in the nearest 10 B-sites was enumerated exhaustively, resulting in 74 motifs. Some example motifs are presented in Figure 1.

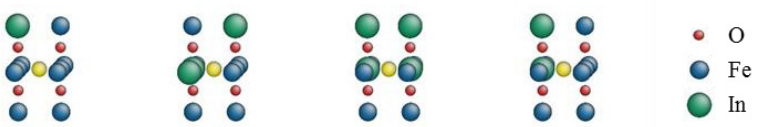

Figure 1: Example motifs and 4x4x4 supercells for DFT evaluation

Given these motifs, geometric descriptors can be defined based on rotationally-unique ways of counting dopant placed around the central oxygen atom. Some example geometric descriptors are presented in Figure 2, including counts of combinations of dopant up to two atoms. The procedure for identifying geometric descriptors can in principle be continued to identify counts of triplets or quadruplets of dopant atoms, but these additional descriptors were expected to have less physical significance on the evaluation of oxygen excess energy, and where hence omitted from consideration.

The DFT data were then paired with the tabulated geometric descriptors and presented to ALAMO for model identification. The model that minimized the Bayesian information criterion is presented below in Eq.(1). It included 6 of the 10 descriptors, exhibiting an average absolute deviation of 0.21 eV. The parity between DFT ("true") evaluations and the simplified structure-function relationship is given below in Figure 3.

$$E = 6.801A_0 - 0.0462B_0 - 0.121B_1 - 0.270B_2 - 0.143B_3 + 0.103B_4 + 4.535 \quad (1)$$

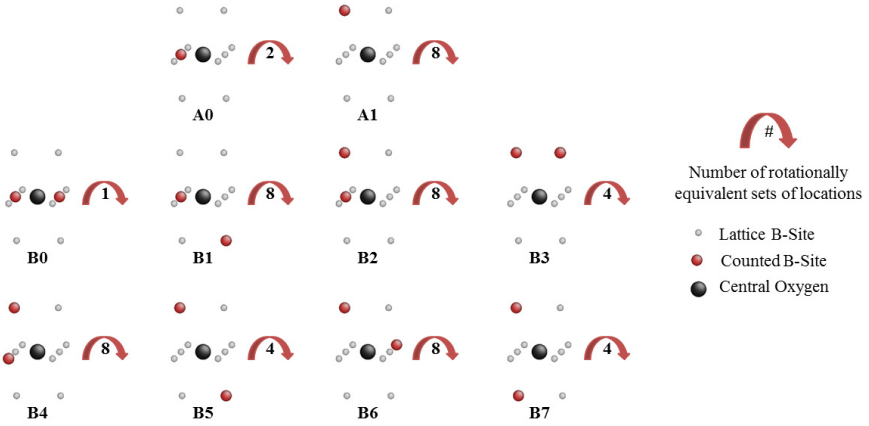

Figure 2: Examples of possible geometric descriptors for placement of dopant on B-sites

Once the oxygen excess energy could be predicted via an algebraic equation, it was possible to formulate a mathematical optimization model that identifies the dopant patterns that are expected to lead to highly reducible oxygen carriers, Eq. (2)-(11). More specifically, the model identifies the placement of dopant that maximizes the density (number) of "easily removable" oxygen sites, which are defined as those sites with a predicted oxygen excess energy that falls below a given threshold. The geometric descriptors for counts of individual dopant atoms (A_{im}) are encoded in Eq.(3). Similarly, the geometric descriptors for counts of pairs of dopant (B_{in}) are encoded in Eq.(4) utilizing variables, X_{ij}, representing the presence of a pair of dopant atoms. The X_{ij} variables are uniquely determined by Eq.(5)-(7). Eq.(8) encodes the simplified structure-function relationship for oxygen excess energy as a function of geometric descriptors. Finally, Eq.(9) indicates the presence of a site with oxygen excess energy below the target threshold, E^*, using indicator variable Z_i. The total number of such sites is maximized in the objective, Eq.(2). Additional constraints on the local concentration of dopant (i.e., per motif) and the global concentration of dopant (i.e., across the entire cell) are also included in Eq.(10) and Eq.(11), respectively. The formulation presented in Equations 2-11 results in a very challenging optimization problem. In order to improve tractability, the authors took advantage of symmetry-breaking constraints presented previously by Hanselman and Gounaris (2016). Furthermore, concentrations of 0 to 30 % dopant locally and 10 to 30 % dopant globally were enforced, representative of materials that can be successfully synthesized experimentally. Even with these constraints, the design space is still highly combinatorial. Models instantiated for supercells of size 3x3x3 can be solved in under 30 seconds, while models for supercells of size 4x4x4 typically require in excess of 24 hours. Further work will attempt to improve the numerical performance by investigating decomposition techniques, which may open the way to obtain solutions that exhibit periodicity over an even larger range. Some observations can be made from the results of this optimization model solved at various levels of target oxygen excess energy, E^*, illustrated in Figure 4. Since there is only one motif with oxygen excess energy below 4.4 eV that satisfies the local dopant concentration limits, the optimal dopant pattern is a single, periodic row of dopant with approximately 15 % of the oxygen sites achieving the target. At a target of 4.5 eV, there are two such motifs, which causes additional packings to be optimal, though they achieve the same density of ideal sites. As the target is raised to

4.55 eV, the majority of oxygen sites become ideal, utilizing the same simple design with a periodic row of dopant.

4. Conclusions

In this work, we demonstrated the application of mathematical optimization to answer an important materials design question, namely how to identify the patterns of dopant that maximize the potential for oxygen release from a perovskite oxygen carrier. This involved using DFT calculations to elucidate the form of a simplified structure-function relationship that could predict perovskite oxygen excess energy in a way that was amenable to be incorporated in a formal optimization model. Optimal patterns for dopant placement were thus identified as a function of target oxygen excess energy, and these patterns can now serve as targets for experimental synthesis. Furthermore, this overall approach built upon a previously developed materials design framework by demonstrating the necessary steps to set up the optimization model from scratch, without a pre-existing structure-function relationship. Importantly, our work illustrated the benefit nanostructuring can have on the performance of oxygen carrier materials.

Abstract

Conjugated semiconducting polymers present a new paradigm in electronics manufacturing. Examination of structure-property relationships in poly(3-hexylthiophene) (P3HT), a workhorse semiconducting polymer, has indicated that highly ordered crystals with long range interconnectivity exhibit the highest charge carrier mobility. Here we demonstrated the utility of using structural characterization to probe for tie chains, chains that tie together crystalline domains. P3HT nucleated via UV-irradiation was mixed with non-nucleated P3HT in a continuous flow system in which the flow rate and recollection tube length were varied. The setting with the lowest flow rate and shear rate (LL:LF) displayed the highest charge carrier mobility. This was associated with a trade-off between the quantity of fibril bundles formed and the interconnectivity. Comparable batch studies with solution aging exhibited higher mobilities than the flow system. The lack of correlations between the orientational order parameter and fiber packing density to charge mobility demonstrated that the structural design space is multidimensional and requires numerous structural metrics.

Keywords: poly(3-hexylthiophene), OFET, solution processing, structure quantification

1. Introduction

The solution processability of organic, conjugated polymeric semiconductors promises a new paradigm in electronic device fabrication. The ability to utilize roll-to-roll processing or other existing printing technologies to produce large area, flexible, and stretchable devices has the potential to drastically reduce manufacturing costs. While organic electronics are not expected to replace high-end, high-performance devices currently dominated by silicon, they are expected to be major competitors in markets that are less demanding computationally but require flexibility and large area coverage. Examples include organic field-effect transistors (OFETs), organic photovoltaics (OPVs), organic light emitting diodes (OLEDs), and biosensors (Facchetti, 2011). The realization of organic semiconducting polymer-based devices is dependent upon maintaining reproducible and optimized electronic properties. A plethora of research has been conducted to relate the processing conditions to charge carrier mobility, a key electronic metric describing how quickly electrons (or holes) can flow through a

material given an applied voltage. With hundreds of process-property data points in the literature each with a unique microstructure, a concerted effort to quantify and identify key process-structure-property relationships is beginning to emerge (Persson et al., 2016a). However, these relationships span multiple length scales, are multidimensional, highly nonlinear, and subject to a high degree of uncertainty. A rigorous process systems approach to elucidate predictive relationships could vastly enhance the field of organic electronics. To this end, poly(3-hexylthiophene) (P3HT) has been utilized as a workhorse polymer to study the role of processing on microstructural order and electronic properties. Advancements in structural characterization techniques have suggested two main features are crucial to high-mobility OFET devices: i) highly ordered crystals on the micro- to mesoscales providing for electron delocalization, and ii) long-range interconnectivity between crystalline domains to provide a percolative network for charge transport. Exposure of P3HT solutions to low-dose UV-irradiation followed by subsequent solution aging has been demonstrated to be a controllable technique to form highly crystalline nanofibers (Chu et al., 2016). However, methods specifically targeting the formation of "tie chains", defined as polymer chains that tie crystalline domains together, are generally lacking despite their perceived importance in macroscale charge transport. In this work, we present a case study to demonstrate the complexity of developing process-structure-property relationships in P3HT-based OFETs. Experimentally, the objective is to utilize structural characterization to probe for tie chains through the design of a continuous flow processing technique. It was found that batch processing of P3HT using UV-irradiation can provide higher charge carrier mobilities compared to the continuous flow process but requires two days of solution aging. Furthermore, the mobility of P3HT can be manipulated in a continuous flow system by controlling the flow rate and tube recollection length. Analysis of the UV-vis absorption spectra in solution indicated that an optimal aggregate percent is necessary for charge transport above 0.1 cm^2/V-s. Finally, analysis of the surface morphology indicates that metrics such as orientational order or fiber length density do not globally predict charge mobility. Instead, the structural design space is multidimensional and cannot be understood using a simple structural measurement yielding a single structural metric.

2. Experimental Methods

P3HT with molecular weight of 95 kDa (PDI 2.2, regioregularity 97 %) was purchased from Rieke Metals. Chloroform was purchased from Sigma-Aldrich. Tubes with an inner diameter of 0.762 mm were purchased from Cole-Parmer Instrument Company. In the continuous flow setup, two tubes of length 3.35 m each were connected to two syringe pumps containing P3HT dissolved in chloroform at a concentration of 5 mg/ml. One of these tubes was exposed to UV light over a residence time of 15 seconds to form nucleated P3HT; the other tube was not exposed to UV light. The streams from these two tubes were then combined in a static mixing tee and flowed through a recollection tube to allow the nucleated and non-nucleated P3HT chains to form an interconnected network. A two-level, two-factor experimental design scheme was used to investigate the impact of flow rate and recollection tube length on P3HT self-assembly into ordered, interconnected fibrillar domains. The high and low levels for the flow rates were 0.025 ml/s and 0.0125 ml/s while the recollection tube length was either 1.5 m or 4.5 m. These settings are summarized in Table 1. A batch processed sample comprising UV-irradiated P3HT mixed with a P3HT solution that had not been exposed to UV

served as the control. This sample was characterized on Day 0 and after 2 days of solution aging.

Table 1. Factor names with corresponding recollection length and flow rate settings

Sample Name	Recollection Tube Length (m)	Flow Rate (ml/s)
LL:HF	1.5	0.0250
LL:LF	1.5	0.0125
HL:HF	4.5	0.0250
HL:LF	4.5	0.0125

*Sample names refer to factor settings in format of recollection length:flow rate.

Electrical characterization of the polymer semiconductors was conducted using a bottom-gate, bottom-contact OFET. Heavily n-doped silicon wafer substrates acted as the gate electrode, and thermally grown SiO_2 (300 nm) served as the dielectric layer (capacitance per unit area: 1.15×10^{-18} cm^{-2}). Source and drain electrodes, 30 nm of Cr as an adhesion layer and 50 nm of Au, were deposited via standard lift-off photolithography techniques. The electrodes had a channel width of 50 μm and length of 2000 μm. The semiconducting films were then deposited using a blade coating apparatus. Drops of solution (4 μL) were placed on the substrate, and blade speed and height were 2 mm/s and 10 μm, respectively. Additional experimental details can be found in previous work (Chu et al., 2016). UV-vis solution spectra were recorded on an Agilent HP 8510 UV-vis spectrophotometer. The surface morphology of the thin films was characterized using a Bruker Dimension Icon AFM system in tapping mode.

3. Results and Discussion

3.1. Electrical Properties

Optimal devices are characterized by high charge carrier mobility with minimal run-to-run variance. The extracted charge carrier mobilities for both the batch experiments and the continuous flow designs are presented in Figure 1.

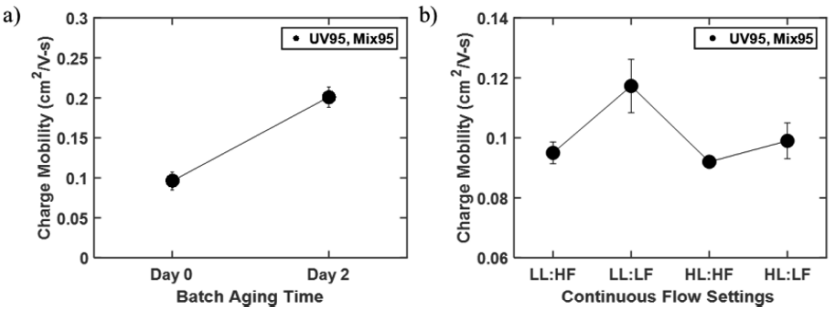

Figure 1. (a) Average charge carrier mobilities of OFETs for batch processing conditions. (b) Average charge carrier mobilities of OFETs for continuous flow processing conditions. Error bars denote standard errors over multiple replicates.

Inspection of Figure 1a shows the impact of batch processed solution aging on mobility, where mobility increases with aging over 2 days. The results are consistent with previous studies and demonstrate the nucleation and growth mechanism associated with UV-irradiation and aging in solution processing (Chu et al., 2016). In the continuous flow study, the low recollection length, low flow rate (LL:LF) setting displayed the highest charge carrier mobility with a value of 0.117 cm^2/V-s. However, this processing

condition also afforded the largest standard error. The mobilities for all other settings were statistically equivalent according to a t-test, with unequal variance for a 95 % confidence level and were only slightly lower than the LL:LF setting. These results suggest a trade-off between processing time and charge carrier mobility. While the batch processing method provided a thin film with the highest overall mobility, this came at the expense of two days of solution aging. In contrast, the Day 0 and continuous flow setup exhibited lower average mobilities but were obtained with no process delays. Further optimization of the continuous system may lead to increased mobility, enabling high performance devices without solution aging.

3.2. Solution UV-Vis Absorption

UV-vis absorbance spectroscopy was used to probe the degree of polymer conformational order and aggregate formation in solution. For all P3HT solutions, a broad absorption peak centred at ca. 455 nm accounts for the wide distribution of isotropic, amorphous chains that do not form aggregates. Shoulder peaks with vibronic bands at ca. 570 nm and 615 nm are associated with the formation of P3HT aggregates. The relative degree of polymer aggregation in solution can be estimated by deconvoluting the absorption spectrum into amorphous and aggregated contributions through the fitting of a Frank-Condon progression shown in Figure 2a (Panzer et al., 2015).

The aggregate fraction values for both the continuous flow and batch results are given in Figure 2b. Unlike the mobility results, there are significant differences in the solution characteristics prior to thin film deposition. Batch processing resulted in 10 % and 19 % solution aggregates for Day 0 and Day 2, respectively. The results for continuous flow processing were markedly different. The LL:LF setting provided an aggregate fraction of 22 %, which was statistically different from the other continuous flow settings according to a t-test with unequal variance for a 95% confidence level. All other settings formed larger aggregate domains with the percentage of aggregates exceeding 35 %. This can be attributed to both the effect of shear on the planarization of polymer chains and the time in which confinement effects force chains to interact and self-assemble.

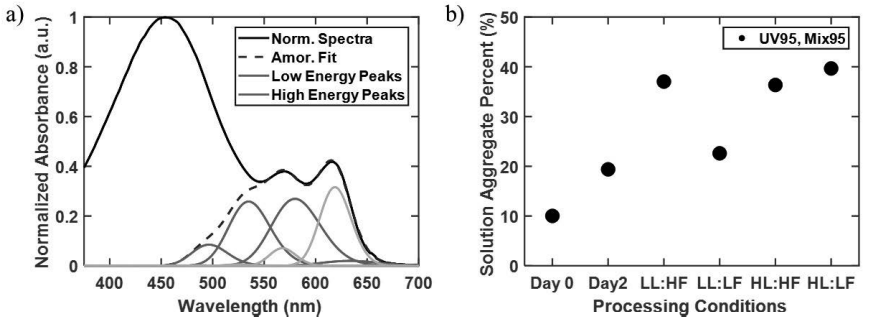

Figure 2. (a) Normalized solution UV-vis absorbance spectra of LL:LF sample deconvoluted into amorphous and aggregate contributions. (b) Solution aggregate percent for both batch and continuous flow processing experiments. The standard errors over multiple replicates were all less than 1.15 %.

Unlike the conventional wisdom where increased levels of crystallization are expected to afford higher mobility, the results here indicate that larger aggregate fractions do not correlate with high mobility. Rather, the data suggests an optimal range of solution aggregate fraction (15 % to 30 %) to obtain mobilities exceeding 0.1 cm^2/V-s. From a

mechanistic perspective, the existence of an optimal range can be readily justified. When the aggregate percent falls below the lower limit, the number of aggregates is insufficient to form the percolated network necessary for efficient charge transport; whereas when the degree of aggregation increases above the upper limit, the resultant films possess too many aggregates resulting in grain boundaries that limit transport pathways.

3.3. Surface Morphology

The nanofibrillar surface morphology of the semiconductor-air interface was imaged using AFM. Typically, AFM image analysis has been used to qualitatively relate the density, orientation, and dimensions of fibers to measured mobility values. However, recent advances in image processing techniques have demonstrated that crucial insights into the mechanisms of aggregate formation can be extracted through quantification of the surface morphology. Persson et al. (2016b) developed a general, open-source computational approach to skeletonize and vectorize individual fibers. This enabled calculation of the orientational order parameter, S_{2D}, the fiber length density (FLD), andapparent fiber dimensions. This process is demonstrated in Figure 3a. Examination of the extracted S_{2D} order parameter and FLD for both the batch and the continuous flow studies suggests different self-assembly mechanisms. The Day 0 batch AFM images appear featureless despite exhibiting a mobility just under 0.1 cm^2/V-s. This lack of nanofibers is vastly different from the continuous flow cases that exhibit similar mobilities (LL:HF, HL:LF, HL:HF), where the surface morphology exhibits a high degree of orientational order and dense fibrillar packing. Furthermore, neither S_{2D} nor FLD appear globally predictive of charge carrier mobility as devices with mobility

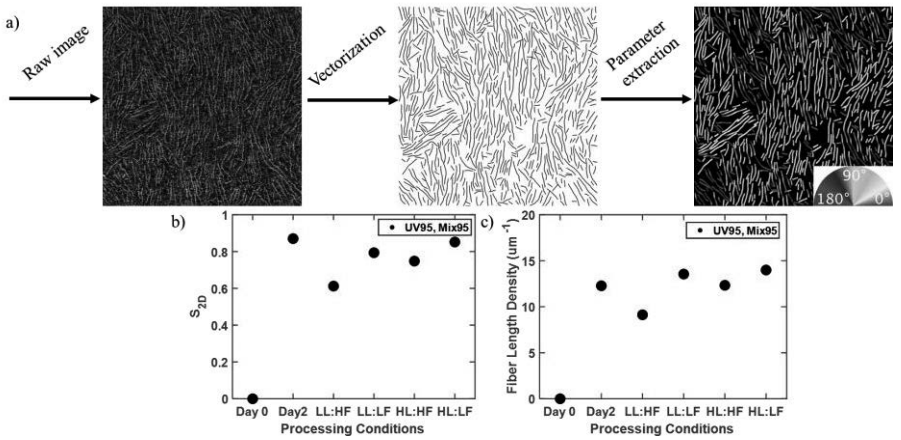

Figure 3. (a) Example of vectorization of P3HT fibers into quantifiable format using LL:LF sample. The image on the far right is referred to as an orientation map (b) S_{2D} orientational order parameter and (c) fiber length density values for batch and continuous flow processing.

both above and below 0.1 cm^2/V-s display similar values. Past studies have correlated these metrics with mobility, but this study demonstrates that the structural design space is multidimensional and a single metric such as S_{2D} cannot fully describe the structure in process-structure-property relations. However, the quantification of AFM facilitates the elucidation of mechanistically different self-assembly mechanisms and their relation to charge carrier mobility.

The orientation map of the LL:LF setting in Figure 3a shows local aligned bundles of nanofibers intermixed with other bundles showing a different directional preference. These fiber bundles are referred to as "shish-kebabs" and have been identified in other flow processing studies (Wang et al., 2015). These structures vastly differ from the well-aligned network structure that forms during batch self-assembly. Notably, the LL:LF setting has the lowest shear rate across the shortest distance, resulting in the self-assembly of fewer shish-kebab bundles. Mechanistically, this implies that more free chains are available to form tie chains during thin film deposition, providing the higher mobility for this flow condition. Understanding the driving force of shish-kebab formation in terms of applied solution shear, tube dimensions and residence time is essential to transfer processing lessons learnt from batch processing to continuous systems for industrial scale up.

4. Conclusions

The requirement of highly crystalline nanofibers with a high degree of interconnectivity to form a percolative network for charge transport has dominated the design of polymer semiconductor solution process techniques. However, limitations in structural characterization techniques have slowed the advancement of robust process-structure-property relationships that can enable the large-scale solution processing techniques. Here, we have proposed a continuous flow method that mixes nucleated and non-nucleated P3HT with the aim of improving charge transport mobility. It was found that while signatures of similar degrees of crystallinity can be found in the solution state, batch and continuous flow processing provide vastly different thin film morphologies. Previously discovered correlations between crystallinity, orientational order, and charge carrier mobility for batch studies do not as readily apply in a continuous flow system. As the organic electronics field progresses, it is imperative to provide as much structural characterization as possible so that multidimensional process-structure-property relationships enabling advancements in charge carrier mobility can be discovered.

Developing Non-linear Rate Constant QSPR using Decision Trees and Multi-Gene Genetic Programming

Shounak Datta, Vikrant A. Dev, Mario R. Eden*

Department of Chemical Engineering, Auburn University, Auburn, AL 36849, USA
edenmar@auburn.edu

Abstract

Developing a QSPR model, which not only captures the influence of reactant structures but also the solvent effect on reaction rate, is of significance. Such QSPR models will serve as a prerequisite for the simultaneous computer-aided molecular design (CAMD) of reactants, products and solvents. They will also be useful in predicting the rate constant without entirely relying on experiments. To develop such a QSPR, recently, Datta et al. (2017) used the Diels-Alder reaction as a case study. Their model displayed great promise, but, there is scope for improvement in the model's predictive ability. In our work, we improve upon their model by introducing non-linearity. This is achieved using multi-gene genetic programming (MGGP). In our methodology, a combination of genetic algorithm (GA) and directed trees was used to develop a branched version of chromosomes, allowing additional possibilities in the generated models. In our work, prior to model development through MGGP, principal component analysis (PCA) was conducted. Lastly, models were evaluated based on metrics such as R^2, Q^2, and RMSE.

