Preface

This book contains papers presented at the 13th International Symposium on Process Systems Engineering (PSE 2018), held at the Manchester Grand Hyatt in San Diego, California, USA, July 1-5, 2018. The PSE series is a triennial conference which has been held since 1982, organized on behalf of the international PSE Executive Committee with representation from countries in Asia-Pacific, Europe, and the Americas. The goal is to create an academic and industrial dialogue, a critical assessment of existing enabling technologies, a discussion on research, education, and industrial needs, and an international forum for new directions, challenges and opportunities in process systems engineering.

The PSE symposia bring together researchers, educators, and practitioners to discuss the latest developments in the field of Process Systems Engineering (PSE), including applications of methods, algorithms, and tools to solve a wide range of problems as well as provide the venue for discussion of new scientific challenges in our field. This symposium will feature more than 425 presentations including invited plenary and keynote lectures, as well contributed papers (both oral and poster) encompassing a large number of core and cross-cutting PSE themes.

The core PSE themes include:

- Process and Product Design/Synthesis
- Process Dynamics and Control
- Scheduling and Planning
- Supply Chain Management and Logistics
- Decision Making Under Uncertainty
- Integration of Process Operations and Design/Synthesis
- Modeling, Analysis and Simulation
- Optimization Methods and Computational Tools
- Education

The cross-cutting themes embrace new and exciting PSE applications in the areas of:

- Energy, Water, Food, Waste Nexus
- Multi-scale Systems Engineering
- Sustainable and Renewable Systems Engineering
- Modular Process Intensification
- Healthcare Systems Engineering
- Industrial Biotechnology
- Molecular and Materials Systems Engineering
- Smart Manufacturing and Plant of the Future
- Smart Grid Systems
- Urban/Building Systems Engineering
- Big Data Research and Development
- Man-machine Interface Systems Engineering
- Safety Driven Systems Engineering

This book includes 11 invited papers and extended abstracts as well as 407 contributed papers. All papers have been reviewed by at least two members of the International Programming Committee. We are very grateful to the members of the International Programming Committee for their assistance and constructive feedback during the review process. We would also like to thank the Elsevier editorial team, particularly Mr. Kostas Marinakis and Ms. Emily Thomson, for their support on this project, which provides an archival and fully indexed record of the conference.

We are dedicating PSE 2018 to the memory of the late Professor Christodoulou A. Floudas, a giant in the field of process systems engineering. When Chris passed away, our community lost a visionary leader and many of us lost a close friend.

Christodoulos A. Floudas was the Director of the Texas A&M Energy Institute, and the Erle Nye ’59 Chair Professor for Engineering Excellence at the Artie McFerrin Department of Chemical Engineering at Texas A&M University. Before moving to Texas A&M he was the Stephen C. Macaleer '63 Professor in Engineering and Applied Science, and Professor of Chemical and Biological Engineering at Princeton University for 29 years. Chris was a world-renowned authority in mathematical modeling and optimization of complex systems, with research interests at the interface of chemical engineering, applied mathematics, and operations research. His research accomplishments were recognized by numerous awards and honors, including election to the U.S. National Academy of Engineering in 2011, to the Academy of Athens in 2015, and to the U.S. National Academy of Inventors in 2015. He was the author of over 300 refereed publications and had delivered over 330 invited lectures, seminars, and named lectureships.

We will honor Chris’ life and legacy by establishing the Christodoulou A. Floudas Distinguished Lectureship sponsored by the Elsevier journal Computers & Chemical Engineering. The inaugural C.A. Floudas Lecture will be given by Professor Art Westerberg, a true pioneer in our field and a close friend of Chris’.

We are indebted to our conference manager, Mrs. Robin Craven, for all of her help and hard work. Similarly, we greatly appreciate the support from the CACHE Corporation and the AIChE Computing and Systems Technology (CAST) Division.

We hope PSE 2018 will foster constructive interaction among thought leaders from academia, industry, and government and that this book will serve as a useful reference for the latest research in all areas of process systems engineering

Abstract

The incorporation of renewable energy sources to the market has brought a new golden era for process synthesis along with new challenges and opportunities. In this work, we give a brief review of the state of the art and then present challenges and future directions in this exciting area. The biggest driver is the rapid improvement in computer technology which greatly increases the number of factors that can be considered during the design process. Thus, some of the key future directions lie in integrating the design process with other aspects of process systems engineering, such as scheduling, planning, control, and supply chain management. In addition, sustainability is now a major consideration in which the design process must consider not only economic sustainability, but social sustainability and environmental sustainability when making design decisions. The tools available to address these challenges are limited but we are in a position to develop them based on strong chemical engineering principles following a multidisciplinary approach with contributions from other disciplines such as biology and biochemistry, computer science, materials, and chemistry.

Keywords: Modelling, process synthesis, raw materials, heuristics, optimization, process design, product design

1. Introduction

The first contribution in the field of process synthesis is dates back to 1973 (Rudd et al., 1973). Traditionally, this is methodological creation of a process to produce chemical products using experience, heuristics, and algorithms. Over time, the boundaries of the analysis expanded as more and more complex concepts and techniques developed, allowing for more layers of rigor to be considered. This included fields such as optimization, modeling, economics, and control, which ultimately resulted in better process designs. However, product design was traditionally considered to be more related to consumer marketing than chemical engineering. Only recently has product design become a part of the scope of process engineers (i.e. Ng et al. 2013). For example, the popular textbook Product and Process Design Principles (Seider et al., 2017) did not get the "Product and" part of the title until the second edition. However, it is only natural that the boundaries of process design have now expanded to include product design since the next level up from the question "What is the best process to make this product?" is "What product should we make to meet market needs?" These products can range from custom chemicals such as catalysts for reactors, solvents for CO_2 capture, or thermal fluids for Rankine cycles to complex products such as cosmetics, pharmaceuti-

cals, and processed food. Furthermore, chemical processes must be controlled and operated carefully as they are the core of the product supply chain. So multiscale analysis in both time and size scales is becoming increasingly important. In addition, a new focus on using renewable resources such as biomass, solar, or wind energy adds additional challenges with regard to consistency and irregular availability. This paper briefly reviews developments and predicts future directions in these areas.

2. A bit of history

2.1. Heuristic-based design

Over the years graphical and heuristic based methods have been proposed and used with high acceptance in industry. The most used examples lie in the area of heat exchanger network (HEN) design from rules proposed by Masso and Rudd (1969) or Ponton and Donaldson (1974), to the pinch method (Linnhoff and Hindmarsh, 1983). Energy integration has evolved into total site integration aiming at exploiting synergies between processes in large complexes to save utilities and resources (Klemes et al., 1997) with an extension to the use of renewables as they entered the energy mix (Varbanov and Klemes, 2010). Water consumption is an interesting case: an effort driven by industry (Carnes et al., 1973), was originally presented as a mathematical problem (Takama et al., 1980). However, the difficulty in solving it lead to the use of heuristic-based conceptual design for many years. El-Halwagi and Manousiouthakis (1989) proposed a targeting graphical method for mass exchange networks. A few years later, Wang and Smith (1994) proposed the so called “water pinch” for minimization of water consumption. Heuristic rules have also been used in the design of sequences of distillation columns (Seader and Westerberg, 1977) while geometric rules were proposed for reactor selection (Glasser et al., 1987). The main procedures for complete process design are the hierarchical decomposition (Douglas, 1985) and the onion model (Smith, 2005). This heuristic based approach has alsobeen applied to process integration and intensification aiming at the efficient use of resources (Klemes et al., 2014).

2.2. Mathematical-based design

The development of computers and solvers has extended the use of mathematical based approaches. For example, early HEN’s were designed using sequential methods (Floudas et al., 1986) and later simultaneous design based on superstructure optimization (Yee and Grossmann 1990). However, large scale problems are still quite challenging; sequential framework approaches are able to handle larger problems, but not prove global optimality (Anantharaman et al., 2010). In the area of mass exchange networks, mathematical optimization for water management was addressed in the early 90’s (Papalexandri et al., 1994). Galán and Grossmann (1998) revisited Takama’s et al. (1980) work and several reformulations have been presented afterwards (Karuppiah and Grossmann, 2006; Ahmetovic and Grossmann, 2011). Simultaneous water and energy integration was presented in a two stage procedure by Grossmann and Martín (2010). Later, simultaneous methods such as targeting procedures (Yang and Grossmann, 2013) or superstructure optimization have been presented (Baliban et al., 2012). Power and steam production systems have also been addressed (Papoulias and Grossmann, 1983). Design procedures that consider flexibility in production have only started to appear recently due to the complex models required (Martín and Martín, 2013), but have been extended to polygeneration systems (Chen et al., 2012) and total site optimization (Nemet et al. 2015). Reactor networks aim at optimizing the conversion and require

considering the dynamics of the kinetics in the formulation (Achienie and Biegler, 1986). The link between reaction and separation led to considering both simultaneously in the formulation (Balakrishna and Biegler, 1993). In terms of separation, with distillation columns the most energy intense units in industry, a number of early works deal with the optimal sequence of columns to separate mixtures (Andrecovich and Westerberg, 1985), including heat integration among them (Floudas and Paules, 1988) as well as the rigorous design of columns (Viswanathan and Grossmann, 1993). More recent advances focus on optimal multicomponent distillation sequencing with the possibility of non-traditional, thermally coupled sequence configurations, which explores a very large combinatorial space of possible designs (Shenvi et al., 2012). PROSYM (now MYPSYN) was developed as an optimization based software for process synthesis (Kravanja and Grossmann, 1990; Kravanja, 2010). The first attempts into general representation for process synthesis date back to Papalexandri and Pistikopoulos (1996). Recently, Super–O has been based on a stage-wise process structure (Constantinou and Gani 2004; Bertran et al., 2017) and automatic process flowsheet generation using blocks and a grid structures have also been presented (Demirel et al., 2017).

For years, design has been process focused while product design was addressed as a separate problem. Typically product design focused on molecular design (Gani and Brignole, 1983), catalyst design (Gounaris et al., 2006), and protein folding (Floudas et al., 2005), for which global optimization became the driver via software like BARON (Sahinidis, 1996) or sbb (Androulakis et al., 1995). General packages for product design have been developed such as the VPPD Lab (Sawitree et al., 2015). However, sometimes process and product design must be solved simultaneously. Examples include the production of specialized ingredient based products (Martín and Martínez, 2013; Gani and Ng et al., 2015), the production of fuels within environmental regulations (Zhao and Wang, 2009), product/process design related to separations (Eden et al., 2004), the design of algae for fully renewable biodiesel production (Martín and Grossmann, 2013), the design of specific molecules with a desired properties such as reactant media (Struebing et al., 2017) or solvent selection (Gopinath et al., 2016), and addressing process design considering product characteristics (Moggridge and Cussler, 2000; Gani, 2004).

2.3. Hybrid approaches

In most cases the actual number of technologies is so high that it makes sense to follow a two stage evaluation procedure to discard those less promising due to their early stage of development or the extreme costs (Martín and Grossmann, 2011). Alternatively, if the number of alternatives is small, a scenario based approach can be performed using rigorous process simulators (Zhang et al., 2013). Finally, stochastic optimization using process simulators is interesting to take advantage of detailed models of distillation columns, liquid-liquid extraction columns, and other models that are implemented in rigorous process simulators (Adams and Seider, 2008; Ramirez et al., 2017).

3. Challenges in process and product design

Figure 1 summarizes the grand challenges of chemical process and product design, from the use of new materials to the development of novel technologies and processes involving the choice of pretreatments or separation schemes. Optimality is usually characterized by economics or business objectives, minimizing wastes, minimizing environmental impact, or combinations of these are becoming more important.

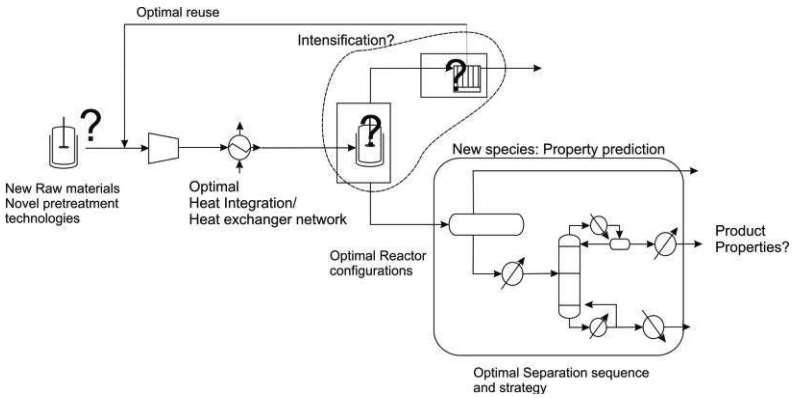

Figure 1. Challenges in process and product design.

3.1. New sources and products

The recent focus on environmental concerns for the chemical industry has brought several new potential feedstocks to the forefront. These especially include biomass, waste, nuclear, solar, and wind as source of energy. However, the variability of renewable sources greatly impacts process design (Martín, 2016) and operation (Zhang and Grossmann, 2017). Uncertainty, either exogenous (e.g. wind velocity) or endogenous (e.g. novel technologies), plays an important role in process design and operation (Pistikopoulos and Ierapetritou, 1995) and the size of the problems require novel solution procedures (Lara et al., 2017; Heuberger et al., 2017).

Similarly, new environmentally-motivated products are now of interest too, such as biodiesel from different alcohols, glycerol ethers (de la Cruz, 2014), biobutanol (Dalle Ave and Adams, 2018), bio-butyl butyrate (Birgen et al., 2016), and dimethyl ether (Ballinger and Adams, 2017). Furthermore, advanced and high added value materials are the key for economically promising bio-refineries. Polymers (Bueno et al., 2015), drugs, proteins, and carotenoids (Psycha et al., 2014) can be produced from biomass and waste. These new materials show the link between process and product design by targeting the properties that meet society needs, which is made possible by good physical property estimation models (Marrero and Gani, 2001). Furthermore, the link between fuels (chemicals) and power must be further analyzed due to the possibility of using power to produce chemicals that allow energy storage and shipping (Martín and Grossmann, 2017), going a step beyond batteries, where power is also stored chemically but whose capacity is still limited (Dunn et al., 2011).

3.2. Electricity and Energy storage

Chemical process engineers have rapidly moved into the field electricity generation processes, traditionally in the domain of electrical and mechanical engineering. However, the interface between electricity and chemical production has become increasingly important. Commonly, this link occurs as a waste handling step in chemical production, in which high-energy off-gases from a process used as fuel for a power plant in various ways, leading to polygeneration processes (Adams and Ghouse, 2015). However, because electric power production is driven by demand, and because electric grids are increasingly dependent on renewables in which power generation cannot be controlled, there is a clear mismatch between production and consumption. Grids with limited amounts of renewables traditionally handled this mismatch by raising or lowering natu-

ral gas combustion rates in response to demand. However, more modern grids with large amounts of integrated renewables face a new problem in which more electricity is occasionally produced than consumed. This leads to a modern problems associated with electricity disposal, which is sometimes resolved by selling it at negative prices.

A number of chemical engineering solutions have been discussed to address this issue. To mitigate the temporary absence of a resource, the integration of several of them provides backup (Yuan and Chen, 2012). Furthermore, thermal or chemical storage of excess energy generated by renewables is increasingly of interest. For example, concentrated solar power plant designs include thermal storage options such as molten salts, hot water, or waxes (Martín and Martín, 2013). Alternatively chemical storage options use reversible exothermic/endothermic reactions such that energy is stored as chemical potential (Lai and Adams, 2017). While these address day-to-day variation, seasonal variation might be better dealt with by integrating solar energy with biomass combustion during less sunny months (Vidal and Martín, 2015), since biomass is how nature already stores solar energy. Instead of thermal pathways, electrolytic pathways can be used to create H_2 from water via electrolysis when extra electricity is available. When combined with CO_2, high energy products such as methane, methanol, DME, (Davis and Martín, 2014, Martín, 2016) can be produced, thus storing the energy in fuel form. Physical pathways are also possible, in which excess energy (or electricity or mechanical work) is stored by compressing a fluid such as air (Nease and Adams, 2013). However, cost remains a major challenge with these storage systems, which is a major focus of current research.

3.3. New targets and metrics

Economic objectives have been the obvious choice for characterizing plant quality, and most heuristics and rules of thumb in the chemical industry have been developed with this in mind. However, they are no longer socially acceptable. A second objective is environmental impact minimization. There are a number of metrics (e.g. GREET, TRACI, ReCiPe) that measure the impact generated by a process, with life cycle analyses the most common technique for obtaining these metrics to be used in process optimization (Kniel et al., 1996; Azapagic, 1999). More recently, social issues are also being included. For example, the Jobs and Economic Development Impact model (JEDI) developed by the NREL can estimate the economic impacts of constructing and operating chemical and power facilities, which can be included in process synthesis (You et al. 2011). Safety, originally presented by (Klenz, 1984) has also been included as an objective for process synthesis (Ruiz-Femenía et al., 2017) and for product and process design (Martínez, 2017). To address them all as multiobjective, several strategies have been used to address its solution, either by producing a single-weighted objective function such as ecoprofit (Cucek et al., 2012) or RePSIM (Martín, 2016), or by using a constraints-based approach. Alternatively, methods on reducing the number of objectives without eliminating solutions of the problem (i.e. Pozo, et al. 2012) or to evaluate the target yields of a particular technology for it to become competitive (Limleamthong et al., 2016) have been developed.

4. Near-Term Future Directions

4.1. Big data approaches to process and product modelling

Modelling is now the root of rigorous process and product design, often striking a balance between model rigour and model speed or complexity. Machine learning to create

data-based models is growing in popularity. Examples include estimating product properties and performance (e.g. wine taste, appropriate smell), which may not even exist yet. Given the more recent inclusion of social objectives, data and theory from outside engineering (including social science) will need to be included in big data approaches for product design. Artificial intelligence (AI) approaches will also become more in use, such as training artificial neural networks (ANN) to recognize heuristics and trends in human-designed processes and then use that to create new processes from the ANN models. For example, IBM's Watson platform is being trained with data from engineering operations documentation in order to make models of oil production operations. Engineers can ask plain language questions to get information about day to day operations or get suggestions on how to deal with problems as they appear (Lewis, 2017). Although not used for design currently, the same approach could be applied with an appropriate data set.

4.2. Process operation: Integrated scheduling and operation

Renewable-based processes rely on resources that are uncertain and seasonal. Thus, dynamics and scheduling will play an important role. For example, demand-side management is starting to address this issue with integration of processes and their operation (Zhang et al 2017). However, key challenges include the problem size, the various time and spatial scales involved, and understanding dynamic process characteristics and operation such as start-up and shut down. This is especially prevalent with systems that include energy storage technologies such as batteries, thermal fluids, and chemicals, in which technology degradation over time becomes an important factor.

4.3. Process control

Integrated process design and control has been growing in popularity to create a more robust or profitable steady state design and control system by considering the inherent controllability of the design in the face of uncertain disturbances (Ricardez-Sandoval, 2012; Washington and Swartz, 2014). In a renewables-driven process, uncertain disturbances such as minute-to-minute wind velocity fluctuation can be incorporated under this framework. However, more predictable disturbances (such as seasonal solar and biomass cycles) are better considered in an integrated design, control, and scheduling framework, which is at its infancy (Pistikopoulos and Diangelakis, 2016). Again, the dynamics of the systems plays a major role in these areas.

4.4. Supply chain management.

Although process and supply chain are at different scales, the design of the supply chain becomes directly linked to the design of the process when environmental considerations are made. In addition, the operation of flexible multiproduct processes that use unreliable feeds (biomass in particular) relies on the information of their supply chains. Either way, the link between process design and supply chain design will become increasingly important in an environmentally conscious world.

4.5. Computer science

Nearly all of the future directions put forward in this paper, from process modelling advances to integrated supply chain management, create large mathematical problems which will require novel algorithms to solve. Efficient decomposition algorithms, modelling approaches, as and better software (or a combination of each) will allow us to solve larger and larger MILP or MINLP problems. Global optimization, despite its many advances, is still limited to small problems. Many of the future directions put

forward in this paper are rooted in the solution of ever-larger problems with more complex models in order to capture and exploit more nuances and characteristics of the system. This means including more detail, non-linearity, and non-convexity, and so global solvers will need to be extended and improved. However, as engineers, a suboptimal solution is better than none, therefore solvers that handle large problems (but not guarantee global optimality) will be a necessary tool for practical process synthesis and operation. These include stochastic, evolutionary, or non-deterministic optimization algorithms which may not be elegant or theoretically attractive, but are undeniably useful.

5. The PSE Technology Tree

To help us prepare for this article, we created a technology tree for process systems engineering. A technology tree maps the progression of research from one technology to another, and how they combine to form new technologies. For example, in order to create a sequential modular process simulator, you must first create an algorithm to solve individual unit operation models, and also create an algorithm to solve sequences of unit operations with recycle using tear streams. Such trees are useful for getting a bird's eye view of both the history of the field and its future directions. However, every researcher might have a different idea about what the tree should look like and how detailed it should be, and the field (and tree) is always changing. That is why, in the spirit of this conference, we created a Technology Tree Wiki on the website psecommunity.org/pse-technology-tree/. We encourage readers to visit the website and contribute by adding to or changing the structure of the tree. Readers can also create, discuss, or edit articles about each individual node, such as providing descriptions, examples, images, videos, or literature citations in each area. In this way, readers can participate in the open creation of an ever-evolving encyclopaedia for our field. An example screen shot is shown in Figure 2.

6. Conclusions

From a big picture perspective, the historical progression of the field of process design is perhaps best characterized by an ever-increasing problem scope. Our fundamental understanding behind major chemical unit operations and their thermophysical phenomena has not changed much over the decades. Instead, the *methodology* of process design has expanded to include more and more rigorous mathematical, dynamics, control, planning, scheduling, product design, uncertainty, economics, and environmental factors, although not yet all at once. All of this is made possible by continually improving numerical methods (particularly optimization and modelling) and software tools which make larger and larger problems more tractable.

Based on the extrapolation of this trend, we envision that the future of process design will be largely driven by software that essentially includes all of these areas integrated together in one large global optimization problem. The designer would specify key objectives (perhaps in plain language) that relates to either particular products or merely product properties. The software would then formulate and solve an optimization problem which automatically synthesizes the design of the dynamic process and its products, together with its dynamic supply chain, plans and schedules, target markets, control systems, and considering all operational details including product flexibility and transitions, startup, shutdown, safety, reliability, uncertainty, and disturbance response. Candidate processes would be ranked on metrics that include a mix of environmental, business, and social factors. Data for environmental impacts, markets, supply chains, unit operations, and chemicals would be automatically drawn from massive databases or database-driven models. The process synthesis would be achieved through AI algorithms which draw upon massive models or databases of both human-derived and AI-created processes, heuristics, and best-practices. All of these aspects already exist in one form or another, it is merely the integration of everything together into one mega-problem that remains.

Multilevel and multiscale PSE: Challenges and opportunities at mesoscales

Jinghai Li, Wenlai Huang, Wei Ge

State Key Laboratory of Multiphase Complex Systems, Institute of Process Engineering (IPE), Chinese Academy of Sciences (CAS), Beijing 100190, People's Republic of China
jhli@ipe.ac.cn

Abstract

This presentation discusses the challenges and opportunities at different levels of process engineering. It is indicated that all processes involve in multilevel structures, each multiscaled, and the complexity of each level exists always at the corresponding mesoscale at the specified level. On the other hand, these mesoscale structures at different levels are all subject to operating regimes, showing the most complex spatiotemporal behavior at mesoregimes between two relatively simple limiting regimes. There is no thereby available approach for mesoscale problems in mesoregimes, leading to the proposition of mesoscience based on the recognition of a common principle for all these mesoscale problems. The presentation will introduce what is the physical principle and mathematical formulation of mesoscience, why it is critical to the paradigm shifting of process engineering, particularly to the realization of virtual process engineering (VPE), which is the dream for process systems engineering (PSE). The presentation will be concluded with perspectives in mesoscience.

Keywords: Mesoscale, Mesoregime, Mesoscience, Multilevel, Multiscale.

1. Introduction: Levels, scales, and mesoscales

To study a system, it is important, and should be the first step to define its domain and its relationship with surroundings. In doing so, it is essential to clarify which level we are studying, which scales should be involved in the study, and what is the boundary and interaction between the system and its surroundings. Subsequently, with these definitions for the specified system, we should further know in which regime the system is operated. Unfortunately, it is quite often that these aspects were not specified well during study, making confusions and debates. Especially, the division of levels, the definition of mesoscale, and the regime transition in a specified level have not received sufficient attention, hindering the development of PSE and the realization of VPE.

As shown in Figure 1, the whole procedure for PSE concerns three levels, i.e., the **material** level (from the scale of an atom or a molecule to the scale of a macroscopic particle), the **reactor** level (from the scale of a macroscopic particle to that of a reactor), and the **factory** level (from the scale of a reactor to that of a factory). These levels belong to different disciplines, i.e., chemistry and materials science for the material level, chemical engineering for the reactor level, and PSE for the factory level, as reviewed by Grossmann and Westerberg (2000). Each level exhibits multiscale characteristics, involving the element scale, the system scale, and the in-between mesoscale where complexity always emerges (Li and Huang, 2014). Currently, lots of investigations have been undertaken at the element scales and the system scales, but

understandings are quite limited on the mesoscale problems at these three levels, e.g., self-assembling at the material level, particle clustering at the reactor level, and process synthesis superstructure (Floudas et al., 1986; Yee et al., 1990) at the factory level. There is no satisfactory physical theory or mathematical approach for describing these mesoscale problems, showing knowledge gaps. In PSE, although the interactions among unit operations are taken into account, and formulated as multi-objective variational or optimization problems, however, the mesoscale problems at the material level and the reactor level are usually handled with averaging (e.g., coarse-graining) approaches, and therefore, the fidelity of the physical models is frequently neglected.

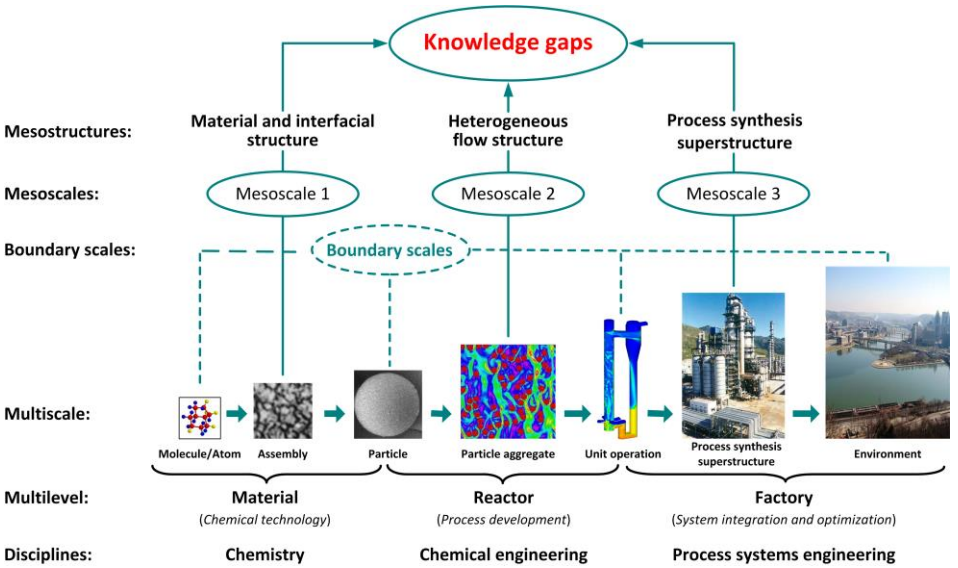

Figure 1 Three levels and corresponding mesoscales of chemical processes. Modified from (Li, 2015a), Copyright 2018, with permission from Elsevier

The complexity of mesoscale problems led to the proposition of nonequilibrium thermodynamics (Onsager, 1931a; 1931b), the theory of dissipative structures (Nicolis and Prigogine, 1977), complexity science (Wikipedia, 2018), etc. Recent investigations on the mesoscale structures at various levels revealed that traditional theories fail to offer satisfactory descriptions, and some common principle seems to exist, along with multi-objective formulations mathematically. Therefore, the concept of mesoscience was put forward (Li et al., 2013; 2014), which will be adopted in this work. In the language of mesoscience, three regimes (Li, 2016; Li et al., 2016) of the mesoscale structures may appear with the change in the operating conditions, i.e. (taking the systems with two dominant mechanisms as an example), two limiting regimes (mechanism *A*- or *B*-dominated) with simple structures, and the in-between mesoregime (*A*-*B* compromising) with complex structures. The complexity in this *A*-*B* compromising regime lies in the joint dominance of different mechanisms. Mesoscience concerns not only mesoscales, but also mesoregimes (Huang et al., 2017; Li, 2017). Therefore, the key (challenging) issues in PSE include bridging different scales in each

level, correlating different levels in a whole process, and distinguishing different regimes at each level.

2. Commonality and speciality of the three levels

All the complex systems at the above-mentioned three levels have common features: (1) They are composed of many elements; (2) There exist complex spatiotemporal structures at the mesoscales; (3) The mesoscale structures can be determined using stability conditions based on the principle of compromise in competition (Li, 2015a; 2015b; Li et al., 2016; Li et al., 2018; Li and Huang, 2018); (4) The stability conditions can be expressed as multi-objective variational problems in mathematics. However, level-specific features exist as well:

1) Dominant mechanisms are level-specific. At the material level, the mechanisms dominating mesoscale structures might be related to the processes of reaction, diffusion, etc. (Wang et al., 2013; Sun et al., 2016). At the reactor level, the dominant mechanisms might be subject to interaction between different phases, and also dependent on the reactor types. At the factory level, in addition to physical and chemical constraints, dominant mechanisms are also subject to the indices of economy, environments, etc. which are set to meet the production requirements.

2) For the first two levels, the processes and corresponding complex structures depend on the intrinsic nature at each level itself, and the interplay between the two levels. However, for the third level, the processes and structures are dependent not only on the constraints from the first two levels, but also on artificial factors (e.g., economic and ecological indices) (Grossmann, 2005; Bakshi, 2002; Triebl et al., 2013), bringing more complexity to PSE.

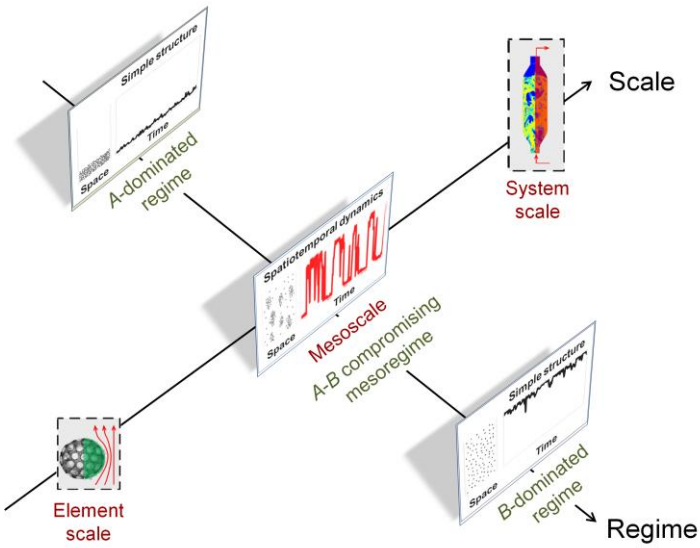

Figure 2 Regime-specific feature of mesoscales, exemplified with the reactor level

3) For the first two levels, the structures are determined by physical mechanisms under specified conditions. However, for the third level, the optimization is conducted firstly according to the specified conditions, and then the optimized

results should be returned to the first two levels to check the possibility of realization, so iterations and correlations between levels are necessary.

The above features already lead to lots of complexity, but moreover, the mesoscale structures at each level may change with the changes in specified conditions, usually exhibiting three distinct regimes, as shown in Figure 2 for the reactor level. Once such regime transitions occur during optimization, the situation should be more complicated. This is beyond our current capability in reactor designing and optimizing, it should be more difficult to account for.

Additionally, there exist problems in the literature, due to the ambiguity or even mistakes in defining levels, scales and mesoscales, which enhance the complexity and difficulty, as follows:

1) Identification of level: Naturally, one level corresponds to one kind of systems, and neighbouring levels might be taken as constraints of such a system, that is, the environment. However, sometimes one blurs different levels into a single problem, and sometimes one defines a "system" (e.g., a reactor) as a "mesoscale". Such treatments usually lead to mistakes or difficulties due to the confusions of different mechanisms at different levels.

2) Definition of mesoscale parameters: Mesoscale, as reviewed in (Li and Huang, 2018), is a relative concept to describe the scale with complex phenomena, between the element scale and the system scale at each level. Therefore, mesoscale parameters should reflect the intrinsic nature behind these phenomena, that is, the related dominant mechanisms should be taken into account, and interaction between the phases corresponding to such mechanisms should be formulated. For instance, in gas-solid fluidization, particle clustering and interaction between the dilute and the dense phases must be represented in its mesoscale model (Li and Kwauk, 1994).

3) Inter-level transfer of parameters: The bottom-up transfer of the parameters at the material level to the reactor level is relatively easy. However, the top-down transfer of the parameters optimized at the factory level to the reactor and material levels is very difficult (even more difficult when considering the regime-specific feature). It is a great challenge in practical optimization, and more transdisciplinary approaches and knowledge are necessary.

Therefore, under such circumstances, the future PSE should address the following issues:

1) Division of levels: Partitioning the overall system into correlating sub-systems, covering different levels, and identifying the dominant mechanisms in each sub-system.

2) Definition of scales at each level: Appropriate parameters should be given for the element scale, the system scale, and the structural unit at the mesoscale. Defining the mesoscale parameters is especially critical.

3) Correlation between levels: Determining the inter-level correlations in both top-down and bottom-up ways.

4) Resolution of mesoscales: Solving mesoscale problems depends on the understanding and description of mesoscale structures and the identification of the regime-specific features. Mesoscience is a promising way to this end.

Addressing these issues properly will pave the way for PSE to a new era, and lay cornerstones for VPE, where mesoscience or something equivalent will be the key.

3. Mesoscience bridges element behaviour and system performance

Over the past three decades, investigations on various mesoscale problems in process engineering have been conducted at IPE, CAS. Different from the methodology in traditional thermodynamics, which aims to find a single-objective variational function, and the complexity science that aims to directly correlate elements with the system, we focus on the complex structures at the mesoscales, and realize that there must exist knowledge gaps. Through analysing the compromise between competing mechanisms, we find the stability conditions for mesoscale structures, and express them as multi-objective variational problems (Li et al., 2004). As shown in Figure 3, such a EMMS principle originated from our EMMS model (Li and Kwauk, 1994) for gas-solid fluidization, and then was confirmed (Li et al., 1999; Ge et al., 2007; Huang and Li, 2016; Han et al., 2016) in turbulence, granular flow, gas-liquid flow, micro-fluidics, foam drainage, emulsion, heterogeneous catalysis, materials, micro-reactors, protein, impinging streams, and other systems. The commonality recognized from these different systems stimulated exploration of its universality, leading to the proposition of mesoscience.

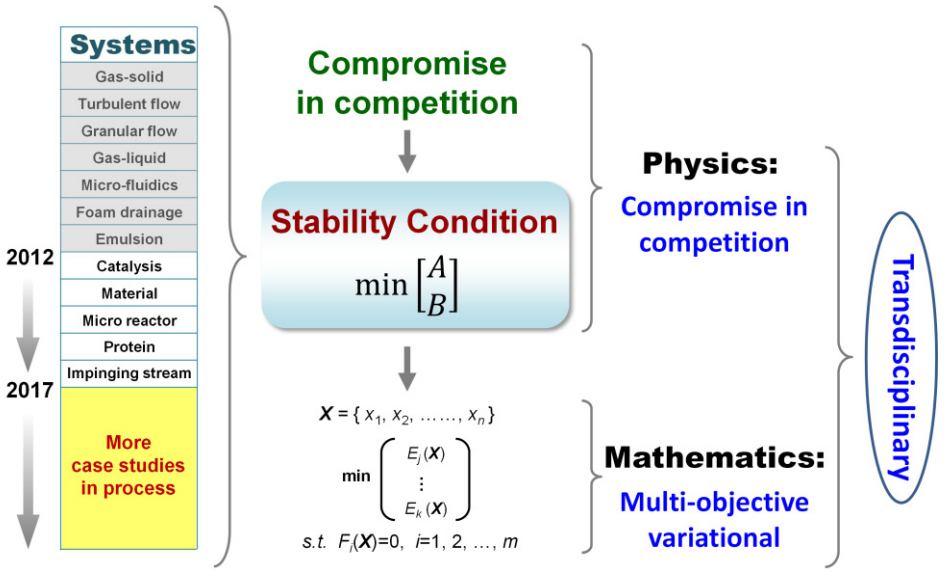

Figure 3 From case studies to common principle

Mesoscale structures are actually the focus of the theory of dissipative structures (Nicolis and Prigogine, 1977) and the complexity science (Wikipedia, 2018). After three decades of exploration, we reckon that the theory of dissipative structures is really revolutionary, but it is a pity that it does not succeed completely in describing complex systems, partly due to the limitation in directly searching for a single-objective

variational function. Therefore, the key is to find multi-objective variational functions, instead of single-objective variational functions. This is possibly the common principle we have revealed through the concept of mesoscience.

As we stated recently in an editorial (Li, 2017), the concept of mesoscience is based on the core principle of compromise in competition. Instead of looking for a single-objective variational function directly, different dominant mechanisms at the mesoscales in mesoregimes are first analyzed. The resulting variational functions are then defined and their compromise in competition is analyzed, mathematically, leading to multi-objective variational formulation. Physically, the origin of complexity is related to the alternate appearance of states dominated by different mechanisms. This shift in research strategy from single-objective to multi-objective optimization might offer a glimmer of hope for understanding the complex world in which nature exits. The solution of such a multi-objective variational problem represents a continuing grand challenge. However, in some cases the possibility to transform it into a single-objective problem, particularly based on physical analysis, should certainly not be excluded, as shown in our EMMS model (Li and Kwauk, 1994).

4. VPE perspective: Towards a new paradigm

The dream of PSE is to realize virtual reality (VR)-like VPE. The key lies in reasonable physical models, sufficient computational capability with high speed and efficiency, and the capability of handling big data. Mesoscience will contribute to all of these aspects, as summarized in Figure 4. Firstly, the establishment of mesoscience will clarify the relationship among the element, the system, and mesoscale structrues, i.e., identifying the intrinsic logic in complex systems. The complex mechanisms will be revealed for the mesoscale structures at each level in the mesoregime, and the physical principle (compromise in competition) and mathematical formulation (multi-objective variational) will be established. Secondly, based on the intrinsic logic, reasonable physical models can be achieved, guaranteeing the reliability of computation. Then, according to the common logic and structural features of mesoscale structures, reasonable computers can be designed, which will provide reasonable logic and structure for the computational science aiming at solving complex problems, establish the logic consistency among the problem, the model, software, and hardware, and hence improve the computational efficiency, achieving high speed and efficiency. This will supply powerful tools for mesoscience. Meanwhile, the analytic processing of the big experimental data will also be performed under the logic framework determined via mesoscience. This will greatly expedite the data processing and improve the capability of revealing underlying mechanisms, providing more evidence for the development of mesoscience and online data for the realization of virtual reality. At present, we have established a VPE center (Ge et al., 2011; Liu et al., 2012), the computational speed supports two-dimensional realtime virtual experiment (Lu et al., 2016). In other words, if one changes the operating conditions, the dynamic evolution of the system can be observed immediately on the screen. If such a scene is realized for three-dimensional industrial apparatuses, realtime VR simulations will be achieved, and VPE will not be far away.

Mesoscience originated from chemical engineering where there are lots of mesoscale phenomena. In developing chemical engineering, we can collect more evidence to verify the universality of mesoscience, and improve the intelligence in chemical engineering (Quantrille and Liu, 1991).

In summary, the complexity of mesoscale structures at different levels exhibits the regime- and level-specific nature. This is the common bottleneck at all the levels in chemical engineering, and also the missing link in current knowledge. The proposed mesoscience aims at solving such challenging problems. Certainly, more evidence is still needed to support our current understandings on the physical principle and the mathematical expression.

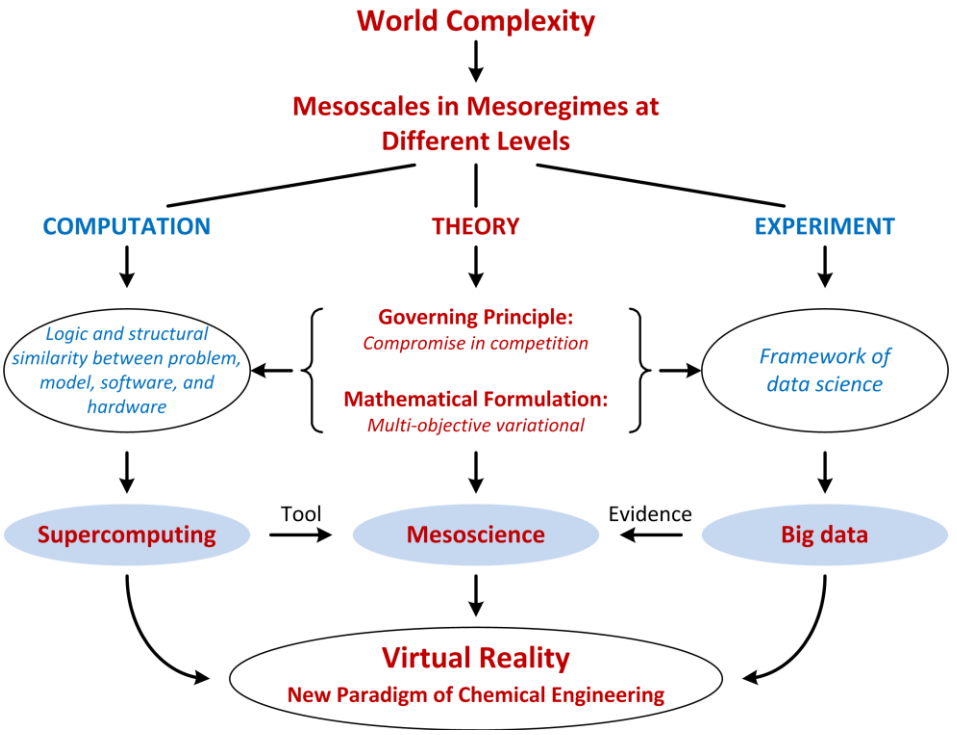

Figure 4 Relationship between big data, supercomputing, mesoscience, and virtual reality, showing the path to a new paradigm of chemical engineering. Modified from (Li, 2015b), Copyright 2018, with permission from Elsevier

Since the complexity in nature, mostly prevailing in mesoregimes, originates from the coexistence and compromise in competition between different dominant mechanisms, it seems difficult for traditional single-objective variational functions to describe such complexity. Different mechanisms follow different rules, and additionally the world is full of diversity, so directly establishing a single-objective description seems more difficult than finding a multi-objective description. Therefore, mesoscience deserves exploring in various fields. Once we collect sufficient evidence to verify the universality of the principle of compromise in competition, and develop the data and computational science as shown in Figure 4, we will greatly promote the realization of VPE—a new paradigm of chemical engineering!

Abstract

After its launch at the turn of the millennium, integrated product and process design has gradually taken root in research and teaching within chemical and biochemical engineering. The transition from primarily process design in which the product is relatively well defined to include product design is primarily driven by economics. With globalization, any product that can be made by multiple producers would eventually exert enormous financial pressure to lower product price, resulting in squeezed profit margin. The only way for a company to survive and prosper is to invent innovative products. Also, with the rapid advances in computer technology, emergence of new business models, and requirements in social responsibility and sustainability, a chemical engineer should and is well positioned to contribute to the entire product life cycle. This article identifies the technical and non-technical issues/problems in integrated product and process design, the relationships among which are captured in a Grand Product Design Model. The methods/techniques and computer aided tools for the design, analysis, and development of molecular products, formulated products, functional products, and devices are discussed. Many of these recent developments have been included in teaching product design to prepare the new generation of chemical engineers.

Keywords: Product design, Grand Product Design Model, Formulated products, Functional products, Devices

1. Introduction

Chemical product design is a diverse subject. In addition to the basic science and engineering underlying the product under consideration, consumer preference, budget, competing products, pricing, supply chain analysis, government policy, corporate social responsibility, sustainability, and so on also need to be taken into account in designing and developing a product. This is captured in the Grand Product Design and Development Model (see Figure 1), which shows the relationships among the different tasks / problems in the product design and development process (Fung et al., 2016). Normally, the development process begins with consumer preferences, which define the desired product quality. The ingredient and production process are then appropriately selected (designed) to yield product properties and product structure, which together provide product attributes that meet product quality requirements. Note that supply chain analysis is used to optimize the selection of product ingredients. After accounting for product cost and non-manufacturing expenditure, a pricing model is needed to maximize profit while meeting corporate social responsibility. Other issues may also be considered such as sustainability, company strategy, aesthetics, and so on. This model is part of a hierarchical, multidisciplinary framework for chemical product design (Seider et al., 2017).

There are 5 elements (highlighted through different colors in Figure 1) of the design framework that are used for carrying out product design. Model-based methods, rule-based methods, and databases do not involve hardware while computational and experimental tools do. Note that not all models from Figure 1 are considered in all product design problems.

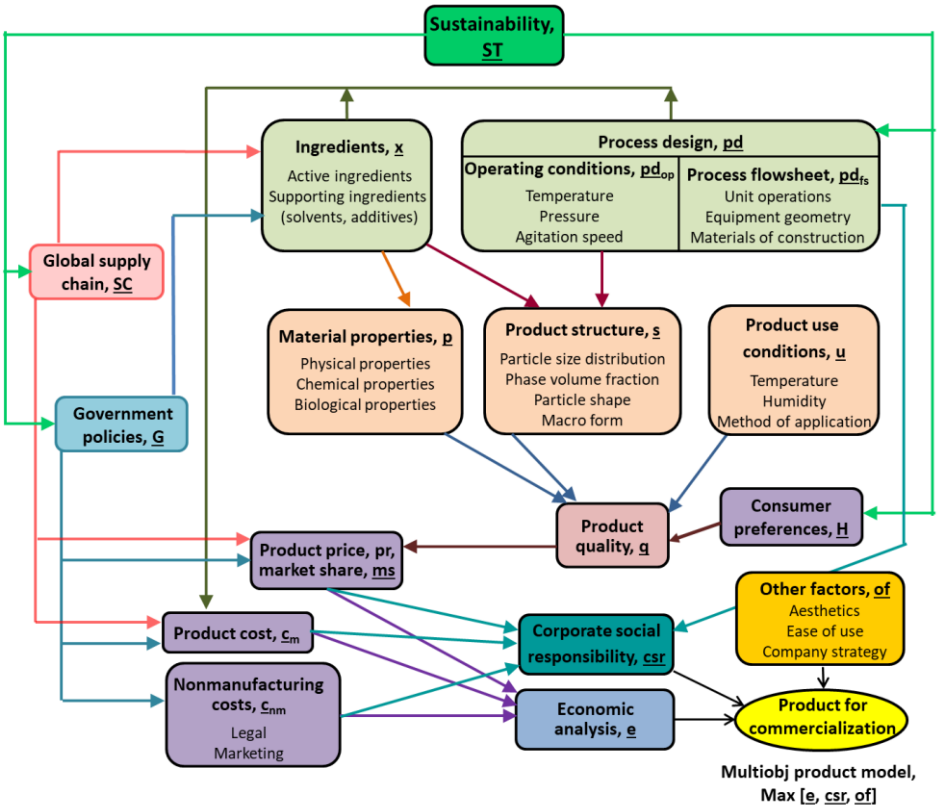

Figure 1: Grand Product Design and Development Model (Fung et al., 2016).

Many chemical products have been considered in product design. These include fuel additives (Sundaram et al., 2001; Hada et al., 2014), refrigerants (Sahinidis et al., 2003), perfumes (Mata et al., 2005), slow release deodorizer (Street et al., 2008), medical diagnostic products (Heflin et al., 2009), disinfectant (Omidbakhsh et al., 2012), biofuel (Dahmen and Marquardt, 2016), solvents for reaction synthesis (Struebing et al. 2017) and so on. A classification of the chemical product types is given by Seider et al. (2017). A review of these publications shows that one or more of the five elements of the design framework is used for design of these products. Model-based design methods often play a prominent role. For example, Bernardo and Saraiva (2015) treated a product design problem as the inversion of three design functions: quality, property, and process functions. Xiao and Huang (2009) developed a model for paint design. Often, two or more of the elements are used synergistically. For example, Wibowo and Ng (2001), Cheng et al. (2009), Smith and Ierapepritou (2010), Conte et al. (2011) and Mitrofanov et al. (2012) used a combination of rule-based methods, model-based meth-

ods, and data-bases in the design of different types of product. Experimental tools are needed in product design either for obtaining data such as material properties that are not available in the database or for fabricating a product prototype for testing its performance (Conte et al., 2012). Similarly, computer-aided tools for product design are highly desirable (Kalakul et al., 2017).

Most of the publications in chemical product design focus on Ingredients, Process design, Material properties, and Product quality of the Grand Product Design Model (Figure 1) and relatively little has been done on product pricing, corporate social responsibility and government policies, sustainability, and so on. This is natural because materials and processing are Chemical Engineers' core competencies. However, the other problems need to be considered in order to answer the seemingly simple question of "what to make?" Making a product that has the best quality on the market does not guarantee commercial success. The product can be priced beyond the consumers' budget even if it has all the product attributes to satisfy the consumer preferences. In product design, nonmanufacturing costs such as legal and advertising costs can be substantial. This is in stark contrast to process design where the raw material cost easily constitutes over half of the product cost. Government policy has a huge impact on what to make. Without government subsidy, electric vehicles (and all the chemical products associated with them) and solar panels would take much longer to open up the market to drive down the product cost. A product proposed by the marketing and engineering teams may not be approved by management because of social responsibilities.

In this article, the aforementioned problems are reviewed in more detail focusing on the design and analysis of the major types of chemical products – molecular, formulated, functional, and devices. Special emphasis is placed on the PSE tools and methods for their design. In view of the fact that product design is being incorporated into the chemical engineering curriculum around the world, the recent developments on the educational front are also discussed. The article ends with a discussion of the challenges, gaps, and opportunities in product design. Unless otherwise mentioned, "product design" in this article refers to "chemical product design"

2. Design, analysis and development

Figure 2 shows the relationships among the four major types of chemical products in product development. Single species products can be further classified as small molecules (refrigerants, solvents) or large molecules (active ingredients, surfactants). Usually, these chemical products have process applications (separation, reaction) as well as product applications (part of formulated or functional products). The single species small molecular products are usually produced in bulk quantities where the process costs are a key to their success, in addition to their product attributes. Design methods for these products are well established (Gani, 2004, Mitrofanov et al. 2012, Samudra and Sahinidis, 2013). Because of the size of the molecules and the product attributes (not all can be modelled), design methods for large or complex molecular products are not well established, although there is increased interest to develop them. For example, Karunanithi and Mehrkesh (2013) reported a method for ionic liquid design, Zhang et al. (2015) for surfactant design, and Gerbaud et al. (2017) for bio-based molecules. Formulated products are obtained by mixing selected components together to get the desired product attributes (Zhang et al., 2017). These include creams and pastes, paints,

shampoos, insect repellents, inks, and so on. They often contain different ingredients to fulfill the desired product attributes. For example, a sunscreen lotion can easily contain around 20 ingredients. In the design of such a lotion, the selection of more complex ingredients including UV absorbing agent, emollient, emulsifier, stabilizer, neutralizer, humectant, film former, thickener, and preservative depends a great deal on experience in the form of rule-based methods and databases. The rules and heuristics for ingredient selection are often based on an understanding of the basic science. In contrast, the solvents used for formulated products can be reliably designed through computational tools because of the extensive database and available models for thermodynamic properties. Suitability of an ingredient is decided not only by its physiochemical properties but also by its supply and cost. Prototyping is performed to check whether the formulation meets the product requirements. Iteration is often required to come up with the final product.

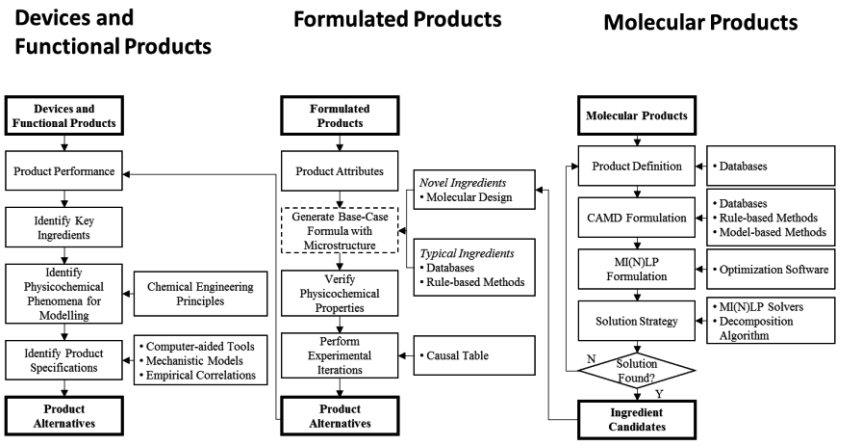

Figure 2: Relationships among the four major types of chemical products.

Functional products are those chemical products made up of materials that perform a desired function. Generally, these products do not have feed and outlet streams, and do not involve mechanical and electrical parts. They serve as barriers (food packaging), delivery vehicles (controlled release granule, transdermal patch), absorbers (silica gel), etc. The performance of functional products depends on the material properties of the ingredients, and the structure, form, shape or configuration of the product. Figure 3 shows a reservoir type transdermal patch with five major parts (Cheng et al., 2010). A drug reservoir that holds the pharmaceutical active ingredient (API) in a carrier. A rate-controlling membrane that controls the rate at which the API is released from the reservoir. A liner that prevents unwanted release. A backing layer that prevents unwanted release and protects the API from the environment. The adhesive layer simply bonds the liner to the rate-controlling membrane. In designing a functional product, each part of the functional product has to play its role to deliver the overall product performance, which can be modelled using chemical engineering principles. Clearly, diffusion, permeation, and adhesion are the key mechanisms in this functional product, and experimental tools such as a Franz diffusion cell system are needed in product design.

Chemical devices are those chemical products that perform a particular purpose, especially those with mechanical and electrical parts. Chemical engineers can view a chemi-

cal device as a single miniaturized chemical processing equipment item, a group of interconnected equipment items, or even a chemical plant. Often, a feed stream to a chemical device is transformed into an outlet stream with characteristics specified in the product attributes by performing reactions, fluid flow, heating/cooling, separations, addition/formation, and/or removal/destruction. The first four items are conventional chemical engineering principles which can be used to model the chemical device. For example, an air purifier with UV-based catalytic decomposition of VOCs can be modelled based on Langmuir-Hinshelwood kinetics (Seider et al., 2017). As will be explained in more detail in the section on Education below, the last two items include unconventional processing techniques such as solution coating, granulation, etching, breakage, and so on. As the boundary of the chemical engineering discipline expands and overlaps with bioengineering, biomedical engineering, material science, data analytics, and so on, it is expected that the integration of systems engineering principles with the newly developed domain knowledge can spur the development of innovative chemical devices, and expand the capability and reach of our profession.

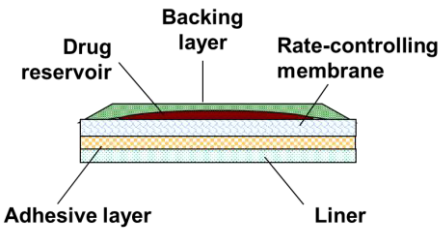

Figure 3: A reservoir type transdermal patch.

3. Computer Aided Techniques & Tools

Like process synthesis and design, chemical product synthesis and design can also be formulated mathematically and solved with many of the available numerical tools. Since the early 1980s, when the first CAMD (computer aided molecular design) technique related to solvent design was proposed, many developments in various directions have been reported. In all cases, the synthesis-design problem is formulated as an optimization (MILP or MINLP) problem, which is then solved in a variety of ways, rule-based methods (Gani 2004), graphical-visual methods (Solvason et al. 2009), decomposition-based methods (Karunanithi et al., 2005) as well as direct solution of the optimization problem (Samudra and Sahinidis, 2013, Zhang et al., 2015; Jonuzaj et al., 2016) with an appropriate numerical solver. The objective of these computer-aided techniques is not to determine the final design but to quickly identify a number of promising candidates, which can be verified by focused experimental means. Therefore, an integration of the computer-aided techniques with experiments is recommended. The text here is divided into two main sub-sections: computer aided techniques and computer-aided tools.

3.1 Computer-aided Techniques

3.1.1 CAMD Techniques: In addition to the earlier generate and test paradigm, computer-aided options have been reported for refrigerants (Sahinidis et al. 2003), ionic liquid design (Karunanithi and Mehrkesh, 2013), enzyme design (Frusicheva et al., 2014), surfactant design (Zhang et al., 2015), for solvents for reaction synthesis (Zhou et al., 2017), lipids or bio-based molecular design (Gerbaud et al. 2017), chemical substitution (Jhamb et al., 2018) and many more, using a variety of methods mentioned above. In all

these problems, single species molecules are synthesized, screened and/or designed by combining building blocks (to represent the molecule) and property prediction tools to estimate the desired (target) molecular properties. The CAMD techniques are well developed because of the availability of large amounts of data and therefore, property models. Integration with process issues is an important factor for these single species products (especially small molecules) and integrated product-process design techniques have also been reported (Hostrup et al., 1999; Li et al., 2007; Lampe et al., 2014).

3.1.2 CAM^{b}D techniques: Unlike the CAMD technique, in this class of problems, a basic set of molecules and their properties are known but which molecules will be present in a single-phase liquid mixture together with their composition in the mixture are unknown. Like CAMD problems, these mixture or blend design problems have also been formulated as MILP or MINLP problems and solved by a variety of ways. Tailor-made fuel blends (Yunus et al., 2014; Ordruei and Elkamel, 2015; Dahman and Marquardt, 2017; Choudhury et al., 2017) and solvent mixtures for gas separation (Jonuzaj et al. 2016) are examples from this area. Although the design steps (work-flow) are the same for different blended products, the molecules, their properties and product attributes are different, thereby increasing the dependence on data and models for a wider application range. Also, a computer-aided framework that is able to provide users with the necessary data and models needed for each step of the design process, becomes a very useful option to have.

3.1.3 Formulation design techniques: Unlike the CAM^{b}D techniques, where molecules from the same set are identified for the blend, here the set of molecules to define the formulation are divided into separate classes: ingredients (performs the main function of the formulated product); additives of different types (improves the quality or performance of the formulated product). Note, however, the formulated product must be a single liquid phase. Although, the potential application range of this kind of technique is very large, their success depends to a large extent on the available data and property models. Conte et al. (2011) employed a decomposition-based technique using data, property models and product performance calculation models to design a variety of formulated products. Here also, the design steps are similar for different formulated products, but the molecules, their properties and product attributes are different, thereby increasing the dependence on data and models for a wider application range. Again, availability of a computer-aided framework becomes a very useful option to have.

3.1.4 Functional products and devices: Here, most of the design techniques are based on heuristics, database, experiments and very limited modelling. For example, Mattei et al. (2015) proposed a knowledge-based system for designing emulsified products. Morales-Rodríguez and Gani (2007) provided models for evaluation of the performance of functional products and devices. Most of developed computer-aided techniques, however, are product specific. Consequently, generic computer-aided frameworks are not yet developed for these types of products.

3.2 Computer Aided Product Design Tool

Although a number of systematic computer-aided techniques for design of various types of products have been reported, only one so-called chemical product simulator, ProCAPD, with similar functions as a process simulator has been reported (Kalakul et al., 2017) and available for general use (see Figure 4). The ProCAPD software tool contains

a large collection of data organized in terms of databases (organic chemicals, solvents, active ingredients, lipids, ionic liquids, and many more); property models organized in terms of pure component properties, functional properties, bulk mixture properties and phase-equilibrium related properties (a total of 56 properties and their corresponding models are currently available); product performance calculation routines (phase stability, solvent evaporation rate, controlled release, etc.); product design templates (solvents, fuel-blends, formulations, functional products and devices); product analysis (model based verification of product attributes); and, utility tools (design template generation, property model creation, etc.). Many of the computer-aided techniques mentioned above (section 3.1) are available in ProCAPD. It is suitable for teaching (See examples in Seider et al., 2017), getting quick estimates for promising new products, evaluating product attributes and many more.

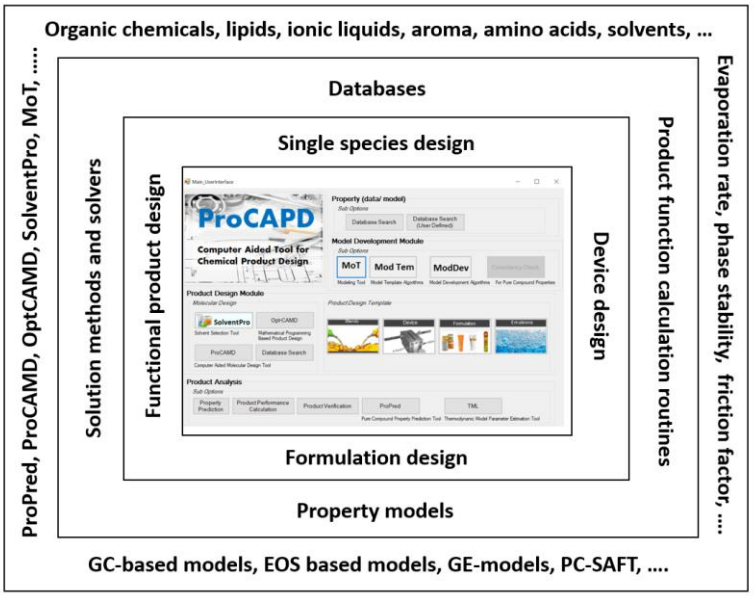

Figure 4: Structure of ProCAPD (design options, models-calculation routines, tools)

4. Education

Generations of chemical engineering students have been taught to design a process to produce a specified product, usually a bulk chemical. There has not been any discussion as to why the particular product is selected and who decided to make it? This is a serious omission for two reasons. From a wider perspective, it takes away the opportunity to challenge the students to innovate to come up with chemical products to meet human needs and to expand the company's product line. Another reason is that an optimal process for an inferior product does not really provide the best return on investment. In other words, the optimal product should be the best product-process combination. In chemical engineering education, it is fine to initially concentrate on the production of single species small molecules in bulk quantities where the process issues play a key role. Then, product design is introduced for single species large molecules or multi-species formulated and functional products, where the molecular structure and the ingredient identity and composition play also a major role. These concepts are included in

product design courses taught at the Hong Kong University of Science and Technology. Table 1 shows the topics covered in a course for chemical engineering seniors. Most of the topics are included in a textbook (Seider et al., 2017). There are still a number of challenges that require a lot more work. Two gaps are highlighted below.

Table 1: Contents of a chemical product design course

Topic	**Sub-topics**
Introduction	*The Diversity of Chemical Products; Companies Engaging in Production of Chemical Products*
Product Design and Development	Multidisciplinary Hierarchical Product Design (Elements of the Product Design Framework for Task Execution); Project management (Objective-time Chart, RAT^{2}IO); Market study (Consumer preference, Conjoint analysis, QFD, House of Quality, Business model canvas); Research & development (Innovation map, Patent search, Technology platform)
Design of Devices, Functional Products, and Formulated Products	*The Use of Models in Designing Devices and Functional Products; Design of Formulated Products*
Design of Processes for Manufacturing B2C Products	Unconventional Processes
Business Decision-Making in Product Development	Cash Flow Diagram; Financial Analysis for Product Development; Make-or-buy Analysis
Microeconomics of Product Design	Supply and Demand; Consumer Behavior; Individual and Market Demand; Pricing
Molecular and Mixture Design	*Framework for Computer-Aided Molecular-Mixture Design Case Studies; ProCAPD (chemical product design software)*
Optimization in Product Design	*Optimization Basics; Design Problem Formulation & Solution with OptCAMD (with GAMS)*
The Grand Product Design Model	*Government and Social Impact; Supply Chain Analysis; Sustainability Analysis*
Case Studies	*Refrigerants; solvents; surfactants; tailor-made fuel-blends; mosquito repellent; creams and pastes; inkjet inks; die attach adhesive; solar control interlayer; desiccant dehumidifier; biosensor; and so on (presented throughout the course duration)*
Presentations	Presentation by students of their design projects

Note: The topics marked in *italics* are parts of a graduate level course on computer-aided chemical product design given by the co-authors at different institutions.

4.1 Unconventional processing techniques

The way unit operations such as distillation, crystallization, absorption, adsorption, filtration, and so on is taught, with support from transport phenomena, thermodynamics and kinetics, has not fundamentally changed for decades. While this is sufficient for the production of commodity chemicals in the form of single species molecular products, it

is grossly inadequate for the manufacture of formulated products, functional products, and devices. As shown in Figure 5, unconventional processing techniques has two major categories. Addition/formation includes solution coating, physical vapor deposition, granulation, tableting, lamination, sintering, and so on while removal/destruction includes etching, homogenization, nanomization, breakage, and so on. These topics require a significant amount of effort to organize the materials for teaching.

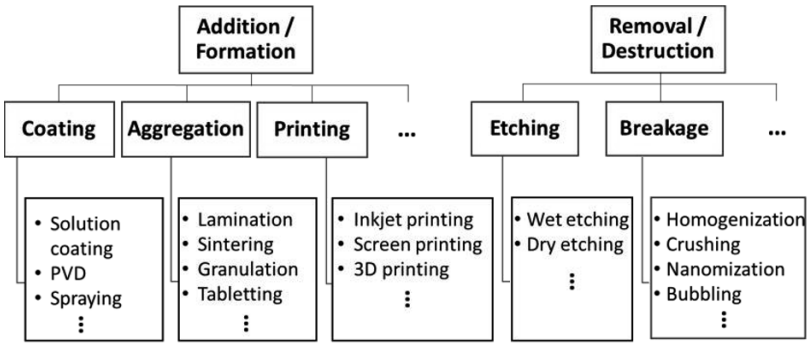

Figure 5: Unconventional processing techniques

4.2 Interface between the underlying science and product design

A thorough understanding of why the product works is necessary to properly design a chemical product. The constituent atoms, configuration, electronic structure, and intramolecular bonds of a molecular product determine its physicochemical properties. The physicochemical properties of the constituents, and microstructure/macrostructure of a formulated product, functional product, and device determine its performance and product attributes. Often, the underlying physics and chemistry is not covered in a typical chemical engineering curriculum. For example, to properly design an inkjet ink, phenomena including suspension dispersion, adhesion, wetting, droplet formation, and so on need to be modelled (Tam et al., 2016). Similarly, understanding of the interaction between biomolecules and fluorescent agents is essential in the design of an L-lactate biosensor (Zhang et al., 2017). Because of the diversity of these chemical products, the instructor may want to emphasize those scientific platforms that are suitable for the students. Case studies can be included in the course to reinforce all the concepts learned (Ng and Seider, 2018).

5. Perspective and Conclusions

Much has been achieved since the launching of product design research and teaching in the chemical engineering community at the turn of the new millennium (Cussler, 1999; Stephanopoulos, 2003; Cussler and Wei, 2003; Hill, 2004; Gani, 2004; Zhang et al., 2016). Despite the ups and downs in its development, it is firmly believed that product design is going to play a much more important role in our profession for a singular reason: the information age has led to changing business models in many market sectors. The chemical processing industry is no exception. Fluctuating revenues and stagnant profit margins in commodity chemical companies are quite common these days. The chemical sectors with high growth potential include healthcare products, high performance materials, consumer products, etc. All of these sectors require the capability to

come up with the product concept and the process to make the product. It is necessary to collaborate and work with other disciplines and faculty from bioengineering, biomedical engineering, materials, and chemistry, to name a few.

There are, however, many gaps to fill and challenges to meet. From a research and development point of view, the methods and computational tools need to be generic, for which sufficient knowledge is still not available. Development of many products is still based on expert knowledge and/or iterative trial and error because the integration of the underlying science and engineering is still not clear for these products. There is a large amount of data available in different forms and at different sources – they need to be collected, checked for consistency and then employed through smart search, retrieve and data-manipulation tools. Efforts should be made to systematically identify gaps in data so that experiments can be designed and planned to fill them, thereby leading to the developments of generic and predictive property models. The integration of product-process needs to be further developed together with issues related to supply chain, sustainability and economics. The business model with appropriate costing and pricing models also need to be developed.

Product design as described in this article is expected to bring together the people in the new areas and the people in process systems engineering (PSE). This integration suggests that PSE should take on a different meaning - Product/Process Systems Engineering. The methods and tools from PSE, when properly refined and applied, can significantly reduce the design and development times for chemical products.

Real-Time Mixed-Integer Optimization for Improved Economic Performance in HVAC Systems

Michael J. Risbeck[a], Christos T. Maravelias[a*], James B. Rawlings[a]

[a]*Department of Chemical and Biological Engineering, University of Wisconsin–Madison*
christos.maravelias@wisc.edu

Abstract

Optimal operation of large-scale heating, ventilation, and air conditioning (HVAC) systems requires many discrete-valued decisions. For example, in large heating and cooling plants, operators must choose which combination of equipment to activate to meet a given load. Such discrete decisions are typically made by operators using heuristics, which can lead to suboptimal performance. In this paper, we discuss how relevant HVAC decision problems can be transcribed into mixed-integer linear programming (MILP) formulations. We first present the general modeling framework we adopt, which is very similar to the resource task network framework adopted in chemical production scheduling. Second, we discuss a series of reformulations, including linearizations of complex unit models. Third, we present solution methods, including decomposition approaches and the employment of surrogate models to approximate the performance of the system over a long planning horizon. Finally, we demonstrate how the resulting optimization problems can be solved online in closed loop to improve system performance.

Keywords: Scheduling, economic model predictive control, reformulations, solution methods, energy building optimization

1. Introduction

In large buildings or campuses, the heating, ventilation, and air conditioning (HVAC) systems are significant and inherently time-varying consumers of electricity (Powell et al., 2013). In such systems, heating and cooling is performed most efficiently by producing hot or chilled water in high-capacity equipment at a central facility (referred to as the "waterside") and then pumping that water to the buildings where it is used to raise or lower the air temperature of occupied spaces (called the "airside"). Due to the significant use of electricity by waterside and airside equipment, utility companies often impose time-varying prices and demand charges (assessed at regular intervals based on the maximum instantaneous rate of electricity purchase within the previous period). These pricing structures can be leveraged by employing thermal energy storage (TES) to temporally decouple utility purchase from heating/cooling demand (Touretzky and Baldea, 2016), leading to lower cost. Broadly, TES can be categorized as "active," storing energy in fluids in insulated storage tanks, or "passive," storing energy in the thermal mass of buildings (Henze, 2005). Thus, to achieve the lowest possible cost, the tradeoff between active and passive TES must be optimized, all while choosing the most efficient combination of central plant equipment wo meet a given load.

To address this problem, various strategies have been proposed that typically focus more heavily on either the airside or the waterside. For airside passive storage, model predictive control strategies have been developed (Oldewurtel et al., 2012; Ma et al.,

2015) to optimize the future temperature trajectory of the buildings using a dynamic model for temperature evolution; passive storage is then utilized by pre-heating or pre-cooling the building. Similar approaches also exist for active TES using models of storage tank dynamics (Ma et al., 2012; Touretzky and Baldea, 2016). In general, these approaches do not consider waterside equipment selection, which is commonly addressed as a separate static optimization problem (Henze et al., 2008; Powell et al., 2013). However, to achieve the greatest cost reduction while accounting for varying ambient or economic conditions, it is necessary to consider all of these layers together. Thus, the goal of this work is to propose a unified optimization problem that can be solved in real time to determine airside temperature trajectories, TES utilization, and equipment selection for large-scale HVAC systems.

2. Optimization Model

In the following subsections, we present a mixed-integer linear programming (MILP) formulation to optimally schedule equipment use and plan temperature trajectory in large-scale HVAC systems. We use lower-case Roman letters to denote subscripts, upper-case Roman letters for variables, Greek letters for fixed parameters, and bold upper-case Roman letters for sets. Additional details can be found in Risbeck et al., (2017).

2.1. Problem Overview

Given a finite discrete-time horizon indexed by times $t \in \mathbf{T}$, the optimization problem seeks to minimize operating costs of maintaining comfortable temperature in airside zones $i \in \mathbf{I}$ by running waterside equipment $j \in \mathbf{J}$ to consume and produce resources $k \in \mathbf{K}$. This abstraction to units and resources is similar in spirit to the resource-task network commonly used for chemical production scheduling (Pantelides, 1994), and it avoids the need for developing separate equipment-specific constraints. Waterside equipment is modeled by continuous variables Q_{jkt} which give the resource production (> 0) and consumption (< 0) rates of the equipment throughout the optimization horizon. Specific resources are consumed in the airside zones via variables G_{ikt} to either increase (hot water) or decrease (chilled water) zone temperatures T_{it}. Other resources are purchased from the utility market at time-varying prices ρ_{kt} via variables P_{kt} and then consumed in central plant equipment such as chillers (electricity) and boilers (gas) to produce airside resources. The remaining resources are produced by some equipment and consumed by other equipment within the waterside central plant (e.g., cooling towers produce cooling water, which is then consumed by chillers).

To accurately estimate system resource requirements, models of the airside system and waterside equipment must be included in the optimization problem. For the airside system, a discrete-time linear model predicts evolution of zone temperatures T_{it} as a linear combination of the current temperature and the current resource consumption G_{ikt}, with a time-varying term to account for occupancy and ambient conditions. For waterside equipment, it is assumed that transient dynamics can be neglected, and only static production/consumption relationships need be modeled. Although such relationships are typically nonlinear, they are approximated as piecewise-linear so that the resulting formulation can remain an MILP. The decision variables Q_{jkt} are then required to lie on the piecewise-linear operating surface. To allow all equipment to be completely shut off, each model includes the (possibly isolated) operating point $Q_{jkt} = 0$.

Based on this problem description, the optimization model can be formulated as an MILP. Waterside, airside, and linking constraints are defined in the following three subsections.

2.2. Waterside Constraints

To avoid symmetry for multiple pieces of equipment with the same model, identical pieces of equipment are treated as indistinguishable by aggregating them into a single index j. The on/off state and operating point for each individual unit can be chosen independently, with the model making no distinction between permutations of states for the identical equipment. For unique types of equipment, the piecewise-linear operating surface for Q_{jkt} is modeled using the following three equations:

$$Q_{jkt} = \sum_{m \in \mathbf{M}_j} \sum_{n \in \mathbf{N}_{jm}} \zeta_{jknt} Z_{jmnt},\ j \in \mathbf{J}, k \in \mathbf{K}, t \in \mathbf{T}, \tag{1}$$

$$\sum_{m \in \mathbf{M}_j} V_{jmt} = U_{jt},\ j \in \mathbf{J}, t \in \mathbf{T}, \tag{2}$$

$$\sum_{n \in \mathbf{N}_{jm}} Z_{jmnt} = V_{jmt},\ j \in \mathbf{J}, m \in \mathbf{M}_j, t \in \mathbf{T}. \tag{3}$$

Integer variables $U_{jt} \in \{0,1, \dots, \mu_j\}$ chooses how many of type j units are active, while $V_{jmt} \in \{0, \dots, \mu_j\}$ and $Z_{jmnt} \in [0, \mu_j]$ are auxiliary variables used to model the piecewise linear approximate equipment models. Sets $\mathbf{M}_j$ and $\mathbf{N}_{jm}$ index the linear subdomains and nodes for the operating surface, while the parameters ζ_{jknt} define the (possibly time-varying) values of the equipment model at the nodes.

To avoid rapid switching of waterside equipment, dwell times are enforced via

$$U_{jt} - U_{j(t-1)} = U_{jt}^{+} - U_{jt}^{-},\ j \in \mathbf{J}, t \in \mathbf{T}, \tag{4}$$

$$U_{jt} \geq \sum_{t\prime=0}^{\delta_j^{+}-1} U_{j(t-t\prime)}^{+},\ j \in \mathbf{J}, t \in \mathbf{T} \tag{5}$$

$$\mu_j - U_{jt} \geq \sum_{t\prime=0}^{\delta_j^{-}-1} U_{j(t-t\prime)}^{-},\ j \in \mathbf{J}, t \in \mathbf{T}, \tag{6}$$

in which the integer variables U_{jt}^{+} and U_{jt}^{-} indicate when units are switched on and off, which then restricts additional switching within the next δ^{+} and δ^{-} time units.

Storage tanks in the central plant are modeled using variables $S_{kt} \in [0, \Sigma_k]$ and the linear relation

$$S_{kt} = \sigma_k S_{k(t-1)} - Y_{kt},\ k \in \mathbf{K}, t \in \mathbf{T}, \tag{7}$$

in which $Y_{kt} \in [0, Y_k]$ gives the amount charged into (< 0) or discharged from (> 0) the storage tank in the given period. Storage inefficiency (e.g., due to imperfect insulation) is modeled by the decay rate σ_k. Initial conditions S_{k0} are fixed parameters. For resources that cannot be stored, the bounds Y_k and Σ_k are set to zero.

The waterside portion of the objective function consists of time-of-use charges for utilities (amounts $P_{kt} \in [0, \Pi_{kt}]$ with prices ρ_{kt}) in addition to peak demand charges

(amounts $P_k^{\max}$ and costs $\rho_k^{\max}$). There is also a penalty on unmet auxiliary demand (via the slack variable B_{kt}; see Section 2.4) These totals are determined via

$$F^{\mathrm{WS}} = \sum_{k\in\mathbf{K}} \left(\rho_k^{\max} P_k^{\max} + \sum_{t\in\mathbf{T}} (\rho_{kt} P_{kt} + \beta_{kt} B_{kt}) \right), \tag{8}$$

with peak demand $P_k^{\max}$ is calculated by

$$P_{kt} + \psi_{kt} \le P_k^{\max},\ k \in \mathbf{K}, t \in \mathbf{T}. \tag{9}$$

in which ψ_{kt} is a forecast of exogenous resource use (utility purchase outside of the HVAC system that is included in the system-wide demand charge calculation).

2.3. Airside Constraints

Airside zone temperature evolution is modeled using the discrete-time linear model

$$T_{it} = \sum_{i\prime\in\mathbf{I}} \left(\alpha_{ii\prime} T_{i\prime(t-1)} + \sum_{k\in\mathbf{K}} \omega_{ii\prime k}\, G_{i\prime kt} \right) + \theta_{it},\ i \in \mathbf{K}, t \in \mathbf{T}, \tag{10}$$

in which $\alpha_{ii\prime}$ and $\omega_{ii\prime k}$ give time-invariant system dynamics, and θ_{it} represents the time-varying disturbance (including the effects of occupancy, as well as ambient temperature and radiation). Resource consumption $G_{ikt} \in [0, \Gamma_{ikt}]$ is permitted for only a subset of the resources (e.g., chilled and hot water), which is enforced by setting the corresponding bounds Γ_{ikt} to zero. Note that the initial zone temperatures T_{i0} are fixed parameters in the optimization problem.

Comfort bounds on zone temperatures are enforced as soft constraints via

$$T_{it} \le \Theta_{it}^{\max} + T_{it}^{+},\ i \in \mathbf{I}, t \in \mathbf{T}, \tag{11}$$

$$T_{it} \ge \Theta_{it}^{\min} - T_{it}^{-},\ i \in \mathbf{I}, t \in \mathbf{T}, \tag{12}$$

in which $\Theta_{it}^{\max}$ and $\Theta_{it}^{\min}$ give the nominal temperature bounds, which are relaxed by nonnegative slacks T_{it}^{+} and T_{it}^{-}. The objective function for the airside consists solely of these penalty terms:

$$F^{\mathrm{AS}} = \sum_{t\in\mathbf{T}} \sum_{i\in\mathbf{I}} (\chi_{it}^{+} T_{it}^{+} + \chi_{it}^{-} T_{it}^{-}). \tag{13}$$

2.4. Coupling Constraints

The coupling of the airside and waterside systems is enforced via the demand balance

$$\sum_{j\in\mathbf{J}} Q_{jkt} + Y_{kt} + P_{kt} + B_{kt} \ge \phi_{kt} + \sum_{i\in\mathbf{I}} G_{ikt},\ k \in \mathbf{K}, t \in \mathbf{T}, \tag{14}$$

in which the sum of airside and auxiliary demand (G_{ikt} and ϕ_{kt} respectively) must be met by waterside supply, which is the net sum direct production Q_{jkt}, storage charge/discharge Y_{kt}, and purchase $P_{kt} \in [0, \Pi_k]$. The slack variable $B_{kt} \in [0, \phi_{kt}]$ is added to soften the auxiliary demand constraint, while the primary demand G_{ikt} is relaxed via the temperature slacks T_{it}^{+} and T_{it}^{-} From Eqs. (11) and (12).

The overall objective function is then

$$\min F^{\mathrm{WS}} + F^{\mathrm{AS}} \tag{15}$$

to minimize the sum of the waterside and airside terms.

3. Reformulations and Decompositions

The chief difficulty of the waterside formulation is the presence of the discrete variables to model equipment on/off states and enforce the piecewise-linear operating surface. In contrast, there are no discrete variables in the airside formulation, but optimization is nevertheless challenging due to the potentially large number of temperature zones. Thus, the problem can take a very long time to even find a feasible solution when solved as a single monolithic instance. To ease this burden, we present a simplified surrogate model and a decomposition strategy that can be employed to find near-optimal solutions to the combined problem in real time.

3.1 Surrogate Model

When there is a large amount of equipment in the central plant, solution progress can be slow due to the large number of integer variables. While the addition of more identical units is partially mitigated by the symmetry-free formulation, the inclusion of auxiliary equipment for both heating and cooling loops leads to a large number of discrete decisions that must be made at each timestep. To ease this burden, we propose a simplified surrogate model that seeks to aggregate multiple pieces of equipment into a single continuous curve.

To perform this computation, we start by defining subsets $\mathbf{K}^+$ of resources exported from the central plant and $\mathbf{K}^-$ for resources purchased by the central plant:

$$\mathbf{K}^+ \coloneqq \{k \in \mathbf{K}: \phi_{kt} > 0 \text{ or } \Gamma_{ikt} > 0 \text{ for some } t \in \mathbf{T} \text{ or } i \in \mathbf{I}\},$$

$$\mathbf{K}^- \coloneqq \{k \in \mathbf{K}: \Pi_k > 0\}.$$

For each major type of equipment (e.g., chillers, heat-recovery chillers, and boilers), we identify the supporting auxiliary equipment to define a small number of "operating groups." For example, the chiller operating group consists of conventional chillers, cooling towers, and chilled water pumps. For each operating group, we choose a representative resource $k^* \in \mathbf{K}^+$ and then pick a series of production rates ϕ_{k^*} that span the minimum and maximum total capacities of the current group. For each value of ϕ_{k^*}, we solve a one-period equipment selection period of the form

$$\begin{aligned}
\min \quad & \sum_{k \in \mathbf{K}} \rho_k P_k \\
\text{s.t.} \quad & \sum_{j \in \mathbf{J}} Q_{jk} + P_k \geq \phi_k, \; k \in \mathbf{K} \\
& Q_{jk} = \sum_{m \in \mathbf{M}_j} \sum_{n \in \mathbf{N}_{jm}} \zeta_{jkn} Z_{jmn}, \; j \in \mathbf{J}, k \in \mathbf{K} \\
& \sum_{m \in \mathbf{M}_j} V_{jm} = U_j, \; j \in \mathbf{J} \\
& \sum_{n \in \mathbf{N}_{jm}} Z_{jmn} = V_{jm}, \; j \in \mathbf{J}, m \in \mathbf{M}_j
\end{aligned}$$

which assumes that time-invariant representative values can be chosen for resource costs ρ_k and equipment models ζ_{jkn}. Note that each problem includes only the equipment in the current operating group. The goal of these subproblems is to determine the required purchase rate for resources in $\mathbf{K}^-$ to produce various values of resources in $\mathbf{K}^+$.

Once all the subproblems have been solved, the Q_{jk} variables are summed to define points on an aggregate operating curve for the current operating group. A straight line is then fit through these points to give an approximate linear operating surface that can be used instead of the individual piecewise-linear operating surfaces. In particular, this simplification means that the set **J** consists of the equipment operating groups, rather than individual pieces of equipment, and the set of resources **K** need only include $\mathbf{K}^+ \cup \mathbf{K}^-$, which eliminates auxiliary resources like cooling water. Furthermore, the equipment model constraints in Eqs. (1), (2), and (3) to be replaced by the much simpler

$$Q_{jkt} = \tilde{\zeta}_{jk} Z_{jt}$$

with $Z_{jk} \in [0,1]$ a single continuous variable, and $\tilde{\zeta}_{jk}$ the full-capacity resource production/consumption rates from the linear aggregate curves. With the removal of the discrete variables U_{jt}, the switching constraints in Eqs. (4), (5), and (6) can be omitted as well, leading to a fully continuous model with significantly fewer variables. While the aggregate operating curves no longer precisely calculate resource consumption and possibly ignore minimum equipment capacities and small total loads, accuracy is typically good enough to produce near-optimal utilization of active and passive storage. This surrogate model can then be employed as described in the next two sections.

3.2. Hybrid Model

When very large well-insulated storage tanks are present, it may be necessary to optimize over a long horizon (i.e., in excess of a week) to make optimal use of the storage tank. This longer horizon leads to many more discrete variables and constraints. However, forecasts of utility prices and auxiliary demand may not be extremely accurate in the later periods of the horizon. Furthermore, because optimization is performed in closed-loop, decisions made at the end of the horizon are never actually implemented. Thus, it is not necessary to fully optimize over the full decision space throughout the entire prediction horizon. This realization suggests the use of a hybrid approach, whereby the full model (with discrete variables and individual equipment models) is used over a modest horizon, with the surrogate model applied over a longer horizon to consider long-term behavior. By linking the appropriate variables (storage capacity S_{kt}, peak demand $P_k^{\max}$, and zone temperatures T_{it} if present) between the two models, the optimal near-term decisions can be determined while approximately accounting for potential storage utilization over a much longer period.

The hybrid optimization strategy can be implemented in one of two ways. In the “two-stage” approach, the surrogate model is first solved over a longer horizon. The values of the linking variables midway through the prediction horizon are then used as terminal constraints for a subsequent optimization of the full model over a shorter horizon. The advantage of the two-stage approach is that the full optimization is smaller in size. As an alternative, the “one-stage” approach solves a single optimization problem in which the first portion of the horizon uses the full model, while the remaining periods use the surrogate model. The advantage here is that the greater accuracy of the full model provides a more representative starting point for the surrogate model. These two approaches are diagrammed in Figure 1.

3.3. Hierarchical Decomposition

To improve solution times for the combined problem, the large model size from the airside can be separated from the discrete variables on the waterside. One method of separation is a hierarchical decomposition, whereby the surrogate model (as defined in

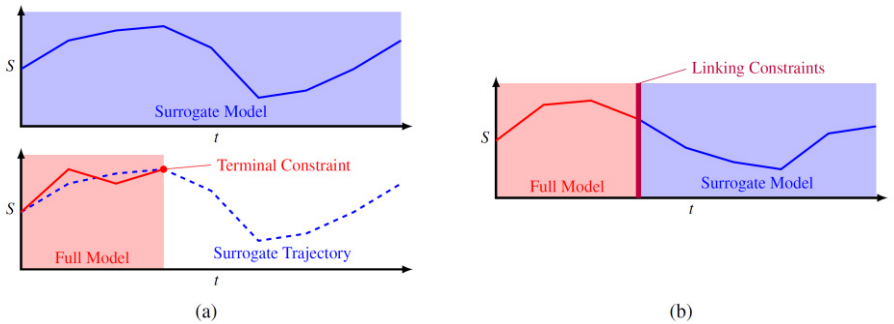

Figure 1: Diagram of two-stage (a) and one-stage (b) hybrid optimization strategies. Axes show different optimization problems, and shaded regions show prediction horizon and model type.

Section 3.1) is first optimized to determine airside demand, which is then sent down as a fixed parameter to a fully detailed waterside-only optimization. More precisely, after solving the surrogate model (which includes the full airside dynamic models but only the approximate operating group models for the waterside), total demand is calculated as

$$\widetilde{\phi}_{kt} \coloneqq \phi_{kt} + \sum_{i \in \mathbf{I}} G_{ikt}\,,\ k \in \mathbf{K}, t \in \mathbf{T}.$$

The total demand $\widetilde{\phi}_{kt}$ is then used in place of ϕ_{kt} in Eq. (14) in the full model, but with the airside variables T_{it}, G_{ikt}, etc. and constraints (10) through (13) now removed from the problem. This decomposition allows passive storage to be determined in the upper-level optimization (which can be solved as a large linear program), while equipment allocation and active storage are optimized in the lower level (a modestly sized MILP). A feasible overall solution is then constructed by combining the airside variables from the upper problem with the solution to the lower problem. To obtain a lower bound, the demand constraint (14) can be dualized (in the Lagrangian sense), which allows dual airside and waterside subproblems to be solved. A guess for the multipliers can be taken from the top-level surrogate model.