Keywords: Multi-gene genetic programming, hybrid algorithm, nonlinear regression, machine learning, stochastic optimization

1. Introduction

The search for QSPR models to predict influence of structures of reactants and solvents on reaction rate constant has long been a challenge. According to Roy et al. (2015), QSPR (Quantitative Structure Property Relationship) models are generally linear or non-linear mathematical relationships that correlate a particular property or activity of a chemical species with their structure. Such structures are generally represented numerically by descriptors, which can be determined experimentally or theoretically as per the definition. Early attempts to develop QSPR models for the prediction of rate constant of a reaction have been limited. Either the rate constant was studied as a function of structures of reactants while keeping the solvent structure constant or the solvent structures were varied but the reactants' structures were kept constant. With regards to the study of the influence of reactants' structures, Chaudry and Popelier (2003) developed a property model to predict the rate constant of hydrolysis of esters by utilizing quantum chemical descriptors. Estrada and Matamala (2007) have used generalized topological indices to predict the gas phase reaction rate constants of alkanes and cycloalkanes with OH, Cl and NO_3 radicals. Recently, Struebing et al. (2013) developed a methodology to design solvents by utilizing surrogate models and quantum chemical calculations. There is a need for QSPR models that capture the

combined influence of reactants' structures and solvent structures. Such models will serve two purposes: The first would be to quickly predict the rate constant without relying fully on experiments, while the second purpose will be the simultaneous design of reactants, products and solvents. With respect to QSPRs that capture reactant and solvent influence, Nandi et al. (2013) developed a quantitative structure-activation barrier relationship for the Diels-Alder reaction that utilizes quantum chemical descriptors. Their aim was to construct a relationship between the activation energy and the structures of the utilized reactants and solvent. However, their data set lacked solvent variety. Recently, Zhou et al. (2014) have studied a variety of solvents for the Diels-Alder reaction in their search for new solvent descriptors though they only used one set of reactants. Thus, we have combined the data sets utilized by Nandi et al. (2013) and Zhou et al. (2014) and created a set which offers more diversity in terms of the solvents utilized. We have utilized this more diverse data set to develop a rate constant model in terms of connectivity indices. It is worth noting that Nandi et al. (2013) relied on the data set utilized in the work of Tang et al. (2012). In our previous work, a hybrid GA-DT algorithm was designed to develop a linear model (Datta et al., 2017). In this work, we have proposed an efficient Multi-gene Genetic Programming (MGGP) algorithm using initialization by a modified DT algorithm for model development which utilizes the "divide and conquer" strategy in combination with Principal Component Analysis. This DT algorithm checks if the addition of branched gene improves model fitness. The MGGP algorithms hold promise as they possess the ability of developing models using a wide variety of nonlinear mathematical basis functions. Both internal and external validations were performed separately to determine model confidence. Additionally, model RMSE and R^2 values in case of both external and internal validation were calculated as they describe model fitness of data.

1.1. Diels-Alder Reaction

The Diels-Adler reaction is a well-studied organic chemical reaction involving a conjugate diene and an alkene, which is also termed as dienophile. Evans and Johnson (1999) have discussed this reaction in detail in their work. This reaction involves cycloaddition of two reactants in the presence of a solvent. Earlier, Rideout and Breslow (1980) discussed the hydrophobic acceleration of the Diels-Alder reaction in their work. Specifically, the influence of hydrophobic cavity in organic structures for acceleration of the reaction rate was discussed. In both of the aforementioned works, the impact of the solvent on the rate constant of the reaction has been observed. This feature of this reaction makes it an appealing choice for the aimed study.

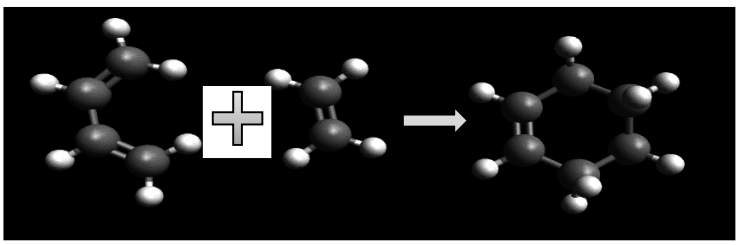

Figure 1: Example of a simple Diels-Alder Reaction drawn in Avogadro Software

2. Methodology

From the work of Tang et al. (2012) and Zhou et al. (2014, 2015), we generated a diverse data set of 72 reactions that consisted of 38 different dienophiles, 19 dienes and 10 solvents. All chemical species were designed using Avogadro software. The structures were optimized using MMFF94s, a built-in geometry optimization algorithm of Avogadro software, as suggested by Datta et al. (2015). The optimized geometries were saved as MOL files. These files were then used as input for Dragon 6 software to calculate descriptors. In our work, one sixth of the reactions were separated for external validation and all other reactions were used to train the model. Keeping reaction design simplicity in mind, only connectivity descriptors were used for model development. Further information about the versions of divide and conquer method and decision tree (DT) method used to reduce number of data points can be found in the work of Datta et al. (2017).

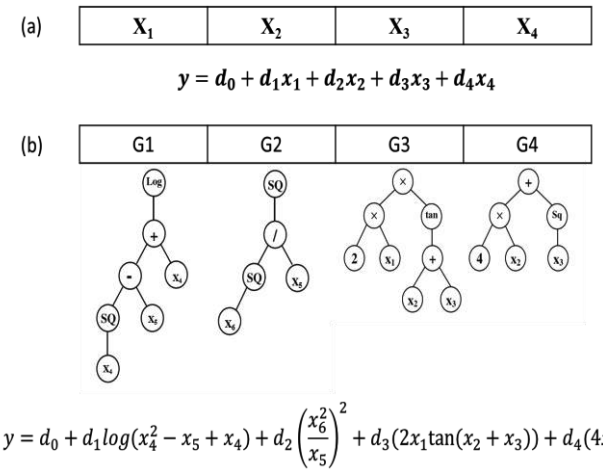
2.1. Multi-Gene Genetic Programming (MGGP)

Genetic Algorithm is widely employed in developing QSPR/QSAR models. As Whitley (1994) describes, such an evolutionary algorithm is efficient as a function optimizer and its applications are very diverse. Houck et al. (1996) has presented a basic idea of GA. In their work, they have proposed these basic steps that can be used as a guideline for designing a GA process for function optimization problems.

- Supply an initial population P_0 of N individuals with respective function values and constraints, if any.
- $i = 1$
- $P_i^{'}$ = selection_function(P_{i-1})
- P_i = reproduction_function($P_i^{'}$)
- evaluate(P_i)
- $i = i+1$
- Repeat 3rd step until termination condition met
- Print best solution achieved

In a feature selection approach using Genetic Algorithm, the chromosomes of the population generally contain position of variables (descriptors) that can be used to develop a property prediction model. The difference in MGGP is, instead of such variable positions, the chromosomes contain genes developed using directed trees (Gandomi and Alami, 2012). In Figure 2, a small example of model development using both (a) GA and (b) MGGP is presented. The genes can be considered branched version of individuals. The figure also shows the development of the final model from the individual developed in MGGP. It is important to note that the initial node of gene developing an MGGP individual is always an arithmetic operator. For maintaining mathematical acceptance of the genes, descriptor nodes are always separated with an arithmetic operator node between them. The tree develops by placing descriptor nodes after operator nodes, and moderators (e.g. sin, e^x, log, root, power) in between as needed. Two operator nodes or two descriptor nodes cannot be connected by a directed edge. However, the moderator nodes can be connected by directed edges. When needed, two or more moderator nodes can be connected with each other. For the crossover operation, the scatter swap method was selected. The mutation operation, however, could choose any node in the genes to alter.

Symbolic regression is used to determine the values of d_0, d_1, d_2, d_3, and d_4. Here, the weight of each gene is calculated and evolutionary algorithms (EA) are used to tune the values (Riolo and Worzel, 2003). For execution of this operation, the GPTIPS 2.0 (Searson et al., 2010) toolbox of MATLAB was used due to its wide flexibility. However, the code was modified to present and improve models based on not only training set fitness but also test set fitness. A great advantage of MGGP over other non-linear model development algorithms is the flexibility of control over choosing numerous arithmetic combinations with high nonlinearity. This is highly useful in cases like this where high level of nonlinearity is a possibility (Gandomi and Alavi, 2011).



$$y = d_0 + d_1 log(x_4^2 - x_5 + x_4) + d_2\left(\frac{x_6^2}{x_5}\right)^2 + d_3(2x_1\tan(x_2 + x_3)) + d_4(4x_2 + x_3^2)$$

Figure 2: Individual development of (a) Genetic Algorithm, and (b) Multi-Gene Genetic Programing

3. Results

As GPTIPS 2.0 gives the opportunity to use various numbers and depths of the genes, the objective was to develop a better model than presented by Datta et al. (2017) using a nonlinear model that contained the minimum number of descriptors possible. Although only connectivity index descriptors were used in this effort, it is beneficial to develop a model with fewer descriptors to increase the interpretability of the model. The population size and number of iterations were kept constant at respectively 50 and 250, respectively. In different settings of number of genes, gene depths, and crossover possibilities iteration numbers, three models possessed better performance metrics than the model presented in the work of Datta et al. (2017). For convenience, they are identified as M1, M2, and M3. It should be noted that, all the selected models represent influence of all the chemical classes involved in the reactions. However, the numbers of descriptors used to develop the models are different. M1 required 13 descriptors, where as M2 and M3 required 10 and 18 descriptors respectively. Here, R^2 and Q^2 represent model fitness for training set and test set data respectively, and RMSE expresses overall root mean squared error of the model. Here, k is reaction rate constant. As presented in Table 1, M3 model shows the best fit compared to the other models. It can also be seen that, in case of M2 and M3, decreasing crossover possibility, and increasing number and depth of gene was able to improve fitness.

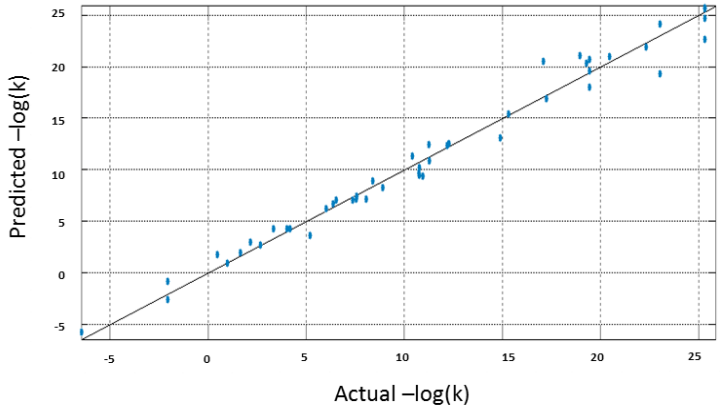


Figure 3: Actual vs. Predicted -log(k) values for model M3

Table 1: Properties of Models developed

Model Number	M1	M2	M3
R^2	0.9825	0.9011	0.9538
Q^2	0.8943	0.8213	0.9316
RMSE	0.5471	0.8410	0.3918
Gene Number	4	5	7
Gene Depth	3	4	5
Crossover	0.8	0.7	0.6
Mutation	0.02	0.02	0.02

4. Conclusions

In this project, the aim was to develop a better model than that previously proposed for the same property using QSPR analysis (Datta et al., 2017). From the work of Datta et al. (2017), it was clear that the hybrid GA-DT method was very efficient in developing linear models of this type. Dev et al. (2017) also concluded that the hybrid GA-DT method provided the best possible model, thus developing a nonlinear model was the only option left to develop a better property model. From the results it can be noticed that M1 and M3 models have similar metrics. However, in case higher level of accuracy is required, use of model M3 is advised. It can be noticed that Model M3 used five more descriptors than M1, but as connectivity index descriptors are very easy to calculate, no severe rise in computational expense is expected. Finally, it can be noticed that the models developed had better quality than the linear model presented for the same property by Datta et al. (2017).

Goal-directed Design of Dynamic Experiments for Cybernetic Models of Bioreactors

Martin F. Luna, Ernesto C. Martínez*

INGAR (CONICET-UTN), Avellaneda 3657, Santa Fe S3002 GJC, Argentina
ecmarti@santafe-conicet.gov.ar

Abstract

The distinctive feature of cybernetic models of bioreactors is their capacity to account for regulatory mechanisms in a cell metabolism by modeling the synthesis of enzymes and their activities. From a process engineering viewpoint, to guarantee its predictive capabilities regarding one or more process objective or goals (e.g. optimization, controllability, etc.), experimental data used to fit a cybernetic model parameters should be the most informative bearing in mind the adequacy of the resulting model to describe the specific objective of interest. To excite the most relevant metabolic modes in the cybernetic model, a dynamic experiment is optimally designed by accounting for the sensitivity of the chosen objective to operating conditions. The bioreactor feeding profile and sampling times are selected to maximize a global sensitivity index. As a case study, biomass production or fermentation to ethanol conversion in the fed-batch cultivation of *Saccharomyces Cerevisiae* are considered as alternative objectives.

Keywords: Bioreactor; Cybernetic Model; Design of experiments; Optimization.

1. Introduction

Mathematical models of bioreactors are gaining widespread acceptance in both academic and industrial practice since it is vividly clear that, in order to be competitive and to keep pace with the new developments in the biopharmaceutical industry, bioprocesses need to be designed, optimized, monitored and controlled using process engineering methods (van Daele, et al., 2017). Cell metabolism is well-known for its dynamic complexity in comparison with pure reaction networks. The microorganisms used as catalyst are living beings that shown different metabolic behaviors depending on the operating conditions. Thus, simple kinetic and transport phenomena are usually not enough to describe the system dynamics. Some insight into the regulatory system of the cell must be considered in order to have a useful model that can predict the response of the microorganism to changes in the abiotic environment. The supplied nutrients undergo different metabolic pathways within the cells, and these alternative uptake modes are regulated by the microorganism enzymes. In this regard, cybernetic models (Ramkrishna and Song, 2016) are capable of explicitly modeling the metabolic behavior by resorting to matching and proportional control laws for the production and activities of enzymes.

However, the complex nature of cell metabolism is translated into a complex formulation of the mathematical models. Usually, cybernetic models involve several differential equations with many parameters. Thus, experimental information from dynamic experiments is needed in order to parameterize them. But if a metabolic mode is not excited during an experimental run, it may be impossible to obtain meaningful values of the parameters related to it. This may hamper model prediction capabilities

which may lead the industrial process to suboptimal operation. Thus, a method to optimize the Design of Dynamic Experiments (DoDE) is needed in order to obtain the maximum information from each experimental run (Franceschini and Macchietto, 2008; Martinez et al., 2013). The design will depend on the way the information gain is measured. In this work, the sensitivity of the process objective will be evaluated as a scalar of the Global Sensitivity Matrix (GSM). Thus, the process objective chosen (e.g. biomass production, metabolite expression, etc.) will determine which metabolic modes are excited during the experiment so that all the available resources are used to account for them properly in the cybernetic model. Here, two possible objective functions are considered for a bioreactor involving glucose consumption by yeast in a fed-batch bioreactor. Both goal-directed optimal designs are compared and the adequacy of each is discussed. It is shown that explicitly accounting for a given objective in the DoDE is advantageous for data generation in fitting a cybernetic model that properly describes regulatory mechanisms among different metabolic pathways.

2. Cybernetic modeling

In the cybernetic approach for bioreactors, the regulatory system of the microorganism is modeled by describing the enzymes production rates and activities. In order to do so, it uses the matching and proportional laws to link the uptake rates to the different metabolic modes. Here, the term metabolic mode refers to the preferential uptake of a carbon source and the subsequent metabolic pathway that it undergoes within the cell. As a case study here, the cultivation of baker's yeast (*Saccharomyces Cerevisiae*) with a feed of glucose as a carbon source, there are three main metabolic modes: i) the uptake of glucose by a fermentative pathway (fermentation), ii) the uptake of glucose by an oxidative pathway (respiration) and iii) the uptake of ethanol (produced by fermentation) by an oxidative pathway. Each mode has different rates and yields, and the switch from one mode to another depends on the cybernetic laws (Ramkrishna and Song, 2016). In this work, the model used is presented in Eq. (1) through Eq. (8). The matching and proportional laws are described by Eq. (7) and Eq. (8).

$$\frac{dX}{dt} = \left(\sum_i r_i v_i - \frac{F}{V}\right) X \tag{1}$$

$$\frac{dGl}{dt} = (Gl_F - Gl)\frac{F}{V} + \left(\frac{r_1 v_1}{Y_1} - \frac{r_2 v_2}{Y_2}\right) X \tag{2}$$

$$\frac{dEt}{dt} = -Et\frac{F}{V} + \left(p\frac{r_1 v_1}{Y_1} - \frac{r_3 v_3}{Y_3}\right) X \tag{3}$$

$$\frac{dV}{dt} = F \tag{4}$$

$$r_i = e_i \mu_i \frac{S_i}{S_i + K_i}\frac{K_{EI}}{Et + K_{EI}} \tag{5}$$

$$\frac{de_i}{dt} = \alpha u_i \frac{S_i}{S_i + K_i} - \left(\sum_j r_j v_j - \beta\right) e_i + \alpha^* \tag{6}$$

$$v_i = \frac{fc_i\, r_i}{\max(fc_j r_j)} \tag{7}$$

$$u_i = \frac{fc_i\, r_i}{\sum_j fc_j\, r_j} \tag{8}$$

Here, X stands for biomass concentration, Gl stands for glucose concentration (subscript F indicates that it is the concentration in the feed) and Et stands for ethanol concentration. Eq. (5) through Eq. (8) are repeated for i=1, 2, 3, which correspond to the three modes: fermentation, respiration and ethanol oxidation. In Eq. (5) and Eq. (6) S_i is equal to Gl for i=1,2 and to Et for i=3. V stands for volume, F stands for the feeding profile, e stands for the enzymes concentration and v and u for the cybernetic variables. In Eq. (7) and Eq. (8) fc_i is the number of carbon atoms per molecule of substrate, which is 6 for i=1, 2 and 2 for i=3. The rest of the symbols shown correspond to the model parameters to be fitted by the method.

The bioreactor is operated in fed-batch mode with complete mixing and it is assumed that no diffusion limitations are present (thus oxygen balance is not taken into account). The feeding profile is parameterized as a sequence of steps. The cybernetic model is parameterized by regression of experimental data generated in one or more dynamic experiments. Distributions (histograms) of the model parameters are generated using bootstrapping and the least-square error method is used to fit them.

3. Design of Dynamic Experiments

The complexity of the proposed model and the number of parameters involved to optimize the information content J of each experiment in order to minimize experimental costs and time constraints. Based on an a priori chosen distribution model parameters, the DoDE optimization problem is posed here as follow:

$$\begin{aligned} &\max\ J = det(Q'.Q) \\ &\text{s.t: } \varphi_{LB} \le \varphi \le \varphi_{UB} \end{aligned} \tag{9}$$

In this work, the information content of a dynamic experiment is measured as the determinant of the matrix Q defined below. The design vector φ includes the feeding profile parameters and the sampling schedule. Each entry in the vector φ has lower and upper limits φ_{LB} and φ_{UB}, respectively. Each entry of the matrix Q corresponds to the global sensitivity index SI_{ij} of the process objective function with respect to the model parameters i at sampling time j. Accordingly, the Global Sensitivity Analysis (GSA) is defined as follows:

$$Q = \begin{pmatrix} SI_{11} & \dots & SI_{1j} \\ \vdots & \ddots & \vdots \\ SI_{i1} & \dots & SI_{ij} \end{pmatrix} \tag{10}$$

This definition of the information content J is key in the formulation of the mathematical program (9). Since the cybernetic model can be used for different process objectives (e.g. biomass or ethanol production), different experimental designs can be used in order to gather more relevant information about the influence of model parameters in better predicting mode switching and its influence on the process objective function of interest.

It is worth noting that the evaluation of the information content J is computationally expensive due to GSA. A Bayesian optimization (BO) method is used here to find the global solution to the mathematical program in Eq. (9). The details for the implementation of the BO algorithm used can be found elsewhere and references therein (Shahriari et al., 2016).

4. Results

The proposed method is used to design dynamic experiments to parameterize a cybernetic model that describes the operation of a bench-scale fed-batch bioreactor containing baker's yeast, with glucose as carbon source. The overall duration of the experiment is set to 9.5 h, including a batch phase of 2 h after which the feeding of glucose begins. The feeding profile is made up of 5 successive steps of fixed duration (1.5 h), whose inflow rates are the entries of the design vector φ. The concentration of glucose in the bioreactor feed is 100 g/L. The sampling schedule consists of six sampling times, of which five has to be designed and the remaining one corresponds to the final time (9.5 h). The concentrations of biomass, glucose and ethanol are determined at each sampling time. The initial volume of the bioreactor is 1 L, with an inoculum of yeast of 6 g/L and initial glucose concentration of glucose of 1.2 g/L (no ethanol is present at the beginning of each experiment).

The initial parameterization of the cybernetic model is fitted with data gathered from the experiments performed in the work of Luna and Martinez (2017). In the available experimental data, the ethanol concentrations at sampling times were not available. Furthermore, the process objective function was the production of biomass, thus the glucose oxidative pathway, which has the higher biomass yield, was of special concern. As a result, the distribution of parameters related to the production and uptake of ethanol has a significantly higher variance.

Two different process objective functions J_p are proposed here to compare the influence of these goals on the design of the experiments. First, the process objective function is chosen to be the production of biomass, measured as the mass of yeast in the reactor. Alternatively, the production of ethanol is selected.

4.1. Biomass production

Using the cybernetic model fitted with the aforementioned data, the DoDE is performed using the production of biomass as the process objective function:

$$J_p = X\,V \tag{11}$$

The feeding profile is presented in Fig. 1(a) along with optimal sampling times. In Fig. 1(b), the cybernetic variables v for the three main metabolic modes are shown. Time-varying profiles of each cybernetic variable is an indicator of the prevalence of each mode over the experiment (a value of 1 indicates that the enzyme of the mode has maximum activity). As can be seen, during the first 2 h when no glucose is fed, the initial amount of glucose is consumed by the fermentative pathway (producing ethanol). When the concentration of glucose decreases the importance of the glucose oxidative mode increases and even surpass the fermentation mode, but it is rapidly overtaken by the ethanol oxidative mode. This metabolic mode prevails until fed-batch operation begins and the cell favors the glucose fermentative mode again. However, the glucose

oxidation pathway is not at all absent and gains momentum as the glucose concentration decreases again (due to an increase in biomass). When the inlet flow rate drops after the fifth hour, the glucose oxidative mode becomes prevalent.

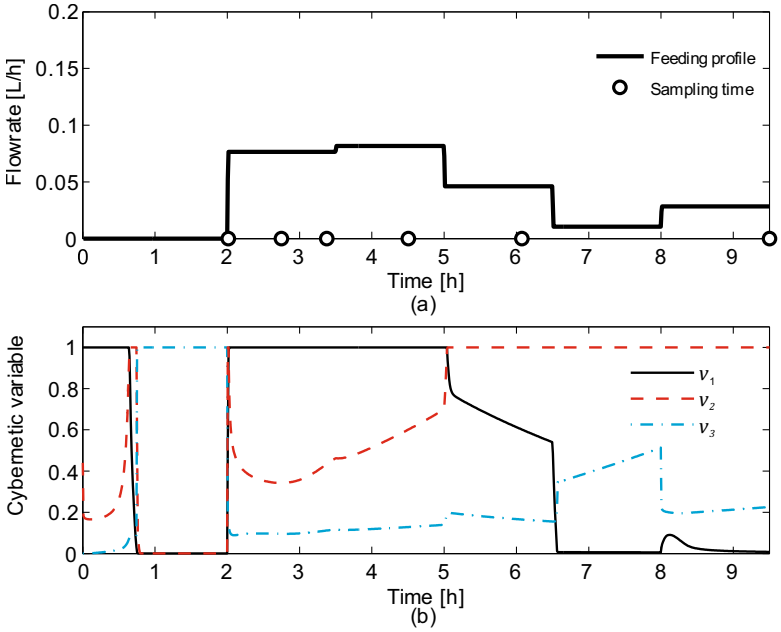

Figure 1. (a) Optimal feeding profile and sampling schedule for the case of biomass production. (b) Values of cybernetic variables for the optimal experimental design.

4.2. Ethanol production

A new experiment is designed using the same model parameters, but using the production of ethanol as the objective function:

$$J_p = Et\ V \tag{12}$$

The feeding profile and the sampling schedule are shown in Fig. 2(a), whereas the cybernetic variables *v* are depicted in Fig. 2(b). As can be seen, all metabolic modes are conveniently excited which generates highly informative data.

It is worth cross-comparing the values of *J* for both optimal designs. The value of *J* for the first design (the one obtained section 4.1), using the biomass production goal is 4.75 10^{-11}, whereas for the second optimal design (the one obtained in this section), using the same process objective the value for the information content *J* is 1.85 10^{-11}. The value for the information content *J* in the first and second DoDE using the ethanol production goal are 1.96 10^{-13} and 1.54 10^{-10}, respectively. The results obtained from cross comparison among optimal designs and information contents are rather expected: the optimal DoDE is dependent on the process objective the model is helping to optimize.