4. Example Simulations

4.1. Hybrid Model

To start, we simulate the closed-loop performance of the hybrid model on a waterside-only system that must meet forecasted cooling demand. Using 22 weeks of hourly chilled water demand and electricity prices provided by Johnson Controls, Inc., closed-loop simulations were performed using various prediction horizons for the full and surrogate models. Each simulation covers 1 week of data, re-optimizing every hour. Because this system is small enough, the optimal week-long schedule can also be determined by solving the full model in a single week-long optimization, which gives a baseline for closed-loop cost. Figure 2 shows a sample optimal trajectory for the system, and Table 1 shows cost performance for the simulations.

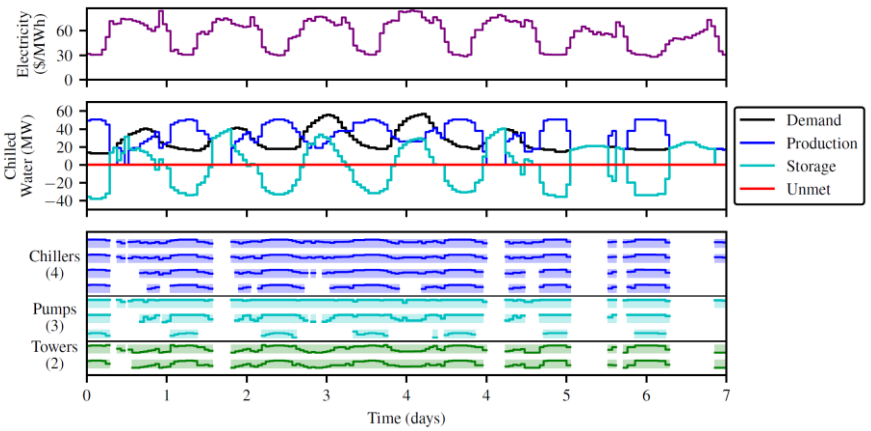

Figure 2: Sample optimal trajectory for the cooling-only system. Central plant equipment is shown in the Gantt chart with light bars showing equipment on/off and solid lines showing loading between minimum and maximum capacity.

From the results in Table 1, we see that use of the one-stage hybrid optimization strategy leads to slightly better performance than simply solving the corresponding standard model, while the two-stage strategy is only helpful for short horizons. In terms of closed-loop cost, the one-stage optimization with a surrogate horizon of 48 performs almost as well as the full model by itself with the same horizon. Thus, including the surrogate model can significantly reduce computational requirements (by reducing the number of discrete variables) without sacrificing closed-loop performance.

Of note in Table 1, the biggest difference between the closed-loop solutions and the optimal solutions is in tradeoff between demand and use charges. Because the closed-loop problems are looking over shorter horizons, they slightly underestimate the effects of having a large peak electricity usage and instead more aggressively exploit low use charges. This change in behavior leads to higher demand charges and slightly lower use charges than in the optimal solution. However, since demand charges are typically assessed on a month-long basis, even these "optimal" solutions may not represent the true month-long minimum. Thus, additional strategies may be needed to address the timescale differences between hourly use charges and monthly demand charges, which could lead to even better performance for the hybrid optimization strategies.

4.2 Decomposition Strategy

To test the decomposition strategy on a realistically sized system, a very large instance is created. The central plant consists of 5 chillers, 3 heat-recovery chillers (HRCs), 2 boilers, 10 pumps, and 5 cooling towers. There is auxiliary demand ϕ_{kt} for both hot and chilled water. The airside system consists of 20 separate buildings, each with 50 interacting temperature zones. Half of the zones represent occupied air zones in which comfortable temperature must be maintained using chilled water, while the other half of the zones are slowly evolving mass zones with no temperature constraints. For this system with 7 day horizon (1 h timestep), the MILP solver Gurobi 7.0 is unable to find a feasible solution to the full problem within 2 h of computation time. Instead, the hierarchical decomposition strategy is applied to the problem. Sizes for the various subproblems are shown in Table 2.

Table 1: Total cost breakdown across 22 simulations (each 1 week long) for the cooling-only system. Demand charges account for most of the performance difference. Costs (%) are relative to optimal 1-week solutions.

Strategy	Full Horizon	Surrogate Horizon	Use Charges	Demand Charges	Total Charges
Standard	12	–	+0.86	+12.42	+1.95
One-Stage	12	48	+0.18	+6.60	+0.79
Two-Stage	12	48	−0.16	+14.49	+1.23
Standard	24	–	−0.11	+10.65	+0.91
One-Stage	24	120	+0.02	+6.97	+0.67
Two-Stage	24	120	−0.23	+12.43	+0.97
Standard	48	–	−0.22	+8.67	+0.62
One-Stage	48	120	+0.16	+2.46	+0.37
Two-Stage	48	120	−0.39	+11.40	+0.72

Table 2: Instance sizes for subproblems in hierarchical decomposition.

Subproblem	Variables ($\times 10^6$)	Integers ($\times 10^3$)	Constraints ($\times 10^3$)	Nonzeros ($\times 10^6$)
Centralized	1.19	0	341.21	3.29
Airside Dual	0.84	0	336.34	2.60
Waterside Dual	1.20	6.38	18.15	1.25
Waterside Primal	0.03	6.38	18.15	0.07

After solving the upper-level subproblem (1.5 min) and the lower-level waterside feasibility problem (10 min, 1.6% optimality gap), a feasible solution was obtained as shown in Figure 3. Using the dual multipliers from the upper-level subproblem the dual airside (0.4 min) and waterside (10 min, 1.2% gap) subproblems, a lower bound was obtained, resulting in a duality gap of 4.3%. Thus, while the full combined problem was completely intractable for this large system, both decomposition strategies produced a satisfactory solution quickly enough for real-time application.

5. Conclusions

In this work, we have presented an MILP model for economic optimization of large-scale HVAC systems. Using a symmetry-free abstract formulation, the model can be applied to a wide variety of systems. With additional reformulations and decompositions, near-optimal solutions can be obtained for large-scale problems within 15 minutes, which enables online application. By employing these optimization methods, HVAC systems can react optimally in real time to changing ambient or economic conditions, leading to improved economic performance over heuristic or other less-frequent scheduling strategies.

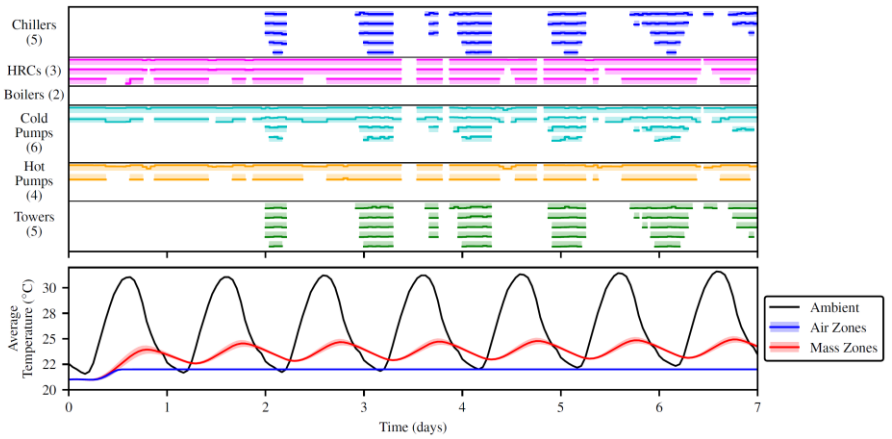

Figure 3: Hierarchical decomposition solution for big instance. Temperature plot shows average $\pm$ standard deviation for 500 air and mass zones.

Abstract

In this paper, we review frameworks for design, control, and operation of dynamic processes and their applications. Recognition that design characteristics of a process limit its achievable control performance dates back to at least the 1940s. Isolated studies appeared in the literature since then, with a watershed in the 1980s, when quantitative analysis of this phenomenon was advanced in a series of studies using the internal model control (IMC) framework. Dynamic optimization was subsequently utilized as a platform to analyze the impact of a plant design on its dynamic performance, and to perform simultaneous plant and control system design. This paper presents a review of approaches toward the analysis of the interaction between design and dynamic performance, and offers some new perspectives on this topic. In particular, the trends of increased globalization, market volatility, and variation in electricity prices have created dynamic conditions that require responsive operation in order to remain competitive. In addition to such processes where transient dynamics between steady states can be considered and exploited, there are intrinsically dynamic processes which cannot be designed based on steady state mass and energy balances. In intrinsically dynamic processes, the intra-cycle and inter-cycle dynamics should be taken into account when optimizing the design, control, and operation. We discuss adsorption processes as an example. Our study includes a description and discussion of advances in these areas.

Keywords: integrated design and control, dynamic optimization, dynamic operability, dynamic resilience, simulated moving bed, intentionally dynamic operation.

1. Introduction

Process plants do not operate in a static environment, and need to respond adequately to disturbances in order to meet safety, operational, environmental and product quality constraints. A plant's achievable dynamic performance is strongly influenced by its design – a phenomenon recognized at least as far back as the 1940s (Ziegler and Nichols, 1943). Isolated studies on this topic appeared over a span of several years (e.g. Anderson, 1966), but it was only in the 1980s and 1990s that this area began to resonate within the process systems engineering community. The traditional plant and control system design process is sequential, with the control system considered after completion of the plant design phase. However, recognition that poor control performance could potentially be avoided through alternative design choices led to advocacy for integrated plant and

control system design approaches (Downs and Doss, 1991) and to research efforts toward the development of systematic approaches for incorporation of dynamic considerations into plant design calculations.

Two key paradigms in the analysis of the interaction between design and control are the notion of a performance limit regardless of controller type, and dynamic performance under the action of a particular controller type and tuning (which could be included in the optimization decision space). Morari (1983) refers to the former as dynamic resilience, and through use of the internal model control (IMC) framework, identified control performance-limiting factors as time delays, right-half-plane transmission zeros, input constraints and model uncertainty. Analyses of their impact on achievable performance are given in Morari (1983) and Holt and Morari (1985a, 1985b). This framework has given rise to open-loop controllability indicators, several of which are described in Skogestad and Postlethwaite (1996). Many subsequent studies have followed an optimization-based approach, some of which incorporate explicit characterizations of dynamic resilience.

Integrated plant and control design paradigms are typically based on the assumption of operation around a nominal steady-state point (which can be included as an optimization decision in the design procedure). However, an increasingly global marketplace with increased variation in product demand, supply, and utility prices has created an increasingly dynamic operating environment for which Backx et al. (1998) advocate "intentionally dynamic operation" in order to be responsive and remain competitive. Applications of this type are relatively sparse in integrated design and control studies. Many processes, on the other hand, are intrinsically dynamic in their operation, examples of which are pressure swing adsorption (Jiang et al., 2004), semicontinuous distillation (Adams and Pascall, 2012), periodically operated reactors (Zahn et al. 2009) and simulated moving beds (Kawajiri and Biegler, 2006). These processes do not have a steady state, and thus process dynamics must always be in taken into account.

In this paper, we present an overview of key approaches for inclusion of dynamic considerations in plant design, and thereafter focus on applications to intentionally dynamic and intrinsically dynamic operation. Section 2 presents a general dynamic optimization formulation which underpins a large class of integrated design approaches, and reviews some key approaches for design with dynamic performance considerations. Optimization-based design of intentionally dynamic and intrinsically dynamic operation is discussed in Sections 3 and 4, with conclusions and future research directions presented in Section 5.

2. General dynamic optimization formulation

Design problems discussed in the sequel can be considered within the context of a general dynamic optimization framework. An optimization-based formulation for design subject to dynamic performance constraints may be stated as follows:

$$
\begin{aligned}
&\min_{\boldsymbol{d},\boldsymbol{u}(t)} \mathcal{J} := E_{\boldsymbol{\theta}\in\Gamma}\left\{\phi\left(\boldsymbol{x}(t_f),\boldsymbol{z}(t_f),\boldsymbol{u}(t_f),\boldsymbol{d},\boldsymbol{\theta},t_f\right)\right\}\\
\text{st: } &\dot{\boldsymbol{x}}(t) - \boldsymbol{f_d}(\boldsymbol{x}(t),\boldsymbol{z}(t),\boldsymbol{u}(t),\boldsymbol{d},\boldsymbol{\theta},t) = \boldsymbol{0}\\
&\boldsymbol{f}_a(\boldsymbol{x}(t),\boldsymbol{z}(t),\boldsymbol{u}(t),\boldsymbol{d},\boldsymbol{\theta},t) = \boldsymbol{0}\\
&\boldsymbol{g}(\boldsymbol{x}(t),\boldsymbol{z}(t),\boldsymbol{u}(t),\boldsymbol{d},\boldsymbol{\theta},t) \le \boldsymbol{0}\\
&\boldsymbol{d} \in [\boldsymbol{d}^L,\boldsymbol{d}^U],\ \ \boldsymbol{u}(t) \in [\boldsymbol{u}^L,\boldsymbol{u}^U]\\
&\Gamma = \{\boldsymbol{\theta} \mid \boldsymbol{\theta} \in [\boldsymbol{\theta}^L,\boldsymbol{\theta}^U]\}
\end{aligned}
\tag{1}
$$

where $\boldsymbol{x}$, $\boldsymbol{z}$, $\boldsymbol{u}$ and $\boldsymbol{d}$ represent differential, algebraic, input and design variables respectively, $\boldsymbol{\theta}$ is a vector of uncertain parameters, $\boldsymbol{f}_d$ and $\boldsymbol{f}_a$ represent differential and algebraic functions, respectively, of the DAE model in semi-explicit form, and E is the expectation operator. An economic objective function is typically optimized, with dynamic performance implicitly accounted for through the path constraints, $\boldsymbol{g}$. The above formulation accommodates open- or closed-loop dynamics through exclusion or inclusion of controller equations. The design decisions can include equipment sizing and plant configuration, a steady-state operating point, controller configuration and tuning, or combinations thereof. The uncertain parameters may be conveniently handled through discretization of the uncertainty set, resulting in a multiperiod dynamic optimization problem. The formulations discussed next utilize various forms of Eq. (1), from a steady-state version of the problem that includes constraints associated with dynamic performance, to a comprehensive dynamic optimization formulation that includes equipment design, control configuration selection and uncertainty.

Luyben and Floudas (1994) utilize open-loop indicators of controllability in the evaluation of design alternatives in a multiobjective optimization framework. While the open-loop controllability metrics are relatively easy to compute, a key drawback is their restriction to individual performance-limiting characteristics. Swartz (1996, 2004) proposes a computational framework for resiliency assessment based on Q- (or Youla) parametrization of all linear stabilizing feedback controllers. It permits performance-limiting design characteristics to be simultaneously accounted for, and also provides a linear feedback controller capable of satisfying the performance criteria, if achievable by linear feedback control. The strategy is applied in Ross and Swartz (1995) to the dynamic operability analysis of flotation circuits, and extended in Ross and Swartz (1997) to account for model uncertainty.

It is widely recognized that the economically optimal steady-state operating point of a plant typically lies at the intersection of constraints (Arkun and Stephanopoulos, 1980). This characteristic is utilized in Narraway et al. (1991) to quantify the economics of control performance through the extent to which the steady-state operating point needs to "back off" from the constraints in order to maintain feasible operation in the presence of disturbances. The back-off magnitude is estimated using frequency response analysis techniques, and related to an economic loss using Lagrange multipliers of the steady-state economic optimization problem. Figueroa et al. (1996) compute the back-off through a dynamic optimization problem in which the economically optimal operating point is determined, subject to path constraints on the dynamic response, and utilize this in the performance assessment of alternative controllers. Soliman et al. (2004) consider back-off under constrained predictive control. The presence of MPC optimization subproblems along the back-off calculation horizon results in a multi-level optimization problem that is transformed into single-level mathematical program with complementarity constraints (MPCC) by replacing the MPC quadratic programming subproblems by algebraic constraints corresponding to their first-order optimality conditions, with the complementarity constraints in turn reformulated as mixed-integer linear constraints.

Lenhoff and Morari (1982) propose a dynamic performance index based on an optimal control formulation which they use in conjunction with steady-state plant economics for plant performance evaluation within a multi-objective setting. Mohideen et al. (1996) present a more general dynamic optimization framework for integrated plant and control system design. Plant economics are optimized with dynamic performance implicitly accounted for through the imposition of path constraints. A mixed-integer formulation

permits discrete design decisions such as number of trays in a distillation column and control structure selection. Baker and Swartz (2004) propose mixed-integer and complementarity constraint formulations for rigorously incorporating actuator saturation effects within a simultaneous design and control formulation. Inclusion of constrained MPC within the design formulation was subsequently considered using an MPCC formulation such as that described earlier (Baker, 2006), but with plant design parameters included as optimization decision variables and the single-level optimization problem solved using an interior point approach. Sakizlis et al. (2003), on the other hand, include MPC within an integrated design framework through the use of a multi-parametric MPC formulation.

Several other studies and applications on the interaction between design and dynamic performance have appeared, utilizing to various extents the concepts and approaches described above. Comprehensive reviews on this topic may be found, inter alia, in van Schijndel and Pistikopoulos (1999), Sakizlis et al. (2004), and Ricardez-Sandoval et al. (2009). We consider in the next two sections particular applications to intentionally and intrinsically dynamic operation.

3. Intentionally dynamic operation

Chemical plants operate in an environment of increased competition in a global marketplace, with increased variation in product demand and raw material supply. The deregulation of electricity prices in many jurisdictions has resulted in large fluctuations in electricity price. It is therefore becoming increasingly important for plants to be able to transition rapidly in order to respond to such variation in order to maximize profits and increase competitiveness. Cryogenic air separation units (ASUs) are a prime example of such plants due to their high electricity consumption, demand variation and complexity of operation through tight thermal integration.

White et al. (1996) present an optimization formulation for switchability analysis that is posed as a dynamic optimization problem that seeks to minimize a measure of transition time subject to dynamic model and path constraints. The formulation is applied to integrated distillation columns in an air separation plant and a binary distillation system, with the columns in both applications modelled using reduced-order compartmental models. They conclude that there are no process constraints limiting the speed of reduction in gas oxygen product, but that a transition between product qualities in the binary system is improved by a reduction in tray holdup. Schenk et al. (2002) present an integrated design and control formulation for an air separation plant in which both disturbances and ramping between operating points are considered. A mixed-integer dynamic optimization problem is posed, with design decisions comprising distillation column diameters and numbers of trays, and the control structure.

Cao et al. (2015) propose a two-tiered optimization strategy to explore design limitations to transition agility in a nitrogen plant, illustrated in Figure 1(a), in response to demand and electricity price changes that is formulated as follows:

- *Tier 1*: Solve a steady-state economic optimization problem to determine the new operating point.
- *Tier 2*: Solve a dynamic optimization problem to minimize a measure of transition time from the current operating point to that determined in Tier 1.

Various constraints are imposed, such as flooding, compressor surge, liquid fraction in turbine inlet, and product purity. Figure 1(b) shows that the flooding constraint is violated

if the transition in response to a 20 % increase in nitrogen gas demand is applied via single step changes in the inputs, motivating the need for determining the optimal input trajectories through dynamic optimization. The flooding and turbine inlet constraints were found to be active for certain of the case study scenarios, indicating design bottlenecks in the column and primary heat exchanger design. The potential benefit of using stored liquid product as additional reflux during transition was also explored, and found to reduce transition times when the product impurity limit was tightened. A current extension involves formulation of the ASU design problem under transition as a two-stage stochastic optimization problem, with preliminary results presented in Jaydeep et al. (2017).

4. Intrinsically dynamic operation

Here we discuss intrinsically dynamic processes where the conventional approaches for steady state design cannot be applied. Such processes can be characterized by cyclic and repetitive operations. These processes never reach a steady state, and we must deal with process dynamics even when we analyse mass and energy balances over a long time period. To design and control such processes, we consider formulating a dynamic optimization problem in the form of Eq. (1).

In this paper, we distinguish batch processes from intrinsically dynamic processes. In batch processes, a sequence of operations is repeated in each batch, and all variables are re-initialized at the beginning of each batch. On the other hand, intrinsically dynamic processes we discuss in this paper are semi-continuous periodic processes where accumulations occur in some or all variables. Due to the accumulations, there exists inter-cycle dynamics in addition to the intra-cycle dynamics. While these processes do not have a steady state, they typically reach a cyclic steady state (CSS) after repeating a certain number of cycles where variables have periodic profiles. The inter-cycle profiles in the transition between CSSs should also be optimized and controlled (Bentley, et al. 2014, Toumi and Engell 2004).

We consider periodic adsorption processes as an example. In adsorption processes, a single or series of columns connected to each other is packed with adsorbent particles. Using these columns, a mixture can be separated into purified products utilizing a difference in the affinity towards the adsorbent. In these processes, profiles of state and differential variables, such as concentration, pressure and temperature, keep propagating

through the columns. These processes are operated in a cyclic manner, where the same sequence of operations (steps) are repeated. As a result, the state variables have periodic dynamics, characterized as the CSS. The dynamics are described as a system of partial differential algebraic equations (PDAEs), which can be discretized in space to formulate an optimization problem shown as Eq. (1).

4.1. Chromatographic processes

Chromatographic separation is a type of adsorption process where multiple components in a mixture travel at different speeds in a packed column, and these components are fractionated at the outlet of the column when they elute out. The simplest design of chromatography is the single-column process, as shown in Figure 2(a). In this conventional batch process, a mixture is injected periodically from the inlet of the column. The mixture is subsequently pushed towards the outlet by the desorbent. As the components travel through the column, the component with the stronger affinity for the adsorbent moves more slowly, while that with the weaker affinity moves faster. These components are fractionated at the outlet of the column.

To improve the performance of chromatography, quantified by product purity, recovery, productivity (throughput), and desorbent consumption, a number of multi-column semi-continuous chromatographic processes have been proposed. A well-known example is simulated moving bed (SMB) chromatography. This process is widely used in industry, where applications include xylene isomer separation, sugar purification, and chiral separation for pharmaceuticals. The principle of the SMB process is shown in Figure 2(b). In this process, a series of columns is connected to form a circulation loop, and the two products, raffinate and extract, are withdrawn continuously while the feed and desorbent are supplied also continuously. The supply and withdrawal ports are switched periodically in the direction of the liquid flow. This switching operation realizes the counter-current flow of the solid phase in a "simulated" manner.

Design of multi-column chromatographic processes can be challenging due to the complex operations. In addition to the standard design and operation shown in Figure 2(b), there have been a number of modifications which have been validated to improve the performance (Sreedhar and Kawajiri 2014). In addition, the SMB process is often integrated with other unit operations in a process flowsheet. In Figure 2(c), the SMB process for enantiomer separation is integrated with two crystallizers, which partly carry out the separation. It has been shown that the capital cost of this hybrid separation process can be substantially lower (Kaspereit, et al. 2005). Figure 2(d) shows a flowsheet that consists of an enzymatic rector and membrane for sugar production. In an example of D-psicose production from D-fructose, the unreacted reactant is separated by SMB and recycled back to the enzymatic reactor (Bechtold, et al. 2006). To design such flowsheets, we can formulate an optimization problem in the form of Eq. (1), but at a significantly larger scale.

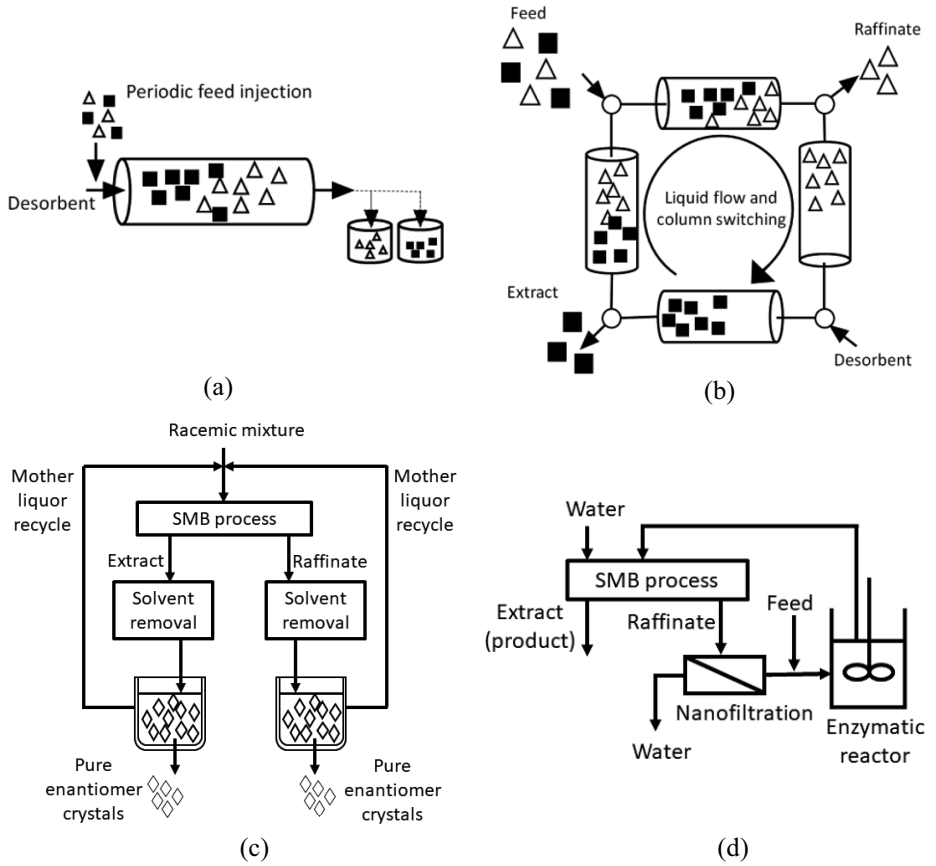

Figure 2 Chromatography processes; (a) single-column batch chromatography, (b) simulated moving bed (SMB) process, (c) integration with crystallizers for enantiomer purification (Kaspereit, et al. 2005), (d) integration with membrane and enzymatic reactor (Bechtold, et al. 2006)

4.2. Challenges for intrinsically dynamic processes

While there are many past studies for optimization of design and operation of periodic processes, there remain many challenges. First, due to the complex dynamics governed by PDAEs and CSS conditions, the problem size can be large and a solution may not be found easily. In multi-column adsorption processes, the number of columns must be treated as integer variables, and process developers must consider a large number of design alternatives. Furthermore, finding a robust design, operation, and control under model uncertainty would be very challenging in the framework of the dynamic optimization. In chromatography, for example, a substantial degree of model uncertainty must be taken into account, since the mass transfer kinetics and adsorption equilibria are not fully understood in many novel applications such as biopharmaceuticals. These difficulties are even more pronounced when designing a flowsheet that embeds an intrinsically dynamic process, as well as in optimizing and controlling inter-cycle transitions between CSSs.

5. Conclusions

The impact of the design of a process on its dynamic performance has led to analysis techniques for assessment of a dynamic resilience, and design formulations that account for dynamic response behavior. While many applications focus on operation around a steady-state point, the present manufacturing of environment is highly dynamic in nature, requiring transient operation in response to often large variations in parameters such as demand and electricity price. In addition, certain processes are inherently dynamic in their operation, necessitating inclusion of plant dynamics in the design procedure. In this paper, we have presented an overview of this topic, highlighting key paradigms that have been followed. A key remaining challenge is solution of the large-scale DAE and PDAE systems that arise when considering larger and more complex configurations, compounded by consideration of uncertainty within the formulation. These problems are moreover often mixed-integer in nature, adding a significant level of complexity. A further interesting research direction is consideration of the interplay between dynamic operation, scheduling and design, a concept that has recently been considered in Patil et al. (2015) and Pistikopoulos and Diangelakis (2016).

Including Nature in Engineering for Innovation and Sustainability: Promise, Progress and Peril

Bhavik R. Bakshi[a]

[a]*Lowrie Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, OH 43210, USA*
bakshi.2@osu.edu

Abstract

Modern engineering keeps ecological systems outside its decision boundary, even though goods and services from nature are essential for sustaining all its activities. This has been the system boundary at least since the industrial revolution when the human footprint was quite small, and nature seemed infinite. With this situation having reversed in the modern world, there is an urgent need to change the engineering paradigm from one that takes nature for granted to one that accounts for the role of nature and works with it while respecting its limits. In this article we argue that such a paradigm shift holds the promises of enabling sustainability and innovation by developing engineering that benefits from nature's ability to treat emissions and provide resources in an economically viable and environmentally sustainable manner. We provide an overview of recent progress in including nature in engineering, for tasks such as design of processes and supply chains, and for life cycle assessment. Despite the promise of including nature in engineering, there are also risks if this inclusion is not done properly. Current methods tend to commodify nature due to which holistic characteristics of ecosystems such as biodiversity and resilience could be lost. The tendency of wanting to over-engineer ecosystems may also need to be restrained.

Keywords: Ecosystem services; Sustainability; Innovation; Design; Life Cycle Assessment; Paradigm shift.

1. Promise

Goods and services from nature are essential for sustaining all human activities. This statement is widely accepted and understood yet most disciplines and even methods meant to enable sustainability do not account for the role and capacity of ecosystems in supporting human activities. Contributions from nature toward human well-being are substantial: worth trillions of dollars. It includes goods such as minerals, biomass, wood and water, and services such as photosynthesis, biogeochemical cycles, climate regulation, and air and water quality regulation.

Conventional engineering has focused on a relatively narrow boundary of a selected product or process. In the last few decades, this boundary has expanded to include processes in supply chains and the corporate enterprise (Grossmann and Westerberg, 2000). By adopting sustainability assessment methods such as waste minimization and life cycle assessment, the boundary has further expanded to account for the environmental impact of industrial activities. However, most methods do not account for the role of nature in supporting and even enhancing industrial activities. Existing methods also routinely ignore the limits of nature's ability to supply resources and

absorb wastes and implicitly assume nature to be an infinite source and sink. Ignoring nature is not limited just to the discipline of engineering. Even conventional economics ignores or undervalues goods and services from nature. For example, if we consider the role of trees, ecosystem goods such as fruits and wood have monetary value due to their being traded in markets, but services such as carbon sequestration by storing atmospheric carbon dioxide as biomass, air quality regulation by mitigating NOx, SOx and particulate matter, and water provisioning by reducing storm water runoff and recharging aquifers have no value since are outside the market. This results in the implicit assumption that these services do not matter and are unlimited. Such ignorance has at least two negative side effects.

- *Unsustainable Engineering.* Keeping nature outside the system boundary can result in decisions that contribute to exceeding nature's capacity, causing ecological degradation, and resulting in an unsustainable engineering.
- *Lost Opportunities for Innovation.* Ecosystems are capable of satisfying many human and industrial needs while relying on only renewable resources, being resilient to disturbances, and sustaining themselves over long periods of time. By ignoring nature, engineered systems loose opportunities of benefitting from innovative designs that could work in harmony with nature.

Recent efforts for quantifying ecosystem goods and services is encouraging the development of frameworks such as techno-ecological synergy (TES) (Urban et al., 2010; Bakshi et al., 2015), which aims to include the role and limits of ecosystems explicitly in engineering to establish mutually beneficial synergies between human and natural systems. The novelty of this approach stems from the fact that it considers nature not just as a resource or a system to be protected, but as a holistic entity with which to build mutually beneficial synergies for sustaining human and other activities. TES accounts for goods and services from ecosystems that directly benefit industry and society. As depicted in Figure 1, in TES technology relies on ecosystems to absorb wastes and produce resources, while ecosystems rely on technological systems to provide essential nutrients, land, and other resources. In addition to meeting industrial needs, ecosystems also provide other cobenefits that could benefit society. Thus, TES goes beyond and combines the best features of existing approaches like circular economy, industrial symbiosis, and cradle-to-cradle design. Increasing synergy can result in a system where there is no net flow of raw materials or pollutants in Figure 1. Such a system could be self-sustaining.

This paper provides an overview of the recent progress in methods for including nature in engineering and its applications, with emphasis on chemical engineering problems. This is the topic of the next section with emphasis on process design, supply chain design, and life

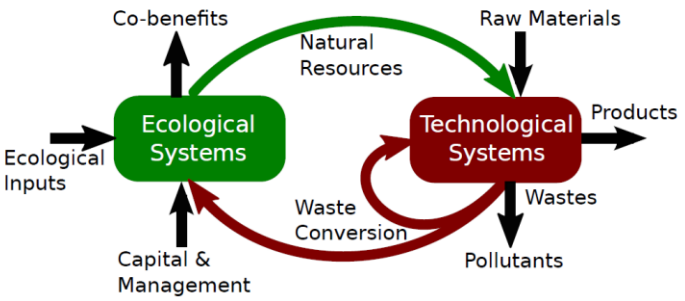

Figure 1. Framework of Techno-Ecological Synergy (Bakshi et al., 2015).

cycle assessment. At the smallest scale of process design, ecosystems are considered analogous to unit operations. At the supply chain scale, availability of ecosystem services influences decisions about choosing suppliers. At the life cycle scale, ecosystems are included just like process modules and the resulting TES-LCA method provides insight about absolute sustainability based on determining the extent to which the limits of ecosystem services are exceeded. Various applications are described to convey the potential benefits of the convergence of engineering with ecology are demonstrated with the help of several examples relevant to chemical engineering. The subsequent section discusses the challenges of including nature in engineering and whether this approach will lead to sustainable development. It identifies the potential pitfalls of this approach and the issues that require close attention in future work.

2. Progress

2.1. Process Analysis

Increasing understanding about the goods and services provided by nature and their importance led to work on determining whether these goods and services are relevant to industrial activity and whether nature could satisfy industrial needs. The most successful commercial use of ecosystems in industry is that of wetlands for treating industrial waste (Vymazal, 2011), as demonstrated by many successful implementations. Most such installations have been used for the last finishing step of water treatment, and are found to be not only economically and environmentally attractive, but also provide additional cobenefits to society through preserving biodiversity, maintaining the water table, and providing recreational and educational opportunities. One such implementation is estimated to have $283 million in net present value savings over the project's life time as compared to a conventional technological alternative (DiMuro et al., 2014).

The Nature Conservancy and Dow Chemical evaluated the ability of vegetation to mitigate air pollutants such as NOx, SOx and particulate matter (TNC-Dow, 2013). This study found that this nature-based solution can be less expensive than conventional technological solutions such as selective catalytic reduction of NOx and scrubbers for removing SOx. Another study (Gopalakrishnan et al., 2016) evaluated a biodiesel manufacturing site with a combined heat and power process for supporting the biodiesel facility. If available land in the vicinity of this site had native trees that were only 15 years old, they were shown to be capable of mitigating a significant fraction of criteria air pollutants. Older trees could drive the site toward zero net emissions. Here, vegetation was considered to go beyond environmental regulations, which is the stated sustainability goal of many corporations. Older trees were also found to have excess capacity than what was needed for the manufacturing process, which can be a cobenefit that the trees provide to the region by mitigating emissions from other local sources. Wetlands on this biodiesel site could also provide fresh water to the local river or aquifer, or back to the process after further treatment. Comparing the net present value of the process with technological versus ecological solutions for removing identical amounts of pollution showed that ecosystems had a higher NPV. Over time, ecosystems become even more attractive than technological systems since ecosystems appreciate over time while technology depreciates.

Comparing air emissions with the capacity of vegetation to take them up in each county across the United States also demonstrates the benefits of relying on nature to go

beyond regulations. Vegetation has substantial capacity to take up SO_2 emissions in 49% of US counties, 13% for PM_{10}, 4% for $PM_{2.5}$ and 5% for NO_x. Restoration of available land to the average current vegetation in each county is found to be more cost effective than using technology for the same task in 75% of US counties. Nature-based solutions are found to be most effective for mitigating emissions from activities such as farming; mining, oil and gas; electricity generation; and residential systems. Such studies convey the benefits of including ecosystems in industrial processes, and have encouraged further work. (Gopalakrishnan, 2017)

2.2. Process design

Reducing the environmental impact of chemical processes has been an area of active research for many decades. These efforts evolved from reducing resource use in individual equipment and process to reducing resource use and impact of emissions over the entire life cycle (Grossmann, 2004). Recent work on including nature in process design is including relevant ecosystems as if they were another unit operation, like distillation columns or heat exchangers. The optimization formulation of this integrated design of technological and ecological systems is as follows,

$$\max Z_1(x, x_e, y); \quad \max Z_2(x, x_e, y)$$

$$\text{s.t. } f(x, y) \leq 0;\ f_e(x_e, y) \leq 0$$

Here, the two objectives represent economic and environmental goals, and subscript e denotes ecological models and variables. Variables x and x_e are continuous while y are integers. The key difference with conventional design is the simultaneous presence of technological and ecological models and variables to enable integrated and synergistic design.

As described in Section 2.1, wetlands are already being used for treating industrial waste water. However, most such uses do not integrate wetlands into the flowsheet like other pieces of equipment. That is, wetlands are usually included as end-of-pipe solutions, meaning that the process is designed first in a techno-centric manner, after which the wetland is added to treat the waste water. Recent work on including ecosystems as unit operations in process design has shown the benefits of integrating wetlands in the process design (Gopalakrishnan and Bakshi, 2018). Integrated design with wetlands results in a design where the main process operates in a way that accommodates the use of wetlands for treating waste water. This results in decisions that avoid chemicals that cannot be treated by the wetland, and larger concentration of those chemicals that can be treated. The wetland is also designed to have the capacity and residence time for treating the industrial waste and producing freshwater of desired quality to satisfy needs of the technological system. Such an integrated design with objectives of maximizing net present value and minimizing net water use is found to be superior to an end-of-pipe design and a design with a technological alternative (anaerobic baffle reactor).

Application of the TES design approach to several problems demonstrates that inclusion of ecosystems can expand the design space as compared to the design space available from conventional, techno-centric designs. The nature of this expansion is depicted in Figure 2. As shown, the Pareto curve for TES design is in a region that is infeasible for conventional, techno-centric design. The additional design space made available by

TES design is indicated by the shaded region. Thus, TES design could provide innovative "win-win" designs that may be economically and environmentally better than conventional designs. Research to date has been demonstrated this for design of a biodiesel process, management of biosolids from urban water treatment, design of agricultural landscape for biofuels, and design of residential buildings. Integration of a local biomass farming system, biofuel manufacture and waste water treatment is also shown to be more self-sustaining than conventional disintegrated approaches (Martinez-Hernandez et al., 2017) and have benefits in terms of the food-energy-water nexus (Hang et al., 2016).

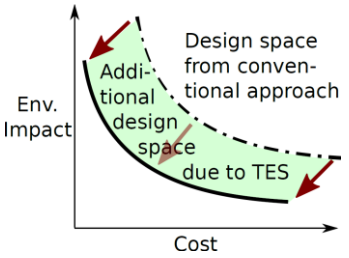

Figure 2. Expansion of design space due to including nature in engineering.

A unique challenge from including nature in engineering is due to the vastly different dynamic behavior of technological and ecological systems. The former exhibit relatively little variation with time, while the latter have high temporal variability with time of day, seasons, etc. For example, deciduous trees shed their leaves in autumn resulting in a drastic reduction in their capacity to mitigate air pollutants, and the productivity of wetlands in temperate regions may be much lower in the winter. Therefore, viable synergies between technological and ecological systems need to address such differences in their dynamics. Efforts toward addressing such issues have considered a local bioenergy-farming-waste water treatment system (Martinez-Hernandez et al., 2015) and a biodiesel design problem (Gopalakrishnan, 2017). The latter problem has been solved over four seasons for a location near Cincinnati, Ohio as a multi-period optimization problem. For mitigating air emissions, it is found that ecosystems can still be viable for capturing a large fraction of emissions by selecting a combination of native deciduous and evergreen tree species, adjusting the use of technologies for capturing emissions, and varying the amount of biodiesel produced in each season. Seasonal variation does deteriorate the overall performance of trees as compared to having the process in a region without seasonal variation, but using trees for going beyond regulations still remains economically more attractive than using technology. Also, evergreen trees continue to mitigate pollutants in the winter and are included in the design.

2.3. Supply chain design

If ecosystems are included in the design of supply chains, the overall goal of minimizing violation of ecological limits encourages inclusion of those suppliers that are closest to satisfying this requirement. It also encourages protection and restoration of ecosystems at and around supplier sites. An illustrative example on designing the supply chain of a biofuel finds a solution that reduces the impact of emissions and enhances ecosystem services, as compared to a conventional solution that reduces only the impact of emissions (Ghosh and Bakshi, 2018).

Ecosystem services may be represented in monetary units to allow aggregation with conventional cost analysis. By using such aggregation and calculating a Green GDP, a biofuel supply chain design problem has been solved recently with ecosystem services (Garcia and You, 2017). This work demonstrates how accounting for ecosystem services in the selected supply chain steps and its geographical region affects the resulting design and optimum value of the objective function.

2.4. Life Cycle Assessment

It is widely accepted that the life cycle of products and processes must be considered to prevent shifting of impacts along the supply or demand network. The method of life cycle assessment (LCA) has been formalized and adopted in process systems engineering for developing designs that aim to reduce life cycle impact along with conventional monetary goals. However, as discussed in Section 1, a significant shortcoming of conventional LCA is its ignorance of ecosystem capacity and goods and services from nature. The idea of developing synergies between human and natural systems has been extended to the approach of techno-ecological synergy in life cycle assessment (TES-LCA). This approach explicitly accounts for the demand and supply for ecosystem services in each step of the life cycle (Liu and Bakshi, 2018).

Accounting for nature requires some modifications and additions to the four steps of conventional LCA, which are goal and scope definition, inventory analysis, impact assessment and improvement analysis. The main goal of conventional LCA is to compare alternatives to choose one that has the smallest life cycle impact. This comparative approach results in relative sustainability metrics. TES-LCA also has this goal, but in addition, it also aims to protect and restore ecosystems that provide needed goods and services and encourage efforts toward staying within nature's capacity. Such an approach can provide absolute sustainability metrics by comparing the demands imposed on nature by industrial activities with the capacity of nature to meet the demand. Absolute environmental sustainability requires the demand to be less than or equal to the supply at the scale of the serviceshed of the selected ecosystem service. The serviceshed is the geographical region that supplies ecosystem services to a beneficiary. For CO2, the serviceshed is the planet since an emitted molecule can be absorbed anywhere on earth. For water the serviceshed is the watershed, and for pollination by insects the serviceshed is determined by the distance travelled by the insects. With this insight, the boundary of TES-LCA includes the local and serviceshed scales. The inventory analysis step of TES-LCA requires information about ecosystem services, which may be obtained from ecological models and remote sensing data. Since such data can have significant spatial variation, it is best to develop spatial models for TES-LCA.

Impact assessment in TES-LCA calculates the sustainability metric, $V_k = (S_k - D_k) / D_k$, for the k-th ecosystem service at selected spatial scales, including the serviceshed. Environmental sustainability requires $V_k \geq 0$ at the scale of the serviceshed. If this criterion is satisfied then the emissions could have zero net impact under the assumption of steady state. However, if $V_k < 0$ then the emissions not taken up by nature will have an environmental impact. We use conventional life cycle impact assessment to determine this impact. The consequences of this impact on degradation or enhancement of ecosystem services may also be quantified.

The unique characteristics of TES-LCA are illustrated in Figure 3 for a corn ethanol life cycle. Here, the x-axis is V_k at a local scale, while the y-axis is V_k at the scale of the serviceshed. If both metrics are positive (Quadrant I), it implies local and absolute sustainability, which is true for the water provisioning ecosystem service in this example. This is due to location of the farming in the water-rich region of Ohio. If an activity is in Quadrant II, the activity demands more from nature than available within the local boundary. However, demand at the serviceshed scale is within nature's limits. Thus, we have absolute sustainability, in this case, but not local sustainability. V_k in

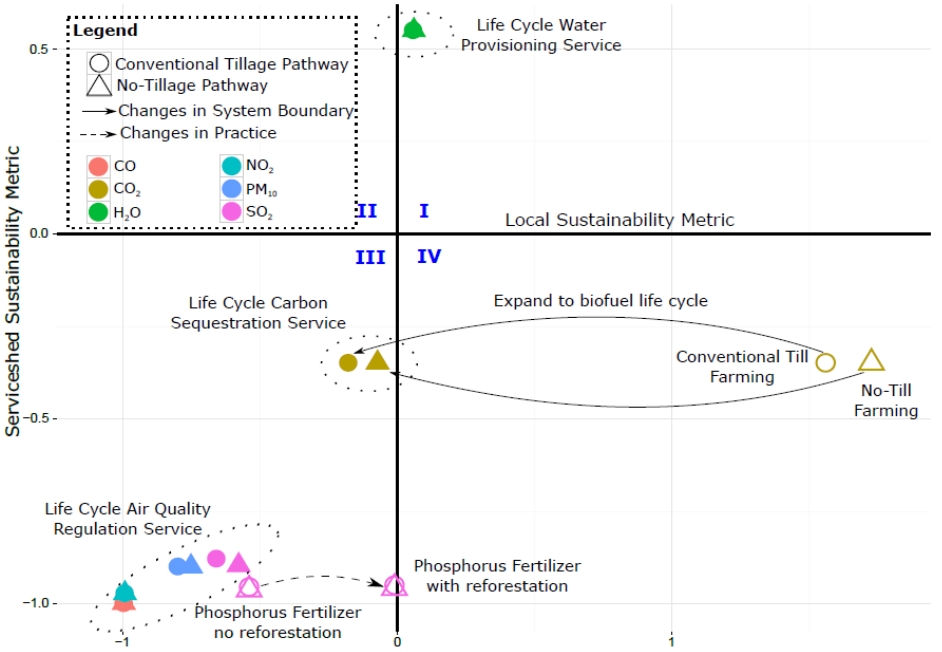

Figure 3. TES-LCA of carbon sequestration, water provisioning, and air quality regulation ecosystem services in the corn ethanol life cycle. (Liu and Bakshi, 2018)

Quadrant III implies local and absolute unsustainability, while Quadrant IV indicates an island of sustainability since the activity is within nature's limits at a local scale, but not in the serviceshed. As we can see from this figure, farming activities are an island of sustainability (Quadrant IV), but including the life cycle causes them to shift to Quadrant III. The Phosphorus fertilizer manufacturing process is in Quadrant III for air quality regulation, but if there was a forest around the facility, the activity moves toward Quadrant IV due to the capacity of vegetation to take up air emissions. Such insight is unique to TES-LCA since it cannot be obtained from conventional LCA.

3. Peril

Progress in the inclusion of nature in engineering decisions described in Section 2 conveys the potential benefits of greater attention to this effort. Many research challenges need to be addressed such as the following.

Data and models. The complex nature of ecosystems means that they are often not as well understood as human-designed systems. However, models of many ecosystems are available that are validated, reliable and widely used. Due to advances in remote sensing and geographical information systems, data about land cover and ecosystem services across the world are increasingly available. Advances in process systems engineering are needed to use these data and models along with technological information for developing innovative synergies.

Spatio-temporal variation. Nature is "self-designed" while technology follows the approach of "imposed design." Self-design of nature means that it requires little direct intervention and develops organically into a system that is resilient and self-sustaining,

but intermittent across space and time. This is because at scales larger than an organism nature follows homeorhesis. In contrast, technological systems are designed for homeostasis and to do few tasks with input of high quality resources that are often non-renewable and unsustainable. High efficiency of technological systems makes them predictable but fragile. Many ecosystems function at a reduced level at night and in the cold. To work with such systems, technological systems need to adapt their functioning or an appropriate combination of technological and ecological systems needs to be used. Integrating nature into engineering systems requires methods to deal with these differences between human and natural systems.

Sustainability and resilience. Technological systems are designed and operated with objectives such as maximizing economic value and minimizing environmental impact. Such strategies may not be appropriate for ecosystems since the objective function of nature is not known. Designing ecosystems with anthropocentric objectives such as maximizing efficiency could compromise their resilience and ability to provide diverse ecosystem services. Thus, conventional optimization-based approaches that have been very successful in engineering design may have to be modified for TES design.

Commodification of Ecosystem Services. Current research in quantifying and accounting for ecosystem services considers each service separately or emphasizes some services more than others. For example, methods exist for quantifying services such as climate regulation and water provisioning in physical or monetary units. However, quantification of cultural services such as spiritual, religious, and aesthetic aspects is difficult to quantify. Therefore, current approaches may result in less emphasis on those services that are more difficult to quantify. In addition, greater emphasis on a few ecosystem services could translate into efforts toward protecting them at the cost of others. For example, interest in being carbon neutral may result in efforts for maximizing the carbon sequestration of vegetation. This could encourage the development and use of monocultures of genetically modified high carbon sequestering trees. Such ecosystems would lack the holistic and self-sustaining properties of nature, and could cause unintended harm to other ecosystem services. Thus, thinking of ecosystem services as separate commodities may result in solutions that are not likely to be truly sustainable.

Ecological literacy. Successful efforts for including nature in engineering requires engineers to have knowledge about ecological systems. Surveys have shown that engineers are among the least ecologically literate. This is an educational challenge that requires a change in the engineer's attitude from considering nature to be controlled and dominated to one of wishing to work with and respecting nature.

There has been a successful convergence between biology and engineering at the micro or reductionist level resulting in many advances and new disciplines such as biomedical and biological engineering and systems biology. Such convergence between ecology and engineering at the macro or systems level may be initiated by efforts toward techno-ecological synergies, as discussed in this paper.

4. Conclusions

The current engineering paradigm keeps nature outside its boundary, which can unknowingly encourage ecological degradation and miss opportunities for innovation by working with nature to benefit from its ability to satisfy industrial and human needs.

This work summarizes the potential benefits, recent progress and outstanding challenges in including nature in engineering decisions. Sustainability and innovation are the two key promises of including nature in engineering. This promise is demonstrated by recent work on integrating nature-based solutions such as the ability of vegetation to treat air emissions and of wetlands to regulate water quality, with conventional technologies. Methods have also been developed for including ecosystem services in life cycle assessment. Full realization of the promise requires advances to address the fundamentally different behavior of technological and ecological systems such as the self-design of nature versus the imposed design of technology. Conventional optimization-based engineering design may also need to be modified to retain the resilience of nature. Engineers also need to learn about ecology to enable a successful and synergistic partnership between technological and ecological systems

Innovations in Process Control Education: A Flipped Classroom/Studio Approach

B. Wayne Bequette

Rensselaer Polytechnic Institute, 110 Eighth St., Troy, NY 12180-3590, USA
bequette@rpi.edu

Abstract

A flipped classroom where students view screencasts and read textbook material and take an on-line quiz before class has been implemented in a process dynamics and control course. The class periods involve brief lectures summarizing what they have learned, and include discussions and advanced problem solving using MATLAB and Simulink. The weekly assignments include a mix of analytical and numerical solutions. Motivating examples, such as automated insulin delivery are used throughout the course. Although a physical laboratory experiment is not used, the class benefits from a tour of the campus boilerhouse system.

Keywords: Learning modules, flipped classroom, simulations, interactive learning

1. Motivation and Background

Process control is a core course in the chemical engineering undergraduate curriculum in most departments, yet it sometimes suffers from an over-emphasis on analytical mathematics and without proper motivation from real process challenges. This paper presents an overview of a flipped classroom approach that best makes use of classroom time to solve realistic, challenging process control problems.

1.1 Process Control Textbooks and Curricula

Current process control textbooks cover much of the same analysis content as Coughanowr and Koppel (1965), which was the textbook used in the course that I took in 1979. Most books have added topics and examples and make use of computer-aided software, such as MATLAB. Many texts cover far too many topics for a one-semester course, so it is important that an instructor be selective about the material covered.

At roughly ten-year intervals the course structure is revisited at a control or education conference; see, for example Edgar (1990), Edgar et al. (2006), and Silverstein et al. (2016). The survey by Silverstein et al. (2016) indicates that 70% of courses use project or problem-based learning and 45% of courses use computers in the classroom.

1.2 Evolution of Teaching by the Author (30 years and counting)

My initial experience teaching process control was at UC-Davis in 1987-88. I used the Stephanopoulos (1984) textbook and analytical solutions. I arrived at RPI in 1988 and was impressed with the computing facilities and software, so I scheduled a weekly computer laboratory for the process control class. Initially I used the IBM simulation package, CSMP, but switched to MATLAB after a year or so. The regular classroom sessions remained largely lecture-based with handwritten derivations, but with as much engagement and active discussions with students as possible. To further motivate

students we developed a set of case studies that the students, in groups of two, would work on during the final 4 weeks of the course (Bequette et al., 1998). They would select from a set 4 topics, perform a literature review, develop models based on step-testing, design SISO controllers, then use the relative gain array (RGA) to decide on controller pairings for the multivariable case. Requirements included short reports each week, a final written report and a final presentation. I would serve as the advisor for one case study, while the TA and two of my other graduate students would be the advisors for the other three case studies. This was very time-intensive but the students were clearly motivated by the opportunity to choose a case study in their area of interest.

1.3 Studio Classrooms

The studio classroom approach was pioneered at RPI, with initial courses in physics and calculus in 1993 (Wilson, 2002). The first classrooms had networked computer workstations, with 2-4 students per computer. I started using a studio classroom for process dynamics and control in 1999 (Bequette et al., 1999). That classroom could handle up to 40 students that could face forward during lectures and discussions, then swivel 180º to work at computer workstations in groups of two. This was not an efficient use of space, and in 1999 RPI began requiring that entering freshmen (class of 2003) purchase laptop computers supplied with relevant computational software.

2. The Flipped/Inverted Classroom at RPI

2.1 Screencasts

A common characteristic of the flipped classroom is that students read and view important lecture material outside the class so that more time can be spent using engaging, interactive learning techniques in the classroom. I feel that it is better for the students to view a couple of short "screencasts" of 5-7 minutes each, rather than viewing a videotaped lecture of 50 minutes in length. The idea is to focus on a specific topic or technique and to have their full attention during the short screencast. The University of Colorado has developed a large set of screencasts for most of the core chemical engineering courses, available at learncheme.com, with 58 videos related to process control. Sometimes the notation is slightly different than that used in my course, so I warn students of this both pre- and post-viewing.

2.2 Brief On-line Quizzes

The flipped classroom works best if all of the students have read or viewed the lecture material in advance. I require the students to take a brief on-line quiz, automatically graded, before class. This typically consists of 5 multiple choice or true-false questions that are relatively easy if they have covered the material. Questions are sometimes related to the previous lecture, often involving impromptu discussions. For example, when Hurricane Harvey hit the Gulf Coast in August 2017, we discussed refining capacity and the effect of plant shutdowns on gasoline prices. I noted that I had worked at a refinery in Port Arthur, Texas and asked the students to name a famous former blues/rock singer from that area; since no one could name Janis Joplin the next quiz included questions based on a Wikipedia page on Janis Joplin.

2.3 In-class Simulation Exercises

In-class simulation exercises change in difficulty throughout the semester. During early exercises I have the students construct simple Simulink diagrams. As we get into more

difficult problems, e.g. cascade control, I supply them with .mdl and script files that they can modify. I feel that over the years some Simulink blocks have gotten too flexible and difficult for students to follow; I need to spend time explaining and discussing the different ways to implement a continuous PID controller, for example. Indeed, when I cover digital control I supply my own block that corresponds to my preferred derivation and implementation of digital PID.

2.4 Weekly Homework Assignments

Homework problems are assigned weekly and cover analytical and MATLAB/Simulink-based solutions. At the time of the assignment the particular topics have not been covered yet, so we quickly go over the assignment and the particular challenges to motivate them for the techniques being covered that week. The daily in-class exercises are used as a springboard for the solution of the weekly homework assignments.

2.5 Case Studies and Detailed Problems

Most years I have used case study projects for the final month of the semester, as discussed in section 1.2. This past year (2017) I decided to use a distillation control problem as a multivariable study example. Another detailed example used and discussed throughout the course is an automated insulin delivery system, as presented in section 4.

2.6 Mid-term and Final Exams

While the in-class exercises and weekly homework assignments involve the use of MATLAB and Simulink, the two mid-term exams and the final exam are based on analytical solution techniques and fundamental modeling and control understanding.

2.7 Additional Topics: Safety, Process Design, Boilerhouse Tour

Process safety is discussed, in one way or another, in almost every lecture. Most control strategies involve a discussion of whether a fail-open or fail-closed value should be used, for example. Early on most students do not have an appreciation of how a valve can be specified for a particular failure mode, so I present cross-sectional diagrams of typical valves and actuators for discussion. When discussing liquid surge drums we think about realistic values for the high and low level alarms. We also take groups of students on a boilerhouse tour with the operator pointing out the various vessels, sensors, actuators and the control room and control system. This is of particular benefit to students that have not had summer industrial experience.

3. Course Topic Overview

Chemical Process Dynamics and Control is a 4-credit course scheduled for 3 days/week (Tu/We/Fr) for one hour and 50 minutes each class period. As a practical matter, to give adequate time for homework problem solving and to accommodate the instructors travel schedule, during many weeks the third class period serves as a recitation, with the TA reinforcing material, and assisting with MATLAB, as examples. Since it is a 4-credit course, we tend to cover about 33% more topics than is covered in most 3-credit process control courses. A typical 15-week semester will include 32 lecture/regular classes, 7 recitations, 2 in-class exams, 1 campus boilerhouse tour, 1 no-class (Thanksgiving week), 1 final course review, and 1 final exam (during finals week).

Table 1. Course Topics	Table 2. Example Processes
Incentives/Motivation for Process Control Mathematical modeling Linearization, state space models Laplace transforms, transfer function analysis Connection between poles and eigenvalues Dynamic behavior, step and impulse inputs Introduction to feedback (FB) control, PID Closed-loop stability Real PID, filtering, derivative on output Internal Model Control and IMC-based PID Digital PID and digital filtering Cascade (CC) and feedforward (FF) Anti-reset-windup Nonlinear PID – surge vessel example Closed-loop control interaction, RGA Singular Value Decomposition (SVD) Plantwide control, startup/shutdown (brief) Model predictive control (brief) Statistical process control (brief) Optimization: Linear Programming (brief)	Gas and liquid surge vessels Insulin pharmacokinetics Biochemical reactor Jacketed reactors (batch & continuous) Steam drum, 3-mode (FF/FB/CC) Gasoline blending – ratio control Automated insulin delivery for type 1 diabetes: (i) response to meals w and w/o feedforward, (ii) effect of sensor bias, quantization & noise Drug infusion in anesthesia – multiple loops Distillation control – multiple loops Gasoline blending – LP problem

4. Motivating Example: Automated Insulin Delivery

In this learning module we first review the natural physiologic control loops involved when a healthy pancreas regulates blood glucose. We then describe the lifestyle of an individual with type 1 diabetes, who must monitor blood glucose levels and administer insulin, either through multiple daily injections or using a continuous insulin infusion pump. We describe typical ranges for basal (steady-state) insulin infusion, carb-to-insulin ratios for meals, and correction factors (amount of insulin required to reduce a glucose level by a certain amount). Someone with type 1 diabetes serves as a controller (feedforward and feedback) through constant diligence; this motivates the development of an automated insulin delivery system shown in Figure 1.

After reading this module and performing the studies a student is able to:

- Appreciate the challenges someone with type 1 diabetes faces in managing blood glucose. Meals increase and insulin decreases blood glucose. One challenge is providing the correct insulin bolus to compensate for a meal. Uncertainty in the carbohydrates in a meal makes it safer to under-bolus to avoid *hypoglycemia*.
- Appreciate the importance of maintaining a consistent healthy value of blood glucose. Blood glucose that is too low (*hypoglycemia*) can cause short-term dangers, such as drowsiness or a diabetic coma. Blood glucose that is too high (*hyperglycemia*) causes long-term risks, such as micro- and macro-vascular problems resulting in retina and other problems.
- Understand the metrics used in reporting clinical performance of glucose control strategies, such as mean glucose, time-in-range (70-180 mg/dL), time in *hypoglycemia* (less than 70 mg/dL), time in *hyperglycemia* (greater than 180 mg/dL), and total daily insulin dose (insulin used each day).
- Approximate the dynamic behavior between insulin and meal inputs and blood glucose outputs using low-order transfer function models.

- Understand the importance of sensors that report discrete quantized values (for example, a continuous glucose sensor reports to the nearest 1 mg/dL).
- Understand the effects of sensor noise and bias on control system performance. A mis-calibrated glucose sensor can be off by 10-20 mg/dL or more.
- Understand that providing an insulin bolus at mealtime (feedforward control) leads to improved glucose control performance compared to feedback-only control.

Figure 1. Example of an automated insulin delivery system currently under study. The components, using Bluetooth communication, include a continuous glucose monitor (CGM), a control algorithm on the smart phone and insulin infused by the insulin pump.

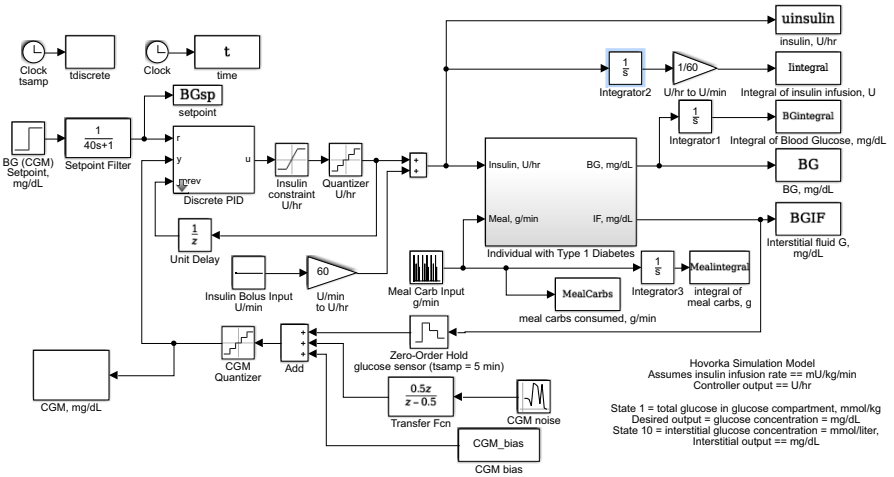

Figure 2. Simulink Diagram for Automated Insulin Delivery. Includes open-loop behaviour by setting the controller gain to 0.

Students are provided with a Simulink diagram (Figure 2) that includes the insulin-meal-blood glucose model of Hovorka et al. (2004) and Wilinska et al. (2005). We added additional lags for the dynamics between the blood and interstitial fluid and the sensor lag, with possible bias and measurement noise. The simulation model also includes a digital PID controller, and it is suggested that the students begin with the tuning parameters proposed by Palerm (2011). An outcome of the simulation exercise is to suggest controller tuning and an appropriate blood glucose setpoint if the sensor can be biased by up to 20 mg/dL, with the objective of reducing the risk of hypoglycaemia to less than 5% (that is, less than 72 minutes per day spent less than 70 mg/dL).

5. Discussion

In a process dynamics and control course the specific examples used may not be as important as the instructors enthusiasm in presenting them. I have been fortunate to be involved in a wide-range of automation and control related problems, ranging from classic chemical processes (petroleum refining, pharma batch reactors) to biomedical systems (automated insulin delivery, drug infusion in anesthesia). It certainly helps that I can bring specific examples that I have worked on into the classroom – such as responding to level sensor failures while serving as an operator in the refining industry, and conducting clinical trials of an automated insulin delivery system. The final course survey results, specifically for the instructor-added questions, shown in Table 3 indicates, that students were generally satisfied with the course; indeed it appears that the on-line quizzes actually provided encouragement for them to read the textbook.

Table 3. Course survey responses to instructor-added questions

Instructor-Added	Number Responding/(%age of Respondents)								
	1	**2**	**3**	**4**	**5**	**Omit**	**Avg.**	**Med.**	**s.d.**
The screencasts have been useful	1 (4%)	3 (11%)	3 (11%)	9 (32%)	12 (43%)	0	4.00	4.28	1.16
The on-line quizzes have been useful	2 (7%)	5 (18%)	6 (21%)	10 (36%)	5 (18%)	0	3.39	3.60	1.20
The studio approach of combining lectures and simulations has been useful	1 (4%)	3 (11%)	1 (4%)	10 (36%)	13 (46%)	0	4.11	4.40	1.13
I have benefited by reading the textbook	1 (4%)	1 (4%)	3 (11%)	14 (50%)	9 (32%)	0	4.04	4.14	0.96
I have adequate time to do the homework	0 (0%)	1 (4%)	3 (11%)	15 (56%)	8 (30%)	1	4.11	4.13	0.75
I appreciate the importance of process control in industry	0 (0%)	0 (0%)	2 (7%)	10 (36%)	16 (57%)	0	4.50	4.62	0.64
MATLAB has been easy to use	7 (25%)	5 (18%)	8 (29%)	5 (18%)	3 (11%)	0	2.71	2.75	1.33
The boiler house tour was useful	0 (0%)	0 (0%)	4 (14%)	8 (29%)	16 (57%)	0	4.43	4.62	0.74
Key **1 = Strongly Disagree**	**2 = Disagree**		**3 = Neutral**		**4 = Agree**		**5 = Strongly Agree**		

6. Approaches and Material from Other Sources

Huang (2017) discusses the results of integrating three MATLAB-based learning modules into a flipped classroom by using teaching videos to be viewed a week before class and quizzes taken at the beginning of class. Marlin (2017) discusses "blended learning" and develops a flipped classroom as one example. E-lessons consist of pre-prepared slides with audio that can be studied via the internet at any time, followed by an un-graded quiz. Class time then involves a mini-lecture reviewing the e-lesson, then workshops (hands-on, interactive learning) to reinforce learning material, followed by a mini-lecture on the next e-lesson). Seames (2017) takes a simulation-based approach, including a new textbook, and requires outside material be studied, with on-line quizzes; re-quizzes can be taken up to 3 weeks later. It should be noted that the text by Svrcek et al. (2014) also takes a simulation-based approach.

There are many learning resources available on the internet. For example, cache.org contains links to material from many sources. The learncheme.com site is particularly strong in the use of screencasts. The Hedengren process dynamics and control course at BYU has lecture material and a low-cost temperature control experiment.

7. Conclusions

A flipped classroom makes better use of a students and instructors time. Students come to class prepared, after taking an on-line quiz, and are more engaged in discussions and problem solutions. Because of the interactive nature of the class-time, it is important to have a teaching assistant willing to engage with the students.

8. Acknowledgments

I wish to acknowledge the outstanding efforts of Edmund Tang and Sambit Ghosh, who served as the TAs the first two times I used a flipped classroom approach.

Abstract

This paper provides a brief introduction to Reinforcement Learning (RL) technology, summarizes recent developments in this area, and discusses their potential implications for the field of process control. The paper begins with a brief introduction to RL, a machine learning technology that allows an agent to learn, through trial and error, the best way to accomplish a task. We then highlight two new developments in RL that have led to the recent wave of applications and media interest. A comparison of the key features of RL and Model Predictive Control (MPC) is then presented in order to clarify their similarities and differences. This is followed by an assessment of five ways that RL technology can potentially be used in process control applications. A final section summarizes our conclusions and lists directions for future RL research that may improve its relevance for process control applications.

Keywords: Reinforcement Learning, Model Predictive Control, Process Control.

1. Introduction

In March 2016, a computer program named AlphaGo defeated Lee Sedol, an 18 time world champion, four games to one, at the ancient Chinese game of Go, generating widespread media attention. In May 2017, a new and improved version called AlphaGo Master soundly defeated Ke Jie, the reigning world No. 1 ranked player, three games to none. It is said that Google DeepMind was already in possession of AlphaGo Zero, a version much stronger than the Master version, at the time (Silver et al., 2017). Go was invented more than 2,500 years ago and is believed to be the oldest board game widely played today. Despite its relatively simple rules, Go is significantly more complex than chess in terms of combinatorial possibilities and defeating the best human players had been a goal of Artificial Intelligence researchers for many years. AlphaGo owes its success to recent developments in Machine Learning (ML), specifically to a branch of ML known as Reinforcement Learning (RL) (Sutton and Barto, 2016). Other notable successes of RL include manoeuvring self-driving cars, soccer robots, and optimizing the operation of a data center (Knight, 2017). One can find many interesting demonstrations of Reinforcement Learning on YouTube, including a robot that learns to defend a soccer goal and one that learns how to flip pancakes.

Given the recent successes of RL technology, and given the similarities between RL tasks and process control problems, it is natural to ask if there are any implications of these developments for the field of process control. This paper attempts to address this question, building on a prior assessment of Machine Learning presented at the

FOCAPO/CPC 2016 meeting by Lee et al. (2016). The paper begins with introduction to RL, a machine learning technology that allows an agent to learn, through trial and error, the best way to accomplish a task. We then highlight two new developments in RL that have led to the recent wave of applications and media interest. A comparison of the key features of RL and Model Predictive Control (MPC) is then presented in order to clarify their similarities and differences. This is followed by an assessment of five ways that RL technology can potentially be used in process control applications. A final section summarizes our conclusions and lists directions for future RL research that may improve its relevance for process control applications.

2. Reinforcement Learning

Machine Learning is customarily divided into three classes of algorithms: Supervised Learning (SL), Unsupervised Learning (UL), and Reinforcement Learning (RL) (Bishop, 2012). In Supervised Learning, an agent is provided with labelled examples (X and Y) and learns a mapping that allows it to predict values of Y for new values of X. For example, an agent may be provided with a number of pictures of animals, each labelled properly with the types of animals in the picture. The agent then learns a mapping that allows it to determine, for example, which of the pictures contain a particular type of animal. In Unsupervised Learning the agent is provided with unlabelled data (X only) and learns about how the data is distributed ($p(X)$). For example, the agent may be able to group pictures according to the types of animals they contain. Reinforcement Learning differs significantly from both Supervised and Unsupervised Learning. A Reinforcement Learning agent has the goal of learning the best way to accomplish a task through repeated interactions with its environment (Sutton and Barto, 2016). In order to accomplish this the agent must evaluate the long-term value of the actions that it takes.

Of course the concept of teaching a computer to accomplish a task has been around since the earliest days of the computer age. Alan Turing, for example, wrote the following in his remarkable paper on computing and intelligence (Turing, 1950):

> *Instead of trying to produce a programme to simulate the adult mind, why not rather try to produce one which simulates the child's? If this were then subjected to an appropriate course of education, one would obtain the adult brain…We normally associate punishments and rewards with the teaching process. Some simple child machines can be constructed or programmed on this sort of principle…I have done some experiments with one such child machine, and succeeded in teaching it a few things, but the teaching method was too unorthodox to be considered really successful.*

The development of RL from such early concepts is well documented in what is probably the best overall introduction to the field, the classic text of Sutton and Barto (2016). Two essential threads of research contributed to the modern theory of RL: Animal Psychology contributed key concepts related to learning a task by trial and error, and Optimal Control Theory provided guidance on how to improve task performance as well as how to know when the task was completed in the best possible way.

2.1 Reinforcement Learning Basics

The basic setting for RL, as abstracted from Animal Psychology, is illustrated in Figure 1. In this setting there are only two entities, the Agent and the Environment. At time t the Agent takes an action A_t that affects the environment, causing it to transition from

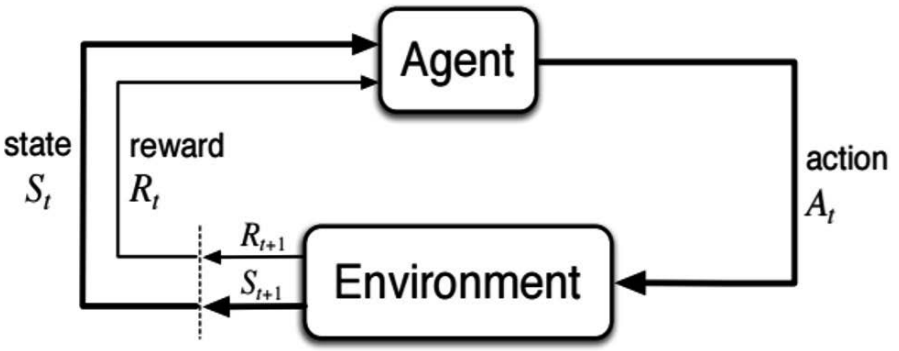

Figure 1 - Basic setting for Reinforcement Learning

state S_t to state S_{t+1}. As a result of the action A_t, and the subsequent transition from state S_t to state S_{t+1}, an immediate reward R_{t+1} is generated. The Agent then uses the state information S_{t+1} and immediate reward R_{t+1} to generate the next action A_{t+1}, continuing the cycle. The goal of the Agent is to learn a mapping from states to actions called a policy $\pi(A_t = a|S_t = a)$ that maximizes a *long-term* sum of future rewards called a value function $v_\pi(s)$:

$$v_\pi(s) = E\{R_{t+1} + \gamma R_{t+2} + \gamma^2 R_{t+3} \cdots |S_t = s\} \quad (1)$$

Here $\gamma \in [0,1]$ is a discount factor that determines the importance of future rewards. When $\gamma = 0$ the Agent acts in a greedy manner, maximizing the reward at the next time step. When $\gamma = 1$ the Agent will place equal importance on all future rewards. Note that every value function $v_\pi(s)$ is associated with a particular policy π that determines the future path through the space of states.

RL algorithms can be thought of as iterative updates that improve the policy so that the associated value function increases for all states. If the Agent modifies the policy appropriately at each iteration, then the policy continues to improve, leading to larger and larger values for the value function at any given state. It is natural to ask if the value function ever attains its best possible, or optimal value, $v_*(s)$. Optimal Control Theory answers this question in the form of Bellman's optimality equation, a condition which must be true for all states if the policy is optimal (necessary condition):

$$v_*(s) = \max_a \sum_{s',r} p(s', r|s, a)\,[r + \gamma v_*(s')] \quad (2)$$

Here the term $p(s', r|s, a)$ is the transition probability for the environment, known as the transition model. It provides, given the current state s and action a, the probability that the environment will transition to state s' with reward r. For a discrete set of actions and states, and for a given process model, Bellman's optimality equation provides a set of nonlinear equations that can, in principle, be solved directly to obtain the optimal value function $v_*(s)$. Once the optimal value function is known, the associated optimal policy $\pi_*(s)$ can be found using the transition model. In practice, however, these equations usually cannot be solved directly because we either do not know the environment model, or the state dimension is so large (possibly infinite) that the solution cannot be found in a

reasonable time. Sutton and Barto consider all RL algorithms as approximate solutions to Bellman's optimality equation, dealing in various ways with these two limitations (Sutton & Barto, 2016).

For continuous states and actions, the most relevant case for process control applications, the state and action dimensions are infinite, requiring that function approximation methods be used to estimate the optimal value function $v_*(s)$ and policy $\pi_*(s)$. Note that while neural networks are often used for this, other types of function approximations can also be used. Let us assume that the policy function is parameterized by parameters θ:

$$\pi(a|s) \cong \pi_\theta(a|s) \tag{3}$$

Sergey Levine (2017) explains that for this case the goal of the RL algorithm is to solve the following optimization problem:

$$\theta_* = \underset{\theta}{argmax} E_{\tau \sim p_\theta(\tau)} \left[\sum_t r(s_t, a_t) \right] \tag{4}$$

This says that the parameters θ are to be chosen so that the resulting policy maximizes the expected value of future rewards. Here $r(s_t, a_t)$ is a reward function and the expectation is over the sequence τ of future actions and states, distributed according the probability $p_\theta(\tau)$:

$$\tau = (s_1, a_1, s_2, a_2, \ldots.) \tag{5}$$

From this perspective, Levine (2017) divides RL algorithms into four main classes:

- Model-Based (MB): estimates the transition model $p(s', r|s, a)$ and then uses this directly for control, to estimate the value function, or to estimate the policy.
- Value-Based (VB): estimates the so called Q function $Q_*(s, a)$ which combines the transition model and the optimal value function in (2), then determines the policy that selects the most beneficial (greedy) action from the current state.
- Policy-Gradient (PG): estimates the value function by summing observed rewards $r(s_{t,} a_{t,})$, then uses the gradient of the objective in (4) to improve the policy by gradient ascent
- Actor-Critic(AC): estimates optimal value function $v_*(s)$ in (2), uses this to predict future rewards $r(s_{t,} a_{t,})$, then uses gradient of objective in (4) to improve the policy by gradient ascent (combines best features of Policy-Gradient and Value-Based)

The last three of these are often referred to as model-free, since they do not require an estimate of the transition model. We will emphasize model-free RL methods here so as to provide a clear contrast with MPC techniques that are widely used in process control today.

The effectiveness of these algorithms on any particular problem may vary widely, due to a number of trade-offs (Levine, 2017):

- Sample efficiency: how many interactions with the environment are required to achieve good convergence?

- Stability and ease of use: how easy is it to choose the algorithm's meta-parameters so as to get reliable convergence?
- Stochastic versus deterministic: does the algorithm work better for stochastic or deterministic environments (and/or policies)?
- Continuous versus discrete: is the algorithm better suited for continuous or discrete states, actions, and/or rewards?
- Episodic or infinite horizon: is the algorithm better suited for episodic or infinite time environments?
- Parallelization: Can the algorithm be parallelized easily when a good simulation of the environment is available?

For example, PG algorithms typically require significantly more interactions with the environment than the other methods (low sample efficiency). However, the actual wall clock time to convergence may be lower if a good simulator is available, since PG algorithms are highly parallelizable. Most of the recent developments in RL theory and application are based on AC algorithms that use Deep Neural Networks (DNN) for function approximation. AC algorithms, first introduced by Witten (1977) and later popularized by Bart, Sutton, and Anderson (1983), combine some of the best features of VB and PG algorithms, resulting in faster, more stable learning.

2.2 Latest developments

We now highlight two relatively recent developments in RL technology that have enabled a significant expansion in the scope and capability of the technology: Deep Learning and Parallelization.

Deep Learning refers to a neural network architecture with a relatively large number of layers, in which the first several layers mostly extract significant features from the data (X), and the last layers are mostly engaged in correlating the extracted features to outputs (Y). This type of architecture, shown in Figure 2, is often referred to as a Deep Neural Network (DNN). Lee et al. (2017) provide more details on the development of Deep Learning technology. The use of DNNs to approximate the value and policy functions is a key factor in the many of the recent RL success stories (Silver, et al., 2016). The ability of a DNN to extract useful features significantly reduces the time and effort required for feature engineering. In the AlphaGo application, for example, the DNNs were able to use the raw 19x19 matrix of board positions to directly deduce the game state (Silver, et al., 2016). One implication for process control applications is that it may be possible to pass all available process measurements to a DNN and allow it to predict future process outputs directly, without having to design and implement a state estimator. This would greatly simplify the design of new control systems, and may provide a straightforward path to improving existing control systems.

A second recent development is the use of parallelization to speed up and stabilize the learning process, which might otherwise be a significant barrier for process control applications. A recent paper from Mnih, et al. at Google DeepMind (2016) discusses the advantages of this. Previous work had found that combining simple online RL algorithms with DNNs led to learning stability problems in that the DNN weights would not converge in a stable manner. This was thought to be due to the correlated nature of the updates that the RL algorithms received online. One popular solution to this problem is to store the

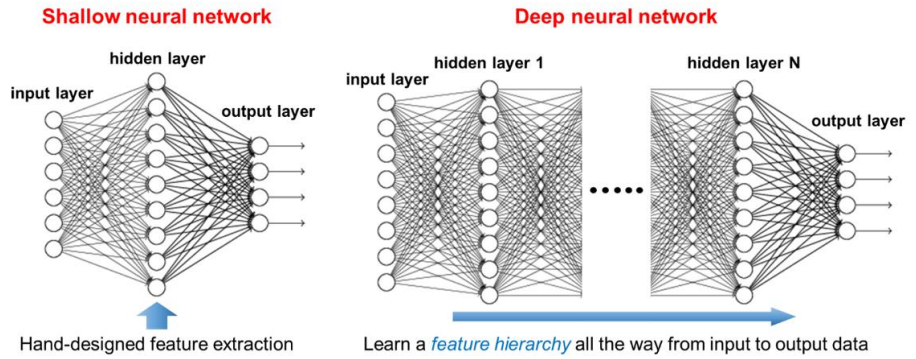

Figure 2 – Comparison of the structure of a Shallow neural network and a Deep Neural Network, from (Lee, at al., 2017)

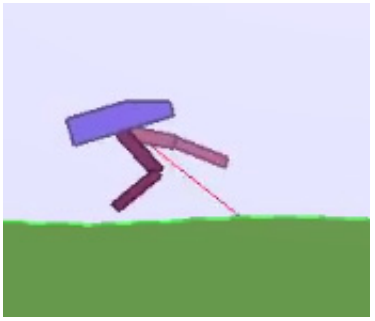
online data in an experience replay memory, where they can be batched or randomly sampled to train the DNN. Mnih et al. (2016) present an alternative method in which a number of distributed agents execute in parallel on identical copies of the environment, each progressing on its own trajectory through the state space due to the use of different exploration policies. Gradients computed locally by the distributed agents are periodically transmitted to a master agent, where they are used to update a master policy. The master policy is, in turn, transmitted periodically to the distributed agents. There are two significant benefits to this approach. The first is that the learning rate increases dramatically, roughly in proportion to the number of distributed agents. The second is that learning is more stable because the gradient updates are uncorrelated. This means that there is no requirement for an experience replay memory. They demonstrate superior performance of their Asynchronous, Advantage, Actor-Critic (A3C) algorithm on a variety of games and control tasks that include both continuous and discrete actions. They conclude that their A3C algorithm is the most general and successful RL algorithm to date. Of course, all of this depends upon the existence of a quickly executing process simulator of sufficient accuracy to be useful.

An extension of this concept, which may prove useful in robust control applications, is to run a number of agents in parallel on slightly different environments, each corresponding to a possible realization of an uncertain process. The knowledge gained in each environment can be assembled in the master agent in the same way. The resulting master policy would be expected to produce more cautious, robust actions.

2.3 An example RL application – OpenAI Gym Bipedal Robot

We now present a simulated bipedal robot example. The bipedal robot environment comes from the OpenAI Gym, an open-source toolkit for comparing reinforcement learning algorithms. Figure 3 illustrates the bipedal robot, which consists of a head (also called a hull) and two legs. Each leg has two joints – at the hip and the knee. Twenty-four continuous states are measured, without error, to determine the dynamic state of the robot. These include position, speed, and angular velocity of the robot components, a sensor that determines if the legs are in contact with the ground, and ten Lidar distance measurements. The four continuous actions are torques applied to each joint. The reward



24 Continuous States	= [hull angle speed, angular velocity, horizontal speed, vertical speed, position of joints, joints angular speed, legs contact with ground, 10 LIDAR rangefinder measurements]
4 Continuous Actions	= [leg joint torques]
Reward	+x: Every time it moves forward. - 0.1: Apply leg motor torque. -100: Fall down.

Figure 3 - Bipedal robot example – states, actions, and rewards

is how many units of forward motion have been achieved with a small penalty for each action (torque) and a large penalty for falling down. The environment is episodic in that each episode begins with the robot standing at the edge of a field, and the episode ends when the robot either falls down or reaches the other edge of the field.

A Deep RL AC algorithm was implemented for this example. The results at various stages of learning are illustrated below in Figure 4. After 3k episodes the robot is able to make some forward progress but its rear leg is folded beneath it much of the time. After 40k episodes it is able to move forward much more rapidly. Further training leads to a very surprising policy, in which the robot hops on one leg, using the other leg as a tail to maintain its balance. This happens because the reward signal penalizes movement of the joints, so the robot has found a way to optimize its overall reward by decreasing its forward speed and moving its legs less vigorously. This points out an interesting feature of RL technology – RL agents can sometimes produce actions that a human control designer would never think of. The AlphaGo agent exhibited similar behaviour in that it sometimes made moves that no experienced Go player would consider. This can be viewed as either a problem or a learning opportunity depending on your point of view.

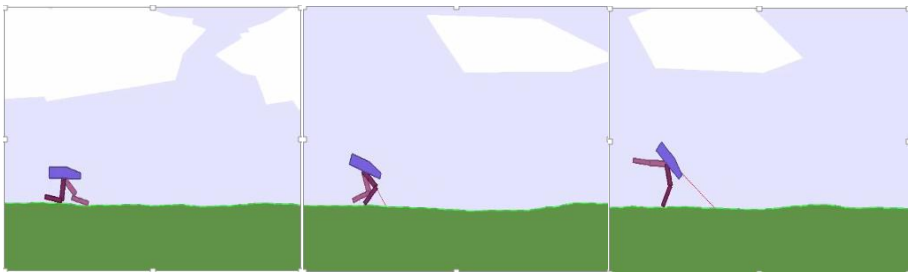


Figure 4 – Results for the bipedal robot using an AC algorithm. On the left after 3k episodes, in the middle after 40k episodes, and on the right after additional training.

Figure 5 presents results from a more sophisticated bipedal robot that learns to traverse a more challenging obstacle course consisting of steps, walls, and pits. This robot uses a parallel AC algorithm similar to that presented by Mnih et al. (2016) discussed above so

that it can learn from a number of environments simultaneously. Each of distributed environments contains the same types of features, but their number and location vary randomly. After sufficient training the robot is able to traverse the obstacles easily, occasionally raising its rear leg in a tail-like manner to restore its balance.

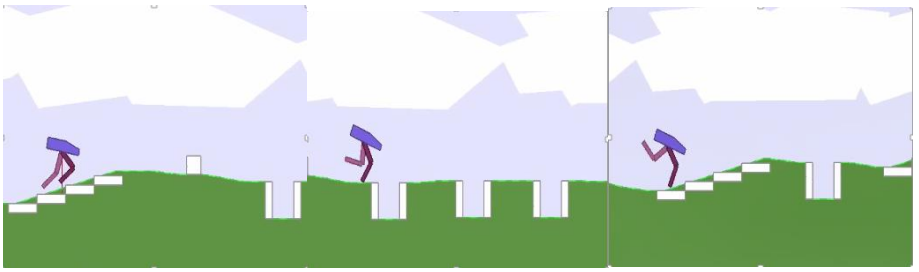

Figure 5 – Results for a bipedal robot using a parallel AC algorithm to traverse a more complex environment consisting of steps, walls, and pits.

3. Comparison of Reinforcement Learning and Model Predictive Control

In order to assess the strengths and weaknesses of RL for process control applications it is instructive to compare RL with MPC, the most widely-used technology developed by the process control community for complex, multivariable control applications (Qin and Badgwell, 2003). In doing so we consider a model-free, on-policy RL algorithm with continuous states and decisions applied to a game, since this is the type of application that has driven much of the recent effort in RL theory and applications. And we consider MPC with a fixed discrete time state-space model, since this is the form that has arguably driven most of the recent developments for this technology. With this in mind, Table 1 provides a comparison of the salient features of these technologies.

The two technologies make somewhat different assumptions about the underlying system. For MPC the underlying system is typically assumed to be a discrete-time state-space system of the form:

$$x_{k+1} = f(x_k, u_k, w_k)\ ;\ \ y_k = g(x_k, v_k) \tag{6}$$

Here x_k is the system state at time k, u_k is the input (action), and y_k is the measured output. The term w_k is a stochastic state disturbance, and the term v_k represents measurement noise. This model form describes how the state traverses through the state space, given a sequence of actions, state disturbances, and measurement noises. RL focuses instead on how the probability of being in a particular state changes from one time step to the next. This is described by a Markov Decision Process (MDP) with the following components (Levine, 2017):

- S - state space, states $s \in S$ (discrete or continuous)
- A - action space, actions $a \in A$ (discrete or continuous)
- T - transition operator, $p(s_{k+1}|s_k, a_k)$
- $r(s, a)$ - reward function, $r: SxA \rightarrow \mathbb{R}$

So basically, a MDP is an unstructured model in discrete state space, describing how the probability of being in a particular state changes over time. It is possible, in principle, to convert the discrete-time state-space model (6) into a MDP by sampling the state transitions. However model-free RL does not require a system model of the form in (6). So model-free RL has the advantage that no explicit system model is required. It also works naturally in a stochastic system environment. However, it has the disadvantage that the relevant system behaviour must then be learned by trial and error.

Table 1: A comparison of Reinforcement Learning and Model Predictive Control

	Reinforcement Learning (model-free)	**Model Predictive Control**
Underlying System Assumption	Markov Decision Process	Discrete-time state space system
Goal(s)	Simple, fixed goal: Just win (don't care about path through state-space)	Complex goal that changes with time: Estimate system state, determine best steady-state consistent with current constraint and setpoint values, follow smooth path consistent with constraints through state-space to best steady-state (smooth, stable path through state-space is critical)
Modeled component	Value function or Policy	Discrete-time state space system
Model learning paradigm	Adaptive model learned through trial and error either offline using simulation or online with real process	Fixed model developed through first principles and/or process identification experiments
Exploration/Exploitation	Simultaneous	Exploration first to get model/Exploitation thereafter
Feedback	Adapting value function or Policy	Disturbance estimation
Online execution time	Very fast - just a forward run of the policy network	Slow - potentially solving three optimization problems at each execution
Stability	Closed-loop stability is not considered	Closed-loop stability is essential.
State Constraints	State constraint enforcement is not considered	State constraint enforcement is essential
Failure tolerance	Failure is necessary for learning (simulation can be used)	Failure cannot be tolerated
Sweet-spot	Accomplishing a task (winning a game)	Keeping a stationary multivariable process within constraints and close to setpoints in the face of measurement noise and process disturbances

The typical goals of RL and MPC algorithms are also quite different. The goal of a RL application is often to complete a task, such as winning a game, where you do not care how the algorithm traverses the state space or how long it takes to win. In the AlphaGo application, for example, the agent does not care how long it takes to win, or how many of its stones get taken. All that matters is to win the game. And the goal of winning does not change during the game. In contrast, an MPC application cares very much about how it traverses the state-space. It is preferable to follow a short, smooth path from the current state to the desired steady-state, and state constraints must not be violated along the way. And the goal for the MPC algorithm can change frequently, in the worst case at every sample, as the operator changes setpoints or constraint limits, and as disturbances perturb the process. However, these distinctions should not be interpreted as fundamental limitations as each method can, in principle, be formulated to address problem type of the other. For example, an RL agent can carry a general stage-wise reward function, which can be used to shape or constrain the transient movement in the state space. And the RL agent can be trained using data that includes many setpoint changes, constraint limit changes, and disturbances. However this additional required training may be very challenging in practice.

For RL the "model-free" label is a bit misleading since these algorithms must still build up models of the value function and/or the policy. The value function for RL is similar to the objective function for MPC with the system model and control policy substituted into it (with a negative sign). So in this respect RL is like MPC where one builds a model of the "closed-loop" objective function rather than of the process itself.

RL learns the value and policy functions primarily through trial and error experiments. If a high-quality simulation is available, which is often the case for games, then one can initialize the value and policy function estimates by performing these experiments on the simulation. In the context of game playing where the environment follows a same set of rules as the agent, one can even train the agent by having it play copies of itself (Silver, et al., 2017). Once the agent is online, it typically spends most of its time exploiting the models to improve the average reward, with the remaining time dedicated to random actions that allow it to update the value and policy function models if necessary. This balance between exploitation and exploration allows the value and policy function models to adapt as the system changes, and is a fundamental aspect of RL technology. So for RL, model prediction error due to time varying nature of the problem is ultimately addressed (feedback) by adapting the value and policy function models.

With MPC the system model is typically developed through some combination of first principles theoretical arguments (e.g. mass and energy balances) and carefully chosen process identification experiments on the real system. It is assumed that the process will not change significantly in the near future so there is no need to update the system model, at least not on a continuous basis. This can be viewed as exploration first (through plant testing), followed by exploitation thereafter (through control with the identified model). Prediction error is integrated away by estimating disturbances that can enter the process through some combination of input, state, or output channels. This would seem to provide an advantage over RL technology for those cases where the core process dynamics do not change significantly and disturbance patterns remain the same.

The RL agent typically executes very quickly online since this involves only a forward run of the policy network. In contrast, MPC may take much longer to execute since it involves solving three optimization problems sequentially (state estimation, steady-state

target calculation, dynamic optimization). This is necessary in MPC because the control problem may change significantly from one time step to the next.

Closed-loop stability is a concept that does not receive much attention in the RL literature, probably because the emphasis is on batch tasks rather than continuous tasks. For MPC applications, closed-loop stability is essential and is now well-characterized following decades of study (Rawlings et al., 2017). Characterizing closed-loop stability for RL algorithms would seem to be a good research opportunity.

State constraint enforcement is something that is critical to MPC applications but does not seem be addressed by RL technology. When operating a fired heater, for example, it is critical to ensure that the tubeskin temperatures in the firebox remain below a critical value. With RL, by contrast, it does not matter where the agent goes on the board as long as it wins the game. As said before, this is not necessarily a fundamental limitation of RL as stage-wise reward or penalty function can be used to shape the transient performance. Working through the details of how to implement state constraints in RL algorithms would seem to be another good research opportunity.

The tolerance for failure in RL is also quite different that for MPC. Since much of RL learning is accomplished by trial and error using random actions, the system must be allowed to fail occasionally, at least during training, where failure is defined as the lowest possible reward. For MPC, failure in this sense cannot be tolerated. For RL this could be mitigated in a process control scenario in three ways. First a high quality simulation could be used initially to train the RL agent. Second, an imminent failure online could be detected through some form of feature engineering, generating an automatic action to restore the system to a better state. Third, the reward function can be designed to reflect transient constraints on the value function or policy learned, but a careful balance between exploration and exploitation should maintained, esp. during the initial learning period.

To summarize this comparison, RL technology appears to be best suited for batch tasks with a simple-fixed goal, carried out on a potentially non-stationary stochastic system, for which a high-quality simulation is available, and for which state and time constraints are not important. In contrast, MPC seems best applied to continuous tasks with complex, time-varying goals, carried out on stationary systems, for which high-quality simulations may not be available, and for which state and time constraints are very important. However, these distinctions are not necessarily fundamental and only reflect the types of applications each has targeted. Even though RL and MPC have been targeted at very different control problems thus far, they are in some ways complementary, and this opens the door for using RL, or at least some of its aspects, for process control applications.

4. Implications for Process Control

In general, a RL agent has the potential to perform any task that requires knowledge and experience gained by interacting with the process. However, as we have seen, this comes at the cost of requiring significant interaction (training) with the process, or at least with a high fidelity process simulation. Nevertheless there are several ways that RL technology may have an impact on the theory and practice of process control. Here we discuss five broad classes of opportunities.

4.1 Directly replace existing process control technology with RL

The most straightforward use of RL in process control involves using it to directly replace existing control technology. On the other hand, since RL technology was developed to

solve a very different class of problems, we view direct replacement to be the least likely path for RL to have an impact on process control. A much more likely way for RL to have an impact will be in combination with conventional control technology such as MPC, or when applied to different, but related problems where MPC would have some difficulty.

4.2 Integrate aspects of RL technology with MPC

Several authors, including some from the process control community, have discussed how RL can be used to complement existing MPC technology. These proposals make use of RL technology in some way to address weaknesses of MPC. Here we summarize three such proposals.

Lee and Wong (2010) point out that MPC has two inherent limitations. First is the high cost of online computation, which scales with the state dimension as well as the horizon length. The second inherent limitation is that the use of an open-loop dynamic optimization means that MPC cannot make use of information about future uncertainty as it is revealed. These limitations are particularly relevant in the case of nonlinear stochastic control problems for which MPC can be highly suboptimal. Lee and Wong propose to mitigate or remove these limitations through the use of Approximate Dynamic Programming (ADP), another name for the class of technology that we have labelled as RL. They propose several possibilities for integration of ADP with MPC. One is to use MPC in the initial stages of simulation sampling in order to determine likely state sequences and state space regions to focus on. A second method is to use the learned cost-to-go (negative of the value function) as the terminal penalty in a MPC formulation in order to reflect the effect of future uncertainties in closed loop and reduce the depth of prediction and optimization needed. A third way is to alternate between the MPC and ADP algorithms, switching to MPC when a new region of the state space is encountered in which the ADP algorithm cannot be trusted.

Morinelly and Ydistie (2016) present an interesting Dual MPC algorithm in which RL is used to introduce the effect of anticipated information. The algorithm is developed for the simple case of a discrete linear system with uncertain dynamics. They demonstrate that the algorithm converges to the optimal linear state feedback policy (Linear Quadratic Regulator) in this case. A simulation example shows good behaviour for the proposed algorithm, which they call RL dual MPC (RLdMPC). This proposal seems quite promising, provided that it can be generalized to full multivariable systems.

Kamthe and Deisenroth (2017) present an algorithm that combines data-efficient RL with probabilistic MPC. Their algorithm improves the data efficiency of RL while simultaneously ensuring the model uncertainty is properly accounted for in the MPC dynamic optimization. They accomplish this by learning a probabilistic transition model using Gaussian Processes (GPs) to incorporate model uncertainties into long-term predictions. This reduces the impact of model errors and results in a RL framework that makes maximum use of available data. Long-term predictions are obtained from the GP model by iterating forward using a deterministic moment-matching Gaussian approximation. Pontryagin's Maximum Principle is then used to solve the MPC dynamic optimization subject to constraints. They show remarkably efficient learning for two standard tasks – the under-actuated cart-pole swing-up and the fully-actuated double-pendulum swing-up - both of which are solved in less than 15 encounters.

We view these suggestions for integrating RL with MPC as very encouraging and worthy of further investigation.

4.3 Use RL to help manage process control systems – Proportional-Integral-Derivative (PID) controller tuning, MPC model gain adjustments, etc.

Process control systems require significant management by operators and control engineers in the form of adjusting limits and tuning parameters as process conditions change. When the feed to a unit is cut by 20%, for example, an experienced control engineer will know which PID and MPC controllers will need to be adjusted and will have a good idea for the types of adjustments that will be required. This type of application seems ideally suited for RL technology, if good process simulators or sufficient amounts of historical data are available.

4.4 Using RL to advise operators during unusual situations (process upsets/start-up/shutdown)

Operating a chemical process is similar in many ways to flying an airplane in that there are long periods of normal, quiet operation punctuated by brief periods of extreme tension when things go wrong. During a process upset, an operator will immediately attempt to bring in additional experienced operators to help diagnose and mitigate the problem. In cases requiring an immediate shutdown, the operator will typically consult a large manual of written instructions that carries with it an implicit assumption of the shutdown scenarios most likely to be encountered. In these situations, RL technology might be particularly helpful as a tool to advise the operator. The RL agent can be trained on the same process simulators that are employed to train the operators, but it can base its recommendations on many thousands of randomly generated scenarios, some of which may not have been anticipated before.

4.5 Use a hierarchical network of RL agents to simplify operation of a chemical plant.

In the not too distant future one can imagine a hierarchical network of RL agents that learn how to perform most of the tasks that human operators currently perform while operating a chemical plant. The hierarchies would reflect the operational priorities of the company operating the plant. These could be, for example:

1. Process Safety
2. Environmental Compliance
3. Reliability
4. Economics

Agents at the same level would cooperate in a distributed manner to optimize the overall goals at that level. Agents at different levels would act according to set priorities. For example, the actions of an economics agent on a particular piece of equipment could be interrupted at any time by a safety agent that has detected a problem and needs to shut down the equipment right away.

There has been significant work in the area of RL agent networks, by Foerster, et al. (2016), for example, but nothing that seems appropriate for off-the-shelf use on this problem.

One should be skeptical, however, of a proposal to replace *all* of the operators in a control room. The development of automation technology such as RL is more likely to lead to a

significant reduction in the need for human intervention, rather than the elimination of all operators in the control room. The march of automation for commercial aircraft has, for example, reduced the number of required cockpit crewmembers from four in the early days to two today. But it is unlikely that passengers will step onto an airliner with no cockpit anytime soon.

5. Future research directions

From our analysis there are several opportunities for process control researchers to have an impact on RL theory. These ideas are aimed augmenting RL technology to make it more appropriate for process control applications:

- Prove algorithmic convergence (value function and policy function approximations converge to optimal value and policy function) for a state-of-the-art RL algorithm such as A3C
- Prove closed-loop stability for the case of a state-of-the-art RL algorithm such as A3C acting on a nonlinear dynamic system
- Augment a state-of-art RL algorithm such as A3C so that it enforces state constraints
- Investigate additional ways to integrate RL and MPC, building on work already published
- Develop robust control technology based on an A3C algorithm in which each parallel environment represents a realization of the system uncertainty.
- Develop technology that allows a hierarchy of prioritized RL agents to accomplish a complex task similar to operation of a chemical plant.

6. Conclusions

In general, a RL agent has the potential to perform any task that requires knowledge and experience gained by interacting directly with the process. Recent technical developments, including deep learning and parallelization, greatly increase the potential scope and capability of RL. Five broad classes of potential process control applications for RL technology have been assessed, and several research directions aimed at improving the relevance of RL for process control applications have been suggested. In summary, we believe that RL technology has the potential to significantly impact both theory and applications in the field of process control.

Abstract

Supply chain management is concerned with the efficient integration of interconnected entities so that products are sourced, manufactured and distributed in the right quantities, to the right locations and at the right time, thus satisfying customer requirements at minimal total system cost. Such systems face complexity due to the multiple material and information flows. In this context, the Process System Engineering (PSE) community has an important role to play in addressing such complexity. Departing from a real-world process supply chain, the industrial gas supply chain, while considering existing PSE contributions, this paper discusses challenges in terms or modeling and implementation. This work also presents perspectives in supply chain management from the industrial and academic standpoints that ought to be explored by the PSE community.

Keywords: Supply Chains, Industrial Gases, Uncertainty, Multiscale, Challenges, Perspectives.

1. Introduction

Supply chains (SC) are systems that comprise several entities placed in different geographical locations. These interconnected systems play a crucial role in organizations as they dictate product availability to the final consumer and consequently the financial success of the involved companies. The management of SC is complex due to the involvement of a large multiplicity of material and information flows, diversified characteristics of the associated entities and often-present conflicting objectives.

Within the process industry, this is not an exception and process supply chains must be flexible, resilient and efficient while guaranteeing customers' demands at minimum costs. Moreover, as the process industry is often associated with a high level of resource consumption and often deal with non-friendly environment processes and products, special attention to supply chain sustainability is required when managing such systems (Barbosa-Póvoa, 2014; Mota et al., 2018).

To deal with such complexity and underlying challenges, both industrial and academic communities identify the application of Process Systems Engineering (PSE) tools as a path to follow (Grossmann, 2012). Such tools support the integration of supply chain decisions under uncertainty while minimizing risk, maximizing service levels, sustainability levels and simultaneously guaranteeing the main SC goals – profitable and reliable operation.

The PSE community can contribute highly in the answer to such challenges (Barbosa-Póvoa, 2014) by studying real-world supply chain problems. These span from strategic (e.g. Network Design in Cardoso et al., 2013 and Mitra et al., 2014a) to tactical (e.g. Planning in You and Grossmann, 2013 and Malinowski et al., 2018) and operational decisions (e.g. scheduling, routing and inventory management in Amaro and Barbosa-Póvoa, 2008; Dong et al., 2014; and Zhang et al., 2015).

Several reviews provide a detailed analysis of such challenges. Shah (2005) identified the main requirements of process supply chains, focusing on the pharmaceutical case. Papageorgiou (2009) provided a comprehensive review of the design and planning of process supply chains and Stephanopoulos and Reklaitis (2012) highlighted the past and future contributions of the PSE community in several areas, from which the supply chain study was identified as essential. Grossmann (2012) presented the enterprise–wide optimization concept and highlighted the need of developing optimization tools that explore the integration of decisions across the different operations along the supply chain, considering different levels of detail. Lainez et al. (2012) reviewed the pharmaceutical supply chain and Barbosa-Póvoa (2014) analyzed the published papers on process supply chain considering the multiple decision levels. Recently, Barbosa-Póvoa et al. (2018) reviewed sustainable supply chains and conclude that particularly (bio) process supply chains have been actively addressing sustainability issues, which nevertheless present a large set of research opportunities.

All the above reviews tend to converge to a common set of critical problems, some already under study by the academic community, whereas many others call for further research. In the next section, we illustrate some of the problems in the context of an industrial gas supply chain. Additionally, while some challenges have been addressed, the implementation of PSE in industry is still far from effective. Significant progress must be achieved in critical issues that are discussed in this paper, both from an industrial and an academic perspective. We conclude that supply chain research has a major financial impact to the process industry and brings scientific challenges where the PSE community has an unquestionable role to play.

2. Process Supply Chain

Process Supply Chains deal with chemical and/or bio-based networks that involve a set of entities, materials and information that transform raw materials into final products using different types of transforming processes. Among these supply chains, several examples exist as is the case of the oil, pharmaceutical, biomass, and gas supply chains. Several challenges exist with respect to the management of such systems and consequently both industrial and the academic communities should be committed to address such problems in close collaboration.

We use an industrial gas supply chain as an example of process supply chains where its different characteristics are described and corresponding challenges identified. This is represented in Figure 1. The manufacturing of Oxygen, Nitrogen and Argon is considered, as well as the retail business (hardgoods) and the supply chain comprises upstream, production, distribution and consumer entities.

Electricity can be purchased from utility companies through various power contracts that may differ in price, availability, and penalty for under- or overconsumption (Zhang et al., 2015). Discount prices and penalties can also be defined with respect to the amount of electricity purchased over a certain period of time, which could be hours, days, or even

weeks. In practice, this means that the cumulative electricity purchase must be recorded, and there are pre-defined meter reading times at which the amount of electricity purchased since the last meter reading is computed. Based on this cumulative electricity purchase between consecutive readings, discounts and penalties are issued (Zhang et al., 2016a).

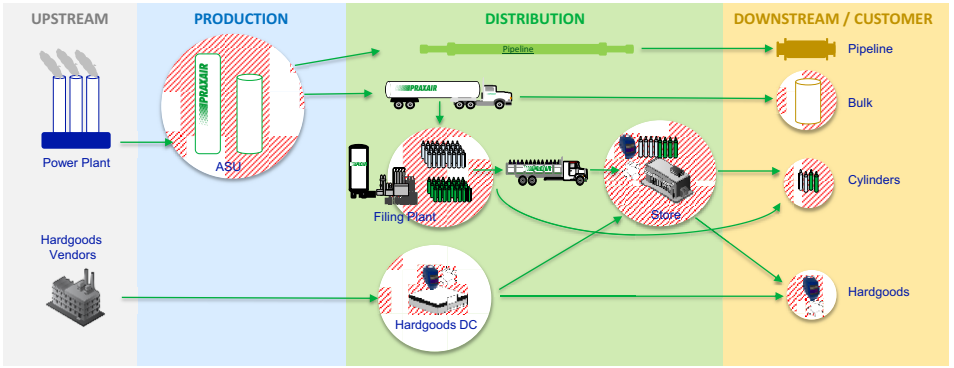

Figure 1- Industrial Gas Supply Chain (Praxair, Inc.)

Cryogenic air separation plants produce liquid oxygen (LO2), nitrogen (LN2) and argon (LAr) as well as gaseous oxygen (GO2) and nitrogen (GN2), all at high purities. Cryogenic process achieve separation through liquefaction followed by low-temperature distillation. All liquid products can be stored on-site in storage tanks. In contrast, gaseous products cannot be stored.

Regarding distribution, industrial gas companies serve customers through three primary distribution modes: large process plants, cryogenic liquid and packaged gases (Megan and Bruton, 2017).

For the largest customers, such as refineries and steel mills, industrial gas plants operate adjacent to their facilities and distribute products via pipeline. These plants act as a vital utility to those customers, similar to electricity and water, and provide an uninterrupted supply of industrial gases to support their operation.

Medium-volume customers, such as hospitals and universities, typically have liquid storage located at their facility, which is then used to provide product throughout their operations. Their inventory is monitored in real time with telemetry and the delivery of product is performed, using a tanker truck fleet, without the customer needing to place an order. This proactive, vendor-managed inventory model provides high reliability for customers while enabling the supplier to manage effectively their costs.

The third mode involves packaged gases. Here a wide variety of smaller packaged gases to laboratories, hospitals and other customers is at stake. These products can range from a cylinder of nitrogen to specialty gas mixtures needed for emissions testing, advanced manufacturing and semiconductor fabrication. As seen in Figure 1, cylinders are either distributed directly to customers or shipped to stores, from which additional deliveries are made or customers pickup their products. A variety of services is also offered, such as embedded regulators and telemetry. The cylinder assets, which helps ensure continuous supply to our customers are owned by the gas company.

In addition to cylinders, stores also retail hard goods that are purchased from vendors and shipped through multiple distribution centers. These in turn either ship products directly to customers or to the stores for pickup or further delivery.

3. Challenges

This section describes the main research and implementation challenges from an industrial perspective as well as these are addressed from the PSE community, including joint collaborations academia-industry.

3.1. Industry perspective

3.1.1. Supply Chain Modeling Challenges

Supply Chain Planning – Planning the merchant liquid supply chain is a very challenging problem. Liquid plants, while all making the same basic set of products, often vary in capacity and efficiency. As merchant liquid customers may receive shipped product from multiple locations, continuously optimizing this supply chain can be challenging. Uncertainties, such as varying customer demand and time-of-day electricity prices, make the system quite dynamic. There is a need for sophisticated forecasting tools and large mixed integer linear programming models in order to determine optimum production and distribution plans on a continuous basis. These planning tools, which should plan over a multi-week time horizon, then must guide the operational tools designed for minute-to-minute optimization of the plants and logistics.

Demand Side Management (DSM) – DSM refers to electric energy management on the consumers' side and encompasses energy efficiency and Demand Response (DR). DR presents challenges and opportunities, primarily the optimization of operational flexibility through the integration of production and energy management. On the strategic level, large industrial electricity consumers often enter into long-term contracts with favorable rates. However, such power contracts require the consumers to commit themselves to the amount that they are going to purchase years in advance when future demand is not yet known with certainty. Hence, there is the need to simultaneously optimize long-term electricity procurement and production planning while considering uncertainty in product demand (Zhang et al., 2018). Regarding mid-term (tactical) decisions, the main challenge is to integrate energy management, production, sourcing and customer-plant allocation (Zhang et al., 2017). This coordination problem gives rise to a multi-scale optimization problem because while a detailed production scheduling model must capture all critical operational constraints on a fine time grid, vehicle routing has to be considered in each time period of a coarser time grid.

Process Modeling - The traditional way of modeling a process involves heat and mass balances, which requires the detailed description of the system's performance (e.g. thermodynamics, kinetics). The disadvantage of this approach is that the model can become prohibitively hard to solve in the context of supply chain optimization due to its nonlinearities and its size. An alternative approach is to build surrogate models in reduced space, e.g. the product space. To determine the feasible region of the plant in the product space, production data can be obtained from extreme operating points or from a sequence of steady-state simulations. Moreover, production modes may represent state of equipment, e.g. "off", "production mode" or "ramp-up transition". Only one mode can be active, in other words the modes are disjoint. The data for each mode is represented as a collection of operating points (slates) that are the extreme points in terms of the products (Mitra et al., 2014a; Zhang et al., 2015).

Inventory Route Planning – Executing a VMI policy in an effective way is nontrivial, because it requires the integration of two components of SC management, inventory control and distribution routing (Dong et al., 2014). In inventory control, the goal is the

determination of orders (time and amount) of customers, while in distribution routing the goal is the generation of schedules to meet these deliveries. The integration of the two problems, which can have a dramatic impact on overall system performance, leads to the inventory routing problem (IRP) which is at the heart of all VMI policies. One of the main objectives in solving the IRP is to reduce the overall distance driven per volume delivered to customers, which has a sustainability impact by reducing fuel emissions.

3.1.2. Challenges in Modeling Approaches

Uncertainty – Uncertainty plays a crucial role in the management of the supply chain. Electricity prices may fluctuate on an hourly basis in certain markets; moreover, to ensure the stability of the power grid, backup capacities are called upon when electricity supply does not meet demand due to unexpected changes in the grid. As part of the demand response efforts in recent years, industrial gas companies are encouraged by financial incentives to provide such operating reserve in the form of load reduction capacities (interruptible load). However, a major challenge lies in the uncertainty that one does not know in advance when load reduction will be requested (Zhang et al., 2016b).

Although industrial gas sites operate at a very high level of availability, there are circumstances in which there are unplanned shutdowns that are caused by electricity supply and/or equipment failure. As mentioned in the previous section, typically plants are directly connected to customer by pipelines to supply gaseous products. Liquid storage tanks are usually installed onsite to be used as a backup when the plant is in outage. Assuming there are data for historical reliability data of individual assets, the main question is how to make design and operations decisions to maximize plant availability. Supply chain management plays an important role in supplying liquid products during plant downtime to guarantee uninterrupted supply to pipeline customers. Hence, the study of supply chain resiliency could bring benefits to the industry.

Besides electricity and plant availability, demand uncertainty plays a pivotal role in production planning & scheduling, inventory routing as well as in long-term capital investments (Mitra et al., 2014b). Figure 2 illustrates product demand uncertainty in short term and long-term decisions, which ultimately affect all operational (production, routing), tactical (safety stock) and strategic (tank sizing, plant capacity) decisions.

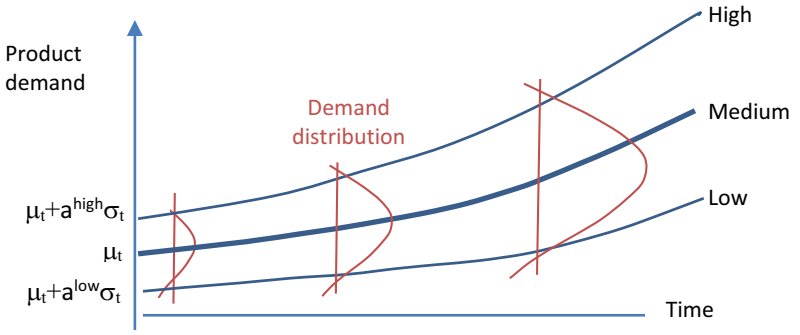

Figure 2. Product demand trajectories in short term and long term (Mitra et al., 2014a). Parameters μ_t and σ_t denote the expected demand and the standard deviation in time t.

Customer demand for packaged gases can also be received dynamically over the planning horizon. Routing plans should flexibly accommodate potential customers who have not

yet called in to request service. Subramanyan et al. (2017) model future potential customers as binary random variables, and seek to determine a visit schedule that remains feasible for all anticipated realizations of service requests.

Finally, in the context of inventory routing for the bulk business in addition to customer demand there are uncertainties with respect to travel times, service times at customers and delivery time windows, i.e., when customers allows access to bulk tanks. These may affect delivery times or even prevent deliveries at end of routes.

Multiscale Modeling – One of the biggest challenges on the design and long-term capacity planning of industrial gas plants is the incorporation of short-term operational decisions. Typically, capacity planning is performed over a 10-15 year horizon. Investigating the trade-off between capital or retrofits, and the operating costs, related to electricity prices, which can vary on an hourly basis, leads to a complex multiscale optimization problem (Mitra et al., 2014a; 2014b). On the mid-term level, there is also the need to coordinate multiple time scales for production (fine) and distribution (coarse), as in Zhang et al. (2017).

3.1.3. Data Challenges

Data Analytics – Industrial gas plants require a high degree of automation and data analytics to ensure that they continuously operate safely, reliably and efficiently (Megan and Bruton, 2017). Examples include condition and predictive monitoring of equipment such as motors and compressors to reduce unplanned downtime. As with large process plants, the vendor managed inventory model for bulk customers requires a variety of analytics, from optimizing assets to scheduling daily deliveries. Packaged gases are a very transaction-intensive business with many distinct products, which leads to many opportunities to use analytics to manage the supply chain, understand margins and better target the sales force.

Big Data Analytics – There has been a paradigm shift in leveraging data for supply chain, particularly external data, which has been experiencing tremendous growth in the past few years. The traditional approach has been to utilize internal data, from few core applications that track the activity of the company and automate various processes. The data is mostly structured and stored in data warehouse(s). Moreover, data is relatively clean and models activity related to customers and processes. With the arrival of external big data, the number of systems and applications may increase by one order of magnitude. Data provided may not be clean or structured; neither will be stored in data warehouses. Models will be a lot more complex as they will relate to both internal and external processes. In addition, a big data strategy must be defined and implemented.

3.1.4. Implementation Challenges

Computational Performance – The complexity of real-world industrial problems translates into large scale models, in terms of constraints and variables. Most SC problems result in mixed-integer linear programming models, which require the investigation of customized solution techniques to obtain good (not necessarily optimal) feasible solutions in reasonable time. Examples in strategic and tactical planning are: a hybrid bi-level decomposition scheme for a two-stage stochastic programming problem with mixed-integer recourse that results from a multiscale capacity planning problem with investment and operational decisions (Mitra et al., 2014b), and Helium SC planning in which a rolling horizon strategy is developed (Malinowski et al., 2018). Short term examples are as follows: IRP for which a dynamic preprocessing algorithm followed by a two-level

decomposition solution method is proposed (Dong et al., 2017), and for the production scheduling of air separation units under uncertainty, an integrated stochastic mixed-integer linear programming model is developed; Conditional value-at-risk is incorporated into the model as a measure of risk, and scenario reduction with multi-cut Benders decomposition are implemented to solve large-scale real-world instances (Zhang et al., 2016b).

Change management – One of the main challenges in the implementation of decision support tools is the management of change with decision makers as well as with the business organization. Unfortunately, the PSE community does not have the training and often oversees the impact of change management in the successful implementation of optimization tools. The change management area has been primarily addressed by the business management community (Cameron and Green, 2015) and ranges from mergers & acquisitions to projects. Although not core to the PSE community, change management should be part of any implementation project. Indeed, there are opportunities to bring design thinking into the area.

3.2 Academic perspective

Process supply chains have been studied by the PSE community with increased focus in recent years. Different challenges have been addressed in line with some of the industrial needs mentioned in the previous section. These span from operational to strategic decision levels and have been covering different types of problems (Barbosa-Póvoa, 2014), but further research is still required.

Multiscale Modeling - at the strategic level, optimal design and planning of supply chains is a well-known problem that, however, continuously faces new challenges. The integration of strategic and tactical decisions is still an area to explore where comprehensive models that account for different supply chain characteristics are required. Uncertainty; sustainability concerns; risk and resilience management should be targeted. Additionally, the availability of large amounts of data is nowadays a reality, which should be explored to lead to more accurate industrial representations and allow further decision-sharing (Ning and You, 2017). The integration of tactical-operational decisions is also an open issue and it has been seldom studied. Supply chain planning and operations appear as a research opportunity, where production planning, inventory management and logistics decisions should be considered simultaneously. Multi-scale supply chain models will help to answer to these challenges where an Enterprise Wide Optimization approach (Grossmann, 2012) should be explored. In this context, not only centralized supply chain decisions, as commonly treated by the academic community, should be considered but rather trade-offs between different supply chain entities need to be accounted for, where decentralized decisions may be at stake (Sahay and Ierapetritou, 2014).

Uncertainty, Risk, Resilience Modeling – uncertainty has been explored mainly using stochastic and robust approaches. The first one focuses on the establishment of representative scenarios to model uncertainty, as the use of a large number of scenarios leads to intractable models. One possible way to tackle this problem is by exploring the use analytics on uncertain parameters data, e.g. in demand and supply (see Figure 2). Statistical, data mining or machine learning techniques, amongst others should be explored to help the definition of more realistic possible scenarios. This has been studied by some authors (Yue and You, 2016; Lima et al., 2018) and constitutes an emerging research area. On the robust approach, research has been focused on how to minimize the conservativeness of the models, but a clear understanding of the problem is still needed.

The modeling of different exogenous and endogenous uncertainties is also a problem to be tackled. Linked to uncertainty arises risk modeling. Different measures have been explored and the authors identify the CVar as the most adequate one (Zhang et al., 2016a). But few works have explored risk when modeling supply chain decisions. With risk comes the need of guaranteeing supply chain resilience (Cardoso et al., 2015), a characteristics critical to supply chains due to the uncertain environment under which they operate. Nevertheless, resilience modeling is not yet well understood and there still exist a long way to trail on this topic.

Sustainability Modeling – increased concern for the management of sustainability in supply chain decisions has been observed in the last decade, often pressed by governmental regulations and societal pressures (Barbosa-Póvoa et al., 2018). This calls for decisions that consider trade-offs between the three sustainability pillars: economic; environmental and social. However, the academic community, when addressing supply chain problems, has been mainly focused on the economic pillar where typically the minimization of costs or the maximization of profit have been considered. But often important aspects have been left out as few models addressed international supply chain characteristics such as international taxes; transfer prices, duties as well as multi-modes and outsourcing options. Regarding the environmental and social pillars, a limited number of works have addressed such concerns (Mota et al, 2018), which are very important when addressing process supply chains. Often process supply chains deal with pollutant and/or hazardous products and/or processes, and a well-defined treatment of such concerns within the supply chain is required. For example, and as mentioned above, the optimization of energy consumption is a constant industrial need, which should be explored not only with an economic objective but also with an environmental concern. Moreover, researchers have been trying to understand the best method to quantify environmental impacts and how this could be used to establish a trade-off with economic concerns leading to a solution of compromise. The LCA method has been one of the main methods studied and along with it different approaches have been explored namely, the Eco-indicator 99, Recipe, and PEF. But comprehensive models that address in a sound form the environmental aspects when designing, planning and operating supply chains are still required. More recently, the social concern has been also studied, but in this case very few works studied this issue. This area is then a great challenge to the PSE community (Barbosa-Póvoa et al., 2018).

Efficient Solution Methods – the treatment of the above identified concerns evidently requires the development of models with increasing complexity. This need calls for new solution methods, where efficient decomposition methods, meta-heuristics, amongst others methods should be explored by the PSE community. Also the solution of non-linear models still needs further treatment (Su et al., 2018).

Finally, the so-called **"Supply Chain 4.0"**is nowadays a reality and the wide availability of data from supply chain process, customer demand, consumption of resources, as well as other associated internal and external activities opens a new challenging research area.

4. Conclusions and Perspectives

Supply Chain optimization presents multiple opportunities for implementation in the process industry and has been the focus of increasing research by the PSE community. However, there are many challenges that still prevent the successful implementation of SC solutions.

In this paper, we describe a real-world, process supply chain through an industrial gas SC whose goal is to illustrate the complexity of the decisions and information involved. Several challenges are discussed that relate to the modeling of entities (energy, production, distribution), the different approaches that result from integrated decision support systems, such as multiscale and mainly uncertainty and its treatment. Finally, we also discuss implementation challenges that result from large scale models that require custom solution methods, as well as the impact of decision support tools that requires the need for the management of change.

The supply chain work available in the literature indicates the need of comprehensive decision support tools required to coordinate cross-functional models. Such tools should allow the treatment of real supply chain characteristics in which different aspects must be considered: the presence of uncertainty - modeling resilience and risk; sustainability goals - accounting simultaneously for economic; environmental and social concerns; international taxes; transfer prices, duties as well as multi-modes and outsourcing options, amongst others. Such challenges lead to further complex, often multiscale models that demand the investment in efficient solution methods.

To conclude we want to raise the need to combine the traditionally PSE models and methods with big data analytics, machine learning, and advanced statistical methods, amongst others, so as to be able to inform the supply chain decision process supporting better decisions. This calls for a close integration between academia and industry aiming to reduce the gap between research and implementation.

Extended Abstract

Safety is one of the critical operability issues and a prerequisite foundation for the prosperity of any process. It needs to be thoroughly respected, planned and maintained during all phases of product and process development, operation and even during the dismantling and salvaging of processes at the end of their life. Considering safety issues during the synthesis and design of processes is especially important, since their implementation at this early step is the most efficient and the least costly. With respect to different strategies, sequential and simultaneous ones can be applied, the former being prevalent in engineering practice. However, considering safety issues simultaneously during the synthesizing and designing processes could lead to significantly safer designs. Safety can be improved during the design phase by applying various direct and indirect measures. An example of direct measures would be performing synthesis of a process scheme simultaneously with a risk analysis in order to foster the *inherent safety* of the design. Simultaneous consideration of other operability issues like availability, reliability and controllability would also be appreciated, since this would indirectly increase the safety of the plant. The following mixed-integer program (S-MINLP) is therefore suggested for performing synthesis of safer and more operable process flowsheets:

$$\begin{aligned} \max \quad & z = c^{T}y + f(x) \\ \text{s.t} \quad & h(x) = 0 \\ & g(x) \le 0 \\ & By + Cx \le b \qquad \text{(S-MINLP)} \\ & Risk(x,y) \le 0 \\ & Oper(x,y)_i \le 0 \\ x \in X = & \{x \in R^n : x^{LO} \le x^{UP}\} \\ y \in Y = & \{0,1\}^m \end{aligned}$$

Any inherent safety increase directly contributes to an increase in process safety. Relying solely on a control system is quite problematic, since every control system has its gaps during any deviation event. Moreover, the significant rate (by some estimates, over 80%) of accidents is a consequence of human error, regardless of any cutting-edge control system. Therefore, minimizing inherent risk is one of the substantial aspects of the process planning. The main factors related to inherent safety are the amount and type of the various substances present in the equipment, and the quality (reliability) of the equipment used. Decisions about these factors are usually made at an early stage of planning;

therefore, inherent safety should be assessed simultaneously with the taking of those decisions, since later changes might be difficult or impossible to implement. In the case of a small-scale Heat Exchanger Network (Nemet et al., 2017), a significantly safer design was obtained while keeping economic performance at a similar level (the risk was halved, while the Net Present Value expense was negligible). This was made possible by the selection of compact heat exchangers that contain lower amounts of substances and, hence, less risk for the same amount of heat exchange. When the approach was applied to a larger scale integration of different plants via a central utility system (Total Site), improved safety was obtained only by making a significant compromise in the economic performance (obtaining a design that was twice as safe led to a 23% increase in TAC). A similar conclusion was reached after synthesis of a methanol production process (30% better risk performance was achieved at the cost of a 27% profit decrease). It is interesting to note that the safer design was obtained at the cost of lower overall process conversion, because the lower recycle rate leads to smaller process units containing lower quantities of the risky substances. There are certainly varied challenges to be considered in the future, e.g. those related to other trade-offs, besides that of economics vs. safety. Moreover, the challenge of selecting numerous pieces of equipment might be too high, since risk assessment of all of them may not be possible. Note also that inherent safety can be limited to each individual unit separately or to the process as a whole. Limiting it to individual units would lead to processes with a higher number of smaller sized units, while limiting it to processes would favor flowsheets with fewer numbers of units, each carrying higher risk. Furthermore, the economy of scale directs the economics-safety trade-off towards larger, hence more risky, processes, while on the other hand, the risk can be decreased for smaller processes with compact, high fidelity equipment. The inherent risk assessment could also serve for the selection of safer raw materials, technologies and products in order to upgrade production sustainability.

Chemical process industries routinely handle hazardous materials that are associated with inherent risk. Abnormalities may lead to incidents with varying consequences – from near-misses, to catastrophic accidents. Various layers of protection are usually deployed to reduce the likelihood of abnormal conditions, or to reduce the severity of their consequences. Even among the various layers of protection deployed in the plant, the role of humans through timely and correct action is critical to ensure proper functioning. Conversely, *human error* can lead to system failures. Moreover, such dependence on humans to 'actively' ensure safety is pervasive. Perhaps because of the belief that human error is inevitable and unpredictable, or that advances in automation will diminish the need for human intervention, the domain of human error has received limited attention. However, various studies across numerous domains, including the chemical industry, have established that human error accounts for over 70% of all accidents today.

Human errors can be grouped into various categories, one important category being cognitive errors, i.e., failures in problem solving. Cognitive errors, especially those made during abnormal situations, can be classified into errors in interpretation (incorrect problem identification), decision making (incorrect selection of task to compensate for the problem), or task planning (incorrect formulation of the sequence of actions based on problem constraints). All of these modes require the operator to utilize a mental model of the plant behavior (which is time-varying) and its state (also dynamic). Any mismatch between the plant's condition and the operator's conception is the precursor to cognitive

error. Hence, inference of such cognitive mismatches would engender a strategy to prevent human error.

Our research has sought to utilize cognitive sensors such as eye trackers to reveal the current focus of attention and the cognitive strategies among control room operators as they operate a (simulated) plant. Modern day, commercial, off-the-shelf eye trackers provide a non-invasive, moment-by-moment assessment of thought processes with millisecond scale temporal resolution, while the operator is seated comfortably in front of a DCS monitor. Our experimental studies with large cohorts of human subjects clearly demonstrate that both the operator's eye gaze and the extent of pupil dilation can offer rich insights into an operator's cognition while dealing with abnormal situations. Specifically, one study found that the gaze distribution of participants on different variables during simulated abnormal situations is related to their performance in handling the situation: participants whose gaze remained longer on uncorrelated variables predominantly failed in handling the situation. Pupillometry has been used to analyze the workload of participants during abnormal scenarios and has established that pupil diameter is a good indicator of cognitive workload during the execution of tasks. The workload of participants who failed in handling an abnormal scenario remained high towards the end, and so did the corresponding pupillary dilation. On the other hand, participants who successfully completed the tasks exhibited consistently decreasing pupil diameter after the first set of corrective actions. In another study, gaze entropy was used to quantify the level of situation awareness of a participant while handling abnormal situations and found that participants with adequate situation awareness looked at only the few variables responsible for the abnormal scenario, which resulted in lower gaze entropy. Lack of situational awareness resulted in the gaze lighting on a relatively large number of variables and thus in a larger value of gaze entropy.

Cognitive sensors such as eye trackers have the potential to be used for real-time performance assessment of plant operators; for assessing operator knowledge during training and for developing more user-friendly Human-Machine Interfaces (HMI), as well as for yielding direct insight into how information from various decision support systems, such as advanced control, alarm management, process monitoring and root-cause analysis, are utilized by the operator.

Abstract

Optimization problems under uncertainty involve making decisions without the full knowledge of the impact the decisions will have and before all the facts relevant to those decisions are known. These problems are common, for example, in process synthesis and design, planning and scheduling, supply chain management, and generation and distribution of electric power.

The sources of uncertainty in optimization problems fall into two broad categories: endogenous and exogenous. Exogenous uncertain parameters are realized at a known stage (e.g., time period or decision point) in the problem irrespective of the values of the decision variables. For example, demand is generally considered to be independent of any capacity expansion decisions in process industries, and hence, is regarded as an exogenous uncertain parameter. In contrast, decisions impact endogenous uncertain parameters. The impact can either be in the resolution or in the distribution of the uncertain parameter. The realized values of a Type-I endogenous uncertain parameter are affected by the decisions. An example of this type of uncertainty would be facility protection problem where the likelihood of a facility failing to deliver goods or services after a disruptive event depends on the level of resources allocated as protection to that facility. On the other hand, only the realization times of Type-II endogenous uncertain parameters are affected by decisions. For example, in a clinical trial planning problem, whether a clinical trial is successful or not is only realized after the clinical trial has been completed, and whether the clinical trial is successful or not is not impacted by when the clinical trial is started.

There are numerous approaches to modelling and solving optimization problems with exogenous and/or endogenous uncertainty, including (adjustable) robust optimization, (approximate) dynamic programming, model predictive control, and stochastic programming. Stochastic programming is a particularly attractive approach, as there is a straightforward translation from the deterministic model to the stochastic equivalent. The challenge with stochastic programming arises through the rapid, sometimes exponential, growth in the program size as we sample the uncertainty space or increase the number of recourse stages. In this talk, we will give an overview of our research activities developing practical stochastic programming approaches to problems with exogeneous and/or endogenous uncertainty. We will highlight several examples from power systems planning and operations, process modelling, synthesis and design

optimization, artificial lift infrastructure planning for shale gas production, and clinical trial planning.

We will begin by discussing the straightforward case of exogenous uncertainty. In this situation, the stochastic program can be expressed completely by a deterministic model, a scenario tree, and the scenario-specific parameterizations of the deterministic model. Beginning with the deterministic model, modelers create instances of the deterministic model for each scenario using the scenario-specific data. Coupling the scenario models occurs through the addition of nonanticipativity constraints, equating the stage decision variables across all scenarios that pass through the same stage node in the scenario tree. Modelling tools like PySP (Watson, 2012) greatly simplify the process of composing large stochastic programs by beginning either with an *abstract* representation of the deterministic model written in Pyomo (Hart, et al., 2017) and scenario data, or a function that will return the deterministic Pyomo model for a specific scenario. PySP automatically can create the extensive form (deterministic equivalent) model from a general representation of the scenario tree. The challenge with large scale stochastic programs with exogenous uncertainty arises through managing the growth of the problem size. Fortunately, there are several well-known approaches to decomposing the problem, both stage-wise (e.g., Benders' decomposition) and scenario-based (e.g., Lagrangian relaxation or Progressive Hedging), enabling the direct solution of stochastic programs with hundreds or thousands of scenarios.

We will then discuss developments in modelling and solving stochastic programs with endogenous uncertainty. These problems are significantly more challenging to both pose and to solve, due to the exponential growth in scenarios required to cover the decision-dependent uncertainties relative to the number of stages in the problem. In this situation, standardized frameworks for expressing stochastic programs do not exist, requiring a modeler to explicitly generate the representations and nonanticipativity constraints. Further, the size of the resulting scenario space (frequently exceeding millions of scenarios) precludes the direct solution of the resulting program. In this case, numerous decomposition algorithms and heuristics have been developed (e.g., Lagrangean decomposition-based algorithms (Tarhan, et al. 2013) or Knapsack-based decomposition Algorithms (Christian and Cremaschi, 2015)).

Computer-Aided Design for Energy Saving in an Ammonia-based Post-combustion CO_2 Capture Process

Jialin Liu[a*], Ding-Sou Chen[b]

[a]*Tunghai University, Taichung, Taiwan, jialin@thu.edu.tw*

Abstract

This work investigated the aqueous ammonia-based post-combustion CO_2 capture (PCC) process using the rate-based model in Aspen Plus, by which the overall energy consumption was minimized under varying the important parameters, such as: the NH_3 concentration (2–5 M), the lean CO_2 loading (0.14–0.28 mol-CO_2/mol-NH_3), and the CO_2 stripper pressure (1–20 atm) on the target of 90 % CO_2 removal and 10 ppm of the slipped NH_3 from the emission. In general, the energy consumption of the CO_2 stripper is directly proportional to the lean solvent requirement, whereas the less lean solvent is required as the higher NH_3 concentration was applied. However, this study reveals that the high NH_3 concentration may result in the intensive energy consumption due to the solid precipitation being formed on the top of the stripper. On the other hand, the regeneration energy can be reduced by applying the pressurized CO_2 stripper; however, the electricity of pumping the rich-out solvent may offset the reduction of the energy consumption. In addition, the configuration of multiple inter-heaters along the CO_2 stripper is investigated. The result shows that the separation efficiency can be improved by adding inter-heaters on the stripper that leads to the energy consumption can be reduced around 18 % comparing with the case without implementing the inter-heaters.

Keywords: Post-combustion carbon capture; regeneration process; energy saving.

1. Introduction

Post-combustion CO_2 capture (PCC) using aqueous ammonia has received great attention as a promising technology because it provides many technical and economic advantages over conventional amine solvents; such as: low cost, low regeneration energy, no sorbent degradation, and an eco-friendly emission. However, the major drawbacks (e.g., slow absorption rate with CO_2 and high volatility of ammonia) necessitate a larger CO_2 absorber where an additional washing column (NH_3 absorber) was added on the top for controlling the NH_3 slipping. This study builds upon the previous work (Liu, 2017) to evaluate the energy consumption of a large-scale PCC process for a 500 MW coal-fired power plant under varying the NH_3 concentration, the lean CO_2 loading, and the CO_2 stripper pressure.

Karimi et al. (2012) investigated the effect of inter-heaters on the CO_2 stripper for the amine-based PCC process. They reported that the inter-heaters would not affect the amount of recovering sensible heat from the high-temperature lean solvent. In addition, the location of the inter-heaters attached onto the stripper might affect the amount of the energy reduction. In this study, the energy saving by implementing the inter-heaters on the CO_2 stripper is investigated for the ammonia-based PCC process. The remainder of

this paper is organized as follows. Section 2 gives a brief description of the simulation settings using the rate-based model in Aspen Plus. Additional details can be found in the previous work (Liu, 2017). In Section 3, the integrated PCC process using aqueous ammonia is described. Section 4 presents the results and discussions of the integrated process with inter-heaters. Finally, conclusions are presented in Section 5.

2. Simulation Model

The flus gas, after the SO_x scrubber, was cooled down to 50 °C prior to entering the PCC process. The flow rate was set to 2125 t/h for simulating the tailed gas from a 500 MW coal-fired power plant and the composition was approximated by 12.4 % CO_2, 11.8 % H_2O and 75.8 % N_2. A rate-based approach using an RADFRAC model was used to simulate the CO_2 and NH_3 absorbers. The design target of the PCC process was to capture three million tons of CO_2 per year, which is the 90 % CO_2 removal from the inlet. Due to the high volatility of NH_3, an ammonia scrubber (NH_3 absorber) was implemented onto the top of the CO_2 absorber in order to suppress the slipped NH_3 concentration at 10 ppm. The Redlich-Kwong equation of state and the electrolyte-NRTL method were used to compute the properties of the vapor and liquid phases, respectively. The parameters of the rate-based model were adopted according to the work of Zhang and Guo (2013), such as: (1) Billet and Schultes correlation for mass transfer, (2) Chilton-Colburn correlation for heat transfer, (3) reactor and mass transfer conditions set to default 0.5, and (4) the liquid holdup at 4% of the free volume. The model was validated again the pilot results of Yu et al. (2011) at Munmorah power station, and the details of the model settings can be found in the previous work (Liu et al., 2017).

3. Integrated PCC Process Design

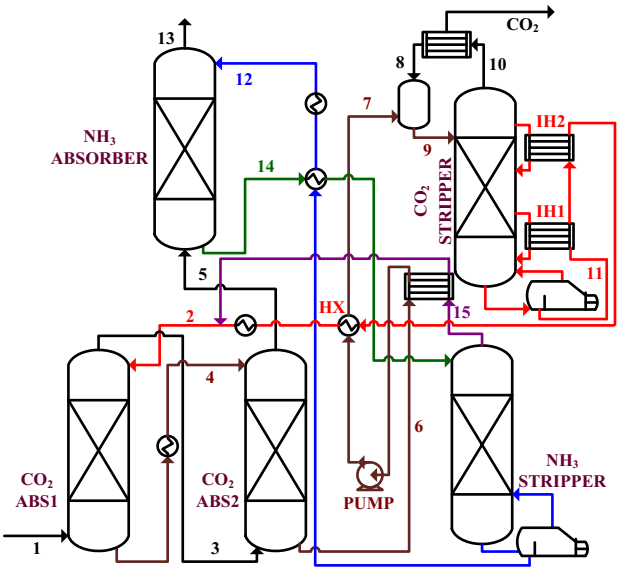

Figure 1. The integrated PCC process with the additional inter-heaters.

In this study, the PCC process flow diagram was modified from the previous work (Liu, 2017), as shown in Figure 1. In order to reduce the slipped NH_3 from the emission, a

two-stage absorber design was implemented (Jilvero et al., 2014). The flue gas (1) was fed into the bottom of the first absorber (CO_2 ABS1) where the lean solvent (2) was fed into the column from the top. Due to the exothermic reaction of CO_2 absorption, the semi-lean solvent (4) was cooled down to 15 °C before entering the top of the second absorber (CO_2 ABS2) where the gas flow from the top of the first absorber (3) was fed from the bottom for further removing CO_2. The CO_2-ridded flow (5) was cleaned by the washing tower (NH_3 ABSORBER) before the gas flow (13) was discharged into atmosphere.

Considering the formation of ammonium bicarbonate from the reflux of the CO_2 stripper, the reflux (8) was heated by the CO_2 rich solvent (7) in order to liquify the solid precipitation before entering into the CO_2 stripper. In this study, the inter-heater configuration was also investigated. As shown in Figure 1, two inter-heaters (IH1 and IH2) were evenly implemented along the CO_2 stripper where the lean solvent (11) was used as the heat source. After the inter-heaters, the remained sensible heat of the lean solvent was recovered by the cross-flow heat exchanger (HX). The separation efficiency of the CO_2 stripper could be enhanced because the top part of the column had a lower temperature, whereas the bottom part kept at the high temperature. In the following section, the result shows that the energy saving was dominated by the number of inter-heaters and the locations of the inter-heaters had a minor effect.

4. Results and Discussions

On the target of 90 % CO_2 removal, the lean solvent requirement was inversely proportional to the NH_3 concentration and directly proportional to the CO_2 loading, as shown in Figure 2. Figure 3 illustrates the regeneration energy of the lean solvent at atmospheric CO_2 stripper. Due to the limitation of the regenerable lean solvent (Liu et al., 2017), the lean solvent using 5 M NH_3 concentration only could be regenerated at 0.28 CO_2 loading where the regeneration energy was up to 7.65 GJ/t-CO_2. The high NH_3 concentration in the overhead vapor encouraged the formation of ammonium bicarbonate, which means the more amount of CO_2 was brought back into the stripper. In order to maintain the target of 90 % CO_2 removal, the more amount of the lean solvent needed to be vaporized as the higher solid fraction in the reflux.

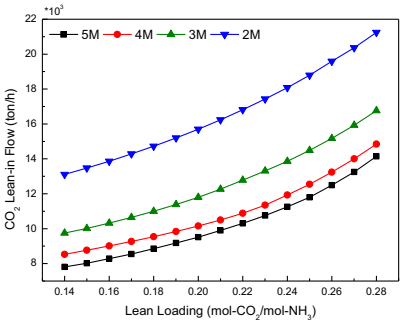

Figure 2. The required lean solvent for achieving 90 % CO_2 removal.

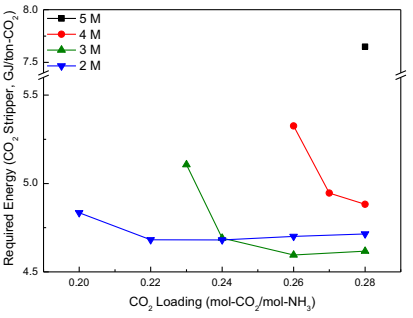

Figure 3. The required energy for the atmospheric CO_2 stripper.

Figure 4 shows almost 70 % solid fraction in the reflux when the lean solvent with 5 M NH_3 concentration was used where the vaporized ratio was 3.4 ton/t-CO_2. Comparing with the lean solvent using 3 M NH_3 concentration, the vaporized ratio was 1.9 ton/t-CO_2 that was 56 % of the lean solvent using 5 M NH_3 concentration. Therefore, the

regeneration energy may not be proportional to the required amount of the lean solvent. As shown in Figure 3, the minimum of the required energy for the CO_2 stripper was 4.59 GJ/t-CO_2 when the lean solvent using 3 M NH_3 concentration and 0.26 CO_2 loading. Meanwhile, the NH_3 stripper took 0.32 GJ/t-CO_2 for regenerating the washing water. The overall energy was 4.91 GJ/t-CO_2 for the atmospheric CO_2 stripper.

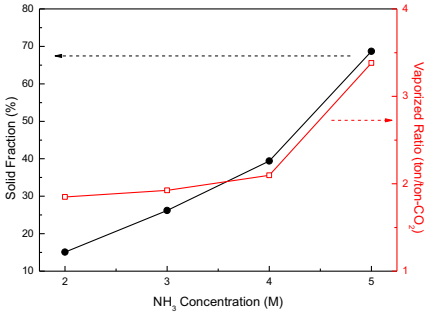

Figure 4. Solid fraction in the reflux and the vaporized lean solvent ratio.

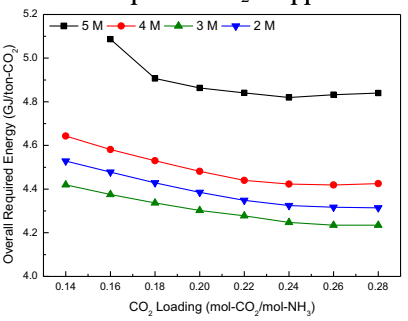
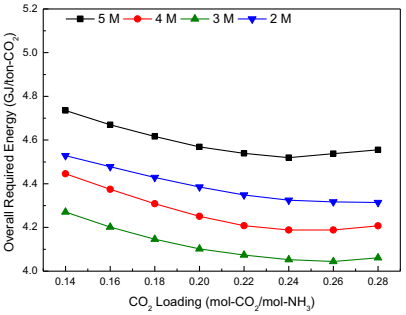
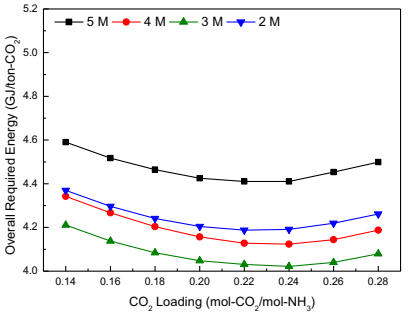


(a)



(b)



(c)

Figure 5. Overall required energy for the pressurized CO_2 stripper, the operating pressure at (a) 5 atm, (b) 10 atm, and (c) 20 atm.

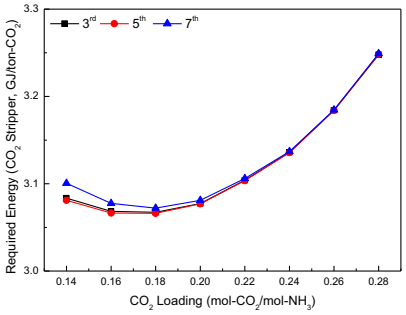


Figure 6. Energy requirement under varying the location of the single inter-heater.

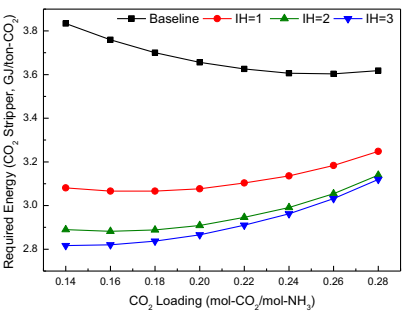

Figure 7. Comparing the reduction of required energy on varying the number of inter-heaters.

In this study, the overall required energy included the regeneration of CO_2 lean solvent and NH_3 washing water; in addition, the electricity of the pump was converted into thermal energy by 35.6 % conversion efficiency. Figure 5 compares the overall required energy under increasing the operating pressure of the CO_2 stripper. The figures show that the overall energy was decreasing as the stripper pressure was increasing; however,

due to the required electricity of the pump, the energy reduction was offset when the operating pressure was increased from 10 to 20 atm in Figures 5(b) and 5(c). Comparing Figures 5(b) and 5(c), the minimum of overall energy at 10 and 20 atm was comparable, which was 4.04 and 4.02 GJ/t-CO_2, respectively. However, considering the reboiler temperature of the stripper at the two operating pressure, which was 145 and 169 °C, respectively, the operating pressure at 10 atm was preferable.

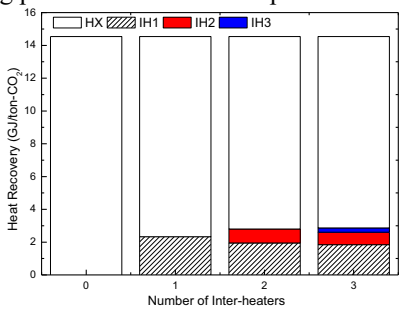

Figure 8. Overall heat recovery by the cross-flow heat exchanger and the inter-heaters.

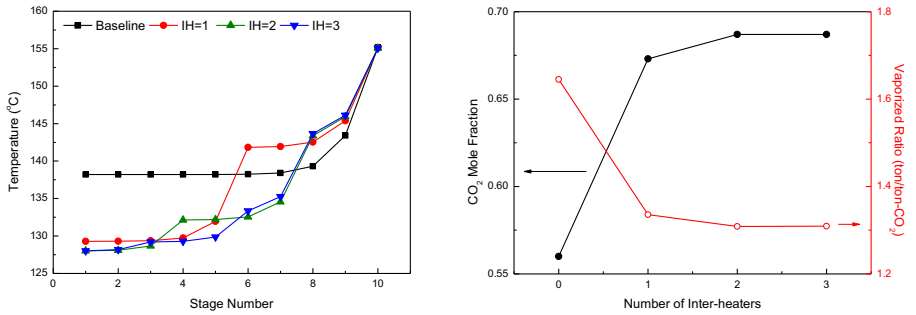
According to the above discussions, the CO_2 stripper at 10 atm and the lean solvent with 3 M NH_3 concentration that was adopted to investigate the effect of inter-heaters for the energy saving. Figure 6 compares the required energy of the CO_2 stripper in which a single inter-heater was implemented on the different locations. The cold liquid flow was drawn from the third, fifth and seventh tray, respectively, and returned back to the next tray after heating by the inter-heater. The result shows that the required energy was not sensitive to the location of the single inter-heater. On the other hand, Figure 7 shows the effect of energy saving by varying the number of inter-heaters where the baseline indicates the results without inter-heaters by applying the same operating parameters. Figure 7 shows that the required energy can be reduced from 3.8 to 3.1 GJ/t-CO_2 at 0.14 CO_2 loading when a single inter-heater was applied, in which the cold liquid was drawn from the middle position of the column. However, the energy reduction was not significant when the number of inter-heaters was increasing from 2 to 3 where the inter-heaters were evenly attached along the column height.



(a) (b)

Figure 9. Investigation of the required energy reduction by the inter-heaters, (a) the temperature profile along the CO_2 stripper, (b) the CO_2 mole fraction at the top of the stripper and the vaporized lean solvent ratio.

Figure 8 investigates the heat recovery by the cross-flow heat exchanger (HX) and the inter-heaters (IHs) at the lean solvent with 0.14 CO_2 loading. The result shows that the

amount of overall recovery was not enhanced by the inter-heaters, which is consistent with Karimi et al. (2012) reported. The temperature profile along the column height was adjusted by implementing the inter-heaters, as shown in Figure 9(a), in which the top temperature of adding the 2nd and 3rd inter-heaters was close that means the CO_2 mole fraction in the vapor phase at the top of the stripper was also close, as shown in Figure 9(b). On the target of 90 % CO_2 removal, the vapor phase with the higher CO_2 mole fraction at the top can reduce the vaporized amount of the lean solvent, as also shown in Figure 9(b). The minimum of overall energy was found at 3.30 GJ/t-CO_2 where two inter-heaters were implemented and the lean solvent with 0.16 CO_2 loading was applied.

5. Conclusions

At a constant CO_2 absorption rate, the required amount of CO_2 lean solvent can be reduced by increasing the NH_3 concentration; however, the regeneration energy for the lean solvent may not be reduced when the less lean solvent was used. The precipitation of ammonium bicarbonate was easily formed at the low temperature of CO_2 condenser when the lean solvent had a high NH_3 concentration. Therefore, CO_2 was brought back into the stripper by the solid precipitation. In order to maintain the constant CO_2 removal rate, the more lean solvent needed to be vaporized, i.e., the more regeneration energy was needed. At atmospheric CO_2 stripper, the minimum of the overall energy was found at 4.91 GJ/t-CO_2. Since the high temperature at the bottom part of the CO_2 stripper favors the desorption reaction of CO_2 from the solvent, the pressurized stripper may relieve the energy burden, effectively. However, considering the electricity of the pump and the temperature of the low-pressure steam, the minimum of overall energy was found at 4.04 GJ/t-CO_2 where the lean solvent with 3 M NH_3 concentration and 0.24 CO_2 loading was applied and the operating pressure of the stripper was maintained at 10 atm. On the other hand, the low temperature at the top part of the CO_2 stripper may promote the CO_2 concentration in the vapor phase; therefore, the amount of vaporized solvent can be reduced on the target of 90 % CO_2 removal. At the conditions of 10 atm CO_2 stripper and the lean solvent with 3 M NH_3 concentration, two additional inter-heaters can further drive the overall requirement to 3.30 GJ/t-CO_2, at which the lean solvent with 0.16 CO_2 loading was applied. Comparing with the minimum of the atmospheric CO_2 stripper, the overall regeneration energy can be reduced 33% by implementing two inter-heaters along the pressurized CO_2 stripper at 10 atm.

Forest residues gasification integrated with electrolysis for production of SNG – modelling and assessment

Johan M. Ahlström[a*], Simon Harvey[a], Stavros Papadokonstantakis[a]

[a]*Chalmers University of Technology, Division of Energy Technology, Maskingränd 7b, 412 58, Gothenburg, Sweden*
johanah@chalmers.se

Abstract

This study investigates opportunities for integrating an electrolysis unit with a biomass gasifier for production of synthetic natural gas (SNG). Gasification is a key technology for production of biofuels and chemicals from lignocellulosic biomass, for which an increased demand is expected in the future. H_2 produced through an electrolyser can be used to increase the output of a gasifier by reaction with CO_2 to form CH_4. Four integrated flowsheet configurations are evaluated with respect to system energy efficiency and process operating revenue. The system energy efficiencies are in the range of 0.55 – 0.8, and the maximum value of operating revenues is 0.245 $/kWh$_{dry\ biomass}$. The results show that feeding the Sabatier reactor with the full product gas flow coming from the methanation unit, and separating the unreacted CO_2 afterwards, is the most attractive configuration with respect to operating revenue.

Keywords: Power-to-gas, Gasification, Biomass, SNG

1. Introduction

Large scale indirect gasification of biomass has been demonstrated at the GoBiGas plant in Gothenburg (Alamia, 2016) and in Güssing (Bolhàr-Nordenkampf et al., 2002). Direct fluidized bed gasification, which is the subject of this work, has been investigated by Hannula and Kurkela (2012) and Gassner and Maréchal (2012). However, no direct blown gasifier with a full scale downstream gas up-grading section have been constructed. When the raw gas from the gasifier is used for methane production, it needs to be upgraded to increase the methane content. The CO_2 remaining after the upgrading step has to be removed, which is done in expensive and energy-intensive sequences of separation steps. Hence, converting the remaining CO_2 into valuable products could significantly improve the economic performance of the process. For this purpose, a hydrogen source is required.

The share of intermittent electricity generation in the power mix is expected to continue to increase significantly. This will induce more volatility in power generation and thereby also in the electricity price (Woo et al., 2011), thereby creating opportunities for variable load applications with a short response time that can help balance the grid. Power-to-gas concepts which produce H_2 and O_2 when electricity prices are low, can contribute to this balancing. H_2 produced by electrolysis can react with CO_2 to produce methane through the Sabatier reaction, whereas O_2 can be used as a gasifying agent in the direct gasifier unit. In this way, the product output of the process is enhanced while the energy loads of

the air separation unit and the CO_2 separation sequence are decreased. To evaluate this concept, it is essential to estimate how the process performance is affected by the amount of H_2 fed to the process.

This paper investigates four different power-to-gas configurations integrated with a direct, oxygen blown, biomass gasifier. The gasifier is assumed to be fed with forestry logging residues. The configurations are compared with respect to system energy efficiency and operating revenues.

2. Process configuration

Forest biomass generally has a moisture content of 40-60%wt, and the fuel must therefore be dried before it is fed to the gasifier to increase efficiency. This study considers the belt dryer concept proposed by Alamia et al. (2015). The moisture remaining in the fuel is vaporized in the gasifier before the fuel volatile components are released. Thereafter, the char gasification starts. At the bottom of the gasifier, combustion of char occurs, which releases the energy that sustains the endothermic reactions in the gasifier.

The raw gas leaving the gasifier contains H_2, CO_2, CO, CH_4, H_2O, inorganic impurities (e.g. H_2S) and organic compounds such as tars. The ash and traces of char in the raw gas are removed in a cyclone, thereafter H_2S is removed. In a pre-methanation step the ratio of H_2/CO is adjusted through the water-gas-shift reaction. The methanation reaction occurs in a series of three adiabatic, fixed bed, reactors. Figure 2 provides an overview of the basic process flowsheet.

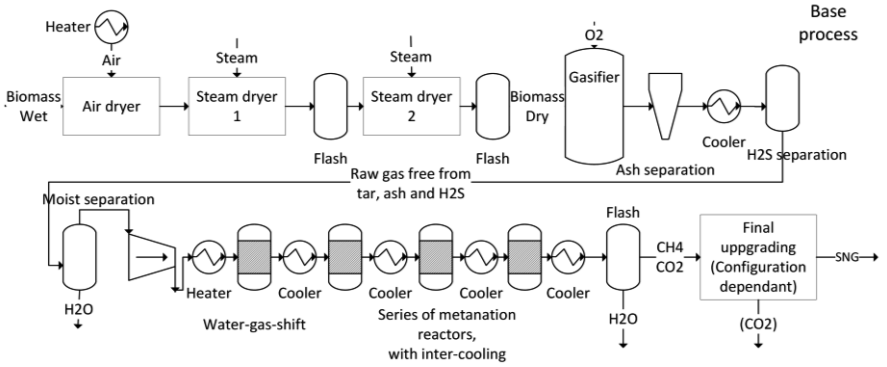

Figure 1. Process flowsheet

After the methanation section, the gas (containing only CH_4 and CO_2) is fed into the final CO_2 removing sequence. Two specification values are considered for the Wobbe index of the SNG product: 44.7-46.7 MJ/Nm^3 and 43.9-47.3 MJ/Nm^3, corresponding to the A, respectively B standards of the Swedish national gas grid. The Wobbe index essentially limits the concentrations of both CO_2 and H_2 in the gas product. A-type SNG is produced if possible, since it can be sold at a higher price, otherwise type B SNG is produced instead. Four possible configurations for the final CO_2 removal sequence are investigated (see Figure 2):

i. The gas from the methanation section is mixed with H_2 from the electrolyser and then compressed before being fed to the Sabatier reactor where H_2 reacts with CO_2 to increase the share of CH_4 in the gas. The gas stream is then dried before

removing the remaining CO_2, in a sequence of two amine-based CO_2 separators, each with a removal efficiency of 90%. The yield of the Sabatier reactor entails that there will be H_2 left in the gas after the reactor if all CO_2 is to be converted. Since configuration (i) does not include a H_2 separation sequence and the gas standards limits the concentration of H_2 in the gas product, there will always be CO_2 in the gas after the Sabatier reactor.

ii. H_2 is added to the gas mix in sufficient quantity to convert all remaining CO_2, thus removing the need for a CO_2 removal step. This configuration requires that the fraction of H_2 in the gas has to be decreased, which is achieved with a H_2 separation unit. As in configuration (i), the gas is dried before the final separation sequence. The separated H_2 is recirculated back to the mixing step before the Sabatier reactor.

iii. CO_2 is separated from the product gas and mixed with H_2 in the Sabatier reactor. The produced gas, containing mainly CH_4 but also some remaining CO_2, is dried and recirculated to the inlet gas stream before the CO_2 removal step.

iv. Similar to Configuration (iii), with the difference that a H_2 separation step is added to the process after the drying step. This provides a process in which all the CO_2 in the raw gas can potentially be reacted to methane, since the excess H_2 can be removed. This results in a more flexible process configuration.

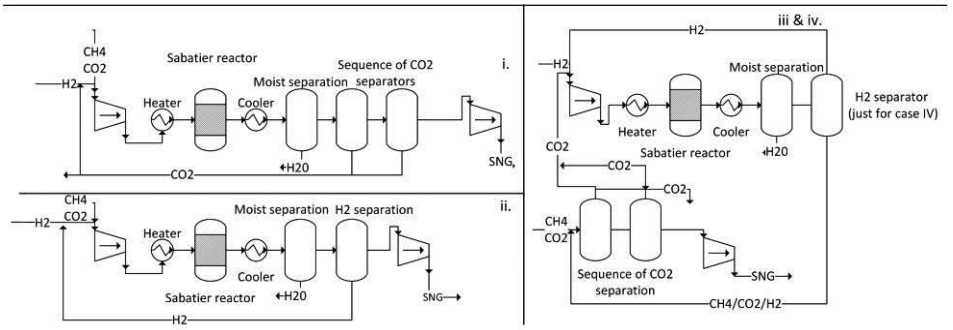

Figure 2. The four process configurations.

Candidate electrolyser technologies include alkaline and Polymer Electrolyte Membrane (PEM) electrolysers. PEM technology is characterized by a shorter start up time, but a lower efficiency. Alkaline electrolyser technology has reached a higher development level, and was therefore selected for this work.

The main difference between the process configurations investigated is the degree of operational flexibility. Configuration (i) is limited by the fraction of CO_2 that can be reacted, since there will be H_2 in the produced gas if all CO_2 is reacted to methane. Configuration (ii) is limited by the absence of CO_2 separation units, meaning that the Sabatier reactor must always be fed with enough H_2 to fully react the CO_2. Thus configuration (i) is more flexible than configuration (ii). In configurations (iii) and (iv), the CO_2 is separated before it is reacted with the H_2. Here configuration (iv) provides the more flexible option; enough H_2 to react all CO_2 can be fed to the process, since a H_2 separation sequence is included.

3. Methodology

All process modelling is performed in Aspen Plus Version 8.8. The biomass feedstock drying model assumes steady-state isothermal operation and negligible pressure drop. The assumed energy required for biomass drying is 0.51 MJ/kg (Alamia et al. (2015)). All simulation results are based on a feed of a 100 $kg_{dry\ biomass}$/h, which gives a flowrate of 2.55 kmol CO_2/h and 1.52 kmol CH_4/h from the methanation unit.

The gasifier is modelled to mimic the results published by Hannula and Kurkela (2012), within an error margin of 10% in terms of gas composition. It is assumed that the tar components are decomposed to CO and H_2. Pressure drop in the gasifier is assumed to be negligible. The methanation section is modelled assuming that the reaction reaches chemical equilibrium. The model accounts for the significant pressure drop in the methanation section (see Alamia (2016)). The Sabatier reactor is modelled as a plug flow reactor with Langmuir-Hinshelwood-Hougen-Watsonis kinetics, as described by Schlereth (2015). The CO_2 and H_2 separation sequences are not rigorously modelled; instead the major component recoveries are inferred by literature data (Heyne and Harvey (2014) and Mivechian and Pakizeh (2013)). Similarly, based on Brynolf et al. (2018), a H_2 yield of 23.7 kgH_2/MWh electricity is assumed for the Alkaline electrolyser.

The system energy efficiency suggested by Heyne and Harvey (2013) is used, including the process by-products and commodities, such as electricity and excess heat

$$\eta_{system} = \frac{\sum \dot{m}_p LHV_p + Q_- + E_-}{\sum \dot{m}_f LHV_f + Q_+ + E_+} \quad (1)$$

ṁ indicates the mass flow of either product, p, or of fuel, f. Q is heat and E electricity, - and +, refer to energy flows leaving or entering the process. Process stream heating and cooling requirements are used to perform heat targeting using pinch analysis and evaluate the possible heat recovery for the process.

The economic performance metric is the operating revenue, obtained by subtracting the cost of biomass feedstock and all utilities from the revenues of selling SNG, process excess heat and the oxygen produced in the electrolyser. Indicative prices for Swedish conditions are assumed; all input data and results are presented in US$. The reference electricity price is set to 0.024 $/kWh and since it is assumed that the electrolyser is run at periods when the electricity price is low, the electricity used for H_2 production is assumed to have a 50% lower cost. Revenue from sales of the SNG product is valued at 1.98 $/kg for A-grade quality and 1.5 $/kg for B-grade quality, the biomass price is 23 $/MWh. All other price data, e.g. catalysts, can be found in the report by Gambardella and Yahya (2017). Sensitivity analysis varying the feed of H_2, together with the recirculation of CO_2 is performed for all configurations except (ii), in which the H_2 flow is constant since the process is designed to react all CO_2 available in the gas.

4. Results

For configuration (ii) the H_2 flow is constant at 10 kmol/h, which is the flowrate required to convert all CO_2 in the gas mix. The system energy efficiency of configuration (ii) is 0.801 and the operating revenues are 0.245 $/$kWh_{dry\ biomass}$. Configuration (ii) results in

the highest revenues and a high system energy efficiency, which is due to the fact that all CO_2 in the raw gas is converted to CH_4. Sensitivity analysis, varying the feed of H_2, is performed for configurations (i), (iii) and (iv). The impact on the operating revenues and system energy efficiency is shown in Figure 3.

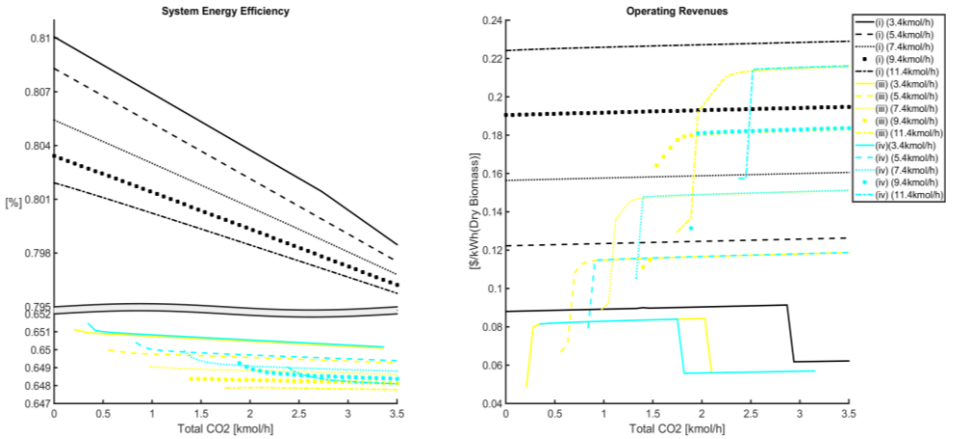

Figure 3. Total system energy efficiency and operating revenues as a function of CO_2 feed. The nuances correspondent to different configurations and the line types correspond to the amounts of H_2 feed.

η_{system}, decreases with increased H_2 feed and CO_2 recirculation rate. This is due to the conversion losses in the electrolyser. The ranges of each curve indicate the cases where the produced gas fulfills the standards of the Wobbe index. The process operating revenues increase for all configurations with H_2 feed and CO_2 recirculation. This indicates that the additional SNG produced by the increased addition of H_2 outweighs the cost of generating the H_2. The increase in revenues is essentially linear, except for some rapid increases and decreases in revenues. These rapid changes indicate the thresholds for the types of SNG produced, namely when the model has to change from type A to type B. Only configuration (i) has an increase in revenue that can be achieved without CO_2 recirculation, which is due to the fact that there is already CO_2 present in the incoming gas flow. For configurations (iii) and (iv), a certain amount of CO_2 has to be recirculated to provide the second reactant to the Sabatier reactor.

5. Conclusions

The results show that the operating revenue increases with increased addition of hydrogen. This indicates that there is an incentive for integration of an electrolyser unit with the process, provided that the investment costs of the processes does not outweigh the increase of operating revenue. This also suggests that the input feed of H_2 should be maximized if this type of power-to-gas concept is implemented. From an economic perspective, the best performing configuration is (ii), which reaches a maximum operating revenue of 0.245 $\$/kWh_{dry\ biomass}$ followed by (i). Even if configuration (ii) outperforms configuration (i) in terms of revenues, it is not necessarily the better alternative; configuration (i) is more flexible, since it allows for different flows of H_2, which could be a major advantage if electricity prices fluctuate a lot. Both configurations (iii) and (iv), in which CO_2 is separated before it is mixed with the H_2, generates lower revenues than the first two configurations. This is a result that highlights that it is more

beneficial to mix the H_2 with the raw gas, rather than to separate the CO_2 before the reactor.

6. Outlook and further work

An essential parameter for future evaluation is the impact of electricity price on the choice of process configuration and design. The model presented in this work constitutes a starting point for such evaluation. To investigate the impact of the electricity price on the process design, a rolling horizon, planning and scheduling optimization algorithm will be developed. By considering the possibility to store hydrogen, and co-running the optimization model with a model of the European electricity system, it becomes possible to determine the optimal process configuration design, accounting for the fluctuations in electricity price. To enable this sort of analysis, it is a necessity to first estimate the investment costs of the different process configurations

Abstract

Dimethyl carbonate (DMC) is a green compound with a broad variety of application. Recently, CO_2-based routes to produce DMC have attracted much attention due to the environment benefits from CO_2 utilization. In the study, we investigate the plant-wide process design of DMC production using CO_2 as a raw material by indirect alcoholysis of urea. The indirect alcoholysis route of urea shows many advantages because of cheap raw materials, mild and safe operation condition, and environmentally friendly chemicals. The DMC production contains the processes of urea synthesis, propylene carbonate (PC) synthesis, DMC synthesis, and DMC/methanol azeotrope separation. The methods of urea synthesis, DMC synthesis, and DMC/methanol azeotrope separation were well developed. In the study, the emphasis is put on the PC synthesis process. Some different methods of PC synthesis are proposed, designed, and optimized. Simulation results reveal that the intensified process containing a reactive distillation column and a conventional distillation column with internal vapor compression provides the most economical design by fully utilizing the special azeotrope characteristic of propylene carbonate and propylene glycol pair. A 21.8% reduction of total annual cost can be achieved by the intensified process in comparison with the traditional process. In addition, the complete plant-wide process for DMC production is designed. The net profit for this production process is also given.

Keywords: dimethyl carbonate, process design, urea.

1. Introduction

Dimethyl carbonate (DMC) is an important organic compound and chemical intermediate with the label of ‘‘green chemical’’. There are several reaction routes to manufacture DMC. Recently, DMC production utilizing CO_2 attracts much attention because it provides direct environment benefits when valuable products are manufactured from emitted and undesired CO_2. The CO_2-based methods to produce DMC include direct synthesis with methanol (MeOH), transesterification of propylene carbonate (PC) or ethylene carbonate with MeOH, direct and indirect alcoholysis of urea. In this work, DMC is produced by indirect alcoholysis of urea. This reaction route provides many benefits, such as cheap and easily available raw materials, mild reaction

conditions, safe operations, environmentally friendly chemicals, etc. Figure 1 shows the concept of the plant-wide process for the DMC production by this route. Urea, PC, and DMC are sequentially synthesized from the plant-wide process. The most important characteristic in this complete plant-wide process is that PG, a byproduct in the transesterification reaction for DMC synthesis, can be used as the reactant for PC synthesis and the released ammonia from PC synthesis can be recycled back to produce urea by reacting with CO_2. The overall process forms a green chemical cycle, which increases the utilization of raw materials for the DMC production. In this work, the emphasis is put on the PC synthesis because urea and DMC synthesis were studied by some literatures (Holtbruegge et al., 2013; Voskov and Voronin, 2016). Five different processes for PC synthesis by indirect alcoholysis of urea are proposed, designed, and optimized by minimizing total annual cost (TAC). These processes can be classified in terms of two operation types, near neat operation and excess reactant operation. Comparison of these processes by TAC is made and the complete plant-wide process for DMC production is also given.

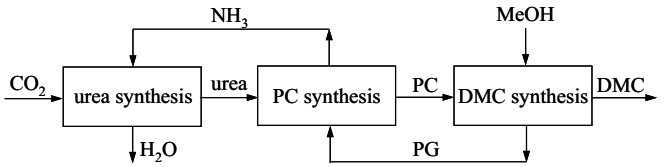

Figure 1. Concept of DMC production by indirect alcoholysis of urea.

2. Kinetics and thermodynamic models

In the reaction route for indirect alcoholysis of urea, three reaction steps are proceeded as follows.

$$CO_2 + 2\ NH_3 \rightleftharpoons Urea + H_2O \quad (1)$$

$$Urea + PG \rightarrow PC + 2\ NH_3 \quad (2)$$

$$PC + 2\ MeOH \rightleftharpoons DMC + PG \quad (3)$$

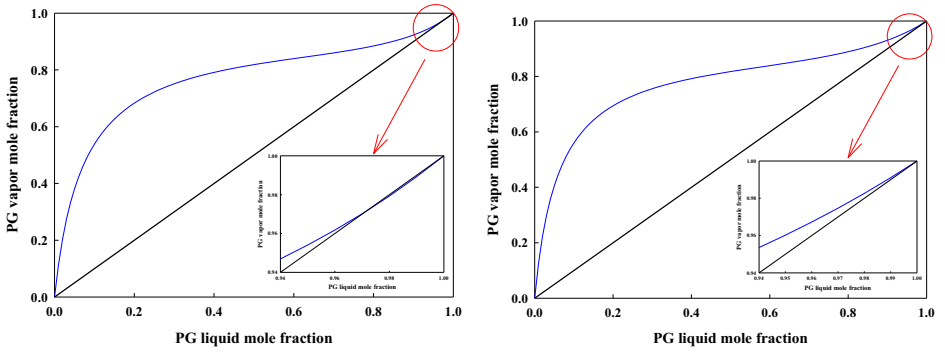
In the first step, urea is produced by reacting CO_2 and ammonia. Next, urea is reacted with PG to coproduce PC and ammonia. The final step is used to synthesize DMC by the transformation reaction of PC and MeOH. The byproducts, ammonia and PG produced from steps 2 and 3, respectively, are recycled back to steps 1 and 2, respectively, as reactants. There are very few studies about the process design for step 2 to synthesize PC. Therefore, in the present study, we primarily explore the design of different PC synthesis processes. Some possible configurations are proposed to synthesize PC.

Wang (2012) presented a kinetic model given below for PC synthesis by using MgO as the heterogeneous catalyst.

$$r_{PC} = 1.5888 \cdot \exp\left(-\frac{562.602}{T}\right) \cdot C_{urea} \cdot C_{PG} \quad (4)$$

where r_{PC} is the reaction rate of PC synthesis (mol liter^{-1} min^{-1}). T and C_i represent temperature (K) and concentration (mol liter^{-1}) of component i, respectively. The catalyst concentration is assumed to be 2 wt%.

In the study, the vapor-liquid equilibrium (VLE) relationship is described by UNIQUAC activity coefficient model in ChemCad software. In the PC synthesis reaction system, only the thermodynamic data of urea-ammonia and PG-PC pairs are found in the literatures (Mathuni et al., 2011; Voskov and Voronin, 2016). The phase-equilibrium relationships for the other pairs are determined in the study by the ideal model. Figure 2 shows the VLE relationship for PG-PC pair. It indicates that homogeneous minimum-boiling azeotrope can be found for this pair under low pressure (0.12 atm) (Mathuni et al., 2011). However, there is no azeotrope under high pressure (1 atm). This important characteristic is fully utilized to reduce energy consumption in the following process design for PC synthesis.



(a) (b)

Figure 2. VLE relationship for PG-PC pair under pressures (a) 0.12 atm and (b) 1 atm.

3. Optimal design of PC+DMC Synthesis

In the study, five configurations are proposed and classified in terms of two operation types, near neat and excess reactant operations. In the process design to synthesize PC, the objective is to minimize the TAC by adjusting design variables. TAC is defined as:

TAC = operating cost + capital cost/payback year (5)

The operating cost (OC) includes the costs of steam, cooling water, catalyst, and electricity. The capital cost (CC) comprises the costs of reactor, flash tank, column shell, stage, heat exchanger, and compressor. The formulas of these cost estimations are taken from Turton et al. (2012). Here, a payback of eight years is used. Figure 3 shows the optimal design performed by sensitivity analysis for two configurations with near neat operation. Figure 3a is a flowsheet for PC synthesis by using some CSTRs, flash tanks, and one conventional distillation (CD) column (named as CSTR+CD configuration). Two reactants are fed into the first CSTR and then the exit mixture from the CSTR is introduced into the first flash tank. Vapor product (mainly containing ammonia) is removed from the flash tank, and liquid product is fed into the second CSTR followed by the second flash tank. CSTRs are used for PC synthesis until the requirement of urea reaction conversion (99.98 mol%) is satisfied. Then the product of the last CSTR is introduced into the CD column for separation. The remaining ammonia, not removed

from the flash tanks, is withdrawn from the partial condenser at column top and high-purity PC is achieved from the column bottom. In the study, urea is fed with the flow rate of 40 kmol/h. The purity of ammonia removed from the flash tanks and the partial condenser is designed at 99 mol% while the PC purity of column bottom is set at 99.5 mol%. The CSTR and flash tank are operated at the same temperature (160 ºC as suggested by Wang (2012)) and pressure. Because PG, a byproduct in the transesterification reaction for DMC synthesis, is converted into the reactant for the PC synthesis by indirect alcoholysis of urea, the optimal reactive distillation (RD) column to synthesize DMC by reacting PC and MeOH is also designed. The kinetic model and the thermodynamic model from Holtbruegge et al. (2013) are adopted in the RD column design for DMC synthesis. DMC and MeOH form a minimum-boiling homogeneous azeotrope. The overhead product of the RD is a mixture of DMC and MeOH. The bottom PG product with 99.9 mol% is recycled back to the CSTR for further reaction. The optimal TAC for PC synthesis by this configuration is 1102.2×10^3 US$/year.

Figure 3b is a flowsheet for PC synthesis by using a RD. Two reactants are fed into the first RD column for PC synthesis. Ammonia is withdrawn from the partial condenser. PC is achieved from the column bottom and then fed into the second RD column for DMC synthesis. The optimal feed ratio of PG and urea is designed at 1.02, very close to the neat operation. Column pressure is 0.12 atm. High-purity (99.5 mol%) PC withdrawn from the bottom of the PC synthesis column is fed into the RD column for DMC synthesis. In the DMC synthesis column, DMC/MeOH mixture is also recovered from the column top while high-purity PG with 99.9 mol% is withdrawn from the column bottom and recycled back to the RD column for PC synthesis. The minimized TAC for the PC synthesis by this RD configuration is 973.4×10^3 US$/year. In comparison with the CSTR+CD configuration, this TAC can be reduced by 11.7 %.