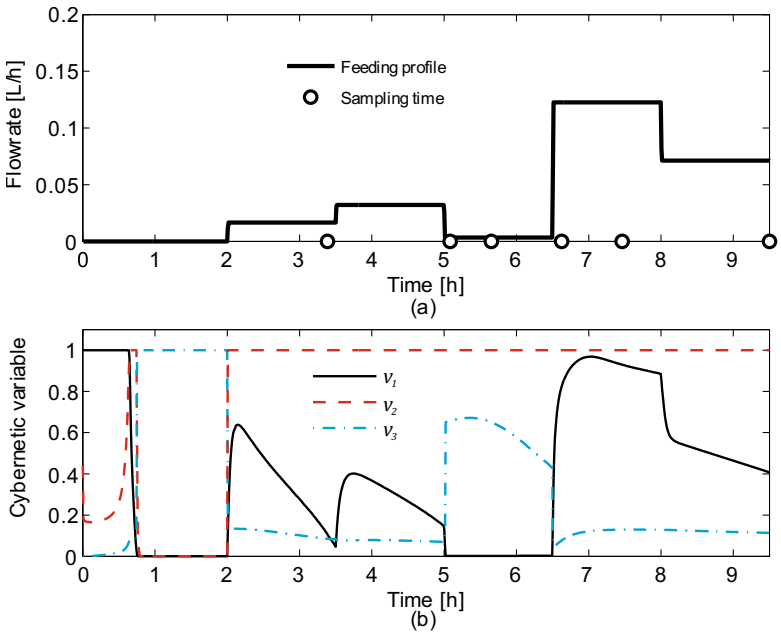

Figure 2. (a) Optimal feeding profile and sampling schedule for the case of ethanol production. (b) Values of cybernetic variables for the optimal experimental design.

5. Conclusions

In this work, a DoDE method for goal-directed parameterization of cybernetic models has been proposed. The importance of the process objective to be modeled is explicitly accounted for in the design of a dynamic experiment, since the same model may need different types of information to better describe the process objective that is being pursued. The method has proven to be useful in the maximization of the information content. However, the high computational burden of the GSA gives rise to the need of speeding up simulation-intensive algorithms used to deal with parameter distributions.

Abstract

Online monitoring of batch reactor is essential to maintain the performance against batch-to-batch variations. A major challenge in using a statistical model for monitoring is to guarantee the data from different batches have similar dynamic characteristics at the same time points. By detecting singular points, uneven batch data are synchronized and the DPLS model of each singular episode is used for process monitoring. A new phase division method is proposed by introducing transition phase at a phase boundary to improve estimation performance around the transition region.

Keywords: Uneven batch synchronization, DTW, PLS, transition phase

1. Introduction

Batch reactors are used in a number of industries producing small quantities of high-valued materials such as cell cultivation, polymer synthesis and crystallization. To operate the batch reactor with success, the final quality performance has to maintain with minimum cost. Though operated with the same recipe, the batch process shows batch-to-batch variations in its specified trajectories. Therefore, online process monitoring is essential to achieve successful batch operation.

Several techniques have been developed to deal with real-time observation of process variables and detection of abnormal operations. The model-based method is the most traditional way to estimate the operation trajectory. It consists of the first principle equation based on mass balance and empirical equations. Though this method shows considerable prediction performance, it is used in limited conditions because it needs much time and cost due to the complexity. Data-driven methods can be an alternative as they need little knowledge of the process. The stored data is used to extract correlation between process variables and quality indicators.

For batch processes, multiway principal component analysis (MPCA) was developed (Wold *et al.*, 1987). In case both quality indicators and process variables are available, multiway partial least square (MPLS) was proposed to estimate batch performance (Nomikos and MacGregor, 1995). Since these models use samples from one operating point, they could deal with a static behaviour only. To analyze time dependent relations, dynamic PCA (Ku *et al.*, 1995) and dynamic PLS (Kaspar and Ray, 1993) were developed. In this study, dynamic version of the MPLS method, called batch dynamic PLS (BDPLS), is used to construct the dynamic model.

Batch synchronization is an important pre-process because batch operations with a same recipe could have various batch lengths due to the inherent nonlinearity and operational constraints. Given the assumption that the data point at the same time point will be similar

in each batch, several approaches are available to synchronize the sampled data for different batches. For example, indicator variables representing the batch progress for the reactions with well-known kinetics were proposed (Nomikos and MacGregor, 1995). After the reference batch is selected, the other batches are adjusted so that the indicator variables would have same values at the same time point.

Dynamic time warping (DTW) minimizes the distance between the trajectories of different time series (Sakoe and Chiba, 1978), which can be used without any prior knowledge of the process. This study employed a phase-based DTW technique (Doan and Srinivasan, 2008) to synchronize the trajectories of different batches by adjusting each phase segment to be a same length.

Singular point (SP) refers to the point that has more information than others (Srinivasan and Qian, 2005), for example, extrema. SPs can be used to separate the phase as the dynamic behavior changes at that point. Though the SP based phase division method has acceptable performance through the whole trajectory, it shows insufficient accuracy around the SP, when the phase changes. In this study, a new method for singular point based phase division is proposed by separating a transition phase from normal ones defined by the SP, so that the performance of the multiphase statistical model is improved.

2. Uneven batch synchronization

2.1. Dynamic Time Warping (DTW)

DTW synchronizes two time series with different lengths in the way to minimize the distance between them (Doan and Srinivasan, 2008). Asymmetric DTW used in this paper adjusts one time series to the same length of the other's, reference, without a change in the length of the reference time series. The series of mappings from $T(M \times J)$ to $R(K \times J)$ with J number of variables and lengths M and K, respectively, is denoted by F:

$$\mathrm{F} = [\mathrm{c}(1), c(2), \ldots, c(P)] \tag{1}$$

$$\mathrm{c(p)} = [i(p), j(p)], \quad 1 \le \mathrm{p} \le \mathrm{K} \tag{2}$$

DTW maps T onto R by optimizing the sequence F of P points by minimizing the distance between two series, $D(T, R)$:

$$\mathrm{D(T,R)} = \frac{\sum_{p=1}^{P} d(c(p)) \cdot w(p)}{\sum_{p=1}^{P} w(p)} \tag{3}$$

with the local distance between specified points in T and R denoted as $d(i, j)$. The weighting coefficients denoted by $w(p)$ are specified 1 in this work.

$$\mathrm{d(i,j)} = \|R(i) - T(j)\| \tag{4}$$

Then the optimal warping sequence is given by

$$F^* = \underset{F}{\operatorname{argmin}}[D(T, R)] \tag{5}$$

2.2. Singular Point (SP)

There are special points called singular point (SP) containing the majority of features of the signal because the information density in a signal is not uniformly distributed. SPs consist of extrema, sharp change or discontinuity and trend change points. The segment

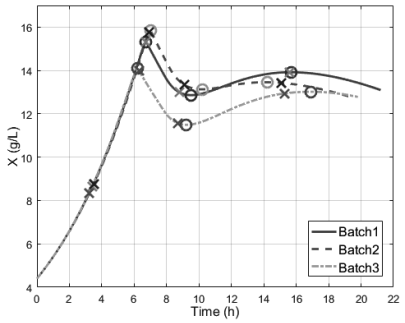

Figure 1. Unsynchronized batch profiles of bioreactor. Each marker indicates the location of SPs in the batch.

Table 1. Position of SP in each batch

Batch 1		Batch 2		Batch 3	
Position[h]	SP Type	Position[h]	SP Type	Position[h]	SP Type
3.4	SP_T	3.5	SP_T	3.2	SP_T
6.7	SP_T	6.9	SP_T	6.2	SP_E
6.7	SP_E	7	SP_E	6.2	SP_S
6.7	SP_S	7	SP_S	6.3	SP_T
8.8	SP_T	9.1	SP_T	8.7	SP_T
9.5	SP_E	10.2	SP_E	9.2	SP_E
15.6	SP_T	14.2	SP_E	15.3	SP_T
15.7	SP_E	15.1	SP_T	16.9	SP_E

separated by adjacent SPs is called a singular episode (Srinivasan and Qian, 2005), treated as a "phase." The phase refers to a distinguishable segment of a batch trajectory (Doan and Srinivasan, 2008).

Figure 1 shows various SP locations among several batches, and Table 1 specifies the types and positions of SPs. SP_T, $\mathrm{SP_E}$, and SP_S denote the type of SPs: trend change SP, extrema and sharp change SP, respectively. As the batch progresses are different, a statistical model can be inaccurate without synchronization because it assumes the data with the same time point in each batch shows similar behaviour. Though normal DTW using whole series at a time could improve the performance as well, phase-based DTW which synchronizes each phase defined by SPs shows higher accuracy (Doan and Srinivasan, 2008).

3. Multiphase PLS

3.1. Partial Least Square (PLS)

Partial least squares (PLS) is used to predict unmeasured properties based on measured process variables (Nomikos and MacGregor, 1995). The 3-way batch data is unfolded and separated into two blocks, independent block X and dependent block Y which both are two dimensional vectors. They are decomposed into the product of the score vector t, and the loading vector p plus residuals E and F, respectively.

$$\mathrm{X} = \sum_{k=1}^{r} t_k p_k^T + E = TP^T + E \tag{6}$$

$$\mathrm{Y} = \sum_{k=1}^{r} t_k q_k^T + F = TQ^T + F \tag{7}$$

where r denotes the number of principal components used to construct a PLS model.

3.2. Dynamic PLS

The data with autocorrelation can be represented by containing previous observations in an augmented form. Dynamic PLS model (Kaspar and Ray, 1993) uses this approach by including previous d observations at each time step:

$$X_d = \begin{bmatrix} x^T(k-d) & x^T(k-d+1) & \cdots & x^T(k) \\ x^T(k-d+1) & x^T(k-d+2) & \cdots & x^T(k+1) \\ \vdots & \vdots & \vdots & \vdots \\ x^T(k+l-d-1) & x^T(k+l-d) & \cdots & x^T(k+l-1) \end{bmatrix} \tag{8}$$

$$\mathrm{x(k)} = \left[x_{1,k}, x_{2,k}, \cdots, x_{J,k}\right]^T \tag{9}$$

where $x(k)$ is the J-dimensional vectors containing the observations of J process variables at time k.

3.3. Multiphase PLS with transition phase

For each phase defined by SPs, DPLS model is constructed assuming a similar behaviour within the phase. The transition region near the SP, however, shows nonlinearity (Ge *et al.*, 2012) having different behaviour from that of the previous phase. In this study, the SP based phase division method is modified by separating the phase transition region as a transition phase. For each SP, the previous d observations and subsequent d observations are included in the transition phase. In case of the SPs with a close position, observations from the point d-step before the former SP to the point d-step after the later SP are considered as a transition phase. The points in a transition phase could be estimated by combining two models of neighboring normal phases. The weighting factors of models to be combined are proportional to the inverse of the distance from each point.

4. Results

4.1. Batch synchronization and phase division

For the 76 batch data, SP based synchronization was carried out so that the positions of SPs become identical throughout the batches. Asymmetric DTW was used for each singular episode and the synchronization results for the batches in Figure 1 are shown in Figure 2. In this study, three methods including normal DTW, SP based phase division and modified SP based phase division, applying transition phase concept, are compared. In normal DTW case, which is a control group, asymmetric DTW is applied to the whole signal all at once without any singular episode considered. After the synchronization, the data is separated into phases defined by SPs to construct DPLS model for each phase. On the other hand, SPs are used to synchronize the data and construct the model in SP based

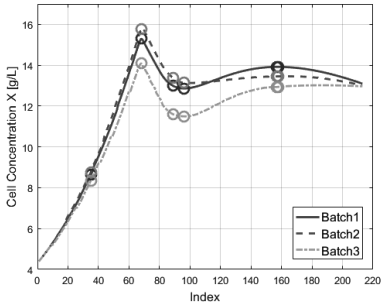

Figure 2. Synchronized batch profiles presented in Figure1. Marker denotes SPs.

phase division method. For the transition phase method, after the SP-based synchronization, the models are constructed only for the normal phases and the transition phases are estimated from them.

4.2. Estimation results

Figure 3 shows estimation results of the three methods around the transition region. The SP based phase division method is more accurate than the normal DTW method because of the improved performance of the synchronization. It has a rapidly changing point where the phase changes occur and lead to discontinuity in estimates as well as increase in error. The transition phase method, on the other hand, shows improvement in estimation accuracy, especially in the transition region. The estimation performances are compared in terms of error in Figure 4 and Table 2.

5. Conclusion

A modified method for estimating batch process using uneven batch data is proposed. The singular points of each uneven batch are detected and synchronized by phase-based DTW. By introducing the transition phase concept, the estimation performance of the DPLS model for each phase is improved, especially at the boundary of each phase.

Abstract

Gas fermentation has emerged as an attractive option for producing renewable fuels and chemicals from carbon monoxide (CO) rich waste streams. Bubble column reactors are being developed for large-scale production, motivating the investigation of multiphase reactor hydrodynamics. We combined two-phase hydrodynamics with a genome-scale reconstruction of *Clostridium autoethanogenum* metabolism and multiphase convection-dispersion equations to compare the performance of bubble column reactors with and without liquid recycle. Hydrodynamics were predicted to diminish column performance with respect to CO conversion, biomass accumulation and ethanol production when compared to column models in which the gas phase was modeled as ideal plug flow plus axial dispersion. Liquid recycle was predicted to be advantageous by increasing CO conversion, biomass production, and ethanol and 2,3-butanediol production compared to the non-recycle reactors. Our results demonstrate the power of combining metabolic models and hydrodynamics for simulating and optimizing gas fermentation reactors.

Keywords: Gas fermentation; metabolic models; hydrodynamics; multiphase reactors

1. Introduction

A promising route to renewable chemicals is the fermentation of carbon rich gas streams (Daniell et al., 2012). Typical feedstocks include industrial waste gases (mainly CO, CO_2 and N_2) and synthesis gas (mainly CO and H_2) produced by gasification of solid waste feedstocks. Compared with alternative technologies, gas fermentation offers several important advantages including operation at ambient temperatures and low pressures, high conversion efficiencies, robustness to gas impurities and high product yields. *Clostridium autoethanogenum* is an anaerobic bacterium that efficiently converts carbon rich gas streams into products such as ethanol and 2,3-butanediol. Wild-type strains of *C. autoethanogenum* produce low yields of ethanol compared to acetate. Researchers at LanzaTech developed an improved *C. autoethanogenum* strain which provides increased CO utilization, ethanol/acetate selectivity and ethanol tolerance (Liew et al., 2017).

Most academic research on gas fermentation has focused on batch and continuous stirred tank reactors due to their operational simplicity. Because mass transfer between the gas and liquid phases typically is the rate limiting step, these reactor configurations are not economically viable at industrial scale due to the high energy cost of agitation. Bubble column reactors are particularly promising for large-scale production due to their low power requirements and low maintenance and operational costs (Munasinghe and Khanal, 2010). We have previously developed computational models of bubble column reactors for converting synthesis gas into ethanol with the bacterium

Clostridium ljungdahlii (Chen et al., 2015). More recently, we experimentally tested a model of a bench-scale bubble column reactor for converting CO into ethanol with *C. autoethanogenum* as the biocatalyst (Chen et al., 2018).

These models were based on highly simplified hydrodynamics, most notably ideal plug flow for the vapor phase and plug flow plus axial dispersion for the liquid phase. Industrial bubble column reactors are complex multiphase processes in which spatial variations in the superficial gas velocity, gas holdup and interfacial area can have profound effects on fermentation performance (Kantarci et al., 2005). In this paper, we demonstrate how two-phase hydrodynamics can be incorporated into our modeling framework and assess the impact of hydrodynamics on the performance of bubble column reactors with and without liquid recycle. The proposed approach allowed the effects of the superficial gas velocity, gas bubble size, gas holdup and gas-liquid mass transfer coefficient on CO conversion and ethanol production to be predicted.

2. Methods

The bubble column models consisted of a genome-scale reconstruction (GEM) of *C. autoethanogenum* metabolism, uptake kinetics for dissolved CO, reaction-convection-dispersion equations for the liquid phase, and reaction-convection equations plus hydrodynamic equations for the gas phase. The GEM developed for LanzaTech's proprietary *C. autoethanogenum* strain consisted of 1,102 metabolites and 1,103 intracellular and exchange reactions. The uptake kinetics for dissolved CO were specified to follow the Michaelis-Menten equation and accounted for CO inhibition. Uptake parameters were estimated from experiments performed at LanzaTech.

The simulated feed gas consisted of CO (50 mole %), CO_2 (20 mole %), and N_2 (30 mole %) to mimic an industrial waste gas stream. Flux balance analysis (FBA) calculations with the *C. autoethanogenum* GEM showed that CO uptake resulted in the production of ethanol, acetate, CO_2 and 2,3-butanediol. Neither CO_2 or N_2 were consumed. Therefore, extracellular mass balances were posed for *C. autoethanogenum* biomass, gas-phase and liquid phase CO and CO_2, and liquid-phase acetate, ethanol and 2,3-butanediol. Transport processes were assumed to occur only in the axial direction of the column such that the spatial variation could be captured by a single variable z.

Two column configurations were investigated, both of which assumed countercurrent flows of the liquid and gas streams. The recycle column (Figure 1) had liquid recycle from the bottom of the column to the top of the column, while liquid recycle was absent in the conventional column. The recycle column was more consistent with industrial practice (Chen et al., 2018), while conventional columns have been the focus of previous UMass research (Chen et al., 2015). Due to the high velocity of the liquid recycle stream (50 m/h) compared to the low velocity of the liquid media stream (0.6 m/h), the recycle column was characterized by low reaction rates relative to convective mass transfer rates. Therefore, the liquid phase was assumed to be well mixed rather than spatially varying. This assumption was validated by comparing predictions to a more complex model in which the liquid phase was spatially varying.

The incorporation of hydrodynamics is illustrated below for the recycle column. The liquid- and gas-phase mass balances have been reported previously (Chen et al., 2018) with the exception that the current model: (1) does not assume constant liquid- and gas-phase volume fractions; and (2) allows CO and CO_2 gas-liquid mass transfer

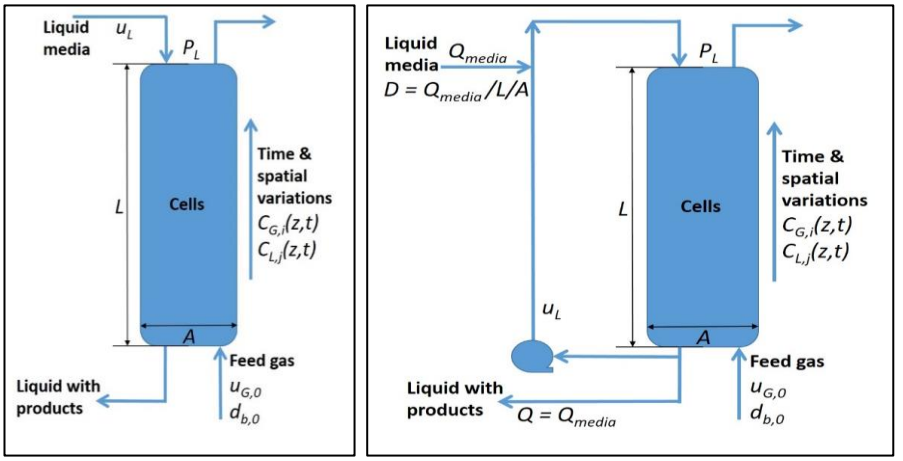

Figure 1. Schematic representation of the countercurrent bubble column reactors. $u_{G,0}$ and $d_{b,0}$ are the feed superficial gas velocity and bubble diameter, u_L is the liquid velocity, L is the reactor length, A is the reactor cross-sectional area, P_L is atmospheric pressure, Q_{media} is the media feeding rate, and D is the dilution rate.

coefficients to vary with time and spatial location according to the local interfacial gas-liquid mass transfer area. These variables were determined from the equations described below. The gas holdup was calculated from the one-dimensional drift-flux model,

$$\frac{u_G}{\varepsilon_G} = C_0(u_G + u_L) + v_b(1 - \varepsilon_G) \tag{1}$$

where ε_G is the liquid holdup, C_0 is the distribution parameter and v_b is the bubble rising velocity. The drift-flux model is commonly used for describing the relative motion of multiphase flows without solving the detailed momentum and energy equations. Eq. 1 is applicable to the bubbly flow regime and gas holdups less than 0.25 (Clark et al., 1990). The equation for bubble rising velocity had the form (Peebles, 1953),

$$v_b = 0.33g^{0.76}\left(\frac{\rho_L}{\mu_L}\right)^{0.52}\left(\frac{d_b}{2}\right)^{1.28} \tag{2}$$

where g is the gravitational constant, d_b is the bubble diameter, and ρ_L and μ_L are the density and viscosity of liquid phase.

The equation for bubble diameter had the form,

$$d_b = d_{b,0}\sqrt[3]{\frac{P_L n_G}{P n_{G,0}}} \tag{3}$$

where $d_{b,0}$ is the bubble diameter of the feed gas, $n_{G,0}$ is the molar flow rate of the feed gas and n_G is the local molar flow rate of the gas stream. This relation accounted for increasing bubble size due to decreasing pressure and decreasing size due to gas consumption. The following equation was used to calculate the superficial gas velocity,

$$u_G = u_{G,0}\frac{P_L}{P}\frac{n_g}{n_{g,0}} \tag{4}$$

where $u_{G,0}$ is the superficial velocity of the feed gas. The interfacial gas-liquid mass transfer area was calculated as,

$$a = \frac{6\varepsilon_G}{(1-\varepsilon_G)d_b} \tag{5}$$

Model parameters were obtained from the literature to the extent possible and are not reported here. The feed superficial gas velocity $u_{G,0}$ and bubble diameter $d_{b,0}$ were specified at atmospheric pressure and were pressure corrected to calculate the actual feed conditions. This approach was necessary because the pressure P_L at the bottom of the column depended on the gas holdup and was unknown until the model was solved. The model consisted of linear programs (LPs) for *C. autoethanogenum* metabolism, algebraic equations (AEs) for hydrodynamics, ODEs in time for liquid-phase mass balances, and partial differential equations (PDEs) in time and space for gas and dissolved gas mass balances. We used our solution strategy (Chen et al., 2015) based on spatial discretization of the PDEs followed by integration of the resulting differential-algebraic equation (DAE) system with embedded LPs with DFBAlab (Gomez et al., 2014). DFBAlab used the MATLAB code ode15s for DAE solution and Gurobi for LP solution.

3. Results and Discussion

To investigate the combined effects of hydrodynamics and liquid recycle, we developed four models: the conventional column (Figure 1A) with and without hydrodynamics and the liquid recycle column (Figure 1B) with and without hydrodynamics. The column models without hydrodynamics used constant values of the superficial gas velocity, gas holdup, gas bubble diameter and interfacial area. To facilitate meaningful comparisons, these values were specified as the corresponding values at the bottom of the column in the models with hydrodynamics. The conventional column models included equations for a spatially varying liquid phase (Chen et al., 2015) and used the same parameter values as the recycle column models except that a much smaller liquid flow rate was used to avoid reactor washout. Dynamic simulations were run for 500 h to obtain steady-state solutions. Because the conventional and recycle reactors had different exiting liquid flow rates, we plotted mass flow rates at the bottom of the column rather than concentrations.

Liquid recycle was predicted to generate high biomass concentrations compared to the conventional reactors without recycle (Fig. 2a) due to increased gas holdup and gas-liquid mass transfer (see below). Correspondingly, the recycle reactors were predicted to have higher CO gas conversion (Fig. 2c) and higher ethanol, acetate and 2,3-butanediol production (Fig. 2d-f). Ethanol and acetate were produced with an approximately equal selectivity for the four cases. By contrast, 2,3-butanediol was produced in appreciable amounts only with the recycle reactors. The conventional reactors produced higher dissolved CO concentrations (Fig. 2b) due to lower CO conversions and higher CO concentrations in the gas phase. The omission of hydrodynamic effects resulted in the overestimation of mass transfer performance, because in reality a significant reduction in gas residence time occurs due to bubble expansion (see below). For both column configurations, hydrodynamics were predicted to reduce biomass production, CO gas conversion, and ethanol, acetate and 2,3-butanediol production. The impact of hydrodynamics was most significant for the recycle reactor.

Differences in reactor performance between the four cases were analyzed with respect to the hydrodynamic variables. For either reactor configuration, the spatially varying hydrostatic pressure was predicted to have a substantial impact on superficial gas velocity (Fig. 3a), gas bubble diameter (Fig. 3b), gas holdup (Fig. 3c) and gas-liquid mass

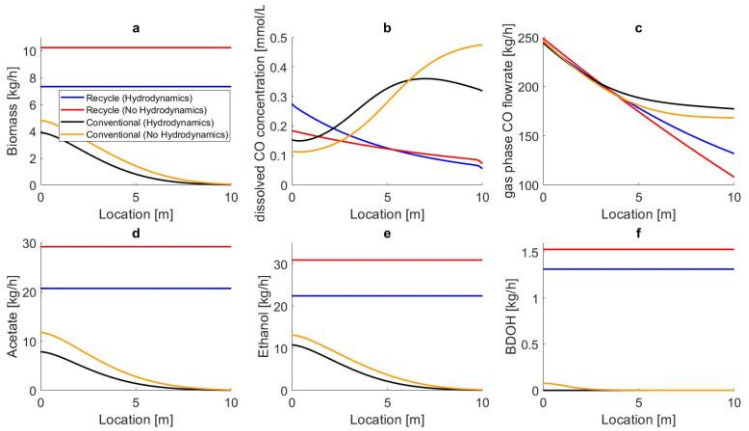

Figure 2. Steady-state production rate profiles predicted for two bubble column reactors (conventional, liquid recycle) with and without hydrodynamics. The liquid phase exited the column at $z = 0$ m and the gas phase exited the column at $z = 10$ m. Liquid-phase concentration profiles for the recycle reactors were flat due to the assumption of homogeneity.

transfer coefficient (Fig. 3d) variations across the column. The gas velocity and bubble diameter were predicted to increase along the length of the column because the effect of reducing hydrodynamic pressure was more significant than the effect of gas consumption (see Eq. 3 and 4). The drift-flux model predicted an increase in gas holdup along the column, primarily due to the increasing volumetric gas flow rate. The gas-liquid mass transfer coefficient was predicted to increase along the column because the effect of increasing gas holdup was more significant than the effect of increasing bubble size (see Eq. 5). The major differences between the conventional and recycle column models without hydrodynamics were the values of the gas holdup and the gas-liquid mass transfer coefficient. Liquid recycle yielded increased values of these two variables as well as a high volumetric flow rate, all of which remained constant along the column in the model where the hydrodynamic effect was neglected. Analogous predictions were obtained for the two column models with hydrodynamics.

Interestingly, liquid recycle was predicted to reduce *C. autoethanogenum* specific growth rates (Fig. 3e) and CO uptake rates (Fig. 3f) over most of the column compared to the conventional columns. The conventional reactors were predicted to have higher average specific CO uptake and specific growth rates due to higher dissolved CO concentrations. However, liquid recycle allowed the use of a media flow rate more than double that possible in the conventional column because recycle substantially increased the range of flow rates that did not result in reactor washout. Thus, the recycle reactors generated higher biomass and byproduct mass flow rates despite lower growth rates.

4. Conclusions

We investigated the impact of two-phase hydrodynamics on bubble column reactor performance by developing spatiotemporal metabolic models for conversion of carbon monoxide (CO) to ethanol using the microbial catalyst *Clostridium autoethanogenum*. The hydrodynamic model allowed the prediction of the superficial gas velocity, gas holdup, gas bubble diameter and interfacial area as a function of time and column location. The incorporation of hydrodynamics was predicted to substantially diminish

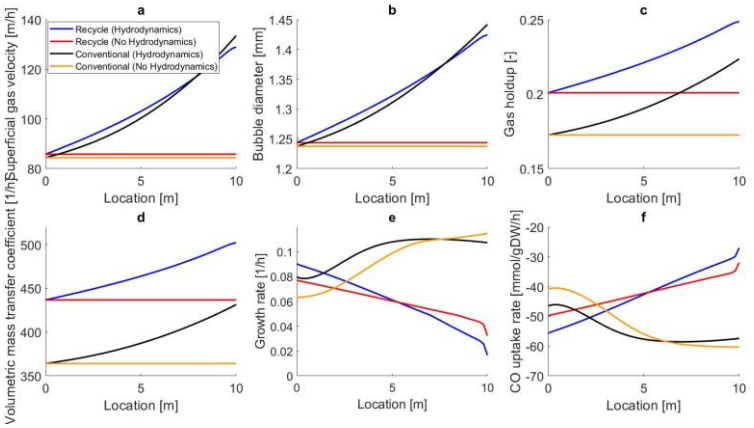

Figure 3. Steady-state profiles of hydrodynamic and GEM variables for two bubble column reactor configurations with and without hydrodynamics.

bubble column performance with respect to CO conversion, biomass accumulation and ethanol production. Therefore, we concluded that the inclusion of gas-phase hydrodynamics is important to generate high fidelity models of these complex multiphase processes. Our models also predicted that liquid recycle would substantially improve performance compared to a conventional reactor without recycle.

Abstract

Typical manufacturing bio-processes operate as multi-step batch operations. Abnormal variations are often experienced in commercial manufacturing which affects the ability to maintain the product supply to the patients. The low titer is usually highly correlated with high lactate in recombinant Chinese hamster ovary (CHO) cells producing immunoglobulin G, but there are limited means to analyze the vast amount of process data archived from manufacturing sites and understand the causes of the multiple sources of process variability. In this study, we investigate diverse data from a cell culture process, from historical runs of a multi-step manufacturing process for a recombinant antibody. Data includes intra-batch measurements, batch conditions and media preparation measurements. Cell culture process stages from inoculum train to production runs.

To analyze manufacturing variability in multiple stages with various sources of data sets, we first adopt principal component analysis (PCA) based monitoring to find in which space high lactate and low lactate batches can be separated, and apply clustering to identify fault directions for intra-batch data from production runs. We then predict final lactate using data from inoculum stages with a nonlinear support vector machine (SVM) classifier. These models are used to uncover potential causes of high lactate. This data-driven modelling can provide new insights on process characteristics to understand the sources of process variability and thus mitigation procedures can be implemented.

Keywords: process variability, cell culture process, PCA monitoring, SVM.

1. Introduction

Multi-step batch processes are widely used in pharmaceutical manufacturing and process variability may be experienced in these complex bioprocesses that utilize mammalian cells for production of recombinant protein therapeutics (Charaniya 2010). Data of enormous volume and various kinds are generated and collected from different cell culture process stages. Therefore, mining the historical data is pivotal to uncover the latent reasons that cause the process variability, and potentially provide means to detect them in early stages and improve process performance.

Low titer in CHO monoclonal antibodies (mAb) production is often correlated to lower cell growth and with high lactate production (Charaniya 2010). Several studies have employed lactate metabolism model to study this phenomena (Mulukutla 2015, Zagari 2013). For example, Mulukutla (2015) proposed a steady state topological metabolic model, indicating the mechanism of lactate consumption and accumulation can explain the cause of high lactate. Nevertheless, these knowledge-based models are built with lactate metabolic pathway simulation and can hardly be applied to the large-scale manufacturing process since concentrations of additional metabolites are needed, which is not done routinely in commercial manufacturing.

Multivariate analysis (MVA) is also a useful way to explore the bioprocess data (Nomikos 1995, 1996). Methods such as Multi-way principal component analysis (mPCA) and Multi-way partial least square (mPLS) have been extensively used to monitor batch process data. For example, Nomikos et al. (1995) applied mPCA and mPLS to extract the information in the trajectory data and developed simple monitoring charts for process fault detection.

This paper aims to investigate the cell culture process variability in multiple manufacturing stages with diverse bio-process data sets. Following introduction, Section 2 presents the large-scale cell culture process and characteristics of the data sets. Section 3 describes the detailed modelling procedure for process anomaly source analysis in different stages and their results. Conclusions and future work are discussed in Section 4.

2. Cell culture process and data set characteristics

In this study, we investigate 241 historical runs of large-scale cell culture process data during year 2008- 2015 from Genentech's facility. The recombinant CHO cells were expanded from inoculum train to production runs. For each stage, data includes offline measurements, initial batch conditions and media preparation measurements.

For each run, the lactate concentration at the end of the production process is measured, scaled to range 0-1 based on the min and max reading and used as the criterion to distinguish high performance run and low performance run. The distribution of the final lactate concentration is shown in Fig.1, runs are recognized as low performance (high lactate) if the normalized value is larger than 0.4, otherwise, are recognized as high performance (low lactate). There are 75 high lactate runs and 166 low lactate runs in total.

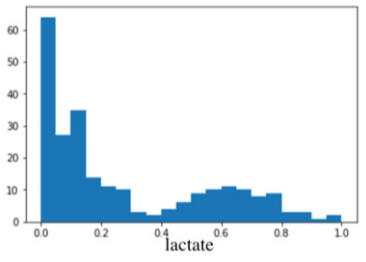

Figure 1 Final lactate concentration distribution

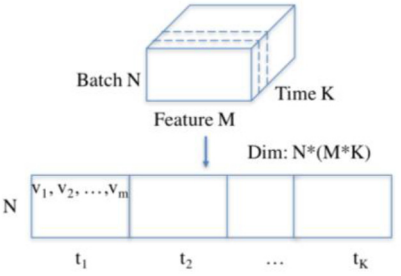

Figure 2 Process data unfolding

3. Multi-step batch data analysis

In this section, we describe how to find process anomaly source in multi-step bio-process. After unfolding the production run batch data, we first find a latent space, and apply clustering in this space to find different hidden patterns, we then adopt classification on inoculum run in order to diagnose the anomaly source in an early stage.

3.1. Intra-batch data preprocessing and unfolding

The features in the intra-batch data set are measured twice a day. After removing duplicates and filling missing data by local interpolation, each feature has 23 sampling points during the production runs. We focus on the first 13 sampling points before the irreversible lactate accumulation for high lactate runs is observed.

The intra-batch data is organized in a 3D tensor X (N * M * K) as shown in Fig.2. It contains n = 1, 2, …, N batch runs, where each of them has m = 1,2,…,M features with k = 1,2, …,K samples. To analyze it at batch level, we decompose it into a 2D matrix with dimension (N * (M * K)) (Nomikos 1995). The 2D matrix has dimension 241* 130, where each column represents a feature at a certain sampling timestamp.

3.2. Production run intra-batch data analysis

Fig.1 indicates that around 30% of the batches end with high lactate concentration, possibly there exist multiple reasons that are correlated to the abnormal lactate accumulation. In this section, we want to figure out how many potential patterns exist by applying clustering methods. The data sets used in this section are the intra-batch data in the production run. By applying unsupervised learning, we want to discover different hidden patterns of process data that are correlated to the final high lactate concentration.

3.2.1. PCA based monitoring

The high and low lactate batches cannot be separated in the original space, so we need to find a latent space in which they are separable. We first do PCA based monitoring on intra-batch data for all 166 low lactate batches, the number of PCs is selected as 48 since it can explain 95% of the total variance. We then calculate corresponding T2 and SPE control limit, which are 65.17 and 9.55 respectively (Qin 2003, 2012). The T2 index and SPE index for both high lactate and low lactate batches are plotted in Fig.3.

It can be observed that in residual space (Fig.3b), the high lactate and low lactate runs can be easily differentiated, while in the principle space, they cannot be easily differentiated. Therefore, further analysis will be performed on the residual space obtained by PCA monitoring.

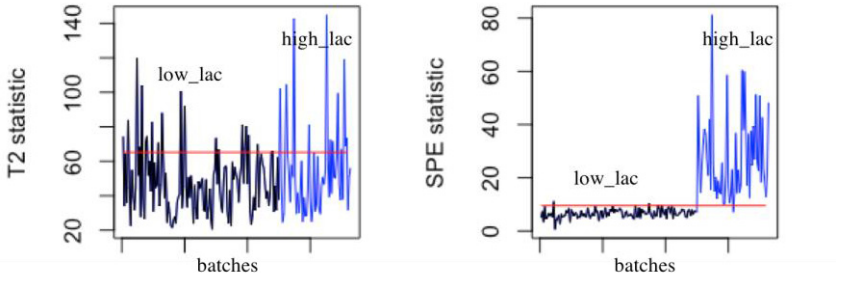

Figure 3. PCA monitoring results. a) in principal space b) in residual space

3.2.2. Hierarchical clustering

It is important to find hidden patterns in the intra-batch data; to achieve it, we perform hierarchical clustering on the residual space obtained by PCA monitoring for all high lactate batches. The number of clusters is 4, which is determined by the elbow method (Kodinariya 2013). Fig.4 shows the hierarchical clustering tree and Fig.5 shows the curve of within-cluster sum of square (WSS) corresponding to the number of cluster k.

To visualize the special distribution of the four high lactate clusters and the low lactate cluster, linear discriminant analysis (LDA) is performed. As shown in Fig.5, in the LD1 and LD2 plot, clusters 2 and 3 are separated and in the LD1 and LD3 plot, clusters 1 and 4 are separated as well.

The hidden patterns in different high lactate clusters can be visualized by the heatmap of every feature. For instance, Fig.7 shows the heatmap of packed cell volume (PCV) in residual space, it can be seen that cluster 2 has different pattern among others.

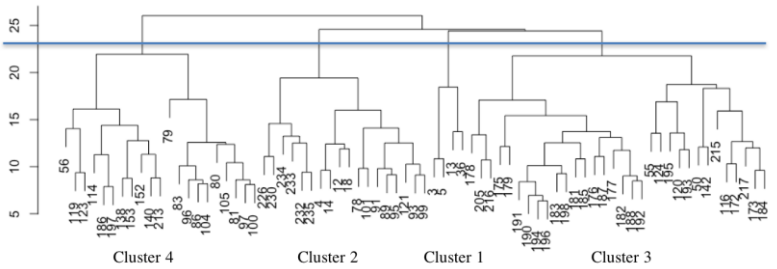

Figure 4. Hierarchical clustering tree

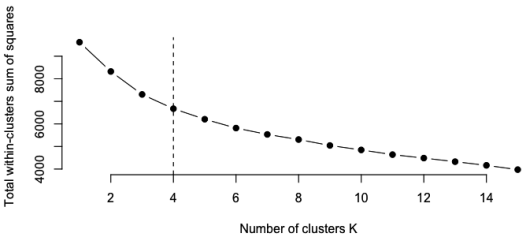

Figure 5. Elbow method to select the number of clusters

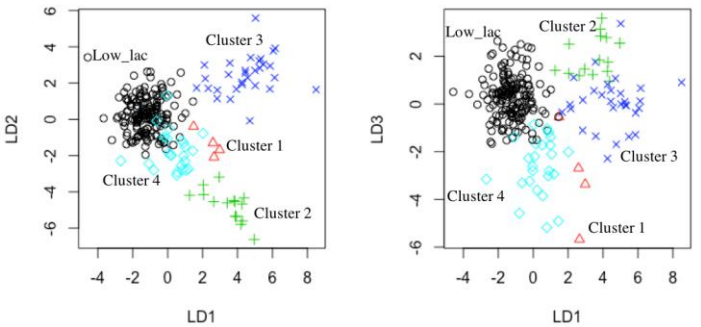

Figure 6. Overplot low lactate with high lactate clusters by LDA

3.3. Step-wise data analysis

In previous section, we discovered that there are four final high lactate clusters. Each cluster is potentially related to a specific reason. Though Fig.7 is helpful to better understand the process, these intra-batch features are mainly related to the cell physiology and chemical environment, which cannot be adjusted by the operators.

A more useful way is to identify the potential causes that can be adjusted in an early stage and make prediction before the production run starts. Therefore, in this section, we focus on the potentially adjustable features in inoculum N-1 train runs. These features are selected based on process knowledge, mainly from initial states, offline measurements, and media preparation data.

23 features are selected and LDA is used to reduce dimension, the corresponding results are in Fig.8. It can be observed that most of the batches in cluster 2 are not overlapped with others, meaning that the anomaly source for cluster 2 batches may happen in inoculum run. To differentiate the abnormal batches with the normal ones, we then use the first three LDs to train a support vector machine (SVM) classifier with RBF ($\gamma = 2$) kernel. In this model, batches in cluster 2 are labelled as abnormal and all others are as normal. The decision boundaries calculated by SVM are also plotted in Fig.8. This model has a good performance with type 1 error as 2.3 % and type 2 error as 20.6 %.

Further, we use box plot to represent features that cause cluster 2 to be separated, two features are selected as examples. It can be observed in Fig.9, low Na2CO3 per media volume and low initial osmolality are the most likely features that differentiate the high lactate batches in cluster 2.

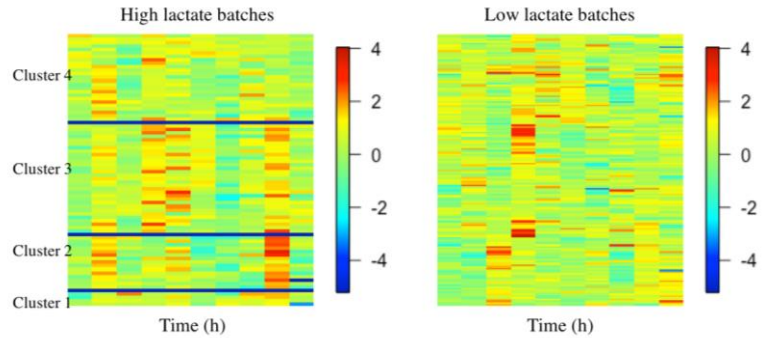

Figure 7. Hidden patterns of PCV in different clusters

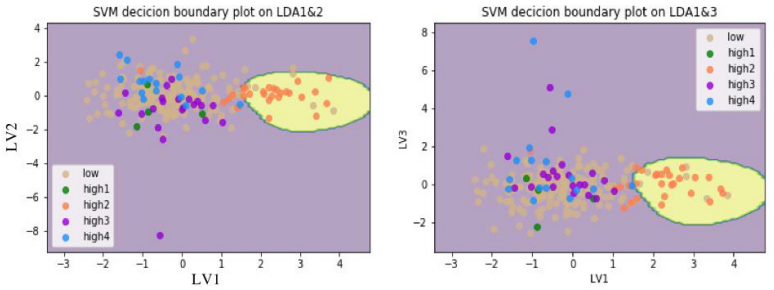

Figure 8. SVM boundary plot after LDA dimension reduction

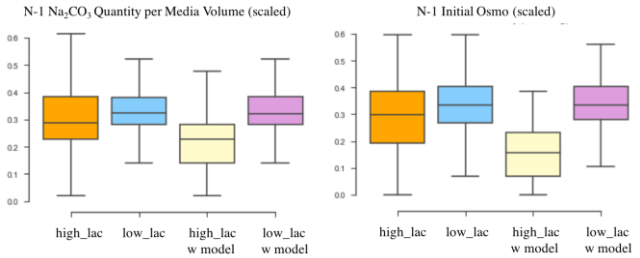

Figure 9. Box plot of the potential high lactate causes

4. Conclusions and future work

In this paper, we analyze the manufacturing variability in a multi-stage cell culture process with historical data. To find the hidden patterns within the data, we first adopt PCA based monitoring to find the latent space in which data is most separated, then apply clustering method. High lactate batches can be grouped into four different clusters. To make early prediction before the production run starts and to uncover potential causes of high lactate, we then adopt a nonlinear SVM classifier to analyze data in inoculum stage. In this way, the causes for cluster 2 batches are identified.

This modelling method provides new insights on process characteristics to understand the sources of process variability and help researchers form a data-driven experimental plan to confirm the root cause. Shortly, we will continue working on finding the high lactate causes related to other clusters. Other data sets such as the thaw data and raw material information will also be explored.

A System Identification Enhanced Phenotype Phase Plane Analysis

Matthew Hilliard[a], Andrew Damiani[a], Q. Peter He[a] and Jin Wang[a*]

[a] *Dept. of Chemical Engineering, Auburn University, Auburn, AL, 36849, US*
wang@auburn.edu

Abstract

Genotype-phenotype relationship is fundamental to biology, and predicting different phenotypes based on the sequenced genome is one of the main goals for genome-scale metabolic model development. Phenotype phase plane (PhPP) analysis is a powerful tool to provide a global perspective on the genotype-phenotype relationship, and to help characterize different metabolic phenotypes. However, the traditional PhPP analysis is based on shadow price analysis, which provides limited information to characterize different phenotypes. In this work, we propose a system identification (SID) enhanced PhPP, which not only obtains information that could be obtained through shadow price analysis, but also provides additional information that helps characterize different phenotypes. The effectiveness of the SID-PhPP approach is demonstrated using an illustrative cell model and a core metabolic network model of *E. coli*.

Keywords: Phenotype phase plane analysis, System identification, Genome-scale metabolic model, Shadow price.

1. Introduction

Systems biology is a rapidly evolving discipline that seeks to determine how complex biological systems function by integrating experimentally derived information through mathematical modeling. Genome-scale metabolic network models represent the link between the genotype and phenotype of the organism. In essence, a genome-scale metabolic model (GEM) is a comprehensive functional database of the organism's cellular metabolism (King et al., 2015; Sánchez and Nielsen, 2015), which consists of a set of metabolites, metabolic reactions (*i.e.*, stoichiometric matrix), and constraints. These models provide a holistic view of the organism's metabolism, and constraint-based metabolic flux analyses, such as flux balance analysis (FBA), have been used extensively to study genome-wide cellular metabolic networks (Kauffman et al., 2003). One major application of GEM is to predict different growth phenotypes (*e.g.*, how fast cells grow, what products are excreted) in various genetic and environmental conditions. Developed by the Palsson lab, phenotype phase plane (PhPP) analysis is a powerful tool that uses FBA with the GEM to provide a global perspective on the genotype-phenotype relationship, and to help characterize different metabolic phenotypes (Edwards et al., 2002). In PhPP analysis, the classification of different phenotypes is based on the shadow price of various metabolites, where a phenotype is defined by all the conditions where a metabolite's shadow price stays constant. However, shadow prices only describe how each metabolite affects the objective function of FBA, without providing any information on how different reactions interact with each other within the same phenotype. Therefore, when PhPP is applied to analyze GEMs, it is usually combined with other *in silico* simulations and gene deletions to

identify and explain the fundamental differences among different phenotypes (Duarte et al., 2004; Edwards et al., 2001).

To address this challenge, the system identification (SID) based framework that we previously developed for genome-scale metabolic model analysis (Damiani et al., 2015) is extended to enhance PhPP, which is termed SID-enhanced PhPP (SID-PhPP) analysis. In the SID framework, we first perturb the metabolic network through designed input sequences, *i.e.*, designed *in silico* experiments; then we apply multivariate statistical analysis tools such as principal component analysis (PCA) to analyze the *in silico* results in order to extract information on how such perturbations propagate through the network; finally, we visualize the extracted knowledge against the network map to provide meaningful and intuitive interpretations of the *in silico* results. The SID framework has been successfully applied to genome-scale model evaluation, as well as guiding the development of an improved genome-scale model of *Scheffersomyces stipites* (Damiani et al., 2015; Damiani et al., 2017). In this work, we first briefly review the traditional PhPP analysis and introduce the SID- PhPP method, using the same illustrative example provided in the original PhPP work (Edwards et al., 2002); then we use the core metabolic network model of *E. coli* to demonstrate the effectiveness of the proposed SID-PhPP approach, and show how a "hidden" phenotype that share the same set of shadow prices with another phenotype could be identified by the SID-PhPP approach.

2. Traditional PhPP Analysis

Metabolic phenotypes can be viewed as different metabolic network utilization profiles. Within each phenotype, all points (culture conditions) share the same set of activated pathways, and the same set of excreted products. In other words, the activated reactions and/or excreted products are different among different phenotypes. The traditional PhPP analysis provides a global view of each phenotype in genome-scale models by breaking down the metabolic behavior in distinct phases through shadow price analysis. Mathematically, shadow price of metabolite i is defined as $\gamma_i = -\frac{dZ}{db_i^v}$ where Z is the objective function of FBA and b_i^v denotes the additional availability for the metabolite (Edwards et al., 2002). In the traditional PhPP analysis, a phenotype is defined by all the culture conditions, defined by two independent variables (typically the carbon and oxygen source), where metabolites' shadow prices stay constant.

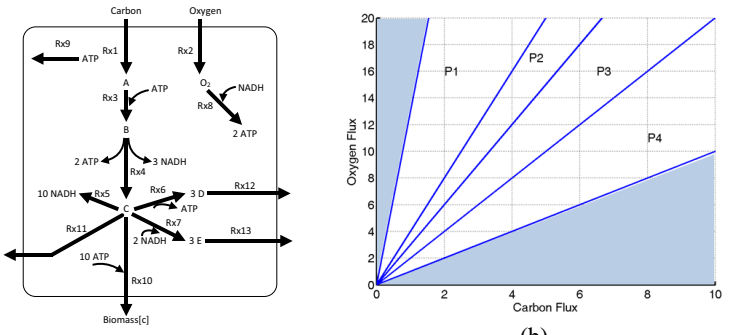

Figure 1. (a) The network map of an illustrative cell model; (b) Phenotype phase plane of the cell model.