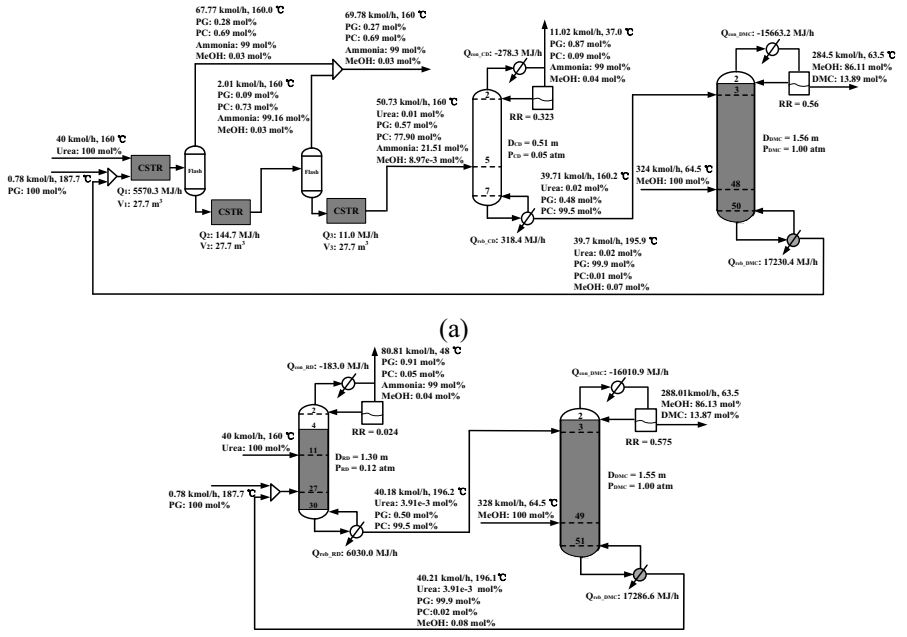


Figure 3. Optimal design for (a) CSTR+CD and (b) RD configurations.

Figure 4 shows the optimal design for three configurations with excess reactant operation. In this type of configuration, excess PG reactant is used in the RD column for PC synthesis. Bottom product, mainly containing PC and excess PG, of the RD column is introduced to a CD column for the separation of PC and PG. Heat integration between the RD and CD columns can then be implemented to reduce the energy consumption of the PC synthesis process by properly adjusting the pressures of RD and CD columns. Figure 4a is the first configuration of heat integrated RD+CD (named as RD+CD_HI1). The overhead temperature of CD column is designed to be greater than the bottom temperature of the RD column. Then the latent heat of the overhead vapor from the CD column can be released to the reboiler of the RD column. The optimal feed ratio of PG and urea is 1.25. The minimized TAC of this configuration is 1055.5×10^3 US$/year. In comparison with the CSTR+CD configuration, the TAC is reduced by 4.2 % for the RD+CD_HI1 configuration. However, the TAC is increased in comparison with the RD+CD configuration.

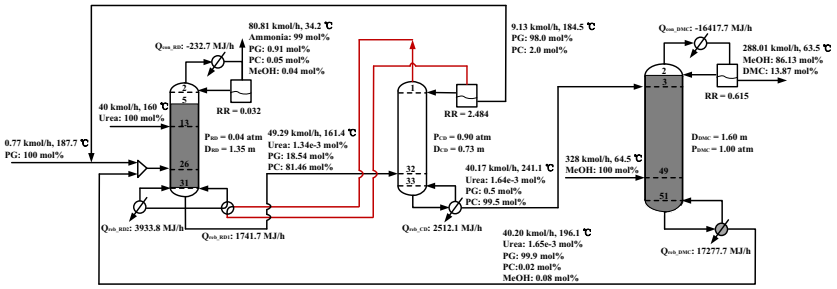

Figure 4. Optimal design for (a) RD+CD_HI1, (b) RD+CD_HI2, and (c) RD+CD_HI3 configurations.

Figures 4b and 4c are the two configurations with the CD column divided into top and bottom sections operated at high and low pressures, respectively. The overhead vapor of the bottom section is compressed by a compressor and used as a heating medium of the base of the top section. Much economical benefit can be achieved because PG-PC azeotrope vanishes under high pressure. Heat integration can be implemented by releasing the latent heat of overhead vapor to the reboiler in the CD column or in the RD column, respectively (named as RD+CD_HI2 and RD+CD_HI3). The TACs of these two configurations are 870.8×10^3 US$/year and 861.6×10^3 US$/year, respectively. RD+CD_HI3 configuration provides the most economical design. A 21.8% reduction of TAC can be achieved in comparison with CSTR+CD configuration.

In the addition to the PC synthesis, we also optimally design the processes for urea synthesis by Stamicarbon technology and DMC/MeOH azeotrope separation by extractive distillation. These two processes are intensified by heat integration to further reduce energy consumption. In this complete plant-wide process for DMC production, the TACs for urea synthesis, PC synthesis, DMC synthesis, and DMC/MeOH separation are 869.1×10^3 US$/year, 861.6×10^3 US$/year, 2775.4×10^3 US$/year, and 2913.1×10^3 US$/year, respectively. The annual costs of raw materials (CO_2 and MeOH) and product (DMC) are 1029.3×10^3 US$/year, 6625.2×10^3 US$/year, and 20667.1×10^3 US$/year, respectively. These indicate that the net profit is 5590×10^3 US$/year and 27% net profit margin can be obtained for this complete plant-wide DMC process.

4. Conclusions

Plant-wide process design of producing DMC by indirect alcoholysis of urea is investigated in this work. Five different configurations are proposed. Simulation results reveal that the RD+CD_HI3 configuration under excess reactant can provide the most economical design. In this configuration, the advantage of the azeotrope characteristic of PC-PG pair is fully taken by adding an internal compressor between top and bottom sections of the CD column. Heat integration is then implemented between column top and bottom to reduce energy consumption. In addition, the design of the complete plant-wide process is also given. Net profit margin with 27% can be achieved for this process.

Design of a Pressure-Swing Distillation Process for the Separation of n-Hexane and Ethyl Acetate Using Simulated Annealing

Xiao-Ling Yang[a] and Jeffrey D. Ward[a*]

[a]*Department of Chemical Engineering, National Taiwan University, #1, Sec. 4 Roosevelt Rd. Taipei 10617 Taiwan*
jeffward@ntu.edu.tw

Abstract

A pressure-swing distillation process for the separation of n-hexane and ethyl acetate, which form a minimum boiling azeotrope, is proposed and optimized using simulated annealing and simulation-optimization. The design variables considered are the two column pressures, the feed stages and total number of stages of both columns. The optimal process design is somewhat more expensive than the optimal extractive distillation process (designed separately) but the pressure-swing process benefits from the fact that no additional component is introduced.

Keywords: pressure-swing distillation, simulated annealing, simulation optimization

1. Introduction

In some azeotropic systems, the azeotrope composition is a strong function of pressure. This property can be exploited to break the azeotrope without the introduction of a third component (an entrainer) by means of pressure-swing distillation. In general, the greater the change of the azeotrope composition with pressure, the more efficient pressure-swing distillation will be. General information about pressure-swing distillation can be found in textbooks including the book by Luyben and Chien (2010).

Mixtures of n-hexane and ethyl acetate are used as solvents for liquid chromatography in the pharmaceutical industry (Rodriguez-Donis et al., 2005). Rodriquez, et al. (1999) and Rodriguez-Donis et al. (2005) studied the design of batch distillation processes with entrainers for breaking the azeotrope. Yang (2017) studied the design of continuous extractive distillation processes for this mixture with several solvents. Vapor-liquid equilibrium data for this mixture have been measured by Acosta et al. (2002) and Gorbunova et al. (1965).

Simulated annealing is a stochastic optimization method that was developed by analogy to annealing in metalworking (Kirkpatrick et al., 1983). At the start of the optimization, the algorithm will accept a move to a higher energy state (larger value of the objective function which is to be minimized) with greater probability in order to avoid becoming trapped in a local minimum. As the optimization progresses, the likelihood of accepting a higher energy state decreases and finally the system becomes “frozen” in a low-energy state that is hopefully nearly optimal. This method of optimization has been applied successfully to many problems in chemical process engineering optimization, including heat-integrated distillation sequences (Wei-zhong and Xi-Gang, 2009) and pressure-swing distillation processes (Cardoso, et al., 2000).

In this work, simulated annealing is applied to the optimization of a process for separating mixtures of n-hexane and ethyl acetate by pressure-swing distillation. The distillation columns are modelled in Aspen Plus and the simulated annealing algorithm is coded in Matlab. These two programs communicate by means of the Aspen Plus automation server. (AspenTechnology, 2002) and Matlab automation client.

2. Process model

Figure 1 shows the Txy diagrams for mixtures of n-hexane and ethyl acetate at pressures of 0.5 and 10 atm. The data are calculated using the UNIQUAC activity coefficient model with parameters taken from the Aspen Plus databank. The model predicts that the composition of the azeotrope shifts from 70 mol% to 55 mol% n-hexane, which suggests that pressure-swing distillation may be a feasible method for separation. To facilitate comparison with an extractive distillation process designed previously (Yang 2017), the feed flowrate and composition are set the same as in the previous work: 100kmol/h of a mixture that is 66.87 mol% n-hexane and 33.13mol% ethyl acetate. Since the feed is rich in n-hexane, it is fed to the high-pressure column where n-hexane is collected as a product.

The steady-state design is shown in Figure 2. In the high-pressure column, nearly pure n-hexane is collected at the bottom and a mixture near the azeotropic composition at high pressure is collected at the top and fed to the low-pressure column. In the low-pressure column, nearly pure ethyl acetate is collected at the bottom of the column, and a stream with composition near to the azeotropic composition is collected at the top of the column and recycled to the high-pressure column. Required pumps are not shown on the diagram for simplicity.

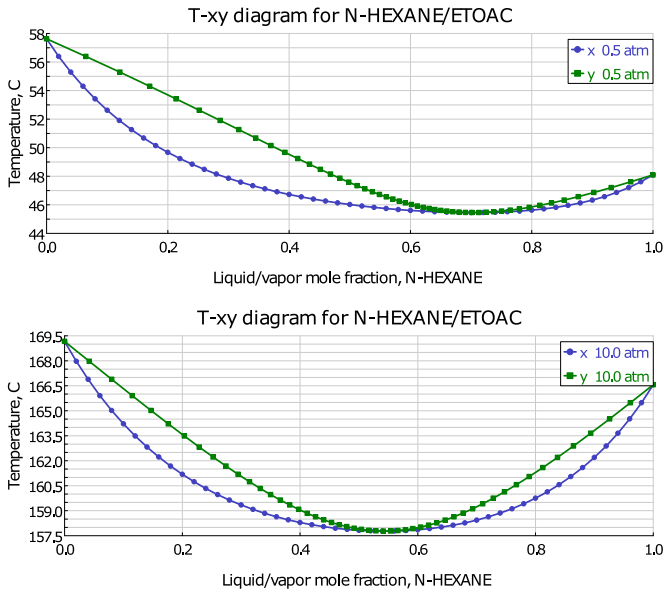

Figure 1. Txy diagrams for n-hexane-ethyl acetate at 0.5 and 10 atm

The variables to be determined by optimization are the total number of stages in the high pressure column (N1), the fresh feed and recycle stream feed tray locations (B1FS

and RS), the total number of stages of the low pressure column and feed tray location in the low pressure column (N2 and B2FS), and the two operating pressures (B1P and B2P). Design variables, their meanings, and the values of constrains are given in Table 1.

Both product purities are held at 99.5 mol% by manipulating the reboiler duties of the columns using the 'Design Spec/Vary' feature in Aspen Plus. In the high-pressure column, the distillate composition is specified to be 2.5 mol% greater than the azeotrope composition at the column pressure, and in the low pressure column, the distillate composition is specified to be 2.5 mol% less than the azeotropic composition at the column pressure. Distillate compositions are fixed by manipulating the reflux ratios in the columns using the Spec/Vary feature. To simplify the simulation, the recycle stream is torn in the Aspen Plus simulation and converged to within 0.1% by iteration in Matlab.

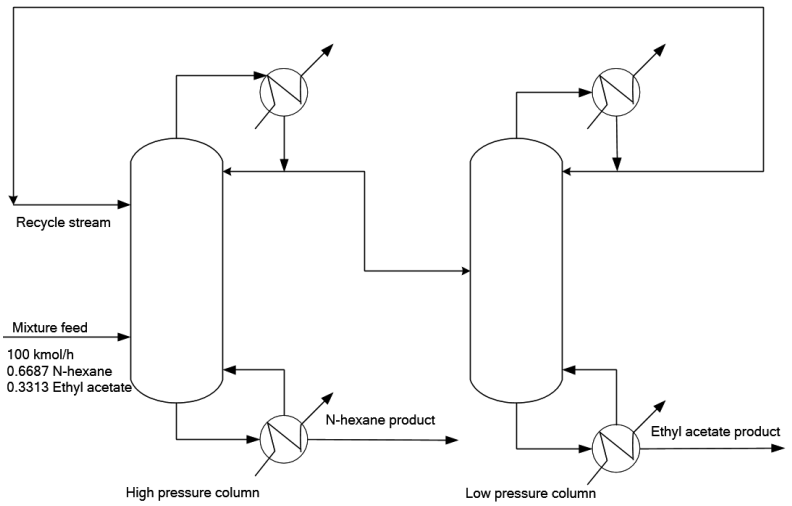

Figure 2. Proposed flowsheet of pressure-swing to separate n-hexane-ethyl acetate mixture

Table 1. Design variables for optimization

Design variable	Meaning	Constraints [min, max]	Nstep
B1P	Column 1 pressure	[8, 12]	0.1
B2P	Column 2 pressure	[0.1, 0.6]	0.01
N1	Number of stages in column 1	[5, 100]	1
B1FS	Fresh feed stage in column 1	[2, N1−1]	1
B1RS	Recycle feed state in column 1	[2, N1−1]	1
N2	Number of stages in column 2	[5, 100]	1
B2FS	Feed stage in column 2	[2, N2−1]	1

3. Optimization method

The SA algorithm was implemented in Matlab. A flowchart of the algorithm is shown in Figure 3. The procedure can briefly be described as follows:

[1] Start with given initial temperature, final temperature and solution space.

[2] Perturb the design variable vector d_i in the neighborhood to generate a new solution vector d_{i+1}. Run the simulation and check if the flowsheet is converged. Repeat this procedure if necessary until a solution vector d_{i+1} is found for which the simulation is converged.

[3] Iterate to converge the torn recycle stream. If the flowsheet fails to converge during the iteration, return to step [2].

[4] Evaluate the objection function $E(d_{i+1})$ and calculate $\Delta E = E(d_{i+1}) - E(d)$. If the $\Delta E \leq 0$, then accept the new value d_{i+1} by updating the current optimal solution. If $\exp(-\Delta E/T) \geq U(0,1)$, also accept d_{i+1}. $U(0,1)$ is a random number between 0 and 1.

[5] Return to step 2 until the system reaches thermodynamic equilibrium at temperature T.

[6] Decrease the temperature according to the cooling schedule. Then reset i=1 and repeat steps 2–5 until the final temperature is achieved.

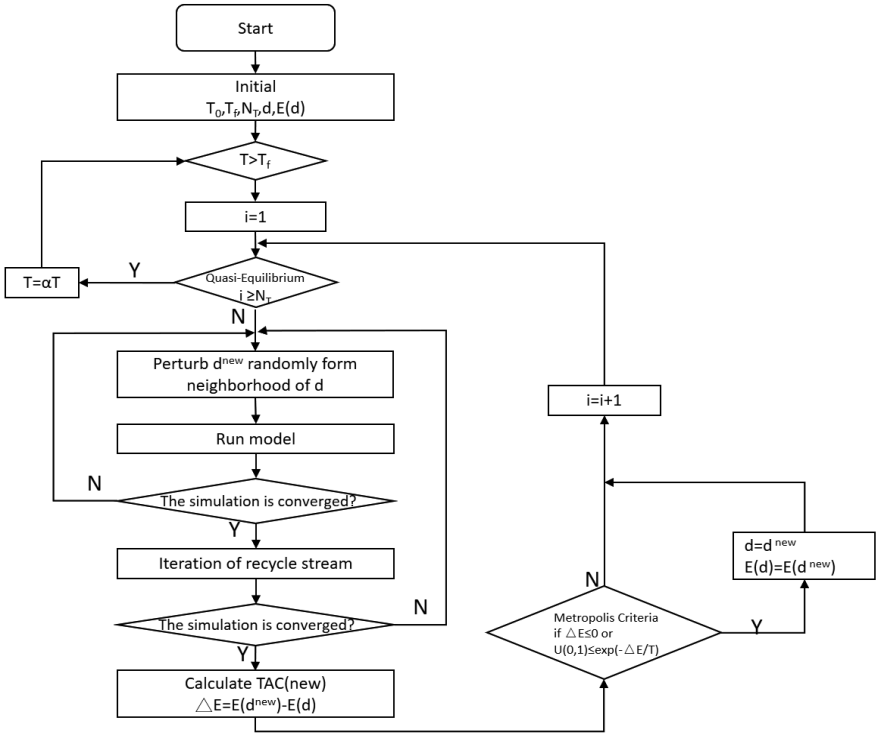

Figure 3. Flowchart of the simulated annealing algorithm

TAC calculations were performed using the methods and equations provided by Luyben (2006) except for the cost of the vacuum system which was determined using the methods and equations of Seider et al. (2009).

4. Results

The results of the annealing process are shown in Figure 4, and the detailed results are shown in Table 2. The lowest TAC obtained by the algorithm is 2,144,300$/yr with the two columns operated at 10atm and 0.19 atm. The SA algorithm was repeated starting at the optimal point determined by the first run, and the results of the second turn were similar to those of the first. The simulation was also repeated starting with different initial conditions and it was always found to converge to nearly the same point, suggesting that this point is near the global minimum.

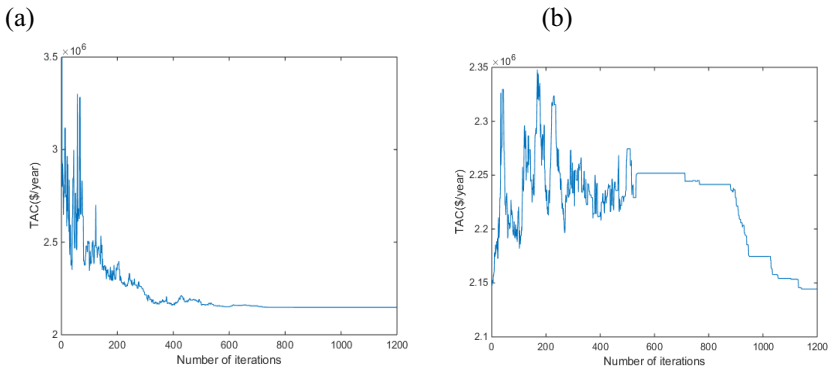

Figure 4. Results of the simulated annealing algorithm

Table 2. Optimal design result of SA algorithm in each turn

	SA(first turn)	SA(second turn)
B1P	10	10
B2P	0.19	0.19
N1	34	30
B1FS	12	10
RS	21	16
N2	23	24
B2FS	15	16
Vacuum cost($10^6$$/y)	0.2431	0.2428
TAC(10^6/y)	2.1478	2.1443

5. Conclusions

A pressure-swing distillation process for the separation of n-Hexane and Ethyl Acetate has been designed and optimized using simulated annealing. The process is modelled in Aspen Plus, and simulated annealing algorithm is implemented in Matlab. Connection between these two programs is facilitated by the Aspen Plus COM server.

The TAC of the pressure-swing distillation process is 2.14 million USD, compared with 0.92–1.76 million USD for entrainer-based separation alternatives depending on the choice of entrainer (Yang, 2017). Although the pressure-swing process is more expensive, it benefits from the fact that no additional component must be added to the system.

Abstract

Ethyl Lactate (L_1E) has been holding as a promising replacement for the petroleum-based solvent in world markets because of its biodegradable and nontoxic identities. However, the process design for production and separation of L_1E is challenging due to its complex kinetics. This work provides a modified design by using a side draw to obtain high purity L_1E from the 1st reactive distillation (RD) column in reactive part. Besides, several separation configurations recycling reactants are implemented to investigate the most economic process design. The final result shows that the heat duty saved as much as 22.3 % in the reactive part by using a side draw. Also, the pervaporation (PV) module in the separation part is more economical than extractive distillation (ED) in terms of total annual cost (TAC).

Keywords: Ethyl Lactate; Process design; Reactive distillation; Pervaporation.

1. Introduction

Ethyl lactate is a common solvent in chemical industry. It is usually produced through the main esterification reaction of lactic acid (L_1) and ethanol (EtOH). However, a key issue is that when the reactant concentration of lactic acid is higher than 20 wt%, several oligomeric reactions, such as reactions (2) and (3) in Table 1 will appear. Consequently, process design definitely becomes more challenging.

Table 1. The overall reaction paths for L_1E system

Main reaction	$L_1 + EtOH \rightleftharpoons L_1E + H_2O$	(1)
Oligomeric side reaction (a)	$2L_1 \rightleftharpoons L_2 + H_2O$	(2)
Oligomeric side reaction (b)	$L_1 + L_2 \rightleftharpoons L_3 + H_2O$	(3)

RD is a technique which combines reaction and separation sections into a single unit thus can highly reduce capital cost. Meanwhile, high conversion and selectivity can be achieved by shifting the chemical equilibrium boundaries. Gao et al. (2007) reported a paper on the L_1E process by using single reactive distillation column. Whereas the process is on an experimental scale and the reaction kinetics only considered the main esterification of L_1 with EtOH. Rattanaphanee (2015) provided a process regarding commercial scale production of L_1E, which consists one RD column and three separation columns. Nevertheless, the kinetics described in the process are also too

simplified that neglected the oligomeric reactions. Miller et al. (2010) first disclosed a commercial scale process concept with completed reaction kinetics to produce L_1E. However, it required two RD columns and one product separation column in the reactive part, which costs a lot. Furthermore, they did not specify which configuration would be implemented in the downstream separation part.

This research centers on the steady-state design and economic comparison of different separation techniques of the commercial L_1E process. To be more specific, two separation techniques, ED and PV are implemented to find the lowest operating and fixed cost.

2. Model Building

2.1. Thermodynamic Property

Nonrandom two liquids (NRTL) activity coefficient model is used to account for the non-ideal vapor-liquid equilibrium (VLE) and possible vapor-liquid-liquid (VLLE) phase behaviors in this system. Also, to account for the dimerization and trimerization of lactic acid in the vapor phase, the second viral coefficients of Hayden -O'Connell (1975) is used. Neither VLLE nor LLE are found in the system. Temperature and composition of azeotropes are given in Table 2.

Table 2. Composition and temperature of the azeotropes for L_1E system (at 1 atm)

	Experimental		Computed	
	Composition	Temp. (°C)	Composition	Temp. (°C)
H_2O/ EtOH	(0.106, 0.894)	78.12	(0.112, 0.888)	78.12
H_2O/ L_1E	-	-	(0.969, 0.031)	99.85
L_1/ L_2	-	-	(0.404, 0.596)	215.38

2.2. Reaction Kinetics

The kinetic parameters from Su et al. (2013) are provided in Table 3. For this system, Amberlyst 15 is used as the catalyst. It should be noticed that this reaction kinetic model is catalyst-weight-based (m_{cat}). Thus, the convert of the tray volume between catalyst weight is necessary. One can solve by assuming that the solid catalyst occupies 50% of the liquid holdup in RD column trays and the density of the catalyst is 770 kg/m^3.

Table 3. Kinetic model for L_1E system

$$r_{L_1E} = m_{cat}(k_{f,L_1E}x_{L_1}x_{EtOH} - k_{r,L_1E}x_{L_1E}x_{H_2O})$$

$$k_{f,L_1E} = 6.52 \times 10^3 \exp\left(-\frac{48000}{RT}\right) \qquad k_{r,L_1E} = 2.72 \times 10^3 \exp\left(-\frac{48000}{RT}\right)$$

$$r_{L_2} = m_{cat}(k_{f,L_2}x_{L_1}x_{L_1} - k_{r,L_2}x_{L_2}x_{L_2})$$

$$k_{f,L_2} = 1.10 \times 10 \exp\left(-\frac{52000}{RT}\right) \qquad k_{f,L_2} = 5.54 \times 10 \exp\left(-\frac{52000}{RT}\right)$$

$$r_{L_3} = m_{cat}(k_{f,L_3}x_{L_2}x_{L_1} - k_{r,L_3}x_{L_3}x_{H_2O})$$

$$k_{f,L_3} = 4.56 \times 10^{-1} \exp\left(-\frac{50800}{RT}\right) \qquad k_{r,L_3} = 2.28 \times 10 \exp\left(-\frac{50800}{RT}\right)$$

r_i (kmol/s), m_{cat} (kg_{cat}), k_i (kmol/(kg_{cat}s)), R = 8.314 (kJ/(kmol/K)), T (K), x_i (mole fraction)

2.3. Pervaporation Model

In this work, a simpler lumped system model (Luyben, 2009) is used. It would be done by dividing the membrane unit into several equal size units which called lumps. Moreover, material and energy balances (Eq.s (4) to (6)) for each lump are applied.
Total mass balance at the steady state:

$$\frac{dM_R}{dt} = 0 = F_{R,n-1} - F_{R,n} - F_{P,n} \quad (4)$$

where M_R is the molar holdup in the membrane, F_n is molar flowrate from cell n, and the subscript R and P are represented as retentate or permeate side respectively. Component mass balance for species i:

$$M_R \frac{dZ_{R,n,i}}{dt} = F_{R,n-1}Z_{R,n-1,i} - F_{R,n}Z_{R,n,i} - F_{P,n}Z_{P,n,i} \quad (5)$$

where z_i is the molar fraction for species i. Energy difference of the inlet flow and outlet flow:

$$M_R \frac{dh_{R,n}}{dt} = F_{R,n-1}h_{R,n-1} - F_{R,n}h_{R,n} - F_{P,n}H_{P,n} \quad (6)$$

where h is the molar enthalpy of liquid in retentate side, H is the molar enthalpy of vapor in permeate side. The permeation rate of water (J_w) and other species i (J_i) are depicted below:

$$J_w = k_a \exp\left(\frac{-E_D}{RT}\right)\left[\exp\left(k_b w_{w,f}\right) - 1\right] \quad (7)$$

$$J_i = k_a \exp\left(\frac{-E_D}{RT}\right)\exp\left(k_b w_{w,f}\right) \quad (8)$$

Table 4. Pervaporation parameters for L_1E system

Component	k_a ($kgh^{-1}m^{-2}$)	E_D ($kJmol^{-1}$)	k_b ($kgh^{-1}m^{-2}$)
H_2O	1.19×10^7	49.96	2.17
EtOH	4.25×10^5	51.41	8.10
L_1E	1.93×10^3	40.93	9.58
L_1	9.72×10^8	76.89	6.34

The pervaporation parameters shown in Table 4 is taken from the paper published by Delgado et al. (2009). It is worth to notice that the membrane is really unfavorable for organic components. Also, the feed stream composed relatively small amount of L_2 and L_3 in the system. Therefore, the flux of L_2 and L_3 can be reasonably neglected.

3. Steady-state Design

The process designed here is to construct the commercial L_1E production process. The commercial simulator, Aspen Plus v9.0 is used for simulation. The membrane module for PV is developed and implemented into Aspen Plus interface via Aspen Custom Modeller. The annual L_1E production rate is set as 25 million pounds (roughly as 13.88 mole/min). The specification of L_1E is 0.990 (molar basis) to meet the product requirement. Besides, the purity of three feed streams, namely, EtOH, L_1, and H_2O are 0.900, 0.152 and 0.995 (molar basis), respectively.

3.1. Reactive Part

Figure 1 shows the base case simulation results of the reactive part from the process concept of Miller et al. (2010). It consists of two RD columns as denoted as RDC1 and

RDC2 and one conventional distillation column (C1) separating L_1E from the top. By analyzing the composition profile in RDC1, we found that the highest purity of the desired product, L_1E does not appear in the bottom. Instead, it arises on the 57th stage and shows the purity of 0.964 that is higher than 0.920 in the bottom stream. Therefore, it can be fairly considered to draw a side stream from the middle of RDC1 to replace C1.

Figure 2 shows the modified design of the reactive part. The product (L_1E) is taken from the 52th stage of RDC1 as a side draw. Additionally, by changing the operating condition, such as the reboiler duty, L_1E in the side draw can meet our specification of 0.990. By comparing this novel configuration with the original design, the energy has been saved for about 22.3 %. The Mix stream that composed mainly of EtOH and H2O will be sent to different configurations for further separation.

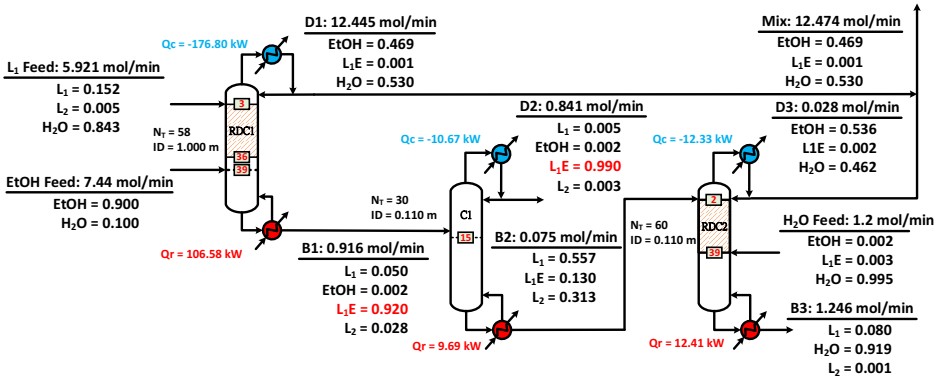

Figure 1. The simulation results from the process concept of Miller et al. (2010)

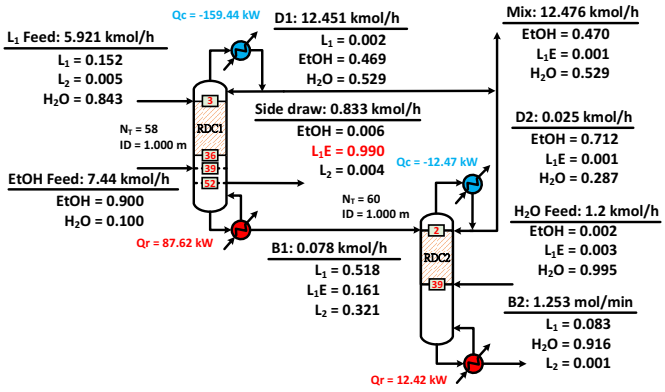

Figure 2. The modified process for reactive part

3.2. Reactive Distillation with Different Separation Configurations

In this section, we investigate the performance of different separation configurations. From the process described in Section 3.1, we will obtain a stream that composed mainly of EtOH and H_2O (stream Mix in Figure 3). Since EtOH will form a typical azeotrope with H_2O, it is impossible to obtain pure EtOH by using a single distillation

column. Accordingly, conventional separation technique called extractive distillation (ED) is being used. On the other hand, novel pervaporation module is also being utilized to find further advantages compared to ED. Figure 3 shows the RD + ED configuration. Since glycerol is non-toxic, it is being used as the entrainer in this system. C1 and C2 in this figure represent EtOH separation column and entrainer recycle column, respectively. Because the system will generate a large amount of H_2O, part of the purified H_2O from C2 will be sent as the reactant for RDC2. Figure 4 illustrates the RD + PV configuration. For physical limitation of the membrane, it is necessary to implement C1 to pre-concentrate EtOH in advance. Then the concentrated stream (D3 in Figure 5) will be sent to 4 parallel membranes. The purified EtOH from the retentate stream will be sent back to the system as the reactant. On the contrary, the permeate will be sent to C1 for further purification of H_2O.

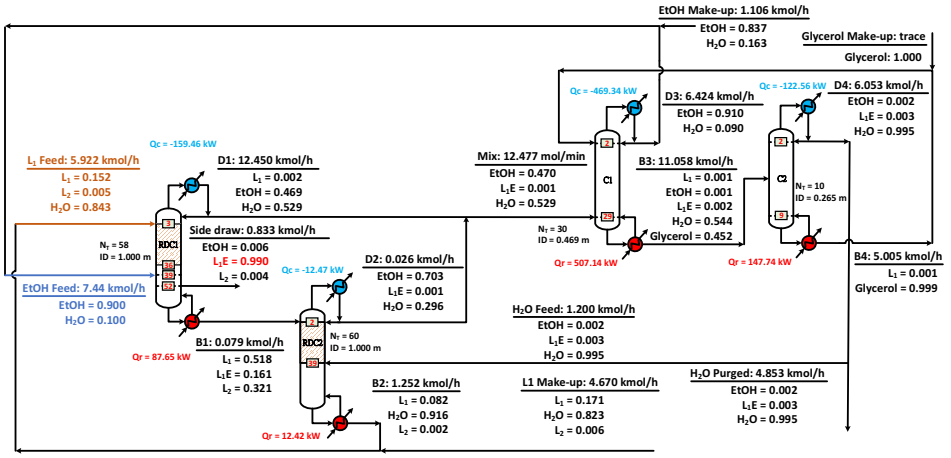

Figure 3. Reactive distillation with extractive distillation (RD + ED) configuration

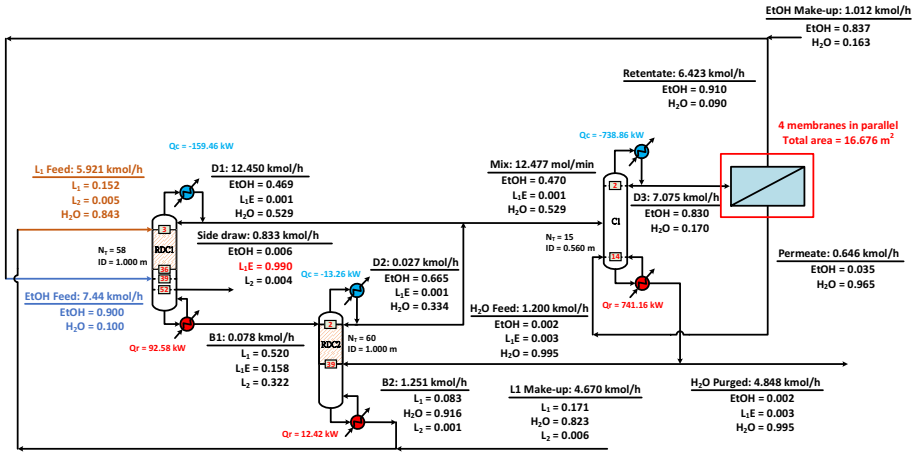

Figure 4. Reactive distillation with pervaporation (RD + PV) configuration

3.3. Economic Analysis

The calculation of TAC includes annual operating cost (AOC) and annual total capital cost (TCC) which is shown in Eq.(9). The payback period is set as 3 years. Table 5 lists the TAC of two configurations. It is clearly that the RD + PV is much more competitive than RD + ED since the TAC can be saved for about 56,000 USD.

$$\mathrm{TAC} = \mathrm{AOC} + \frac{\mathrm{TCC}}{\text{payback period}} \tag{9}$$

Table 5. Comparison of TAC between two configurations

Configuration	Fixed Cost (1000 USD)	Operating Cost (1000 USD)	TAC (1000 USD)
RD + ED	1173.84	32.79	1206.63
RD + PV	1121.47	29.12	1150.59

4. Conclusion

Two commercial L_1E production processes had been constructed. For the reactive part, taking a side draw to replace product column can save 22.3 % energy. For the separation part, PV shows more potential than traditional ED process because it would reduce TAC for around 56,000 USD.

Potentials for CO_2 Utilization: Diethyl Carbonate Synthesis from Propylene Oxide

Meng-Kai Chen and I-Lung Chien*

Department of Chemical Engineering, National Taiwan University, Taipei 10617, Taiwan
ilungchien@ntu.edu.tw

Abstract

Production of dimethyl carbonate (DMC) has received much attention in CO_2 utilization recently. The conventional route of DMC synthesis from CO_2 is converting CO_2 with ethylene oxide into ethylene carbonate and followed by transesterification with methanol. However, the azeotrope of methanol-DMC mixture makes separation system energy intensive. In this paper, CO_2 utilization to instead produce diethyl carbonate (DEC) is investigated. Fortunately, because ethanol-DEC mixture would not generate azeotrope, the energy consumptions of this CO_2 utilization route to produce DEC is much less than the DMC route.

Three alternative processes to produce DEC are rigorously designed in this paper. The first one is the conventional two-step process to produce DMC and then followed by transesterification of DMC with ethanol to produce DEC. Two other alternative DEC synthesis routes are proposed: (1) converting CO_2 with propylene oxide into propylene carbonate and then transesterification of propylene carbonate with ethanol, (2) one-pot synthesis of converting CO_2, propylene oxide and ethanol into DEC. These two routes would not involve DMC, therefore, separation is easier. For these two alternative routes, propylene glycol is the by-product instead of ethylene glycol in the conventional process. Rigorous simulation of three routes and CO_2 emission calculation are performed in Aspen Plus V8.8. Due to lack of reaction kinetics of one-pot reaction, hypothetical simulation and discussion are made based on the experimental data from a recent paper.

Result shows that the first alternative route avoids 46.0 % of CO_2 emission per unit weight of DEC produced as compared with the conventional process. In addition, it saves 24.0 % for capital cost and 35.3 % for utility cost. The one-pot synthesis route also has potential to reduce CO_2 emission of 17.7 %.

Keywords: CO_2 utilization, diethyl carbonate, propylene oxide, process design.

1. Introduction

Transformation of captured CO_2 into valuable compounds is one way to reduce the global CO_2 emission. The utilization of CO_2 could avoid part of the usage of petrochemical, and the profit from the valuable product could compensate the cost of the capture process. Urea, polycarbonate, methanol, dimethyl ether and dimethyl carbonate (DMC) are usually considered as the potential target compounds. In the process of DMC synthesis from CO_2, there are two major options without involvement of toxic phosgene, direct synthesis and two-step transesterification. For direct synthesis process, methanol (MeOH) and CO_2 are converted in one reactor, producing water and

DMC. For two-step transesterification process, cycloaddition of CO_2 with epoxide to cyclic carbonate is followed by transesterification between cyclic carbonate and methanol, producing diol and DMC. There are several challenges of direct synthesis process, such as low yield and thermodynamic limitation. Compare with direct synthesis process, two-step transesterification process is more realizable recently. However, azeotrope of methanol-DMC mixture makes separation system energy intensive.

The major application of DMC are fuel additive, solvent and organic feedstock for other organic carbonate, such as diethyl carbonate (DEC), diphenyl carbonate and polycarbonate. Among of those derivative organic carbonates, DEC has similar or even better performance than DMC in the application field. In the view of fuel additive, although the oxygen content of DEC (40.7 wt %) is lower than DMC (53.3 wt %), it is still much higher than methyl tert-butyl ether (MTBE) (18.2 wt %). For octane number, both of DMC and DEC are higher than 100. The distribution of DEC in gasoline/water two-phase system is much better than that of DMC (Pacheco et al., 1997). In addition, DEC could not only be used as gasoline additive but also as diesel additive, which could reduce particulate emission about 30 % with lower than 10 % CO, hydrocarbon and NOx additional emission (Kozak et al., 2012).

Comparing with conventional DEC synthesis from transesterification of DMC with methanol, transesterification of cyclic carbonate with ethanol (EtOH) is an alternative way. The major advantage of this synthesis route is that there is no azeotrope between ethanol and DEC, as shown in Figure 1. Therefore, the separation is much easier than the separation of methanol/DMC mixture.

In recent study, DEC synthesis from propylene oxide (PO), CO_2, ethanol over a heterogeneous catalyst, cross linked poly(ionic liquid) integrated with MgO, has been investigated (Wang et al., 2017). This work demonstrates a one-pot synthesis composed of cycloaddition and transesterification in one reactor, which might make DEC synthesis process simpler.

In this study, three the above-mentioned DEC synthesis routes from PO are discussed and designed. Those process steps which have been studied and designed in the existing literature are reproduced in the same product yield basis to make a fair comparison. CO_2

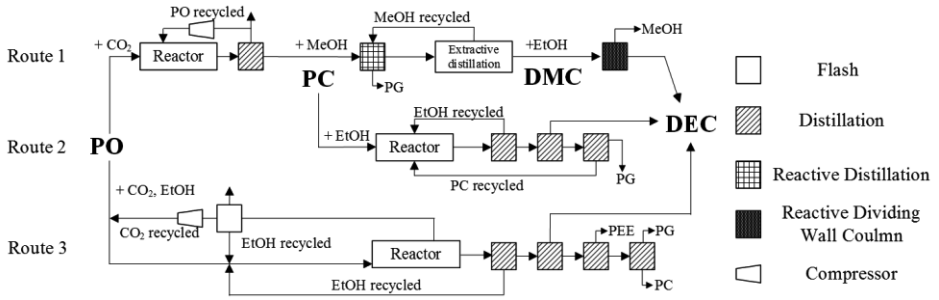

Figure 2. Illustration of three DEC synthesis routes.

emission calculation and economic analysis are applied. Due to lack of reaction kinetics of one-pot synthesis, hypothetical simulation and discussion are made based on the experimental data from Wang et al. (2017).

2. Process Description

Figure 2 shows the illustration of three DEC synthesis routes in this study. In all the three routes, PO is used as reacting agent to convert CO_2 and generate propylene glycol (PG) as valuable by-product. The process basis for this study is 20 kmol/hr CO_2 consumption as raw material (7.04 kt/y). All the product purity specifications are 99.5 mol%. All the operating pressures are 0.1 MPa if not specified.

2.1. Route 1

In Route 1, three steps are required to produce DEC. Among of them, the processes of transesterification of propylene carbonate (PC) with methanol (Holtbruegg et al., 2015) and transesterification of DMC with ethanol (Zheng et al., 2017) are already studied in the previous literature. The former applies reactive distillation first and pressure swing distillation to separate methanol and DMC. Reactive distillation could make almost 100% conversion of PC with excess methanol. However, the azeotropic composition of methanol/DMC mixture does not change obviously with pressure (93.7 mol% MeOH at 1 MPa and 86.5 mol% MeOH at 0.1 MPa), and Wang et al. (2010) shows that extractive distillation with phenol as entrainer is a better alternative to separate methanol/DMC azeotrope rather than pressure swing distillation. Furthermore, Hsu et al. (2010) found that extractive distillation with aniline as entrainer performs better than phenol. Therefore, a revised process consisting of reactive distillation and extractive distillation with aniline as entrainer is applied in this study.

Reactive dividing wall column is applied for transesterification of DMC with ethanol by Zheng et al. in 2017. The reactive distillation of DMC and ethanol is combined with the separation of methanol and ethanol. In this study, all key operating conditions follows Zheng et al.'s work (2017).

For cycloaddition of CO_2 and PO, kinetic model is studied with DEAE ion-exchange catalyst in a semi-batch slurry reactor (Jin et al., 2017). Modified Eley-Rideal type mechanism is used to describe this liquid phase reaction. First, PO and CO_2 (with 10% excess) are both compressed and sent to a tubular reactor at 95 °C with 10% bypass. The discharge from reactor is sent to a stripping column to purify PC, and unreacted CO_2 is compressed and sent back to reactor. A purge from recycled gas is needed to avoid

accumulation of CO_2. RK-SOAVE model is applied to describe phase equilibrium in this reaction system, and UNIQUAC model is applied for all other downstream systems.

2.2. Route 2

The first step in Route 2 is the same one in Route 1. As mentioned earlier, the process of converting PC and ethanol into DEC and PG in thermally-coupled reactive distillation column has been studied. In this quaternary system, two products are intermediate boiling between two reactants, which is the most difficult type to apply reactive distillation. Fortunately, the minimum azeotrope between methanol and DMC makes sure DMC could be withdrawn from distillate with excess methanol, and PG is obtained from bottom. The existence of minimum azeotrope breaks the bottleneck of reactive distillation for this type of boiling point rank. However, there is no azeotrope between ethanol and DEC (shown in Figure 1.), therefore, the reactive distillation structure should not be the one proposed by Wang et al. in 2014, which uses the same structure as transesterification between PC and methanol. Therefore, conventional reactor-distillation sequence is applied in this study rather than their proposed process.

PC and excess ethanol are sent to reactor at 30 ºC first and purified by the following separation section. Separation comprises direct sequence of three columns. Ethanol, DEC, PG are obtained respectively from three distillates, and PC is obtained from the bottom of the last column. Unreacted ethanol and PC are recycled back to reactor.

2.3. Route 3

One-pot synthesis between PO, ethanol, CO_2 has been studied by Wang et al. in 2017. Reaction conditions in the experiment are 0.510 mol ethanol, 0.035 mol PO, 3 MPa CO_2 initial pressure, 160 ºC and reaction time is 4.5 h. Under this condition, yields for DEC, PG, PC are 44.4 %, 56.6 %, 21.3 %, respectively, and 96.0 % PO conversion are reached. The difference between the yields of DEC and PG is due to hydrolysis of PO. In this system, propylene glycol monoethyl ether (PEE) with 7.4 % yield is another by-product from reaction between PC and ethanol.

Due to no kinetic model of this reaction system can be found in previous literatures, simulation of this synthesis route follows the same yields, selectivity and operating condition in the experiment. Therefore, it should be noticed that this process is merely a hypothetical simulation, and we could not alter the operating condition carelessly. Reactor outlet, ethanol and CO_2 in major, is flashed, and most of vaporized ethanol is condensed and sent back to the reactor. The remaining CO_2 is recompressed and then recycles to reactor. A purge from recycled gas is needed to avoid accumulation of CO_2. Separation also follows direct sequence of four distillation columns. Ethanol, DEC, PEE, and PG are obtained respectively from the four distillates. Excess ethanol is recycled back to reactor while PC is regarded as another by-product and not recycled in this route.

Table 1. Equivalent CO_2 emission amount and price of utility

Utility	Equivalent CO_2 emission (kg/GJ)	Price (USD/GJ)
Steam, 0.5 MPa, 160 ºC	72.86	13.28
Steam, 1.0 MPa, 184 ºC	76.60	14.19
Steam, 4.2 MPa, 254 ºC	91.14	17.70
Electricity	96.95	16.80
Cooling water	-	0.354

The yield of DEC is lower than the previous two routes because part of the intermediate, PC, inevitably remains unconverted in one-pot synthesis.

3. Carbon Emission and Economic Analysis

Carbon emission considered in this study is from steam and electricity. Three different grades of steam are used referring to the book from Turton et al. in 2009. The corresponding CO_2 emission amount follows the calculation method proposed by Gadalla et al. in 2005 and listed in Table 1.

The evaluations of capital cost and operating cost follow the book from Turton et al. in 2009. Only the first two synthesis routes are considered because Route 3 is a hypothetically scaled-up process. The cost of reactor could not be estimated because of the missing information of kinetic model.

4. Result and Discussion

In this study, only the significant variables are optimized, such as temperature in reactor, alcohol excess ratio, and operating pressure in the distillation column for alcohol separation. The result of CO_2 emission calculation and economic analysis for three alternatives DEC synthesis routes are summarized in Table 2. Even though all three routes emit CO_2 more than consumption, it should be noticed that the avoided CO_2 emissions in Route 2 and Route 3 revealing the potential of emission reduction.

The cycloaddition step accounts for minor CO_2 emission, and the following transesterification reaction emits tens of times more. In the transesterification step, alcohol is excess to make sure enough conversion of carbonate (PC or DMC). There is a tradeoff between conversion in reactor and energy consumption. The more alcohol used, the more alcohol should be vaporized and removed from product (DMC or DEC), which accounts for the major energy requirement. The optimal alcohol excess ratios in the transesterification reactions are 10.5 (PC to DMC), 6 (DMC to DEC) and 8 (PC to DEC). Additionally, the EtOH excess ratio in Route 3 is 14.6.

Because Route 2 uses one less transesterification step and lower alcohol excess ratio than Route 1, the advantage of Route 2 is obvious. Not only less amount of utility is required, but less capital investment in Route 2. Additionally, no azeotrope in EtOH/DEC mixture makes Route 2 more appealing. However, even though Route 3

Table 2. Result summary

	Route 1	Route 2	Route 3
Utility cost (kUSD/y)	6260 (0 %)	4050 (-35.3 %)	3870 (-38.2 %)
Capital cost (kUSD)	8170 (0 %)	6210 (-24.0 %)	-
CO_2 emission (kt/y)	Step 1: 0.97 Step 2: 19.75 Step 3: 10.79	Step 1: 0.97 Step 2: 19.30	20.67
CO_2 consumption (kt/y)	7.04	7.04	7.04
Net CO_2 emission (kt/y)	24.46	13.22	13.63
DEC production (kt/y)	18.89	18.89	12.79
Net CO_2 emission (kg CO_2/kg DEC)	1.30 (0 %)	0.70 (-46.0 %)	1.07 (-17.7 %)

further simplifies the synthesis process, large alcohol excess ratio and by-product generated still makes it not favourable in the reduction of CO_2 emission. Even so, if some catalyst could maintain the selectivity of one-pot reaction with less alcohol excess in the future, the potential for CO_2 emission reduction might be more significant.

5. Conclusions

In this study, three synthesis routes from PO to DEC are designed, and carbon emission for these three routes are compared to discuss the potential of CO_2 reduction in DEC production. The transesterification reaction accounts for the majority of energy requirement. Result shows that 46.0 % and 17.7 % net CO_2 emission reduction by Route 2 and Route 3, respectively, as compared with Route 1. In addition, Route 2 saves 24.0 % capital cost and 35.3 % utility cost, which shows that Route 2 not only has the potential of CO_2 emission reduction but is more economically favourable.

Abstract

In the present work, a process synthesis framework for the conversion of softwood biomass to liquid (BtL) transportation fuels was developed. We defined processing blocks out of promising thermochemical and upgrading technologies, and performed individual blocks rigorous simulations in Aspen Plus® V8.8. The simulations and experimental data taken from the literature were used to predict conversions, recovery factors, capital and energy costs of the processing blocks. From the simulations, it was found that Gasification-Low Temperature Fischer-Tropsch (LTFT) followed by fractional upgrading and fractionating units (BC-GLTUF), was the most cost-effective, in terms of total annual cost (TAC) and liquid fuels production. Then, given the preliminary results, the possibility of combining blocks between the thermochemical routes, as well as mass and energy integration were explored. A superstructure was proposed and defined as a Mixed Integer Non-Linear Programming (MINLP) problem coded in GAMS 24.5.6, which sets the objective to minimize the TAC´s of BtL fuels under different cases and integration scenarios. The results showed that a combined alternative of Gasification followed by simultaneous high and low temperature FT reactions (CA-GLTHT) could increase the liquids fuels production and product distribution from 87 % to 90 % (wt) and reduce the TAC in around 26 % if mass and energy integration are considered.

Keywords: thermochemical, biofuels, process synthesis, simulation, superstructure, MINLP.

1. Introduction

By the end of 2016 in the United States 95 % of petroleum usage went directly to transportation fuels and only 5 % of liquid transportation fuels production originates with renewable resources (EIA, 2017). Thermochemical conversion processes such as gasification, pyrolysis, supercritical fluid extraction and direct liquefaction can convert biomass into syngas, bio-oil, char and gaseous products (Demirbas, 2001). From these, bio-oil can be used as an intermediate step to produce transportation liquid fuels such as diesel and gasoline. However, the larger capital cost for BtL is a strong motivating factor for the development of new processes to refine the fuels at lower costs. For advanced biofuels the main factor is capital costs (35 % to 50 %), followed by feedstock costs (25 % to 40 %) (IEA, 2009).

Hence, a process synthesis framework for the conversion of softwood to gasoline and diesel was defined in order to reduce the capital and operating costs. This general strategy for BtL facilities development proposes a combined methodology of rigorous simulations

and a MINLP model. The optimization-based process synthesis strategy can simultaneously analyze distinct thermochemical-based process designs and determine the alternative that minimizes the overall softwood BtL fuels production system cost. For instance, mathematical modeling has been applied to a thermochemical-based refinery for the conversion of hardwood BtL (Baliban et al., 2013). However, to our knowledge there are not explicit works in the literature that consider simultaneously various thermochemical conversion routes, upgrading technologies and separation units using rigorous simulations as performance and cost sources.

2. Thermochemical-based superstructure base cases

We proposed through an optimization-based process synthesis framework, a thermochemical-based superstructure to convert softwood biomass (30 wt % moisture) to gasoline, diesel, and by-products. Norway spruce and Scots pine were selected as feedstocks. Two thermochemical routes were explored: Pyrolysis and gasification, since these are actively studied technologies and sufficient experimental data can be collected.

In the gasification routes, the pretreated biomass is sent to a gasification reactor, where it reacts with air, oxygen, or steam to produce a gaseous mixture known as raw gas (Mponzi, 2011). Then, the product raw gas is cleaned and the syngas obtained is sent to a Fischer-Tropsch reactor (FT). The FT process produces hydrocarbons from gasified biomass. Two main regimes have been used: LTFT that gives long chain molecules, and high temperature Fischer-Tropsch (HTFT), that gives shorter chain molecules (Maitlis and De Klerk, 2013). Before the upgrading, the FT products are split into fractions, since each fraction requires different upgrading (aromatic alkylation, gas oligomerization, naphtha aromatization, distillate hydrotreating, wax hydrocraking and aqueous products hydrogenation). Alternatively, the HTFT products can be upgraded by hydroprocessing: wax hydrocracking and distillate and naphtha product hydrotreating (Bechtel, 1998).

Regarding pyrolysis, biomass is heated in the absence of oxygen to produce pyrolysis oil also called bio-oil, which can be upgraded into chemicals and fuels. Upgrading bio-oil to a conventional transport fuel can be accomplished by two main routes: hydroprocessing or catalytic cracking over acidic zeolite catalysts (Czernik and Bridgwater, 2004).

In total five base cases consisting of different thermochemical conversion routes, upgrading technologies and separation units were proposed and evaluated: Pyrolysis-Hydroprocessing-Separation (BC-PHS), Pyrolysis-Catalytic Cracking-Fractionation (BC-PCCF), Gasification-LTFT-Fractional Upgrading-Fractionation (BC-GLTUF), Gasification-HTFT-Fractional Upgrading-Fractionation (BC-GHTUF), Gasification-HTFT-Hydroprocessing-Separation (BC-GHTH).

3. Methodology

3.1. Softwood BtL base cases: Synthesis and Conceptual Design

As initial analysis for the conceptual designs, each technological base case was primarily divided into three sections, namely, (1) thermochemical conversion: pyrolysis or gasification followed by LT and/or HT FT, (2) upgrading technology: hydroprocessing, catalytic cracking, oligomerization, aromatization, hydrocracking, isomerization, alkylation, and hydrotreating, and (3) separation section.

Section (1) converts softwood biomass into pyrolysis oil via pyrolysis or syngas via gasification. Then, the syngas from gasification is sent to the FT reactor for hydrocarbon

production via two types of FT reactions (HT and LT). In section (2), the pyrolysis oil is upgraded to biocrude via catalytic cracking or hydroprocessing. On the other hand, the FT product is sent to the fractional hydrocarbon upgrading or hydroprocessing units to produce syncrude. Finally, in section (3), the biocrude or syncrude is fractionated into gasoline, diesel, gases and aqueous products. The distinct process sections not only define the different thermochemical routes, but also determine the process technologies in terms of production costs as well as the final product profiles.

Then, the processing blocks conforming each technological section were defined and analyzed using the simulation software Aspen Plus® V8.8 to predict thermodynamic properties, conversion and separation factors, as well as capital and utilities costs of the unit operations. Simultaneously, liquid, solid and gas emissions were quantified, and from the total emissions, different possibilities of mass (water and gases) and energy (heat and power self-generation) integration were explored. From the data collected, process synthesis, integration and combination of processing blocks (performing similar tasks and presenting similar costs) into a superstructure were performed. Finally, an optimization model with an economic objective function solved through deterministic global optimization approaches evaluated the superstructure and selected the conversion route that reduces the TAC of BtL-fuels.

3.2. Superstructure formulation: definition of individual processing blocks and rigorous simulation.

3.2.1. Individual processing blocks definition

For the superstructure formulation, first the unit operations conforming the base cases´ technological sections were defined. Then, the unit operations were grouped into processing blocks (reaction and/or separation). A processing block is considered as a set of units where the mass composition of the feed stream changes. This is done to simplify the analysis of the processing blocks that can be combined into a superstructure. To exemplify the procedure, the formulation of reaction and separation blocks for the Pyrolysis-Hydroprocessing-Separation (BC-PHS) flowsheet is depicted in Figure 1.

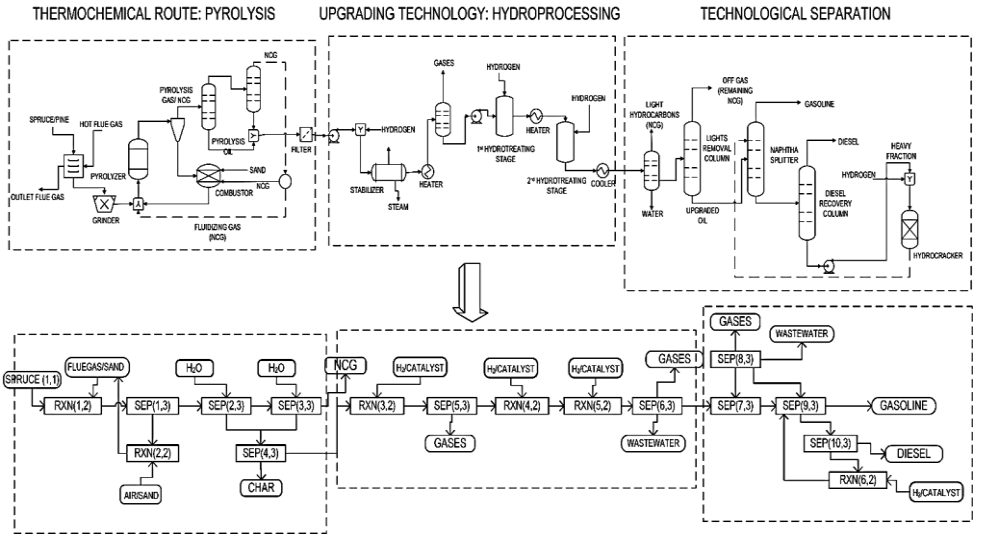

Figure 1. Formulation of processing blocks for BC-PHS: reaction (RXN) and separation (SEP)

3.2.2. Processing blocks simulation

The process simulator Aspen Plus® V8.8 was used to perform rigorous simulation of the pyrolysis, gasification, upgrading and separation blocks. The thermodynamic packages Soave-Redlich-Kwong equation of state with Kabadi-Danner mixing rules for the gasification route and Peng-Robinson for the Pyrolysis route were selected. The components not included in the Aspen database, such as, spruce, pine and ash were defined as non-conventional components based on their ultimate analysis including C, H, O, N, S, Cl and Ash elements, and proximate analysis (ECN, 1997). The biomass lower heating value (LHV) from the analyses was also specified with the HCOALGEN and DCOALIGT property models chosen to estimate the biomass enthalpy of formation, specific heat capacity and density. Each individual process setup was supported by literature and experimental data (operating conditions, conversions, representative components, and products obtained). Separation performance was based on the simulation´s thermodynamic models.

Aspen Process Economic Evaluator V8.8 was used to predict the energy consumption and equipment designs and costs of the reaction and separation blocks. The capital and utilities cost (electricity, heating and cooling) were calculated for a fixed capacity of 500 kg/h of spruce and pine.

3.2.3. Superstructure formulation

After the processing blocks definition and evaluation, it is possible to proceed with the formulation of the softwood BtL transportation fuels superstructure. The superstructure diagram defined is depicted in Figure 2.

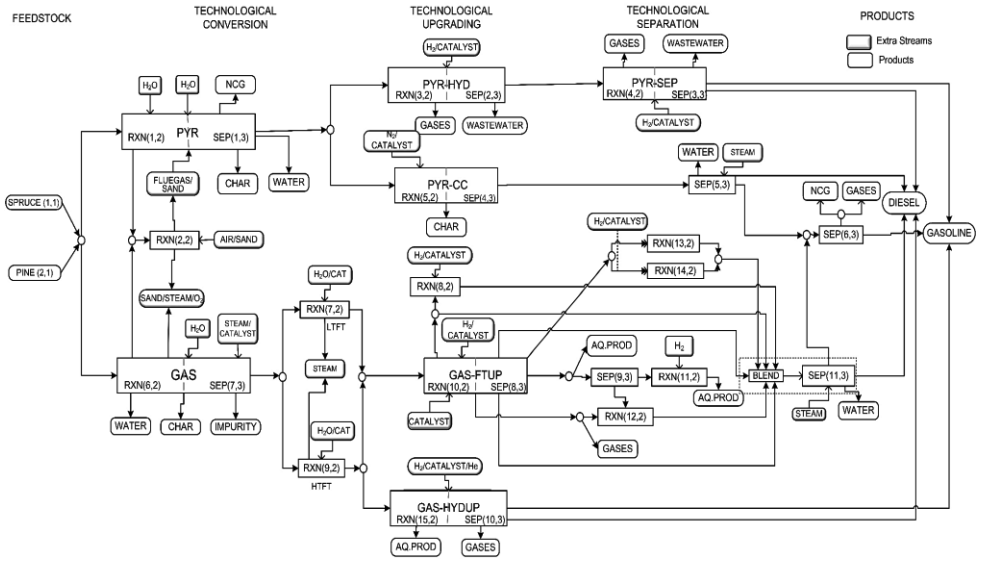

Figure 2. Thermochemical BtL process synthesis network superstructure

The possibilities of blocks combination between the base cases were analyzed by identifying blocks that perform similar tasks and present similar capital and energy costs. It was found that most of the blocks are sequential, so that we proposed lumped-process blocks performing major tasks like: biomass conversion to syngas via gasification RXN(6,2)-SEP(7,3); bio-oil via pyrolysis RXN(1,2)-SEP(1,3); pyrolysis oil catalytic

cracking RXN(5,2)-SEP(4,3); pyrolysis oil hydroprocessing RXN(3,2)-SEP(2,3); upgraded product separation: SEP(3,3), SEP(5,3), SEP(6,3) and SEP(11,3); and HTFT hydroprocessing RXN(15,2)-SEP(10,3). In addition, in the HTFT and LTFT hydrocarbons upgrading section, it was found that the reaction blocks aromatization and alkylation, as well as some separation units, perform similar tasks and present similar capital and energy costs. Therefore, these process blocks were combined into block RXN(10,2)-SEP(8,3), leaving outside reaction and separation blocks that are not in common between the base cases, as well as the ones that perform similar tasks but do not present similar costs.

3.3 Mathematical representation

We defined the synthesis network superstructure as a MINLP with the information collected from the rigorous simulations (thermodynamic properties, conversions, recovery factors, capital and energy costs). In previous works, it has been proven that MINLP can handle similar synthesis problems (Torres-Ortega et.al, 2017). The five base cases were studied with and without integrations, to produce diesel and gasoline simultaneously from one or two feedstocks. The objective was to analyze how these variables affect the product distribution and TAC. With this strategy, the MINLP problem explores the superstructure and proposes new pathways that increase the softwood conversion to transportation fuels and minimizes the TAC. The thermochemical-based processes´ TAC values were evaluated considering 10 years as time for recovering the investment. The objective function is depicted in Eq. (1):

$$minimize\ \ TAC = \sum \left[\left(\frac{Capital\ Cost}{Time\ of\ investment} \right) + Utility\ costs \right] \tag{1}$$

The advantages of the proposed methodology are consistency in the processing blocks parameters, individual processing block´s outputs and performance, as well as easier evaluation of the connectivity between processing blocks via MINLP.

4. Results

The superstructure was coded on GAMS 24.5.6 and the MINLP problem was solved by DICOPT and BARON solver. The five base cases described in previous sections were analyzed during the optimization and to test the performance of the model the desired final product requirements were specified. The MINLP solution is presented in Table 1 and additionally a combined alternative case consisting of Gasification-Simultaneous LT and HT FT-Fractional Upgrading-Separation (CA-GLTHT) was proposed and compared to the previous five cases. The individual process setup to reach the given profiles was confirmed by literature and experimental data. Likewise, each case was evaluated with and without mass and energy integration: gases and part of the water produced in each case were sent to a cogeneration plant for electricity and steam generation. The integration cases considered the cogeneration products, plant capital and energy costs.

From Table 1, we can observe that when the final biofuels profiles prefer more gasoline, BC-GHTH, BC-GHTUF and CA-GLTHT are the suitable technological routes. On the other hand, when the final biofuels profiles prefer more diesel, process routes BC-GLTUF and BC1-PHS are the suitable technological routes. Overall, the case with the highest liquid fuels production and the second lowest TAC was CA-GLTHT, achieving a TAC of 202,460.8 $/year, a product distribution of 69 % (wt) gasoline and 21 % (wt) diesel, and a TAC reduction of 26 % if mass and energy integration are considered.

Table 1. Case studies analyzed during the optimization

5. Conclusions

In this work, a process synthesis framework for the conversion of woody BtL transportation fuels and simultaneous heat, power and mass integration, and blocks combination was developed. Multiple existing technologies including softwood gasification, pyrolysis, FT, upgrading and separation units were combined into a superstructure formulation. The rigorous simulations and MINLP approach solution were used to evaluate and compare the base cases and determine the alternative for liquid fuel production that minimizes the overall system cost. It was found that CA-GLTHT is the most favorable even when it presents a higher cost compare to BC-GLTUF. It produced more liquid fuels compare to the other cases and the TAC can be reduced if mass and energy integration are considered. It was demonstrated that this methodology applied to softwood BtL transportation fuels production can explore and propose optimal conversion pathways that reduce the costs of BtL-fuels and increase their viability.

Abstract

1,2-Pentanediol (1,2-PeD), which can be used as a monomer of polyester, has been produced from fossil resource by environmentally-unfriendly process using toxic solvents (propionic acid and benzene). We present the environmentally-friendly process for the production of 1,2-PeD from bio-renewable FF (furfural) using water solvent and shows its economic feasibility. This study consists of experimental investigation and simulation study. First, we determine a suitable process route to maximize the yield of 1,2-PeD through the experimental investigation. FF is converted to 1,2-PeD through two sequential catalytic conversion steps using Cu-MgO and Ru-MnO_x catalysts. Next, the simulation study including process design, heat integration, and economic analysis is performed to present the economic feasibility for the developed process. The minimum selling price of 1,2-PeD is $ 3,118 per tonnes, and it is close to the current market price. We minimized the separation costs for the integrated process by designing efficient separation subsystems and heat exchanger network. Despite of using an expensive raw material, the environmentally-friendly process can be cost-competitive with conventional process.

Keywords: furfural; 1,2-pentanediol; process design; economic evaluation

1. Introduction

Lignocellulosic biomass that consists of cellulose, hemicellulose, and lignin has a potential as a sustainable carbon source to replace fossil resources (Saxena et al., 2009). It can be converted to fuels and chemicals by catalytic conversion process (Chundawat et al., 2011; Zhou et al., 2011). Furfural (FF) is a valuable chemical obtained from hydrolysis of hemicellulose fraction of lignocellulosic biomass, and it is currently well produced an industrial scale (Huber et al., 2006). FF can be used as a precursor for synthesis of valuable furan-based chemicals as well as an additive in pharmaceutical and agrochemical industry. The previous studies for catalytic conversion process using metal catalysts to produce furan-based compounds such as furfuryl alcohol, furfuryl acetate, and furoylglycine from biomass-derived FF have been reported recently (Yan et al., 2014). Zhang et al. have reported a catalytic conversion process for production of 1,2-pentanediol (1,2-PeD) by a highly selective catalytic hydrogenolysis of furfuryl alcohol (FFA), which can be obtained from catalytic hydrogenation of FF (B. Zhang et al., 2012). 1,2-PeD is a valuable polyol that can be used as a preservative in cosmetics or a monomer of polyester (Antoce et al., 1998; Mizugaki et al., 2014). Especially,

polyester is a representative polymer used for engineering plastic, textile, etc. As the increment of polyester usage, the global demand for polyester polyol has been gradually increased (C. Zhang, 2015). In the fossil-based process for production of 1,2-PeD, pentene is converted to 1,2-PeD by epoxidation and saponification using propionic acid and benzene (Siegmeier et al., 1986). The conventional process can cause resource depletion and environmental toxicity problems, due to using fossil feedstock and toxic solvent.

This paper presents the environmentally-friendly process for the production of 1,2-PeD from bio-renewable FF using non-toxic water solvent and shows its economic feasibility. A suitable process route to maximize yield of product is determined by an experimental investigation that analyses reaction conditions (temperature, pressure, catalyst, solvent, reaction time, etc.) and results (conversion and yield) of each conversion technologies. Then, we develop a simulation model for the large-scale process based on the process route determined by the experimental investigation and evaluated the process economics based on the simulation results.

2. Method

2.1. Experimental investigation

FF-to-1,2-PeD conversion consisted of two catalytic conversion subsystems: (i) hydrogenation FF to FFA and (ii) hydrogenolysis of FFA to 1,2-PeD. The biomass derived FF can be converted to FFA through a fixed bed reactor containing Cu-MgO catalyst. Nagaraja et al. reported that the effect of Cu content in the catalyst and reaction temperature on the hydrogenation of FF to FFA (Nagaraja et al., 2007). They measured the yield of FFA by changing reaction temperature (450-530 K) and Cu loading in catalyst (5-80 wt %) while fixing pressure (1 bar) and molar ratio of FF and H_2 (1:2.5). The highest yield (96%) of FFA was observed over Cu-MgO catalyst containing 16wt% Cu at 453 K, and we applied this reaction condition to the integrated process. Next, FFA can be converted to 1,2-PeD through an autoclave reactor containing Ru-MnO_x catalyst (B. Zhang et al., 2012). Zhang et al. reported the optimized reaction condition that promotes the FFA hydrogenolysis to produce 1,2-PeD, while inhibiting the FFA hydrogenation. They analyzed the correlation between the major reaction condition (temperature and H_2 pressure) and results (1,2-PeD yield) and showed the high temperature and the low H_2 pressure increase the generation of 1,2-PeD. In the autoclave reactor using 10 wt % FFA in a water solution, FFA can be hydrogenolysed to 1,2-PeD with a 38 % molar yield at 423 K and 20 bar. Simultaneously, tetrahydrofurfuryl alcohol (THFA) was converted from FFA with a 48 % molar yield through FFA hydrogenation. This reaction condition was applied to design the integrated process. Consequently, the total experimental yield for FF-to-1,2-PeD calculated based on the process route determined by experimental investigation was 36 %.

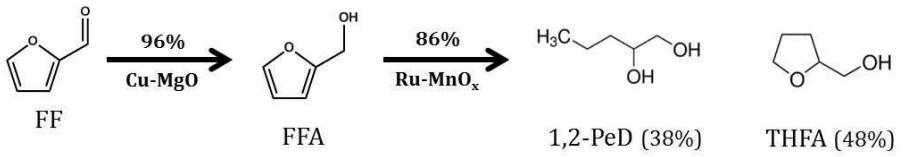

Figure 1. Reaction schematic view of FF-to-1,2-PeD and THFA

2.2. Simulation study

Simulation study followed three steps: (1) process design, (2) heat integration, and (3) economic analysis. First, we designed integrated process including conversion and separation subsystems based on the conversion route determined at experimental investigation by using ASPEN Plus Process Simulator. The processing rate of FF was 42,900 tonnes per year (t/y) which was produced from a large-scale process with a processing capacity of 350,000 dry t/y of white birch. Next, heat integration was performed to minimize the energy requirements for the integrated process by using ASPEN Energy Analyzer. Finally, we performed economic analysis including cost analysis and minimum selling price (MSP) calculation by using n^{th} plant analysis. The n^{th} plant analysis was assumed that the process could be scaled up without performance loss when the operating conditions are equal to experimental data. Capital cost was calculated by using ASPEN Economic Analyzer, while operating cost was determined by using cost data used in previous studies for biomass conversion process. The MSP of 1,2-PeD which makes revenue equal to cost was determined using a discounted cash flow analysis.

3. Results and discussion

3.1. Process design

We developed an integrated process to produce 1,2-PeD and THFA from FF. The integrated process included six subsystems: FFA production, 1,2-PeD production, 1,2-PeD purification, wastewater treatment (WWT), utilities, and storage (Figure 2).
Gaseous FF (42,900 t/y) was sent to a fixed bed reactor (R-1 in Figure 2) using Cu-MgO catalyst, and it was hydrogenated to FFA under H_2-rich condition. After FF hydrogenation, a resulting mixture containing FFA, unreacted H_2, and BR was sent to a flash tank (S-1 in Figure 2) at 393 K and 1 bar. Unreacted H_2 stream (14,700 t/y) obtained from the top of S-1 was recycled to R-1, while bottom liquid (58,600 t/y) was

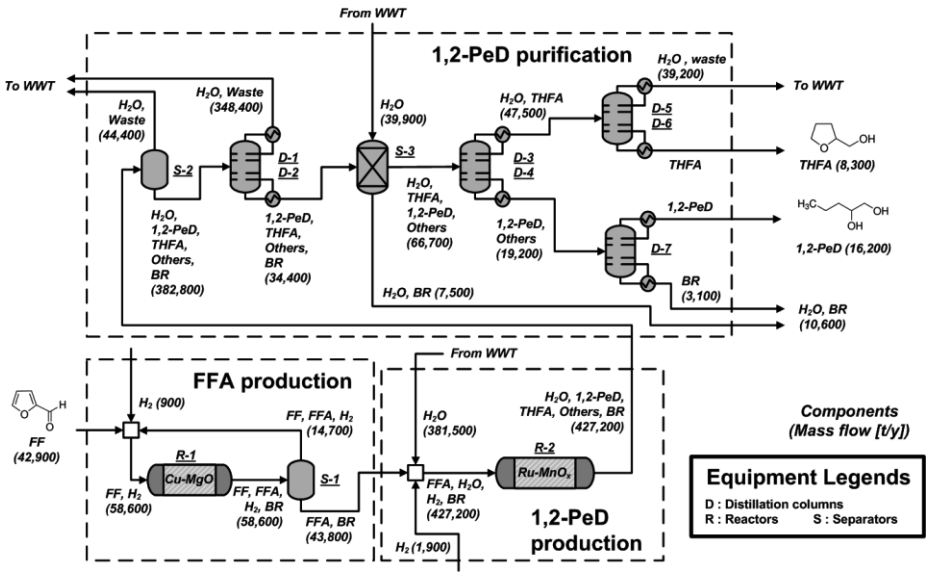

Figure 2. Simplified process flow diagram for the integrated process to produce 1,2-PeD and THFA from FF

sent to an autoclave reactor (R-2 in Figure 2) using Ru/MnO_x catalyst. After FFA conversion, the resulting mixture (427,200 t/y) containing water, 1,2-PeD, THFA, biomass residue (BR), and others was sent to 1,2-PeD purification subsystem to recover high purity (99 wt %) chemicals (1,2-PeD and THFA). First, 99 % of water (392,800 t/y) was separated from the mixture through a flash tank (S-2 in Figure 2) and two distillation columns (15-stage distillation column (D-1) and 10-stage distillation column (D-2) in Figure 2) connected in series. When the most of water was separated, 56 % of THFA was removed with water. Then, the bottom liquid obtained from D-2 was sent to a pressure filter (S-3 in Figure 2) to separate BR with the addition of water. BR can be used as a heat source by combustion, and it was considered to be sold as a fuel. After BR separation, THFA and water (47,500 t/y) was separated by two distillation columns (10-stage distillation column (D-3) and 20-stage distillation column (D-4) in Figure 2) and it was sent to two distillation columns (20-stage distillation column (D-5) and 3-stage distillation column (D-6) in Figure 2) to recover 99 wt% of THFA (8,300 t/y). The bottom liquid (19,200 t/y) obtained from D-4 was sent to a 40-stage distillation column (D-7 in Figure 2), and 99 wt % of 1,2-PeD (16,200 t/y) was obtained at the top of D-7.

Consequently, 95 % of 1,2-PeD and 39 % of THFA were recovered by the 1,2-PeD purification subsystem, respectively, and the total numerical yield for FF-to-1,2-PeD and THFA was 53 %.

3.2. Heat integration

When 30.4 megawatt-equivalent (MW_e) of FF and 11.1 MW_e of H_2 were processed to produce 24.3 MW_e of chemicals (1,2-PeD and THFA) and 6.6 MW_e of BR, the integrated process required 43.0 megawatts (MW) of heating energy, 75.9 MW of cooling energy, and 0.1 MW of electricity. The largest heat energy (35.7 MW) was required for 1,2-PeD purification subsystem, and 74 % of heat energy (26.4 MW) was required to remove water solvent. Because the total heating requirement was much larger than electricity requirement, we only conducted a heat integration to minimize the heating requirements. After heat integration, 57 % of heating energy (24.7 MW) was recovered, and the heating energy requirements were reduced to 18.3 MW. The energy flow in the integrated process after heat integration was shown in Figure 3. The energy efficiency which was the ratio of energy input (FF, H_2, primary energy) and energy output (1,2-PeD, THFA, BR). The energy of chemical species (FF, 1,2-PeD, THFA, BR) was calculated based on higher heating value, while the primary energy was calculated based on biomass-to-heat and electricity production efficiency (71 % and 30 %). The energy efficiency of the integrated process after heat integration was 45 %, which was 15 % point higher than the process without heat exchanger network.

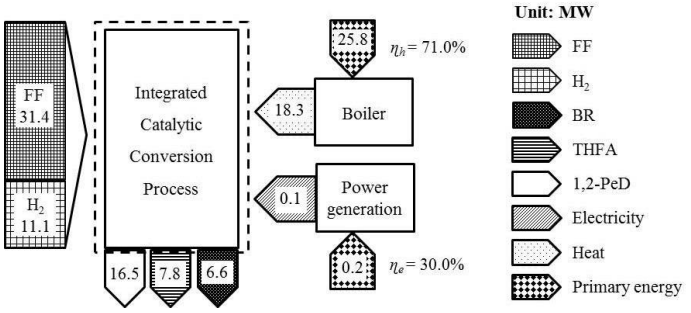

Figure 3. Energy flow diagram after heat integration

3.3. Economic analysis

Capital and operating costs for the integrated process were calculated based on simulation results, and all costs were converted on an annual basis to analyze significant cost drivers for the integrated process. Total cost (TC) for the integrated process was \$ 63.2 million per year (\$ million/y), and it was calculated by the sum of annualized capital cost (ACC) and annualized operating cost (AOC). Annualized costs for the integrated process were shown in Table 1.

Capital costs including direct and indirect costs, land cost, and working capital cost were annualized by capital charge rate calculated from a discounted cash flow analysis. ACC for the integrated process was \$ 7.4 million/y (12 % of TC), and the 1,2-PeD production (\$ 2.5 million/y, 4 % of TC) and purification (\$ 1.7 million/y, 3 % of TC) subsystems had the significant share of capital cost. Operating costs consisted of variable costs (material, utility, other variable operating costs) and fixed costs (labor, maintenance, insurance). AOC for the integrated process was \$ 55.9 million/y (88 % of TC), which was about 7.6 times that of ACC. FF cost (\$ 43.0 million/y, 68 % of TC) had the largest share of total AOC, followed by the H_2 cost (\$ 5.9 million/y, 9 % of TC). By-product revenue for the integrated process was \$ 12.9 million/y, and it consisted of THFA (\$ 12.4 million/y) and BR (\$ 0.5 million/y) revenues.

The MSP of 1,2-PeD was determined to ensure that TC and total revenue were the same by using discounted cash flow analysis, and it was expressed in terms of tonnes of 1,2-PeD ($/$t_{1,2\text{-PeD}}$) for the integrated process. The MSP of 1,2-PeD for the integrated process was \$ 3,118/$t_{1,2\text{-PeD}}$, and it was close to the market price of 1,2-PeD (\$ 3,000/$t_{1,2\text{-PeD}}$). In this process, high price of FF and loss of THFA in the separation process led to increase the MSP of 1,2-PeD. If a cost-effective process to produce FF from biomass and recover process to highly recover THFA is considered as a further study, the MSP of 1,2-PeD can be lower than the market price.

Table 1. Annualized capital and operating costs

	Value (\$ million/y)	Ratio (% of TC)
Total Cost (TC)	63.2	
Annualized capital costs (ACC)	7.4	12
FFA production	0.8	1
1,2-PeD production	2.5	4
1,2-PeD purification	1.7	3
WWT	0.7	1
Storage	0.4	1
Utilities	1.2	2
Annualized operating costs (AOC)	55.9	88
Variable operating costs	52.6	83
FF	43.0	68
H_2	5.9	9
Utility	3.4	5
Other variable operating costs	0.4	1
Fixed operating cost	3.3	5

* Other variable operating costs consist of water, WWT chemicals, and catalyst regeneration

4. Conclusions

In this paper, we developed a large-scale process for the production of 1,2-PeD from bio-renewable FF and showed the economic feasibility of the process. We designed the integrated process producing 16,200 t/y of 1,2-PeD from 42,900 t/y of FF based on experimental data. The developed process required large amount of heating energy, and heat integration was conducted to reduce the heating requirements. Fifty-seven percent of heating energy was recovered by heat integration, and the energy efficiency was increased from 30 % to 45 %. In this process, operating cost was significantly larger than capital cost. The FF cost was the largest cost driver among the operating costs, and it accounts for 71 % of total cost. The MSP of 1,2-PeD was \$ 3,118/$t_{1,2\text{-PeD}}$, and it was close to current market price of 1,2-PeD.

Abstract

A process for methanol production from natural gas containing 30-80% CO_2 was analyzed. For this design a partial feed hydrogenation process is followed by a combined reforming operation and H_2 injection in order to obtain syngas of appropriate quality. A methanol plant of 400,000 t/y that uses a Lurgi reactor for the synthesis reaction, was simulated to obtain mass and energy balances. Although the total amount of required H_2 increases with the CO_2 content up to $H_2/CO_2 \approx 2$, it is considerably lower than the quantity required by direct CO_2 hydrogenation processes. It was also demonstrated that the reformer size decreases and the global CO_2 conversion to methanol increases leading to lower emissions. An economic analysis showed that this methanol process has lower investment costs, but higher operating costs in comparison with a methanol plant based on CH_4 steam reforming. This is related to the high H_2 cost, which was assumed to be obtained by water electrolysis. A preliminary financial analysis indicated that a positive net present value based on current H_2 and methanol prices is obtained when the CO_2 content is less than 50%.

Keywords: CO_2 hydrogenation, combined reforming; syngas; methanol synthesis

1. Introduction

Numerous studies are being conducted on methanol production processes based on CO_2 hydrogenation with the aim of reducing the emissions and the high energy consumption of the classical steam reforming process. One proposal is the CAMERE process (Joo et al., 1999), where syngas is produced by application of the RWGS reaction to pure CO_2 at 600 ^oC, followed by a methanol synthesis reactor working under standard conditions. However, CAMERE's industrial applications are mainly limited by the amount and high cost of H_2 produced by a carbon free process. The availability of a high flow of pure CO_2 introduces another technical and economic constraint. An alternative process that partially reduces these difficulties is based on the direct utilization of natural gas (NG) with a high CO_2 content, as available on numerous gas fields, followed by a combined reforming operation (Cañete et al., 2014). However, if the feed contains more than 30-35% CO_2, it becomes necessary to reduce its content by removal or hydrogenation. It has recently been demonstrated (Cañete et al., 2017) that partial hydrogenation of a feed containing 50 % CO_2 using a RWGS reactor operated at 600 ^oC, followed by a combined reforming process at 950 ^oC, leads to a syngas composition close to the one needed for methanol synthesis. In this way, the CO_2 emissions are

reduced and the global conversion of CO_2 is about 25 %. Moreover, an economic analysis demonstrated that the introduction of the RWGS reactor followed by a combined reforming furnace and a methanol synthesis reactor leads to lower capital investments for the methanol plant in comparison to the one based on CH_4 steam reforming. However, the operating costs are larger due to H_2 demand, although its incidence on the financial analysis is significantly reduced when compared to a plant based on the CAMERE process. In the present study we have analyzed in technical and economic terms the suitability of the mentioned process for methanol production from NG containing 30-80 % CO_2. The H_2 amount needed for partial hydrogenation of the feed mixture, the energy consumption in the reformer, the global CO_2 conversion to methanol and the amount of emitted CO_2 were estimated as a function of the feed composition. Based on this information, investment and operating costs were determined for a 400,000 ton/y methanol plant.

2. Process scheme and plant simulation

Figure 1 shows the proposed process scheme to produce methanol.

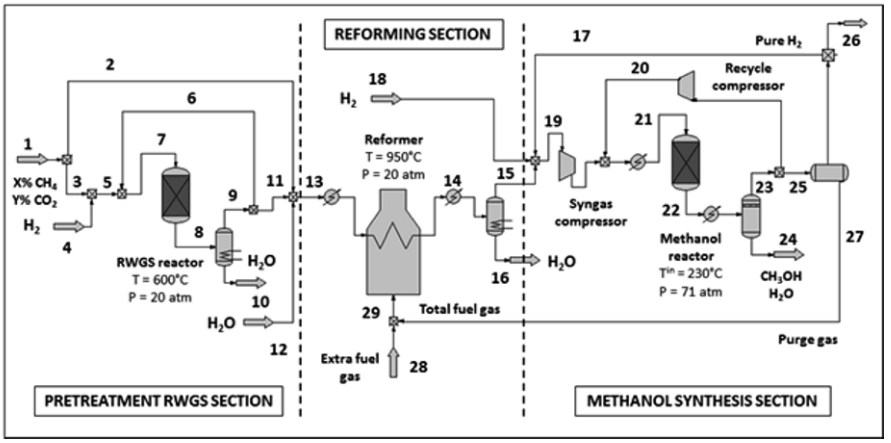

Figure 1. Methanol production from NG with a high CO_2 content. Flow diagram.

The main difference with a conventional methanol plant is the inclusion of a hydrogenation section prior to the reformer furnace. In this step an isothermal RWGS reactor operating at 20 bar and 600 ºC was used to process 40 % of the feed (whatever the CO_2 content), with a H_2/CO_2 ratio of 1.7 and a recycle ratio of 1.9 in order to increase the CO_2 conversion. In Cañete et al. (2017) the energy balances involving the RWGS and the reformer were coupled. The working conditions for the combined reforming furnace were 20 bar and 950 ºC with a H_2O/CH_4 ratio of 2, whatever the feed composition. The methanol synthesis reactor was simulated assuming a Lurgi-type unit operating at 230 ºC and 71 bar with a recycling ratio of 3. The Soave-Redlich-Kwong (SRK) equation of state was also employed for the simulation. The injection of pure H_2 (stream 18) from an external source and/or extracted with a membrane separator from the methanol-loop (stream 17) was considered in order to adjust the composition of the syngas to the value recommended for methanol production (M = 2). When the amount of removed H_2 exceeds what is necessary to adjust the syngas composition, it is used as fuel for the reformer (stream 26). The energy required for the reformer is mainly supplied by the purge gas (stream 27) and NG injection (stream 28). Kinetic

information of commercial catalysts was used for the RWGS (Joo, 2018) and Lurgi (Vanden Bussche and Froment, 1996) reactors simulation, while the reformer was assumed to be operating at equilibrium conditions. The RWGS reactor was simulated using a heterogeneous model and taking into account mass transfer limitations in the catalyst pellets. On the other hand, a pseudo homogeneous model was used for the methanol synthesis reactor. Reactor tubes of 1.5 inches in diameter and a length of 7 meters were adopted. A plant to produce 400,000 ton/y of methanol was simulated under steady state conditions using the gPROMS platform (PSE, 2017) in order to obtain the corresponding mass and energy balances.

3. Results and discussion

3.1. Simulation

The simulation work allowed us to obtain the flow rate and composition of all process streams identified in Figure 1. From this information, CO_2 conversion in the RWGS reactor, the conversion of CO_2 and CH_4 in the reformer, the methanol yield, the global CO_2 conversion into methanol and CO_2 emissions were calculated. In addition, the feed flow rate, the H_2 consumption and the NG amount that is necessary as reformer fuel were also estimated. It is important to remark that the extra H_2 requirement was considered to have been obtained from a zero emission source, such as water electrolysis. This consideration has a direct impact on the economy of the process, as it will be shown in Section 3.2. The results are presented in Table 1 as a function of the CO_2 content in the NG. Before proceeding with a detailed analysis of these results, it is interesting to note that the estimated size of the RWGS reactor was not significant when compared with the reformer or the methanol synthesis units. Regarding the size of the methanol reactor, it was found that, when the CO_2 concentration varied from 30 to 80 %, the number of catalyst tubes required in order to produce 400,000 ton/y of methanol increased slightly, from 3,912 to 4,117 units. Consequently, it may be assumed that the size of the methanol reactor is independent of the feed composition.

Table 1. **Main simulation results**

CO_2 %	Feed (kmol/h) CO_2+CH_4	X_{CO2} RWGS (%)	X_{CH4} REF (%)	X_{CO2} REF (%)	Yield CH_3OH* (%)	F_{CH4} (kmol/h)	CO_2 emission (ton/y)	X_{CO2}^{G}** (%)	F_{H2} (kmol/h)

80%	1,943	63.8	94.9	44.2	82.0	248	162,285	70.0	3,386

* Yield = $[F_{CH3OH}^{S22} - F_{CH3OH}^{S21}]/[F_{CO2}^{S19} + F_{CO}^{S19}]$

** Global CO_2 conversion = $[F_{CO2}^{S1} - (F_{CO2}^{S29} + F_{CO}^{S29} + F_{CH4}^{S29})]/[F_{CO2}^{S1}]$

According to the results in Table 1, the feed flow rate of NG +CO_2 to the plant is nearly constant because it exhibits a maximum variation of 7 %, as a function of CO_2 content. Assuming that the feed gas price is proportional to the heating value, a large reduction of this operating cost is expected as CO_2 concentration increases.

The overall CO_2 conversion in the hydrogenation reactor was nearly constant (63-66 %). Consequently, the CO_2 amount to be hydrogenated and the hydrogen required for the RWGS reaction (stream 4) increased with the CO_2 content in the feed. It went from 411 to 1057 kmol/h when the CO_2 content in the feed moved from 30 to 80 %.

Despite the CO_2 hydrogenation process, the feed to the reformer (stream 13) became richer in CO_2 as the concentration in the feed mixture increased. Therefore, the incidence of the dry reforming reaction in the CR process was higher and the CO_2 conversion in the reformer shifted from 7.9 to 44 %. Despite the increase in the extent of the reforming reactions, the energy required to heat the reactants and to maintain the reaction temperature decreased, mainly due to the fact that the amount of H_2O feed to the reformer decreased as the CO_2 concentration became higher. For this reason, the amount of NG that was necessary as extra fuel also decreased, as reported in Table 1. The dependence of the total energy required for the reformer as a function of the CO_2 content is shown in Table 2.

Table 2. Energy demand for the reformer as a function of the CO_2 content

%CO_2 (S_1)	30	40	50	60	70	80
Q (MW)	186	158	136	117	98	82

As the CH_4 conversion increases slightly, the quality of the syngas emerging from the reformer is characterized by a decreasing M module, as shown in Table 3. Therefore, increasing amounts of H_2 are necessary to satisfy the condition of M=2 for methanol synthesis, as shown in Table 3. Approximately 2 mol H_2 per mol CO_2 are required under the most unfavorable condition (80 % CO_2). This amount is considerably lower than the one required for methanol production by the CAMERE process.
In addition to an M module equal to 2, a common industrial practice in methanol production is to restrict CO_2/CO ratio to less than 0.5 and to limit CO_2 concentration at the loop entrance to 8 %. In the present study, these conditions are satisfied well for feed mixtures containing 30 to 60 % CO_2.

Table 3. Dependence of the syngas M module on the CO_2 content

% CO_2	30	40	50	60	70	80
M	1.94	1.56	1.26	0.96	0.65	0.36
H_2 (S18) (kmol/h)	0	620	762	1,265	1,816	2,329

In view of the results in Table 1, the methanol yield is higher than 80 % for all feed conditions. Accordingly, the methanol concentration at the synthesis reactor end (stream 22) is nearly constant (7.4 – 7.9 %).

Finally, it is important to point out that a large reduction in the amount of emitted CO_2 was achieved as a result of the diminution in the amount of NG employed as fuel and the parallel increase in CO_2 conversion in the reformer. The results in Table 1 indicate

that the global CO_2 conversion in the methanol plant increased continuously from a negative value up to 70 %, when the CO_2 feed content moved from 30 to 80 %.

3.2. Economic analysis

Taking into account that the proposed process presents advantages (lower feed cost; reduced energy demand in the reformer) and a main disadvantage (increased demand of high cost H_2), when it is compared to a classical methanol plant, an economic and financial analysis was performed to evaluate the feasibility of an industrial application. The RWGS reactor, the reformer, the turbine and the recycling compressors were considered in order to determine the capital costs. Equipment purchase and installation costs were estimated using Ulrich´s method (Ulrich & Vasudevan, 2004). These values were updated with The Chemical Engineering Plant Cost Index (2016). The total investment cost was found to be lower compared to a methanol plant based on CH_4 steam reforming. The consumption of NG with a high CO_2 content, pure NG as a fuel (0.139 US$/m^3), process and cooling water and H_2 produced by alkaline electrolysis (4 US$/kg), were considered in order to evaluate the operating costs. Regarding H_2 cost, the considered price is perhaps below the one resulting from water electrolysis when electricity from renewable energy sources is used. However, the chosen value (4 us$/kg) is much higher than the one corresponding to hydrogen produced by classical steam reforming (approximately 2 us$/kg). We have not included the electrolysis plant as a part of the process scheme and consequently, it was not present in the economic analysis. The price of NG with CO_2 was calculated as a function of the heating value. Mainly due to the high cost of H_2, the operating costs were in all cases higher than those expected for a typical methanol plant. In order to determine the feed conditions that make the proposed process viable, the net present value (NPV) was determined assuming a methanol price of 396 US$/t, which is an average price (Methanex, 2017). An interest rate of 10 % was considered for the NPV calculation. The additional information required for NPV calculation was taken from a previous study (Cañete et al., 2017).

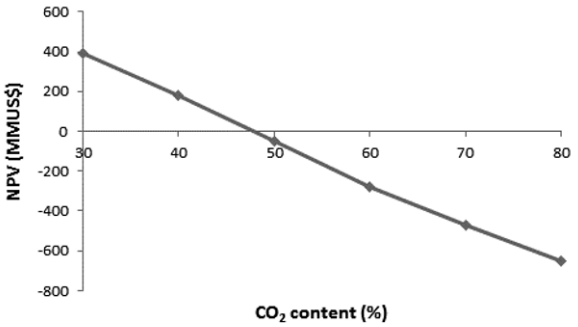

Figure 2. NPV vs CO_2 feed content.

Figure 2 shows that a positive NPV value is obtained when the CO_2 content in the feed is below 50 %. By using a similar procedure, it was determined that the H_2 price should decrease to 2.9, 2.5 or 2.4 US$/kg in order to obtain positive NPV values for feeds containing 60, 70 and 80 % CO_2, respectively.

4. Conclusions

Natural gas with CO_2 content in the 30 to 80 % range could be used to produce syngas and then methanol if partial hydrogenation of the feed is accomplished prior to a combined reforming furnace. It is shown that a substantial reduction in H_2 consumption is achieved in comparison with methanol processes based on total CO_2 hydrogenation. It is also demonstrated that the energy required for the reformer operation decreases as the amount of CO_2 in the feed increases. As a result, operational and investment costs for the reformer are reduced. Other favorable results are a high methanol yield (>80 %) and an increasing global CO_2 conversion, due to the higher incidence of the dry reforming reaction in the reformer. Consequently, CO_2 emissions are much lower. Despite the reduced H_2 consumption, an economic analysis demonstrated that operating costs are higher than those of a methanol plant based on CH_4 steam reforming. However, a financial analysis showed that the proposed process leads to a positive NPV value for a feed containing up to 50 % CO_2, provided that an H_2 cost of 4US$/kg is assumed. For a feed containing more than 50 % CO_2, H_2 price should be from 30 % to 40 % lower for the process to be competitive.

Abstract

Atomic Layer Deposition (ALD) is used to fabricate ultrathin and conformal thin film structures for many semiconductor and thin film device applications. ALD is particularly advantageous for integrated circuit manufacturing which requires control of film structure in the nanometer or sub-nanometer scale. A growing area of interest is Cu interconnect encapsulation with thin Co films. Thin Co films have been shown to greatly improve electromigration performance of Cu interconnects in integrated circuits. Further shrinkage of electronic devices brings new challenges for more selective and controlled deposition of thin Co films. By bridging atomistic and reactor scales, this paper will focus upon applying the systems approach to precursor design to better understand the interaction of relevant substrates and process conditions with the organometallic precursors used to deposit thin Co films.

First-principles analysis of ALD mechanisms can significantly decrease experimental costs through initial virtual screening of both potential precursors and surface cleaning requirements. Simultaneously, these studies can also improve the fundamental understanding of precursor stability and surface reactivity. In this collection of studies, Density Functional Theory (DFT) at the BLYP/DNP level of theory was employed to study ligand dissociation energies, decomposition mechanisms, adsorption/desorption, and surface reactions of various commercially available Co precursors on substrates found in common integrated circuits. These studies have employed both gas-phase and periodic surface slab models in efforts to balance computational time and accuracy. Cobalt precursors considered include Co amides and Co carbonyls with cyclopentadienyl, allyl, and alkyne ligands. These studies have also investigated Co nucleation on various substrates by direct comparison of precursor adsorption and dissociation energies on small Co clusters relative to the underlying substrate surface.

Atomistic modeling results agreed with experiments and have provided insights on the parameters which should be considered in the systematic design of new ALD precursors for thin Co film deposition. This work demonstrates how theoretical investigations in parallel with experiments are directly impacting precursor discovery and deposition understanding in industry.

Keywords: Computational chemistry, Density Functional Theory (DFT), nonlinear eigenvalue problem, product design, surface reactions

1. Theoretical Background

1.1. Atomic Layer Deposition (ALD) reactor system

ALD is a thin-film manufacturing process in which the growth surface is exposed to an alternating sequence of gas-phase chemical precursor species separated by purge periods to prevent gas-phase reactions. ALD is characterized by self-limiting heterogeneous reactions between the gas-phase precursor species and surface-bound species, which, when allowed sufficient conditions to reach saturation, results in highly conformal thin films, on both planar and non-planar geometries, with atomic level control of film deposition. The rate of ALD depends strongly on the instantaneous state of the growth surface, and this state changes continuously through each exposure and purge period. Due to the heterogeneous nature of these ALD reactions, adsorption, desorption, and surface reaction kinetics play a crucial role in the deposition process. The overall ALD reactor material balance follows Eq.(1). Here the total moles of gas-phase species in the ALD reactor, $m_{rxr}(t)$, is a function of total molar flow rates of the feed gases, $\dot{m}_{in}$, and residual product gases, $\dot{m}_{out}$, and the instantaneous rates of precursor consumption, Γ^{react}, and leaving group production, Γ^{prod}, per unit area of the total growth surface, A_{rxr}, due to the deposition reactions.

$$\frac{dm_{rxr}}{dt} = \dot{m}_{in} - \dot{m}_{out} + (\Gamma^{react} + \Gamma^{prod})A_{rxr} \quad (1)$$

This paper will apply computational chemistry, specifically Density Functional Theory (DFT), to estimate the underlying thermodynamic driving forces for reaction rates, Γ, in Eq.(1) related to surface deposition. In turn detailed understanding of thermodynamic driving forces will allow for targeted product design and discovery of new precursors.

1.2. Density Functional Theory (DFT) - Molecular structure and energetics

DFT begins with a theorem by Hohenberg and Kohn (1964), which states that all ground-state properties of a polyatomic system are functionals of the charge density, n(**r**), in Eq.(2). For constrained nuclear positions (Born-Oppenheimer approximation), the modified Kohn-Sham (KS) DFT self-consistent field (SCF) procedure is used to solve the coupled set of KS equations in Eq.(3), which constitutes a nonlinear eigenvalue problem. Here ψ is an eigenvector of molecular orbitals (KS one-electron orbitals) dependent on electron position **r**, ε is a set of molecular orbital energy eigenvalues, and $\hat{h}_{KS}$ is the KS Hamiltonian matrix operator corresponding to the total electronic energy of the polyatomic system, where N is the total number of occupied molecular orbitals.

$$n(\boldsymbol{r}) = \sum_{i=1}^{N} |\psi_i(\boldsymbol{r})|^2 \quad (2)$$

$$\hat{h}_{KS}\psi_i(\boldsymbol{r}) = \varepsilon_i\psi_i(\boldsymbol{r}) \qquad i = 1, N \quad (3)$$

In practice, it is convenient to expand the molecular orbitals, ψ, as a linear combination of atomic orbitals (basis functions), χ, forming a basis set given in Eq.(4), where M is the total number of basis functions. Because atomic orbitals are not necessarily orthonormal, Eq.(3) is reformulated to Eq.(5), where **F** is the Fock matrix approximating the single-electron energy operator, **C** is an eigenvector of molecular orbital expansion coefficients, ϵ is a set of molecular orbital energy eigenvalues, and **S** is the overlap integral to ensure atomic orbital orthogonality.

$$\psi_i(\boldsymbol{r}) = \sum_{j=1}^{M} C_{ij}\chi_j(\boldsymbol{r}) \qquad i = 1, N \quad (4)$$

$$\boldsymbol{FC} = \epsilon\boldsymbol{SC} \quad (5)$$

The orbital coefficients, **C**, that are varied to minimize the total electronic energy are dependent on the energy through **F** and **S** so an iterative SCF procedure is used. This procedure requires solution of the secular determinant in Eq.(6). In each SCF cycle, new **F** and **S** are constructed. In Eq.(7), the matrix elements of **F** are given in *bra* (for ⟨|) and *ket* (for |⟩) notation which resemble outer and inner products in linear algebra. The **F** matrix elements are one-electron integrals for kinetic energy and external potential, and two-electron integrals for coulombic interaction and exchange-correlation (Saad et al., 2010). The eigenvector of coefficients, **C**, and set of energy eigenvalues, ϵ, to construct the density matrix and to calculate new total electronic energy, respectively, are obtained by solving Eq.(6). This procedure is repeated until the input and output charge densities are identical to within a given tolerance. Total electronic energy as a function of charge density is then defined in Eq.(8) as the sum of energy eigenvalues over occupied molecular orbitals and an energy correction, $E_{corr}(n)$. The energy correction can vary depending on the DFT level of theory as the Hohenberg-Kohn theorem provides no guidance as to the form of $E(n)$.

$$\sum_{\upsilon=1}^{M}\sum_{\mu=1}^{M}\left|F_{\upsilon\mu}-\epsilon_k S_{\upsilon\mu}\right|C_{\mu k}=0 \qquad \text{k = 1, M} \tag{6}$$

$$F_{\mu\upsilon}=\left\langle\chi_\mu\left|-\frac{1}{2}\nabla^2+\upsilon(\boldsymbol{r})+\int\frac{n(\boldsymbol{r}')}{|\boldsymbol{r}'-\boldsymbol{r}|}d\boldsymbol{r}'+\upsilon_{XC}\big(n(\boldsymbol{r})\big)\right|\chi_\upsilon\right\rangle \tag{7}$$

$$E(n)=\sum_{i=1}^{N}\varepsilon_i+E_{corr}(n) \tag{8}$$

To further minimize total electronic energy and optimize geometry, nuclear positions are relaxed after each completed SCF procedure. This is the process of finding a nuclear arrangement where, according to the DFT model of chemical bonding, the net inter-atomic force on each atom is acceptably close to zero, and the position on the potential energy surface is a local energy minimum. This geometry optimization problem follows the objective function definition in Eq.(9) for all nuclei.

$$\min E(\boldsymbol{R})\ \text{s.t.}\ \partial E/\partial\boldsymbol{R}=0\ \text{and}\ \partial^2E/\partial\boldsymbol{R}^2>0 \tag{9}$$

DFT is used to calculate the energy, E(**R**), the derivative of energy with respect to nuclear positions, $\partial E/\partial\boldsymbol{R}$, and the second derivative matrix of the system, $\partial^2E/\partial\boldsymbol{R}^2$, also known as the Hessian matrix, which describes the energy surface curvature at **R**. The optimization algorithm will minimize the atomic forces by a Quasi-Newton method, where $\partial E/\partial\boldsymbol{R}$ is used to estimate Hessian matrix.

2. Precursor Design with Computational Chemistry

2.1. Objectives

Knowledge of the existing ALD process conditions, including the state of the growth surface, is required for establishing the design space for new Co precursors. Computational screening will aid how the design space is mapped more efficiently. When benchmarked against known precursor performance, virtual screening with computational chemistry can be used to create molecular libraries for future experimental testing or to better understand the deposition of existing precursors. The primary objectives of this paper are to study:

- Gas-phase thermal stability and reactivity of Co precursors by comparing ligand dissociation energies.
- Adsorption and initial nucleation energies of Co precursors on various surfaces by comparing adsorption energies on both bulk and cluster-terrace surfaces.

- Surface reaction mechanisms by comparing decomposition energies of a selected precursor to Co metal on various surfaces.

2.2. Computational methodology

For DFT calculations, the Dmol^3 module in BioVia Materials Studio 7.0 software, from Dassault Systèmes was used. All electrons were included for each atom, and the BLYP functional, DNP numerical basis set, and 4.4 Å orbital cutoff were employed. For selected ligand dissociation energies, the more computationally intensive B3LYP functional was evaluated, and the relative ranking of electronic energy differences was the same as the BLYP functional. Global geometry optimization for gas-phase and surface slab systems was achieved by creating multiple input geometries of different conformations and spin state multiplicities. Experimental bulk crystal structures were cleaved at the most thermodynamically stable crystal planes to create surface slab models. The surfaces were then terminated based upon known experimental surface pre-treatment. Cluster-Terrace models were created by geometry optimization of a Co_4 cluster on Ta_3N_5 and SiO_2 substrates. Periodic boundary conditions were applied with atomic constraints on the bottom 2 layers of each 3-layer surface slab to minimize edge effects and improve geometry convergence.

To estimate thermodynamic driving forces, ligand removal, adsorption, and surface reaction energies were calculated by the difference in total electronic energies of reactants and products. For CO and Cp removals from Co-Cp (Figure 1), standard enthalpies of reaction were calculated to evaluate thermal effects. Reaction energies using only electronic energies were found to be within 5% of the standard enthalpies of reaction. Thermal effects were not incorporated for the remaining relative electronic energy differences due to the high correlation between reaction energies and enthalpies. This work instead focuses upon ranking relative electronic energy differences between elementary reaction steps of similar entropic changes (Stowasser and Hoffmann, 1999). This assumption allows for high-throughput screening of precursor candidates, where only promising leads are pursued for more computationally intensive analysis and experiments. The computational time for geometry optimization with electronic energy calculations for each polyatomic system scales with N_b^3 dependence, where N_b is the total number of basis functions. Each DFT calculation was performed on an Intel Xeon 2.2 GHz 16-core compute node.

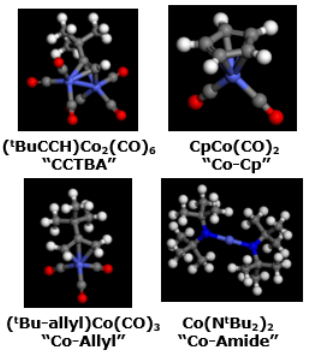

Figure 1: Optimized geometries of Co precursors in this study.

3. Case Studies – Design of Co Precursors for Selective Deposition

3.1. Gas-phase thermal stability and reactivity

Precursor delivery dynamics is an important aspect of the ALD process. Table 1 contains calculated ligand dissociation energies for the Co precursors in Figure 1 to better understand thermal stability and reactivity. It was found that compared to CCTBA, which has known poor gas-phase stability, Co-Cp, Co-Allyl, and Co-Amide showed better gas-phase stability because ligand removal energies are higher or less favorable to dissociate. Co-Cp is the most stable in the carbonyl series. CCTBA is expected to deposit the cleanest

films due to low dissociation energy of the organic ligand, but also it is the least stable. Cleavage of the organic ligand from Co-Cp, Co-Allyl, and Co-Amide requires high energy, which may result in carbon contamination during deposition. Co-reagents are then needed to remove the ligand during deposition.

Table 1: BLYP/DNP Co precursor ligand removal energies in kcal mol^{-1}.

Precursor	Co Oxidation State	Carbonyl Removal	Organic Ligand Removal
Co-Cp	1	28.8	42.3‡
Co-Allyl	1	19.5	30.4‡
CCTBA	0	15.7	1.4
Co-Amide	2	Not Applicable	143‡

‡ Denotes homolytic bond dissociation.

3.2. Surface adsorption and initial nucleation

Multiple growth surfaces were studied because selective deposition is critical for ALD applications such as integrated circuit manufacturing. This study ranks the relative adsorption and initial nucleation energies of Co precursors on various substrates. For the Co precursors in Figure 1, Table 2 contains calculated adsorption energies on bulk Cu, Ta_3N_5, SiO_2, and Co surfaces. CCTBA showed the least difference in adsorption energies between the surfaces. The differences in adsorption energies for Co carbonyl precursors on different surfaces are too small to explain experimentally observed selective deposition. The energy differences required to remove the organic ligand are likely responsible for Co deposition selectivity. Co-Amide showed favorable adsorption energy on OH-terminated SiO_2 with significant difference compared to naked Cu, suggesting preferential nucleation on the SiO_2 surface.

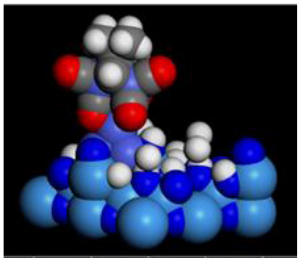

Figure 2: Optimized geometry for CCTBA adsorption on a Co_4 cluster with Ta_3N_5 terrace. Periodic boundary conditions are not shown for clarity.

Table 2: BLYP/DNP Co precursor adsorption energies on various surfaces in kcal mol^{-1}.

Precursor	Naked Cu111	NH-and NH_2 terminated Ta_3N_5 001	OH-terminated SiO_2 001	H-terminated Co001
Co-Allyl	-0.4	-2.1	-4.1	-1.6
Co-Cp	-0.9	-5.8	-3.7	-1.3
CCTBA	-0.3	-0.5	-1.4	0.4
Co-Amide	7.2	5.9	-8.6	-4.3

To quantify adsorption energies beyond the first ALD cycle, cluster-terrace surfaces were developed (Figure 2). Cluster-Terrace surfaces were modeled as a more realistic approach to study the initial stages of Co precursor nucleation, which is an ongoing challenge for the deposition of first-row transition metals (Knisley et al., 2013). Table 3 contains calculated adsorption energies of CCTBA on Co_4/Ta_3N_5 and Co_4/SiO_2 cluster-terrace surface models. In contrast to the adsorption energy on the bulk H-terminated Co surface in Table 2, CCTBA shows stronger adsorption on the naked Co cluster in the cluster-terrace surface model due to the presence of higher energy binding sites. During

adsorption on the metal cluster of the cluster-terrace surface, it was observed that CCTBA underwent spontaneous CO bridging suggesting a possible decomposition pathway consistent with *in situ* infrared absorption spectroscopy experimental observation in literature (Kwon et al., 2011). The differences in energies between cluster and terrace adsorption are lower for the SiO_2 surface than for the Ta_3N_5 surface. This result suggests that CCTBA will have better wetting on OH-terminated SiO_2 than on NH- and NH_2-terminated Ta_3N_5, which is consistent with experimental observations.

Table 3: BLYP/DNP CCTBA adsorption energies on cluster-terrace surfaces in kcal mol^{-1}, where Δ is the absolute difference between cluster and terrace adsorption energies.

Precursor	NH- and NH_2-terminated Ta_3N_5 001 terrace with naked Co_4 cluster			OH-terminated SiO_2 001 terrace with naked Co_4 cluster		
	Cluster	Terrace	Δ	Cluster	Terrace	Δ
CCTBA	-7.7	+4.5	12.2	-7.0	-4.2	2.8

3.3. Surface reaction mechanisms

Reaction energies for the complete decomposition mechanism of Co-Cp with H_2 co-reagent to Co metal on naked Cu and OH-terminated SiO_2 surfaces is shown in Figure 3. Ultimately, Co-Cp showed the best selectivity toward Co deposition on the naked Cu surface as opposed to the OH-terminated SiO_2 surface. The overall Cp ligand hydrogenation and CO removal energies are endothermic for both surfaces, but less favorable on the OH-terminated SiO_2 surface than on the naked Cu surface. Therefore, selective Co deposition on the naked Cu surface is preferred over the OH-terminated SiO_2, which is observed experimentally.

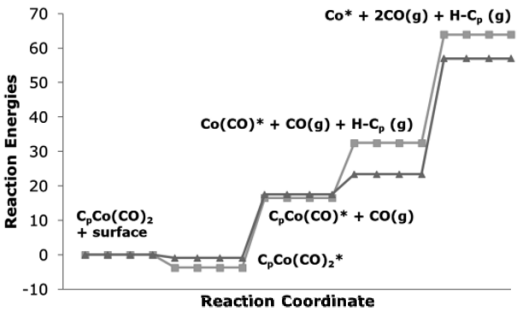

Figure 3: BLYP/DNP reaction energies for Co-Cp decomposition with H_2 co-reagent on naked Cu 111 (▲) and OH-terminated SiO_2 001 (■) in kcal mol^{-1}, where * denotes a surface species.

4. Conclusions

Computational chemistry techniques have been extended to Co precursor design and fundamental deposition understanding. This extension allows for improved mapping of the precursor design space by reducing experiments and providing new atomic-level insights to guide decision making. Future work for Co precursor design and deposition understanding will focus upon introducing thermal effects to current models (Eom et al., 2015) and estimating kinetic parameters for the development of multi-scale ALD reactor models.

Methanol Production from Coke Oven Gas and Blast Furnace Gas

Lingyan Deng, and Thomas A. Adams II*

Department of Chemical Engineering, McMaster University, 1280 Main St. West, Hamilton, Ontario L8S 4L7, Canada
tadams@mcmaster.ca

Abstract

In this paper, a novel process is proposed which converts coke oven gas (COG) and blast furnace gas (BFG) from steel refineries into methanol. Specifically, we propose to use blast furnace gases (BFG) as a carbon source, which is a fuel with a low heating value that contains CO_2 and other gases. CO_2 is stripped from the BFG and blended with H_2-rich COG to adjust the $(H_2 - CO_2)/(CO + CO_2)$ molar ratio for methanol conversion. We also propose an advanced desulphurization process to remove certain sulphur compounds from the COG which can poison the methanol synthesis catalysts. The process design and simulation results using Aspen Plus are reported and used in a feasibility analysis to determine the potential environmental and energy benefits.

Keywords: Coke oven gas, blast furnace gas, COG desulphurization, CO_2 emission reduction, methanol production.

1. Introduction

In steel manufacturing, there are three major by-product off-gases: coke oven gas (COG), blast furnace gas (BFG), and basic oxygen furnace gas (BOFG). BOFG is produced in batch mode, which will not be considered in this particular paper. COG has the highest calorific value and a high H_2 content, while BFG has low calorific value but generally produced in the largest volumes (about 14 times that of COG). BFG consists of about 22 vol.% CO_2, 23 vol.% CO, and the rest mostly N_2. Detailed compositions of COG and BFG are shown in Table 1.

Table 1. COG and BFG compositions. * in PPMV. Source: Yang et al. (2009) and Uribe-Soto et al. (2015).

	HHV	Composition (vol.%)									
	MJ/kg	C_2H_2	CH_4	CO	CO_2	H_2	N_2	O_2	H_2S*	CS_2*	C_4H_4S*
COG	22.6-32.6	1.5-3.0	22-28	5.0-9.0	1.0-3.5	45-60	3.0-6.0	0.1-1.0	3420-4140	72-102	20-40
BFG	2.7	-	-	23.5	21.6	3.7	46.6	0.6	-	-	-

BFG is traditionally combusted for low-grade heat, leading to a very large amount of CO_2 emissions. Since steel manufacturing is a major source of CO_2 emissions, BFG valorization is an important pathway for CO_2 emissions mitigation.

As the world's largest producer of crude steel (Worldsteel Association, 2017), China has the most experience in dealing with steelmaking off-gases. According to the official Chinese Industrial Information website (2012), more than 57 commercialized methanol synthesis plants have been built and successfully operated in China, which use COG as the main raw material. However, the R parameter—the $(H_2 - CO_2)/(CO + CO_2)$ molar ratio—of COG is around 8 due to its large H_2 content. This is too high for methanol synthesis. According to Bermudez et al. (2013), the optimal R parameter is about 2.04. To bring it down, Bermudez et al. (2013) proposed that the reverse water gas shift reaction along with CO_2 injection can be used, or CO from coal gasification syngas can be blended with COG as Wu (2008) explained. However, refineries that co-produce COG and BFG are not taking advantage of the CO_2 and CO available in the BFG.

The idea for using BFG as a CO/CO_2 source is not new. Ghanbari et al. (2013) proposed and optimized a polygeneration system in which COG, BFG, and BOFG are used as raw materials to generate electricity, DME, or methanol. Later works by Ghanbari et al. (2015) studied replacing the coke used in blast furnaces with alternative reduction agents such as biomass, hydrogen, oil, natural gas, pulverized coal, and COG. Economic analyses of the polygeneration system were also performed (Ghanbari and Saxen, 2013). Although these initial studies showed promising results for the concept, they were based on the assumption that COG is sulphur free, and also did not use COG and BFG flow rates / production ratios that are comparable to commercial steel refineries. In fact, the methanol synthesis process is highly sensitive to sulphur: less than 0.1 ppmv in the syngas is permitted as Zhao et al. (2015) and Chen et al. (2009) stated according to commercialized MeOH synthesis experience. Some of the sulphur compounds such as thiophene (C_4H_4S) are particularly difficult to remove. Li (2009) stated that thiophene removal can be achieved with a complex two-stage hydro-desulphurization process which is commercialized in China for COG to Methanol but not for COG + BFG to methanol. Since the prior work did not consider thiophene or other sulphur compound removal, the proposed design structure and corresponding techno-economic analyses are likely to under-predict costs.

Therefore, it is important to consider many possible processes for thiophene removal. According to Wu (2008), two possible thiophene removal methods include (1) two-stage hydrodesulphurization and (2) non-catalyst partial oxidization (NCPO), which can crack methane and organic sulphur compounds simultaneously. Bermudez et al. (2010) and Cao et al. (2007) proposed CO_2 dry reforming (CDR) as a third approach. However, both the NCPO and CDR approaches have only been shown at the lab scale. CDR is a particularly promising technology because it can not only crack organic sulphur compounds and methane at the same time, but also, consume CO_2 to adjust the R parameter. Thus, from a systems perspective, the CDR approach has the potential for secondary benefits by reducing the complexity and size of the COG + BFG to MeOH synthesis process as a whole. Therefore, in this study, we present a new process and analysis which uses the CDR approach.

2. Methodology and Process Description

The proposed process, shown in Figure 1, was modelled in Aspen Plus v10 using the PR-BM physical property package for the gas related units and STEAMNBS for all water streams/operations. First, BFG (having a composition shown in Table 1) is fed to an MEA absorption-based unit (MEA) to extract the amount of CO_2 needed in the downstream process. The detailed MEA process was designed and simulated in ProMax according to the Tobiesen et al. (2007) study on blast furnace CO_2 capture, and the reader is referred

to that work for details. However, only a portion of the CO_2 in the BFG is extracted, since the available supply exceeds the downstream demand. The results of the ProMax simulation were implemented in Aspen Plus via a SEP block. The extracted CO_2 and the COG are fed to the CDR reactor, which is placed inside a furnace and maintained at high temperature (1200°C). In the CDR, the methane in the COG is reformed into synthesis gas, and the thiophene and carbon sulphide in the COG are reformed into H_2S, as demonstrated at the lab scale at this temperature by Zhang and Dong et al. (2010) and Cao et al. (2007). The CDR is modelled with RGIBBS, assuming chemical equilibrium. The results of the model show that organic sulphur is almost entirely converted to H_2S.

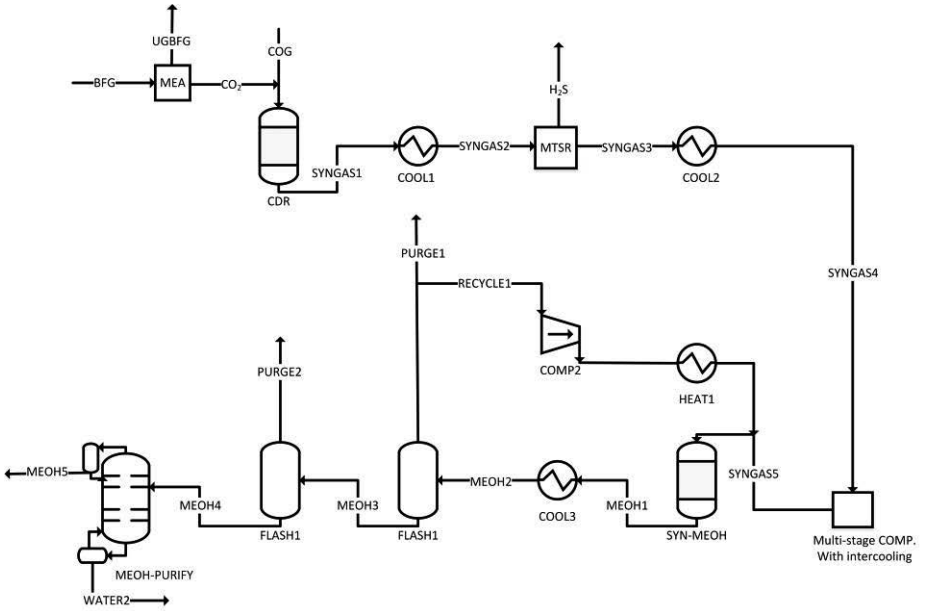

Figure 1. The proposed COG + BFG to methanol process using CDR for sulphur handling.

The reactor effluent is then cooled to 350°C and sent to a solvent-based middle temperature sulphur removal (MTSR) process. The model uses a SEP block for H_2S removal using recovery results from a previously published MDEA-based absorption process and ZnO catalyst-based middle temperature H_2S removal unit proposed by Li (2009), which reduces the H_2S content in the syngas to less than 0.1 PPMV. Note also that there are obvious heat integration opportunities that exist in this process (such as with off-gas recycle) or elsewhere in the steel refinery that were not considered in this work since this is a feasibility study.

The cleaned syngas is then feed to a multistage compressor to pressurize to 100 bar, using default compressor efficiencies (0.72) and air as the inter-stage coolant. The methanol synthesis reactor is a boiling-water shell-and-tube type, which helps maintain the temperature at 240°C. This is modelled using an isothermal RPLUG model with kinetics from Abrol et al. (2012) in order to account for the effects of recycle and inert content on reactor performance. Because economics were not considered in this preliminary study, the dimensions of the reactor (along with downstream recycle ratio) were manually adjusted to strike a balance between reactor yield and reactor weight. The reactor product

is cooled and flashed (using a FLASH2 block), with a percentage of the gas product recycled using a recycle compressor, with the rest being purged (flaring of this purge is not modelled). The liquid product contains methanol with higher-alcohol impurities, which are separated via distillation (modelled using RADFRAC).

The retentate BFG (mostly CO and N_2) could be used for heating in downstream steel manufacturing processes. Alternatively, the CO could also be extracted from the retentate after CO_2 separation via temperature swing adsorption (TSA). According to Ghanbari et al. (2013), up to 99 vol.% of CO could be extracted in this fashion. The high purity CO could then be recycled back to blast furnace (BF) to help reduce the coke requirement. However, the investigation of these options is out of the scope of this study.

3. Results and discussion

The results of the simulation are summarized in Table 2, with key stream conditions provided in Table 3. Overall, the system is effectively able to convert 99.90% of the CS_2 and 100% of the thiophene in the COG into H_2S, and 99.99% of the methane into CO and H_2. The conversion ratios of thiophene and methane increase with CDR reforming temperature, while the conversion ratio of CS_2 decreases with CDR reforming temperature. Approximately 0.58 kg CO_2 (in the BFG) is consumed per kg of MeOH produced.

Table 2. Important Aspen Plus / ProMax simulation results

CS_2 conversion rate (%)	C_4H_4S conversion rate (%)	CH_4 conversion rate (%)	COG production ability (kg-MeOH/kg-COG)	CO_2 consumption (kg-CO_2/kg-MeOH)
99.90	100	100	1.27	0.58

The carbon efficiency (defined as the number carbon atoms in the methanol divided by the number of carbon atoms in the BFG and COG) is 11.77%, which is low because only 10.86% of the CO_2 in the BOG was captured for methanol conversion. A more meaningful metric is the percentage of carbon atoms in the COG + captured CO_2 feed to the CDR that end up as methanol, which is much higher at 91.75%. The total direct CO_2 emissions for this process (through combustion of the two purge streams and of natural gas in the CDR furnace) is 0.85 tCO_2 per tMeOH produced. This is also 0.62 tCO_2 per tonne of raw material that goes into the CDR, which is about 43% lower than if the same amount of raw material are combusted directly (as they sometimes are in steel refineries).

The thermal efficiency—defined as the higher heating value (HHV) of the methanol divided by the sum of the HHV of the COG consumed, the HHV of the natural gas consumed in the furnace, and the utilities consumed in the process (including the MEA section)—is 45.40%. This is actually quite reasonable considering the primary feedstock is a waste source, and can be improved with proper heat integration. For example, the energy needed for heating is about 10.37 kJ/tMeOH, while the energy needed for cooling is about 15.80 kJ/tMeOH, demonstrating ample heat integration opportunities that is left for future work.

Table 3. Key stream conditions

	Temperature (°C)	Pressure (bar)	Flow rate (kg/kg MeOH)	HHV (MJ/kg)
COG	32.00	1.45	0.79	32.58
BFG	70.00	1.00	16.42	2.65
CO_2	70.00	1.00	0.58	0.00
UGBFG	70.00	1.00	11.82	3.67
Purge1	56.40	41.00	0.28	6.60
MEOH5	65.00	1.00	1.03	23.50

Although the CO_2 consumption potential of the process and a reduction of direct CO_2 emissions compared to ordinary combustion has been demonstrated, these results cannot be used to be conclude that this process is better for the environment than the status quo. Instead, a full cradle-to-grave life cycle analysis (LCA) is needed. This would largely be application specific, because although COG and BFG are usually ultimately combusted for one reason or another, how they are used varies from process to process. For example, displacing COG combustion for heat to produce methanol instead would probably require the combustion of some other fuel (likely natural gas) to provide the necessary heat, offsetting the reduction in CO_2 emissions somewhat. Or, displacing COG combustion for electricity generation to instead make methanol would then require increased electricity purchases to make up for the deficit in electricity. This could either increase or decrease the net lifecycle CO_2 emissions depending on the CO_2 intensity of the local grid. There are other secondary impacts which could cause an increase or decrease in net CO_2 emissions, such as the displacement of fossil-based methanol or the potential for increased use of fossil fuels. This is left for future work.

4. Conclusions

A process for converting COG and BFG to methanol has been presented, including the consideration of the removal of thiophene and other sulphur compounds. Overall, about 0.78 kg of COG (typically used for combustion) and 0.58 kg of CO_2 contained in BFG (typically destined for release to the atmosphere) are consumed per kg of methanol produced. The feasibility study demonstrated that the process is reasonably efficient and results in a net reduction in direct CO_2 emissions for a steelmaking process which would traditionally combust all of the COG and BFG for heat or other needs. This indicates that it is a good candidate to consider for a future techno-economic analyses or LCA in order to determine the potential economic and environmental benefits when considering the balance-of-refinery. However, the economic or environmental benefits of this process compared to business-as-usual will vary widely from existing refinery to refinery, and are likely to depend strongly on local factors such as carbon taxes, grid intensity, and the ways in which COG and BFG are currently used. For example, refineries that currently use COG for electricity production that have access to an electric grid with low CO_2 intensity are likely to gain the most environmental benefit by replacing the existing COG-to-electricity process with COG+BFG-to-methanol and purchasing additional grid electricity instead.

Abstract

This project aims to design a novel drug molecule via a computer aided molecular design approach to treat the bacterial infections caused by *Acinetobacter baumannii*. Research is acutely needed to develop novel therapies to treat resistant infections. *A. baumannii*, a pathogen causing infections such as pneumonia and bacteremia is on the highest priority. In order to treat this pathogen, a molecular design problem is formulated with pazufloxacin as a starting point. This multi-optimization problem has two objectives: minimizing MIC (Minimum Inhibitory Concentration) and maximizing the LD-50 value. Quantitative Structure Activity Relationships (QSAR) are created based on 3D-MoRSE descriptors and are used to predict these properties. The optimization problem is formulated using a multi-objective format in order to discover the trade-offs between various solutions. It includes both objectives as well as the structural feasibility constraints, resulting in a multi-objective, mixed integer non-linear program (MINLP). Because of the large number of potential chemical structures and the uncertainty in the structure-property correlations, stochastic algorithms are preferred to solve the resulting MINLP. The problem was solved using a stochastic algorithm, artificial bee colony (ABC), to find a set of near-optimal solutions, corresponding to novel candidate antibiotics. ABC's use of swarm intelligence provides a breadth of information which can be applied to the evaluation of pareto-optimal surface.

Keywords: stochastic optimization, multi-objective optimization, 3D structural descriptors.

1. Introduction

Antibiotics have been helping combat various bacterial infections for over a century. However, bacteria develop resistance towards these drugs, often by developing alternative metabolic pathways to circumvent inhibited ones. WHO recently published an article that describes a list of bacteria which have become resistant to multiple antibiotics, thus specifying the necessity for developing new drug molecules (WHO Report, 2017). *Acinetobacter baumannii* is a multidrug resistant bacteria that thrives in hospital environments and a major cause of nosocomial infections (Perez et al., 2007). In order to treat the infections caused by this bacteria effectively, a novel pharmaceutical is required. The traditional approach of developing a new drug is expensive, time consuming and requires much trial and error. However, computer aided molecular design (CAMD) is a tool that allows the creation of a molecule having certain property values, using comparatively less amount of time and money (Gani et al., 2002).

CAMD uses optimization techniques to form a new molecule. The optimization problem formulated for this work contains two objective functions, and structural feasibility constraints, which results in a mixed integer non-linear program. Due to the non-convex nature of this problem, stochastic algorithms are preferred. We have used the Artificial Bee Colony (ABC) algorithm to find near-pareto optimal solutions to the problem. This is the first time, CAMD approach has been used for the design of an antibiotic molecule using ABC algorithm.

When a molecule having more than one target property value is to be designed using a single objective, the properties are weighed against each other and combined into an equation. The solution of this problem is a point where one property is favored over the other. The goal of multi-objective optimization is to obtain a set of points which represent trade-off between the properties as all the properties are given equal importance. Hence, instead of getting a global or near-optimal value, we get a series points along the pareto-optimal curve. We can then choose one that meets our purpose from a range of points representing different set of property values.

2. Property prediction using 3D-MoRSE descriptors

Property prediction is implemented in this work using structure-property relationships. The property values used in developing such relationships are found experimentally or taken from published data and then correlated using structural descriptors. The structural descriptors used in this work are 3D-MoRSE descriptors, (Molecular Representation of Structure based on Electron diffraction). These descriptors contain information about the 3-D orientation of groups within. This information is obtained from the function called 'molecular transform'. The descriptors are calculated by using Equation 1.

$$I(s) = \sum_{i=1}^{A-1} \sum_{j=i+1}^{A} w_i w_j \frac{\sin(sr_{ij})}{sr_{ij}} \tag{1}$$

where *I(s)* is the MoRSE index, *w* is an atomic number, r_{ij} are the atomic distances between *i* th and *j* th atoms, s represents scattering of electrons by the group of *A* atoms at point r_i and *A* is the number of atoms (Todeschini and Consonni, 2008).

Antibiotics are used to treat the bacterial infection within host body, so it is very important that they are strong enough to inhibit the growth of bacteria. At the same time, they should not cause toxicity to the host which will produce undesired side effects. Hence, MIC and LD-50 value are used as objectives for this work. Both these properties are completely dependent on the biology of the organism. It is very difficult to predict such dependence with the help of topological/2-D descriptors, as they only provide information on the structural features of the molecule and hence work best for predicting physicochemical properties. However, when biological activity of a compound is to be predicted, it is important to consider the way that molecule binds with a biological target to create certain response. For example, in most of the cases for antibiotics, the response is generated when the drug molecule is attached to one of the

enzymes in a micro-organism (Saíz-Urra et al., 2006). Here, we are considering MIC and LD-50 values. MIC values represent the minimum concentration required to inhibit the growth of bacteria. LD-50 values represent the dose that causes death of half of the host population. Both these properties are strongly dependent on the way an antibiotic molecule interacts with receptors in body of the organism in question. Hence, 3D descriptors are needed for effective predictions of biological properties. Also, 3D descriptors have been successfully employed in developing structure-activity relationships in previous work (Schuur et al., 1996).

The quantitative structure activity relationships (QSARs) used in this work were developed for MIC and LD-50 values for an antibiotic class, fluoroquinolones as mentioned before.

Table 1: Correlations and their statistics

Property	**Correlation**	**Correlation Coefficient (R^2)**	**q^2**
MIC	Log(MIC) = 4.74 -0.01*Mor01u - 0.1*Mor02u - 0.59*Mor03u + 1.14*Mor04u + 0.87*Mor07u + 1.18*Mor08u + 3.35*Mor09u + 3.11*Mor10u	0.87	0.88
LD-50	Log(LD-50) = 8.46 +0.01*Mor01u + 0.25*Mor02u + 1.64*Mor03u – 0.72*Mor04u - 3.79*Mor07u + 1.42*Mor08u + 1.38*Mor09u	0.94	0.84

MIC values and LD-50 values were obtained from the literature. Mor01u, Mor02u, Mor03u, Mor04u, Mor07u, Mor08u, Mor09u, Mor10u are 3D-MoRSE descriptors evaluated by the online software e-Dragon (Tetko et al., 2005). Different combinations of these descriptors were used to get best fit models for MIC and LD-50 values using the method of least squares. These models are given in the Table 1. The statistics of the correlations are also shown in the table. q^2 is the prediction quotient that shows how well the correlation predicts the property value, for a similar compound that was not part of the data.

3. Formulation of the MINLP

Since, we are solving multi-objective optimization problem, we have two objectives. They are the QSARs for MIC and LD-50. The constraints include structural feasibility and connectivity constraints. Even though these constraints are not explicitly present in the problem, we make sure that they are accounted, by replacing a group with another group having the same valency. Pharmacophore is part of a pharmaceutical molecule that is responsible for getting the desired biological effect. So, another constraint was implicitly added, which does not allow the pharmacophore structure to change. As it can be seen from Equation 1, the information obtained from molecule is presented in the non-linear form, which introduces element of non-linearity in the optimization problem.

4. Artificial Bee Colony (ABC) algorithm

Many algorithms have been explored in the past to solve non-linear optimization problems. However, a comparative study (Karaboga and Akay, 2009) has shown that ABC, an algorithm based on swarm intelligence, can perform better than other stochastic algorithms. The ABC algorithm is based on the intelligent foraging behavior of a group of honeybees. ABC possesses three kinds of agents: employed bees, onlooker bees and scout bees. These bees are represented in the form of partitioned adjacency matrix of the molecule. The algorithm goes through three phases: the employed phase, the onlooker phase and the scout phase. In the employed phase, a set of feasible solutions are created by changing one group at a time. In the onlooker phase, these solutions are evaluated by onlooker bees and ranked from best to worst depending on their property values. Finally, in the scout phase, if a solution is not improved within a certain number of iterations, it is abandoned and replaced with a new solution. The algorithm repeats itself through these phases until a near-optimal solution is obtained (Karaboga and Basturk, 2007).

The ABC colony algorithm has been successfully used before to solve multi-objective problems (Akbari et al., 2012, Luo et al., 2017). However, this algorithm has not previously been used for multi-objective CAMD problems.

5. Result and conclusion

Drug discovery is a process consisting of many stages. The new molecule designed in this work can serve as a good starting point in that process. CAMD helps us design a molecule and predict its properties before any experiments are carried out. We are interested in getting the property values that are closer to the target property values and ABC algorithm, being stochastic in nature efficiently finds the near-optimal solution. A deterministic algorithm will find the global optimum of an optimization problem, if it exists, however that will definitely take more time than a stochastic algorithm.

The goal of this work was to design a molecule having minimum MIC and maximum LD-50 value. The solutions of the MINLP for both, single objective and multi-objective optimization problems, were pazufloxacin derivatives. The solutions of multi-objective problem were variety of structures offering wide range in MIC and LD-50 values. The use of multi-objective optimization allows to explore the pareto-optimal front, giving multiple solutions. The use of 3D-MoRSE descriptors to develop QSARs resulted in giving mathematical models with higher predictive power. For future work, the performance of ABC algorithm can be studied for different classes of antibiotics and different multi-objective problems.

Design and Control of Diphenyl Carbonate Synthesis involving Single Reactive Distillation with the Feed-Splitting Arrangement

Hsiang-Ning Chang[a], Chien-Ying Chen[a], Hao-Yeh Lee[a*]

[a]*Department of Chemical Engineering, National Taiwan University of Science and Technology, Taipei 10607 Taiwan*
haoyehlee@mail.ntust.edu.tw

Abstract

This study presents an innovative diphenyl carbonate (DPC) process via diethyl carbonate (DEC) and phenyl acetate (PA) as reactants applying single reactive distillation (RD) with the feed-splitting arrangement. This paper uses the boiling point ranking of reactants and feed-splitting to attain the equivalent design. The optimal design was determined by the minimum total annual cost (TAC). In process dynamics, all the product and byproduct can achieve the specifications by using temperature controllers during $\pm$10 % throughput and 10 % composition disturbances. In contrast to Chen et al. in 2015, the results show proposed design can have high energy saving and good control performance.

Keywords: Reactive distillation; Feed-splitting; Diphenyl carbonate; Diethyl carbonate

1. Introduction

DPC is an essential and nontoxic precursor for the polycarbonate (PC) production. With the development of carbonate industry, the need for DPC will be increasing. Kim and Lee (1999) suggested a transesterification way of dimethyl carbonate (DMC) and phenol to manufacture DPC. However, the equilibrium constant for transesterifications of DMC and phenol was only 3×10^{-4} at 180 °C in the research of Tundo and Selva (2002). To overcome this problem, diethyl carbonate (DEC) and phenyl ester (PA) transesterification to produce the product DPC and the byproduct ethyl acetate (EtAc) was proposed. The advantages of this process include higher equilibrium constant and no azeotropes.
The study for the innovative design of DPC process via one RD with the feed-splitting arrangement is divided into five sections. Section 2 presents the thermodynamic and kinetic models. Next, Section 3 explains the DPC process of transesterification reaction from DEC by applying RD and feed-splitting concept. The process dynamics with throughput and composition disturbances are presented in Section 4. The final section is the conclusion of this paper.

2. Thermodynamic and kinetic models

2.1. Thermodynamic model

In this study, the DPC synthesis via DEC as reactant is called DEC configuration. In DEC configuration, thermodynamic properties are described by NRTL model. The experimental vapor-liquid equilibrium (VLE) data were given by Ho et al. (2014). The boiling point ranking is in order of: DPC (302.0 °C) > EPC (239.5°C) > PA (195.7 °C) > DEC (126.8 °C) > EtAc (77.2 °C).

2.2. Kinetic model

The kinetics of DEC configuration were referred to Lin (2014). DPC process is two-step reaction. First step reaction is transesterification of reactants DEC and PA to intermediate ethyl-phenyl carbonate (EPC) and byproduct EtAc. Next step, EPC and PA generate the main product DPC and byproduct EtAc. The two-step reactions are shown in Eq.(1) and Eq.(2).

$$DEC + PA \leftrightarrow EPC + EtAc \tag{1}$$

$$EPC + PA \leftrightarrow DPC + EtAc \tag{2}$$

The DEC configuration used titanium (IV) ethoxide as the homogeneous catalyst. The equilibrium constant rate is described by the Arrhenius equation which is presented in Eq.(3). In addition, the kinetic parameters are listed in Table 1.

$$k_i = k_0 e^{-E_a/RT} \tag{3}$$

Table 1: The kinetic parameters of DPC synthesis

	k_0 (m^3/kmol·s)	E_a (kJ/kmol)
k_1	2.8×10^5	83,973
k_{-1}	6.2×10^0	49,960
k_2	2.4×10^1	49,979
k_{-2}	1.0×10^{-1}	22,676

3. Process design

This section is divided into two parts: conventional/thermally coupled design, and proposed design.

3.1. Conventional RD process and thermally coupled design (Chen et al.,2015)

Chen et al. (2015) investigated DEC configuration with excess PA in thermal coupling design. Figure 1 compared the conventional design (Figure 1(a)) with thermally coupled design (Figure 1(b)). The thermally coupled arrangement is applied between the RD2 and C3 by removing the condenser of RD2. In the thermally coupled arrangement, the vapor stream from the top of RD2 was fed to the distillation column (C3). C3 extracted a liquid stream from stage 5, and this stream was recycled back to the top of RD2. The results show that the thermally coupled configuration can save around 10 % energy requirement than the conventional one.

3.2. Proposed design

This research offered the equivalent design by using the feed-splitting arrangement to adjust PA mole flow rate. According to the boiling point ranking, the heavier component feeds in the upper section of RD. Identically, the lighter component feeds in the lower section of RD. Therefore, the transesterification reaction occurs in the middle section of RD.

This work illustrates the proposed design to achieve 99.5 mol % DPC and 99.5 mol % EtAc for industrial use. There are seven design variables in both configurations which are total stages (N_T), reactive section (N_{rxn}), column pressure (P), the spilt ratio (SR) of PA feed, the 1st PA feed stage ($NF1_{PA}$), the 2nd PA feed stage ($NF2_{PA}$), and DEC feed stage (NF_{DEC}). SR is defined as the 1st PA feed flow rate over total PA feed flow rate. In the terms of catalyst, the decomposition temperature is 312 °C. Hence, the stage temperature over 312 °C was presumed that there is no reaction.

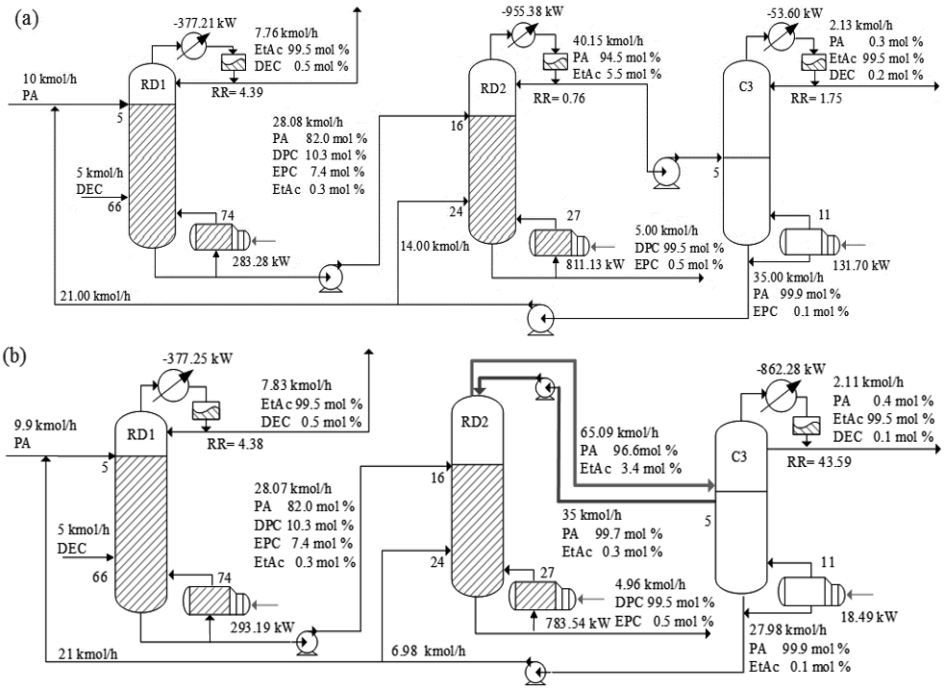

Figure 1: (a) Conventional RD configuration; (b) Thermally coupled design (Chen et al., 2015)

As shown in Figure 2, $NF1_{PA}$ must be arranged upper than NF_{DEC} because DEC has the lower boiling point than PA. The first-step reaction occurred in the top section of the reactive zone to generate EPC and EtAc. To achieve the counter-current flow for reactants in the second-step reaction, the other PA feed location, $NF2_{PA,}$ should be specified at the lower section of the reactive zone to produce DPC and by-product. Hence, the high purity by-product and DPC can be obtained and drained out from the top and bottom of RD column, respectively. Besides, the optimal is determined by the minimum TAC, which is shown in Eq.(4).

$$TAC = TAC_{operating} + TAC_{capital}/3 \tag{4}$$

The optimal results are shown in Figure 2(a). RD involves 59 stages in the total, and reactive section is from stage 2 to stage 47. In the RD column, the fresh PA stream was set 10 kmol/h and split into two streams. $NF1_{PA}$ is located at the second stage of RD. $NF2_{PA}$ is set in stage 47. The SR is 0.35 which means the flow rate of $NF1_{PA}$ and $NF2_{PA}$ are 3.5 and 6.5 kmol/h, respectively. In addition, PA: DEC is 2: 1 in the overall reaction. Therefore, the flow rate of DEC is set as 5 kmol/h and fed in stage 46.

Figure 2 (b) and (c) indicate the composition and temperature profiles of the proposed configuration. As shown in Figure 2 (b), DEC was consumed in the top reactive section because the first-step reaction occurs at the top of the RD column, whereas PA reacted in the middle of the column. Therefore, the mole fraction of PA had a downward trend in the center of the column. The PA mole fraction tended to increase in the bottom portion of the column because the other PA stream was fed in stage 47. Meanwhile, EPC had a slight increase in the bottom column due to the higher boiling point. Furthermore, EPC and PA reacted at the bottom of the reactive section. In the same pattern, EtAc decreased from the top to the bottom of the RD column. In contrast, DPC rapidly increased at the bottom of the RD column. In the temperature profile, the temperature gradually rose from the top to the bottom of the RD column since the transesterification reactions are endothermic reactions.

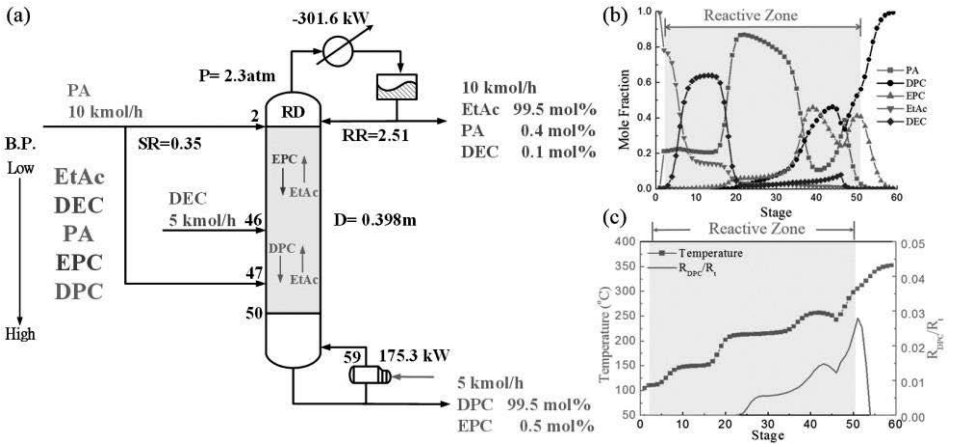

Figure 2: The DEC proposed design of (a) steady-state results (b) composition profile (c) temperature profile

Compared with the study of Chen et al. (2015), the proposed configuration could reduce energy consumption by 75.66 % for condenser duty, 83.97 % for reboiler duty, resulting in a 79.57 % lower TAC.

4. Process dynamics

In the dynamic simulation, two control loop level designs were employed: Inventory control loop and quality control loop. The objective of the inventory control loop scheme is to maintain the system safety. The main purpose of the quality control loop is to attain the product specifications for industrial usage. To be more precise, the quality control loop scheme adopts the temperature controller to meet the product specifications. This work investigated the open-loop sensitivity analysis with 0.05 % change in reboiler duty (QR), feed ratio (FR), reflux ratio (RR), and split ratio (SR). On the basis of sensitivity analysis, the tray temperatures are chosen by finding the location where the temperature profile is steep: stage 6, 18, 37 and 54.

The RGA analysis results of dual and triple temperature control are summarized in Figure 3(a). In CS1, FR and QR were as two manipulated variables for dual-point temperature control. FR was selected to control the stage 18, and QR was selected to control the stage 54. In addition, the tray temperature of stage 18 is controlled by manipulating FR, and the tray temperature of stage 54 is controlled by manipulating RR, named CS2. From triple

RGA analysis, the suggested pairings are 6th stage temperature to pair with RR, 18th stage temperature to pair with FR, and 54th stage temperature to pair with QR in CS3. The proposed overall control strategy, CS3 is presented in Figure 3(b).

The processing throughput was affected by the economic situations in reality. To simulate the actual situations, this research did the ±10 % throughput disturbance and 10 % composition disturbance, and the results are shown in Figure 4 and 5, respectively. Furthermore, this study explores the feasibility of control schemes.

In the proposed configuration, CS3 is the best control structure among three different control strategies. According to the results demonstrated in Figure 4 and 5, the deviation (%) of product DPC and by-product EtAc purities is the smallest in CS3 because CS3 adopted triple temperature control to control the sensitivity trays. CS3 settles to steady state within 6 hours in both throughput and composition disturbance.

(a)

$$\Lambda = \begin{matrix} \text{FR} & \text{QR} \\ \begin{bmatrix} 0.90 & 0.10 \\ 0.10 & 0.90 \end{bmatrix} & \begin{matrix} T_{18} \\ T_{54} \end{matrix} \end{matrix}$$

$$\begin{matrix} \text{FR} & \text{RR} \\ \begin{bmatrix} 0.90 & 0.10 \\ 0.10 & 0.90 \end{bmatrix} & \begin{matrix} T_{18} \\ T_{54} \end{matrix} \end{matrix}$$

$$\begin{matrix} \text{FR} & \text{QR} & \text{RR} \\ \begin{bmatrix} 0.11 & -4.63 & 5.52 \\ 0.85 & -0.66 & 0.81 \\ 0.05 & 6.28 & -5.33 \end{bmatrix} & \begin{matrix} T_6 \\ T_{18} \\ T_{54} \end{matrix} \end{matrix}$$

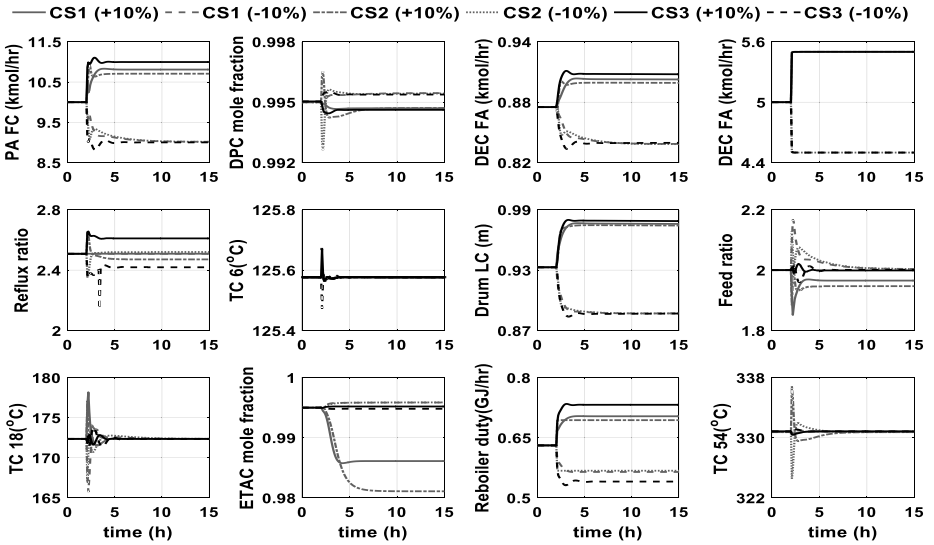

Figure 4: The results of ±10 % throughput disturbance in CS1 to CS3.

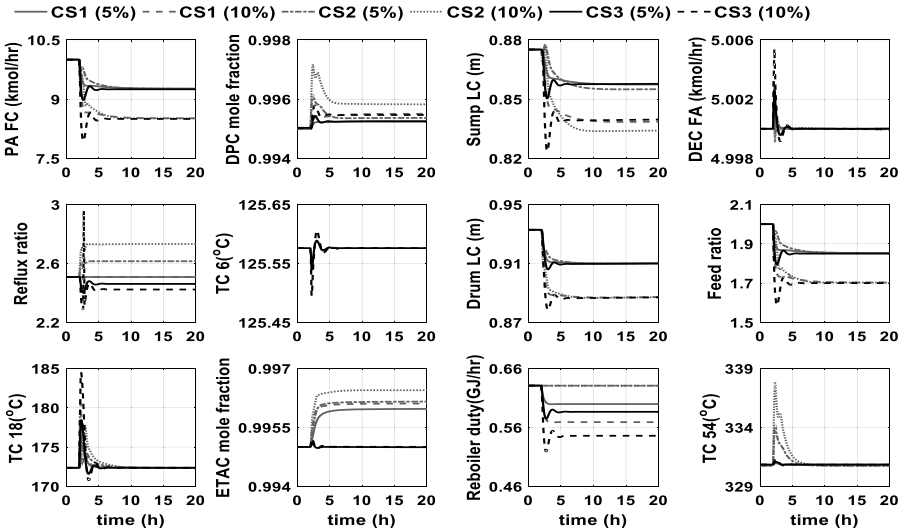

Figure 5: The results of 10 % composition disturbance in CS1 to CS3.

5. Conclusion

This research produced some major contributions: First, in comparison with the studies of Chen et al. (2015), the proposed design combines the RD column and distillation column into single RD column. Besides, there is no remixing effect was observed in the proposed design. Second, compared to the aforementioned design, the DEC proposed configuration with equivalent design can save 75.66 % in condenser duty, 83.97 % in reboiler duty, and 79.57 % in TAC. Third, dynamic performance results reveal that CS3 is the best control scheme in three different control strategies.

Abstract

In this work, a scale-up model of a pharmaceutical batch cooling crystallization process was developed. The model is based on a compartmentalization approach of a large-scale crystallizer. The compartmental properties (*e.g.* volume, location and flux connections) were extracted by using two different, manual and automatic zoning, strategies. Each compartmentalization technique is based on a mixing study in the large-scale reactor with the help of computational fluid dynamics (CFD). The scale-up model was simulated in MATLAB/Simulink environment. The simulation results show the significant role of the fluid dynamics on the simulated process performance in terms of crystal size distribution and final average crystal diameter by means of comparing the multi-compartment model with a single-compartment well-mixed model.

Keywords: Scale-up modeling, pharmaceutical crystallization, compartmental modelling, computational fluid dynamics.

1. Introduction

Prediction of the influence of the crystallizer scale on the process behavior and performance (*e.g.* crystal quality attributes) is one of the major challenges in the design of industrial crystallization processes. Fluid dynamic conditions of large-scale crystallizers are far from well-mixed behavior compared to lab scale systems. This leads to spatial variations of critical process variables such as temperature, super-saturation, particle concentration within crystallizer geometry (Kramer et al., 1999). Crystallization process models based on the assumption of well-mixed behavior are not representative for a scaled-up process, therefore not credible for the use in supporting optimal design of industrial crystallizers. A more detailed insight into mixing behavior and its consequences for local crystallization phenomena – such as a spatially distributed parameter model - must be taken into account in order to achieve reliable process design and scale-up (Kramer et al., 2000, Myerson, 2002). The main objective of this work is to develop a predictive scale-up model of a pharmaceutical crystallization process based on a compartmentalization approach. Fully developed computational fluid dynamics (CFD) models (*e.g.* including the crystallization kinetics, population balance etc.) could be used for modeling the large-scale system, as opposed to compartmental modeling. However,

the major drawback of the full CFD models in the industrial practice is the high computational demand. In comparison, 3 min. transient CFD simulation of a non-reactive mixing in a reactor with 218 L liquid volume and 100 rpm stirrer speed took about 6 days to be completed on a computer cluster with 2x Intel Xeon 2.80 GHz processor with 128 GB RAM. Further implementation of the crystallization kinetics and population balance equation (PBE) into CFD simulation will increase this computational demand from days to weeks. On the other hand, a compartmental model simulation of the same system including crystallization kinetics and PBE for a 50 min. of crystallization, which was run in MATLAB/Simulink on computer with Intel Core i5-6200U 2.30 GHz processor with 8 GB RAM, took 10 min. to be completed. Compartmental modeling is a reduced-model approach, in which the detailed mixing and fluid dynamic information obtained from non-reactive CFD simulation is coupled with the process kinetics in a simpler simulation environment (Wells and Ray, 2005). Besides, this approach provides a unique opportunity to take into account the effects of non-homogeneous mixing on the process performance in many other applications as well *e.g.* process control and sensitivity analysis. While compartmental modeling is a well-known and successfully applied technique in other areas of process engineering, there is a significant lack of study on the full application of a compartmental modeling to scaling-up of a pharmaceutical crystallization processes.

2. Development of The Scale-up Model

2.1. Crystallizer configuration

A pilot scale crystallizer as shown in Figure 1 was used for the development of the scale-up model. The diameter of the vessel, T is 0.64 m and the liquid height, H is 0.74 m, corresponding to a liquid volume of 218 L. A marine type of impeller with impeller diameter, D 0.30 m is located 0.27 m above the bottom of the vessel (impeller clearance, C). Four baffles are located with 9 mm clearance from the vessel wall.

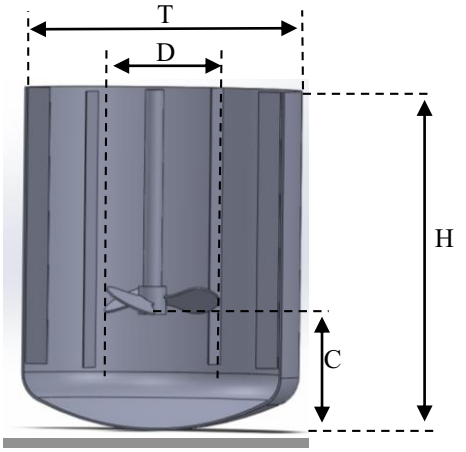

Figure 1. Pilot scale crystallizer.

2.2. CFD simulation

Transient CFD simulations of the crystallizer were performed with ANSYS CFX release 17.1. The representative Navier-Stokes equations were solved to predict fluid dynamics behavior in a single-phase volume. The standard k-ε model was used as the turbulence model. Rotation speed, N was 100 rpm that creates a turbulent flow within the studied

volume. The crystallizer vessel was divided into two domains: a rotating zone (rotating domain) and a stationary zone (stationary domain), which correspond to a cylindrical zone around impeller rotating at the impeller speed and a zone covering the rest of the crystallizer, respectively. The rotation of impeller was modelled with frozen rotor approach as frame change/mixing model between the intersections of two domains. The stationary domain consists of hexahedron mesh of 1,037,970 elements, while the rotating domain consists of tetrahedron mesh with total 118,895 elements. The time step used in the simulations was equal to 0.001 s. When the velocity field was fully developed, or in other terms, the steady state behavior of the velocity components was observed, the simulation was stopped and transient-average value of the flow velocity components was recorded.

2.3. Compartmentalization

Application of compartmental modelling to pharmaceutical batch cooling crystallization requires the division of the crystallizer into a finite number of compartmental volumes. Minimized or negligible gradients *e.g.* in temperature, crystal distribution, super-saturation and energy dissipation should exist within individual compartmental volumes. However, the fundamental challenge is to characterize the network of compartments with respect to volume, location, mass and energy fluxes between adjacent zones as well as the affected properties due to non-ideal fluid mixing (Kramer et al., 1999, Bezzo and Macchietto, 2004). To determine the compartmental zones within the volume of pilot-scale crystallizer equipment, primarily the fluid dynamics, mixing and heat transfer were studied by means of CFD simulations. The results of CFD simulations can be processed through a manual or automatic zoning technique in order to identify the compartments (Delafosse et al., 2010). Manual zoning is a user-dependent method and it can be troublesome and time-consuming especially when handling the complex 3D structures. On the other hand, automatic zoning technique is computationally inexpensive, reliable and practical for 3D geometries (Bezzo et al., 2004, Bezzo and Macchietto, 2004). In the automatic zoning technique, one or several property of the system can be selected as a base criterion for creating the compartments. A tolerance value for this specific property should be specified. The compartments are built-up by the agglomeration of the cells, in which the value of the specific property of the system is uniform with respect to the given tolerance (Delafosse et al., 2010). In this work, both manual and automatic zoning techniques were utilized to analyze results of CFD simulations. In both zoning approaches, three components of the average flow velocity in 3D space were chosen as base criterion, since the mixing in the system significantly is linked to the velocity fields. The compartmental volumes, location and flux connections were extracted from data analysis to define the interconnected compartment network.

2.4. Crystallization process simulation

Seeded-batch cooling crystallization of paracetamol from ethanol (solvent) is chosen as a case study in this work. Related solubility and kinetic data can be found in the literature (Fernandes, 1999, Mitchell, 2012). In the model, a linear cooling rate of 0.4 ^{o}C/min is applied to the initial solution, which has an initial concentration of 0.26 kg paracetamol / kg ethanol and an initial temperature of 40 ^{o}C, for 50 min. The overview of the model is shown in Figure 2. Even though the process is in batch mode, every individual compartments are in continuous mode with multiple inlet and outlet streams. Therefore, the batch process model was extended to continuous crystallizer model for the compartments. The crystallization process modeling based on compartmentalization approach is implemented in MATLAB/Simulink. The same set of model equations and

model parameters are defined in order to solve the conservation balance equations for crystallization process system (population, mass, etc.) for every compartment. However, spatial variations in the crystallizer volume are modelled by temperature gradients between compartments.

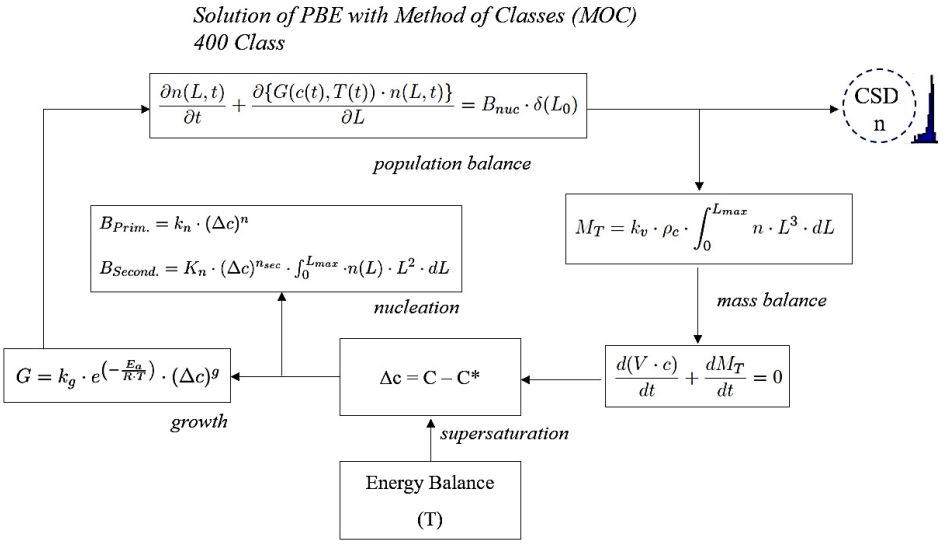

Figure 2. Batch cooling crystallization model (Adapted from Giuletti et al., 2001).

3. Results and Discussion

3.1. CFD simulation and compartmentalization

CFD simulations were performed to study primarily the fluid dynamic behavior in the large-scale crystallizer as mentioned previously in Section 2.1 and 2.2. Besides, heat transfer from a cooling jacket to the liquid in the vessel was also implemented in order to monitor the temperature gradients in the system. The overall flow pattern was extracted in order to be used as a base criterion for creation of the compartments. Total six compartments were detected by manual zoning technique, which is shown in Figure 3. On the other hand, an automatic zoning algorithm was developed in MATLAB environment to analyze the results of the CFD simulations. The network of compartments were identified by accepting the tolerance limit of 0.3 m/s in axial and 0.15 m/s in radial flow vector, at each compartment. The achieved compartmental map with respect to each individual target parameters, radial and axial flow, is illustrated in Figure 4. The results of compartmentalization techniques were used as input in the simulation of scale-up model of pharmaceutical crystallization process in the next section 3.2.

3.2. Simulation of the scale-up model of pharmaceutical crystallization process

The performance of the pharmaceutical batch cooling crystallization process was analyzed in terms of crystal growth rate, crystal size distribution and final average crystal size. The multi-compartment model was compared with a single-compartment well-mixed model to examine the influence of the mixing and corresponding temperature gradients on the process performance. CFD simulations showed that there is a difference in average temperature over time between different locations in the crystallizer vessel, so

called in the different compartments. Hence, crystals are subjected to different growth and nucleation rates in different compartments. This leads to wider final crystal size distribution and less growth (as illustrated in Figure 5) with a final average crystal diameter of 113 µm compared to the single-compartment model (final average crystal diameter is 135 µm).

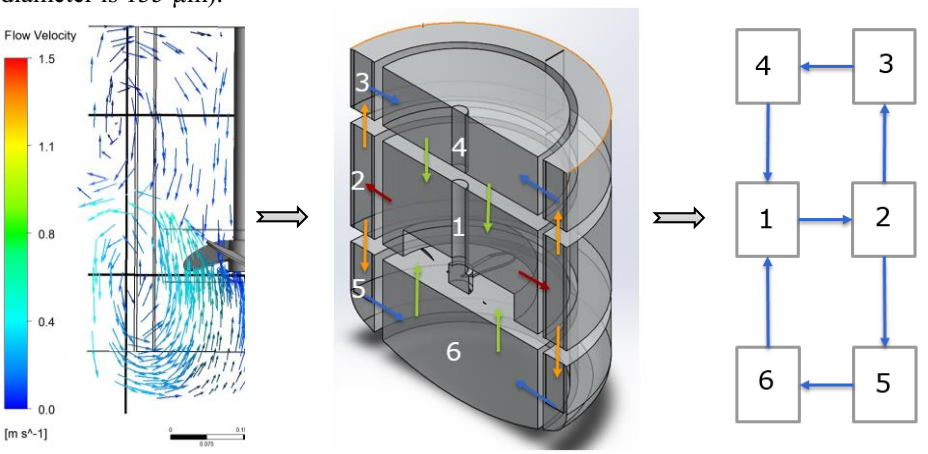

Figure 3. Characterization of compartmental zone network via the manual zoning.

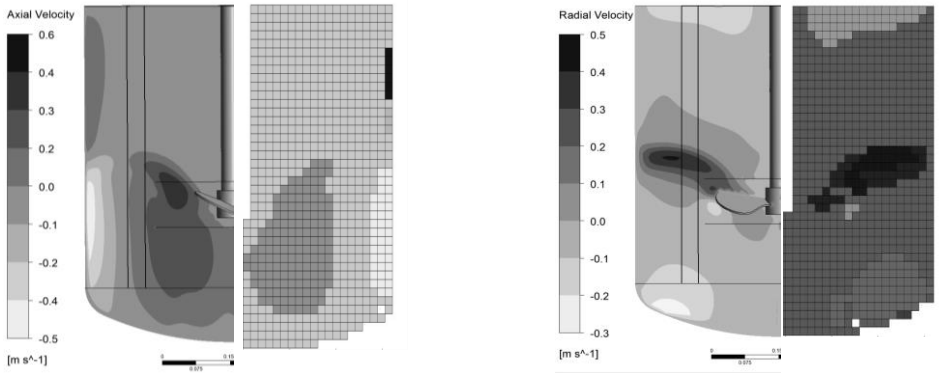

Figure 4. Characterization of the compartmental zone network via the auto zoning with 0.3 m/s tolerance of flow velocity: (left) axial direction, (right) radial direction.

4. Conclusions

A scale-up model of pharmaceutical batch cooling crystallization process was developed based on the compartmentalization approach. Fluid dynamics, mixing and heat transfer in the large scale system were studied by means of CFD simulations. Based on CFD simulations results, compartmental zones in the crystallizer vessel were determined via using both manual zoning and automatic zoning techniques. The simulated process performance in multi compartment model was compared with the single compartment well-mixed model. In this study, it was clearly observed that fluid dynamics and mixing have a significant impact on the final crystal size distribution as well as final average crystal diameter. It plays an important role in scale-up systems and, therefore, it should be taken into account in the modeling large systems. Moreover, future work will focus on

the experimental validation of the results in lab and pilot scale studies as well as compartmental model-based control and monitoring for improved process control of quality attributes.

Optimization of extractive distillation – integrated solvent selection and energy integration

Thomas Waltermann[a*], Tamara Grueters[a], Mirko Skiborowski[a]

[a]*TU Dortmund University, Department of Biochemical and Chemical Engineering, Laboratory of Fluid Separations, Emil-Figge-Strasse 70, 44227 Dortmund, Germany Thomas.Waltermann@tu-dortmund.de*

Abstract

The separation of azeotropic mixtures is of particular importance for bio-based processes in the chemical industry. Extractive and heteroazeotropic distillation are oftentimes the favored solution for medium to large scale processes due to their proven robustness and the economics of scale. The feasibility as well as economic efficiency of these processes depends strongly on the selection of a suitable mass separating agent (MSA). Furthermore, energy integration can increase the energy and economic efficiency of these thermal processes. Since, MSA selection, process design and energy integration are usually performed as consecutive steps in process design, potential synergies are easily missed, resulting in sub-optimal choices. In order to determine an optimal process design, including solvent selection and energy integration, an efficient optimization-based approach for the design of extractive distillation processes is proposed. The application of the method is illustrated for the separation of the azeotropic mixture of acetone and methanol. The results highlight that the optimal MSA choice under consideration of energy integration differs from the selection without energy integration.

Keywords: Extractive distillation, optimization, solvent selection, energy integration

1. Introduction

The separation of azeotropic mixtures is a complex task that is frequently encountered in chemical process design and of special importance for bio-based processes. Despite the availability of potentially less energy intensive separation techniques such as membrane processes, the separation by extractive or heteroazeotropic distillation is often the preferred separation technique due to the proven robustness and favourable economics, particularly for large scale processes (Kiss and Suszwalak, 2012).

The design of extractive and heteroazeotropic distillation processes is particularly challenging due the numerous design degrees of freedom (DDoF) and the integration of the separation and the solvent recovery column. In order to enable a systematic process design often a hierarchical design procedure, such as the one illustrated in Figure 1 is followed (e.g. by Douglas, 1985).

At first possible process variants are generated based on heuristic rules or expert knowledge. This especially includes the selection of a suitable mass separating agent (MSA), which has a significant effect on the feasibility as well as the cost and energy efficiency of the separation process (Julka et al., 2009). Nowadays, computer-aided molecular design methods are readily available and can be used to identify suitable MSA based on a purely computational screening (Gani et al., 2006).

Figure 1 Hierarchical design procedure for process design

Next, the feasibility of the generated process variants is evaluated by means of simplified methods. For extractive distillation the influence of the MSA on the relative volatility between the azeotropic components and the residue curve map of the mixture with the MSA can be analysed (Julka et al., 2009). Such classical methods for the pre-selection of MSA focus only on the general feasibility of the separation. However, a more meaningful analysis already includes the effort for the recovery of the MSA. Such pre-selection in terms of the process performance can already provide an estimate of the economic performance, but requires appropriate shortcut methods, like the rectification boundary method (RBM), which are able to account for the non-ideal thermodynamic behaviour of the mixtures (Brueggemann and Marquardt, 2004; Kossack et al., 2008).

Only a small selection of promising MSA candidates is further evaluated based on detailed process models. In case of extractive distillation this is normally done based on equilibrium-stage stage models in combination with rigorous thermodynamics, while the objective function represents the economic performance. Since each MSA entails its specific optimal process design a simulation-based design approach is very tedious due to the numerous DDoF and the integration of both columns. Optimization-based methods allow for a more efficient economic optimization of the process variants and evaluation of the best MSA (Kossack et al., 2008).

Finally, additional options for energy integration are considered in a consecutive step to further optimize the selected process variant. Energy integration can be achieved by conventional heat integration between the columns (HI), vapour recompression for each column (VRC), or thermal coupling in separate columns (TC) respectively in a divided wall column (DWC). However, the investigation of energy integration options is usually restricted to the previously selected MSA and process design, although the saving potential of the different options depends strongly on the selected MSA. Therefore, a consideration of the different means for energy integration for all promising MSA candidates is desirable, in order to exploit possible synergies and identify the most economic solution.

Since this requires the evaluation and optimization of a large number of process options with a significant number of DDoF, a computationally efficient and reliable design approach is required. Conventional simulation-based process design approaches applying manual procedures (Brito et al., 2016) or the combination of a process simulator and a metaheuristic to optimize the design (Tututi-Avila et al., 2014) are only of limited use. Models and appropriate initialization routines for strongly integrated processes, such as DWC's are mostly missing (Waltermann and Skiborowski, 2017a). Therefore, even if a metaheuristic could efficiently handle all DDoF of the different process configurations, a feasible initial solution would first need to be developed manually for each process configuration and every MSA. The exploitation of equation-based modeling and mixed-integer nonlinear programming (MINLP) enables the creation of tailored optimization models and automated initialization procedures, such that the manual demand can be reduced to a minimum. The current contribution illustrates the potential of such an approach for the design of extractive distillation processes.

2. Optimization-based design approach

The evaluation of the different MSA candidates for extractive distillation based on the process performance of optimized process configurations has previously been addressed by Kossack et al. (2008). The proposed approach considered a shortcut-based evaluation of the minimum energy requirements and a subsequent economic optimization of the most-promising candidates. In order to extend this approach towards different energy integration concepts we combine the approach with our previously proposed optimization-based design approach for the design of azeotropic distillation processes (Waltermann and Skiborowski, 2016; Waltermann and Skiborowski, 2017b). This approach builds on the optimization of superstructure models based on rigorous equilibrium-stage models including non-ideal thermodynamics, embedded in external functions. Different g^E models such as Wilson, NRTL and UNIQUAC, as well as some cubic equations of state are readily available in the implementation. For each specific case only the necessary property parameters need to be provided. The resulting MINLP problems are solved by means of a sequentially relaxed series of nonlinear programming (NLP) problems in combination with an embedded solution of thermodynamic equilibrium computations in from of implicit functions (Kraemer et al., 2009; Skiborowski et al. 2015a).

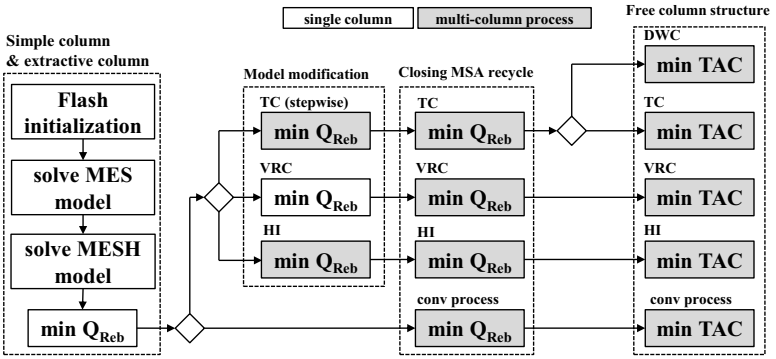

Figure 2 Automatic initialization & optimization routine

The special solution approach considers a set of initialization and optimization models (cf. Figure 2), which enables an automated evaluation of the conventional as well as energy integrated process variants. Therefore, only the separation problem, the constraints and appropriate bounds need to be provided, while no initial solution in terms of a feasible simulation result is required. This enables a numerically efficient evaluation with computational times of less than 20 minutes for each process variant (executed on a PC with a 3.2 GHz quad-core CPU).

3. Case Study – Separation of the azeotropic mixture acetone / methanol

3.1. Problem statement

In order to illustrate the influence of the MSA selection and energy integration on the optimal process design and to demonstrate the developed method, the separation of the azeotropic mixture of acetone and methanol is investigated. A saturated liquid feed with a molar flow rate of 150 mol/s and a composition of 75 mol-% acetone and 25 mol-% methanol is to be separated into product streams with at least 99.5 mol-% purity at a

recovery of at least 99 mol-%. The considered MSA are based on the pre-selection considered by Kossack et al. (2008) and include chlorobenzene, DMSO, ethanol, p-xylene and water. The evaluation of the best process configuration is based on the total annualized costs (TAC). To account for different utility choices low (3 bar), medium (15 bar) and high pressure steam (25 bar) at costs of 12, 14 and 16 €/t, cooling water at 0.05 €/t and electricity for a price of 0.06 €/kWh are considered. An operating time of 8000 h/y and a depreciation period of 10 years with an interest rate of 6 % are assumed to determine the TAC. Column sizing and costing is performed assuming packed columns with Sulzer BX^{TM} structured packings, considering a HETP value of 0.24 m. The non-ideality of the liquid phase is modeled based on the UNIQUAC model and the extended Antoine equation, while an ideal gas phase is assumed. The specific enthalpies are determined based on DIPPR correlations for the calculation of specific heat capacities and heat of evaporation.

3.2. MSA selection based on the conventional process

Taking into account the described economic parameters, the TAC values of the optimized conventional process configurations for each investigated MSA are shown in Figure 3.