Table 1. Shadow prices of different metabolites in different phenotypes

	Carbon	O_2	ATP	B	NADH	C	D	E	Biomass
P1	-1.30	0.10	0.00	-1.30	-0.10	-1.00	-0.33	-0.40	0.00
P2	-0.21	-0.17	-0.09	-0.30	-0.01	-0.09	0.00	-0.04	0.00
P3	-0.05	-0.23	-0.09	-0.14	0.05	-0.09	0.00	0.00	0.00
P4	0.50	-0.50	0.00	0.50	0.50	-1.00	-0.33	0.00	0.00

Here we use a simplified cell model to illustrate how PhPP analysis works. Figure 1 (a) shows the network map of the illustrative example, which was first introduced in (Edwards et al., 2002). Figure 1 (b) plots "phenotype phase plane" of the model cell, which exhibits 4 different phenotypes (*i.e.*, P1~P4). The boundaries between different phenotypes are determined by the shadow prices, with a few of them listed in Table 1. It is worth noting that, according to PhPP, a zero shadow price indicates the metabolite would be secreted because it has no effect on the objective function (Edwards et al., 2002).

3. The SID Enhanced PhPP Analysis

The SID-PhPP is proposed in this work as an alternative approach to characterize different phenotypes. Figure 2 provides an overview of the SID-PhPP. The same illustrative example from Section 2 is used to demonstrate how SID-PhPP works. First, the designed one-dimensional *in silico* experiments are conducted to determine the boundaries of the different phenotype phases. As shown in Figure 3 (a), one set of designed experiments is to hold carbon uptake flux constant while varying oxygen update. Next, PCA was applied to analyze the resulted flux matrixes, and the resulted scores corresponding to the first principal component (PC) are plotted in Figure 3 (b). Each linear segment in the score plot indicates one phenotype, and Figure 3 shows that the phenotype boundaries determined through SID-PhPP exactly match those determined through shadow price analysis. It is worth noting that SID-PhPP does not require running simulations that cover the whole plane. Instead, only few sets of one-dimensional *in silico* experiments are needed to determine the phenotype boundaries.

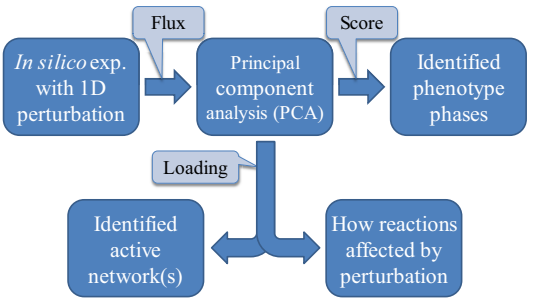

Figure 2. Overview of the SID enhanced PhPP

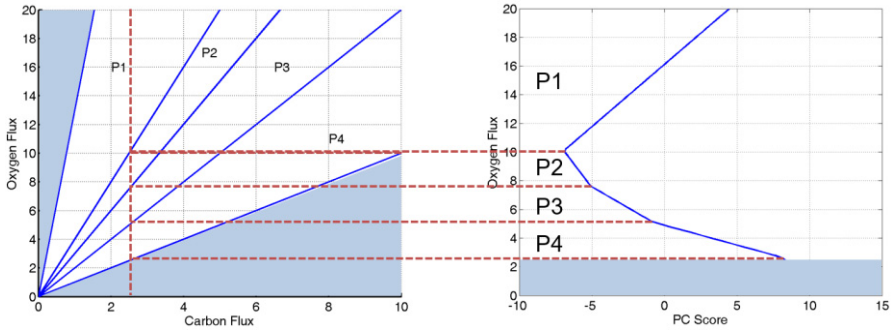
In the next section, we use the *E. coli* core model as an example to illustrate how SID-based framework can help characterize different phenotypes, as well as to discover "hidden" phenotypes that share the same set of shadow prices with another phenotype.



(a) (b)

Figure 3. (a) Designed in silico experiments at fixed carbon uptake and varying oxygen uptake; (b) Phenotype boundaries determined through PC scores.

4. Application to *E. coli* core model

4.1. E. coli core model

The central carbon metabolic model of *E. coli* proposed by Orth et al. (2010) contains 95 reactions and 72 metabolites, with major reaction pathways including glycolysis, both branches of the pentose phosphate pathway (PPP), TCA cycle, and electron transport chain. The two substrates chosen for this study are glucose and oxygen. Five by-products could be excreted are CO_2, lactate, formate, ethanol, and acetate. The biomass reaction is used as the objective function.

4.2. The traditional PhPP analysis

First, the traditional PhPP was applied to predict phenotypes based on the *E. coli* core model, which results in 4 different phenotypes (P1~P4) as shown in Figure 4 (a), with different by-products excreted (Table 2). The shadow prices of a few key metabolites are listed in Table 3. It is worth noting that although formate has shadow price of 0 for all 4 phenotypes, it is only excreted in P3 and P4, not in P1 or P2. For ethanol, although its shadow price is not zero for P4, FBA simulations show that ethanol is excreted in P4; similarly for acetate, although its shadow price is not zero for any phenotypes, it is excreted in P3 and P4 confirmed by FBA simulations. This finding indicates that the statement about zero shadow price by Edwards et al. (2002) is inaccurate.

Table 2 By-products excreted in different phenotypes

Phase	By-products
P1	CO2
P2	CO2
P3	Acetate, Formate, CO2
P4	Acetate, Formate, Ethanol

Table 3 Shadow prices of some key metabolites in different phenotypes

Metabolite	P1	P2	P3	P4
Glucose	-0.1373	-0.0459	-0.0325	-0.0304
Oxygen	0.0229	-0.0230	-0.0325	-0.0359
CO2	0	0	0	-0.0014
Formate	0	0	0	0
Acetate	-0.0458	-0.0026	-0.0027	-0.0028
Ethanol	-0.0686	-0.0128	-0.0054	-0.0028

4.3. The SID-enhanced PhPP analysis

SID-PhPP is performed to analyze the same model, with results shown in Figure 4 (b). It can be seen that SID-PhPP identified 5 different phenotypes. Three of them (P1, P2 and P4) are the same as those identified by the traditional PhPP, while P3 identified by the traditional PhPP is split into two phenotypes (P3' and P3") by SID-PhPP. It is confirmed that the shadow prices of different metabolites in P3' and P3'' are exactly the same as those of P3 listed in Table 3. According to the traditional PhPP, P3' and P3" should be the same phenotype. However, SID-PhPP analysis shows that, for *in silico* experiments conducted in P3, the resulted scores form two linear segments, indicating two different phenotypes. To determine whether the two linear segments represent two different phenotypes, we visualized the SID-PhPP analysis results against the network map for P3' and P3'' in Figure 5 (a) and (b), respectively. Figure 5 clearly shows that P3' and P3'' are two distinct phenotypes, with different activated reaction pathways (oxidative PPP active in P3', while inactive in P3") and different by-product excretion patterns (acetate only in P3', while acetate and formate in P3"), although they share the same set of shadow prices.

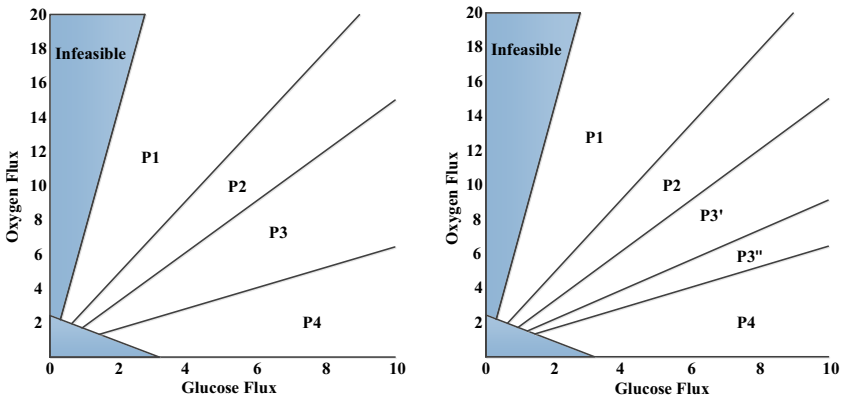


Figure 4. (a) The traditional PhPP reveals four different phenotypes; (b) The SID-PhPP reveals five different phenotypes.

5. Conclusions

Genome-scale metabolic network models represent the link between the genotype and phenotype of the organism, and phenotype phase plane analysis is a prevalent method to characterize different phenotypes predicted by genome-scale model. However, certain limitations exist for the original PhPP analysis approach. For example, as we have shown using the *E. coli* core model, the metabolites with zero shadow prices are not always excreted, while the metabolites with non-zero shadow prices could be excreted. This is because the shadow prices only quantify the effect of the overall flux of a metabolite on the FBA objective function, without taking the interactions among different activated pathways into account. However, it is the interactions among different activated pathways that determine the function and behaviour of a given phenotype. To address this limitation, we propose SID enhanced PhPP in this work. In the SID-PhPP, the designed *in silico* experiments are conducted to determine the boundaries between different phenotypes with significantly reduced computation. More importantly, SID-PhPP provides additional information that help fully characterize

different phenotypes. The effectiveness of the SID-PhPP approach is demonstrated using an illustrative example and a core metabolic network model of *E. coli*. Our results show that SID-PhPP is a powerful tool for revealing the metabolic capability of a metabolic network model, and enables better and more intuitive systems level understanding which provides the foundation for improved strain development.

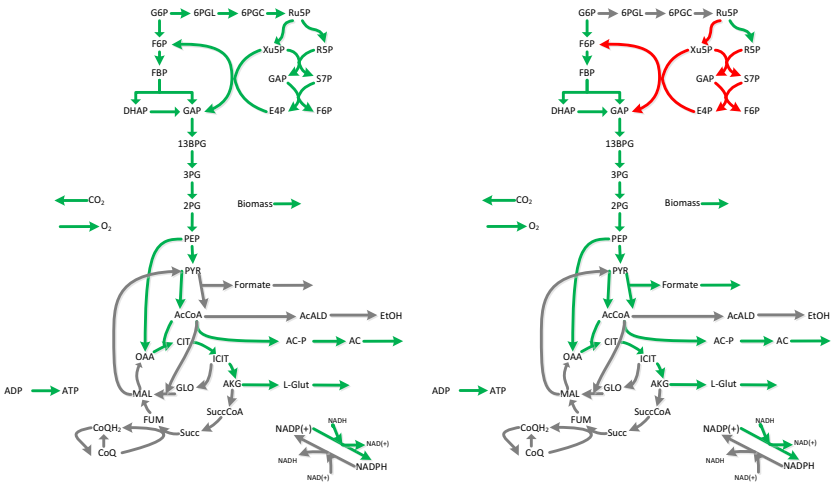

Figure 5. Different activated pathways and by-product excretion patterns in P3' (a) and P3'' (b) with an increasing oxygen uptake, where green arrows indicating increasing flux, red arrows indicating decreasing flux.

Abstract

Real-time energy pricing has caused a paradigm shift for process operations with flexibility becoming a critical driver of economics. As such, incorporating real-time pricing into planning and scheduling optimization formulations has received much attention over the past two decades (Zhang and Grossman, 2016). These formulations, however, focus on 1-hour or longer time discretizations and neglect process dynamics. Recent analysis of historical price data from the California electricity market (CAISO) reveals that a majority of economic opportunities come from fast market layers, i.e., real-time energy market and ancillary services (Dowling et al., 2017).

We present a dynamic optimization framework to quantify the revenue opportunities of chemical manufacturing systems providing frequency regulation (FR). Recent analysis of first order systems finds that slow process dynamics naturally dampen high frequency harmonics in FR signals (Dowling and Zavala, 2017). As a consequence, traditional chemical processes with long time constants may be able to provide fast flexibility without disrupting product quality, performance of downstream unit operations, etc. This study quantifies the ability of a distillation system to provide sufficient dynamic flexibility to adjust energy demands every 4 seconds in response to market signals. Using a detailed differential algebraic equation (DAE) model (Hahn and Edgar, 2002) and historic data from the Texas electricity market (ECROT), we estimate revenue opportunities for different column designs. We implement our model using the algebraic modeling language Pyomo (Hart et al., 2011) and its dynamic optimization extension Pyomo.DAE (Nicholson et al., 2017). These software packages enable rapid development of complex optimization models using high-level modelling constructs and provide flexible tools for initializing and discretizing DAE models.

Keywords: electricity markets, demand response, smart manufacturing, nonlinear programming, distillation

1. Introduction: Frequency Regulation Markets

Modern electricity infrastructures use complex hierarchical wholesale markets to coordinate generation, loads, and transmission networks. This results in temporal and spatial variations in prices set at multiple timescales (e.g., 1-hour prices in day-ahead markets, 5- to 15-minute prices in real-time markets) that directly impact large electricity producers/consumers including traditional utility companies, aggregators, and some

industrial sites. Dowling et al. (2017) and Zhang and Grossmann (2016) provide thorough background in electricity markets and emphasize emerging opportunities for industrial participants. Many recent studies focus on extending planning and scheduling formulations to account for time-sensitive energy prices.

Ancillary services, i.e., spinning/non-spinning reserves and frequency regulation capacity, are critical to provide contingency at fast timescales (minutes to seconds) and ensure grid reliability. Resources providing reserve capacity are compensated for making a commitment to either increase generation or shed load if dispatched. Often this dispatch occurs once a week or less and can provide new revenue opportunities for flexible industrial sites. Zhang et al. (2015) explore optimal scheduling strategies of reserve capacity under uncertainty for air separation units. Analysis of California market data shows that frequency regulation offers significantly greater revenue opportunities, but also requires more intimate integration with the grid (Dowling et al., 2017). Resources providing FR capacity must adjust their energy production/demands every 4 seconds in accordance with grid dispatch. As such, this market opportunity has received significantly less attention as it requires careful consideration of system dynamics. Dowling and Zavala (2017) formulated FR capacity allocation as a dynamic optimization problem,

$$
\begin{aligned}
&\min \int_0^{t_f} \phi\big(z(t), u(t), d(t)\big) dt \\
&\text{s.t.,} \quad \dot{z} = f(z(t), u(t), d(t)) \\
&\qquad g(z(t), y(t), d(t)) \leq 0 \\
&\qquad y(t) = h(z(t)) \\
&\qquad d(t) = r_+ \beta_+(t) - r_- \beta_-(t) \\
&\qquad 0 \leq r_+, r_-
\end{aligned}
\tag{1}
$$

where $z(t)$ represents the states, $y(t)$ represents the observations, $u(t)$ represents the controls, and $d(t)$ represents the disturbances. The (non)linear functions $f(\cdot)$, $g(\cdot)$, and $h(\cdot)$ capture the system dynamics, operating restrictions, and transformation from states to observations, respectively. In this formulation, the dispatch signals coming from the grid for regulation up and down are encoded in β_+(t) and β_-(t), respectively, and are treated as disturbances. The economic objective is often $\phi = r_+\pi_+ + r_-\pi_-$ where r_+ and r_- are the committed regulation up and down capacities during an hour and π_+ and π_- are the respective capacity prices. Thus, problem (1) seeks to maximize the revenue from frequency regulation capacity (i.e., maximizes the size of the disturbance) while determining a control strategy that maintains operational feasibility. This formulation is a generalization of Fares et al. (2014), which focuses exclusively on grid-scale redox flow batteries. Other emerging FR market participants include aluminium smelters (Zhang and Hug, 2014) and commercial HVAC systems (Lin et al., 2015).

2. Mathematical Models and Software Implementation

Many industrial sites have on-site utility plants that can directly participate in electricity markets. In this context, providing FR capacity requires either modulating electricity

demands of equipment such as pumps, arc furnaces, etc. (Zhang and Hug, 2014) or modulating steam production rates. Using the general formulation (1), Dowling and Zavala (2017) characterized revenue opportunities for a methanol-water distillation system providing FR by adjusting the energy input (reboiler steam flow rate). A key limitation of this analysis is that it relies on the simple two-input two-output transfer function model from Wood and Berry (1973) for a laboratory-scale system. Instead, the present work combines optimization formulation (1) with more detailed differential algebraic equation models. Thus, we seek to extend the results to industrial scale systems and explore how design decisions (e.g., holdup capacities) impact system dynamics and thus revenue opportunities. We start by considering the dynamic model from Hahn and Edgar (2002) adapted to a methanol-water separation with 8 trays:

Total condenser (tray 1): $\frac{dx_1}{dt} = \frac{1}{A_{cond}} V(y_2 - x_1)$ (2)

Rectifying trays (i = 2, …, 4): $\frac{dx_i}{dt} = \frac{1}{A_{tray}} [L_r(x_{i-1} - x_i) - V(y_i - y_{i+1})]$ (3)

Feed tray (i = 5): $\frac{dx_i}{dt} = \frac{1}{A_{tray}} [F\, x_f + L_r\, x_{i-1} - L_s\, x_i + V(y_i - y_{i+1})]$ (4)

Stripping trays (i = 6, …, 9): $\frac{dx_i}{dt} = \frac{1}{A_{tray}} [L_s(x_{i-1} - x_i) - V(y_i - y_{i+1})]$ (5)

Partial reboiler (tray 10): $\frac{dx_i}{dt} = \frac{1}{A_{reb}} [L_s\, x_{i-1} - (F - D)x_i - V\, y_i]$ (6)

Condenser mass balance: $V = L_r + D$ (7)

Saturated liquid feed quality: $L_s = L_r + F$ (8)

Reflux ratio: $R = \frac{L_r}{D}$ (9)

Constant relative volatility (i = 2, …, 10): $\alpha = \frac{y_i(1-x_i)}{(1-y_i)\, x_i}$ (10)

Reboiler energy balance: $Q = \Delta H_{vap} V$ (11)

where index *i* indicates the tray, $x(t), y(t)$ are mole fractions of methanol, F and x_f are the constant feed flow rate and composition, $L_r(t)$ and $L_s(t)$ are the liquid flow rates in the rectifying and stripping sections, respectively, $V(t)$ is the vapor flow rate, $D(t)$ is the distillate product flow rate, $R(t)$ is the reflux ratio, $Q(t)$ is the reboiler duty, and ΔH_{vap} is the constant heat of vaporization (40 kJ/mol). This model assumes constant total molar holdups ($A_{cond} = 0.5,\ A_{tray} = 0.25,\ A_{reb} = 1.0$ mol), constant molar overflow, and constant relative volatility ($\alpha = 4.02$). Eqns (2) – (8) arise from mass balances, Eqn (9) is a definition, and Eqn (10) captures vapor-liquid equilibrium. Eqns (2) – (10) are from Hahn and Edgar (2002), whereas Eqn (11) was added to calculate the reboiler energy input. Similar to Dowling and Zavala (2017), we use the reboiler duty to track the regulation signal as follows:

$$Q(t) = \beta_+(t)\, r_+ - \beta_-(t)\, r_- + \bar{Q} \quad (12)$$

where $Q(t)$ is the time-varying reboiler duty, $\beta_+(t)$ and $\beta_-(t)$ are the regulation tracking signals (input data), r_+ and r_- are the regulation capacity commitments (decision-variables) and $\bar{Q}$ is the reboiler duty offset (decision-variable). For most industrial sites, the distillation system would not be bidding by itself into the market, but instead the electricity generation of the onsite utility system would be modulated to track the FR signal. This would cause variations in the steam production flowrate, which would be absorbed by the flexibility of several steam consumers. The present study focuses on the distillation system and does not consider dynamics of the utility plant. Thus Eqn (12) is a simplification and corresponds with an electrically heated reboiler. Using operational

bounds on the distillate $0.92 \leq y_1(t) \leq 1.0$, bottoms $0.0 \leq x_{10}(t) \leq 0.02$, and reflux ratio $0.1 \leq R(t) \leq \rho$ and Eqns (2) – (12), we express the FR market participation problem in the form of (1). Unit conversions are omitted for brevity.

For each hour of data, we solve a nonlinear program (NLP) to determine the regulation capacity commitments, $\boldsymbol{r_+, r_-}$, and optimal reflux ratio control profile, $\boldsymbol{R(t)}$, that maximizes FR market revenue while satisfying path constraints (i.e., product quality bounds). Input data were obtained from the ERCOT website[1] and include the regulation capacity prices, $\boldsymbol{\pi_+, \pi_-}$, which are set in 1-hour intervals and the regulation dispatch signals, $\boldsymbol{\beta_+(t), \beta_-(t)}$, which are available in 4-second intervals. These models are implemented in Pyomo and Pyomo.DAE. Pyomo is an algebraic modeling language built on top of the Python programming language and Pyomo.DAE is an extension to Pyomo for representing and solving dynamic optimization problems. Moreover, Pyomo.DAE allows us to directly implement the derivatives and differential equations in Eqns (2) – (12), exploit DAE simulation tools for initialization, and automate the transformation of the continuous-time model into a discrete approximation. For this particular problem, we choose a backwards Euler discretization (although several other discretization schemes, including collocation over finite elements, are also natively supported in Pyomo.DAE) with a 4-second time step to match the resolution of $\boldsymbol{\beta_+(t), \beta_-(t)}$. A 1-hour horizon resulted in a NLP with approximately 32,000 variables (with bounds) and equality constraints. IPOPT (Wächter and Biegler, 2006**)** was used to solve these problems, requiring up to 5 minutes per instance.

3. Results and Discussion

The previously described NLP was solved for each hour of March 1st, 2016 using historical market data $\pi_+, \pi_-, \beta_+(t), \beta_-(t)$ as input parameters. Figure 1 shows the time-evolution of the bottoms composition, distillate composition, and reflux ratio. For the bottoms composition and the reflux ratio, the upper bounds are active during the first 1-hour horizon.

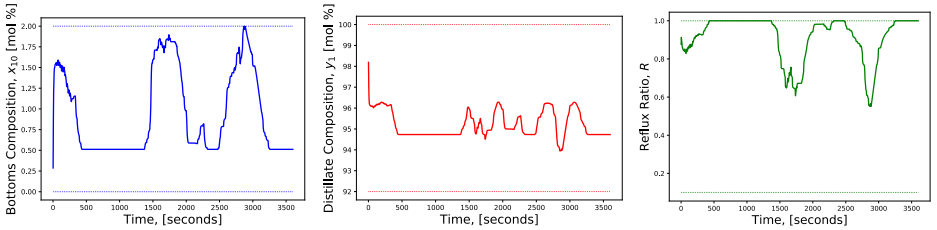

Figure 1. Composition of the bottoms (left), composition of the distillate (center), and reflux ratio (right) as a function of time with $\rho = 1$. Dashed lines indicate operational bounds.

A key advantage of model Eqn (2) – (12) and formulation (1) is the ability to explicitly connect design decisions with revenue opportunities from FR markets. Interestingly, we find that increasing the reboiler holdup A_{reb} from 1.0 mol to 10.0 mol only increases revenues by 3 %. This trend makes sense as larger holdups give rise to slower system dynamics which further increases the ability to reject fast market signals. We also find that revenues are extremely sensitivity to the maximum reflux ratio ρ as shown in Figure 2.

[1] http://www.ercot.com/mktrules/pilots/frrs

Furthermore, realizing the revenues for $\rho = 10$ requires dramatic changes in the reflux ratio, which may not be acceptable to operators. This is because of the constant holdup and constant molar overflow assumptions in the system model. The vapor flow rate V and thus reboiler duty Q are tightly coupled with the reflux ratio R, and thus ρ acts as an implicit bound on Q and thus regulation capacity. Furthermore, the chosen composition operating bounds are such that the upper bound on R limits the FR capacity and not the system dynamics. Again, this explains why revenues weakly depends on A_{reb}. These insights are not available from the transfer function model previously analysed.

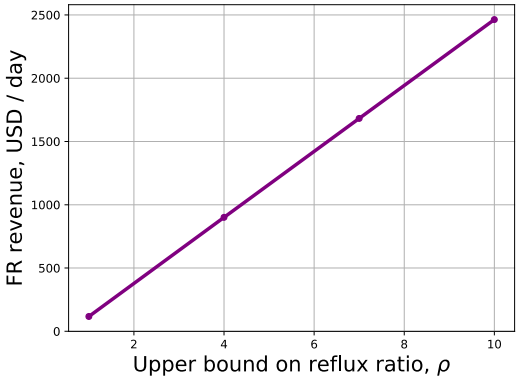

Figure 2. Sensitivity analysis of revenue with respect to the upper bound for reflux ratio (ρ). Revenue is scaled for nominal reboiler duty of 1 MW.

4. Conclusions and Future Directions

Opportunities in FR markets are emerging for chemical industrial systems. Their inherently slow dynamics filter out high-frequency disturbances from market signals. This paper expands upon a dynamic optimization framework that explicitly calculates revenue opportunities from historic market data and dynamic process models. We believe that the presented modelling and optimization tools are an essential first step to understanding and exploiting revenue opportunities ranging from \$100 to \$2,500 / day for a 1 MW (nominal) system. In the presented distillation case study, sensitivity analysis is used to understand how design decisions impact system dynamics and market revenues. In particular, we find that column diameter (which limits reflux ratio) is much more important than reboiler holdup capacity. Pyomo and Pyomo.DAE facilitate rapid model development, debugging, initialization, and automation of data-driven analysis, which has historically been difficult for dynamic optimization with algebraic modelling languages such as GAMS, AMPL, AIMMS, etc.

As future work, we plan to consider more detailed dynamic models with variable material holdups, such as those from López-Negrete et al (2013). We hypothesize that the current case study underestimates the flexibility and thus revenue opportunities of distillation systems because holdup capacities are fixed. We anticipate that it is possible to further increase the range of feasible energy inputs by strategically controlling holdups levels. An industrial FR capacity provider would likely exploit flexibility from several sources. We plan to investigate other equipment (e.g., pumps) as well as plant-wide coordination schemes. Moreover, the present analysis assumes perfect information and may overestimate realistic market revenues. As future work, we plan to characterize the impact

of market uncertainty on chemical manufacturing systems, and anticipate PySP, a separate Pyomo extension for stochastic programming, will be especially helpful (Watson et al, 2012). Finally, we plan to expand the case study to balance new market revenue against operating costs from more dynamic operation such as equipment wear-and-tear.

Abstract

Unused renewable resources can be collected in some regions as, for example, agricultural or forestry residues. To corroborate such locally available resources with energy systems mainly composed of fossil resources, technologies for their sourcing, transferring, storing, and operating should be systematically selected and integrated into a system. In this paper, we tackled with the design support of smart energy systems, where locally available resources are utilized and collaborated with fossil-based conventional systems. To demonstrate the design of energy system, a case study in isolated islands in Japan was conducted, where the power grids are not connected with other islands and can be regarded as microgrids. The solutions for the design of regional energy systems are generated through the consideration of local availability of renewable resources. As the technologies utilizing local resources, photovoltaic, biomass-derived combined heating and power, and biomass-derived boilers were taken into account, and existing developed models were utilized in this paper for the analysis of designed smart energy systems. The design results demonstrated that the utilization of locally available biomass can become strong options for the isolated islands whereas strategic reconstruction of the industrial cooperating networks should be incorporated. Bridging the gaps of the objective functions and constraints among existing industries should be addressed by computer-aided visualization and simulation as a design support.

Keywords: Micro grid, Bagasse, Timber, combined heating and power.

1. Introduction

The design of energy systems has become an issue in all over the world. A single optimal system cannot be suggested, because the availability of infrastructure and resources should be considered locally. Unused renewable resources can be collected in some regions as, for example, agricultural or forestry residues. For example, the utilization of forest biomass as energy source has become practical in some regions in European Union (EU), where forest biomass supplies over 50 % of renewable energies (Bentsen and Felby 2012). To collaborate such locally available resources with energy systems mainly composed of fossil resources, technologies for their sourcing, transferring, storing, and operating (Kato et al., 2016) should be systematically selected and integrated into a system. Simulation-based design support is necessitated for specifying possible solutions

considering multiple requirements on energy such as low carbon resources, high stability, and high economic performance.

In this study, we tackled with the design support of smart energy systems, where locally available resources are utilized and collaborated with fossil-based conventional systems. To demonstrate the design of energy system, a case study in isolated islands in Japan is conducted, where the power grids are not connected with other islands and can be regarded as microgrids. The solutions for the design of regional energy systems are generated through the consideration of local availability of renewable resources. As the technologies utilizing local resources, photovoltaic, biomass-derived combined heating and power (CHP), and biomass-derived boilers are taken into account, and existing developed models on cane sugar mills (Ouchida et al., 2017) and woody biomass (Kanematsu et al., 2017a) are utilized in this paper for the analysis of designed smart energy systems.

2. Materials and method

2.1. Concepts for smart energy systems in isolated islands

The meaning of "smart" energy systems has been discussed with diversities on their sourcing, operability, resilience, security, and responses for demands (Kikuchi, 2017a). The common premises can be regarded as the utilization of renewable resources which are usually treated as less stability, controllability, and usability than fossil resources. Energy systems should be able to equip somehow redundancy with reasonable socioeconomic costs to accept the fluctuation of renewable resources. Especially in isolated islands where industries have difficulties in procurements of fossil fuels, the utilization of locally available resources such as the residues of agriculture and forestry has been desired by local governments and industries.

In Tanegashima, an isolated island in Japan, a cane sugar mill is operated to produce raw sugar, where a bagasse-based CHP plant is utilized and a plenty of unused energy is generated (Kikuchi et al., 2016). In other words, the bagasse can provide energy not only for sugar milling but also other energy demand. For example, the processing potato factories for Shochu or starch needs around 100 to 130 °C which is not high temperature heat and can be supplied by the excess low-pressure steam in the sugar mill (Kikuchi et al., 2016). The developing thermal energy storage and transport system can also be employed to decrease the fossil fuel utilized in such factories (Fujii et al., 2016). At the same time, woody biomass can also supply the heat with such temperature. Because appropriate forestation and harvesting has been needed for sustainability in ecosystem (Oosawa et al., 2016), the timber demand for fuel is one of the option. The cane sugar mill is only operated for five months each year, from December to April, the harvesting season for sugarcane. The expanded use of bagasse-based CHP that burns excess bagasse and/or forest biomass in off-season of sugar production can be considered. The installation of a decentralized biomass CHP is also possible as the option for energy systems.

2.2. Case examples of design problem

Adequate resource allocation should be addressed for integrated design of multiple energy systems due to the limitation of resource within one region. Design support of smart energy system should be able to make a consensus on such allocation based on some evaluation indicators such as environmental impacts (Kanematsu et al., 2017c) and

social values (Kikuchi et al., 2017b). In this paper, case examples on forest resources were shown for demonstrating the design problems on locally available resources. Forest resource availability should be estimated based on the long-term forest reformation against the maldistribution of age-class (Oosawa et al., 2016). Two CHP plants were taken into account in this case study: in-house CHP at cane sugar mill (CHP1) and decentralized CHP located at city center (CHP2). CHP1 has the specific capacity for meeting the heat and power demands at cane sugar mill, e.g., 1,750 kW_e in Tanegashima (Kikuchi et al., 2016). On the other hand, the CHP2 at city center can be adjusted for the timber availability by adopting small packaged CHP units, i.e., 40 kW_e power + 70 kW_{th} heat per unit, and their parallelization (Kanematsu et al., 2017a). The power is sold for the micro grid, while the heat is only utilized for the demand at cane sugar mill (Kikuchi et al., 2016) in CHP1 and connected buildings around CHP2, which was estimated by the data conversion of investigated actual heat demands in Tanegashima as shown in Figure 1. The greenhouse gas emission from the life cycle (LC-GHG) of energy facilities was evaluated in this paper.

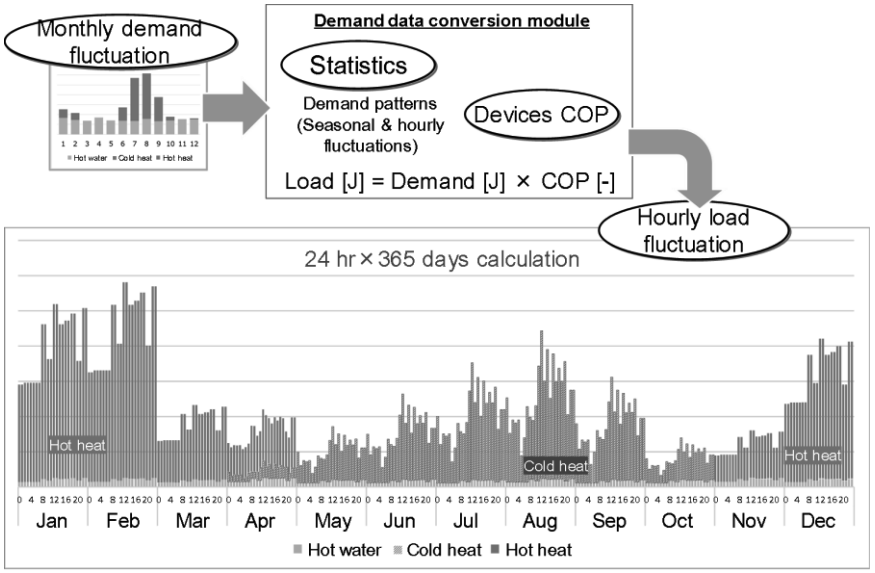

Figure 1 Data conversion of monthly demand of heat in Tanegashima, where the monthly data was investigated from actual buildings. The coefficient of performance (COP) of installed devices was also obtained from the investigation.

3. Results and discussion

3.1. LC-GHG emission reduction by timber utilization

Figure 2 shows the LC-GHG results for the forest resource allocation in Tanegashima. The LC-GHG can be reduced by the installing decentralized small-packaged CHP units in CHP2, which can replace both of heat and power around CHP2. The fuel needs for heating were larger in CHP2 than CHP1. While such local energy demand should be addressed in the design of CHP, the power can replace the fossil fuel burned at the centralized power plants by CHP1 and CHP2. As the LC-GHG of micro grid has relatively higher than that of power grids in the other areas of Japan, the locally available

resources have an advantage in isolated islands rather than those in the other areas. Thus, the increase of small-packaged CHP units resulted in the decrease of LC-GHG because their power conversion efficiency is higher than that of CHP1 which utilize back pressure steam turbine. To pay back the LC-GHG induced by the forestry to keep the reforestation at Tanegashima, ten, nine, and eight units of CHPs are required in CHP2 in three resource availability cases, i.e., Figure 2 (a), (b), and (c), respectively.

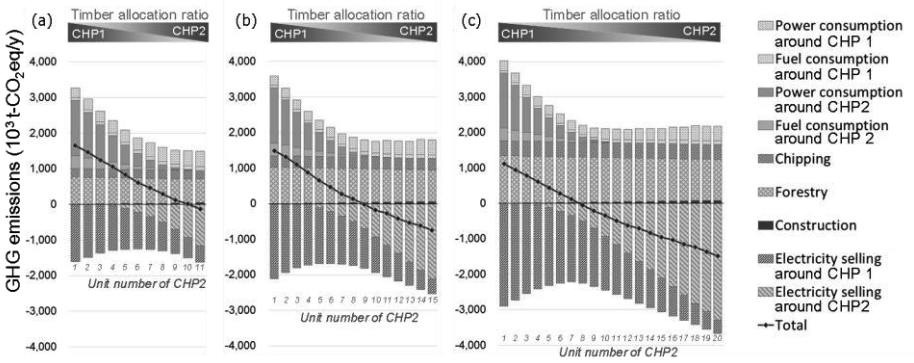

Figure 2 LC-GHG based on the forest resource allocation in Tanegashima to CHP1 and CHP2, where three patterns of resource availability were considered: (a) 15,700 m^3-timber/y, 21,100 m^3-timber/y, and 27,600 m^3-timber/y. Although GHG emitted from fossil resources was considered in LC-GHG, that from the feedstock of biomass was not included on this graph.

3.2. Design support needs for decision makers

The resource allocation should be addressed on the basis of the consensus among related decision makers. Figure 3 schematically shows the related decision makers for design problems on locally available forest resources (Kanematsu et al., 2017b). For the forestry workers, the sustainable forest management is an emerging issue to keep the forest in Japan (Oosawa et al., 2016), while the stable wood demand should be guaranteed to start the dynamic forestry plans to mitigate the maldistribution of age-class of trees. For the energy suppliers, the stable fuel supply plan is strongly needed before constructing energy plants. On that meaning, CHP1 is preferable to start the biomass-derived energy supply because CHP1 is existing plant for cane sugar mill. Based on Figure 2, however, the CHP2 has larger emission reduction than CHP1 partly because it can adjust the capacity of heating and power generation and has higher power conversion efficiency.

3.3. Scenario planning for energy systems in a region

Design support of smart energy system at local systems should be able to visualize the benefits and risks on technology implementation. Cooperative plans are strongly needed for obtaining the locally available resources, otherwise the misunderstandings among players in energy systems could be occurred and resulted in the failure of design. Computer-aided approach can visualize the scenarios of technology implementation. The number of installed small-packaged CHP units in CHP2 shown in Figure 2 can become useful in scenario planning with forestry revitalization.

The phase of forestry management for supplying timber should be monitored and taken into account in the introduction of CHP devices. At that time, the larger unit number of

CHP2 can reduce more GHG emission as shown in Figure 2. To enhance the profitability of energy company of CHP2, the fuel wood from the outside of Tanegashima can be transferred/imported and utilized in CHP2. Because the transferred/imported fuels cannot circulate the domestic economy and support domestic forestry management, their amount should be gradually decreased along with the increase of domestic timber supply. The scenario should be planned with such consideration on the local efforts on the resource circulation.

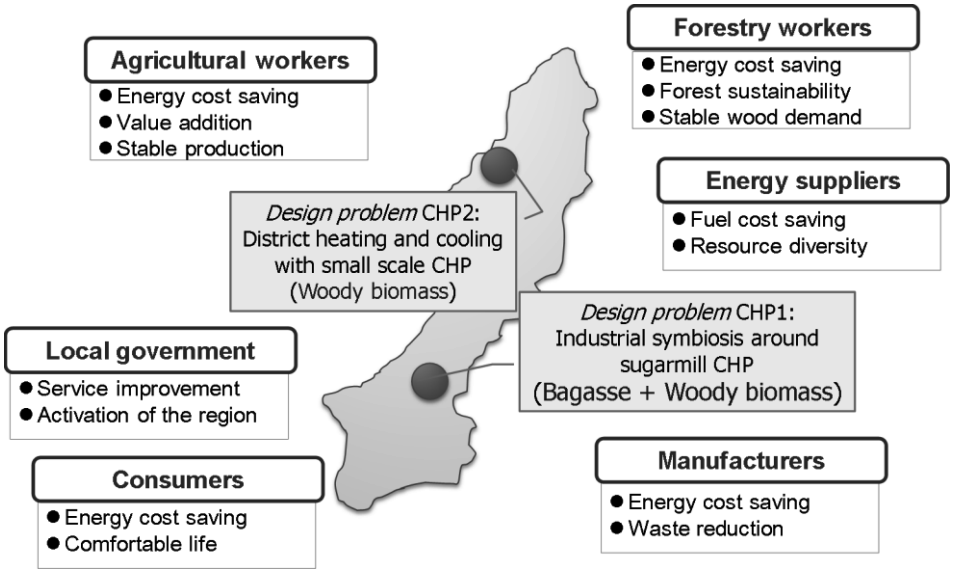

Figure 3 Related decision makers for design problems on locally available biomass

4. Conclusions

The local industries and ecosystems should be considered for designing "smart" energy systems. The utilization of locally available resources should involve the potential players in the region such as manufacturers, farmers, forestry workers, and local governments. The resource availability is significantly related with their cooperation. At that time, computer-aided approach can be employed as the visualization of the benefits and risks of technology implementation. For the deep decarbonization, such technology-oriented analysis is not enough and sociotechnical analysis should be conducted (Geels et al., 2017). The visualization of the benefits and risks is definitely required steps for system design to reveal the behaviours and performances of designed systems. Additionally, actual design support for smart energy systems need the roles of communication with related stakeholders through computer-aided design tools.

A Mathematical Programming Approach to Optimal Design of Smart Distributed Energy Systems

Evgenia Mechleri* and Harvey Arellano-Garcia

Department of Chemical and Process Engineering, University of Surrey, Guildford, United Kingdom
e.mechleri@surrey.ac.uk

Abstract

The UK is committed to reducing its greenhouse gas emissions by at least 80% by 2050, relative to 1990 levels. For this to happen, we need to transform the UK economy while ensuring secure, low-carbon energy supplies to 2050. The future electricity distribution system, known as smart grid, will integrate advanced digital meters, distribution automation, communication systems and distributed energy resources. There has been a lot of discussion about the importance of the Internet of Things (**IoT**) in future smart grids and smart cities stating that IoT offers many applications and can be used to integrate efficiency renewable energy sources in the smart grid by making the electricity grid more robust and scalable.

This study will focus on the development of an integrated IoT-Distributed energy systems (**DES**) model for the efficient energy management of a microgrid under the integration of the intermittent renewable energy resources. In this work, we expand the definition of flexible options to include demand and supply together with design and operation strategies using internet of things (IoT). Our framework brings weather data and sensor information into a virtual energy plant optimisation model that connects supplier and consumer to optimise potential flexibility gaps arising from supply and demand mismatch. The problem is posed as a hybrid mixed-integer linear programming (MILP) optimisation model combining flexibility analysis and optimal synthesis for integrating energy supply and demand, where environmental information is added to each stage. Finally, we combine traditional mathematical programming approaches such as flexibility analysis and optimal network synthesis and within a single optimisation framework combining IoT and urban DES.

Keywords: Distributed energy systems (DES), Internet of things (IoT), mixed-integer linear programming (MILP).

1. Introduction

In the last century, there has been an overwhelming rural-urban migration, with the movement of people from the countryside to the city, this has resulted in urban growth and urbanisation. Consequently, and along with the modernisation of everyday life, the demand for energy has, since then, been increasing greatly (Giordano et al., 2011). In parallel, the way energy has been produced over the years, and still is today, with a great use of fossil fuels, has contributed largely to high emission rates of carbon into the atmosphere (Muslikhin et al., 2016).

The power industry needs to rearrange the energy supply chain distribution to not depend solely on the processes currently used in the energy sector, which is likely to face a collapse shortly. In a whole, the energy sector requires the optimisation of all four stages of the supply chain: generation, transmission, distribution and consumption (Wang et al., 2014).

The power grid consists of a vast interconnected framework infrastructure with the main purpose of distributing electricity from power plants to consumers. Recently, even though information and control frontiers have been through significant changes, the advance of power systems was not able to keep up with technology development and innovation. In this context along with the need for a fully upgraded energy utilisation, distribution, transmission and generation, an idea of the smart grid has emerged as the power grid system new key factor (Federal Energy Regulatory Commission 2012). Of the most important concepts for the success of this new way of energy distribution, is the idea of a "prosumer", a user that when connected to the power grid is able to produce or consume energy within the concept of the smart grid. This would be made possible by smart meters installed at the user's' place, which consists of a device that characterises the Smart grid is and is connected to the power utility, determining a two-way communication between them. In order to achieve this communication, the idea of integrating IoT with the smart grid has emerged. The IoT is a new communication and network paradigm in which a variety of items or objects become an integral part of the Internet. In other words, the objects become "smart objects" which are equipped with microprocessors and transceivers, which makes them able to communicate with each other and provide intelligent services to users autonomously (Bui et al., 2012). The IoT has been realised as one of the most promising networking paradigms that bridge the gap between the cyber and physical world.

Several studies have already been done encompassing IoT applied in homes, buildings, cars, health and cities. A model structure of optimisation of energy based in IoT and realised in a "green technology" has been proposed by Huang et al. (Huang et al., 2014). Kim et al., (Kim et al., 2015) proposed an IoT-based home energy management system considering a home area with your appliances and photovoltaic boards as distributed energy sources. Although there has been a lot of discussion around the idea of IoT and how it can be deployed in smart-grids, only a small number of research efforts have practically addressed the integration of smart-grids with IoT. The main aim of this work is to develop an optimisation model for a virtual energy plant that connects supplier and consumer using IoT and urban Distributed Energy Systems. In order to provide an optimal design for a distributed energy system and fill the gaps that may arise from supply and demand discrepancy, the focus of the research will be on the integration between the power grid with environmental information, energy storage technologies and renewable energy sources using IoT.

The remainder of this paper is formulated as follows: In section 2 the power grid with its power flow equations, the energy sources and the loads are mathematically modelled, and the objective function of the optimisation problem is deduced, in section 3 a case study of a microgrid is presented and section 4 summarises conclusions and future research directions.

2. Methodology

In order to optimise a distributed urban energy system, the demand response problem will be formulated with an approach with convex optimization. First, the power flow equations will be defined, then the system with all the utility and devices of a distributed energy system.

2.1. Power flow equations

In order to characterize the power flow on a Power grid, a diagram for the branches, buses (nodes) and connection between them and the ground is used, as presented in Figure 1. The y_{jk} denotes for a branch linking bus on position j to bus k, the admittance value y_k for the element at bus k and I_k for the current injection on bus bar k.

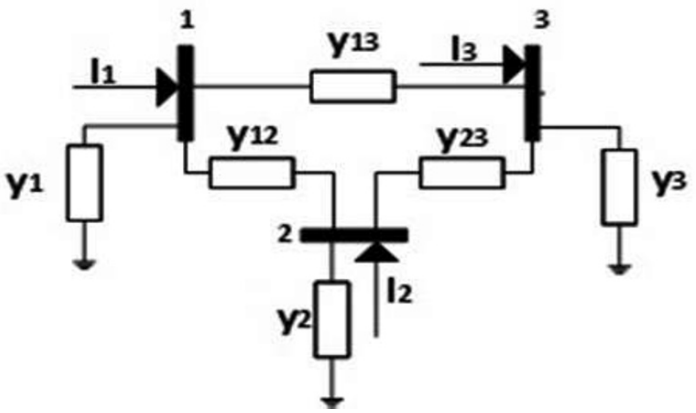

Figure 1. Electrical system transmission diagram

2.2. Mathematical system model

In this subsection the mathematical system model for building up the energy management system is presented. It is assumed a distributed energy system (DES) with heterogeneous types of energy resources where there is an Energy Management System (EMS) responsible for interact with all the active devices to the DES. The EMS acts at an operational level, gathering all the data collected by the devices on the buses, smart meters and power controls\monitor on the energy source and with all the data given acts as a controller of the power energy sources. Consider an urban energy grid with an arrangement of distributed generators units denoted by $G = \{g_1, g_2, g_3, \dots, g_g\}$, and distributed storage units denoted by $B = \{b_1, b_2, b_3, \dots b_b\}$, and buses indexed as N by $i = \{1, \dots, n\}$ and controllable loads indicated by $L = \{l_1, l_2, l_3, \dots, l_l\}$. The system is assumed to operate in discrete time, where the time is represented by $t \in \{0, 1, 2, \dots\}$ and time interval Δt.

We consider two kinds of Distributed Generator (DG) units in the grid: non- dispatchable renewable distributed generator units denoted by $g \in G_r$ and dispatchable conventional distributed generator units denoted by $g \in G_c$. For each DG, its complex power output is denoted by $s_r(t) = p_r(t) + iq_r(t)$ and $s_g(t) = p_g(t) + iq_g(t)$ for renewable energy source and conventional generator unit respectively. The active and reactive power are

$p_g(t)\ and\ q_g(t)$. Similarly we have modelled the traditional distributed generation fossil fuel motor unit, the renewable distributed generator taking into account photovoltaic units and wind turbines and also the battery system model and export to the grid which are not presented due to space limitations.

The demand requests from the user are assumed to be unknown and stochastic. The demand is given to the EMS by the user on each time t. It is considered a demand side management to the grid just about the production of energy. The load demand has a fixed value on time t. The customers loads need to be supplied interely for the grid. Where the complex power is denoted by $s_l(t) = p_l(t) + iq_l(t)$.

The Objective function of the system is defined as $C(t)$. The total cost of the power used on the system is the sum of the cost of the different decentralised units, the price of energy acquisition from the grid and the energy lost on the system.

$$C(t) = \sum_{g\in G} C_g(p_g(t)) + \sum_{b\in B} C_b(p_b(t)) + C_o(t, p_o(t) + \sum_{rg\in R} C_{rg}\left(p_{rg}(t)\right) + \varphi \sum_{(i,j)\in E} r_{ij} l_{ij}(t) \quad (1)$$

where φ is a coefficient to penalize the power lost, C_g, C_b, C_o and C_{rg} are the generation cost of traditional DG unit, of the battery, the price of the energy acquisition from the grid and the cost of the renewable generator, $p_b(t)$ is the active power of the battery, $p_o(t)$ can be negative or positive. $p_o(t)$ positive means that the urban grid is buying power from the external grid, $p_o(t)$ negative means that the urban grid is selling power to the main grid, $p_{rg}(t)$ is the power output of the renewable energy unit.
The objective of the model and energy management system (EMS) is to minimise the DES operational cost, while satisfying the power loads.