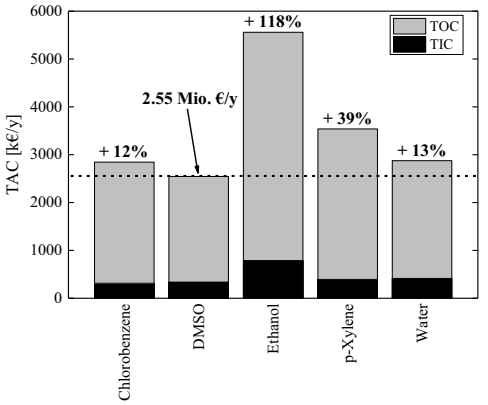

Figure 3 Annualized costs of the optimal designs for the MSA candidates based on the conventional extractive distillation process

Based on the conventional extractive distillation process DMSO is identified as the MSA option with the lowest TAC.

3.3. Influence of energy integration on the optimal process

While the use of ethanol and p-xylene as MSA result in significantly larger costs, the application of chlorobenzene and water results in only marginally more expensive processes. Consequently the latter may be able to outperform the DMSO-based process, if energy integration is considered. The optimal designs of the energy-integrated processes are illustrated in Figure 4. As a reference to the previous results, the costs of the conventional DMSO-based process design are indicated by the dotted line. It becomes apparent that none of the means for energy integration are able to improve the DMSO-based process. While the option to apply compression of the top vapour streams is just discarded in the optimization of the VRC case, the increasing use of high pressure steam in the single reboiler of the TC process and the DWC results in significantly increased operating costs. For DMSO the HI variant is not considered due

to the necessity of either using steam with a pressure of about 100 bar or a fuel heated reboiler.

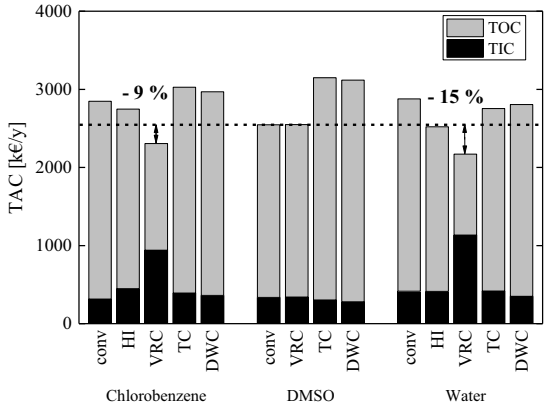

Figure 4 Annualized costs of the optimal, energy-integrated process designs for the MSA candidates chlorobenzene, DMSO and water

For chlorobenzene the TC and DWC options also result in increased operating costs due to similar reasons as for DMSO. However, the HI and the VRC variant allow cost savings compared to the conventional chlorobenzene process. The VRC process is even superior to the conventional DMSO process, allowing for savings of about 9% in TAC.

All considered means of energy integration are able to reduce the TAC of the water-based process. The main reason for this difference to the other two MSA is the lower boiling point of water, which allows for the use of low pressure steam in all cases, except for the HI process. However, the HI water process can still save about 1% of the TAC in relation to the DMSO-based process. Overall, the water-based VRC process results in the most economic process variant, saving about 15% of the TAC of the DMSO-based process. The design of this process is illustrated in Figure 5.

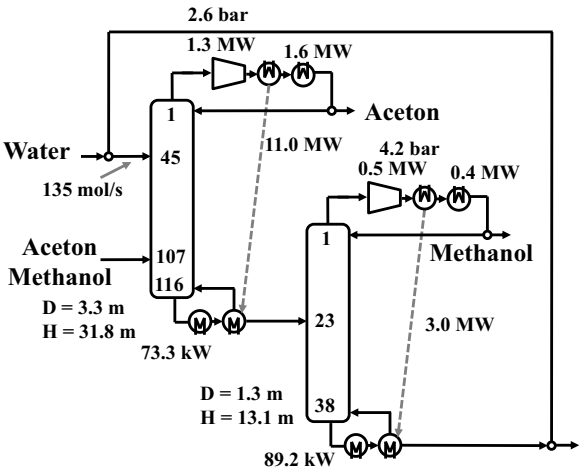

Figure 5 Optimal design of the VRC water process

VRC is used for both columns and thus, reduces the demand for external thermal energy from 13.9 MW to only 0.2 MW. In order to drive the compressors about 1.8 MW of

electrical energy is required. While the capital investment for the additional compressors results in a large increase in the overall capital costs, the operational costs are reduced by more than 50%. Thus, considering an operation beyond the depreciation time, the water-based VRC process will operate at less than half of the cost of the DMSO-based process.

4. Conclusions

In this contribution the influence of an integration of solvent selection and energy integration on the optimal process is investigated. Based on the investigated case study it is demonstrated that the optimal MSA choice under consideration of energy integration can differ from the selection without energy integration. The illustrated advantages require a consideration of the economic performance, since an energy-based evaluation cannot account for the alternating utility requirements and an exergy-based evaluation cannot correctly account for the capital investment of the compression stages. The proposed optimization-based approach allows for a computationally efficient evaluation of the increased number of process variants with the various DDoF, taking into account a selection of promising MSA, means for energy integration as well as the column sizing and operating conditions. The resulting complex optimization problems are solved effectively without the need of an initial feasible solution based on the developed solution approach. In order to further automate and improve the design process future work will investigate the combination of the approach with a hybrid evolutionary-deterministic optimization approach (Skiborowski et al., 2015b).

Abstract

The layout of an industrial park can significantly impact its economic benefit and safety. In terms of economy, a good layout means shorter pipeline length, leading to lower pipeline cost and material transport cost. In practice, the layout of an industrial park is manually determined based on experience according to the relationship of upstream and downstream. In academia, few systematic programming method has been proposed, and most of them only consider one-to-one connection pattern, pipeline networks with multi-branch are ignored. For systematic programming method, it has always been difficult to calculate the minimum length of pipeline network with multi-branch in an industrial park. FLUTE (Fast Lookup Table Based Wirelength Estimation Technique) algorithm is an accurate and fast method to solve rectilinear Steiner minimum tree problem based on a lookup table. In this paper, a novel method based on FLUTE algorithm is came up to calculate the minimum length of steam pipeline network in an industrial park and determine the layout. The total pipeline cost, which includes steam pipeline cost and material pipeline cost, is set as an objective function. Genetic algorithm is employed to optimize the layout of several plants in an industrial park. In the case study, it can be seen that, the calculation time is significantly reduced, and a better layout is obtained.

Keywords: Industrial park layout; Pipeline network; Rectilinear Steiner minimum tree; FLUTE; Genetic algorithm

1. Introduction

Layout design is a key step which must be passed in the process of chemical engineering design and construction. A good layout can reduce the capital cost for the pipeline and operation cost for material transportation, and enhance safety. Economy and safety are the main factors considered in the layout problem. Researches in chemical engineering layout can be divided into two aspects: one is to study the facility layout within a plant, and the other is to study the plant layout within an industrial park.

Many researches about the facility layout within a plant are reported. Penteado and Ciric (1996) proposed a MINLP approach to determine the coordinates of facilities in a plant, considering land cost, piping cost, protection devices cost and risk cost. In their work, protection devices can prevent accidents or minimize the damage to the other nearby facilities, resulting in a protection devices cost at the same time. Patsiatzis et al. (2004)

quantified the risk cost using FEI (Dow Fire & Explosion Index) system, while piping cost and protection cost were also involved to determine the layout of a plant. Latifi et al. (2017) worked out an optimal layout of a plant considering uncertainty and domino effects, and the allowance of multi-layer layout in this work makes this model more practical.

Very few works have been done for designing the plant layout in an industrial park. A noteworthy difference between the facility layout and plant layout is pipeline network with branches. Pipeline networks, such as steam pipeline work, existed widely within an industrial park. Studies about facility layout mentioned above only calculated the lengths and costs of pipelines with point-to-point structure. It has always been difficult to calculate the minimum length of pipeline network with multi-branch in an industrial park. Wu and Wang (2017) firstly came up with an algorithm based on Kruskal algorithm to work out the minimum length and arrangement of pipeline network within an industrial park. Then Wu et al. (2016) combined this algorithm with risk evaluation to determine the layout of plants. But their algorithm is expensive in calculation time.

A rectilinear Steiner minimal tree (RSMT) is a tree with minimum total edge length in Manhattan distance to connect a given set of nodes possibly through some extra nodes (Chu and Wong, 2008). Many algorithms have been come up to solve RSMT problem. GeoSteiner is an exact RSMT software developed by Warme et al. (2015) , but is relatively expensive in calculation time. Chen et al. (2002) proposed an algorithm called Refined Single Trunk Tree (RST-T), which is very effective for low-degree networks but not for high-degree networks. FLUTE (Fast Lookup Table Based Wirelength Estimation Technique) (Chu and Wong, 2005) is a fast and relatively accurate algorithm for RSMT. It achieves a good balance between calculation time and accuracy (Chu, 2004b).

In this work, an industrial park layout design method is proposed, in which the problem of minimum length of pipeline network is converted to RSMT problem and calculated based on FLUTE algorithm. In the case study, the proposed method was compared with Wu and Wang's work (2017). From the result, it can be seen that, when solving the same case, the calculation time of the proposed method is 38.9 s and Wu's method is 69215.0 s. Calculation time is reduced sharply, and a better layout is obtained.

2. Methodology

2.1 Problem statement

The objective function and constraints in this work are based on Wu and Wang's work (2017). The free space in the industrial park is divided into several grids with the same size. Plants are treated as points. Each plant can only occupy one grid, which is put in the center of the grid. The distance between two plants is the distance between centers of the two grids and the distance is absolutely safe for plants. The pipeline must be arranged horizontally or vertically. Moreover, some plants should be put in some specific locations, according to the geographical and meteorological condition of the area where the industrial park sits. For example, the railway transportation plant should be located as near as possible to the railway line, and the air separation plant should be located in the upwind direction. Based on the assumption mentioned above, the aim of this work is to determine the location of plants in an industrial park to minimize the capital cost of the pipeline, including material pipeline and steam pipeline.

2.2 Objective function

The objective function is set as the sum of material pipeline cost and steam pipeline cost, as is shown in Eq. (1).

$$\min\ C = \sum_{i=1}^{n} a_i K_i + \sum_{j=1}^{3} b_j L_j \tag{1}$$

Where C is the total pipeline cost, n is the quantity of material pipeline, i represent different kinds of material flow, a_i is the unit prize of i-th material pipeline, K_i is the length of i-th pipeline; j represent 3 different kinds of steam, b_j is the unit prize of j-th steam pipeline, L_j is the length of j-th steam pipeline network. a_j and b_j come from the market prize.

As the pipeline must be arranged horizontally or vertically, the K_i can be calculated by Eq. (2)

$$K_i = | x_{in} - x_{out} | + | y_{in} - y_{out} | \tag{2}$$

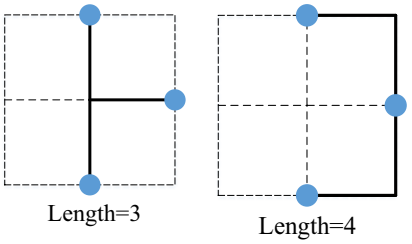
Where (x_{in}, y_{in}) and (x_{out}, y_{out}) is the coordinates of input and output plants respectively.

The calculation of L_j is very complex that will be expressed in the next section.

2.3 Minimum length of steam pipeline network

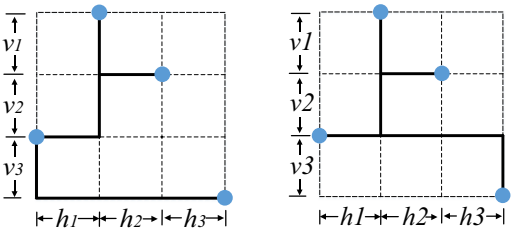
As mentioned in Introduction, the calculation of the minimum length of pipeline network has always been a thorny problem. In this work, this problem has been converted into RSMT problem. RSMT problem is to find a way to connect several given points by only horizontal and vertical lines. As is shown in figure 1, figure 1 (a) is the RSMT of the 3 given points, and figure 1 (b) is not. The Pipeline network connecting the plants of the steam generator or steam user, is the RSMT of those plants.

Length vector is used to represent a certain connection. Figure 2 (a) is a connection of 4 given plants. The pipeline length of this connection is L_1=2*h_1+2*h_2+h_3+v_1+v_2+v_3, so the length vector of this connection is p_1= (2,2,1,1,1,1); figure 3 (b) is the shortest connection for the 4 plants, and the length is L_2=h_1+2*h_2+h_3+v_1+v_2+v_3. The relevant length vector is p_2= (1,2,1,1,1,1), which is called the optimal length vector. We can know which connection is shorter by comparing the length vector directly, instead of calculating the total length. For instance, length vector of (1,2,1,1,1,1) is shorter than (1,2,2,1,1,1) certainly.



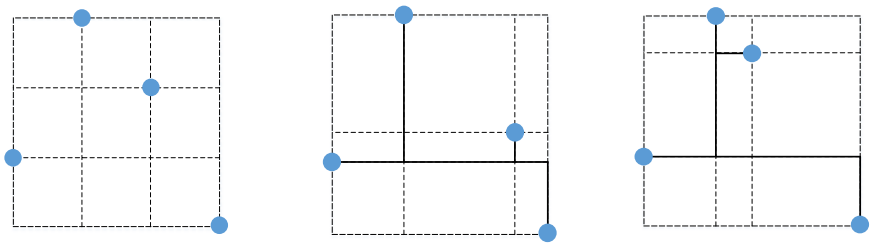
(a) (b)

Figure 1 Examples of RSMT and non-RSTM



(a) (b)

Figure 2 Two connection patterns of 4 given plants



(a) (b) (c)

Figure 3 Different relative locations of 4 plants

If the relative location of several plants is given and the edge lengths of grids are not given, many connections may be the shortest connection. Figure 3 (a) shows a kind of relative location of 4 plants (assuming that the lengths of edges are not determined). Both p_3= (1,1,1,1,2,1) and p_4= (1,2,1,1,1,1) may be the optimal length vector. Which one is optimal depends on the lengths of grid edges. In figure 3 (b), p_3 is shorter, and in figure 3 (c) p_4 is shorter. So p_3 and p_4 are called potential optimal length vector. For a certain relative location of plants, only few length vectors are potentially optimal comparing with all feasible connections. The authors of FLUTE previously calculated all the potential optimal length vectors for each condition of the relative location of points and saved the results. When the coordinates of plants are given, the relevant potential optimal length vectors for the relative location of those plants can be found. Then we calculate the lengths of each potential optimal length vector, and choose the shortest one. The minimum length of steam pipeline network and the arrangement can be obtained. This algorithm is very fast.

3. Case study

3.1 Basic data

The case from Wu and Wang's work (2017) is used, so that the proposed method can be compared with theirs. The case comes from a real petrochemical industrial park, which contains 20 plants and they should be arranged as 4×5 form. The distance between adjacent plants is set as 400 m. The plants and steam requirement are shown in Table 1, in which 1 means the plant needs steam and 0 means the plant does not need steam. This case contains 76 material flows. The type and diameter of a pipeline can be determined according to the property, flow rate and flow velocity of the transported material. In this work, the steam pipeline for the same degree has the same diameter.

According to the geographical and meteorological condition of the area where the industrial park sits, 5 plants should be placed in the specific locations. They are shown in Figure 4.

Both Wu and Wang's method and the proposed method are implemented respectively to determine the layout of this case. The program of Wu and Wang's method is provided by them. MATLAB is used to run the two programs. Genetic algorithm, which is also adopted in Wu and Wang's work, is employed to solve the model for a fair competition. Genetic algorithm is generally regarded as one of the most effective algorithms. The generation is set as 1000, and the individual is set as 50. FLUTE is supplied by the authors in their official website (Chu, 2004).

Table 1 The plants and steam requirement of industrial park

Number	Name	High pressure steam	Middle pressure steam	Low pressure steam
1	Power station	1	1	1
2	Crude oil fractionation plant	0	1	1
3	Gas separation plant	1	1	1
4	Hydrogenation plant	0	1	1
5	Residue and wax hydrodesuifurization plant	1	1	1
6	Air compression and separation plant	0	1	1
7	Fluid catalytic cracking plant	1	1	1
8	Light hydrocarbon recovery plant	1	1	1
9	Liquefied petroleum gas desulfuration and demercaptan plant	1	1	1
10	Sulfur recovery plant	0	1	1
11	Aromatic combine plant	1	1	1
12	Hydrogen production	1	1	0
13	Continuous reforming plant	1	1	0
14	Naphtha hydrotreating	0	1	0
15	Polypropylene and polyester	1	1	1
16	Delayed coking plant	0	1	0
17	Sewage treatment area	0	0	1
18	Tank farm	0	1	0
19	Railway transport department	0	1	0
20	Central control room	0	0	1

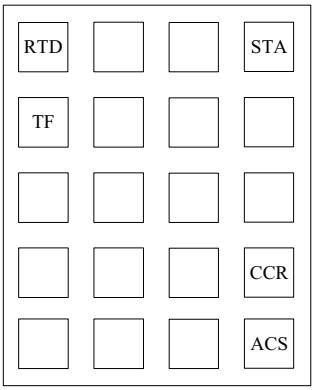


Figure 4 The plants with fixed location

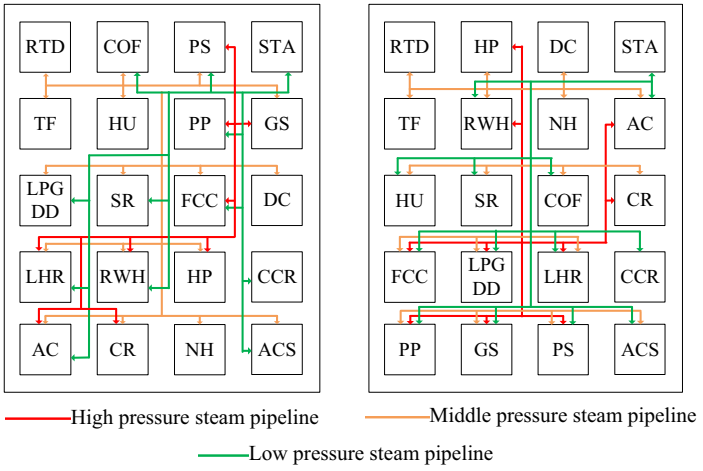

(a) The layout form Wu's method (b) The layout from the proposed method

Figure 5 The layouts from two methods

3.2 Results

The numerical results are presented in Table 2. The final layouts from Wu and Wang's method and the proposed method are shown in figure 5 (a) and figure 5 (b) respectively.

Table 2 Numerical results of the two methods

	Wu and Wang's method	The proposed method
Calculation time	69,215.0 s (19.2 h)	38.9 s
Steam pipeline cost (10^3 ¥)	2,475	2,660
Material pipeline cost (10^3 ¥)	10,581	9,818
Total pipeline cost (10^3 ¥)	13,056	12,478

From the result, we can see that the calculation time has been reduced sharply. The proposed method is 1779 times faster than Wu's method. And a better layout with lower total pipeline cost is obtained.

4. Conclusion

The calculation of the minimum length of pipeline network has always been a thorny problem in the process of industrial park layout design. In this work, FLUTE algorithm is firstly applied in the calculation of the minimum length of a pipeline network. And a mathematical model is established to obtain the layout of an industrial park with the lowest pipeline cost. Both the previous method and the proposed method are used to solve the same case. The result illustrates that, with the proposed method, the calculation time is reduced sharply while a better layout is obtained.

Abstract

The optimal design of flowsheet is a complex task, making it difficult to obtain a global optimum solution. Furthermore, in several processes, there are epistemic uncertainties in the evaluation of the performance of unit operations. This epistemic uncertainty is generated due to a lack of knowledge of the behavior of unit operations. This lack of knowledge generates the need to use semi-empirical models, or define some operational conditions a priori based on some approximation. Usually, these empirical models use parameters that are a function of the flowsheet design. Therefore, it is not possible to adjust these models based on experimental data as the experimental conditions are not known at the design stage. This work analyzes the effect of the epistemic uncertainties in the selection of flowsheet structures. Flotation circuit without grinding, flotation circuit with grinding units, and fractional crystallization were considered as case studies. As a result, this paper demonstrated that few structures exist that are optimal for a wide range of values in the performance of the process units. To demonstrate that there are few optimal structures when there is high uncertainty in the process units, two methods of proof were used: proof by construction, and proof by exhaustion.

Keywords: flow sheet design; epistemic uncertainty; grinding; flotation; crystallization

1. Introduction

The optimal design of flowsheet based on optimization is a complex task as the mathematical model is nonconvex and includes binary variables (usually representing the structure of the flowsheet), making it difficult to obtain a global optimum solution. Examples of these situations are mineral concentration plants (Cisternas et al., 2016), heat exchanger networks and utility systems (Martelli et al., 2016), reverse osmosis desalination processes (Sassi and Mujtaba, 2011), and reactive distillation (Ropotar et al., 2009), among many other cases. The determination of the optimal design comprises three steps: (a) postulation of a superstructure that represents a set of process alternatives, (b) its formulation as a mathematical programming model, and (c) determination of the optimal configuration and operation conditions by solving the model with an optimization algorithm (Chen and Grossmann, 2017).

Furthermore, in several processes, there are epistemic uncertainties. The epistemic uncertainty is associated with the lack of knowledge of the behavior of a unit process.

This lack of knowledge is generated because the exact value of some parameters is not known, the model is not able to adequately represent the unit process, or for both reasons. This lack of knowledge generates the need to use semi-empirical models, or some operational conditions are defined a priori based on some approximation. Furthermore, these empirical models use parameters that are a function of the flowsheet design. Therefore, it is very probable that these semi-empirical models are not capable of adequately representing the unit process generating uncertainty.

This work analyzed the effect of the epistemic uncertainties in the selection of flowsheet structures, but not on operational conditions. A hypothesis was postulated that few structures exist that are optimal for a wide range of values in the performance of the process units.

2. Procedure

As indicated above, the hypothesis postulated was that few structures exist that are optimal for a wide range of values in the performance of the process units. The performance of process units are recoveries, conversion, equilibrium concentration, among other indicators. To demonstrate that there are few optimal structures when there is uncertainty in the process units, an a priori approach or first principles was used. Two methods of proof were used: proof by construction, and proof by exhaustion. Proof by construction is the construction of a concrete example with a property to demonstrate that something having that property exists. In this work, the design of the flotation circuit without grinding, flotation circuit with grinding units, and fractional crystallization were considered in the proof by construction. In proof by exhaustion, the conclusion was established by dividing it into a finite number of cases and proving each one separately. Here, the performance of operation units was represented by uniform distribution functions from which a large dataset formed by random values was obtained. The optimal structure design was obtained for all the values in the dataset. The idea was that given a reasonably large dataset, the set of optimal structure design is equal to all optimal designs in the region represented by the uniform distribution functions. In all cases, one structure design was different from another if it contained a different stream and/or equipment. Table 1 presents the proof approach.

3. Examples for proof by construction

3.1. Flotation circuit without grinding

The example of flotation circuit without grinding considered the concentration of copper ore. The feed to the circuit corresponded to 6 t/h of chalcopyrite (33% of copper), 12 t/h of chalcopyrite slow (16% of copper), and 300 t/h of gangue. The superstructure considers five flotation stages. If all interconnection was allowed, there were over 3 million circuit structure alternatives. However, if origin-destination matrices were used to eliminate nonsense and redundant alternatives, the number of feasible flotation circuits was 6912. The procedure utilized for the postulation of a superstructure and the formulation of the mathematical programming model was the one utilized by Calisaya et al. (2016), which corresponded to a MINLP. The variables with uncertainties corresponded to the stage recoveries of the chalcopyrite, chalcopyrite slow, and gangue. The stage recoveries were difficult to model as there is not a model that can be used under all flotation circuit

structures included in the superstructure. Here, the stage recoveries were represented by values obtained from the uniform distribution. Under these conditions, the design problem is a MILP.

3.2. Flotation circuit with grinding

The postulation of the superstructure and the formulation of the mathematical programming model for the example of flotation circuit with grinding was generated using the procedure described by Cisternas et al. (2006). Nine species were considered to represent the ore including three components (Chalcopyrite, Chalcopyrite slow, and silica) and three particle sizes. Three flotation stages and one grinding stage were included in the superstructure that represented twelve process structures. These twelve process structures included six with and six without grinding stages. Note that, if all interconnection was allowed there were 4096 alternatives, but by eliminating nonsense and redundant alternatives, the twelve process structures were obtained. In addition to the stage recoveries of all species, the "conversion" from one particle class to another particle class was considered as uncertain variables. Forty-eight variables were represented using a uniform distribution function; twenty-seven corresponded to stage recovery and twenty-one corresponded to conversion in the grinding stage. In addition to stage recovery, grinding is also difficult to model as it is a function of feed which is not known.

It is important to indicate that particle size is an important material property to be considered in the design and operation of various types of chemical and mineral processes. For the flotation process, particle size affects energy, water consumption, and mineral liberation.

Table 1. Description of proof approach.

Phase 1: Proof by construction	For the design of flotation circuit without grinding, the design of flotation circuit with grinding, and the design of fractional crystallization, the first two steps of the determination of the optimal design is performed. This is: (a) The postulation of a superstructure that represents a set of process alternatives, and (b) Its formulation as a mathematical programming model, usually a MINLP.
Phase 2: Proof by exhaustion	For each design problem of phase 1, the unit operation performance is represented by a uniform distribution. The unit operation for flotation stages is stage recoveries; for grinding, it is the "conversion" from one particle class to another particle class; for fractional crystallization, the equilibrium composition in multiple saturation points. Then, the following steps are performed: (a) The uniform distribution is sampled, and the values are used as parameters in the mathematical programming model, which usually became a MILP problem. (b) Determination of the optimal configuration by solving the model with an optimization algorithm. (c) If the solution is new, it is saved. (d) Steps (a) to (c) are repeated several times.

3.3. Fractional crystallization

The fractional crystallization problem corresponds to the separation of sodium sulfate and magnesium sulfate from astrakanite ($Na_2SO_4.MgSO_4.4H_2O$). This problem was formulated by Cisternas (1999). Eleven equilibrium states at four temperatures were considered in the superstructure. The superstructure represented 3456 process structures. The variables with uncertainties corresponded to the equilibrium compositions. The equilibrium compositions were a function of the temperature and composition. A thermodynamic model can be used to predict the conditions, but the prediction is not always accurate and adds computational cost to the mathematical programming model. For this reason, in this study, a hundred and five compositions were represented by a uniform distribution.

4. Results and discussion

4.1. Flotation circuit without grinding

Only three flotation structures were obtained from the 30,000 cases studies analyzed. The 30,000 cases were generated by random sampling the uniform distribution function that represented the stage recoveries. These uniform distributions are $\sim U(0.8,0.9)$ for chalcopyrite, $\sim U(0.5,0.6)$ for chalcopyrite slow, and $\sim U(0.02,0.1)$ for gangue. Only 0.04% (three flotation structures) of the 6912 feasible circuit structures were optimal in a wide range of stage recoveries, which is a remarkable result. Figure 1 shows the regions where each optimal solution was obtained.

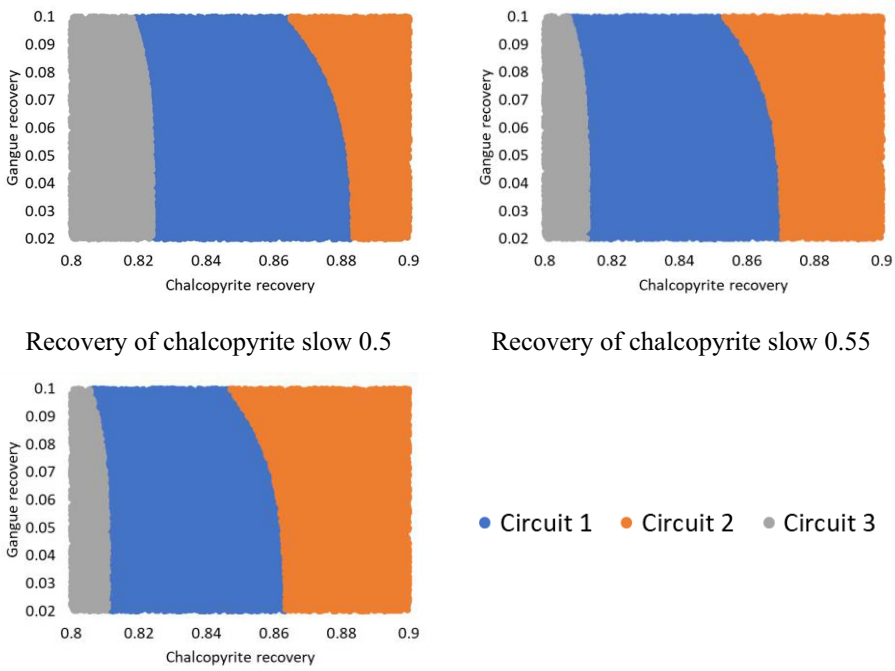

Figure 1. Regions of optimal design circuit structures.

Figure 1 clearly shows that there were regions where each flotation circuit was optimal, and that within each region only one structure was optimal. Additionally, Figure 1 can assist in identifying the range of recovery values a structure will remain as optimal.

4.2. Flotation circuit with grinding

This example was solved 60,000 times for different combinations of the stage recoveries and grinding conversions. Only two process structures were obtained from the twelve feasible structures. These structures are shown in Figure 2. The structure without grinding was obtained in 82% of the cases, whereas the structure with grinding was observed in 18%. The fact that a structure was optimal in 82% of the cases is remarkable considering that 46 variables were represented by uniform distributions.

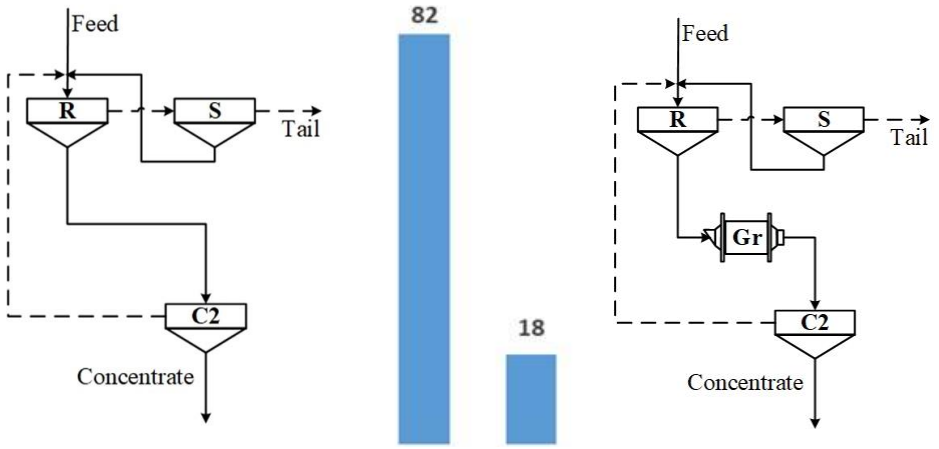

Figure 2. Optimal process structures obtained after 60,000 cases studies.

4.3. Fractional crystallization

This example was solved 30,000 times for different combinations of the equilibrium compositions. Sixteen process structures were obtained from the 3456 feasible options. Furthermore, only five process structures were obtained in more than 5% of the 30,000 cases analyzed (see Figure 3).

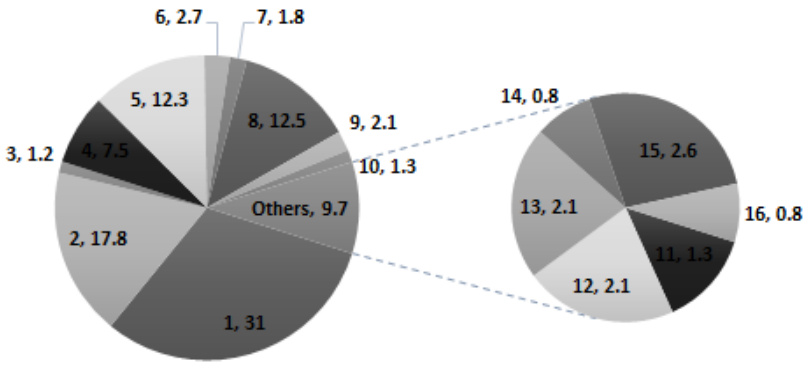

Figure 3. The percentage that each fractional crystallization structure was obtained.

The fact that only 0.46% of the feasible process structures were optimal in a wide range of stage recoveries is a remarkable result as it allows the selection of a set of optimal process structures without a process unit model by using uniform distribution functions.

5. Conclusions

In all the examples studied, it was observed that there were few process structures that were optimal for a wide range of values in the performance of the process units. A remarkable aspect of this conclusion is the possibility of separating the flowsheet design into two steps. First, a set of optimal flowsheet processes can be identified using uniform distribution functions to represent the unit operation performance. Then, after selecting a set of optimal processes, the equipment design parameters and operating conditions can be defined based on simulation and laboratory tests. In addition, these optimal structures can be evaluated from different points of view—economic, environmental, control, flexibility— to make a final design decision.

Abstract

Batch processes have received considerable attention from both industry and academia because of their flexibility to produce low volume, high value-added products. Sustainable water management and strict environmental regulation drive the development of systematic methods for water integration in batch plants. In batch processes, scheduling plays a critical role towards resource conservation. In some cases, production rescheduling can further reduce freshwater consumption and wastewater generation. Although many papers about simultaneous optimization of batch water network integration and product scheduling have been published, the insight-based method is scarce. This work proposes a dynamic programming (DP) method for the optimal design of batch water networks with a flexible product scheduling. The proposed methodology is explained as follows. Firstly, water-using units are ranked based on the ascending of inlet limiting concentration. The whole process is divided into N stages and each concentration locates at a specific stage. Secondly, the target of freshwater consumption of the process can be determined using the recursive function of DP model. Thirdly, once the target is determined, the optimal match between water sources and sinks are identified. The timing of each operation could be further determined. If the batch water network is feasible, the final batch water network is determined. If the obtained water network is infeasible, it will return to the second step to relax the target or chose another alternative with the same target until obtaining feasible batch water network. Two illustrative examples from literature were considered to demonstrate the feasibility of the proposed method. In the first case study a regenerator with a fixed outlet concentration is incorporated in batch water network. In the second case study is presented a batch plant with multiple contaminants in which a fixed removal ratio model is employed.

Keywords: Water network, Process integration, Flexible scheduling, Batch processes.

1. Introduction

Wastewater minimization has gained significant attention from both academia and industry due to the stringent legislation on effluent and the scarcity of freshwater. Reduction of freshwater consumption not only makes the plant save operation costs, but also discharges less wastewater to the environment. Batch processes have been widely used in chemical industry because of their suitability for the production of small volume, high value added products, as well capability of adjusting to fast market changes. Hence, it is urgent to develop a systematic approach to minimize wastewater consumption by

exploiting opportunities for water reuse and removing hazardous contaminants through effective regeneration operations.

Graphical methods and mathematical programming have been effectively utilized to minimize freshwater consumption in batch processes (Gouws et al., 2010). Especially, much effort has been placed on water integration of batch processes with the predefined schedule. However, results obtained from these studies could be suboptimal. In the work of Adekola and Majozi (2011), the optimal product schedule can result in further reduction of freshwater consumption.

Recently, wastewater minimization and optimal production scheduling have been considered simultaneously based on mathematical programming. The formulations could identify the minimum freshwater consumption together with the corresponding production schedule. Chen and Chang (2007) proposed a general mixed integer nonlinear programming model to synthesize water networks in batch processes. In their work, better overall designs can be generated. Zhou et al. (2009) developed a systematic design methodology to optimize batch process scheduling and water allocation networks simultaneously. A continuous-time based time model is introduced and an improved state-space superstructure with state-event network and state-task network representations is adopted to capture the structural characteristics of the integrated water-allocation network for batch processes. Li et al. (2010) used the mathematical technique to deal with single- and multiple-contaminant batch water allocation networks. A flexible scheduling model was presented by integrating batch production scheduling and water allocation networks. Adekola and Majozi (2011) addressed the problem of wastewater minimization with a flexible product schedule. Results showed that the proposed model can achieve a wastewater reduction of 19.2 % and 26 % for the two case studies considered. Chen et al. (2011) developed a mathematical model based on resource-task network representation for simultaneous scheduling and water minimization in multipurpose batch plants. The objective function is to maximize the profit by taking into account the net income from production and water-related costs. Chaturvedi and Bandyopadhyay (2014) proposed a mathematical formulation to minimize the operational cost of water allocation networks in a flexible schedule plant by utilizing multiple freshwater resources. The results of two examples showed that reductions of 17 % and 32 % in operating costs are observed when multiple water resources are used. Chaturvedi et al. (2016) analyzed the effect of multiple water resources in a flexible schedule water network. The findings indicated that once the optimum schedule for a single resource that results in the minimum operating cost is obtained, the same schedule can be applied for problems involving multiple resources. Lee and Foo (2017) considered simultaneous process scheduling and water minimization using pinch-based automated targeting model and a state-task network based discrete-time scheduling model. Li and Majozi (2017) used the match ranking matrix approach to prioritize the matches between water sources and sinks. Based on the ranking, batch water networks can be designed considering the time-dependent nature of batch processes. Some progress of optimization of water integration and production scheduling is presented in the text book (Majozi et al., 2017).

These methods are all based on mathematical programming. However, insight-based methods to deal with these issues are rare. The contribution of this work is to consider the optimization of water utilization in flexible batch processes using dynamic programming (DP). This research aims to investigate the opportunity to further reduce freshwater consumption and wastewater generation by optimizing product scheduling.

2. Problem statement

This work addresses the problem of optimizing water resources for flexible schedule batch processes. The problem can be stated as follows.

Given:

(i) the production recipe for each product, including mean processing times in each unit operation,

(ii) the contaminant mass load of each contaminant,

(iii) water requirement and the cleaning duration for each unit to achieve the required cleanliness

(iv) maximum inlet and outlet concentrations of each contaminant,

(v) the performance of the regenerator and

(vi) the time horizon of interest

Determine the production schedule that achieves the minimum freshwater consumption by exploring opportunities of water recycle/reuse and regeneration.

3. Methodology

The dynamic programming (DP) method is used to determine the target of freshwater consumed in the process. DP is generally used to reduce a complex problem with many variables into a series of optimization problems with one variable in every stage. It is characterized fundamentally in terms of stages and states. Each stage constitutes a new problem to be solved in order to find the optimal result. In each stage the problem can be described by a relatively small set of state variables. The states in this work are decisions that are made on whether to use freshwater and/or reuse wastewater or regenerated water. The dynamic programming equation is updated using the chosen state of each stage. At the last stage, it thus obtains the target of freshwater for the whole problem. The dynamic programming equation can not only assure in the present stage the optimal solution to the sub-problem is chosen, but it also guarantees the solutions in other stages are optimal through the minimization of recurrence function of the problem. The principle of optimality of DP is explained in Bellman (1957). The details of DP approach are introduced in Li and Majozi (2017).

The detailed procedure for design of flexible batch water network is shown in Figure 1. As shown in Figure 1, the first step is to divide the process into many stages. The stages can be determined based on the inlet concentration of each operation. Next, the target of freshwater consumption for the whole process, as well as the specific freshwater consumption for each stage can be identified using DP method. Since the information of freshwater consumption, reused water in each stage is determined, the sequence of operation can be subsequently identified. In other words, the receiving unit should start immediately after the wastewater generating unit finishes. It can thus design the initial water network of batch processes with the constraint of time. If the initial water network is feasible, it will obtain the final batch water network.

If the process requires considering water regeneration scenario, the timing of operation for water reuse/recycle scheme can be used as the basis for further investigation. In every stage, regenerated water as a water resource is incorporated into the analysis and the

match with minimum freshwater and/or minimum quantity of regenerated water is selected as the optimal strategy. The same procedure of water reuse/recycle is repeated to get the final batch water network.

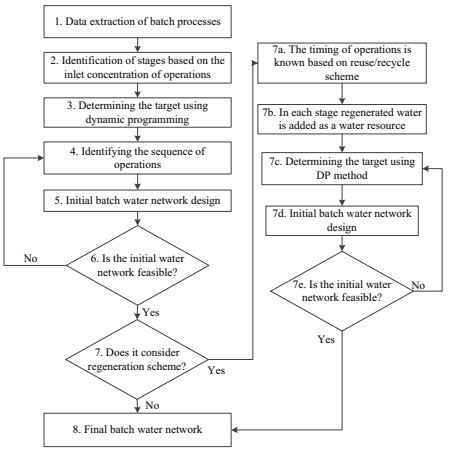

Figure 1 The design procedure for batch water network

4. Illustrative examples

4.1. Example 1

A literature example adopted from Liu et al. (2009) is introduced to illustrate the design procedure for batch water network. Based on the inlet concentration of operations, the whole process can be divided into 5 stages, as shown in Figure 2. The target of freshwater consumption for the whole process can be determined using the DP method (Li and Majozi, 2017). Therefore, the optimal match between water sources and sinks can be determined in each stage with the objective function of minimizing freshwater consumption. For example, wastewater from processes A and B can be reused in processes C, D and E. Thus, when processes A and B are finished, processes C, D and E should start at the same time, this information can assist to determine the sequence of operations achieving the goal of minimum freshwater consumption. On the other hand, the time horizon of interest is fixed as 8.5 h. The water storage profile for Example 1 is shown in Figure 3. The resultant water networks with reuse/recycle and regeneration are shown in Figures 4 and 5, respectively. The freshwater targets of Liu et al. (2009) and Adekola and Majozi (2011) are 68.594 t and 64.07 t, respectively.

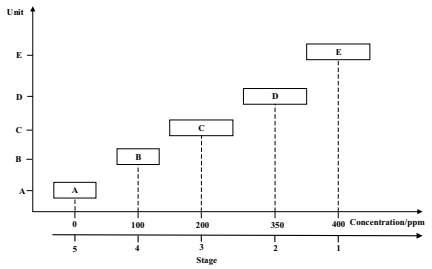

Figure 2 The identification of stage

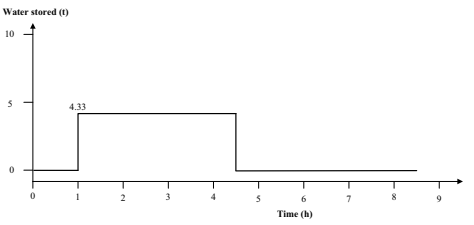

Figure 3 Water storage profile of Example 1 (reuse)

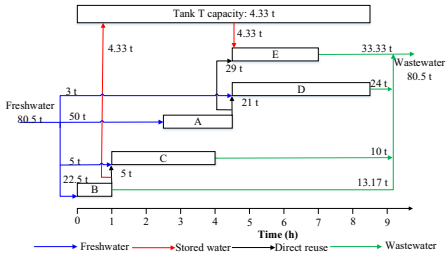

Figure 4 Results of Example 1 (reuse)

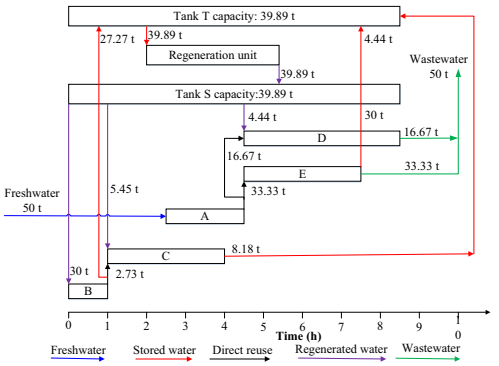

Figure 5 Results of Example 1 (regeneration)

4.2. Example 2

This example taken from Adekola and Majozi (2011) is based on a section of a pharmaceutical production plant, which produces four types of products, i.e. shampoos, deodorants, lotions and creams. Each product was produced by a specific mixer. Mixer 1 was dedicated to the mixing of shampoos, mixer 2 was dedicated to the mixing of deodorants, mixer 3 was dedicated to the mixing of lotions and mixer 4 was dedicated to the mixing of creams. Raw material is charged to a mixer. The raw material is then mixed until the required physical characteristics are obtained. Once a product is mixed, it is removed and stored. The mixers are then washed. Freshwater consumption could be further reduced by changing the sequence of batch operations. The resultant water network with water reuse/recycle scheme is shown in Figure 6, while in Figure 7 it shows the batch water network with regeneration scheme. The result of regeneration scenario in this work is less than that of Adekola and Majozi (2011), i.e. 2653 t. The solution time of Adekola and Majozi (2011) was 464 s. However, the computational time of this work is incomparable. This is because in this work the complex problem has been decomposed into a few small problems, which can be easily solved using direct search algorithm. It is also inappropriate to compare the summation of solution time of sub-problem with that of mathematical programming. The solution time of each sub-problem is substantially reduced compared with the gradient-based algorithm.

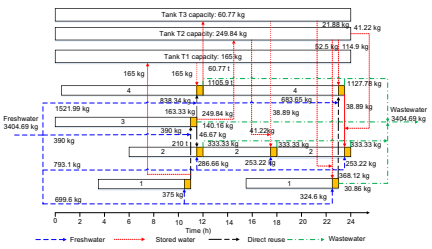

Figure 6 Results of Example 2 (reuse)

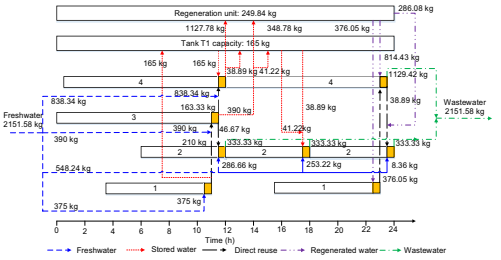

Figure 7 Results of Example 2 (regeneration)

5. Conclusions

A DP approach is used to identify the optimal water using policy that could achieve the target of minimum freshwater consumption and minimum storage capacity. In every stage, the optimal matches between water sources and sinks are determined and the

sequence of operation can also be identified. Based on the obtained sequence of operations, the product can be rescheduled to minimize freshwater target and storage facilities with the constraint of time horizon of interest. Two different examples from literature are used to demonstrate the applicability of the proposed approach. The obtained results match with published literature. Future work should focus on the robust design of batch processes with minimum freshwater consumption and optimal product scheduling.

A Novel Method of Integrating Flexibility and Stability for Chemical Processes under Parametric Uncertainties

Ying Chen, Zhihong Yuan, Bingzhen Chen*

Department of Chemical Engineering, Tsinghua University, Beijing, 100084, China
dcecbz@mail.tsinghua.edu.cn

Abstract

Process optimization under parametric uncertainties is a challenging topic of practical importance in the Process Systems Engineering. Flexibility and stability are two crucial components of chemical process operability. In previous research, flexibility and stability usually have been studied separately, resulting in flexible regions containing unstable areas that are difficult to operate and control. The major difficulty of integrating flexibility and stability lies in how to convert the Lyapunov stability conditions into specific constraints embedded within the flexibility analysis model. This paper proposes a novel method for the integration of process flexibility and stability, which incorporates stability constraints obtained by using singularity theory based stability analysis method into the MINLP model for calculating flexibility index. As a result, a stable flexible region is obtained, which not only adapts to variations in uncertain parameters, but also ensures stable operation and process inherent safety. Two cases: 1,3-propanediol fermentation system and methyl methacrylate polymerization process, have been studied to demonstrate the effectiveness of the proposed methodology. The obtained results illustrate that the novel method for considering flexibility and stability simultaneously possesses distinct computational advantages over the eigenvalue optimization algorithm, so it has great potential for applications in large-scale systems.

Keywords: parametric uncertainties; flexibility; stability analysis; singularity theory

1. Introduction

Parametric uncertainties are inevitable in all stages of chemical production, ranging from process design and synthesis, to operational planning, production scheduling and supply chain optimization. Uncertainties in feedstock's properties, kinetic constants and transfer coefficients widely exist in chemical process design and operation. Since the solution of an optimization problem generally exhibits high sensitivity to the parameter variations, it is obviously significant to account for the effect that uncertainties can have on both the optimality and feasibility of the chemical process operation (Halemane and Grossmann, 1983).

Flexibility and stability are two crucial components of chemical process operability (Swaney and Grossmann, 1985). Flexibility guarantees feasible steady-state operation over a range of uncertain operating conditions and denotes static resiliency. Stability reflects the tolerance for slight perturbations in the open-loop system and emphasizes the dynamic characteristics of a system. Stability is a basic feature that can significantly decide the fate of a design and the inherent safety of a system (Wang et al., 2009).

In previous research, flexibility and stability usually have been studied separately, resulting in flexible regions containing unstable areas that are difficult to operate and control, as shown in Figure 1. Although the flexible regions can satisfy the production requirements, underlying instability limits the degree of inherent safety of a system. Within the unstable areas, the system may experience a dramatic change or even run away under very slight disturbance. Therefore, we want to find an operating region that is not only robust to parametric uncertainties, but also ensures stable operation without complex control system.

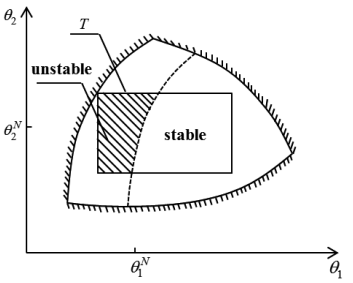

Figure 1. Stable and unstable part of flexible region(Jiang et al., 2014)

The more recent trend has been to integrate various indicators of operability. The major difficulty of integrating flexibility and stability lies in how to convert the Lyapunov stability conditions into specific constraints embedded within the flexibility analysis model. Jiang et al. (2014) first integrated flexibility with stability through an eigenvalue optimization algorithm, in which the necessary condition of stability where the real part of the eigenvalues is smaller than zero is transformed into the positive definiteness of a real symmetric matrix so that the stability condition is expressed explicitly, as illustrated in Figure 2. The limitation of this approach is that it can only deal with the problem in which the inner optimization is convex. Moreover, the positive definiteness of a real symmetric matrix is judged by the positive definiteness of the successive principal minors of matrix, which leads to great computational expense. Hence, it is not suitable for practical applications in large-scale systems.

$$\mathrm{Re}(\lambda_i(J(h))) < 0 \xrightarrow[\text{Lyapunov equation}]{} \begin{matrix} J^T P + PJ + I = 0 \\ P \text{ - Positive definite} \end{matrix} \rightleftharpoons \begin{matrix} J^T P + PJ + I = 0 \\ \det(P_k) > 0 \end{matrix}$$

Figure 2. Eigenvalue optimization algorithm

This paper presents a singularity theory based stability analysis method with the aim to obtain concise stability constraints which could be easily embedded into the flexibility analysis model. The proposed method possesses distinct computational advantages over the eigenvalue optimization algorithm and has great potential for applications in more complex systems.

2. Novel method for integrating flexibility and stability

The proposed method is described as follows. First of all, by adjusting the value of uncertain parameters and control variables within a given range, a series of steady-state solution curves is depicted, which reflects how process stability changes with the variations of operating conditions. It is essential to identify singularity points where the transformation of system's stability characteristics may take place. Then the dynamic trajectories of singularity points extracted from the series of curves are regressed into functions of uncertain parameters and control variables. Finally, based on the stability region partition, the obtained functions are transformed into inequality constraints, which are further embedded into the optimization model for calculating flexibility index. After adding the stability constraints, the boundary of feasible region becomes stable, the flexible region shrinks and the flexibility index reduces accordingly. The flowchart of the novel method for integrating flexibility and stability is shown in Figure 3.

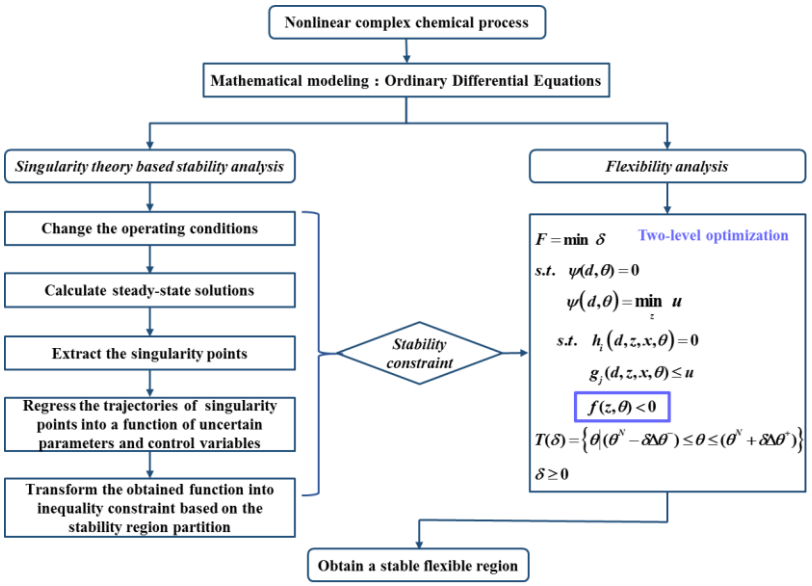

Figure 3. Flowchart of the novel method for integrating flexibility and stability

The general form of calculating flexibility index through active constraint algorithm (Floudas et al., 2001) with consideration of stability is presented as follows:

$$
\begin{aligned}
&F = \min \delta \\
&\text{s.t. } \psi(d,\theta) = 0 \\
&\quad \psi(d,\theta) = \min_{z} u \\
&\quad \text{s.t. } h_i(d,z,x,\theta) = 0,\ i \in I \\
&\qquad g_j(d,z,x,\theta) \le u,\ j \in J \\
&\qquad f(z,\theta) < 0 \\
&\qquad T(\delta) = \left\{\theta \middle| (\theta^N - \delta\Delta\theta^-) \le \theta \le (\theta^N + \delta\Delta\theta^+)\right\} \\
&\qquad \delta \ge 0
\end{aligned}
\tag{1}
$$

This is a two-level optimization problem which can be further solved by applying the necessary and sufficient KKT optimality conditions to transform the flexibility index problem into a single optimization problem. However, it is worth noting that the application of the KKT conditions to reformulate the inner level model may not be correct in cases where regularity conditions do not hold.

In this way, the integration of flexibility and stability is formulated as a MINLP problem that could be solved by extensively used GAMS. Consequently, we obtain a stable flexible region that not only adapts to variations in uncertain parameters, but also ensures stable operation and inherent safety.

$$
\begin{aligned}
&F = \min_{\theta,x,z,\delta,s_j,\mu_j,\lambda_j,y_j} \delta \\
&\text{s.t. } g_j'(d,z,x,\theta) + s_j = 0,\ j \in J \\
&\quad h_i(d,z,x,\theta) = 0,\ i \in I \\
&\quad \sum_{j=1}^{J} \lambda_j = 1 \\
&\quad \sum_{j=1}^{J} \lambda_j \frac{\partial g_j'}{\partial z} + \sum_{i=1}^{I} \mu_i \frac{\partial h_i}{\partial z} = 0 \\
&\quad \sum_{j=1}^{J} \lambda_j \frac{\partial g_j'}{\partial x} + \sum_{i=1}^{I} \mu_i \frac{\partial h_i}{\partial x} = 0 \\
&\quad \lambda_j - y_j \le 0,\ j \in J \\
&\quad s_j - U(1 - y_j) \le 0,\ j \in J \\
&\quad \sum_{j=1}^{J} y_j \le n_z + 1 \\
&\quad \theta^N - \delta\Delta\theta^- \le \theta \le \theta^N + \delta\Delta\theta^+ \\
&\quad \delta \ge 0, y_j = \{0,1\}, \gamma_j \ge 0, s_j \ge 0, j \in J
\end{aligned}
\tag{2}
$$

g_j' denotes the inequalities, including the product quality requirements g_j and the stability constraint $f(z,\theta) < 0$

3. Case studies

3.1. 1,3-Propanediol Fermentation

The anaerobic fermentation system is a highly nonlinear complicated chemical process, which generally exhibits oscillation and multi steady-state characteristics. These characteristics severely affect the stable process operation and the quality of desired products. The mathematical model of 1,3-propandiol fermentation process is presented as follows (Xiu et al., 1998) and the range of process parameters is listed in Table 1.

$$\begin{aligned}
\frac{dx}{d\tau} &= x(u-d)\\
\frac{dy}{d\tau} &= d(y_0-y)-x\varphi_1\left(\beta_1+\gamma_1 u+\frac{y}{y+\alpha_1}\right)\\
\frac{dz}{d\tau} &= x\varphi_2\left(\beta_2+\gamma_2 u+\frac{y}{y+\alpha_2}\right)-zd\\
u &= \frac{y}{y+\alpha_3}(1-y)(1-z)
\end{aligned} \tag{3}$$

Table 1. Ranges of process parameters (1,3-Propanediol Fermentation)

Parameters	Ranges
x	0.29-0.6
z	≥0.58
d	0.3-0.4

x, y and z are the state variables which denote dimensionless biomass concentration, substrate concentration and product concentration respectively. The control variable is dimensionless dilution rate d and the two uncertain parameters are dimensionless feed substrate concentration y_0 and dimensionless critical parameter α_3. Given the nominal operating point, $y_0^{\mathrm{N}} = 0.228$, $\alpha_3^{\mathrm{N}} = 1.4 \times 10^{-4}$ and the maximum positive and negative deviations of the two uncertain parameters are $\Delta\theta_1^{+} = 0.02$, $\Delta\theta_1^{-} = 0.02$ and $\Delta\theta_2^{+} = 2 \times 10^{-5}$, $\Delta\theta_2^{-} = 2 \times 10^{-5}$.

The singularity theory based stability analysis method can characterize regions in parameter space over which different kinds of stability characteristics may exist (Wang et al., 2009). As shown in Figure 4 and Figure 5, the steady-state solution curve is divided by singularity points into three sections which have different stability.

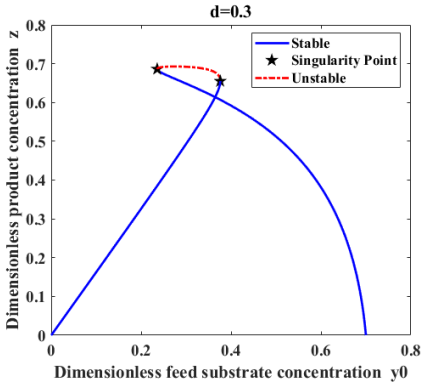

Figure 4. Different stable regions separated by singularity points when $d = 0.3$

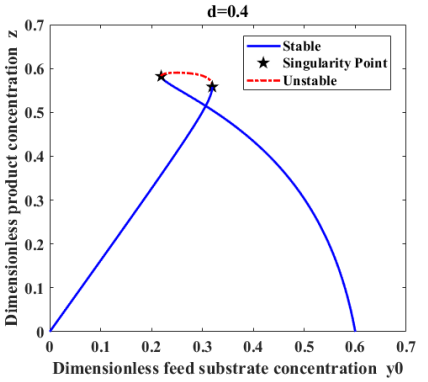

Figure 5. Different stable regions separated by singularity points when $d = 0.4$

Moreover, the stability characteristics of the system will change with the variations of parameters. A series of steady-state solution curves is depicted in Figure 6 by changing the value of control variable d and uncertain parameter α_3 within a range. The dynamic trajectories of the left singularity points and the right singularity points can be regressed

into functions of uncertain parameters and control variables respectively. By connecting the left and the right moving singularity points, a linear equation, which distinguishes the stable regions from the unstable one, can be obtained. Based on the stability region partition, we can get the concise form of stability constraint, $f(z, y_0, \alpha_3, d) < 0$, which can be further embedded into the optimization model for calculating flexibility index.

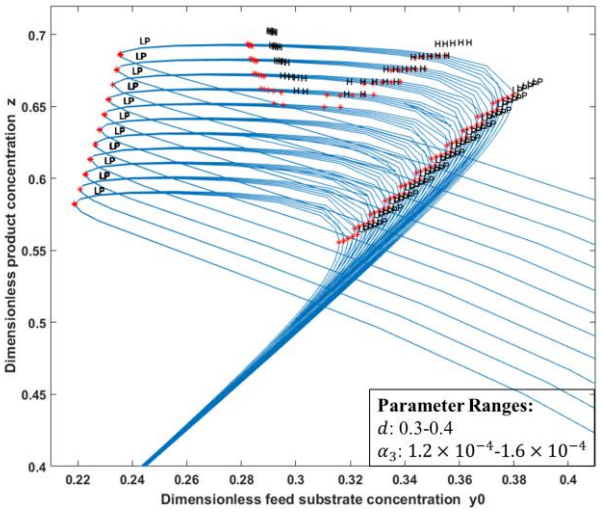

Figure 6. Stability varies with the control variable and uncertain parameters within a given range

The comparison of flexibility index without/with stability is presented in Table 2.

Table 2. Comparison of flexibility index without/with stability

Method	Flexibility Index	Computation Time (BARON)
Traditional flexibility analysis without stability	0.453	1003.30 s
Integrating flexibility and stability	0.343	1003.64 s

3.2. MMA Polymerization

The dynamic behaviour of free-radical continuous stirred tank polymerization reactors has received extensive attention. The MMA polymerization reaction takes place in a CSTR with a cooling jacket to remove extra heat, as shown in Figure 7. Six differential equations constitute the mathematical model of the MMA polymerization reactor, which can be acquired from the previous literature (Silva-Beard and Flores-Tlacuahuac, 1999).

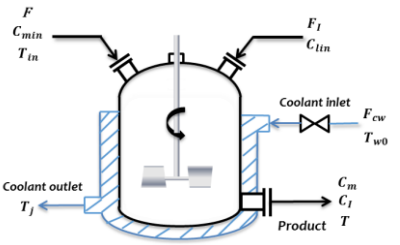

Figure 7.Polymerization reactor flow sheet

Here, the state variables are C_{m}, C_{I}, T, D_0, D_1 and T_{j}, and the control variable is the flow rate of cooling water F_{cw}. There are two uncertain parameters: monomer feed concentration C_{min} and monomer feed flow rate F.The nominal operating points and the maximum positive and negative deviations of uncertain parameters are given as follows: $C_{\mathrm{min}}^{N} = 6.4678\ \mathrm{kmol/m^3}, F^N = 1\mathrm{m^3/h}, \Delta\theta_1^+ = 0.3, \Delta\theta_1^- = 0.2, \Delta\theta_2^+ = 0.2, \Delta\theta_2^- = 0.2$. The use of singularity theory based stability analysis method to distinguish regions with different dynamic characteristics is illustrated in Figure 8 and Figure 9.

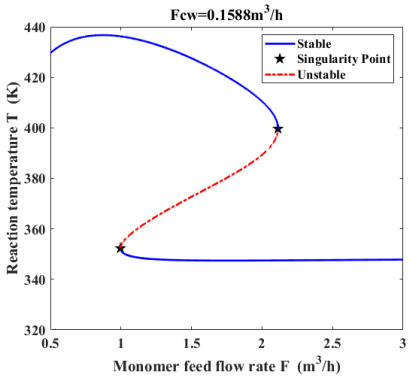

Figure 8. Different stable regions separated by singularity points when F_{cw}=0.1588m^3/h

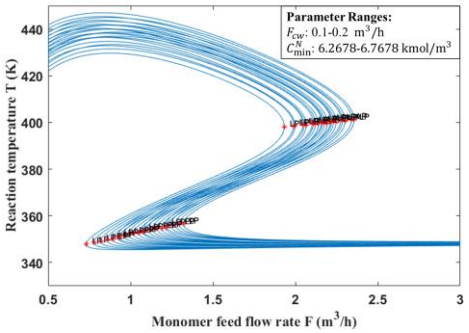

Figure 9. Stability varies with the control variable and uncertain parameters within a given range

The comparison of flexibility index without/with stability is presented in Table 3.

Table 3. Comparison of flexibility index without/with stability

Method	Flexibility Index	Computation Time (BONMIN)
Traditional flexibility analysis without stability	0.495	3.83 s
Integrating flexibility and stability	0.260	5.36 s

4. Conclusions

This paper presents a novel method for the integration of process flexibility and stability, in which singularity theory based stability analysis method is utilized to convert the Lyapunov stability conditions into stability constraints embedded within the flexibility analysis model. Due to the concise form of stability constraints, the proposed method possesses distinct computational advantages over the eigenvalue optimization algorithm. Accordingly, it has great potential for applications in large-scale systems. Attractive as it is, it also has a certain limitation. It can only deal with the uncertainties within a specific range in which process stability observes a certain changing trend.

Abstract

A model-based approach is demonstrated, to analyze a heat integrated horizontal distillation system for separation of light alcohol mixtures from second-generation biomass. The objective is to develop an engineering tool, based on process systems engineering concepts. This tool is used to analyze and evaluate the proposed separation system to provide guidelines with respect to specific design and process variables. The model is simulated and comparative studies for different mixtures containing alcohols are carried out. It is shown that separation of mixtures with low concertation of light alcohol content requires less energy compared to conventional distillation systems.

Keywords: Horizontal distillation system, Energy recovery, Process modelling, Process analysis and evaluation.

1. Introduction

The production of chemicals from second-generation (2G) feedstock requires gathering adequate feedstock for one central plant (Maity et al. 2015), which can be challenging. This makes small-scale factories based on local flexible production an attractive alternative. Thus, one may explore a small-scale modular separation system tailor-made for mobile refineries, to enable fast and cost-effective manufacturing of customized products at various locations. Therefore, a container format that is easily configured for different products and processes is considered here. The container format allows on-site transportation to provide manufacturing anywhere, enabling the benefits of localized service delivery without duplication of equipment at multiple locations. We focus on the development of separation technology for the separation of mixtures containing light alcohols from small-scale production facilities of alcohols from 2G biomass (such as straw and wood chips). The paper deals with development of a steady-state model using process systems engineering tools. Its purpose is to describe sufficiently the separation system and perform analysis and evaluation in terms of energy requirements. The proposed horizontal separation system aims at reduction of the costs (such as capital cost and operating cost) associated with conventional distillation systems and novel intensified and highly integrated designs such as reactive distillation, diabatic distillation, internally heat integrated distillation column (HIDiC) and the divided wall column (Kiss et al. 2013). The feasibility of other horizontal distillation systems, in separating binary liquid mixtures, has been demonstrated by experimental and numerical simulation studies (Seok et al. 1985, Ramirez-Gonzalez et al. 1992). Recently, Kim et al. (2013) and Jang et al. (2015) have shown experimentally and numerically the potential energy savings using a diabatic rectangular horizontal column in liquid binary mixtures. Here, the separation

system is also horizontal. It consists of two sections, i.e. a stripper and a rectifier. The system has no trays. Therefore, the separation is rate-based. It operates in continuous mode, it can handle viscous liquids (or liquids containing solids), high-value temperature sensitive components and offers opportunities for heat integration. The steady state model is based on the two-film theory of mass transfer. It assumes phase equilibrium at the vapor-liquid interface and counter-current flow of the vapor and liquid phases. It is applied to different mixtures and is compared with conventional separation technologies.

2. Horizontal heat integrated separation system

The system is shown in Figure 1. It consists of two, co-axially arranged tubes. The inner tube operates as a stripper and the outer one as a rectifier. The feed consists of light alcohols, water and temperature sensitive compounds and enters the stripping section at reduced pressure preventing decomposition of the temperature sensitive compounds. The heavy product of the stripper consists of water and valuable compounds and the light product consists of more light alcohols. The stripper light product is compressed and charged into the rectifying section, where the alcohols are concentrated and collected as light product, whereas the bottom product is returned to the stripper after expansion. Heat integration is thereby made possible between the rectifying and the stripping chambers.

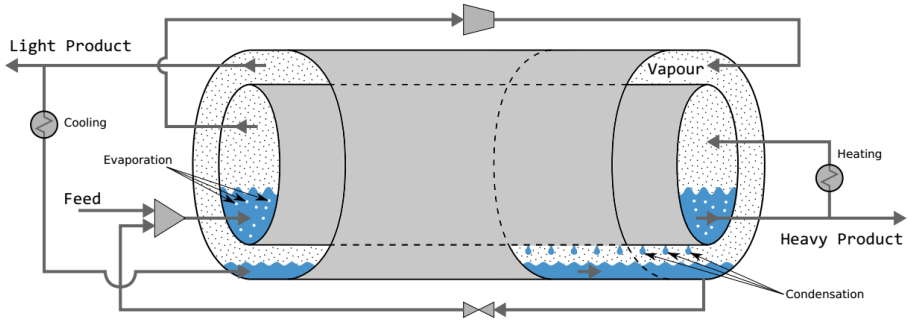

Figure 1. The heat integrated distillation system. The stripper is represented by the inner chamber and the rectifier is represented by the outer chamber. Dimensions: Length = 2 m, stripper diameter = 1.8 m and rectifier diameter = 2 m.

3. Model development

3.1. Modelling objective

The objective is to develop a model to describe the fundamental phenomena taking place in the diabatic horizontal distillation system. The model needs to predict, qualitatively, for both chambers the internal flow rate profiles, the temperature and the composition profiles in the vapor and liquid phases. The model, at steady-state, is applied to simulation studies, sensitivity analysis, evaluation and analysis in terms of economics and energy and for design studies. The model is used as a tool, which in the absence of experimental data and low technology awareness may assist in analysis and evaluating preliminary process designs, and for comparative and optimization studies.

3.2. System phenomena and assumptions

The following phenomena have been considered to model the system.

- Mass transfer controlled separation

- Counter-current flow of vapor and liquid phases in both chambers
- Heat transfer between rectifying and stripping section
- Compression of the strippers exiting vapor and pressure reduction of the rectifiers (outlet) liquid

The following assumptions have been made to develop the model:

- Vapor-liquid equilibrium is assumed only at the interface
- The pressure of the rectifying and stripping section is perfectly controlled
- The reflux ratio and the boil-up ratio are perfectly controlled
- Heat and mass transfer coefficients are calculated using known correlations (Bravo et al. 1985 and Chilton and Colburn (Taylor, R., Krishna, 1993) respectively).

3.3. Model construction

The basis of the rate-based model is shown in Figure 2a, where a segment, j, together with mass and heat transfer phenomena as well as the vapor-liquid equilibrium at the interface is shown. The model for compartment j has been used as a building block for N consequtive segments and has been combined with reboiler and condenser models as well as models for compression and valve (see Figure 2b). The model consists of mass and energy balance equations for the vapor and liquid phase, mass and heat transfer rates, equilibrium equations, and summation equations. In addition, the steady-state rate-based model employs activity coefficient models, fugacity coefficient model and the required physical properties such as densities and vapor pressures. For the calculation of the activity coefficient, the Wilson model has been selected as a thermodynamic model. The resulting equation system consists of algebraic implicit equations that requires non-linear solvers and it can be implements in various programming languages.

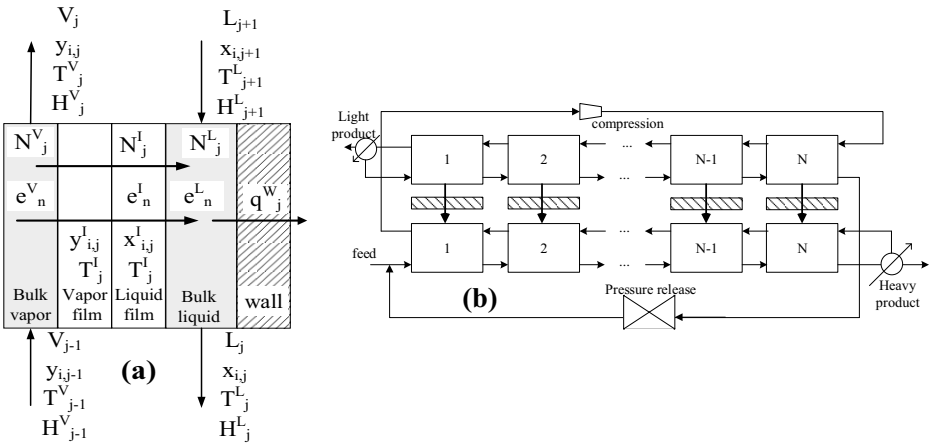

Figure 2. Model representation. (a) Single segment *j* and (b) integration of the N segments, together with compression and expansion.

3.4. Heat Integration-calculation sequence

Heat integration takes places between the rectifying and the stripping sections. The rectifying section operates at higher pressure, to ensure sufficient temperature difference. The heat transferred from the rectifying to the stripping section per segment j is:

$$Q_j = UA_j \Delta T_j \tag{1}$$

Here U is the overall heat transfer coefficient in $\frac{kW}{m^2K}$, A_j is the heat transfer area in m^2, and ΔT_j is the temperature difference between the rectifying and the stripping section $\Delta T_j = T_{R,j} - T_{S,j}$ in K. For the overall heat transfer coefficient a value of 1 $\frac{kW}{m^2K}$ has been chosen. Heat transfer area has been calculated considering that the minimum heat transfer area per segment j is the surface of the stripping segment j. The temperature profiles for the rectifying and stripping section are calculated through simulations, considering no heat integration. Once all the right-hand side variables of Eq. (1) are known, heat integration is added in the model calculations. Here, the value of the product UA_j is uncertain due to the low technology readiness level of the system; however, it can be analyzed as a sensitivity variable to investigate its effect on the separation performance. For example, a maximum value of UA_j might exist and above that limit, the system might may not have further improvements or it might lower the performance, leading to over-design and higher capital costs that are prohibited for such applications.

3.5. Sensitivity analysis

Sensitivity analysis has been performed in order to gain a deeper understanding of the effects of certain design and process variables. First, sensitivity analysis is used to investigate the effect of variables such as mass, heat transfer and interfacial area coefficients and heat transfer area on process variables such as reflux and boilup ratio in order to achieve the high separation performance in terms of product purity, flow rate and recovery. Changes above 50-60% may increase dramatically the energy requirements.

4. Model application and results

Case 1: Ethanol-water. The mixture of ethanol-water has been selected to highlight the application of proposed design using the developed steady-state model. That mixture is common after fermentation of 2G biomass. Table 1, lists the values of the variables specified to solve the model.

Table 1. Process variables used for the simulation of the heat integrated horizontal system.

Process Variables	Values	Process Variables	Values
Inlet flow rate	0.1 kmol/sec	Rectifier pressure	0.3 atm
Inlet Temperature	40 °C	Reflux ratio	2.5
Inlet Pressure	0.1 atm	Boil-up ratio	0.15
Ethanol composition	10 wt.-%	Phase contact area, S	50 m^2/m^3
Stripper pressure	0.1 atm	Phase contact area, R	50 m^2/m^3

Solving the heat integrated distillation system over the tube length, the internal flowrate, temperature and composition profiles have been obtained, as shown in Figure 3a-c, respectively. Figure 3a shows the internal flow rate of the liquid (subscript "L") and vapor (subscript "V") phase in the stripping (S) and rectifying (R) sections. The feed is at length equal to zero (0) where the flow rate has the maximum value for both vapor and liquid phases. The flowrate of the liquid phase reduces towards the tube's end due to evaporation taking place in the stripping section while the flowrate of the vapor phase increases towards the start of the tube due to the evaporation of the liquid. Similarly, in the rectifying section, the vapor flow rate decreases from the end towards the start of the tube while the liquid flow rate increases towards the end of the column due to the condensation. In Figure 3b, the temperature profiles in the stripping and rectifying sections are shown, in stripping section the temperature profiles are nearly constant, close the boiling point of the mixture and lower than 60°C (maximum temperature limit in the

stripper). In the rectifying section, the temperature is high at the inlet of the rectifying section (length at 6 m) due to the vapor compression and reduces towards the end of the rectifier due to heat transfer to the stripping section. In Figure 3c, the ethanol composition in the liquid and vapor phase is shown. In the stripping section, the composition reduces towards the end of the tube meaning that no ethanol is in the heavy product due to evaporation. In the rectifying section, the composition of ethanol increases from the inlet towards the end of tube due to the condensation process. The obtained profiles shown in Figure 3 are in good agreement with the two-film theory of mass transfer.

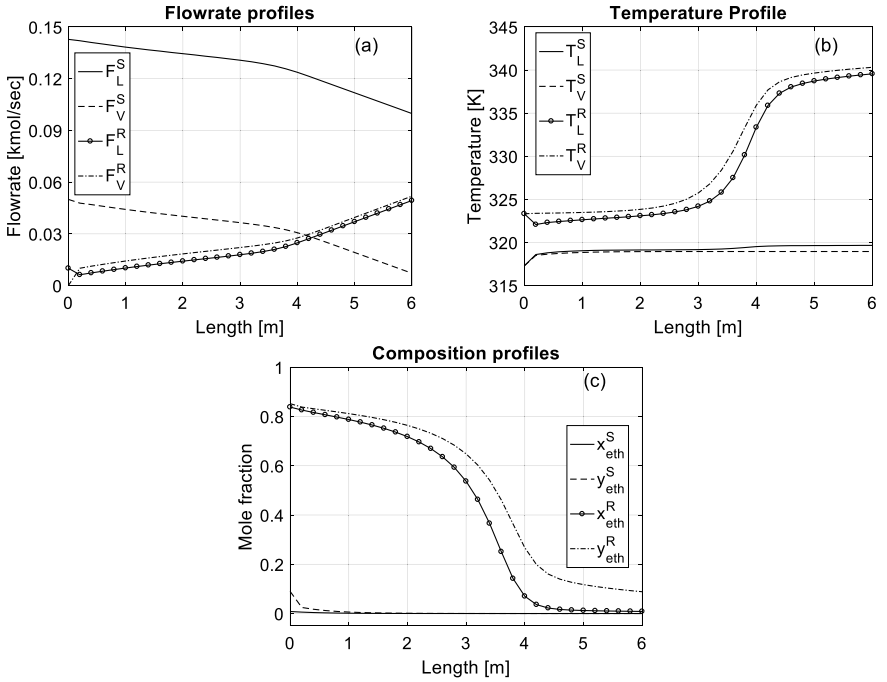

Figure 3. Simulation results for the heat integrated horizontal system. (a) Internal flow rate profiles, (b) internal temperature profiles and (c) internal composition profiles. Note that in the liquid flows direction [0→6 m] and the vapor flows at the opposite direction.

The process performance of the adiabatic horizontal distillation system has been compared to a conventional distillation column and a non-heat integrated horizontal system. For the analysis, process performance criteria such as product flow rate (0.19 kg/sec), purity (93 wt.-%) and recovery (93%) were kept constant while the energy requirements were evaluated. For the analysis, an equilibrium-based distillation column has been considered with the same feed conditions (Table 1), 15 equilibrium stages, feed location 5th stage from the top and reflux ratio 3.94. In Figure 4, the process performance criteria for the three different cases are shown, and it can be seen that the potential of reducing the energy requirements is very high (approximately 55% energy reduction).

Case 2. Mixtures of isopropanol-methanol (52 mol% methanol, Kim et al. 2013). The model has been applied to the mixture of isopropanol-methanol and it has been shown that for such a mixture the heat and mass transfer in the stripping section should not be very low, otherwise, the separation is not efficient (separation performance: 89 mol% methanol as light product, 85% product recovery, Kim et al. 2013) and the system is not suitable for this separation. However, in case of enhanced mass and heat transfer, the

separation compared to conventional technologies might be beneficial (energy savings app. 20%). The application in this mixture shows that the specific design should be used in mixtures where the light component is in small quantity (approximately 15 mol%).

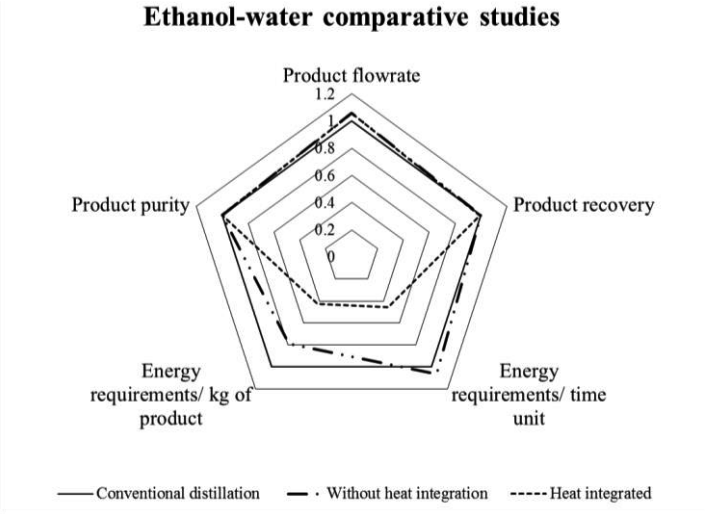

Figure 4. Ethanol-water separation comparative studies.

5. Conclusions

In this paper, an adiabatic horizontal distillation system, intended for small-scale separations of chemicals from 2G bio-refineries, has been described. The development of a process model to provide a meaningful description, in absense of experimental data, of the separation system using process systems engineering tools, has been demonstrated. The model predicts the internal flow rate, temperature and composition in stripping and rectifying sections as well as the energy demands. It serves as a tool to assist in conceptually design and to evaluate the separation performance of the system. Simulation studies and comparative studies demonstrate the potential improvements in reduction of the energy requirements over conventional separation schemes in mixture containing small amounts of light alcohols. Complementary work to investigate process economics, dynamics and operability is planned.

Abstract

Distillation is one of the most widely used unit operation for separations in chemical and petrochemical industries. It is well-known that the number of distillation configurations available for the separation of an n-component mixture increases combinatorially with n. In this article, we describe a tool we have developed that screens through the entire search space to identify a handful of distillation configurations that are attractive for an application. Towards our goal, we formulate a novel Mixed Integer Nonlinear Program (MINLP) using Underwood's method to estimate the vapour duty in each column. The MINLP formulation is integrated with DISTOPT: an easy-to-use in-house visualization software that takes feed properties as input, solves the optimization problem, and displays attractive configurations pictorially. The capabilities of the developed tool are illustrated with two case studies.

Keywords: Multicomponent distillation, column sequencing, MINLP

1. Introduction

Separations are ubiquitous in chemical, biochemical and petrochemical industries. Majority of the separations are energy intensive, and account for 40-70 % of the total plant energy requirement. Of the numerous unit operations, 90-95 % of the liquid separations are carried out using distillation (Humphrey and Keller, 1997). Even for gas separations, distillation is the only alternative for larger throughput and high purity products. According to one estimate more than 40,000 distillation columns are in operation in the US. These columns consume energy equivalent of 1.2 million bbl oil per day (Humphrey and Keller, 1997). Given the scale of operation, within given cost constraints, it is essential to make the processes as efficient as possible in order to reduce the overall energy consumption.

Majority of the industrial distillations involve the separation of three or more components. Such separations require a sequence of columns known as a configuration. The number of configurations available for a multicomponent separation increases combinatorially with increase in number of components in the process feed. For example, there are over half a million configurations available for a six-component system (Shah and Agrawal, 2010). All these configurations differ in the composition of distillate and residue from each split in a configuration and thermal qualities of internal transfer streams (referred to as submixtures). Consequently, the extent of remixing losses differ among different configurations, making some configurations more energy

efficient compared to others. This raises the following questions: (a) which configurations consume less energy for a given separation task? (b) under what operating conditions, will these configurations require the least amount of energy? We address these questions in this article. We use the total vapour duty; defined as the sum of vapour flows in all the reboilers, as a proxy for energy consumption.

Traditionally, owing to the size of the search space, the design of configurations is made using heuristics, trial-and-error and experience of the practitioner. Such practices often lead to suboptimal solutions resulting in high energy penalty (Shah and Agrawal, 2010). Even with sophisticated process simulators, like ASPEN PLUS, screening through the entire search space is not feasible in a reasonable amount of time. Besides, our experience shows that the rigorous simulators face convergence issues with thermally coupled and satellite-column configurations. Therefore, we develop an easy-to-use software that enables an industrial practitioner to identify a handful of attractive configurations after considering the entire search space. Towards our goal, we formulate and solve a novel Mixed Integer Nonlinear Program (MINLP). The solution of the MINLP gives the optimal configuration and its optimal operating conditions. As a first step, we focus only on non-azeotropic mixtures. Consequently, Underwood method (Underwood, 1948) can be used to estimate column vapour duties, providing a mechanism to screen the configurations. The screening process results in a handful of candidate configurations. Rigorous simulations can then be performed only on the candidate configurations to determine the configuration appropriate for an application. Finally, we integrate our formulation with DISTOPT, a software developed by our group, to aid visualization of distillation configurations.

2. Summary of MINLP formulation

In this section, we briefly describe the MINLP formulation. The first step in the problem formulation is the isolation of the search space of feasible configurations. We define binary variables indicating the presence/absence of streams and heat exchangers. Constraints on these variables are formulated on the lines of the method proposed by Shah and Agrawal (2010). The second step in the problem formulation is mass balance equations. We adapt the superstructure in Caballero and Grossmann (2004) by proposing some modifications. We observe that, by appropriately bypassing streams through pseudocolumns, we can embed the entire search space in the superstructure. We treat the problem as a multicommodity network flow problem, where each pseudocolumn is analogous to a node on which component mass flows are modelled. The rectifying and stripping sections of a pseudocolumn are analogous to edges that carry material from one node to another. When a pseudocolumn carrying out the split of a stream is absent, the component, vapour and liquid flows are bypassed (Caballero and Grossmann, 2004). On the other hand, when the pseudocolumn is present, the component flows are redistributed between the rectifying and stripping sections while satisfying Underwood constraints to minimize column vapour flow. Underwood's method is a shortcut to reasonably estimate the minimum vapour flow for a separation, while avoiding tray-by-tray equilibrium calculations. Unfortunately, the resulting problem is nonconvex, even for a fixed configuration, and can be challenging to solve to global optimality.

Nonconvex problems are typically solved by iteratively refining the search region using bounding schemes. Since simple factorable relaxations for the nonconvex problem do not produce reasonable bounds for this process to be effective, we improve these bounds

by adding valid cuts that improve the bound quality. For example, we exploit the monotonic nature of the Underwood equations. Though these constraints have not been used in formal MINLP models, they have been used to argue that Underwood roots 'flow' or 'carryover' from one column to another (Carlberg and Westerberg, 1989; Halvorsen and Skogestad, 2003). These constraints play a vital role during the range reduction process for thermally coupled columns. Other constraints are derived using Reformulation-Linearization Technique (RLT), a simple yet powerful convexification technique (Sherali and Adams, 1992). All these constraints aid the global solvers in navigating to global optimum by improving the bounds and linear relaxations. We remark that our constraints on binary variables are at least as tight as the intersection of the current formulations in the literature (Caballero and Grossmann, 2004; Giridhar and Agrawal, 2010; Shah and Agrawal, 2010). To measure the vapour duty of a configuration, we sum the vapour flows of all reboilers in the configuration. The resulting MINLP is solved to ε - global optimality (with 1% as relative tolerance for convergence) using BARON (Tawarmalani and Sahinidis, 2005).

3. DISTOPT: Configuration visualization tool

To aid the visualization and the interpretation of the results from MINLP, we have integrated our formulation with DISTOPT: a software developed by our group for the optimization of distillation configurations. The software takes the process feed composition and the relative volatility information as input, formulates and solves the MINLP using BARON, interprets the output from BARON, and displays the configurations pictorially. It also displays the optimal component, vapour and liquid flow rates in each stream. In addition to the optimal solution, the software can determine up to the 'K^{th}' best solution, where K is a user specified positive integer. The solutions are obtained by successively eliminating configurations as they are obtained using binary cuts and/or branch-and-bound. Furthermore, through the user-friendly interface, practitioners can customize the search space to only include those configurations with certain desired properties. Few of the options currently available include specification of maximum number of sloppy splits, thermal couplings, submixtures, thermal quality of the side-draw, etc. Other features such as enforcing the presence/absence of specific streams and/or heat exchangers, are being built into the software. Since MINLP problems can be computationally intensive, narrowing the search space by excluding the undesirable configurations could improve the computational speed. When no customization option is specified, the program optimizes over the entire search space. In short, the software enables identification of attractive configurations for a given application with just a click of a button!

4. Case studies

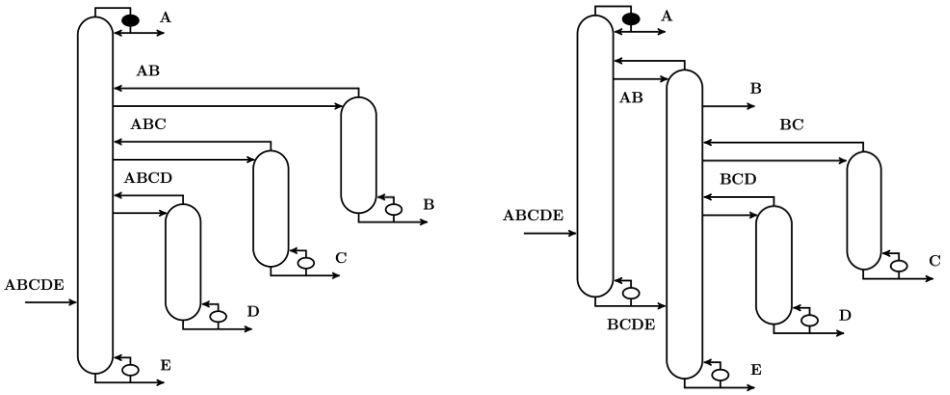
It has been hypothesized for a general n-component system that the Fully Thermally Coupled (FTC) configuration requires the least vapour duty (Fidkowski and Agrawal, 2001; Halvorsen and Skogestad, 2003). Nevertheless, with maximum number of column sections and transfer streams, FTC might be unattractive from the perspective of capital cost and operation. However, is it always necessary to construct FTC to achieve the maximum energy benefits/savings? The answer is no (Shah and Agrawal, 2010), and we will show via a case study that examples of this sort are easy to find with our tool.