3. Results and discussion

Figure 2, presents displays the layout of a real distributed energy system in Tohoku Area, Japan. This DES consists of four power generation sources and one battery bank working as a storage energy unit. The energy sources are divided in two groups of diesel combustion conventional motor generator connected to bus 1 and bus 9 (output power of 6000KW and 1000KW respectively); two renewable generation unit being one of the solar energy (maximum output power 1000KW) and other wind energy (maximum output power possible 3000KW) connected to the bus 13 and 14 respectively. The battery bank has a maximum capacity of storage 500KW, and it is connected to the bus 7.
This is consideredan online DES, and it is connected to the external grid (national grid). The load on each bus corresponds the maximum values demanded by the users connected to that bus. The day starts at 12 am in the simulation. Because the disponibility of data, the time interval Δt is comprehended in intervals of one hour. The day is denoted by T= {1,2, 3…,24}, where each t denotes the hour T.

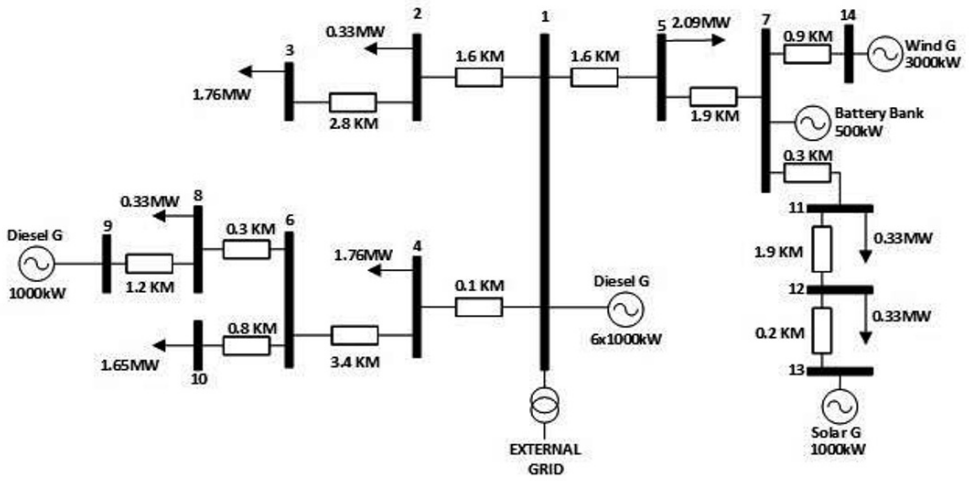

Figure 2. Distributed energy system-case study

The mathematical model described in chapter 3 with the considerations cited above was submitted and run on a commercial Software. A computer Intel core i5, 2GB RAM was responsible for running. The time spent on the activity to run for an interval T= {1,2,3,…,24} is 12 minutes and 35 seconds. Figure 3, shows the results provided by the mathematical model for an interval of 24 hours.

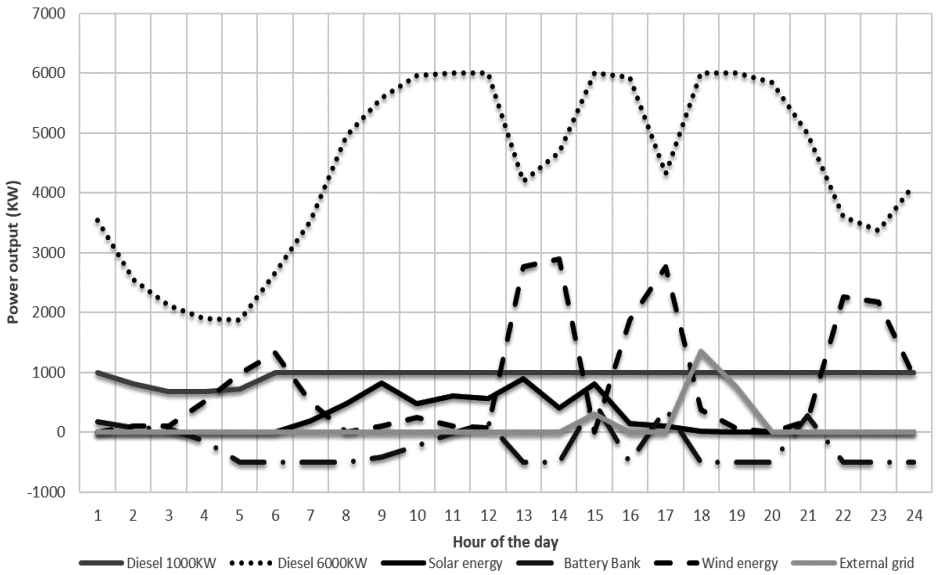

Figure 3. Power output of DES in one-day period

The wind energy and solar energy source are used most of the time for power production. In relation to the battery bank, the values show the energy level of the battery bank with positive and negative values. When the values are positive the battery is discharging and injecting power to the grid, and when negative the battery is charging. It is important to mention that the model´s objective function finds a better solution looking for all the

interval of 24 hours, so it is better for the system to keep the energy battery storage and then discharge on interval time above when the renewable energy is not available (i.e. hour of the day 14 and 20). As expected, the electricity is purchased from the external grid only when the load demand is superior of the DES internal production and when this happens all the DES production is utilised. In relation to the DG diesel source, the results show that the optimal solution is always scheduling the energy's sources to afford the load on the bus near the sources. (i.e. Hour of the day between 2 and 5).

4. Conclusions

A distributed energy system was studied addressing the demand response issue. A mathematical model was formulated to describe the power flow relationship between the power grid utilities and the power production of renewable energy sources and storage on a virtual power network. The final mathematical model was simulated with a real case scenario of a distributed energy system. This study has followed an approach to model a distributed energy system with an IoT structure, considering real-time data and the The IoT characteristic of collecting real-time data and capacity of command transmission will be an important support on a future smart power grid.

Dynamic Real-Time Optimization of Air-Conditioning Systems in Residential Houses with a Battery Energy Storage under Different Electricity Pricing Structures

Moataz N. Sheha, Kody M. Powell*

University of Utah, Department of Chemical Engineering, 50 S Central Campus Drive, Salt Lake City, UT 84112, United States of America
kody.powell@utah.edu

Abstract

This paper investigates potential cost savings in operating residential houses air-conditioning systems through dynamic real-time optimization (D-RTO). Standard design data collected from BEopt (Building Energy Optimization) software were used in Matlab/Simulink to simulate cooling energy consumption of a house model in Salt Lake City, Utah. Two different electricity pricing structures were employed; time-of-use (TOU) and real-time pricing (RTP). The D-RTO was formulated as a linear programming problem with the air conditioning temperature setpoint, the cooling energy, the battery state of charge, the charging energy and discharging energy of the battery being decision variables of the model.

The D-RTO determines day-ahead values for the dynamic variables of the system based on the weather forecast and energy price signals. The D-RTO uses a model predictive control (MPC) like approach in which the problem is solved for 24 hours in advance, but the solutions are implemented on a receding horizon, where the prediction interval moves forward by one hour each time step. Results show significant energy cost reductions for the optimized cases with a battery energy storage versus the cases without a battery under each pricing structure. Also, both pricing structures are ranked based on their capabilities for cost and energy savings and peak shifting.

Keywords: Dynamic real-time optimization; Smart Grid; Matlab/Simulink; Battery energy storage; Air conditioning systems.

1. Introduction

Air conditioning systems in residential houses consume big amounts of electricity and is usually accompanied with peak demand issues. Because of this, the residential sector has enormous potential to be a key player in the future of grid management [1]. Thus, optimizing the use of air conditioning systems is a topic that earned global interest.

Different modeling techniques have been implemented through the years to study the effect of optimizing the electricity consumption through air conditioning systems [1]–[5]. Passive thermal energy storage might not be enough to achieve the purpose of cost reduction and peak shifting under variable energy prices, thus, incorporating an energy storage system (e.g. a battery) is something that needs to be studied.

This paper presents a simple model for optimizing the cooling energy cost in residential houses through dynamic real-time optimization (D-RTO) incorporating a battery energy storage system under two different electricity pricing structures; time-of-use (TOU), and real-time pricing (RTP). The work demonstrates that dynamic optimization with a battery storage system can decrease the energy cost and shift the peak energy consumption periods towards off-peak price hours better than optimization without an energy storage system.

The rest of this paper is organized as follows. Section 2 present an overview of the system. Section 3 discusses the formulation of the model. Section 4 is devoted to the results of the study. Section 5 presents the conclusion.

2. Overview of the System

The system modelled in this study consists of four main elements. The first element is the heat transfer between the house and the surroundings to simulate the indoor temperature of the house. TMY3 (Typical Metrological Year, version 3) data set for Salt Lake City, Utah, were used to represent the weather in the surroundings of the house.

The second element is the optimizer used to minimize the cost of electricity for the house under two different electricity pricing structures; Time of Use (TOU), and Real Time Pricing (RTP).

The third element is the battery model and the fourth element is the air conditioning system represented by a PI controller that adjusts the required cooling energy based on the temperature setpoint obtained from the optimizer every hour. The formulation of the system is discussed in details in section III.

3. Model Formulation

3.1. Heat Transfer between the House and the Surroundings

Modeling the heat transfer through the boundaries of a house requires knowledge of the properties of the elements of the house involved in this process (e.g. thermal resistance and heat capacity). These elements include; the exterior walls of the house, windows, door, ceiling, floor slab, and all the interiors of the house (e.g. furniture, kitchen appliances, etc…).

In order to simulate realistic data, standard properties for the walls, windows, door, ceiling, and floor slab of the house were obtained from BEopt (Building Energy Optimization) software to represent a standard design for the house. The TMY3 weather file for Salt Lake City, Utah, were obtained from BEopt as well.

The following 1st order ODE was used to simulate the heat transfer through the boundaries of the house:

$$A\frac{dT}{dt} = B(T_{amb} - T_{house}) - Q + C \quad (1)$$

Where $\frac{dT}{dt}$ is the rate of change of indoor temperature with time in K/s, T_{amb} is the ambient temperature in K, and T_{house} is the indoor temperature of the house in K.

"A" is a constant which accounts for all the thermal masses within a house including the thermal mass of air, exterior walls, ceiling, interiors, and floor slab. All the heat capacities of the aforementioned elements were assumed to be constant over the operating temperature range. "A" has units of J/^{o}C.

"B" can be defined as: $B = \sum_{i=1}^{n} U_i A_i$, where U_i is the overall heat transfer coefficient of "i" and A_i is the heat transfer area relevant to "i". "B" accounts for the heat transfer coefficients and heat transfer areas of the exterior walls, windows, door, ceiling, and a fitting term to account for the neglected items (e.g. heat transfer through the floor slab driven by the ground temperature which was assumed to have a minor effect). "B" has units of W/^{o}C.

"Q" represents the cooling energy required per unit time and has units of Watts and "C" is a fitting parameter to account for any other neglected sources of heat (e.g. heat transfer through floor slab and heat radiation from the sun). C has units of Watts.

The proposed heat transfer model has been validated against the results of BEopt to make sure that the values for indoor temperature and the cooling energy obtained from Matlab/Simulink model and BEopt at every time step are close enough to each other.

3.2. Cost Optimization

The cost optimization problem was formulated as a linear programming problem with 120 decision variables; the temperature setpoint of the air conditioning system within each house for 24 hours, the cooling energy required for each of them for 24 hours, the battery state of charge for 24 hours, the charging energy for the battery for 24 hours, and the discharging energy of the battery for 24 hours. The temperature setpoint and the battery state of charge does not appear in the objective function but appears in the constraints.

The problem solves for the temperature setpoint and the cooling energy for 24 hours in advance, but the solutions are implemented on a receding horizon, where the prediction interval moves forward by one hour each time step. This is because there is no guarantee that the indoor temperature will reach the setpoint every hour, so the prediction needs to be updated continuously to account for that. The objective function is given by the following form:

$$min \sum_{i=1}^{24} EP_i \times (CEC_i + P_{C_i} - P_{DC_i}) \tag{2}$$

Where EP_i is the electricity price at "i" in \$/kWh, CEC_i is the cooling electricity consumption at hour "i" in kWh, P_{C_i} is the charging energy of the battery at hour "i", and P_{DC_i} is the discharging energy of the battery at hour "i".

The optimization problem is subject to two equality constraints at every hour during the 24 hour period which makes them a system of 48 equality constraints. 24 of these equality constraints are a numerically integrated form of (1) using Backward Euler's method for every hour and has the following form:

$$(A + \Delta tB)T_{i+1} - AT_i + \Delta tQ_{i+1} = \Delta tBT_{amb} + \Delta tC \tag{3}$$

Where T_{i+1} is the temperature setpoint at time "i+1", Q_{i+1} is the cooling energy at time "i+1", T_i is the temperature setpoint at time "i" (i.e. the initial condition for time "i+1), Δt is the time step, and A, B, C are the same parameters defined in (1). The cooling electricity consumption is related to the cooling energy consumption by the following relation:

$$CEC = \frac{Q}{SEER} \tag{4}$$

Where SEER is the Seasonal Energy Efficiency Ratio defined as the cooling output divided by the electric energy input. Each air conditioning system employed in this study has its own SEER rating.

The other 24 equality constraints are a numerically integrated form of the battery function. The battery function is given as follows:

$$\frac{d(SOC)}{dt} = \eta_C P_C - \frac{P_{DC}}{\eta_{DC}} \tag{5}$$

Where $\frac{d(SOC)}{dt}$ is the rate of change of the state of charge of the battery with time in kWh per unit time. η_C and η_{DC} are the charging and discharging efficiencies of the battery, respectively. Consequently, the 24 constraints for the battery each is a numerically integrated form of (5) using Backward Euler's method at every hour and has the following form:

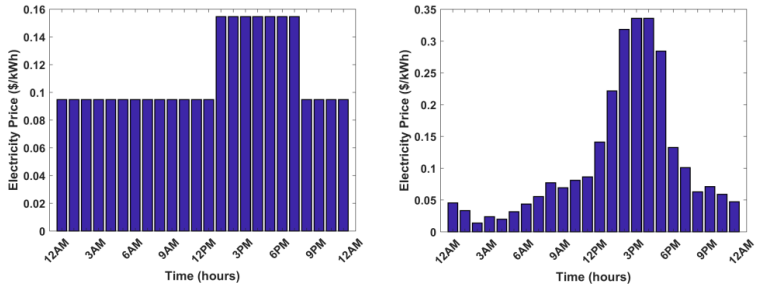
$$SOC_{i+1} - SOC_i + \frac{\Delta t}{\eta_{DC}} P_{DC} - \Delta t \eta_C P_C = 0 \tag{6}$$

Each of the 120 decision variables is subject to a lower and an upper bound, where the temperature setpoint for each house is subject to $T_{min} < T_i < T_{max}$, the cooling energy is subject to $0 < Q_i < Q_{max}$, the state of charge is subject to $0 < SOC_i < SOC_{max}$, the battery charging energy is subject to $0 < P_{C_i} < P_{C_{max}}$ and the battery discharging energy is subject to $0 < P_{DC_i} < P_{DC_{max}}$. For the house simulated in this study, a maximum state of charge of 1.5 kWh was used [6].The operating range of the temperature setpoint

expands during unoccupied periods. It was assumed that half the house was unoccupied from 8 AM till 6 PM.

Two different electricity pricing structures were used and both were built on the basis of an average daily price of 0.1122 $/kWh. The pricing structures used are defined below:

- Time of Use (TOU): Where electricity prices usually have 2 or 3 different values per day depending on the time of the day. In this study, 2 different prices were employed every day. The average electricity price for residential houses in Utah is 0.1111 $/kWh [7]. Peak hours in Utah during summer are from 1 to 8 PM, the price of electricity during the off-peak hours reduces by 0.016334 $/kWh and increases during peak hours by 0.04356 $/kWh [8]. Using the average value and the peak and off-peak modifications, the TOU price was taken as 0.0947 $/kWh for the off-peak hours and 0.1546 $/kWh for the peak hours. This would result in an average price per day of 0.1122 $/kWh. The TOU pricing structure that was used is presented in Figure 1a.
- Real-Time Pricing (RTP): where electricity price varies every hour during the day based on the electricity consumption. In this study, we employed 24 different electricity prices one for each hour and used the same values through the entire period of summer. The used RTP pricing structure is depicted in Figure 1b.



(a) TOU Pricing Structure (b) RTP Pricing Structure

Figure 1: Employed TOU and RTP Pricing Structures

3.3. Air Conditioning System

This paper studies only the cooling systems of the houses, nothing related to the heating system was included because the house is assumed to be gas heated. The cooling system was formulated as feedback PI controller. The controller takes the house indoor temperature and the setpoint as inputs and then adjusts the cooling energy of the house (output) based on how far is the indoor temperature from the temperature setpoint.

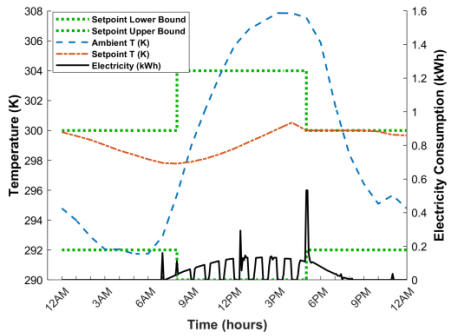
The system was solved dynamically in a real-time optimization (D-RTO) form using Matlab/Simulink. D-RTO uses a model predictive control (MPC) like approach in which the problem is solved for 24 hours in advance, but the solutions are implemented on a receding horizon, where the prediction interval moves forward by one hour each time step.

4. Results

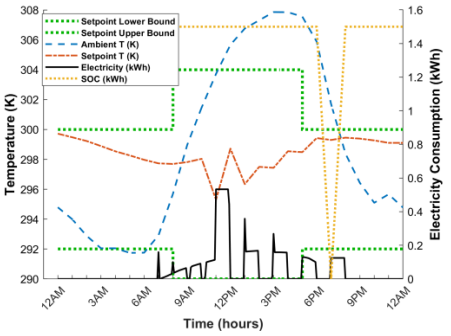
Figure 2a through 2d illustrate the results for the two pricing structures; TOU (2a and 2b) and RTP (2c and 2d), respectively, by presenting hourly cooling energy consumption for the house in a hot summer day in August vs. the temperature setpoint and the ambient temperature. The state of charge for the cases with a battery storage system is plotted as well. The electricity consumption is plotted over intervals of five minutes for a 24 hour period. In Figure 2a, it can be noticed that the peak electricity consumption is at 5 PM, which is during the peak hours of TOU (Figure 1a). This means that the optimizer resulted

in a peak consumption during a peak hour. So, what happened here is that the optimizer could not shift the peak energy consumption outside the peak hours. Instead, the optimizer tried to maintain low energy values during the peak hours, but eventually, the temperature setpoint became very high with the ambient temperature being high as well, therefore, the setpoint dropped around one degree resulting in a peak energy consumption during the peak hours of TOU. This is because the thermal masses of the house were not enough to store sufficient amount of energy to optimize the consumption. In Figure 2b, where a battery is being used as an energy storage system, the system is optimized and the peak consumption is shifted towards an off-peak hour for TOU (11 AM). Notice the plot of the state of charge of the battery where the battery discharges at the last peak hour preventing the air conditioning system from consuming more energy from the grid.

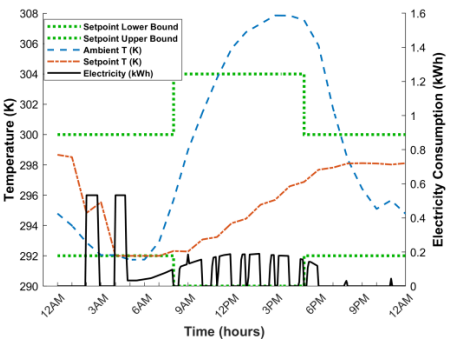
In Figures 2c and 2d, it can be illustrated that RTP was able to optimize the system in Figure 2c without a battery and had no peak consumptions during peak hours (Figure 1b). But still Figure 2d shows that using a battery storage system resulted in decreasing the peak consumption at 2 AM and 4 AM.



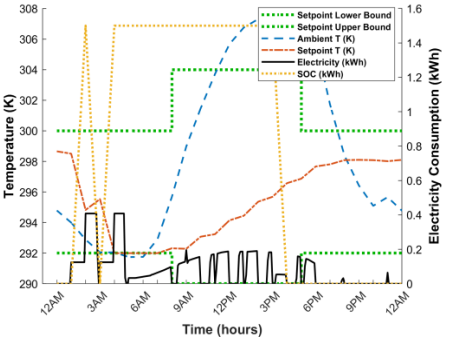
(a) Setpoint and cooling energy for TOU without a battery



(b) Setpoint and cooling energy for TOU with a battery



(a) Setpoint and cooling energy for RTP without a battery



(b) Setpoint and cooling energy for RTP with a battery

Figure 2: Setpoint and cooling energy for a 24 hour period for all cases

Table 1 shows the total cost, total consumption and percentage savings for all cases. An interesting observation from Table 1 is that however RTP without a battery was enough to optimize the system efficiently, it still resulted in higher energy consumption and higher price than TOU without a battery which was not optimized efficiently. The same observation can be drawn for the cases with a battery storage system. This means that TOU pricing structure with a battery storage system shall be the favoured operating strategy over the other studied cases.

Table 1: Total Energy Cost and Total Energy Consumption for All Cases during Summer Period (May through September)

Case	Energy Cost ($)	Energy Usage (kWh)	Energy Cost Savings (%)	Energy Usage Savings (%)
TOU without battery	106.1	996.3	-	-
TOU with battery	88.6	886	16.5	11.07
RTP without battery	214	1,752.2	-	-
RTP with battery	182.9	1,590.8	14.5	9.21

5. Conclusion

Dynamic real-time optimization of air conditioning systems is necessary for peak shifting purposes as well for reducing electrical energy consumption and electrical energy cost. Two different electricity pricing structures were studied. TOU pricing structure and RTP pricing structure both with and without a battery energy storage system. Results showed that TOU pricing structure with a battery storage system was able to shift the peak towards off peak hours and resulted in more energy and cost reduction than RTP pricing structure.

In future work, distributed generation (e.g. solar panels) will be incorporated to the system to study the effect of distributed generation on the optimization of air conditioning systems in residential houses with the presence of a battery energy storage system and for grid frequency regulation.

Abstract

This paper closely evaluates three conventional methods of calculating the maximum groundwater level to be used for design purposes in Perth, Western Australia, in order to identify the shortcomings. The results of all of the methods are incorporated into ArcGIS in a study area in Perth for the interpretation of groundwater changes in calculated levels and to assess their reliability. The range of differences in results by application of the methods is presented at monitoring locations and other places over the study area.

A comparison of the methods shows that, despite similar principles in calculation, the results are very different, thus creating uncertainty for decision making and risks for urban structures, people and the environment. The results vary as a consequence of different density and types of data used in each method, the inconsistent period of data selection, impact of anthropogenic activities and climate change, as well as the physical properties of the aquifer, such as slope. In areas of high groundwater levels and in major engineering projects, it is critical to more accurately calculate the maximum groundwater levels.

Therefore, a combination of detailed data analysis in order to estimate maximum groundwater level accurately at monitoring locations at certain times is proposed, along with using a numerical simulation of physical processes to reduce and define uncertainty for planning. This can pave the way towards the development of a reliable method for the calculation of maximum groundwater levels.

Keywords: Maximum groundwater level, urban development, groundwater contours.

1. Introduction

Urban development impacts groundwater levels and, in turn, groundwater level variations may result in major risks to infrastructure and the environment, which can cause economic losses. For example, subsidence, inundation of road surfaces, drying surface water bodies or promoting insect breeding are all possible consequences of variation in groundwater levels.

Urbanisation in Perth, Western Australia (WA) causes a higher runoff and recharge rate and, subsequently, groundwater levels rise (Appleyard, 1995; Barron, et al., 2013). Despite the drying climate, in Perth, groundwater levels near the surface (3-10m) are not as affected by a decline in rainfall due to the impact of urbanization (McFarlane et al., 2012). In order to avoid the adverse impact of high groundwater level below the road and building structure, various processes are put in place such as constructing drainage, importing sand fill, and using water tolerant designs or materials.

Furthermore, there is a compromise between the need to reduce costs, whilst still ensuring the protection of infrastructure and groundwater users, both human and environmental (C. G. Davies et al., 2017). Inaccuracies in defining the groundwater level may result in unacceptable risks or over conservatism in the construction of urban structures that will potentially cause inequitable lot fill, costly design and materials (Boronina, 2015).

Groundwater planning and design in urban development depends on maximum groundwater levels. However, until now, no standardized method exists to determine maximum groundwater levels (Boronina et al, 2015; Fürst et al., 2015).

2. Methods

Three methods that have been used in WA to determine maximum groundwater levels are evaluated to assess the reliability of results. All of these methods are based on interpolation, which is a common method for groundwater level assessments.

2.1. Perth Groundwater Atlas (PGA)

Perth Groundwater Atlas is an online spatial dataset provided by the WA Government to help drillers, irrigators, and private householders to establish groundwater bores in the water table aquifer within the Perth metropolitan area. The "Groundwater Contours Historical Maximum" layer is 1-meter interval groundwater contours based on measured maximum groundwater level records from the early 1950's through to the 1970's, which were hand drawn interpolations from 1: 2,000 map sheets. Due to the fact that the contours are not related to any particular period of groundwater level records and because of changes in groundwater and natural surface levels that can occur over time, these contours are indicative only, providing merely a regional overview.

2.2. Average Annual Maximum Groundwater Levels (AAMGL)

The use of the AAMGL has been advocated by the WA Government for new drainage works, road construction and pavement design (J. Davies et al., 2004). There is no explicit rule in respect to calculating AAMGL in the WA guidelines, and anomalies occur when this method is used by different practitioners. Usually, in order to calculate AAMGL at a site, onsite groundwater monitoring is undertaken for 12 to 18 months to capture maximum groundwater level. This short-term data is then modified with long-term AAMGL at a regional groundwater monitoring bore close to the site. The difficulty in defining AAMGL is discussed by Davies et al (2004), which is related to undefined period of data over which the AAMGL shall be calculated, the method of correlation with long term data to a particular site and lack of consideration for existing drainage systems.

2.3. Design Groundwater Level (DGWL) methodology for infrastructure projects

The Gateway WA project is a road project undertaken by Main Roads Western Australia. A new methodology was applied for the project, which is based on hydrogeology concepts and incorporates various types of data, such as groundwater levels in open drains or surface water bodies (Boronina et al, 2015). In this method, a year in the history that corresponds to a reasonable maximum is selected, with consideration of changes in groundwater levels owing to the construction of drainage. At all locations, maximum groundwater level for the same year was estimated and groundwater contours were created by interpolation of groundwater elevation from point data, with a clear level of confidence in monitoring locations based on the quality of the data.

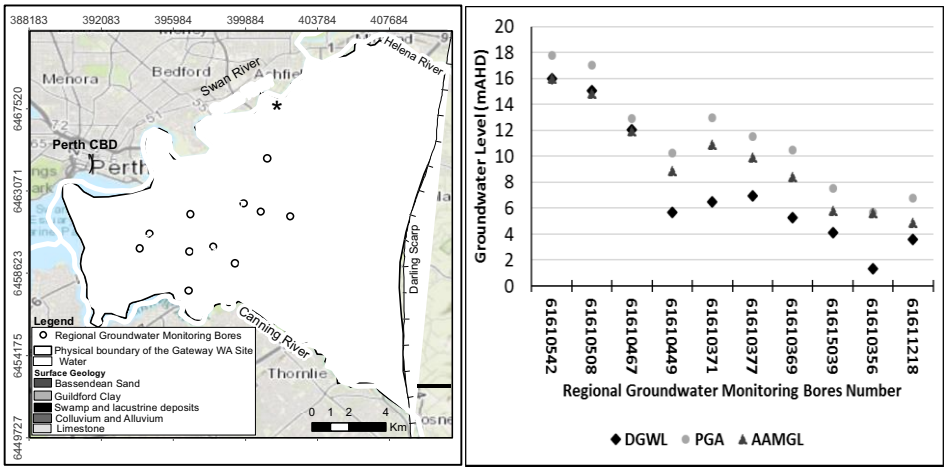

Figure 1 Surface geology and locations of regional groundwater monitoring bores (DWER)(left) and differences of methods at regional groundwater monitoring bore locations (right)

3. Study Area

The study site is related to the Gateway WA and it is located in the Perth basin, comprising a multi-layered unconfined aquifer, covering an area of 185 Km^2 (Figure 1, left). The site is bordered by Darling Scarp to the East, Helena River to the North-East, Swan River to the North and West and Canning River to the South.

Rainfall data in the Perth Airport station inside the study area shows a downward trend over the last few decades (from 900mm in 1945 to below 700mm in 2016).

The dominant 'Superficial formations' (late Tertiary to Quaternary sediments) in the study area is Bassendean Sand, comprising of quartz sand, and Guildford Clay, consisting of low permeability material and a perched water table (Davidson, 1995). The regional groundwater flow direction is from Darling Scarp at East towards the Swan River at West.

4. Data Collection and Analysis

Spatial data including "Groundwater Contours Historical Maximum" layer and all the groundwater monitoring bore data and information, is collected from the WA Government. The regional monitoring bores in the superficial aquifer with long-term records (>30 years), up to the present, are selected for further analysis (Figure 1).

At the construction time of the Gateway WA project, many bores were drilled in the superficial aquifer for monitoring. The water level data and groundwater contours created by the DGWL method for the Gateway project are provided by Main Roads WA. The water level measurements are predominantly during 2013 and 2014 and it is specified that in most locations annual maximum groundwater levels occurred in October.

For the AAMGL calculation of Gateway WA project bores, those with groundwater level measurement in Oct 2013 are selected and their maximum level is linearly modified with AAMGL of the regional monitoring bores with long-term records to estimate AAMGL at the locations of the selected bore at the construction site. Based on available data, these estimated water levels along with calculated AAMGL at the regional monitoring bores are used to generate groundwater contours.

Three groundwater contours resulted from the PGA, DGWL and AAMGL methods are integrated into ArcGIS. In order to standardize the contours, all of them are changed to raster data and subtracted from each other to understand their range of differences. They are also subtracted from the digital elevation model (DEM, a 2008 LIDAR survey) in order to determine the locations that show the groundwater level above the surface.

5. Results and Discussion

Although groundwater contours are all created based on interpolation between groundwater elevation at points inside the study area, Figure 2. (A) shows that, due to different levels of density of the points and different periods of selection used in each method, they bring about very different results and their accuracy is not clear.

The comparison of methods at monitoring locations is depicted in Figure 1, and bore number 61610542 is presented as an example in Figure 3. Maximum groundwater level calculated based on each method at this bore is shown on the groundwater level data (Figure 3). AAMGL value is AAMGL of measured data from 1983 to 2017 and maximum groundwater level values for the PGA and DGWL methods are extracted from their contours at the bore location. The same principle is applied for comparing maximum groundwater levels of three methods at monitoring locations, as shown in Figure 1 (right).

It can be concluded that, if the groundwater level trend is downward owing to the drier climate, drainage design or abstraction, and if long-term data is available (in this analysis, 33 years), there is rarely a risk of annual exceedance of groundwater level from the long-term AAMGL at monitoring points (Figure 3). Moreover, Figure 1 (right), reveals that, except for the bores which are used in the calculation of DGWL, at bores which are not used in the calculation, the DGWL method underestimates the maximum groundwater levels and PGA overestimates them in all bores. In accordance with the different period of selection, overestimation of maximum levels in the PGA method could originate from climate change and human intervention. Anthropogenic activities could have a big influence that should be taken into account. For example, there is about a one-meter decline in the groundwater level in the late 1960's at bore number 61610542, which is related to drain construction (Boronina et al, 2015). Underestimation of maximum level in DGWL at monitoring points farther away from the construction site could be originated from a lower density of data, along with different physical properties at those locations.

Surfaces made from groundwater elevations of each method subtracted from DEM of the area are presented in Figure 2 (B). According to the negative values which are representative of the area and the amplitude of the groundwater level above the ground, DGWL is the most efficient method (-3.7-0 m) and AAMGL resulted in the least reasonable values (-13.5-0 m). It is related to the density and types of data used in the creation of these surfaces and the fact that AAMGL is not corrected by topography.

A comparison of methods over the study area in Figure 2 (C) shows that the range of differences between methods is quite large (10 and 15m) which, for detailed designs, is unacceptable. The largest difference between the PGA and DGWL methods (5-8.2m) might be related to the change in topography, due to the steeper slope in this part.

The DGWL method for infrastructure projects has some advantages compared with PGA and AAMGL, which have brought about better results. For example, different types of data and a change in the groundwater level trend based on anthropogenic activities are considered in this method.

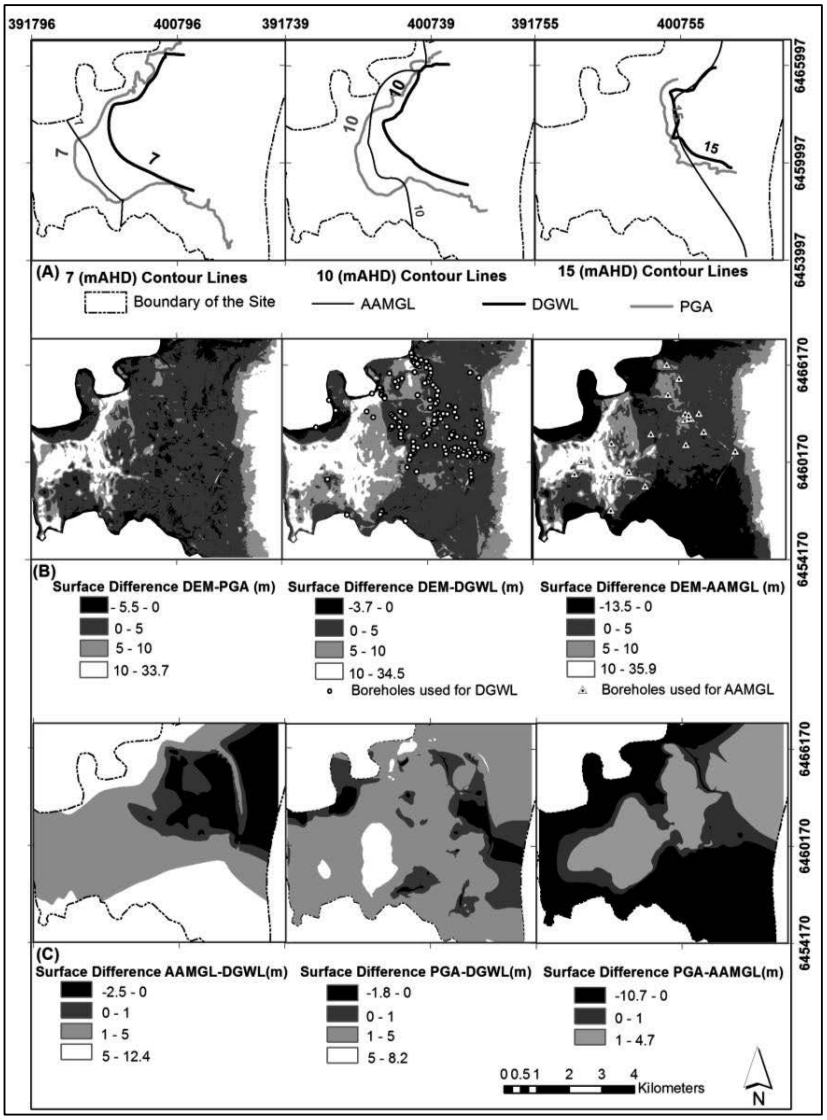

Figure 2 Groundwater contours created by different methods (A), Subtraction of surfaces generated from DEM (B), Surface difference resulted from subtraction of two methods (C).

However, interpolation doesn't account for physical processes and optimum bore density and focal locations for monitoring according to the site complexity is not clear.

Based on this comparison, a similar approach of the DGWL method that includes all types of data and an accurate estimation of maximum groundwater level at monitoring locations, in combination with numerical modelling to consider physical properties, is proposed. In numerical modelling, simulation at the steady state for a certain time derived from data analysis is suggested, with a focus on reducing the difference between the modelled level with calculated or measured levels at points, as well as estimating uncertainty for planning.

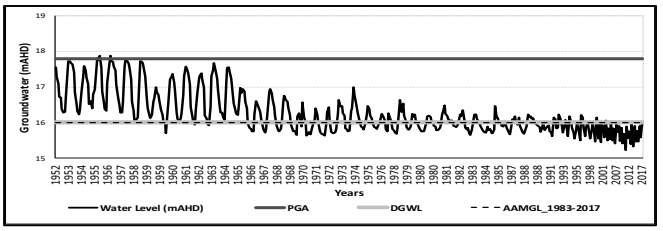

Figure 3 Groundwater level data and values calculated based on methods at bore 61610542

6. Conclusion

The comparison of three methods for the calculation of maximum groundwater level in WA shows that, in spite of a similar theory in the basis of interpolation, there is a significant spatial difference in their results. The DGWL that incorporates different types of data could present more reliable results spatially, and the AAMGL method, despite its high efficiency at monitoring points, could result in the least reliable surface. The greatest differences between results correspond with the different density of data, period of selection and the change in topography. For engineering projects and detailed designs, more accuracy in maximum groundwater level calculations is advised, as this could prevent damages and risks related to exceeding water levels from their allowable limits and a rise in costs as a result of the damages or conservatism in design. To achieve higher accuracy, a similar approach to the DGWL, along with a simulation of maximum level through numerical modelling to reduce uncertainty, is proposed.

Extracting Heuristics for Designing Sustainable Built Environments by Coupling Multiobjective Evolutionary Optimization and Machine Learning

Xinyu Liu[a], Bhavik R. Bakshi[a*]

[a]*William G. Lowrie Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus OH 43210, USA*
bakshi.2@osu.edu

Abstract

In sustainable process design, computational optimization methods are often used to find a single or a set of Pareto optimal or near-optimal solutions. However, knowledge about what makes the solutions optimal can be more valuable as it can be formulated as heuristics for guiding future designs of similar systems. In this paper, we propose a methodology that couples multiobjective optimization and machine learning to extract design heuristics. The methodology has been demonstrated by a case study on sustainable residential system design. Potential heuristics for sustainable buildings include: 1) keep the house as warm as comfortable in the summer and as cold as comfortable in the winter; 2) place vegetable garden, shading trees, and rain water harvesting system around the house. This further indicates the benefits of the synergistic design between technologies and ecosystems. The approach of combining optimization with learning is general enough to be applied to other systems, ranging from local manufacturing processes to urban systems.

Keywords: Heuristic extraction; multiobjective optimization; machine learning; sustainable built environment

1. Introduction

In sustainable process design (SPD), it is common to use multiobjective optimization (MOO) for understanding the trade-offs between various objectives and obtaining Pareto curves. However, what may be more valuable is to extract knowledge about what makes the solutions optimal, which can result in design heuristics. The motivation for finding such heuristics is because solving optimization problem can be expensive in terms of both computational power and human expertise. Therefore, instead of repetitively performing similar tasks, a more practical approach would be to discover design heuristics that can better explain optimality and guide the future design of similar systems without detailed optimization. To obtain such insights, additional analyses are required to go beyond just computing the optima (Deb and Srinivasan, 2008).

Conventionally, heuristics are obtained through human experience. For example, we can develop distillation sequences based on previous experience (Seider et al., 2017), look at points on Pareto curves and search for common characteristics (Urban and Bakshi, 2013), or represent different problem identities in closed-form mathematical expressions (Deb and Srinivasan, 2008). However, these approaches might become intractable when facing large dataset or complex problems. Heuristics extraction has also been a research topic in the field of machine learning (ML) and knowledge

discovery. There are two approaches for heuristics extraction in ML. The first is to apply a symbolic learning algorithm such as decision trees directly; while the second is to extract tree-structured representations of trained models (Al Iqbal, 2012).

On the other hand, most SPD problems ignore the role played by nature in supporting engineering systems. Similar to technological systems, ecosystems also have limits in terms of goods and services available. Ignoring these limits while designing systems may result in unintended harm, including ecological degradation. Methods for making decisions toward environmental sustainability need to encourage satisfaction of two necessary but not sufficient conditions: 1) goods and services demanded from ecosystem should not exceed the ecological carrying capacity; 2) the proposed solution should not shift the problem outside the system boundary. The TES-LCA methodology explicitly accounts for the capacity of ecosystems to provide the goods and services demanded in the life cycle across multiple spatial scales (Liu and Bakshi, 2017).

In this work, we extract heuristics from sustainable designs of the built environment. The rest of this paper is organized as follows. A methodology for heuristic extraction by coupling optimization outputs with ML is proposed in Section 2. This methodology is demonstrated by a case study on sustainable residential system design via TES-LCA methodology.

2. Methodology

Our systematic approach to extract design heuristics couples optimization outcomes and ML algorithms. As indicated in Figure 1, multiobjective optimization can be used to obtain not only the Pareto front, but also determine whether a solution is optimal or not, along with its associated decision variables and objectives values. This information about decision variables that correspond to optimal and non-optimal solutions can be the input to ML for the extraction of knowledge about what makes the solutions optimal. This can be formulated either as a classification or a regression problem. In the classification context, solutions are labelled either as optimal or non-optimal; while in the regression context, solutions are labelled by their objectives values. Decision variables are identified as heuristics if they contribute to a more thorough classification or explain more variability of objective values.

3. Case Study

3.1. System Description

The methodology has been applied to the design of a single-family residential system located in Columbus, Ohio. The house is assumed to be 185 m^2 with no basement

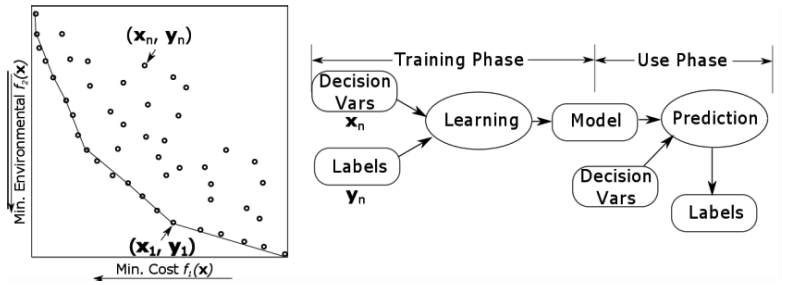

Figure 1: Coupling optimization outputs with ML for heuristics extraction

construction (Urban and Bakshi, 2013). Our scope only considers the operational stage of the residential house, without considering its construction and dismantlement stages. During the operational stage, the house mainly needs to purchase utilities from public supplies to sustain its demand. Therefore, it is reasonable to estimate the house's life cycle impacts with those of utility supplies, namely, water, natural gas, and electricity. We compare different design alternatives to the base-case residential system with no changes involved. Therefore, we mainly focus on optimizing the changes in the life cycle impacts associated with purchased goods and utilities. The functional unit of this study is its occupation time of 10 years and the amount of electricity, natural gas, and water that are required during this period. To prevent the impacts from shifting outside the boundary, we consider designs at Scope 1 (local), Scope 2 (local + utility generation) and Scope 3 (life cycle). The design variables are specified in Table 1. The bold values are associated with the base-case. Three objectives are minimized simultaneously, namely net carbon footprint, net water footprint, and relative life cycle cost. Nine optimization scenarios are considered by combining three variable types (Technological, Techno-Ecological, Techno-Eco-Behavioral) and the three scopes (1, 2, and 3).

3.2. Simulation-based Optimization

This study utilizes a simulation-based optimization methodology that couples building simulation software Energyplus and an optimization algorithm non-dominated sorting genetic algorithm-II (NSGA-II) to seek optimal designs (Palonen et al., 2013). NSGA-II is chosen due to its suitability to derivative-free optimization and its ability to archive all points evaluated in the optimization. Figure 2 shows the flow chart of the simulation-based optimization process. Energyplus simulates the utility usage in the building and Perl language extracts such information to calculate optimization objectives. NSGA-II selects a new generation that optimizes the objectives, which is used to create new simulation files that are again passed to Energyplus simulator. The optimization process completes when the termination criteria are meet.

3.3. Heuristic Extraction

In this case study, the problem is formulated as a classification problem, using the decision tree algorithm, which has the ability to detect interactions and identify groups that have similar outcomes, along with the associated predictor variables (Neville, 1999). The predictor variables that lead to a more thorough classification can be determined and identified as design heuristics. Decision variable values of an instance are used as input features; while whether the evaluated instance is on the Pareto curve is used as output label. The decision tree classifiers are trained and pruned by applying hyperparameter grid search method. A 5-fold cross validation is performed with a train/test ratio of 4. All trained classifiers obtained ~0.9 area under receiver operating characteristic curve score, which is a commonly used performance indicator for binary classifiers. Feature importance is then computed as the normalized total entropy reduction brought by that feature. However, since the decision tree algorithm only provides the absolute value of feature importance, linear support vector machines have also been fitted to each of the nine scenarios to determine whether the decision variables contribute positively or negatively to optimality.

3.4. Results

The results for each scenario are shown in Figures 3, 4, and 5, respectively. Of all design variables in Table 1, only those whose importance rank is in the top ~50 % are shown in the bar plots. Black bars indicate that increasing variable value contributes negatively to optimality while grey bars indicate the opposite. The sums of variable importance grouped by their categories are also provided to facilitate the comparison

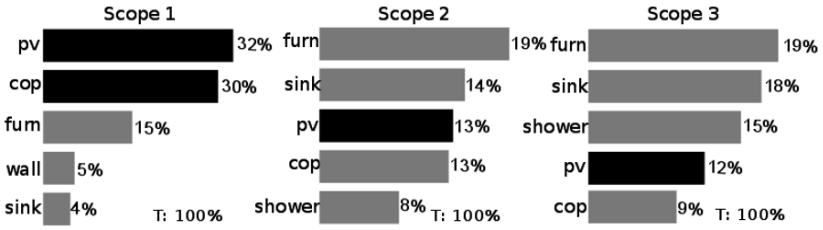

Figure 3: Designs with only Technological Variables

between different categories. From Figure 3, it can be inferred that of 11 technological decision variables, the top 5 most influential variables remain similar across scopes. Also, increasing the percentage of roof covered by photovoltaics would contribute negatively to optimality across all scopes. This is because the cost of photovoltaics is too high to offset the electricity saving. However, with increasing scope, the emission reduction from electricity generation renders the contribution from photovoltaics installment less negative.

From Figure 4, it can be inferred that the significance of technological and ecological variables is similar: technological variables contribute less than 60%, while ecological variables more than 40%. This also justifies the ecological variables in our design problem. Moreover, we can observe that the improvement of coefficient of performance (cop) is not beneficial at scope 1 because of its high cost; however, it is beneficial at large scopes. This shows the necessity to consider different scopes to prevent the impacts from shifting outside the boundary. In other words, even though some changes are not promising from a local perspective, it might be beneficial from a life cycle perspective and vice versa. Furthermore, existence of ecosystems on-site, e.g. vegetable garden, shading tree, and rain water harvest system, are beneficial across scales. The same trend is also shown in Figure 5.

Additionally, Figure 5 indicates that technologies may not be the only option, since their importance generally decreases with increasing scopes. Also, we can infer that "cheap" technologies, such as sink and shower faucet, are beneficial across variables types and scopes, and thus should be implemented; while "expensive" technologies, such as photovoltaics installation, are the opposite, and thus should be implemented with caution. Moreover, it can be observed that heating set point becomes more prominent with increasing scope. This is because the effect of utility saving becomes more important when upstream processes are considered. Furthermore, as indicated by all three scopes, we should keep the temperature cooler in winter and warmer in summer.

4. Conclusions

In this paper, we propose a methodology that couples multiobjective optimization and ML to extract design heuristics. The methodology has been demonstrated by a case study of designing a residential system consisting of a house and its yard. Potential heuristics for sustainable buildings include: 1) keep the house as warm as comfortable in the summer and as cold as comfortable in the winter; 2) place vegetable garden, shading trees, and rain water harvest system around the house; 3) implement cheap technologies first such as efficient showerheads and faucets before expensive ones such

as solar panels. This further indicates the benefits of the synergistic design between technologies and ecosystems and justifies the use of TES-LCA methodology. Coupling optimization outcomes with ML algorithm helps to extract useful design heuristics for guiding the future design of similar systems. This approach is general enough to be applied to other systems, ranging from local manufacturing processes to urban systems.