4.1. Determination of attractive configurations: Mixture of Alcohols

Here, we consider the separation of an example mixture of alcohols from literature (Caballero and Grossmann, 2004): Ethanol (A), Isopropanol (B), 1-Propanol (C), Isobutanol (D) and 1-Butanol (E). The process feed flow is taken to be 200 kmol/h at saturated liquid state. The process feed consists of 20 % of A, 30 % of B, 20 % of C, 20 % of D and 10 % of E. The relative volatilities of the components w.r.t component E are 4.1, 3.6, 2.1 and 1.42, respectively. The data can be fed to the software, and the underlying algorithms can determine the optimal solution over the entire search space with default options. This often leads to configurations which have several submixtures. The presence of each submixture in a configuration increases the number of column sections, and thus the capital cost. Thus, we will seek a configuration that simultaneously minimizes the number of submixtures/column sections (measure of capital cost) and the vapour duty (measure of operating cost).

With minimum number of submixtures/column sections, sharp-split configurations are attractive in terms of capital cost. Moreover, sharp-split configurations have been preferred in industry due to their simplicity and ease of operation for decades. To determine the optimal sharp-split configuration and vapour duty, we tailor the search space by adding a constraint that enforces exactly n-2 submixtures in a configuration. This constraint characterizes sharp-split configurations. By specifying the maximum number of submixtures as n-2, the software automatically adds the constraint to the MINLP model before solving it. Figure 1(a) shows the optimal sharp split configuration for the separation of the mixture of alcohols. This configuration is known in the literature as the indirect split configuration. The vapour duty of the configuration scaled w.r.t the vapour duty of the FTC is 1.479 i.e., the best sharp-split configuration requires 47.9% more vapour duty compared to the FTC. Clearly, while potentially attractive in terms of capital cost, the optimal sharp split configuration is not attractive in terms of operating cost. Therefore, we will focus on the next best alternative: configurations with n-1 submixtures. The optimal solution for this case is shown in Figure 1(b).

The solution in Figure 1(b) is attractive w.r.t to both capital and operating costs for three reasons. First, the configuration requires only two additional sections, and thus the



(a) Vapour duty is 47.9 % higher than FTC (b) Vapour duty is the same as that of FTC

Figure 1: Candidate configurations for the separation of alcohols: (a) Optimal sharp-split configuration (b) Optimal configuration with one sloppy split

capital cost is not too far off compared to a sharp split configuration. Second, each column has a heat exchanger allowing for a better control of reflux, and makes the start-up and shutdown process easier. Finally, the vapour duty of the configuration is the same as that of FTC. We point out that energy savings of the order of 48% are estimated by just allowing one sloppy split.

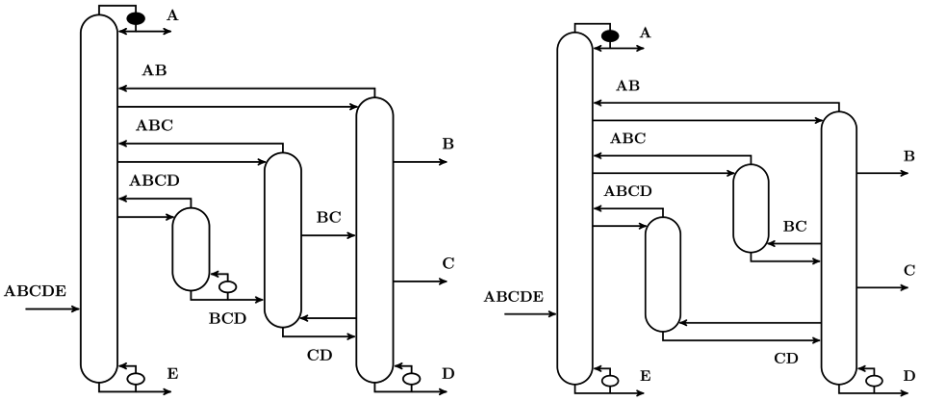


Figure 2: Configurations amenable for retrofitting of indirect split configuration, for light crude fractionation example. (a) and (b) require 19.4 % and 16 % less vapor duty compared to indirect split configuration

4.2. Retrofitting applications: Light crude distillation

The MINLP can also aid in identifying novel configurations that are amenable for retrofitting. We demonstrate this using the example involving separation of light crude (Shah and Agrawal, 2010). We treat light crude as a mixture of Naphtha (A), Kerosene (B), Diesel (C), Gas Oil (D) and Residue (E). The feed flow is taken to be 100 kmol/h, and it consists of 46.1 % A, 19.5 % B, 7.3 % C, 11.4 % D and 15.7 % E. The relative volatility of components w.r.t E is taken to be 45.3, 14.4, 4.7 and 2, respectively.

Ignoring details such as liquid pump-around, the indirect split configuration shown in Figure 1(a) is used for crude fractionation currently. We highlight that our formulation also identifies this configuration as the optimal sharp-split configuration. This shows that the assumptions and the simplifications made in the problem formulation are justifiable. As shown in the previous example, sharp-split configurations, in general, require significantly more energy. Clearly, there is a scope and need for better configurations. Since ab initio redesign of an existing plant is unlikely to be economical, practitioners would be interested in configurations which are amenable for retrofitting. We tailor the search space with such configurations by adding structural constraints that are desired in a configuration.

For issues associated with fouling, residue is preferred to be separated in the first column. Hence, we enforce that all the submixtures which contain residue viz., BCDE, CDE and DE must be absent. In addition, if any other transfer streams are desired, they can be enforced to be present. The optimal and the second best configurations are shown in Figure 2. These configurations require 19.4 % and 16 % less vapour duty compared to the indirect split configuration. By comparing with Figure 1(a), these configurations look attractive for retrofitting.

5. Conclusion

The objective of this work is to briefly describe an easy-to-use tool for the optimization of multicomponent distillation configurations that we have recently developed. The tool formulates and solves a novel MINLP, with minimization of vapour duty as the objective function. By appending appropriate cost or exergy models, the MINLP can be extended to minimize the total annualized cost or exergy loss. The MINLP has been integrated with our easy-to-use software, DISTOPT, to aid visualization and selection of the desired configurations to consider during optimization. Finally, different features of the software are illustrated through two five-component examples. This tool enables the industrial practitioners to systematically design distillation configurations for an application, and eliminates the dependence on the heuristics and trial-and-error methods.

Acknowledgements

We express our gratitude to the U.S. Department of Energy, award number: DE-EE0005768, for the financial support. T.G.R. would like to thank Tony Mathew for his help in the integration of the MINLP with DISTOPT, and Zheyu Jiang for valuable discussions.

Abstract

Distillation columns are conventionally controlled at fixed reflux ratio to maintain the quality of the overhead product. If the cooling temperature of condenser becomes cold, the reboiler heat increases to cope with the internal reflux flow. Also, the loss of product recovery happens at the bottom of the column during the control delay of maintaining the bottom temperature. The reflux ratio is adequately adjusted by based on a proposed hybrid model analysis using the fist principle model (FPM) and least squares regression. According to the sensitivity case analysis with FPM on benzene / toluene binary distillation column, the reflux rate is substantially estimated by the multivariate least squares regression using the following explanatory variables; 1) feed flow rate, 2) column temperature in certain of stages, 3) column pressure, 4) sub-cooling temperature of condenser.

To confirm the effectiveness of the hybrid approach, the dynamic simulation study cases of benzene / toluene binary distillation column are carried out. The simulation results show the effectiveness of the hybrid approach to reduce the energy consumption of reboiler heat duty and loss prevention of product.

Keywords: Distillation operation optimization, Hybrid model analysis, Least squares regression, Steady state and dynamic process simulation, Column reflux optimal control, Low calculation cost, Model reduction.

1. Introduction

The industrial importance of distillation column is widely recognized. As the high purity products can be recovered, it still occupies a dominant part of the process industry. On the other hand, it requires the large amount of heat consumption so that the internal vapor flow is generated to operate the separation utilizing the vapor-liquid equilibrium condition. With respect to the composition and temperature control of distillation column, the control of reflux flow rate becomes slower than that of reboiler boiling up. Since the liquid mass holdup existing in the column is much higher than the vapor one, temperature change in liquid holdup is delayed due to the large amount of liquid mass and mass transfer in column internal. Boiling up through reboiler is often used to maintain the required condition of column operation according to the readiness response (Shinskey, 1984). If the high purity products are recovered from column overhead, the reflux control is not expected to maintain the specification of the overhead. Therefore, the reflux control

is conventionally fixed with constant flow rate including the margin to compensate the uncertainty of dynamics characteristic. The control response, the unexpected process disturbance or the equipment performance change are the representative dynamic uncertainty.

To adapt the reflux rate with the minimum required condition to maintain the product specification of the overhead, RTO-MPC (real time optimization – model predictive control) software system is widely utilized. This is the combination approach of the steady state optimization of RTO and the transmission of optimized set point according to MPC. Darby *et. al.* (2007) describes the RTO-MPC basic methodology and its performance assessment regarding the unsuccessful supporting and maintaining, complication of modelling, and calculation waiting time of steady state model. Also, the Grey-box model including both physical (first principle) knowledge and empirically determined constitutive equations are mentioned.

A presented hybrid approach proposes the solution as the alternative methodology of RTO-MPC using the model reduction technique.

2. Methodology - Hybrid model analysis

The proposed hybrid model analysis includes the following three steps;

1) To obtain *a priori* knowledge of optimized target value within certain constraints, the sensitivity study using the steady state simulation model is carried out (refer to section 2.2).

2) The multivariable inputs-outputs relationship extracted from the sensitivity study results of the steady state model is statistically transformed to the reduced variable model (refer to section 2.3).

3) The statistical reduced variable model is applied to the optimized set point estimator (refer to section 3.2).

The hybrid model analysis is a gray-box approach which enables to combine *a priori* knowledge regarding the system characteristic with various operation condition change and the fast calculation environment due to the reduced variable model.

2.1. The steady state simulation model

As an example distillation model, the simple binary system of benzene and toluene is considered. The basic condition of this example is shown as follows;

Feed throughput:	2,000kmol/h
Column diameter:	4.0m
Number of theoretical plate:	30

Condenser type is assumed as air fin cooler. The condenser temperature is varied as the intent of day-change. The representative process variable such as flow rate, pressure and temperature is shown in Fig.1. Benzene product recovery of 99.8% and toluene product recovery of 99.0% are assumed at the overhead and the bottom of distillation column, respectively.

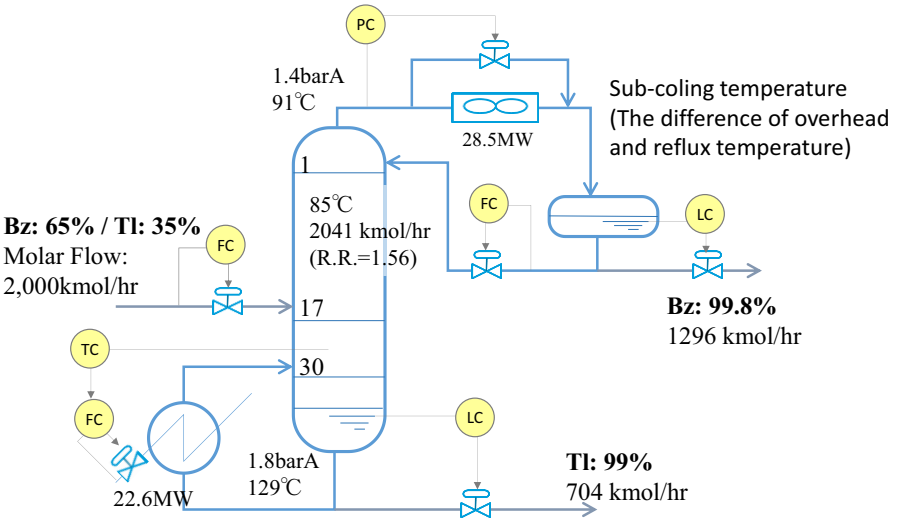

Fig.1 Example distillation column model and representative process variables

2.2. Sensitivity study cases

Sensitivity of the following process variables are investigated to confirm the required reflux rate; (1) feed compositions, (2) feed flow rate, (3) overhead pressure, (4) sub-cooling temperature according to condenser temperature change. From the sensitivity study, inputs-outputs relationship shown in Table 2 is obtained.

Table 1 Inputs-outputs relationship achieved from sensitivity study

No. of Case Study	Feed Flow Rate	Feed Comp.	Over-head Pressure	Sub-cooling Temp.	Column Temperature in Each Stage				Reflux Flow Rate	Reboiler Boiling Up Flow Rate
Run 1	F_1	x_1	$P_{1,1}$	ΔT_1	$T_{1,1}$	$T_{2,1}$	$\cdots$	$T_{n,1}$	R_1	V_1
Run 2	F_2	x_2	$P_{1,2}$	ΔT_2	$T_{1,2}$	$T_{2,2}$	$\cdots$	$T_{n,2}$	R_2	V_2
⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮
Run i	F_i	x_i	$P_{1,i}$	ΔT_i	$T_{1,i}$	$T_{2,i}$	$\cdots$	$T_{n,i}$	R_i	V_i

Variables as input of sensitivity study

Variables as output of sensitivity study and observable value in real operation

Variables as output of sensitivity study and objectives of control

To consider the on-line measurement problem, feed composition is difficult to select as the explanatory variable of statistical estimator. It is supposed that the column internal temperature has an inferential characteristic with respect to the feed composition change. Feed benzene compositions are changed from 0.5 to 0.75, and feed flow rates are changed from 1,400 kmol/h to 2,400 kmol/h. Feed compositions and flow rate are varied with 15 data points. Overhead pressure is changed from 1.0 to 2.0 bar with 5 data points.

Subcooling temperature is changed from 0 to 20 ℃ with 6 data points. Totally, 450 data points are provided for the expression of operation design space.

2.3. *Statistical model to predict the optimum reflux rate*

The relationship of multivariable inputs-outputs relationship is statistically expressed by the least squares. As the explanatory variable are **X** and objective variables are **Y**, the following equation (1) is the least squares basic form.

$$\mathbf{Y} = \mathbf{X\theta} \quad (1)$$

Where, $\boldsymbol{\theta}$ is the parameter of determining the relationship of **X** and **Y**, and $\boldsymbol{\theta}$ is calculated as follows;

$$\boldsymbol{\theta} = (\mathbf{X}^{\mathbf{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathbf{T}}\mathbf{Y} \quad (2)$$

According to the least squares regression, the required reflux flow rate can be estimated well by the four types of variables mentioned in section 2.2. Estimated results are shown in Fig.2.

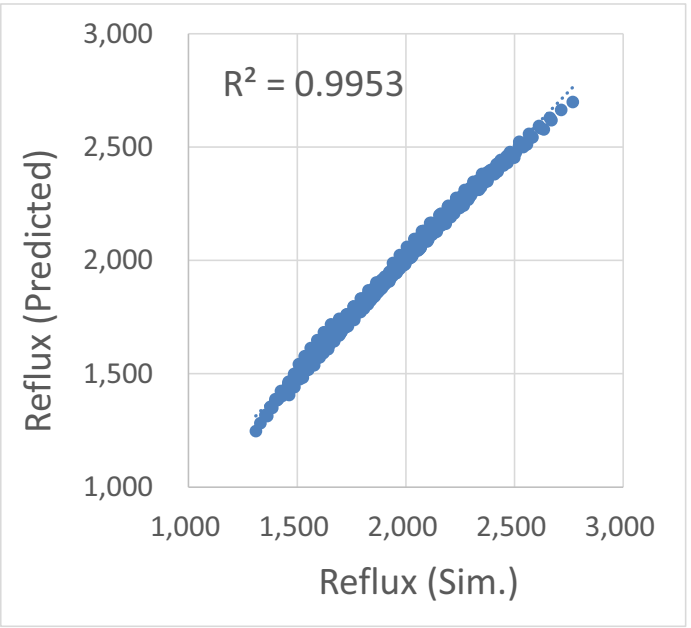

Fig. 2 Estimated results of required reflux flow rate by least squares regression

3. Verification of dynamic simulation model

The effectiveness of hybrid model estimator for required reflux flow is verified in the dynamic simulation model. The design information is achieved by the steady state model. Basic control configuration is shown in Fig.1 (refer to section 2.1).

3.1. Connection of the statistical model to process controller

The hybrid model estimator and the set point of reflux flow rate are combined without consideration of dynamics effect. An amount of margin is incorporated in that connection of statistical model to process controller shown as equation (3).

$$F_R = \hat{Y}_R + m \quad (3)$$

Where, F_R is the set point of reflux flow,
$\hat{Y}_R$ is the estimated value of required reflux flow, and m is the margin to compensate the error occurred by dynamic effect especially caused by the delay of column internal liquid distribution and reboiler heat up by PID control.

3.2. Case Study & Simulation results

The ambient temperature change shown in Fig. 3 is applied to the dynamic simulation model.

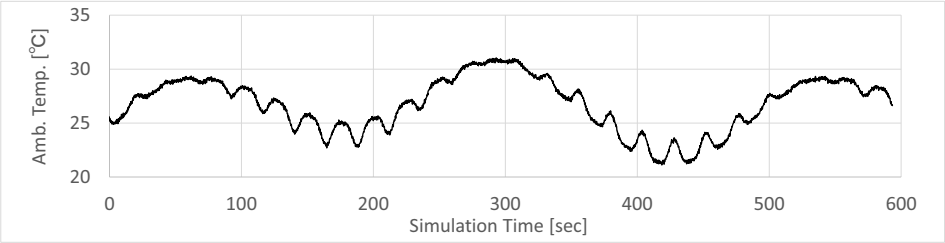

Fig.3 The ambient temperature change applied to the condenser inlet

The cycle of simulated temperature change is adjusted to the 240 seconds instead of the 24 hours cycle of day change (Fig.3). The reason of setting the shorten cycle of temperature change is as follows;

1) To confirm the dynamic effect in the severer condition.
2) Reduce calculation cost of dynamic simulation.

Two study cases are verified;

Type-A: Fixed reflux flow rate

Type-B: Variable reflux flow rate with fixed benzene composition

The simulation results for the comparison of type-A and type-B are shown in Fig. 4, Fig. 5, Fig. 6, Fig. 7.

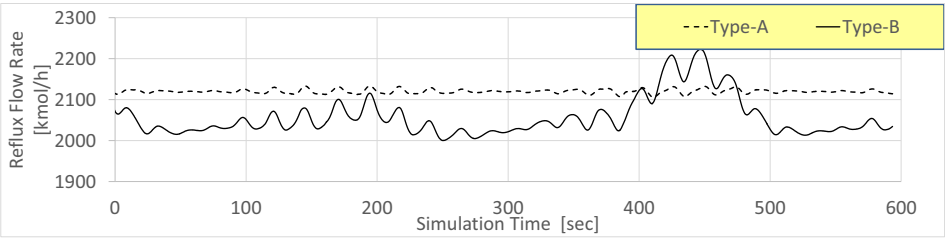

Fig. 4 Dynamic simulation results of the reflux flow rate

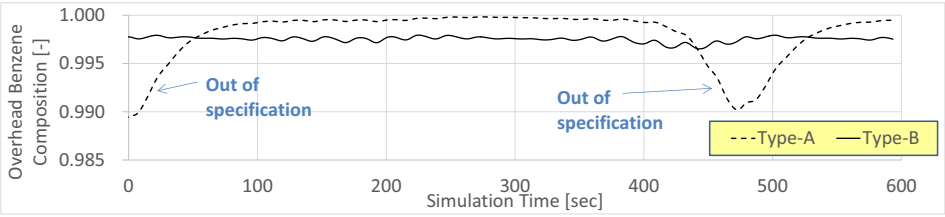

Fig. 5 Dynamic simulation results of the overhead benzene composition

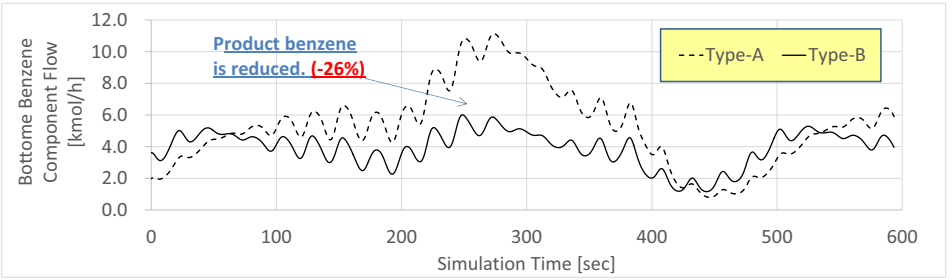

Fig. 6 Dynamic simulation results of the bottom benzene component flow rate

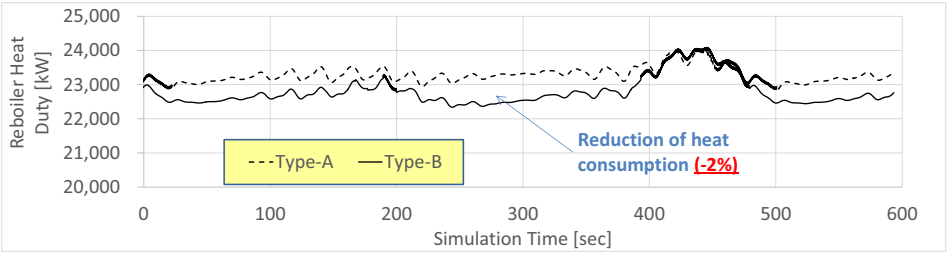

Fig. 7 Dynamic simulation results of reboiler heat duty

The reflux rate (type-A) is stable, on the other hand, the reflux rate (type-B) is changed (Fig. 4). According to the adjustment of the reflux rate (type-B), the overhead benzene composition is maintained to the specified composition. In the results of type-A, duration of the out of specification is found (Fig. 5). Since the reflux rate of type-B is maintained with lower amount than that of type-A, the benzene slip amount at the column bottom is reduced by 26% during the simulation verification period (Fig. 6). Also, the reboiler heat duty in type-B is reduced by 2% from that in type-A (Fig. 7).

4. Conclusions

Hybrid model analysis of the steady state simulation and the regression model is proposed. *A priori* knowledge such as the system changes in operational process variables can be extracted by the sensitivity study conducting in the steady state process simulator. An illustrative case study of a distillation column with process control is successfully demonstrated. Application of the hybrid model approach to the more complicated process systems will be the future work. According to the increase of process model complexity, the problem regarding to overfitting and robustness of regression model will be expected to emerge. Future work will not only focus the regression model building but its appropriate variable selection method and robustness.

Abstract

Reaction solvents have been playing an important role in liquid-phase organic synthesis. To identify the optimal solvents for accelerating reaction rates, a GC-COSMO based computer-aided molecular design model is formulated, in which a new reaction kinetic model is proposed with the help of parameter reformulation strategy based on the conventional transition state theory. The high-performance solvent with the maximum reaction rate constant is generated using the proposed design model. This solvent design method can be applied to various reaction types. The validity of our method is demonstrated for the selected *Menschutkin* reaction.

Keywords: solvent design, computer-aided molecular design, kinetic reaction, solvation effect, group contribution.

1. Introduction

With the development of process industry, solvents are widely used in physicochemical processes. When involved in liquid-phase organic synthesis, solvents can have significant impacts on rates and selectivity to facilitate the existing synthetic routes or even develop new routes (Struebing et al., 2013). Thus, the choice of reaction solvents is particularly important to product yield and economic benefit. However, it is impossible to perform thousands of kinetic experiments for screening reaction solvents. Therefore, efficient methods should be developed to help the solvent selection.

In the last few years, Computer-Aided Molecular Design (CAMD) technique has been successfully adopted for the optimal design of solvents. Although it has contributed a lot to solvent design in the separation processes, there are few contributions in the reactions comparatively. Gani et al. (2008) proposed a systematic method for the selection of solvents, which shows great applicability for a wide range of reaction systems. However, their method requires abundant priori knowledge about the reaction systems for the construction of solvent score table and can only give qualitative predictions on the solvent choice. For quantitative predictions, the pure Quantum Chemical (QC) calculations (e.g., ab initio or DFT computations) can be employed to make the reaction rate constants prediction available without any experimental data. But it is time-consuming and the obtained results are usually inaccurate.

Another popular way to study the reaction rates is the Quantitative Structure-Property Relationships (QSPR) method, which is often represented as a multiple linear

relationship between experimental rate constants and a set of solvent descriptors. Folić et al. (2008) have employed a solvatochromic equation to correlate the rate constants with solvent properties. Although this method can generally provide satisfactory predictions with some prespecified solvents, it has poor abilities in extensive solvent screening as the solvent properties are extremely dependent on considerable experiments. Zhou et al. (2015) have introduced new solvent descriptors based on the COSMO-RS (COnductor like Screening MOdel for Real Solvents) model. The reaction kinetic model avoids large numbers of experiments for the solvent properties, and it shows excellent prediction results in the Diels–Alder reaction. But this approach has little supporting theoretical basis. Most importantly, it may only be adapted to a certain reaction type, which means it lacks extensive adaptability in other kinetic reactions.

In the second part of this paper, a new reaction kinetic model is proposed based on Conventional Transition State Theory (CTST). Then, a CAMD model is developed for the reaction solvent design, in which the COSMO-SAC (Segment Activity Coefficient) model is employed for the calculation of infinite dilution activity coefficients, Group Contribution (GC) method is integrated for the prediction of other solvent properties. Next, an MINLP problem is formulated, and followed by a decomposition-based solution algorithm to reduce the difficulty in dealing with the nonlinear COSMO-SAC equations. In the third part, the validity of our method is demonstrated by a selected *Menschutkin* reaction in the case study.

2. The CAMD model for the reaction solvent design

CAMD uses mathematical modelling to determine the molecule or molecular structure that matches the predefined target properties with a given set of building blocks. The development of CAMD methods started in 1980s, and nowadays have been successfully applied in various type of products, such as solvents, refrigerants and polymers. Here, a CAMD based framework is developed for the reaction solvent design, which consists of three sub-models as shown in Figure 1. In the reaction model, the rate constant (Eq.(4)) is derived with the help of parameter reformulation strategy and the knowledge based descriptor selection.

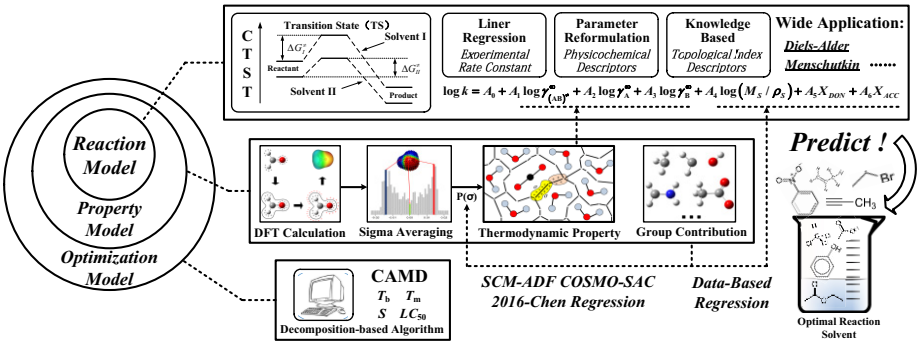

Figure 1. Reaction solvent design framework

In the property model, the key descriptors, infinite dilution activity coefficients, are calculated inexpensively based on the state-of-the-art COSMO-SAC model (Chen et al., 2016) in SCM-ADF (Velde et al., 2001), which guarantees the accuracy compared to the previous COSMO versions. Other descriptors are available from the database. Then, a GC method has been developed to associate molecular structure with theoretical

solvent descriptors. In the optimization model, the CAMD problem is formulated as an MINLP model and then solved by a decomposition-based approach. Finally, the optimal reaction solvent with the highest rate constant is identified.

2.1. Product attributes identification

Nowadays, kinetic controlled reactions have played important roles in organic synthesis. Reaction rate constant, which has been regarded as the objective product attribute, is one of the most crucial variables to control the reaction rate under the conditions of constant reactant concentration, temperature and pressure. Besides, to ensure normal operations and environmental sustainability, other solvent attributes, such as melting point, boiling point, solubility and LC_{50}, are also taken into account in the CAMD solvent design.

2.2. Reaction model

Solvents are widely used as reaction media in liquid-phase synthesis. The variation of solvents can dramatically change the reaction rate and mechanism. This phenomenon is explained as solvation effect, which can be quantitatively assessed through the solvation free energy. Here, a strategy of parameter reformulation and the knowledge based descriptor selection are employed to develop the kinetic equation. Firstly, the reaction rate constant (Eq.(1)) has been derived based on CTST. Since the solvation free energy can be expressed as Eq.(2) in the COSMO model, Eq.(3) is subsequently formulated.

$$k = \kappa \frac{k_B T}{h} \prod_i \left(c_i^{\theta,L}\right)^{\nu_i} \prod_i \left(q_i'^{IG}\right)^{\nu_i} \exp\left(-\frac{\Delta^{\neq} \underline{E}_i^{el,IG}}{RT}\right) \cdot \exp\left(-\frac{\Delta^{\neq} \Delta \underline{G}_i^{p\to c,IG} + \Delta^{\neq} \Delta \underline{G}_i^{\theta,solv}}{RT}\right) \tag{1}$$

$$\Delta \underline{G}_i^{\theta,solv} = RT \ln \gamma_i^{\infty} + RT \ln P_i^S + RT \ln \frac{M_S}{\rho_S V_{gas}} \tag{2}$$

$$\begin{aligned} k = \kappa \frac{k_B T}{h} \prod_i \left(c_i^{\theta,L}\right)^{\nu_i} \prod_i \left(q_i'^{IG}\right)^{\nu_i} \exp\left(-\frac{\Delta^{\neq} \underline{E}_i^{el,IG}}{RT}\right) \cdot \exp\left(-\frac{\Delta^{\neq} \Delta \underline{G}_i^{p\to c,IG}}{RT}\right) \\ \cdot \exp\left(\Delta^{\neq} \ln \gamma_i^{\infty} + \Delta^{\neq} \ln P_i^S + \Delta^{\neq} \ln \frac{M_S}{\rho_S V_{gas}}\right) \qquad \Delta^{\neq} = (AB)^{\neq} - A - B \end{aligned} \tag{3}$$

$$\log k = A_0 + A_1 \log \gamma_{(\mathrm{AB})^{\neq}}^{\infty} + A_2 \log \gamma_{\mathrm{A}}^{\infty} + A_3 \log \gamma_{\mathrm{B}}^{\infty} + A_4 \log\left(M_S / \rho_S\right) + A_5 X_{DON} + A_6 X_{ACC} \tag{4}$$

The assumptions of constant temperature T and transmission coefficient κ is proposed for model simplification. Then, it's easy to find out that most of other parameters, such as Planck constant h, Boltzmann constant k_B and gas molar volume V_{gas} are constants, while the standard state concentration $c_i^{\theta,L}$, partition function q'^{IG}, electronic energy $\underline{E}_i^{el,IG}$, Gibbs free energy change $\Delta \underline{G}_i^{p\to c,IG}$ and saturated vapor pressure P_i^S are all solute related, which means that the rate constant is only correlated with infinite dilution activity coefficient γ_i^{∞}, solvent relative molecular mass M_S and density ρ_S. On the basis of the analysis above, the solvent-independent parameters can be regarded as solute-determined constants. In this way, a multiple linear expression can be obtained through logarithmic treatment on the both sides of Eq.(3). In addition, as hydrogen-bond interaction has great impacts on the kinetic reaction rates, hydrogen bond

donor/acceptor are also chosen as topological index descriptors based on knowledge, and Eq.(4) is obtained for the reaction solvent design.

2.3. Property model

Property models are need for the estimation of solvent descriptors in Eq.(4), among which the infinite dilution activity coefficients between solutes (reactants and transition state) and solvents can be calculated inexpensively by sigma-profiles and COSMO volumes using COSMO-SAC model. Unlike the UNIFAC model, COSMO-SAC is a continuum solvation model used in QC calculation. It doesn't require any experiments for regression of binary interaction parameters and can be easily applied to the transition state. Other descriptors including solvent relative molecular mass, density and hydrogen bond donor/acceptor are obtained from the database. Later, a GC method is developed to associate functional groups with solvent descriptors, which are regressed for 75 groups with a sample of 151 solvents.

2.4. Optimization model

Integrated with reaction and property model, the CAMD problem can be formulated as an MINLP model. It includes an objective function, molecular structural constraints and the property constraints. Reaction rate constant is selected as the objective function to be maximized. The molecular structural constraints restrict the combination of numerous functional groups to develop a feasible chemical structure. Property constraints are set to ensure the application of the solvent and low environmental impact. More details can be found in Zhang et al. (2015). The boiling point T_b, melting point T_m, solubility S and LC_{50} are obtained using GC method (Marrero and Gani, 2001).

2.5. Solution algorithm

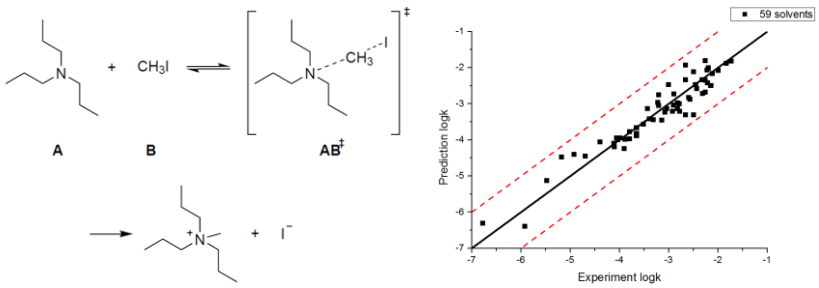
The GC-COSMO based CAMD problem is finally formulated as an MINLP model. Although the discrete choices and conditional constraints in the COSMO-SAC model can be reformulated using GDP and Big-M method, the large number of nonlinear implicit equations can hardly be solved by BARON solver. Thus, a decomposition-based algorithm (Karunanithi et al., 2005) is employed. In this algorithm, the MINLP model is decomposed into an ordered set of sub-problems, in which linear constraints and equations are first considered to generate a certain number (N) of feasible solutions. Then, nonlinear parts are iteratively performed with the calculation of reaction rate constants. Finally, the candidate molecules can be sequentially obtained in the order of objective function maximization, and the solution of this method is equivalent to the original problem as long as N is large enough.

2.6. Verification

In this step, the GC-estimated descriptors like activity coefficients and other solvent properties can be verified from the Density Functional Theory (DFT) and database search separately. As for reaction rate constants, rigorous models or kinetic experiments need to be performed for further demonstration.

3. Case study

A case study of *Menschutkin* reaction for reaction solvent design is presented. The mechanism of *Menschutkin* reaction is shown in Figure 2 (a). To demonstrate the reaction model, a sample of 59 solvents with experimental rate constants is employed for linear regression. We have applied Zhou et al. (2015)'s model to the *Menschutkin* (R^2/0.291, MAPE/20.29 %), our result is excellent with R^2/0.905 and MAPE/8.07 %. Another case study (Diels-Alder reaction) is also performed in our work with good results (R^2/0.918, MAPE/2.80 %), which indicates that the proposed reaction model is more reliable in different types of kinetic controlled organic synthesis and conducive to the design of optimal reaction solvents, including ionic liquids. The predicted rate constants are shown in Figure 2 (b). As all the other researchers have adopted the expression log$k$ in their results, we thus choose log$k$ rather than k for a better comparison. Besides, the current existing studies are still difficult to predict k in high accuracy. Further corrections are needed in the CTST and COSMO model.



(a) The mechanism of *Menschutkin* reaction (b) The predicted logk vs experimental logk

Figure 2. The mechanism and regression results of *Menschutkin* reaction

Table 1. The candidate molecules of the case study

Formula	$C_8H_{14}O_2$	$C_7H_{12}O_2$	$C_8H_{14}O_2$	$C_7H_{13}NO$	$C_8H_8O_2$
Groups	1 CH_3 3 CH_2 1 CH 1 CH_2=CH 1 COOH	1 CH_3 2 CH_2 1 CH 1 CH_2=CH 1 COOH	2 CH_3 3 CH_2 1 CH=C 1 COOH	1 CH_3 3 CH_2 1 CH_2=CH 1 HCON	5 ACH 1 $ACCH_2$ 1 COOH
Molecular structure					log$k$	0.0408	-0.2382	-0.3114	-0.4468	-0.6672

Based on the established reaction model, the MINLP model is built and decomposition-based algorithm is adopted to obtain the solution. 1525 feasible solutions are first generated by using the property constraints of T_b, T_m, S and LC_{50} as these properties are linear equations. Then, all the generated solutions are tested by the COSMO-SAC model and reaction model using GC method. Five best solvents are selected in Table 1. It should be noted that the candidate $C_7H_{13}NO$ has similar groups with N,N-dimethylformamide, which is already proved to be a great reaction solvent (Lassau and Jungers, 1968). Based on the analysis of the optimal results, molecules containing

alkenyl group with carboxyl or acylamino may have good performance, which can be verified in further experiments.

4. Conclusions

In this paper, a GC-COSMO based CAMD model for the design of reaction solvent is developed, in which a new reaction model is proposed. Then the MINLP model is established and solved using the decomposition-based algorithm. A case study is presented with the excellent results of R^2/0.905 and MAPE/8.07 % in the reaction model, which demonstrates the effectiveness of our reaction solvent design model.

Abstract

SCR, the selective catalytic reduction using reduction agent, is essential in diesel vehicles in order to meet the tightening NOx emission regulations. This study proposes a first-principle model for the SCR with the urea injector with a consideration of the effect of catalyst deactivation. In order to determine an optimal reactor sizing, sensitivity analysis is used. The optimal design performance is analysed with the following factors: the NOx emission, the amount of ammonia slip, and the capital cost. The optimal length is found to be 25 ~ 30 cm, under the premise that the total length is restricted to 40 cm.

Keywords: Urea-SCR, NOx emission, ammonia slip, cost, optimal sizing

1. Introduction

With global environmental issues emerging, regulations on diesel automobile NOx emissions are also being tightened. In particular, the Euro 6 emissions standards, which began in 2014, are far more stringent than those of the previous Euro 5. In order to meet the Euro 6 standards, an exhaust aftertreatment system must be added, which may incur additional costs. As a result, the future of environmentally friendly vehicles faces the challenge of achieving high fuel efficiency and low pollutant emissions at a reasonable cost.

Continuous efforts have been made towards reducing NOx from diesel automobiles, and one of the exemplary technologies is Urea-SCR (Selective Catalytic Reduction). In the Urea-SCR, injected urea is decomposed by the high temperature exhaust gas. The generated ammonia is then used as a reducing agent of NOx, converting NOx into nitrogen gas. Copper-Zeolite is mainly used as the SCR catalyst, and the kinetic model is available from previous studies (L. Olsson et al. 2008).

Depending on the location of the urea injector, the amount of produced ammonia can vary. This in turn affects the NOx conversion in the SCR. Considering the limited available space for aftertreatment system in a vehicle, the location of urea injector and the length of SCR need to be carefully designed. For example, as the length of SCR increases, the NOx conversion increases and the amount of ammonia slip decreases. On the other hand, if the distance between the urea injector and SCR is too short, the urea may not go through enough thermal decomposition.

2. Urea-Selective Catalytic Reduction System

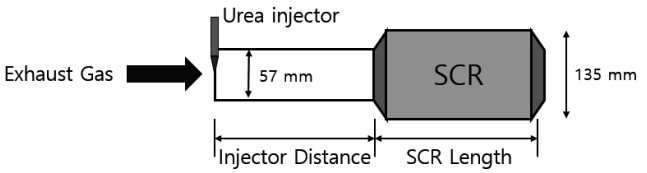

Figure 1. Configuration of SCR with urea injector (not in scale)

The configuration of urea-SCR system is shown in Figure 1. The diameter of the urea decomposition pipe is 57 mm, while the diameter of the SCR system is 135 mm. This nominal design is adapted from Y. Cho et al. (2014). The total length is limited to 40 cm.

In this study, 1-dimensional model suggested by C. Depcik et al. (2007) is used for sensitivity analysis. The governing equations derived from mass balance and energy balance equations are described as follows:

$$\frac{\partial C_{g,j}}{\partial t} + u\frac{\partial C_{g,j}}{\partial x} = \frac{-k_{m,j}G_a}{\varepsilon}(C_{g,j} - C_{s,j}) \tag{1}$$

$$\frac{dC_{s,j}}{dt} = \frac{k_{m,j}G_a}{\varepsilon_{wc}(1-\varepsilon)}\left(C_{g,j} - C_{s,j}\right) - \frac{G_{ca}\sum_{i=1}^{Rxn}\nu_{j,i}R_i}{\varepsilon_{wc}(1-\varepsilon)} \tag{2}$$

$$\Gamma\frac{d\Theta_m}{dt} = \dot{s_m} \tag{3}$$

$$\rho_g\tilde{c_p}\frac{\partial T}{\partial t} = \frac{U_0G_a}{\varepsilon}(T_{wc} - T) - u\rho_g\tilde{c_p}\frac{\partial T}{\partial z} \tag{4}$$

$$\left(\rho_g\tilde{c}_{p,wc} + \frac{\rho_s\tilde{c}_{p,s}}{\varepsilon_{wc}\varepsilon_s}\right)\frac{\partial T_{wc}}{\partial t} = \frac{\alpha(T_e - T_{wc})}{\varepsilon_{wc}\varepsilon_s} + \frac{U_oG_a}{\varepsilon_{wc}(1-\varepsilon)}(T - T_{wc}) \tag{5}$$

$$+\frac{G_{ca}}{\varepsilon_{wc}(1-\varepsilon)}\sum_{i=1}^{Rxn}\nu_{j,i}R_i\Delta H_{Rxn,j,i}(T_{wc})$$

It is also necessary to consider the washcoat porosity (ε_{wc}) in order to express the system more accurately. When the equations represent the behavior of a system containing chemical reactions, a forward integration of the equations becomes difficult (H. Robertson, 1966). MOL (Method of Lines) is appropriate for such stiff differential equations. Another method, Rothe's method, which allows choosing a different mesh for each time step, is too complex to use in this system. Therefore, in this study, MOL shall be used to numerically solve the PDE model.

Before the SCR reaction occurs, injected urea is decomposed into ammonia and isocyanic acid. The chemical reactions involved in the system are reported in S. Yim (2004). The produced isocyanic acid is hydrolyzed into ammonia, which plays the role of a reducing agent in SCR reactions. Since exhaust gas has high temperature, the injected urea solution is immediately vaporized and thermally decomposed. The reactions of urea decomposition into isocyanic acid and hydrolysis of isocyanic acid are as follows:

$$CO(NH_2)_2 \rightarrow NH_3 + HNCO \tag{6}$$

$$HNCO + H_2O \rightarrow NH_3 + CO_2 \tag{7}$$

The SCR reactions and their reaction rates are shown in Table 1. Since ammonia adsorption reaction is reversible, the storage amount of ammonia in SCR depends on the temperature as well as the size of SCR. The kinetic parameters are adapted from L. Olsson et al. (2008). All SCR reactions are inserted in the governing equations (1) ~ (5) as R_i.

Table 1. Reactions and reaction rate for SCR

Reaction	Reaction rate expressions
$NH_3 + S1 \leftrightarrow NH_3 - S1$	$r_1 = k_{1,f} c_{NH_3} \theta_{S1-vacant} - k_{1,b} \theta_{NH_3-S1}$
$2NH_3 - S1 + \frac{3}{2}O_2 \rightarrow N_2 + 3H_2O + 2S1$	$r_2 = k_2 c_{O_2} \theta_{NH_3-S1}$
$NO + \frac{1}{2}O_2 \leftrightarrow NO_2$	$r_3 = k_{3,f} {c_{O_2}}^{1/2} c_{NO} - k_{3,b} c_{NO_2}$
$4NH_3 - S1 + 4NO + O_2 \rightarrow 4N_2 + 6H_2O + 4S1$	$r_4 = k_4 c_{NO} \theta_{NH_3-S1}$
$2NH_3 - S1 + NO + NO_2 \rightarrow 2N_2 + 3H_2O + 2S1$	$r_5 = k_5 c_{NO} c_{NO_2} \theta_{NH_3-S1}$
$4NH_3 - S1 + 3NO_2 \rightarrow 3.5N_2 + 6H_2O + 4S1$	$r_6 = k_6 c_{NO_2} \theta_{NH_3-S1}$
$2NH_3 - S1 + 2NO_2 \rightarrow N_2 + 3H_2O + 2S1$	$r_7 = k_7 c_{NO_2} \theta_{NH_3-S1}$

3. Sensitivity Analysis Results

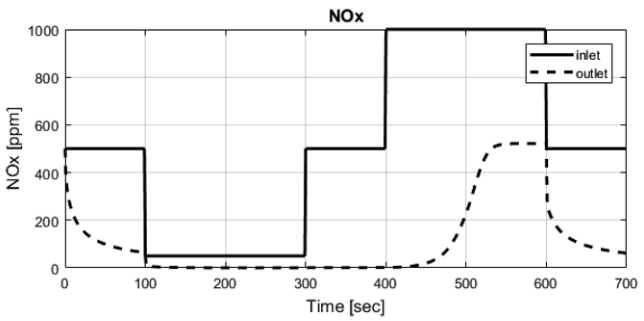

Figure 2. Inlet and outlet concentration of NOx

It is assumed that the exhaust gas has 8 % oxygen. The ratio of NO_2/NOx is assumed to be 0.1 (J. Heywood, 1988). As shown in Figure 2, sensitivity analysis shall be made under the premise that the NOx concentration of inlet gas changes over the time horizon

5 times, in a step-like manner. From 0 to 100 seconds, the inlet concentration of NOx is 500 ppm. Then the NOx concentration in the outlet decreases as a result of the SCR reactions. In the second step, from 100 to 300 seconds, the NOx concentration of engine exhaust gas is lowered to the level of 50 ppm. Since the NOx concentration is very low, the ammonia produced by urea decomposition is stored in catalyst or exits the exhaust pipe in the form of ammonia slip. In the following 400 to 600 seconds, the inlet concentration of NOx is relatively high, 1,000 ppm, which means the amount of ammonia is deficient. Since unreacted ammonia is stored in the catalyst as a result of the previous step, NOx is converted into nitrogen for a while. The amount of stored ammonia increases as the size of the module becomes large. That is to say, the longer the SCR, the more amount of ammonia shall be stored when there is no NOx. In turn, the ammonia stored in increased amount is then used to convert more NOx when its concentration becomes high.

Using the data of 700 seconds in Figure 2, the cumulative amounts of NOx emission, ammonia slip, and the capital cost are calculated according to the length of SCR and distance of urea injector. The capital cost of SCR is calculated by using data from J. GerMan (2012). The SCR cost includes not only the cost of the catalyst but also the cost of urea pump, injector, and tank. However, since these are constant regardless of the reactor size, only substrate and washcoat costs and canning costs are considered in this study. The objective function is defined as a function of SCR length (L).

$$f_0(L) = w_a NOx(L)/NOx^o + w_b NH_3(L)/NH_3{}^o + w_c COST(L)/COST^o \quad (8)$$

In this study, the total length from urea injector to SCR exit is limited to 40 cm. The superscript ^{o} in Equation (8) indicates the order of magnitude of its nominal value. Since the amount of NOx is the most important for a system's performance, w_a shall be set to 3 whereas the others shall be set to 1. If NOx emission is controlled more strictly, w_a can be even bigger, and the optimal length will change accordingly.

As the length of SCR increases, the NOx conversion increases and the amount of ammonia slip decreases. On the other hand, if the distance between the urea injector and SCR is shortened, the urea may not go through enough thermal decomposition. In addition, the capital cost increases as the module becomes larger. Therefore, it is clear that there exists an optimal SCR length which minimizes the objective function.

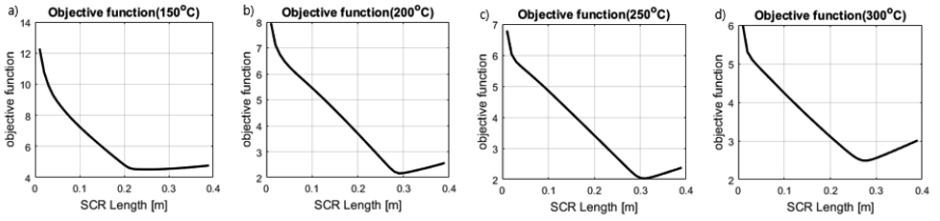

Figure 3. Objective function with sensitivity analysis of a) 150 ℃, b) 200 ℃, c) 250 ℃, d) 300 ℃

The results of sensitivity analysis are shown in Figure 3. The optimal length of SCR is between 25 cm and 30 cm. Therefore the distance of urea injector should be between 10 cm and 15 cm in order to respect the constraint of the total length, 40 cm.

Within the given temperature range in Figure 3, NOx conversion is the highest at 250 ℃. In the low temperature range (150 ℃), the optimal length of SCR is shorter than that of

250 ℃. This does not imply that there is no need for large amount of catalyst to minimize NOx emission. In this low temperature, the catalytic reaction rate is slow, therefore the catalyst efficiency per unit length is also low. A large module only increases the total cost. On the other hand, in the high temperature range (300 ℃), substrate desorption reaction of ammonia is accelerated and thus the amount of ammonia that can be stored in the module is reduced. Therefore, the optimal SCR length is shorter than that of 250 ℃.

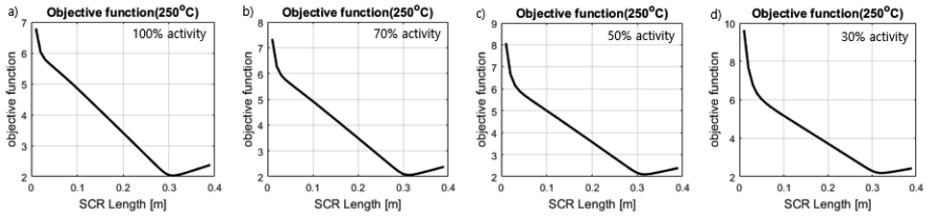

Figure 4. Sensitivity analysis of the objective function of a) 100 % activity, b) 70 % activity, c) 50 % activity, d) 30 % activity at 250 ℃

In this study, deactivation of SCR catalyst is also considered. One problem related with automobile exhaust gas catalysts is the problem of reduced activity due to aging of catalyst. Contaminants such as Sulfur adhere to the catalyst surface and interfere with the catalytic reactions. Hot temperature also causes sintering which results in significant loss of catalyst activity. In this study, the catalyst deactivation was performed by multiplying reaction rate constants by a fixed number, between 0 and 1. In all, cumulative amount of NOx emission and ammonia slip increased, but the optimal SCR length at which the objective function is minimized remained practically unchanged.

Commercial urea-SCR size is shown in Y. Cho et al. (2014). General geometry of urea-SCR for 2.7 L engine consists of 150 mm urea decomposition pipe and 234 mm SCR system. With this geometry and inlet gas shown in Figure 2, the cumulative amounts of NOx emission and ammonia slip are 288.9 mg and 88.41 mg, respectively. In addition, the capital cost of SCR is $117.23. Through sensitivity analysis with the objective function, the optimal configuration of total 384 mm urea-SCR system is calculated as 77 mm injector distance and 307 mm SCR catalyst. With this geometry, the cumulative amounts of NOx emission and ammonia slip are 145.0 mg and 5.40 mg, respectively, and the capital cost of SCR is $153.83. A mere additional cost of $36.6 reduced the cumulative amount of NOx emission by 143.9 mg and ammonia slip by 83.01 mg, respectively.

4. Conclusion

In this study, optimal urea injector position and optimal SCR size are determined by sensitivity analysis. The objective function has three factors; cumulative NOx emission, cumulative ammonia slip, and capital cost. The total length is limited to 40 cm, and the simulation results showed that the optimal SCR length is found between 25 cm and 30 cm. The catalyst deactivation, which is problematic in automotive catalysts, is also considered. Compared to the conventional commercial SCR, the cumulative amounts of NOx emission and ammonia slip are reduced by 143.9 mg and 83.01 mg respectively, under the inlet data used in this study. By creating a new objective function in combination with the weights, we can observe the change of the objective function value under various scenarios. It will be dealt with more deeply through Pareto front observation in our future work.

(novelty) This study is the previous stage to observe the change of the objective function considering various factors and to derive the optimal condition for each case. Pareto front observation will be continued as a future research.

Novel Symbolic Regression-Mathematical Programming based Predictions of the Molecular Cetane Number with Small Sampling Data

Jiawen Wei, Zhihong Yuan*

Department of Chemical Engineering, Tsinghua University, 100084 Beijing, China
zhihongyuan@mail.tsinghua.edu.cn

Abstract

In order to conduct the high-throughput screening of molecules and subsequently speedup the process of exploring latent new fuels with desirable properties such as high CN (Cetane Number) which is one of the most vital signatures to assess the fuels combusted in the engine, a novel machine learning method named hybrid Symbolic Regression-Mathematical Programming based approach for extracting surrogate model from data sets is proposed. We formulated the Symbolic Regression Tree (SRT) as a Generalized Disjunctive Programming (GDP) model. Via the Big-M, the GDP model is transferred to a mixed integer nonlinear programming (MINLP) model. BARON is then utilized to solve the MINLP. The established model in this paper demonstrates a good advantage in training efficiency, model representation and prediction accurate.

1. Introduction

Concerns about diminishing fossil fuel reserves along with climate change and national security have promoted considerable research activities on exploring alternative, environmentally friendly processes for producing liquid transportation fuels. During the past decades, industrial and academia have doing their bests to pursue the proper biofuels, which have desirable combustion properties and strong competitiveness, to partially or completely replace traditional petroleum-driven gasoline and diesels.

The CN (Cetane Number) is one of the most important signatures to evaluate the fuels combusted in the engine, which is a correlation based on ignition delay from the start of fuel injection. In general, the higher a fuel's cetane number is, the shorter ignition delay period the fuel has. Cooperative Fuel Research (CFR) and Ignition Quality Tester (IQT) are two mainly used methods in determining CN. The American Society for Testing and Materials (ASTM) Standard D613 (ASTM D613, 2015) uses the single-cylinder CFR for determination of CN, while ASTM Standard D7170 (ASTM D7170-16, 2016) and ASTM Standard D6890 (ASTM D6890, 2015) utilize the IQT. All the methods provide accurate CN measurements, while the CFR can mostly reflect a fuel's actual combustion behaviour in the engine and the IQT offers a faster measure process with lower volumetric requirements.

Clearly, if a series of new biofuel molecules are experimentally synthesized one by one to test the potential CN, a huge amount of time and money will be spent inefficiently. To some extent, a proper experimental data driven predictive model representing the structure-CN relationships of molecules approximately, which can help chemists screen the molecules and subsequently speed up the process of exploring latent new fuels with good performance, is desirable.

Motivated by the tremendous advancement of machine learning, predicting molecules' properties from their structures is an obvious way and has been extensively investigated. Yang used backpropagating neural networks to predict the CN of iso-paraffins and diesel fuels based on quantitative structure property relationship (QSPR) (Yang H, 2001). Taylor utilized the QSARIS software to calculate more than 100 molecular descriptors of 275 compounds that may be used to build the predictive model of the CN. Then the software determined which descriptors are most relevant in modelling the CN using a genetic algorithm and built a predictive model (RMSE = 9.1CN units) (Taylor J, 2004). Although this model is not accurate enough, Taylor's work did provide QSPR inputs for later research to predict CN and indicated which molecular descriptions are crucial. For example, Kessler retained 15 molecular descriptors to build a backpropagation neural network based prediction model of cetane number for furanic biofuel additives, with a total RMSE of 5.97 for the core data set of 284 molecules (Kessler T, 2017). Some other types of models such as utilizing an inverse function method (Smolenskii E, 2008) and using the genetic function approximation (GFA) (Creton B, 2010) have also been used to predict CN. Apparently, these methods have made it possible to describe the relationship between molecular descriptors and properties accurately in a single chemical family of similar chemical properties within test range.

Although the aforementioned methods have pretty good robustness and can fit the relationship between CNs and molecular descriptors quite accurately, it is easy to overlook that in choosing which molecular description to be included in a predictive model of CN. To some extent, humans' choices may limit the performance of the predictive model since these choices are made following humans' knowledge. Alpha Go Zero, which beat Alpha Go by removing the constraints of human knowledge, is an implicational instance. Under such circumstance, it is very important and interesting to formulate a method for surrogate model building, which can automatically select the molecular descriptors while guaranteeing the prediction accurate, to predict molecular CN. Considering the excellent characteristics of Symbolic Regression and Mathematical Programming, the objective of this paper is to propose a novel machine learning method to explicitly correlate the relationship between CNs and molecular descriptors.

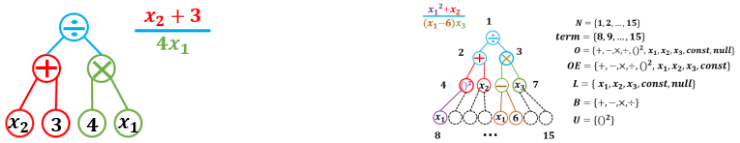
2. Method Description

2.1. Symbolic Regression

Existing literature demonstrated that symbolic regression can give concise analytical expressions without humans' prior knowledge so that it may help scientists to discover laws behind some focused phenomenon (Schmidt M, 2009). An expression tree such as shown in Figure 1(a) can illustrate how symbolic regression runs. It is obvious that any explicit function can be represented by expression trees. What a symbolic regression algorithm does is to combine the pre-set operators such as $\{+,-,\times,\div,\exp\ldots\}$ and operands including variables and parameters to form an explicit function which can represent the mathematical link among the input/output data sets. Due to the absence of any information except basic data set, symbolic regression aims to form proper functional forms and calculate corresponding parameters simultaneously.

Conventionally, most symbolic regression algorithms are based on evolutionary computation which is approached as an application of Genetic Programming (GP). Genetic operations like crossover and mutation would generate more proper expressions, some of which are redundant ones. On the other hand, the expressions may not be concise and may not be even be local optimal due to the GP's stochasticity. To our knowledge,

there is no strict global optimization algorithm to solve the problem of Symbolic Regression.



(a) An instance of expression tree (b) Description of an expression tree

Figure 1. Description of Symbolic Regression Tree.

2.2. The mathematical programming formulation of symbolic regression

To describe an expression tree, several sets and parameters are introduced. As shown in Figure 2(b), the set N is proposed for the number (1 to 15) representing the corroding node of the tree in a sequence. The set O is the compilation of operators and operands. Obviously, there are some absent nodes, so an operator "null" is introduced to represent them. For convenience, some subsets are also defined. OE refers to the compilation of operators and operands except "null", L refers to operands and "null", U refers to unary operators while B refers to binary operators. Furthermore, the variable v_n is given to each node and the link function f^{oe} is introduced to make the tree computable. For convenience, we set v_{ln} to be the left child node's value of node "n", and v_{rn} to be the right one's value. j_n is introduced to represents a constant. Necessarily, for some operators and operands, the constraint $g^{oe} \leq 0$ is enforced to avoid math error or meaninglessness such as the dividend is zero. The binary variable y_n^o describes which operator or operand the node "n" takes. Logical constraints such as each node taking only one operator or operand are also added. I represent the number of data sets. We can measure the fitness of the expression tree by the error between v_{1i} and the sample dependent variable z_i. Therefore, a symbolic regression tree can be formulated as the following Generalized Disjunctive Programming (GDP).

$$\min s = \sum_i (z_i - v_{1i})^2 \tag{1}$$

$st.$

$$\bigvee_{o \in O} \begin{bmatrix} y_n^o \\ f_{ni}^o(v_{lni}, v_{rni}, x_i, , j_n, v_{ni}) = 0 \\ g_{ni}^o(v_{lni}, v_{rni}, x_i, , j_n, v_{ni}) \leq 0 \end{bmatrix} \vee \begin{bmatrix} y_n^{null} \\ v_{ni} = 0 \end{bmatrix} \qquad \forall n \notin term \tag{2}$$

$$\bigvee_{o \in L} \begin{bmatrix} y_n^L \\ f_{ni}^L(x_i, j_n, v_{ni}) = 0 \\ g_{ni}^{const} = \varepsilon - |j_n| \leq 0 \end{bmatrix} \vee \begin{bmatrix} y_n^{null} \\ v_{ni} = 0 \end{bmatrix} \qquad \forall n \in term \tag{3}$$

$$\sum_o y_n^o = 1 \qquad \forall n \notin term \tag{4}$$

$$\sum_{o \in L} y_n^o = 1 \qquad \forall n \in term \tag{5}$$

$$\sum_{o \in BVU} y_n^o = \sum_o y_{ln}^{oe} \qquad \forall n \notin term \tag{6}$$

$$\sum_{o\in B} y_n^o = \sum_o y_{rn}^{oe} \qquad \forall n \notin term \qquad (7)$$

$$y_n^o \in \{0,1\} \qquad (8)$$

$$\underline{V} \le v_{ni} \le \bar{V} \qquad (9)$$

$$\underline{J} \le j_{ni} \le \bar{J} \qquad (10)$$

$$y_{ln}^{cst} + y_{rn}^{cst} \le 1 \qquad \forall n \notin term \qquad (11)$$

$$y_n^{\div} + y_{rn}^{cst} \le 1 \qquad \forall n \notin term \qquad (12)$$

$$y_n^{-} + y_{rn}^{cst} \le 1 \qquad \forall n \notin term \qquad (13)$$

$$\sum\nolimits_{o\in U} y_n^o \le 1 - y_{ln}^{cst} \qquad \forall n \notin term \qquad (14)$$

$$y_{ln}^{x} + y_{rn}^{x} \le 1 \qquad \forall n \notin term \qquad (15)$$

If equations and constraints in (2) and (3) are overwritten with Big-M constraints, the GDP model can easily be transformed into a MINLP model.

3. Results and Discussions

To intuitively test the efficiency of the approach, 13 n-alkanes (C_3~C_{15}) are chosen as the training data sets and then 5 n-alkanes (C_{16}~C_{20}) are predicted. Six descriptors listed in Table 1 are fed to the above GDP model. The final descriptors appeared in the explicit expression will be optimally decided through solving GDP model by BARON (Tawarmalani M, 2004).

Table 1. Definitions of the chosen molecular descriptors (Kessler T, 2017).

Descriptor	Definition
Mor32e	3D-MoRSE - signal 32 / weighted by atomic Sanderson electronegativities
EEig08x	Eigenvalue 08 from edge adj. matrix weighted by edge degrees
CIC1	Complementary information content
RDF090m	Radial Distribution Function - 9.0 / weighted by atomic masses
RDF020p	Radial Distribution Function - 2.0 / weighted by atomic polarizabilities
L/Bw	Length-to-breadth ratio by WHIM

In addition to the set of GDP, a Mixed Integer Nonlinear Programming (MINLP) is also directly built to represent the symbolic regression tree. An Artificial Neural Network (ANN) with six inputs (six descriptors), one output (CN), two hidden layers of 32 neurons which is actually as same as Kessler's work (Kessler T, 2017) is also set. The aim for setting MINLP and ANN models is to conduct the comparisons with GDP to demonstrate its efficiency.

The surrogate model driven by ANN is traditionally inexplicit. Equations (16) and (17) offer the explicit expression between CN and descriptors from GDP and MINLP, respectively.

$$\text{GDP: CN} = (\text{Mor32e} + 0.125) \times \left(7.687 + 2 \cdot \text{CIC1} - 4.964 + \frac{\text{CIC1} - 2.419}{0.59 \cdot \text{Mor32e}}\right) \times \frac{\text{RDF090m} - 2.8 \cdot \text{EEig08x} - 21.595}{\text{CIC1} - 2.19} \quad (16)$$

$$\text{MINLP: CN} = (\text{RDF020p})^2 + \frac{(\text{RDF090m})^2}{\text{CIC1}} + 19.032 \cdot \text{CIC1} - \frac{284.364}{\text{L/Bw}} \quad (17)$$

Clearly, GDP chosen optimally More32e, CIC1, RDF090m, and EEig08x as the independent variables, while MINLP chosen RDF020p, RDF090m, CIC1, and L/Bw. The overall results are shown in Figure 2. The MINLP model showed the worst fitness in the train set. The ANN demonstrated the worst prediction performance. Three models' average relative errors of the prediction are 20.32%(ANN), 8.20%(MINLP), 1.11%(GDP). The GDP model performs the best CN predictions of new molecules which are not listed in the training sets.

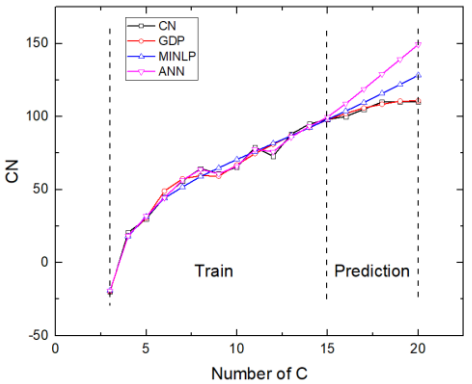


Figure 2. The predicted and original CNs of n-alkanes (C_3~C_{20}).

A 31-node tree containing $\{+, -, \times, \div, ()^2\}$ is used in both the GDP and MINLP model. The MINLP model has 15,504 equations, 6,210 continuous variables and 372 binary variables. The GDP model's size is smaller with 4,653 equations, 838 continuous variables and 403 binary variables. The main factor to cause the different results of the GDP model and the direct MINLP model is the complexity of the calculation. Each constraint, even the loose constraint is concerned when the MINLP problem is solved, such consideration may lead to very long computational time and each cause the wrong results. While the GDP problem can select necessary constraints according to the logical variable y_n^o. Therefore, the GDP model can find a better result. Obviously, excellent training and prediction capacities may be achieved if more operators and nodes are introduced.

Although the prediction capacity of ANN can also be improved through adding more layers and more nodes (Deep learning), a very large data sets are required. In other words, the accuracy of deep learning with ANN may not be high enough when facing small sampling data. However, our proposed method can efficiently tackle small sampling data than ANN through automatically and optimally selecting the equation structure and parameters. Apparently, the mechanism of the proposed method is totally different from the trail-and-error approach of ANN.

The properties of liquid fuels such as CN should be considered during the process design stage under the pressure of clean energy manufacturing. The computational intractable associated with the optimal design/synthesis for liquid fuels production may happen if the complex inexplicit model for CN representation is introduced, as one kind of constraints, to the overall optimization framework. Clearly, the explicit model can accelerate the process design for quality-oriented liquid fuels production. Our computational experiments (including the tests of large training-testing data sets) suggest that the computational burden for the proposed method grows rapidly following the increases on the problem size. Therefore, the tailored algorithm for the proposed method is being developed.

Conclusion

We established a novel Symbolic Regression-Mathematical Programming based method to predict n-alkanes' CNs. The descriptors were selected spontaneously to form the explicit expressions. The proposed method demonstrated better prediction performance when compared to ANN with multiple hidden layer especially when facing small sampling data. If more molecules are put in the training set, more operators and nodes need to be calculated to form the expression tree. Needless to say, the calculation burden would be significantly heavier. Therefore, a tailored solving algorithm is under the exploration. The optimal design/synthesis and operation can benefit from the proposed method due to its capacity to generate explicit surrogate model.

Abstract

Aerosol-Assisted Chemical Vapour Deposition (AACVD) can be used to manufacture, for example, transparent conducting oxides (TCOs), liquid crystal displays (LCDs) and light emitting diodes (LEDs). This paper presents an integrated model to support the scale-up of the AACVD process, which is comprised of three modules: aerosol generation, transport and delivery. Latin Hypercube Sampling (LHS) method is used to generate input data for the sensitivity and uncertainty analysis. Based on industrial ranges of process parameters, the incorporation of AACVD into current TCO industrial plants, without replacing their existing facilities, was found to be mainly impacted by the flow rates, the length of the transport system and the temperature of the chemical deposition site.

Keywords: AACVD, aerosol, process scale-up, LHS, machine learning.

1. Introduction

Solar cells exploit the photovoltaic effect to convert incident light into electricity. They provide clean and renewable energy, which has the potential to reduce our dependence on fossil fuels. The demand for solar cells has been increasing steadily and the advancement of their manufacturing process is crucial. Solar cells rely on the production of Transparent Conducting Oxide (TCO) films, which is usually accomplished by Chemical Vapour Deposition (CVD). This technique involves the vaporisation of volatile precursors and their transport to the reaction site, where the deposition and film formation take place. A modification of the CVD technique results in the Aerosol-Assisted Chemical Vapour Deposition (AACVD), which generates aerosol droplets from the precursor solution instead of vaporising it. Hence, for AACVD, the precursors do not need to be volatile and a new range of them becomes available. The aerosol is then transported to the reaction site for the synthesis of films such as the TCOs, as well as coatings, powders and composites for different final applications.

As examined by Grossmann and Westerberg (2000, 2017), the computational tractability of complex problems is challenging. To mitigate this concern, we avoided the use of Computational Fluid Dynamics (CFD) packages and tried to build a tractable model for the whole AACVD process, which allowed us to repeatedly run simulations to perform a global sensitivity analysis. It takes seconds to run hundreds of simulations, which would not be possible using CFD. This will be very useful in the optimisation of the entire process, which is part of the future work. For the moment, we present an integrated model to support process scale-up, comprised of three modules: aerosol

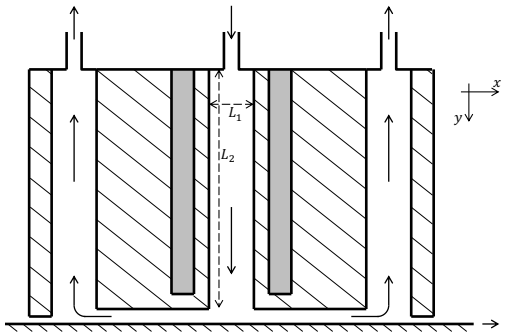

Figure 1. Cross-section of the deposition site in the direction of the flowing glass.

generation, transport and delivery. There is a range of droplet sizes obtained when generating aerosol, which needs to be properly represented. Using models from the literature, the generation of aerosol by ultrasonic vibration is therefore described by a distribution of droplet sizes. Such a distribution is the input to a transport model that incorporates the impact of aerosol losses, which depend on the properties of the droplets, the flow and the piping system. The output distribution provides sufficient information to predict the amount and sizing of aerosol reaching the deposition site. The transport model has been applied to different scenarios, using horizontal, inclined and vertical pipes of different lengths connected by bends. The delivery module includes the droplet evaporation after leaving the transport system and it accounts for uncertainties in the temperature profile of the deposition site. This is a key factor for the droplet evaporation, which sets the precursors free to react and form the desired products. The scale-up of an AACVD process has not been studied or performed yet, to our best knowledge. Additionally, switching from conventional CVD, commonly used in the industry, to AACVD is challenging. Ideally, this transition could happen without having to replace any equipment, aiming at lower costs and the achievement of the same final products or improved ones.

2. Modelling of Aerosol Generation, Transport and Delivery

The generation of aerosol droplets can be done by ultrasonic vibration, using a piezoelectric transducer. The sizes of such droplets are known to be approximately log-normally distributed (Ramachandran and Cooper, 2011). Therefore, assuming a log-normal distribution for the diameter of the aerosol droplets generated, the median diameter $\overline{d_d}$ [m] can be predicted by:

$$\overline{d_d} = f(\boldsymbol{x_n}) \cdot (\sigma_d \cdot \rho_d^{-1} \cdot f^{-2})^{1/3} \tag{1}$$

where σ_d [N·m^{-1}] and ρ_d [kg·m^{-3}] are, respectively, the precursor solution surface tension and density; f [Hz] is the ultrasonic frequency; $f(\boldsymbol{x_n})$ is a function of the vector $\boldsymbol{x_n}$, which takes into account the atomised fluid flow rate, viscosity, surface tension, density and the properties of the ultrasonic atomiser, which are the ultrasonic frequency and power surface intensity. The present work uses Equation 5 from Ramisetty et al. (2013) to describe $f(\boldsymbol{x_n})$, given the good agreement with experimental data.

After generating the aerosol, its transport is done via horizontal, inclined or vertical pipes and bends. Correlations from the literature were used to model the losses of aerosol during transport. Such losses are mainly caused by gravitational settling, diffusional deposition and turbulent inertial deposition, as described by Brockmann (2011). Details about modelling and experimental validation of the aerosol transport system were previously presented by Filho et al. (2017).

Table 1. Range of parameters for the aerosol generation (G), transport (T) and delivery (D) integrated modules. The last column describes which variables are the input for each of the three modules.

Symbol	Parameter	Range	Unit	Module
$c_{p,d}$	Droplet specific heat	$[2.0, 4.0] \cdot 10^{3}$	$J \cdot kg^{-1} \cdot K^{-1}$	D
c_p	Carrier fluid specific heat	$[1.0, 1.1] \cdot 10^{3}$	$J \cdot kg^{-1} \cdot K^{-1}$	D
d	Pipe inner diameter	$[0.5, 2.0] \cdot 10^{-2}$	M	T
d_d	Droplet diameter	$[5.0, 9.0] \cdot 10^{-6}$	M	T, D
f	Ultrasonic frequency	$[1.0, 3.0] \cdot 10^{6}$	Hz	G
$h_{vap,d}$	Droplet specific heat of evaporation	$[1.0, 1.4] \cdot 10^{6}$	$J \cdot kg^{-1}$	D
I	Power surface intensity	$[1.0, 3.0] \cdot 10^{3}$	$W \cdot m^{-2}$	G
k	Carrier fluid thermal conductivity	$[3.5, 4.8] \cdot 10^{-2}$	$W \cdot m^{-1} \cdot K^{-1}$	D
L	Pipe length	$[0.5, 8.0] \cdot 10^{0}$	m	T
N	Number of 90° pipe bends	0 to 4	−	T
Pr	Carrier fluid Prandtl Number	$[6.8, 7.2] \cdot 10^{-1}$	−	D
Q	Carrier fluid flow rate	$[0.1, 1.0] \cdot 10^{-4}$	$m^3 \cdot s^{-1}$	T, D
Q_p	Precursor solution flow rate	$[0.1, 1.0] \cdot 10^{-11}$	$m^3 \cdot s^{-1}$	G
Q_T	Reciprocating nozzles total flow rate	$[0.1, 1.0] \cdot 10^{-2}$	$m^3 \cdot s^{-1}$	D
T_w	Wall temperature	$[5.0, 7.0] \cdot 10^{2}$	K	D
μ	Carrier fluid dynamic viscosity	$[1.8, 3.7] \cdot 10^{-5}$	$N \cdot s \cdot m^{-2}$	T, D
μ_d	Droplet dynamic viscosity	$[0.3, 1.1] \cdot 10^{-3}$	$N \cdot s \cdot m^{-2}$	G, T
ρ	Carrier fluid density	$[0.4, 1.2] \cdot 10^{0}$	$kg \cdot m^{-3}$	T, D
ρ_d	Droplet density	$[0.7, 1.0] \cdot 10^{3}$	$kg \cdot m^{-3}$	G, T, D
σ_d	Droplet surface tension	$[2.0, 5.0] \cdot 10^{-2}$	$N \cdot m^{-1}$	G
ϕ	Pipe inclination angle	$[0.0, 0.5] \cdot 10^{0}$	rad	T

Once the aerosol droplets reach the deposition site, they are heated. The solvent evaporates and the reactions take place, resulting in the film formation. The deposition site shown in Figure 1 is based on the International Patent 96/11802 (Soubeyrand, 1996). The diagram shows a cross-section of the device, where the aerosol arrives from the top middle part and reaches the surface of a moving glass in the x-axis direction on the bottom part. The formation of a thin film with specific optoelectronic properties on the glass is the final objective. The grey part in the diagram is a heat exchanger, which allows the temperature of the deposition site walls to be controlled. The glass width, in the direction perpendicular to the xy-plane, is 3 m, while $L_1 = 0.03$ m and $L_2 = 0.3$ m. The temperature of the carrier fluid travelling between the walls of the reaction site can be modelled as shown in Equation 2:

$$dT/dy = (h_1 \cdot (T_w - T) \cdot P)/(\dot{m} \cdot c_p) \quad (2)$$

where T [K] is the carrier fluid temperature; y [m] is the vertical distance travelled by the fluid; h_1 [$W \cdot m^{-2} \cdot K^{-1}$] is the heat transfer coefficient; T_w [K] is the wall temperature; P [m] is the surface perimeter; $\dot{m}$ [$kg \cdot s^{-1}$] and c_p [$J \cdot kg^{-1} \cdot K^{-1}$] are, respectively, the carrier fluid mass flow rate and specific heat at constant pressure.

The modelling of the droplet evaporation is based on mass and energy balances. Two differential equations are numerically solved simultaneously:

$$h_{vap,d} \cdot \dot{m}_v + c_{p,d} \cdot m_d \cdot dT_d/dt = h_2 \cdot (T_w - T_d) \cdot \pi \cdot d_d^2 \quad (3)$$

$$dd_d/dt = -2\,\dot{m}_v/(\rho_d \cdot \pi \cdot d_d^2) \quad (4)$$

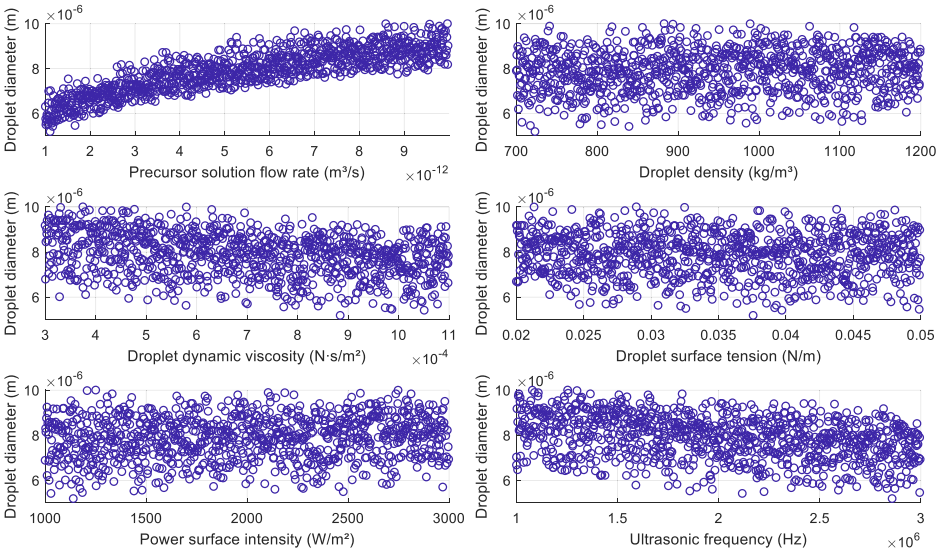

Figure 2. Scatter plots of parameters affecting the droplet diameter obtained using an ultrasonic vibration atomiser. Each parameter is described in Table 1.

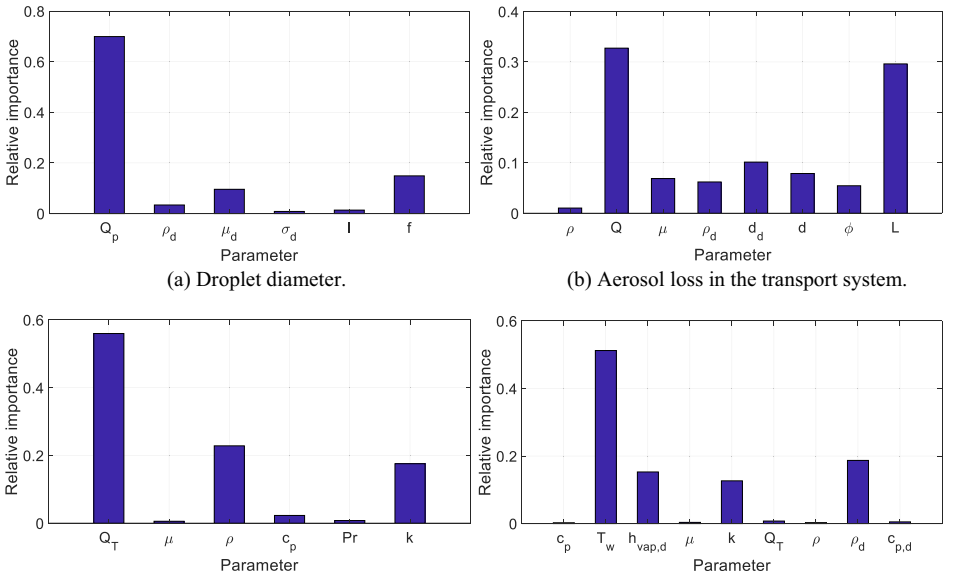
where $h_{vap,d}$ [J·kg^{-1}] is the droplet specific heat of evaporation; $c_{p,d}$ [J·kg^{-1}·K^{-1}], m_d [kg], ρ_d [kg·m^{-3}], T_d [K] and d_d [m] are, respectively, the droplet specific heat at constant pressure, mass, density, temperature and diameter; t [s] is time; h_2 [W·m^{-2}·K^{-1}] is the heat transfer coefficient; T_w [K] is the wall temperature; $\dot{m}_v$ [kg·s^{-1}] is the mass transfer rate, given by $\dot{m}_v = k_c \cdot (\rho_{v,s} - \rho_{v,\infty}) \cdot \pi \cdot d_d^2$, where k_c [m·s^{-1}] is the mass transfer coefficient; $\rho_{v,s}$ [kg·m^{-3}] and $\rho_{v,\infty}$ [kg·m^{-3}] are, respectively, the partial vapour densities over the droplet surface and far from it. Correlations for the heat and mass transfer coefficients were found in Mezhericher et al. (2008). The thermophysical properties of possible precursor solutions and carrier fluids were found in Bergman et al. (2011). The aerosol droplets, the reactive solute and the evaporating solvent, are assumed to be in thermal equilibrium with the carrier gas. Therefore, the droplet temperature is a function of time and indirectly of the vertical distance travelled by the carrier fluid.

3. Methodology, Results and Discussion

The model presented by Filho et al. (2017) focused solely on aerosol transport and presented a local sensitivity analysis. This is now expanded to include the aerosol generation and delivery, along with a global sensitivity analysis. The AACVD process can be operated using a number of different precursors, with different thermophysical properties. The generated aerosol can also be carried by different fluids to the reaction site. Therefore, the global sensitivities of the model provide understanding of which parameters have the greatest relative importance to the objective variables. Additionally, uncertainty analysis is performed by propagating the uncertainties through the entire process.

Based on lab-scale experiments and extrapolating to the industrial-scale process, for different precursors and settings, a range for each parameter of interest is described in Table 1. The generation of samples for all the variables described in Table 1, based on



(a) Droplet diameter.

(b) Aerosol loss in the transport system.

(c) Carrier gas temperature.

(d) Droplet drying time.

Figure 3. Relative importance of different parameters given their impacts on each output variable from the regression trees, as described in the legends of each subfigure. The parameters are described in Table 1.

the range column, is done by implementing the Latin Hypercube Sampling (LHS) method. The range of each parameter is divided into equally probable subintervals and a random sample is taken from each permuted subinterval. This method created 1000 samples fully stratifying the initial range of all parameters. Figure 2 shows scatter plots obtained for the droplet sizes of the generated aerosol. It can be seen how the precursor solution flow rate has the greatest impact on the droplet sizes. Some impact can also be observed for the ultrasonic frequency and droplet dynamic viscosity.

Using the dataset generated by the simulations, regression trees are grown for the response variables using the parameters in Table 1 as predictors. Surrogate splits are used with the CART method (Loh, 2014). The use of regression trees can be justified by their accuracy and computational speed. However, the main reason for their use in this work is the interpretability of the tree structures, making it easy to rank parameters by importance. This is done by summing changes in the mean squared error due to splits on every predictor and dividing the sum by the number of branch nodes. For example, Figure 3 (a) confirms what can be visually seen from Figure 2 regarding the most impactful parameters on the droplet size: the precursor flow rate has the greatest impact and, to a lesser extent, the ultrasonic frequency and droplet dynamic viscosity. Density, surface tension and power intensity have minimal impact. Overall, Figure 3 shows that the aerosol generation, transport and delivery are mainly impacted by the flow rates, the length of the transport system and the wall temperature in the reaction site. These results are based on the ranges of parameters that can be used in the industrial-scale process. Therefore, they serve as a guide to the AACVD scale-up. Additionally, the most impactful parameters will be chosen to optimise the reactions and film formation, which are the next modelling steps.

4. Conclusions and Future Work

The use of CVD to manufacture TCO materials is sometimes limited by high costs, environmental impacts and scarcity of precursors. Therefore, it is important to look for cheaper and more sustainable precursors, which becomes less challenging when a new range of them is unlocked by the use of AACVD instead of CVD. Preliminary simulations worked as a proof of concept for the feasibility of keeping the current CVD equipment used in the industry to operate using the AACVD technique instead. The modules for aerosol generation and transport have already been validated using experimental data. Future work includes further model validation, covering the delivery module. Finally, the feasibility study will be completed by modelling the chemistry in the reaction site. Then, it will be possible to optimise the film growth rate and its optoelectronic properties.

The integrated model presented is suitable for application on the scale of industrial processes. It can also be used for any range of the parameters studied and it is suitable for applications that rely on atomisation and transport of particles, for example, spray drying or cooling, ink-jet printing, agricultural sprays and fuel combustion. Furthermore, lessons learned in modelling uncertainties and their impact on process scale-up motivates research into formulation, modelling and solution methods for such applications. The aim should be to ease the procedure of design under uncertainty for process scale-up. The representation and impacts of these uncertainties form the basis of future research for the AACVD case study and the treatment of uncertainty in general, through the development of a novel modelling framework focused on the treatment of uncertainty in process design and optimisation.

A Fluidized Bed Process Model of a Chemical Looping Combustion Fuel Reactor

Chinedu O. Okoli, Andrew Lee*, Anthony P. Burgard and David C. Miller

National Energy Technology Laboratory, 626 Cochrans Mill Road, Pittsburgh, PA, 15236, USA
andrew.lee@netl.doe.gov

Abstract

The development of a bubbling fluidized bed chemical looping combustion (CLC) fuel reactor model to support process synthesis and large-scale optimization is presented in this work. The model is built using the Institute for the Design of Advanced Energy Systems (IDAES) PSE framework and is implemented in Pyomo. It is equation-oriented and consists of a set of differential algebraic equations, which describe the gas and solid phase reactions between the fuel gas and oxygen carrier (OC), as well as the mass and heat transfer phenomena occurring in the different regions of the fluidized bed. In addition, the model provides axial profiles of the hydrodynamic and state variables. The capabilities of the model are demonstrated for the simulation of an industrial scale CLC fuel reactor which uses a hematite-based solid as the OC for natural gas combustion. The impact of select design variables on the performance of the model is evaluated, and the results show that methane conversion is more sensitive to changes in bed diameter than to the OC/fuel ratio. In addition, negligible performance differences are seen between the co-current and counter-current configurations indicating that good mixing between the gas and solid phases occurs within the bed.

Keywords: chemical looping combustion, fluidized bed, fuel reactor, process model.

1. Introduction

Chemical looping combustion (CLC) is a promising approach to provide cost effective, low carbon energy from fossil fuels. It creates a CO_2 rich flue gas with less equipment than other technologies such as oxy-combustion, which requires an air separation unit, or post-combustion carbon capture in conjunction with a conventional fossil-based power plant (Adanez et al., 2012). CLC is an active area of research and development in the areas of materials, process design, optimization, and scale up.

The CLC process consists of two interconnected reactors, a fuel reactor and an air reactor, with a metallic oxygen carrier (OC) circulating between them. In the fuel reactor, the OC is reduced, oxidizing the fuel to produce nitrogen free flue gas consisting mainly of CO_2 and H_2O. In the air reactor, the reduced OC is oxidized with air. Fluidized bed reactors have been investigated as reaction vessels for CLC because of their excellent gas/solid contacting. The overall performance of the CLC process is dependent on efficient and effective gas and solid contacting in the fuel reactor.

Computational models used in conjunction with an experimental development program can help to accelerate the development of new energy technologies. The models provide a representation of complex physical phenomena that might be difficult or expensive to measure in physical prototypes. In addition, the models can be used to optimize a

Table 1. Feed Conditions and fluidization properties

Gas Feed Conditions		OC Feed Conditions		OC Fluidization properties	
Flow rate (mol/s)	298.11	Flow rate (kg/s)	1,235	Min Fluid. Vel. (m/s)	0.04
Temperature (K)	800	Temperature (K)	1186	Min. Fluid. Void. (-)	0.45
Composition (%):		Composition (%):		Particle Diam. (mm)	0.28
CH_4	45.82	Fe_2O_3	45	Solid Density (kg/m3)	3,252
CO_2	47.72	Fe_3O_4	0		
H_2O	6.46	Al_2O_3	55		

complete, integrated process to identify the design and operating conditions that should be studied during bench and pilot scale testing. Finally, the models can be used in conjunction with statistical design of experiments to maximize the learning from expensive pilot scale testing.

A particular research need when developing a new technology such as CLC is to consider systems integration and optimization. A systems level CLC process will comprise of phenomena ranging from the micro-scale, such as mass transfer associated with gas diffusion into the OC particle, to the macro-scale, such as the interaction of different unit operations in the flowsheet. Understanding and balancing these interactions can be best accomplished by employing large-scale optimization models of the complete system. Because such systems typically have nonlinear interactions, rigorous optimization approaches are able to identify important trade-offs and process synergies, which cannot be readily observed from simple sensitivity experiments.

To effectively employ these large-scale optimization methods requires the development of suitable models that are sufficiently rigorous to capture all the important underlying physics of the process, from micro to macro scale, while also formulated in a way that is computationally efficient. Models built using an equation-oriented framework are particularly suitable for large-scale optimization since they provide first and second derivative information which is required by advanced optimization solvers capable of exploiting large, sparse matrices.

To address these challenges, the Institute for the Design of Advanced Energy Systems (IDAES) is developing an open-source PSE framework to enable the rapid development and optimization of next generation advanced energy systems. The framework is based on the Pyomo algebraic modeling language (Hart et al. 2017). This paper describes the development of a bubbling fluidized bed (BFB) CLC fuel reactor within the IDAES framework. The model is developed in a modular fashion from two standalone models – a reaction kinetics and physical properties model and a fluidized bed hydrodynamic model. The capabilities of the overall model are demonstrated for the simulation of an industrial scale CLC fuel reactor in which natural gas is combusted using a hematite-based OC.

2. Methodology

2.1. Bed hydrodynamic model

The fundamentals of the hydrodynamic model developed in this work are based on the three-region BFB model described by Kunii and Levenspiel (1968). The three-regions are the bubble, emulsion, and cloud-wake regions. In this model gas bubbles formed at the distributor plate rise through a dense emulsion phase carrying along a cloud of gas with suspended solids. The rest of the gas is in the emulsion phase, which also contains most of the solids. The Kunii and Levenspiel model assumes that the solids are

isothermal and well-mixed, thus neglecting the impact of axial variations in the solid phase. Furthermore, they assume an average bubble diameter to estimate the bed hydrodynamic properties.

Lee and Miller (2013) utilized the Kunii and Levenspiel approach in their modeling of a BFB for CO_2 adsorption from flue gas, extending the approach by considering axial variations in both the gas and solid phases, because adsorption processes are strongly impacted by temperature and pressure variations. They also use a bubble growth equation to model the bubble diameter as a function of height. The resulting model is a steady-state one-dimensional system of differential algebraic equations (DAEs). This model has been extended for the hydrodynamic model of the CLC fuel reactor with changes made to the relevant model equations to account for the different reaction kinetics.

2.2. Reaction kinetics and physical property model

It is assumed that natural gas contains only methane, with the higher hydrocarbons treated as methane equivalents. In the fuel reactor, the Fe_2O_3 based OC is reduced to Fe_3O_4 by reaction with CH_4. It is assumed that methane reforming within the reducer is negligible; thus, the overall reaction considered here is given by Eq.(1):

$$CH_4 + 12Fe_2O_3 \rightarrow 8Fe_3O_4 + 2H_2O + CO_2 \tag{1}$$

The reaction kinetics used in this model for the reaction of a hematite based OC with methane are as reported by Abad et al. (2007) and shown in Eq.(2):

$$\frac{dX}{dt} = \frac{3bkC^n}{\rho_m r_g (1-X)^{\frac{2}{3}}} \tag{2}$$

where X is the fraction conversion of the metal oxide in the OC, C (mol/m^3) is the reaction gas concentration (CH_4 in this case), b is the reaction stoichiometric coefficient (12 moles of Fe_2O_3 converted per mole of CH_4), k (m$^{1.9}$mol$^{-0.3}$s^{-1}) is the kinetic rate constant, ρ_m is the molar density of the carrier particle (32,811 mol/m^3), and r_g is the particle grain radius (2.6e-7 m) within the OC particle. The value of n is 1.3.

The kinetic constant k follows an Arrhenius type relationship with temperature, T (K).

$$k = 0.0008\exp\left(\frac{-49}{RT}\right) \tag{3}$$

Since the system operates at high temperature and low pressure, the ideal gas law was used for the state variables in the gas phase. The heat capacity of both the gas and solid phases are calculated using the standard Shomate correlations (Chase, 2008). Gas phase diffusivity (Wilke method), thermal conductivity (Wassilijewa equation) and viscosity (Wilke method) correlations are obtained from Poling et al., 2001.

2.3. Model implementation

The CLC fuel reactor model is built by integrating two standalone models: the bed hydrodynamic model, and the reaction kinetics and physical property model. This approach allows the fuel reactor model to be adapted to study other OCs by changing the reaction and physical property model. It also allows the CLC fuel reactor model to be integrated into large scale flowsheets for systems optimization.

The resulting system of DAEs is discretized using Pyomo's automatic discretization tool, pyomo.dae (Nicholson et al., 2017), with orthogonal collocation on finite elements using the Lagrange-Radau method. 16 finite elements with 3 collocation points per element were used. The resulting discretized model consists of 12,710 variables and

12,710 equations. The model is solved using IPOPT on an Intel Xeon CPU with 31 GB RAM. The solution times (including initialization) are 15.52 s for the co-current configuration and 15.70 s for the counter-current configuration.

3. Results

The primary application for this model is the development and optimization of advanced CLC systems. Feed conditions and fluidization properties used for this simulation case study (see Table 1) are obtained from a techno-economic study (Keairns et al., 2014) for a commercial scale industrial, natural gas-fueled, steam generation plant. It is assumed that the natural gas contains only methane and that the combined natural gas and fluidization gas (steam and CO_2) streams are pressurized to 400 kPa and preheated to 800 K before entering the fuel reactor. The fuel reactor is assumed to have a diameter of 5.57 m, which is comparable to the industrial scale values used in Keairns et al. 2014, and the bed height (22.14 m) is selected such that the gas outlet pressure is close to atmospheric conditions.

The profiles of select variables of a simulated co-current configuration are shown in Figure 1. In the co-current configuration both the gaseous fuel and solid OC are fed at the bottom of the bed ($x = 0$) and exit at the top of the bed ($x = 1$). From Figure 1(a), it can be seen that the reaction is very fast in the first 10 % of the bed since most of the methane conversion takes place in the lower regions. There is also a noticeable variation between the mole fraction and temperature profiles (Figure 1(b)) in the bubble and emulsion regions of the bed suggesting that there are mass transfer limitations and inefficient mixing of gases between those regions. This can be partly explained by an increase in gas bubble size from 0.02 m at the bottom of the bed to 3.05 m at the top of the bed as shown in Figure 1(c). As bubble size increases mass transfer resistances

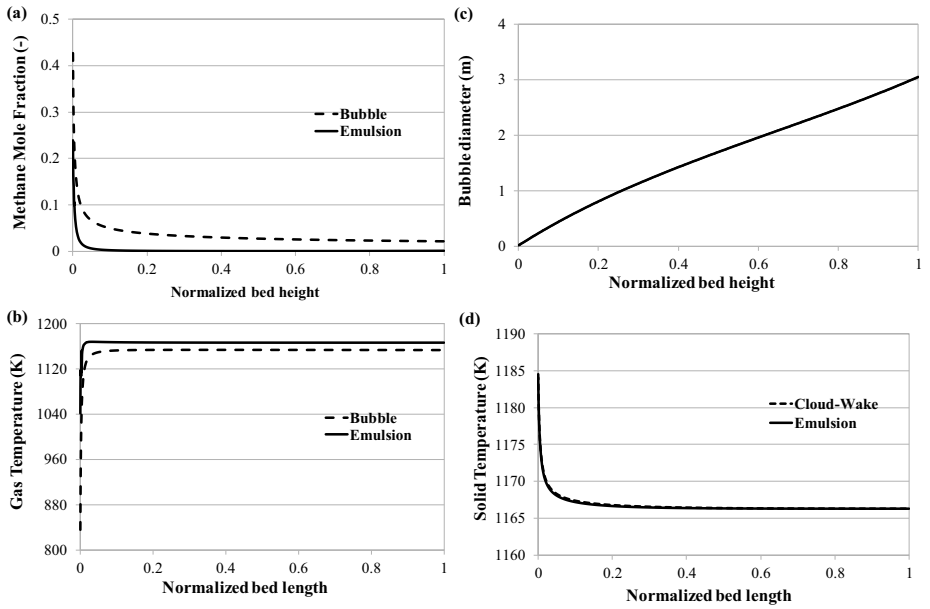

Figure 1. Profile data of selected variables vs. bed height (a) Methane mole fraction (b) Gas velocities (c) Gas Temperatures (d) Solid Temperatures

between the bubble and the cloud-wake and emulsion regions increase; thus gas mixing between regions becomes poorer. The temperature profile of the solid phase (Figure 1(d)) shows that the temperature drops from 1186 K at the inlet to 1166 K at the outlet because the reaction is endothermic. Note also that the temperature profiles of the cloud-wake and emulsion regions are virtually identical, suggesting that good mixing occurs between these two regions of the solid phase.

The sensitivity of the co-current configuration's methane conversion to some design parameters was also evaluated. It was found that increasing the bed diameter by 9 % leads to a 2.1 percentage point increase in methane conversion while reducing the bed diameter by 9 % leads to a 2.7 percentage point decrease in methane conversion. Furthermore, a 24 % increase in OC flow rate results in a 1.1 percentage point increase in methane conversion, while a 24 % decrease in OC flow rate results in a 2.3 percentage point decrease in methane conversion. These results suggest that the methane conversion is more sensitive to changes in bed diameter than in OC flow rate, indicating that residence time is more important than the OC/fuel ratio for improving fuel conversion.

Table 2 summarizes the model results for co-current and counter-current configurations. In the counter-current configuration, the solid OC is fed at the top of the bed ($x = 1$) and exits at the bottom of the bed ($x = 0$), thus both configurations will have different solid temperature and composition profiles. For the given design conditions, 91.4 % methane conversion is achieved, with 43 % of the OC converted for the co-current configuration while 93.28 % methane conversion and 44 % OC conversion is achieved for the counter-current configuration. The close similarity between the values for both configurations suggest that they have similar gas/solid residence times, and that the impact of good mixing within the bed as a result of fluidization dominates compared to the impact of the solid feed/exit locations. Thus, other design considerations such as controllability or ancillary unit setup need to be evaluated before any configuration selection decisions can be made.

The kinetic model has been validated at small scales (Abad et al. 2007), and the hydrodynamic trends of the model such as the bubble diameter profile are similar to those available in literature (Lee and Miller 2013). On-going future work is focusing on using pilot scale data to validate the model's hydrodynamic parameters and the kinetic parameters of oxygen carriers of interest for a wide range of operating conditions. The resulting robust, validated model will be used in the IDAES PSE framework to optimize the design and performance of a complete CLC system consisting of the fuel and air reactors, as well as ancillary equipment such as turbines and heat exchangers.

Table 2. Comparison between co-current and counter-current configurations

	Co-current configuration	Counter-current configuration
CH_4 Conversion (%)	91.38	93.28
OC Conversion (%)	43.03	43.93
Exit Gas Pressure (kPa)	107.58	108.41
Exit Gas Flowrate (mol/s)	547.75	552.93
Exit Solid Flowrate (kg/s)	1,227.17	1,227
Exit Gas Temperature (K)	1,153.33	1,165.77
Exit Solid Temperature (K)	1,166.29	1,165.72

4. Conclusions

This work discusses the development of a fluidized bed CLC fuel reactor model suitable for use in the large scale optimization of CLC systems using the IDAES PSE framework. The model was applied to the simulation of a CLC fuel reactor and shows that in a co-current configuration most of the fuel conversion occurs in the lower regions of the bed due to very fast reaction rates. Furthermore, methane conversion is more sensitive to changes in bed diameter than to the OC/fuel ratio. Another important finding was that good gas/solid mixing within the bed from the fluidization leads to negligible performance differences between co-current and counter-current configurations.

Abstract

A test system for the air resistance of plate fin heat exchanger (PFHE) in an open environment was developed. A combination of three nozzles is used to measure the air volume flowrate through the PFHE. The combination of three nozzles keeps the pressure difference between their two ends less than 800Pa, therefore a high precision measurement is implemented. The influence of temperature & humidity on the density of wet air in the open environment is discussed, and the variety of Reynolds number with the change of humidity is analysed. A compensation formula is present to cope with the fluctuation of temperature and humidity. An expert fuzzy-PID controller is developed to control the air volume flowrate with a faster speed and higher precision. The results show that the performance of the proposed measurement system is satisfied.

Keywords: open environment, plate fin heat exchanger, high precision measurement, air resistance, fuzzy-PID control.

1. Introduction

Because of the advantages of compact structure, high heat transfer efficiency, lightweight, the plate fin heat exchanger (PFHE) has been wildly used in the fields such as air separation, petrochemical industry, refrigeration, liquefaction, and so on (M. Liu, 2007). The most significant features of the PFHE is its air resistances under the certain airflows on the standard working condition. A high precision test of its air resistance is the most necessary step for PFHE before it leaving the factory (NB/T47006, 2009). However, most of the PFHEs are too large to be put into the standard closed test room. It is a challenge to make a high precision test for those large PFHEs in an open environment (X. Li, 2011). This paper focuses on how to make a high precision test of air resistance of PFHE in an open environment. There are two mainly parts, one is how to get a high precision measurement of air volume flowrate, and another is how to make a high precision, quickly control of air volume.

2. The test system for PFHE

The structure of test system (air volume flowrate: 1000~6000m^3/h) is shown in Figure 1. A standard measuring box with three nozzles with different throat sizes, 110mm, 150mm, 189mm, respectively, is used to measure the air volume flowrate, and an induced draft fan is used to produce the required air volume by changing the speed of

motor with a frequency conversion. When the air volume flowrate is adjusted to the design value, the pressure difference between the import and export of the PFHE will be its air resistance.

A fast speed control is necessary for the test system, so that the system can step into the steady state quickly. Meanwhile, a high precision measurement of air volume flowrate is required to as the feedback information to the control system.

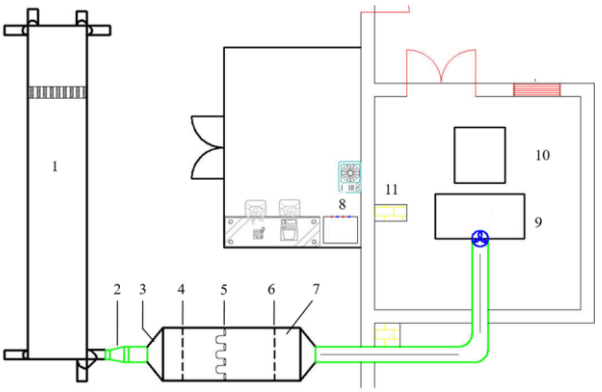

Figure 1. Structure of test system of air resistance of PFHE.
1—PFHE; 2—Adjustable pipeline; 3—Conical diffuser; 4，6—Uniform flow plate; 5—Nozzles; 7—Standard air volume measuring box; 8—Control system; 9—Induced draft fan; 10—Frequency conversion motor; 11—Frequency converter.

3. High precision measurement of air volume flowrate

The general expression for the volume flowrate, Q_v, through the measuring box is given by Eq.(1) (ISO 5167-3, 2003). By measuring the pressure difference Δp between the inlet and outlet of the nozzles, volume flowrate is given.

$$Q_v = \frac{C}{\sqrt{1-\beta^4}} \varepsilon \frac{\pi}{4} d^2 \sqrt{\frac{2\Delta p}{\rho_T}} \tag{1}$$

Where, β is the radio of the throat diameter of nozzles d to the internal diameter D of the measuring pipe upstream of the primary device; C is the discharge coefficient; ρ_T is the upstream air density; ε is the expansibility factor, when $\Delta p/P_\alpha \leq 0.4$ (P_α is the pressure of upstream air), $\varepsilon \approx 1$.

When more than one nozzles are used to measure the volume flowrate, the total volume flowrate Q_t is the sum of all nozzles, as Eq.(2).

$$Q_t = \sum Q_i \tag{2}$$

The discharge coefficient, C, is given by Eq.(3) (ISO 5167-3, 2003).

$$C = 0.9900 - 0.2262\beta^{4.1} - (0.00175\beta^2 - 0.0033\beta^{4.15})\left(\frac{10^6}{Re_D}\right)^{1.15} \tag{3}$$

Where, Re_D is pipe Reynolds number, is given by Eq.(4).

$$Re_D = \frac{vd}{\gamma} \tag{4}$$

Where, v is the velocity of air, and γ is the kinematic viscosity of fluid.

The air density ρ_T and discharge coefficient C change when the environment changing, especially when the fluid is not a single component.

4. High precision control of air volume

The high precision control of air volume flowrate is another essential technology in this test system, which is required not only high precision close to the set point, but also high speed to get the steady state. An expert fuzzy-PID method is presented to meet the requirements.

The expert system refers to that many experiments have been done to get the relationship between several common set values of air volume and the frequency when the test system was set up. Then, we can fit the relationship between the air volume and the frequency by using these data. When adjusting the air volume flowrate to a certain value, the fitted frequency getting by the experiment is used to get the initial value of air volume. Therefore, an approximate value of the set point is obtained very quickly, instead of getting the set value slowly from zero by using a standard PID. Then, a fuzzy PID algorithm is used to get the high precision control of air volume under the changing working condition. The fuzzy method is used to obtain the parameters of PID algorithm dynamically in a changing working condition, especially in different seasons in Hangzhou. By this way, a quick, high precision control method of air volume is realized.

5. Simulation results and discussion

This paper mainly discuss the condition of wet air. The temperature, humidity and components of wet air are the influence factors of wet air on the air volume flowrate.

5.1. Effect of Temperature and Humidity on Air Volume Flowrate

The density of wet air is given by Eq.(5).

$$\rho_\alpha = \frac{1000\ (P_\alpha\text{-}0.378P_V)}{287\Theta} = 3.48\frac{P_\alpha}{\Theta}\left(1 - 0.378\frac{\psi P_b}{P_\alpha}\right) \tag{5}$$

Where, Θ is the absolute temperature of wet air; P_V is the partial pressure of steam in the wet air, $P_V = \psi \cdot P_b$, ψ is relative humidity of wet air; and P_b is the saturated vapor pressure; P_α is the air pressure under test conditions.

In the open environment, the wet air, which flows through the PFHE, is not on the standard condition (0 ℃, 1 atm, ψ = 0%). So, when calculating the air volume flowrate, the effect of temperature, pressure and humidity should be taken into account.

However, the pressure is changed just a little tiny from 1 atm when in a natural open environment (less than 0.5 %), so we could ignore it and focus on the other two aspects: temperature and humidity. Figure 2 and Figure 3 give the effects of temperature and relative humidity on the air volume flowrate respectively: the higher the temperature and humidity, the greater the error. In the typical working condition in the rain season in South China, when the temperature up to 45 ℃ from 0 ℃ (standard condition), the error will grow up to 7.5 %.

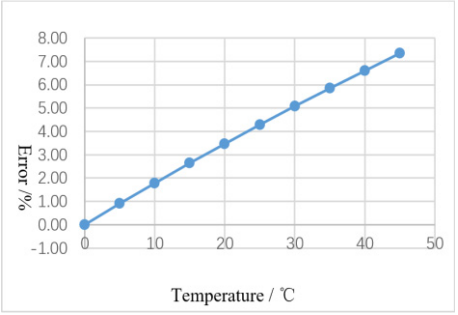

Figure 2. Effect of temperature on the error

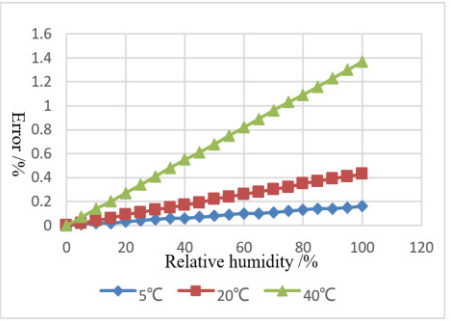

Figure 3. Effect of relative humidity on the error

Where, the effect of temperature and humidity on the error is different: the former is higher than the latter. Figure 3 is the effect of relative humidity at 5 ℃, 20 ℃, and 40 ℃ respectively, which are mostly the temperatures of winter, spring/fall, and summer in the South China. Those two figures show that the temperature has higher effect on error than the humidity, so the temperature correction is necessary when measuring the volume flowrate, but the humidity is not.

5.2. Effect of Air components on Air Volume Flowrate

When calculating the volume flowrate by the Eq.(1), the pipe Reynolds number, Re_D, is needed. But the air components effect the dynamic viscosity, μ, and the kinematic viscosity, γ, of the wet air, shown by Eq.(6) and Eq.(7) respectively.

$$\mu = \frac{\sum_{i=1}^{n} \alpha_i M_i^{1/2} \mu_i}{\sum_{i=1}^{n} \alpha_i M_i^{1/2}} \tag{6}$$

$$\gamma = \frac{\mu}{\rho} \tag{7}$$

Where, α_i is the volume percentage of gas component i in the mixed gas; M_i is the molecular weight of gas component i; μ_i is the dynamic viscosity of gas component i.

In this paper, the fluid is wet air, which is mixed with steam and dry air. The molecular weight of dry air and steam are 28.959 and 18.016 respectively. The percentage of dry air and steam are effected by the relative humidity of wet air, shown as Eq.(8) and Eq.(9) respectively.

$$\alpha_1 = \frac{V_1}{V_1+V_2}\times 100\% = \frac{P-\psi P_b}{P}\times 100\% \tag{8}$$

$$\alpha_2 = \frac{V_2}{V_1+V_2}\times 100\% = \frac{\psi P_b}{P}\times 100\% \tag{9}$$

Changing of component in wet air makes the volume flowrate different from the standard working condition.

For example, there we use the data from an abominable working condition obtained from the test site in Lin'an, Zhejiang Province, South China on Jul. 9, 2016: relative humidity ψ = 90 %, ambient temperature t = 28 ℃, ambient atmospheric pressure p = 100,600 Pa.

By calculating the Q_α by Eq.(1)~(4) under the real working condition, and compared with the standard working condition Q_s the measuring error is shown by Eq.(10).

$$\varepsilon rror = \left(\frac{Q_\alpha - Q_s}{Q_s}\right)\times 100\% = \left(\frac{5.470.90-5428.47}{5428.47}\right)\times 100\% = 0.78\% \tag{10}$$

It is known that the affection of component is far less than the temperature and relative humidity, so it can be ignored in some non-strictly required test.

5.3. High precision control of Air Volume Flowrate

An expert fuzzy-PID is used to get the fast high precision control. Here, we use the transfer function of controlled object in this test system in Lin'an, Hangzhou, which is described by Eq.(11).

$$G_o(s) = \frac{2.9386s^2 + 0.5877}{s^3 + 0.4326s^2 + 0.0665s + 0.0047} \tag{11}$$

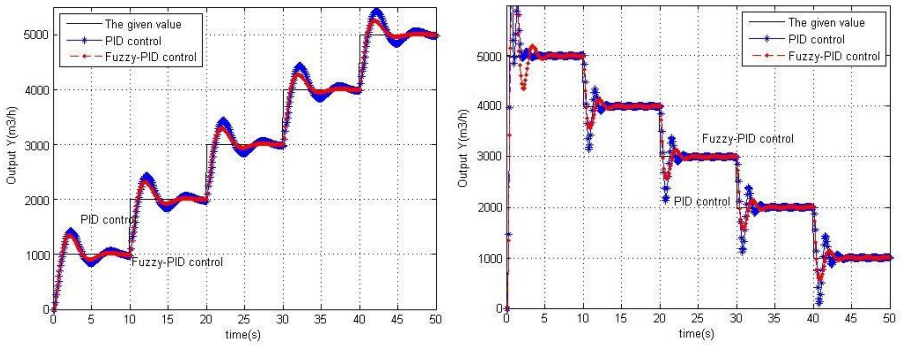

Figure 4: Comparison between fuzzy PID and traditional PID control

Two kinds of adjustment, one goes up from low value to some certain set points and another goes down from high value to the set points, to validate the algorithm (shown by Figure 4).

The fuzzy-PID adjusts the PID parameters automatically when the condition is changing by using fuzzy law. Comparing with a traditional PID ($K_p(0) = 0.07$, $K_i(0) = 0.05$, $K_d(0) = 0.12$, self-tuning by Ziegler-Nichols law and not changing), the fuzzy-PID has a faster turning period and less overshoot. Fuzzy-PID is easier to get the steadiness than traditional PID, especially when the setting value is changed.

6. Conclusions

When test the air resistance of PFHE in an open environment, a fast high precision control is necessary. A high precision measurement of air volume flowrate is the basis of the control. This paper discusses the factors that effect on the high precision measurement, and the compensation formulas are given. An expert fuzzy-PID method is presented to make an advanced adjustment process, which has a shorter regulation time and less overshoot than the traditional PID.

Conflict of interest: The authors declared that they have no conflicts of interest to this work.

Abstract

The collection and exploitation of emerging data regarding algae systems is a difficult and challenging task, which requires coordination between the different sources. Relations between algae feedstocks, technologies and products are ambiguous at best and the ones that are established need to be documented. The systems platform presented in this paper deals with the challenges and sets a benchmark for a wide reange of products and pathways. Drawing on the platform, relations between the elements of the database are formed on a conceptual level indicating feasible solutions to the respective problem. Ontology engineering is the tool to achieve classification of the elements as well as to form connections between them based on provided properties. In combination with optimization and knowledge engineering, the platform offers high-capacity screening with featuring criteria (techno-economic, environmental etc.), hosts models of different scales, enables bounds on the number of options to screen and delivers the best set of solutions according to each different criterion.

Keywords: systems platform, synthesis, algae, biorefineries, ontologies

1. Introduction

Over the last decades, algae attract plenty of research due to their versatility in terms of products and their flexibility in terms of integration with other types of biorefineries. The plethora of algal strains can provide a multitude of specialty chemicals of pharmaceutical, nutraceutical and cosmeceutical use as well as products that can serve the aquaculture sector. Among them are products of high market value and compounds that cannot be produced by another natural source in a specific form.

As the incentives for the design of algae biorefineries are strengthened, the challenges that need to be overcome become more evident. The specialty products included in algae value chains have short life cycles, volatile markets and equally volatile or even unknown prices. Moreover, the algae value chains are characterized by competitive and alternative chemistries and include chemicals with unknown thermodynamic properties. The lack of industrial applications and the consequent lack of information on industrial scale only add to the challenges of the incentive. The majority of the data derive from lab-scale or pilot facilities, which on the one hand provides useful information but on the other hand, it is difficult to obtain the information due to the multiple sources. The scattered data can be experimental or even empirical and their collection and exploitation is a difficult and challenging task, which requires coordination between the different sources.

The imperative need for a centralized repository in the field of algae biorefineries is evident. Such ventures have been implemented for the case of lignocellulosic (Siougkrou and Kokossis, 2016) and waste (Barla et al., 2016) biomass systems. However, the unique nature of algae systems requires a holistic approach to the problem. The systems platform presented in this paper addresses the challenging task of collecting and exploiting emerging data in algae systems. The platform exploits Information and Communication Technology (ICT) Infrastructures to provide users with various online services in regard to the synthesis of algae biorefineries.

2. Multi-objective methodology

2.1. Ontology engineering

Ontologies are considered a formal way to describe taxonomies and classification networks, essentially defining the structure of knowledge for various domains: the nouns representing classes of objects and the verbs representing relations between the objects. Ontologies have been successfully used for engineering purposes (Brandt et al., 2008; Cecelja et al., 2015), especially because of their dynamic characteristic, which allows for any data to be updated without redesigning the database itself. The platform exploits semantics and ontology engineering to express the system flows, process components and their relationships and finally to represent the synthesis options. An ontology which formulates the value chain of an algae biorefinery has been designed using Protégé, a free, open-source ontology editor and framework for building intelligent systems. Figure 1 illustrates the basic classes and subclasses of the constructed ontology; the key classes are feedstock, technologies, products and intermediates.

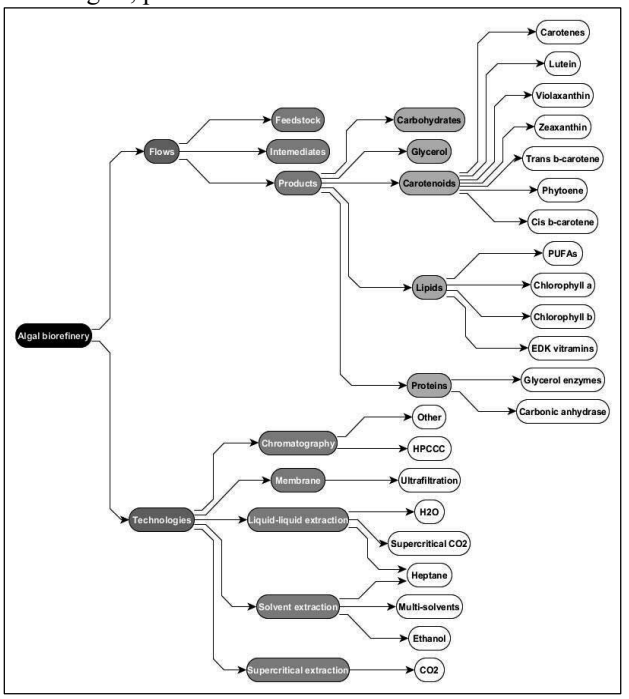

Figure 1: Platform ontology classification (colored background: classes and sub-classes; no background: individuals)

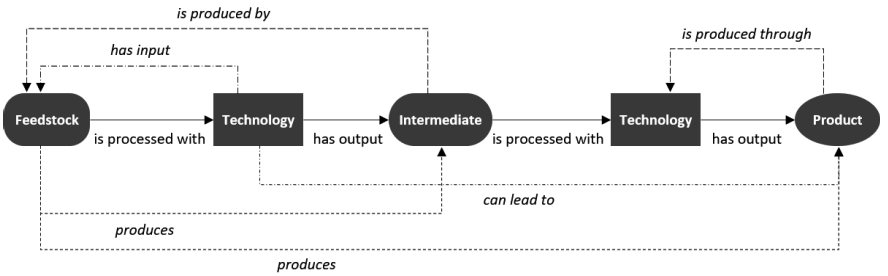

Figure 2: Object properties for a generic synthesis pathway

The ontology main components include the basic or "ground level" objects or instances, which represent the *individuals*, the sets, collections, concepts or types of objects, which are the *classes*, and the aspects, properties, features, characteristics, or parameters that objects (and classes) can have, which are the *attributes*. The attributes which relate individuals to individuals are called object properties and the ones which relate individuals to literals are categorised as datatype properties. The object properties defined for the representation of a typical synthesis pathway are depicted in Figure 2. For each individual only has_input and has_output properties are explicity used to represent a relation. All the other statements are implicity constructed through the first-order logic rules and axioms provided by the OWL 2 language.

2.2. Knowledge engineering and optimization

The platform repository includes all data and information regarding the microalgal value chain (feedstock, intermediates and products), the involved processes for the extraction or conversion of compounds to products and the relevant economic parameters for the final evaluation of processing paths (Psycha and Kokossis, 2017). The models incorporated into the repository come from different sources (literature, experimental, customized models) and as a result are of different types and scales. Specifically, they can range from a detailed equation-based model to a conceptual black box with basic input-output data. The same case applies to physical property models; thus, it is of high importance for the repository to be able to accommodate all available data. Specific information is filled and stored in the database, which is the same for every model regardless of its complexity. In that way, all models provide the required use, which can vary depending on the detail of the respective model.

The concept of the platform is to include all available information without focusing on specific results. On that note, all possible options are incorporated into the background modelling; however, these options are not exhaustive, since some combinations may be encouraged or prohibited due to practical limitations. The background modelling follows the guidelines of the synthesis model developed in previous work (Psycha and Kokossis, 2016) according to which all paths are screened simultaneously and evaluated to yield optimal solutions. With the use of mathematical techniques (integer cuts), cluster of solutions can be retrieved to the user's convenience.

3. Systems platform

3.1. Architecture

The systems platform has been developed upon Yii framework, a high-performance PHP framework for creating Web 2.0 applications. Yii is considered to be very fast and secure featuring the Model-View-Controller (MVC) software design pattern. Thus, the platform architecture is MVC based and it consists of two separated layers, the back-end and the front-end. The former contains two types of data collections and the system controllers. The first type data structures are stored into a database using the relational model and managed by the MySQL database management system. The second ones lie on a RDF triple store powered by Ontotext GraphDBFree, a highly-efficient graph database used as a semantic repository for the platform ontology. The front-end provides the user interface and its functionalities in conjunction with the back-end. It is implemented using the HTML, CSS and JavaScript languages and two powerful components, Bootstrap and yFiles for HTML. yFiles for HTML is a JavaScript diagramming for analyzing, drawing and arranging graphs. yfiles enables the graphical visualization of the synthesis pathways.

3.2. Services

The systems platform offers services related to synthesis as well as graphical representation of possible options (superstructure). The user is able to select between the formulation of value chain and/or the formulation of processing paths as well as define the starting point of the search (feedstock, technologies, products). Moreover, the platform dynamically builds and visualizes the processing pathways using modelling components and displays the paths by utilizing the constructed process designs and integrated schemes. The model screens for optimal solutions and the paths are highlighted on the superstructure scheme thus facilitating the user. The corresponding output data are calculated and economic information on each solution path are available. In addition, charts are outlined including costs breakdown and product/technology percentage frequencies.

The dynamic nature of the platform supports the addition of data and methods; thus, it is constantly being updated as new information and research emerge. The goal is also to activate user-driven entries for prices and other parameters in order to produce customized solutions according to provided data and deal with uncertainties (uncertainty analysis).

4. Benchmark implementation

The platform offers the option of building the value chain of the selected feedstock, which includes potential fractions and products from the specified alga without the processing technologies. Presently, three algae are incorporated (Dunaliella, Haematococcus and Nannochloropsis) and more will be added as the database grows. Figure 3 illustrates the value chain formulation of Dunaliella and the respective superstructure (processing paths formulation), which includes the suitable technologies to recover the desired products. All the blocks of the superstructure correspond to the individuals listed in Figure 1. For the formulation of the processing paths, the user has the ability to select any combination of technologies and/or product types and if the corresponding connection exists in the ontology, it will appear in the demonstration area of the platform. For the purpose of this paper, only the feedstock is selected, thus all possible options appear.

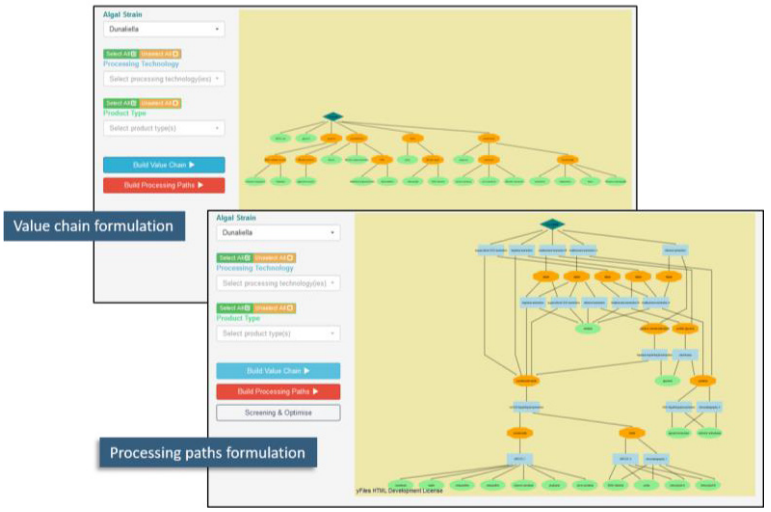

Figure 3: Platforms representation of value chains and processing paths

The key aspect of the platform is that it works as a screening and optimization tool to be used ahead of design and provide designing options according to the users input. As shown in Figure 4, the best ten solution paths are produced (in terms of profitability) in a decreasing order, which allows the user to better comprehend the problem. The analytics section of the platform includes further information and analysis on the results for each produced processing path as well as for the entire group of solutions (capital and operating costs, revenue, product and process frequency). One can select a solution and observe the graphical representation of each path, as depicted in Figure 4. Specifically, each solution path is highlighted to indicate the selected technologies, intermediates and products.

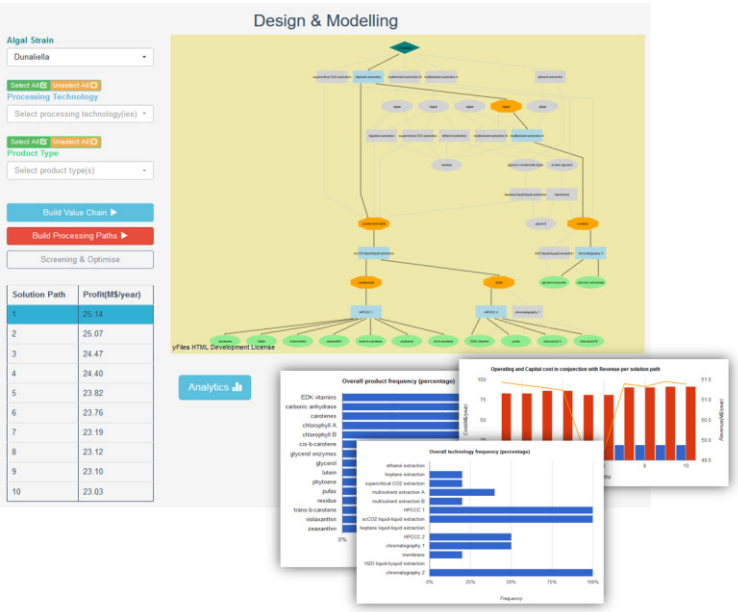

Figure 4: Screening, optimization and analytics of the platform

5. Conclusions

The systems platform for algae systems constitutes a powerful modelling tool, which dynamically builds and graphically represents value chains and processing paths from algal strains. Moreover, high-throughput screening and optimization are featured, and multiple solution paths are produced highlighting the flexibility of the platform as well as the importance of previewing opportunities ahead of detailed designs. The respective numeric results are calculated (profit, capital and operating cost, revenue) and are graphed in column charts. Furthermore, the product and technology frequencies are estimated taking into consideration all solution paths. The incorporation of other strains and the integration between various value chains is a promising venture and can yield significant results in the future.

Abstract

In this work we present a framework to generate surrogate models from rigorous process models embedded in a modelling environment or a process simulator. These unit operations (i.e. process flowsheet subsystems) are treated as black-box models to generate data for fitting and deriving the surrogate. Further, the methodology includes the formulation of a superstructure optimization problem and solving it to identify the optimal process flowsheet structure and point of operation from the possible alternatives. The superstructure optimization incorporates selection and interconnection of each surrogate and multi-objective optimization in respect to total annual cost and environmental impact. In this paper we highlight the surrogate building step of the methodology with a rigorous counter-current spray column model and assess the performance of different surrogate modelling methods.

Keywords: Polynomial Chaos Expansion, Gaussian Process Regression, Optimization, Superstructure Generation

1. Introduction

Surrogate models are popular to substitute black-box models which are either computationally expensive to evaluate, have noisy output behaviour or don't supply gradients (Quirante et al., 2015). Surrogates can also be beneficial to perform e.g. sensitivity analysis or optimization through Monte Carlo simulation (Crestaux et al, 2009). Superstructure optimization is another field where surrogates can be embedded in the problem formulation to perform rigorous calculations. In this work multivariate adaptive regression splines (Friedman, 1993), polynomial chaos expansion (PCE) (Feinberg and Langtangen, 2015) and Gaussian process regression (GPR) (Rasmussen and Williams, 2006) are applied to gain insights how these different surrogate modelling techniques perform in the context of oleochemical process modelling.

2. Overview of Surrogate Modelling Methods

2.1 Multivariate Regression Splines

We assume:

$$y_j = f_j(x_1, \ldots, x_p) + \epsilon_j \quad (1)$$

as the output to input relation of the system under research where f is the approximating function and ε the error. A training data set is fit to obtain $\widehat{f_j}$ to each function f_j with the expansion of basis functions:

$$\hat{f}(x_1, \dots, x_p) = \sum_{m=0}^{M} a_m B_m(x_1, \dots, x_p) \tag{2}$$

Least-squares minimization gives the coefficients a_m weighting the basis functions which take the form of a hinge function $h(x_i)$. The linear combination of a constant, a linear function and several hinge functions is iteratively calculated with a two-step forward/backward algorithm. In the first forward step the surrogate model is being built by adding hinge functions while maximizing the goodness of fit until a user-defined level of complexity has been reached. The second pruning and pass step will compare subsets of the potential hinge functions by means of a true cross-validation score (GCV) to prevent overfitting. The subset with the lowest GCV is chosen.

2.2 Polynomial Chaos Expansion (PCE)

In case of PCE a sum of weighted multivariate polynomials represents the surrogate to be built from input-output data:

$$\hat{f}(x) = \sum_{n \in N^M} c_n \Psi(x) \tag{3}$$

To retrieve the Fourier coefficients c_n a linear regression is performed where the multivariate Legendre polynomials $\psi(x)$ are fitted to the output generated in the simulation step with uniformly distributed samples within the boundaries of the input parameters x_i.

2.3 Gaussian Process Regression

Gaussian Processes can be described as a linear combination of polynomials and basis functions where we introduce a mean function $\hat{\mu}$ for the polynomial and a covariance function (also known as kernel) $R(x_i, x_j)$ for the basis part to describe a normal distribution over a set of functions:

$$\hat{f}(x^*) = \hat{\mu}(x^*) + r^T R^{-1}(y - 1\hat{\mu}) \tag{4}$$

The predictive mean $\hat{\mu}$, variance and log marginal likelihood (LML) are obtained through matrix inversion using Cholesky factorization as described by Rasmussen and Williams (2006) with Algorithm 2.1.

3. Methodology for Surrogate-based Superstructure Optimization

The application of surrogate modelling is subject to the variation of the input parameters of the model. The steps of the methodology are presented as follows:

1. *Sampling of the Design Space*: The independent variables (i.e. design degrees of freedom) of the process under research are identified and the boundaries specified. Different experimental designs exist to cover the domain of variation such as Monte Carlo samples obtained with random generators, Latin hypercube

samples or quasi-random (low-discrepancy) sequences, e.g. Sobol, Hammersley or Halton sequences. A hypercube is generated and used for the next step to perform Monte Carlo simulation. Due to optimization (step 6) the bounds of the independent variables will get iteratively updated to ensure feasible solutions.

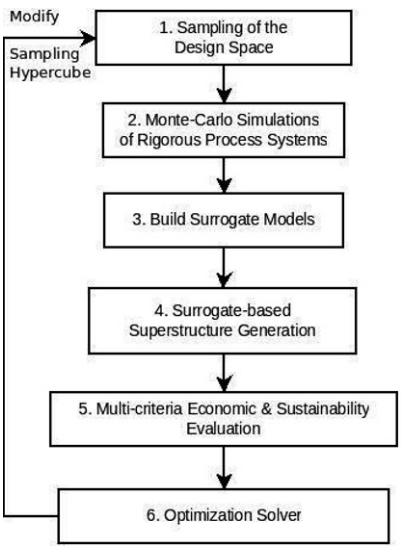

Figure 1: Methodology for superstructure generation with surrogate models

2. *Monte Carlo Simulation of Rigorous Process Systems*: The model is evaluated for each sample and the matrix of observations (model outputs) is stored for the surrogate modelling step.

3. *Build Surrogate Models*: To build a surrogate model the sampling hypercube and matrix of observations obtained from step 1 and 2 are used to apply methods such as multivariate regression splines, polynomial chaos expansion or Gaussian process regression as described in section 2 of this work.

4. *Surrogate-based Superstructure Generation*: A superstructure formulation of the interconnected surrogates and all possible combinations of process structures with operating set points are generated through enumeration or transforming a disjunctive program into a mixed integer non-linear program (MINLP).

5. *Multi-criteria Economic & Sustainability Evaluation*: The different process structures are evaluated in terms of capital, operating and total annual costs and total environmental impact is assessed to take the sustainability of a process into account.

6. *Optimization Solver*: In this step the optimization problem is solved where the economic and environmental objective function is formulated as the minimization of total annual cost and environmental impact subject to boundary conditions. To ensure that we obtain a feasible solution the bounds of the independent variables get updated every time a solution is found which violates the specified bounds defined in the previous iteration step.

4. Rigorous Counter-Current Spray Column Model

This work concentrates on the oleochemical domain where in the following case the chemicals taking part in the mass transfer and reaction phenomena are: triglycerides, fatty acids, glycerol and water.
The counter-current spray column model serves as the rigorous model to be substituted by a surrogate. The hydrolysis reaction in the column produces 3 moles fatty acids and 1 mole glycerol from 1 mole triglyceride and 3 moles water. The rigorous model comprises

a finite volume discretization of the column with a two-phase system made up by a continuous (oil) and dispersed (aqueous) phase. The water and the glycerol components in the dispersed and in the continuous phase form both a liquid-liquid equilibrium between the phases which dictates the theoretical extent of the mass transfer. The model includes back-mixing (axial dispersion) and is based on the works by Spencer et al. (1981) and Ricker et al. (1981). The base case uses the experimental data given by Jeffreys et al. (1961) in the experimental run number 6.
The design space of the model is summarized in Table 1. The same boundaries are defined to generate identical hypercubes for all surrogate modelling methods. The sample size of the hypercube is 500 and populated with Sobol sequences. The model is solved with the input hypercube and the output (overall conversion) is stored for the surrogate modelling step.

Table 1: Design parameters with design space boundaries for the counter-current spray column model

Parameter	Unit	Lower Bound	Upper Bound
Feed flow rate	kmol/h	2000	3500
Solvent to feed ratio	-	1.4	1.9
Temperature	K	473.15	533.15

5. Comparison between Surrogate Modelling Methods

The sampling and observation data was split half wise for training and testing. The surrogate models were built with the train set and the predictions were then compared with the test set. The coefficient of determination and the mean square error are given in Table 2 to compare the different surrogate modelling methods as well as the accuracy of mapping the rigorous (black-box) model to a surrogate model.

Table 2: Coefficient of determination (R^2) and mean square error (MSE) for the predictive performance of the surrogate models derived from a rigorous spray column model (black-box) with a sample size of 500

Surrogate Modelling Method	R^2	MSE
Multivariate Regression Splines	96.2	0.1e-03
Polynomial Chaos Expansion	99.7	0.55e-05
Gaussian Process Regression	99.9	0.40e-05

With x_1, x_2 and x_3 being the feed flowrate, solvent to feed ratio and temperature, the model described with multivariate regression splines is:

$$\hat{f}(x_1, x_2, x_3) = 0.1318 + 0.0016 * h(x_3 - 510.767) - 3.3521 * 10^{-8} * h(x_1 - 2.4716 * 10^6) + 6.5607 * 10^{-8} * h(2.4716 * 10^6 - x_1) - 0.0529 * h(x_2) + 0.0021 * h(x_3 - 487.095) - 0.0010 * h(487.095 - x_3) \quad (5)$$

The surrogate obtained through polynomial chaos expansion is as follows:

$$\hat{f}(x_1, x_2, x_3) = 4.3580 - 0.0230 * x_3 + 0.5354 * x_2 + 3.1109 * 10^{-5} * x_3^2 - 0.0015 * x_2 * x_3 + 4.0402 * 10^{-7} * x_1 - 1.1506 * 10^{-9} * x_1 * x_3 + 0.0418 * x_2^2 + 2.8782 * 10^{-8} * x_1 * x_2 + 1.5982 * 10^{-14} * x_1^2 \quad (6)$$

In respect to the Gaussian process regression surrogate, the covariance function was defined as a Matérn kernel:

$$R = k(r) = \left(1 + \frac{\sqrt{3}r}{l}\right) exp\left(-\frac{\sqrt{3}r}{l}\right) \tag{7}$$

Figure 2 shows how the cross-validation score, in this case R^2, behaves as a function of the number of samples used for training the model. With a training set of more than 15 samples the fitted model will give predictions with R^2 greater 95 %.

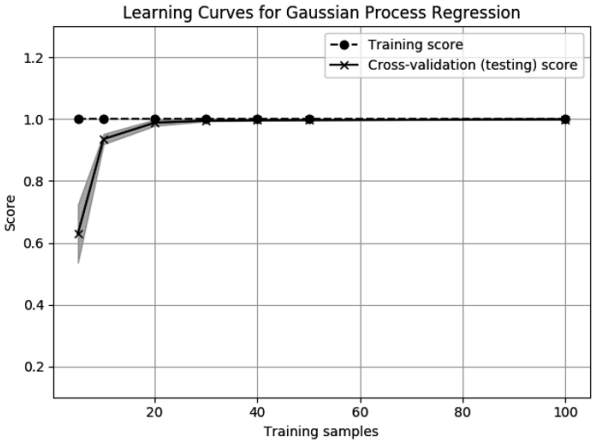

Figure 2: Comparison between the behaviour of training score and testing score as a function of the used training samples

6. Superstructure Optimization

The intention of building surrogate models from rigorous models embedded in different modelling environments and process simulators is to use the surrogates for generating and evaluating a superstructure for the most efficient design in respect to raw material and product specifications. Figure 3 shows the oleochemical process domain under research in this project. We presented in this publication the surrogate building procedure of a rigorous spray column model written in Fortran. The other rigorous models for a continuous stirred tank reactor (Fortran, Matlab), flash based glycerol purification (Pro/II), distillation column (Python) and solvent crystallization (Python) undergo the same procedure as described in the previous chapter. A superstructure can then be formulated with the models obtained with multivariate regression splines, polynomial chaos expansion or Gaussian process regression. The program will then choose between either a CSTR or spray column for the hydrolysis step, distillation or solvent crystallization for the separation of fatty acids and the number of flash purification units to recover higher graded glycerol based on economic feasibility and product specifications. The possible process structures can be generated through an enumeration approach where every possible configuration is evaluated by means of total annual cost and environmental impact. Another approach would be to formulate a disjunctive program with the surrogates and perform Big-M or convex hull transformation to obtain a MINLP to solve for.

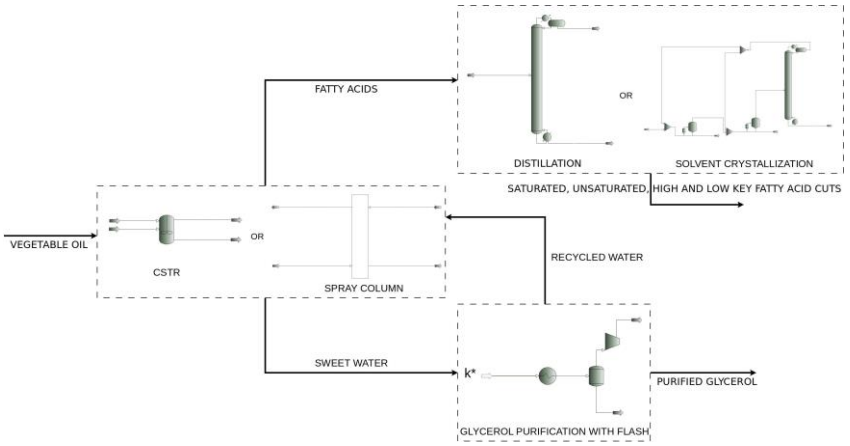

Figure 3: Schematic representation of possible process steps for the oleochemical process domain under research

7. Conclusions

We showed how superstructure optimization can be applied with rigorous models by using surrogate modelling techniques and highlighted the generation of these surrogates. Promising results have been obtained by Henao and Maravealis (2011) who used neural networks to obtain the surrogates. We, in contrast, applied multivariate regression splines, polynomial chaos expansion and Gaussian process regression to compare the different methods and evaluate in future work how the surrogates perform for superstructure optimization. The beauty of multivariate regression splines and polynomial chaos expansion are the simple models received and which are easily introduced in a disjunctive programming superstructure formulation whereas Gaussian process regression has shown to give the best predictive results compared to the two other methods and the surrogates can be used in the enumeration approach to evaluate all possible process configurations.

Abstract

Pilot plant test campaigns can be expensive and time-consuming. Therefore, it is of interest to maximize the amount of learning and the efficiency of the test campaign given the limited number of experiments that can be conducted. This work investigates the use of sequential design of experiments (SDOE) to overcome these challenges by demonstrating its usefulness for a recent solvent-based CO_2 capture plant test campaign. Unlike traditional design of experiments methods, SDOE regularly uses information from ongoing experiments to determine the optimum locations in the design space for subsequent runs within the same experiment. However, there are challenges that need to be addressed, including reducing the high computational burden to efficiently update the model, and the need to incorporate the methodology into a computational tool. We address these challenges by applying SDOE in combination with a software tool, the Framework for Optimization, Quantification of Uncertainty and Surrogates (FOQUS) (Miller et al., 2014a, 2016, 2017). The results of applying SDOE on a pilot plant test campaign for CO_2 capture suggests that relative to traditional design of experiments methods, SDOE can more effectively reduce the uncertainty of the model, thus decreasing technical risk. Future work includes integrating SDOE into FOQUS and using SDOE to support additional large-scale pilot plant test campaigns.

Keywords: Bayesian method; computational tool; space-filling design; minimizing uncertainty

1. Introduction

Pilot plant test campaigns can be expensive and time-consuming, limiting the number of test conditions that can be evaluated. Thus, a prudent choice of design schemes is needed to maximize the amount of knowledge gained from pilot plant experiments. Standard approaches to designing experiments are based on the properties of the input space, without leveraging the error in prediction of the output space (Politis et al., 2017). The

general procedure for many designed experiments follows a static approach: generate the complete set of input combinations, use them to perform the experiment, analyze the experimental results, and terminate the test campaign without adjustment. With this static approach, there is a possibility of under- or over-sampling, or placing runs in locations that provide minimal new information. Since pilot scale testing is expensive, test runs should be maximally informative. Therefore, a sequential design of experiments (SDOE) for pilot scale testing is proposed. This technique uses a combination of exploration (collecting data throughout the design space, especially in poorly-represented areas characterized by high uncertainty) and exploitation (sampling in the most advantageous regions of the known design space) (Garud et al., 2017). Intermediate results are used to determine the location of new design points by applying optimization strategies.

While SDOE can provide test guidance to improve learning, there are challenges to enable its effective use, including managing the computational burden, and incorporating the methodology into a computational tool. These challenges are exacerbated by the fact that accounting for variable uncertainty leads to large and computationally expensive models (Weaver et al., 2016). Thus, a computational tool that combines optimization, uncertainty quantification, and surrogate model development, organized into a Bayesian design of experiments framework, can enable a practical and efficient means to implement SDOE to maximize learning from experimental tests at both the bench and pilot scales.

We addressed these challenges by first using SDOE in conjunction with the Framework for Optimization, Quantification of Uncertainty and Surrogates (FOQUS) (Miller et al., 2014a, 2016, 2017), a software tool developed as part of the Carbon Capture Simulation Initiative (CCSI) (Miller et al., 2014b). FOQUS can interface with commercial process simulators to enable uncertainty quantification, optimization, and the development of surrogate models. Its ability to manage parallel execution of process simulations enables the efficient generation of reduced-order models that are essential for SDOE. SDOE uses a Bayesian method that leverages new data and process models to determine an optimal set of test conditions. This procedure can reduce the total number of experiments required to explore the input/output space of the process model, while improving the model's accuracy. Thus, the approach identifies the experiments and conditions that will provide the most benefit to increased understanding of the process, thereby reducing technical risk. The methodology has the potential to speed up deployment of new technologies at a reduced cost by improving test campaigns.

We implemented pilot scale SDOE for a solvent-based CO_2 capture plant at the National Carbon Capture Center (NCCC), where the surrogate model predicts the CO_2 capture percentage of the plant given a set of input variables. The results demonstrate reduced uncertainty compared with traditional design of experiments methods. This paper is organized as follows. Section 2 outlines the methodology for SDOE. Section 3 describes a case study used to demonstrate the methodology. Section 4 presents and discusses the results of implementing SDOE on the case study. Finally, Section 5 provides the conclusions and future direction of this work.

2. Methodology

The process for SDOE is as follows:

1.) Identify the criteria for optimization. It is possible to consider more than one criterion, and the relative importance of each criterion can be changed as the experiment progresses. Common criteria include: refining the region of interest,

reducing the uncertainty in the estimation of model parameters, reducing the uncertainty in the model's predictions for new observations in the design space, reducing the error in the model's predictions, or optimizing the value of an output response.

2.) Develop a working model of the process based on the underlying science to estimate the value of the criterion/criteria defined in Step 1.
3.) Identify the input variables or factors to be varied during the experiment, define their ranges, and identify constraints or regions in the input space that are not of interest or are intractable.
4.) Identify input combinations of the variables from Step 3 to be considered for the experimental runs during the sequential design.
5.) Develop a working model of the process that can be updated with new data. Sometimes, this model is the same as in Step 2. This model will quantify changes in the criterion/criteria from Step 1 using results from previous experiments.
6.) Develop a plan for N number of sequential batches, with the size of N determined by a realistic time frame to complete the experiments. Each batch consists of a unique subset of the candidate input combinations from Step 4. For each batch:
    a. Run each candidate input combination through the working model.
    b. Measure the responses (i.e., outputs).
    c. Update the working model from Step 5.
    d. Optimize the location of new experimental runs with respect to the criterion/criteria from Step 1.
7.) Execute the plan developed in Step 6.
    a. Identify the initial batch of experimental runs (developed in Step 6).
    b. Run this batch of experiments, update the working model with new experimental data, and use this model to select the next batch of runs.
    c. Iterate Steps 7a and 7b for the entire budget of runs.

3. Case Study

In this section, we describe the implementation of SDOE for a test campaign at NCCC. The objective is to determine the optimal input combinations for improving our surrogate model's predictions of the plant's CO_2 capture percentage (as a means to quantify the predictive capability of the model) throughout a range of different operating conditions. The surrogate model was used to compute the CO_2 capture percentage, because it is less computationally expensive than using the process simulator Aspen Plus® and offers an adequate compromise between computation time and accuracy.

NCCC, located in Wilsonville, AL, USA, is a test facility that uses flue gas provided by Plant Gaston's 880 MW coal-fired power plant operated by Southern Company (Brown et al., 2017). One of the post-combustion CO_2 removal systems used at NCCC is a solvent test unit consisting of an absorber and a stripper. For this case study, the solvent is a non-proprietary aqueous solution of monoethanolamine (MEA) (Bumb et al., 2017) that is commonly used as a baseline for comparing more advanced solvents. MEA has a fast reaction rate with CO_2 and a chemical structure that allows for high water solubility and alkalinity (necessary for CO_2 capture) (Morgan et al., 2017).

Table 1 summarizes the five available configurations of the CO_2 absorber column of the MEA system. Because of limitations on the amount of data that can be collected, we focus on the C3i configuration. The following variables were investigated: flue gas flowrate (1,000 to 3,000 kg/h), CO_2 mass fraction in the flue gas (0.125 to 0.175), lean solvent

loading (0.1 to 0.3 mol CO_2/mol MEA), and lean solvent flowrate (3,000 to 13,000 kg/h). Some combinations of the factors were not reasonable, as they would not produce meaningful results. Therefore, the region of interest was defined as an irregular region inside the space parametrized by the ranges above.

Table 1. The five configurations of the CO_2 absorber column of the MEA system.

Notation	Number of Beds	Intercooling	Number of Available Experimental Data Points	Number of New Experimental Runs
C3i	3	Yes	15	24
C3	3	No	1	4
C2i	2	Yes	2	4
C2	2	No	2	4
C1	1	No	3	8

Time and resource constraints allowed for a total of 44 new experimental runs. Given the available experimental data, the first stage in determining the location of new input combinations uses space-filling designs for each configuration. The procedure involves exploration of the region of interest (CO_2 capture percentage of 50 % to 95 %) and reduction of the uncertainty in the surrogate model's prediction. This process is conditional on the locations in the design space that has already been explored with historical data. The second stage uses SDOE to minimize the estimated width of the confidence interval of the CO_2 capture percentage. It incorporates the results from the first stage to determine the location of the next experiment. For the space-filling design, the minimax criterion (Masoudi et al., 2017) was used. This objective seeks to minimize the maximum distance between any location in the design space of interest and where data have already been obtained. Given the limited number of experiments that can be run, this condition ensures that new input combinations are located far from existing experimental conditions, which allows for a more effective coverage of the input space.

4. Results and Discussions

Figure 1a shows a comparison of the surrogate model's prediction uncertainty before and after Bayesian update of the surrogate model's parameter distributions (denoted as "Before Update" and "After Update") for the C3i configuration. The uncertainty is quantified using the width of the 95 % confidence interval (CI), where a smaller value denotes smaller uncertainty. The objective is to reduce the uncertainty of the detailed models from Aspen Plus (i.e., the hydrodynamics and mass transfer models) by reducing the size of the model's parameter space to better understand the probability of observing a given CO_2 capture percentage value within a certain range. Figure 1a shows a reduction in the uncertainty of the surrogate model's output, which was calculated to range from 22.2 % to 70.2 %. This plot highlights the benefits of additional data and sequentially updating the surrogate model with new experimental results. In Figure 1a, the first fourteen points (1 to 14) represent the width of the 95 % confidence interval of the surrogate model for the new data obtained using the space-filling design (denoted as "Stage 1"), and the last three points (15 to 17) represent the width of the 95 % confidence interval of the surrogate model after the second phase of SDOE (denoted as "Stage 2").

The performance of the surrogate model's predictions after updating the model with data from SDOE is shown in Figure 1b, where the standard deviation of the percentage error is 7.70 %. Figure 1b shows that most of the historical data (denoted as "Historical") are clustered close to the 100 % CO_2 capture percentage region, whereas the new data

obtained using the space-filling design (denoted as "Stage 1") provide better coverage of the desired range of CO_2 capture percentage. The second stage data (denoted as "Stage 2") are collected to further reduce the width of the confidence interval. They are located in the 90 % to 100 % CO_2 capture percentage region because of the large estimated uncertainty (as shown in Figure 1a) of the surrogate model's predictions in this region. More points in this region would be maximally advantageous for refining the prediction.

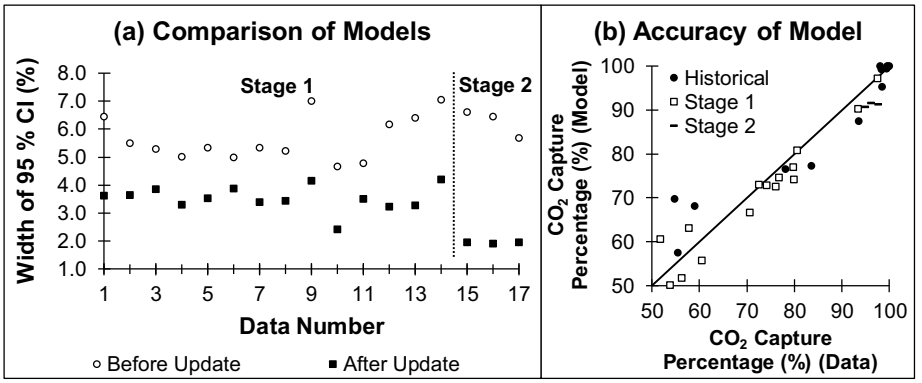

Figure 1. Performance of surrogate model: (a) Reduction of uncertainty, (b) Parity plot of CO_2 capture percentage in the absorber (solid line represents parity line).

5. Conclusions and Future Direction

SDOE was applied to the NCCC test campaign and used to update the test plan as new experimental data were obtained. The results show a reduction in the uncertainty of our surrogate model's predictions of the CO_2 capture percentage. SDOE provides a flexible method that can be adapted to multiple study objectives, and make optimal use of experimental resources. Potential improvements to SDOE include developing algorithms capable of generating accurate surrogate models with fewer data points for cases where the evaluation of the detailed model (e.g., the prediction from Aspen Plus) is computationally expensive, and developing algorithms for switching between the detailed model and the surrogate model to improve the Bayesian inference. Future work includes integrating SDOE into FOQUS, and using SDOE to support large-scale pilot tests at Technology Centre Mongstad (TCM), a post-combustion carbon capture facility located in Mongstad, Norway that can operate with a flue gas flow rate of 60,000 Sm^3/h (Bumb et al., 2017).

Abstract

The chemical industry has evolved in recent years and has driven the research in the manufacture of high added-value products that satisfies specific requirements of consumers. The design of these products requires methodologies that integrate the multiscale approach, manufacturing process, consumer considerations and market parameters. In this work, a computational framework that allows integrated optimal design for Oil-in-Water emulsions was used. Predicted properties by the mathematical models were compared with the experimental behavior of these colloidal systems. The results concerning to computational and experimental design gave valuable information about the robustness of the optimal model and allows an understanding of phenomena in the microscopic structure of emulsions, which will helps in the improvement of computational design modules.

Keywords: Computational framework, Integrated optimal design, O/W emulsion, Experimental adjustment

1. Introduction

Oil-in-Water (O/W) emulsions are widely used in a variety of consumer products, such as moisturizing creams, sunscreens and cosmetics. These systems are thermodynamically unstable colloids and their performance as products is determined by the complex set of interrelationships among molecular, microscopic and macroscopic variables (Pradilla et al, 2015). In this work, the properties predicted by an optimal product design model were compared with experimental data of O/W emulsions. This computational tool was developed with a focus on moisturizing creams and the objective of producing two optimal cream formulations (Torres et al, 2016): one that allows to obtain the maximum profit and another that assures the highest preference based on physical characteristics perceived by the consumer (Bagajewicz et al, 2011).

The optimal product design model was formulated with a multiscale approach encompassing three levels. At the molecular scale, the properties of the surfactant or surfactants mixture were predicted through molecular interactions and structure (Mattei et al, 2014). The microscopic level was reflected in droplet diameter calculations. Finally, apparent viscosity was selected as a macroscopic variable, which was calculated from microscopic and molecular responses (Smith and Ierapepritou, 2010). This multiscale design was implemented in Pyomo, which allows the integration of a modular representation for product structure and properties, consumer preferences and

economic performance and it was using Bonmin solver for programming problem in order to reduce the computational time according to Torres et al (2016). It was possible to obtain cream formulations, properties and basic manufacturing conditions by defining impeller diameter and type into de computational framework.

2. Methodology

The optimal formulations were taken as a starting point for the experimental design and some operating conditions that were not considered in the property models, such as mixing time, incorporation flow rate and tank diameter, were well-defined in the laboratory. Although the computational tool provides the emulsifier mass fraction, it does not consider the cost of surfactant molecules and, consequently, this formulation contains a large mass of emulsifiers. As a result, these fractions were adjusted in the experimental design. Once these conditions were fixed (see Table 1), the moisturizing cream design was performed in order to compare droplet diameter and apparent viscosity predicted with experimental information of these microscopic and macroscopic variables.

Table 1. Design parameters for formulation

Design parameters		
Emulsifier mass fraction	[%]	4.00
Emulsifiers	[−]	Tween 20 Span 80
D_{Imp}/D_{Tank}	[−]	0.75
Impeller type	[−]	Vertical Flat blade
Mixing Time	[s]	900
Incorporation flow rate	$\left[\frac{m^3}{s}\right]$	$5x10^{-7}$

The emulsions were prepared from two optimal formulation cases: maximum consumer preference and maximum profit. With the surfactant adjustment, the resultant formulations had a 20% dispersed phase concentration in both cases. Considering that emulsion properties depends on every aspect related to molecular interactions, microscopic structure and operating conditions in the manufacturing process, the product design began only with water and mineral oil/petrolatum at a first stage in order to obtain experimental measures for an early approach with the computational framework and, subsequently, follow step-by-step the predicted formulation at subsequent stages of this research. This methodology allows a better understanding of the manufacturing process of emulsions, and consequently, it is possible to evaluate robustness, scope and every consideration in mathematical models.

3. Mathematical models and experimental measurements

The results of optimal formulations and experimental measures of droplet diameter distribution, mean drop diameter d_{32} and viscosity as a function of shear rate are reported in Table 2

Table 2. Formulation of preference and profit case obtained with computational tool (models).

Results			
Droplet Diameter	[µm]	19.11	25.76
Apparent viscosity	[Pa*s]	0.385	0.394

For drop diameter, the model proposed by Tcholakova et al (2011) was used. This approach depends on density of continuous phase ρ_C, viscosity of dispersed phase μ_D, interfacial tension σ_{ow} and other factors that quantify the hydraulic and differential pressure contributions. This model also takes into account the turbulent energy dissipation given by agitation velocity N_s, impeller diameter D_{Im} and parameter b_1 related to impeller type.

$$d_{32} = A_1\left(1 + \frac{A_2 * \mu_D * \epsilon^{1/3} * d_{32}^{2/3}}{\sigma_{ow}}\right)^{3/5} \sigma_{ow}^{3/5} * \rho_C^{-\frac{3}{5}} * \epsilon^{-\frac{2}{5}} \quad (1)$$

$$\epsilon = b_1 * N_s^3 D_{Im}^2 \quad (2)$$

The model used for viscosity prediction in diluted emulsions was developed by Oldroyd (1953) and complemented by Pal (2000). In this case, the emulsion viscosity depends on the viscosity of continuous phase μ_C, viscosity ratio of both phases κ, volumetric fraction of dispersed phase ϕ and capillary number N_{Ca} that includes shear rate $\dot{\gamma}$ and mean drop diameter d_{32}.

$$\mu_e = \mu_c\left[1 + \frac{5\kappa + 2}{2(\kappa + 1)}\phi + \frac{(5+2)^2}{10(\kappa+1)^2}\phi^2\right]\left[\frac{1 + \lambda_1\lambda_2 N_{CA}^2}{1 + \lambda_1^2 N_{CA}^2}\right] \quad (3)$$

$$\lambda_1 = \frac{(19\kappa + 16)(2\kappa + 3)}{40(\kappa + 1)}\left[1 + \frac{19\kappa + 16}{5(\kappa+1)(2\kappa+3)}\phi\right] \quad (4)$$

$$\lambda_2 = \frac{(19\kappa + 16)(2\kappa + 3)}{40(\kappa + 1)}\left[1 - \frac{3(19\kappa + 16)}{10(\kappa + 1)(2\kappa + 3)}\phi\right] \quad (5)$$

$$N_{Ca} = \frac{\mu_{cd_g}\dot{\gamma}}{2\sigma_{ow}} \quad (6)$$

The contribution of a rheology modifier was described with the Huggins equation with specific parameters for the thickener used in experimental design. Where $[\eta_i]$ represents the relative increase in viscosity, $[\eta]$ represents the intrinsic viscosity, C_{th} is the thickener concentration and k_H is the Huggins slope.

$$[\eta_i] = [\eta]C_{th} + k_H[\eta^2]C_{th}^2 \quad (7)$$

$$[\eta] = 45.8 * \exp(-0.0005\dot{\gamma}) \quad (8)$$

$$k_H = 0.0047 * \dot{\gamma} - 0.0005 \quad (9)$$

For experimental measures of drop diameter and viscosity, a particle size analyzer and a rotational rheometer were used respectively. Considering the shear rate of 100 s^{-1} defined by Wibowo and Ng (2001) for moisturizing creams and pastes viscosity measurements were performed in a range of $[90,120]\ s^{-1}$. As mentioned before, O/W emulsions with just mineral oil and water were initially prepared. The resulting measures of this basic formulation are reported on Table 3. Table 4 reports results for experimental measures of profit and preference approach that includes a second profit formulation in which was eliminated the thickener with the purpose to identify it direct effects in the emulsion structure.

4. Optimal model vs Experimental information

As it can be seen in Table 4, the measured properties of the basic formulation were lower in comparison to the predictions, for the reason that these models include the contribution to viscosity of additional compounds. The results of the optimal cases were significantly closer to mathematical models for one of two estimated properties, depending on the case evaluated. For the preference approach, the comparison for mean droplet diameter denoting a difference of 3% related to calculated diameter. However, in the case of viscosity, a divergence between experimental and predicted properties was noted. This was attributed to the effect of the thickener. The profit approach includes a high concentration of thickener, which produces high viscosities in the emulsions. Although the values of viscosity were not quite close in comparison to the model, both values stayed in the same order of magnitude. Nevertheless, predicted droplet diameter was significantly smaller from the computational model. In order to determine which phenomena drive this behavior, it is necessary to analyze the microscopic behavior of these emulsified systems.

An ample space between droplets exists in diluted emulsions. However, flocculation and coalescence mechanisms tend to produce larger drops. When a thickener is used, its molecules occupy the space between particles, preventing coalescence and favoring smaller drop sizes (Akiyama et al, 2005). In the computational tool, this effect was not included. For this reason, a second profit approach formulation was proposed without thickener. As show in Table 4, the drop diameter obtained implies a difference of 9%.

5. Conclusions and future work

The comparison between the experimental and computational data gave valuable information about the robustness degree of the optimal model. The mean diameter calculated in two formulations, without the effects of thickener, predicted satisfactorily the microscopically behavior of emulsion evidenced in experimental execution; hence the mathematical model for microstructure of emulsion was appropriated in the design

of computational framework. On the other hand, the viscosity model that includes the contribution of thickener in the properties calculation, did not predict entirely the structure of emulsion due to the fact that this model not consider the effects of rheology modifier in coalescence of dispersed drops.

As previously exposed, it was possible to conclude that the computational framework was a useful tool for emulsion design and gives accurate information about drop diameter that keeps relation with stability of these colloidal systems. Also, the experimental design performed in this work had an important role in the validation of predicted properties, it allows to understand phenomena that not consider the mathematical model and as a result of this is possible to overcome some limitation in the computational tool by designing a specific module that includes the thickener effects in coalescence of drops for specific concentrations defined in a new experimental design. So is possible to integrate the microscopically and macroscopically effects of rheology modifier in the emulsion structure, and consequently, providing an accurate prediction of properties that have an influence on operating conditions, consumer preferences and economic yield.

Abstract

Large-scale processes for catalytic production of gamma-valerolactone (GVL) from two different feedstocks (levulinic acid; LA and ethyl levulinate; EL) are presented based on experimental results. In LA-based process, cellulose and hemicellulose of corn stover are converted to LA using dilute sulfuric acid catalyst and subsequently converted to GVL over $RuSn_4$/C catalyst in the present of GVL solvent. Instead of LA, EL converted to GVL on Pt-ZSM 35 catalyst using ethanol solvent obtained as a by-product in EL-based process. The simulation study including process design, heat integration, and economic analysis is performed to show the economic feasibility for the EL-based process compared with LA-based process. The minimum selling price of EL-based GVL ($ 1.64/kg) is higher than LA-based GVL ($ 1.16/kg). The sensitivity analysis shows that if EL-based process uses lower feedstock cost and energy requirements, it will be comparable with the LA-based process.

Keywords: Gamma-valerolactone; Ethyl levulinate; Levulinic acid; Heterogeneous catalytic hydrogenation; Techno-economic analysis

1. Introduction

Gamma-valerolactone (GVL) derived from lignocellulosic biomass can be used as a value-added platform chemical for the production of biofuels, fuel additives, and polymers. Ethyl levulinate (EL) or levulinic acid (LA) can be converted to GVL through the heterogeneous catalytic hydrogenation. GVL is mainly produced by LA, obtained from the hydrolysis of lignocellulosic biomass (cellulose and hemicellulose) (Alonso et al., 2013). Recently, several conversion studies of EL or LA into GVL by the heterogeneous catalytic hydrogenation were reported (Quiroz et al., 2016; Li et al., 2017). We present two catalytic conversion strategies for the production of GVL from different feedstocks. In the EL-based process, EL can be converted to GVL on Pt-ZSM 35 catalyst using ethanol solvent obtained as a by-product, while in the LA-based process, LA over $RUSn_4$/C catalyst can be converted to GVL using solvent GVL (Alonso et al., 2013; Chen et al., 2016). Both processes have three common advantages as follows: (1) The use of ethanol and GVL as reaction solvent enables to reduce its makeup of reaction solvent; (2) Heterogeneous catalysts can be effectively separated and recycled; (3) Both processes show 99% high yield for GVL production. Here, compared to LA-based process, EL-based process has a higher feedstock cost but a lower separation cost because of the lower boiling point of the solvent.

In this work, integrated processes are developed combining separation systems with reaction systems by using ASPEN Plus process simulator based on the same processing

rate of the feedstock (2,000 dry tonnes of biomass per day) as well as the same economic assumptions and parameters. To reduce the total energy requirement of the process, we design a heat exchanger network by using the ASPEN Energy Analyzer. Finally, we conduct techno-economic analysis and comparison of minimum selling price (MSP) between both processes shows which process is an economically competitive approach.

2. Technical overview

A EL-based process is presented for the catalytic production of GVL from biomass-derived EL based on the experimental studies, and is compared with biomass derived LA-based GVL production.

Biomass derived LA-based GVL production consists of two catalytic conversion subsystems: (i) biomass deconstruction and (ii) GVL production (Figure 1). In the biomass deconstruction, cellulose and hemicellulose can be converted to LA and furfural (FF) with 61 % and 56 % molar yields at 443 K and 16 bar, containing dilute sulfuric acid (SA) catalyst in a GVL–water solution (Alonso et al., 2013). In the GVL production, FF and LA can be converted to GVL though three catalytic tubular reactors connected in series. First, FF can be converted to furfuryl alcohol (FFA) with a 90 % molar yield at 373 K and 35 bar in the first reactor using Pt_3Sn/SiO_2 catalyst. Next, FFA subsequently converted to LA with a 70 % molar yield in the second reactor using Amberlyst 70 catalyst. Finally, the LA can be converted to GVL with a 99 % molar yield at 493 K and 35 bar on a RuSn (1:4)/C catalyst.

Chen et al. (Chen et al., 2016) reported that EL is hydrogenated to GVL with a high yields (99 %) using commercial zeolite supported Pt (Figure 2). They investigated the influence of four reaction conditions (catalyst, temperature, pressure and solvent) in GVL yields. First, 1 % Pt/ZSM-35 was the most efficient catalyst among other catalysts (Pt/MCM, Pt/SAPO, Pt/HY, Pt/USY and Pt/MOR). EL is hydrogenated with different range of temperature (180-220 ℃), and the highest yield of GVL is achieved at 200 ℃. As increment of H_2 pressure (10-60 bar), the H_2 concentration on the surface of the catalyst that accelerates the reaction rate is increased. Finally, the study confirmed that the selectivity of GVL was influenced by solvent. Consequently, Pt/ZSM-35 was found to show the highest activity as a results of the catalyst screening, under optimized conditions (200 ℃, 60 bar, ethanol solvent) and 100 % conversion of EL with a high GVL selectivity (99 %) were achieved. Additionally, the EtOH is produced as a byproduct.

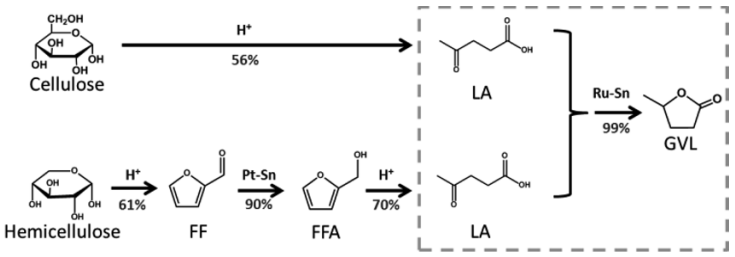

Figure 1. Reaction scheme of the LA-based GVL production from lignocellulosic biomass.

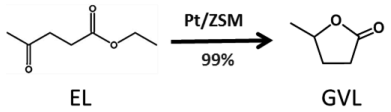

Figure 2. Reaction scheme of the EL-based GVL production.

3. Techno-economic results and discussion

Two large-scale processes for catalytic production of GVL from two different feedstocks (LA and EL) were designed based on the technologies outlined and the experimental data described in the previous section by using ASPEN Plus process simulator. In the ASPEN simulation, standard method was used for the convergence. The base capacity of both GVL production processes was set to 2,000 tonnes per day (t/d) of dry corn stover.

3.1. LA based process: simulation and energy analysis

The LA-based process (Han, 2016) consists of five subsystems: biomass deconstruction, GVL production, GVL recovery, wastewater treatment (WWT), and storage (Figure 3). A mixture of shredded corn stover in GVL–water solution (4:1) containing 0.1 M SA is supplied to a biomass deconstruction reactor (R-1 in Figure 3) for coproduction of LA and FF from cellulose (41 %) and hemicellulose (24 %) of corn stover. For the subsequent catalytic conversion of LA and FF, SA is removed by precipitation using $Ca(OH)_2$ (S-1 in Figure 3). In the GVL production subsystem, LA and FF are simultaneously converted to GVL (R-2 in Figure 3). The resulting mixture containing GVL, water, biomass residues (BR), and CO_2 is sent to GVL recovery subsystem to effectively separate GVL and water from CO_2 and BR (S-2 and S-3 in Figure 3). The water and wet BR are treated in WWT subsystem. Most of GVL used as a solvent is recycled back to the biomass deconstruction subsystem, and the remaining GVL is fed to distillation column (D-1 Figure 3) for producing a high purity (99.9 wt%) of product. Finally, the GVL (375 t/d) is obtained at the bottom of D-1.

Next, we performed an energy analysis of the proposed process. To produce GVL, the process requires 186 MW of heating, 196 MW of cooling, and 1 MW of electricity. We conduct a heat integration to minimize energy requirements with heat exchanger network (HEN) between hot and cold process streams by using the ASPEN Energy Analyzer. The heat integration result shows considerable energy reduction in the heating requirements of the process (99 MW). In the biomass deconstruction and GVL production subsystems, most of the heat requirement in their cold process streams could be transferred from hot process streams in GVL recovery subsystem.

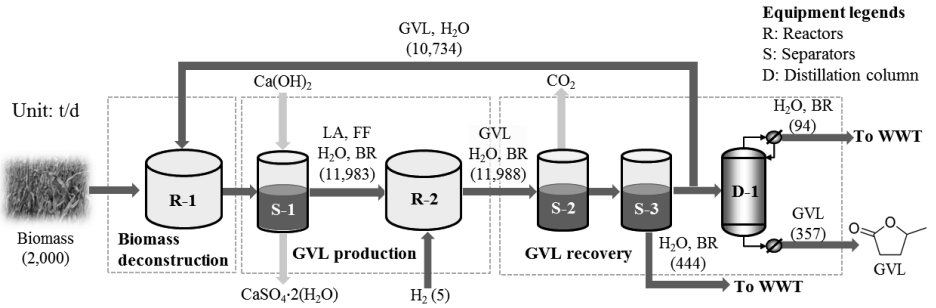

Figure 3. Simplified process flow diagram of LA-based GVL production process.

The energy efficiency which is the ratio of the energy output (GVL) to energy input (biomass feedstock, H_2 and primary energy) is increased from 18.1 % (before heat integration) to 23.2% (after heat integration).

3.2. EL based process: simulation and energy analysis

The EL-based process consists of three main subsystems, as shown in Figure 4: GVL production, GVL recovery, and storage. We used the same cellulose and hemicellulose-to-EL mass yields (54 %) in the previous study (Chen et al., 2016). Based on this yield and feedstock compositions given in LA-based process, the amount of EL required for EL-based process was estimated to 702 t/d. Feed solution (1.2 wt% of EL in EtOH solvent) and H_2 are supplied to the catalytic reactor (R-1 in Figure 4) in GVL production subsystem. EL is converted to GVL through the hydrogenation at 60 bar and 200 ℃ with Pt-ZSM catalyst. The resulting mixture containing dilute GVL (1.3 wt%) is sent to GVL recovery subsystem to effectively separate GVL from ethanol solvent. High purity of GVL (99.9 wt%, 490 t/d) is obtained at the bottom of distillation column (D-1 in Figure 4), while high purity of EtOH (99.9 wt%, 225 t/d) is obtained at the top of D-1. The most of EtOH is recycled back to the GVL production and the remaining EtOH (2%) is sold as byproduct.

The process requires 249 MW of heating, 254 MW of cooling, and 2.8 MW of electricity. Considerable amount of heat (162 MW) are required in GVL production subsystem to raise temperature of conversion reactor. To reduced energy requirements of the process, we also performed heat integration. But, the result of heat integration shows only 1% of total energy reduction, resulting still large amount of heat energy requirement in the GVL production system. There are a few chances to heat transfer between hot process streams and cold process steam in the other subsystems because most of the temperature of cold process stream is higher than them of hot process streams. In this study, EL-based process has a portion of process flows to produce GVL from the biomass compared to LA-based process. The limited number of process streams reduces the optimization possibility of HEN which can reduce heat energy requirements to be minimized. The energy efficiency of EL-based process is increased from 25.3 % (before heat integration) to 25.5 % (after heat integration).

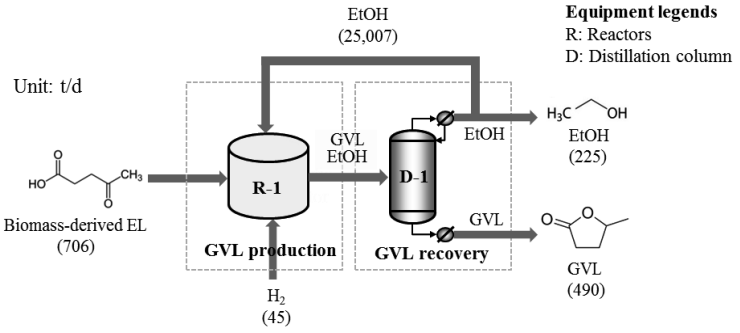

Figure 4. Simplified process flow diagram of EL-based GVL production process.

3.3. Techno-economic comparison of two processes

In this section, we conducted techno-economic comparison of two processes to present possibility that EL-based GVL production process could be alternative to LA-based

process. Based on the simulation results, capital and operating costs were calculated by using ASPEN Economic Analyzer. We performed an economic analysis by using a discounted cash flow to determine a MSP of GVL that makes the net present value equal to zero. The MSP (\$1.64 per kg; $/kg_{GVL}$) of GVL for EL-based process was higher than that of LA-based process ($1.16/kg_{GVL}$). This is because the high feedstock and utility costs are required in EL-based strategy. In case of feedstock cost, EL price is much higher than LA derived from biomass (Hayes, 2013; Han et al., 2014). Although the production of GVL from EL-based process (490 t/d) was higher than LA-based process (375 t/d), total cost of EL-based process is much higher than that of LA-based process. Utility cost of EL-based process (\$ 77 million per year; \$ million/y) is 97 % higher than LA-based process (\$ 39 million/y) (Table 1). The EL-based process only included GVL production and recovery subsystems, while the LA-based process included various subsystems to produce GVL from biomass. Process integration with the process that can produce EL from biomass at low cost and supply heating energy to EL-based process can decrease the MSP of GVL. We performed sensitivity analysis to present the impact of process integration on the MSP of GVL. The EL price could be reduced by improving economics of the EL production process, and the utility costs could be reduced by heat integration with other process using waste heat.

Table 1. Annualized capital cost and operating cost of EL-based GVL production process (\$ million / y).

	ACC	OC
Subsystem		
GVL production	16.9	254.4
GVL & ETOH recovery	4.0	2.8
Storage	1.6	1.1
Utilities(HEN)	6.2	77.0
Total ACC/OC	28.7	335.3
TC	364.0	

ACC : Annualized capital cost OC : Operating cost

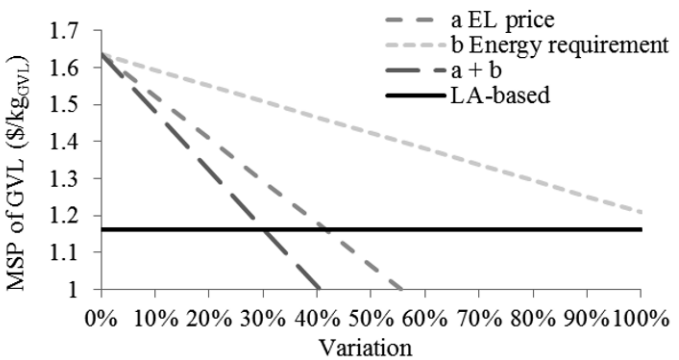

Figure 5. Sensitivity analysis of the MSP of GVL with respect to major cost drivers.

The feedstock cost is the most significant factor affecting the MSP of GVL. When the EL price is decreased by 42 %, the MSP of GVL is decreased to that of LA-based strategy (\$ 1.16/kg_{GVL}). Even if the energy requirements are decreased to zero, the MSP of GVL is still higher than that of LA-based process. When the EL price and energy requirements are simultaneously decreased by more than 30 %, the MSP of GVL can be lower than that of LA-based process (Figure 5).

4. Conclusion

Two processes for catalytic production of GVL from EL and biomass derived-LA were designed. Techno-economic comparison presented a replaceability of feedstock with the results that EL-based GVL production process could be alternative to LA-based process. The EL-based process had higher MSP (\$1.64/kg_{GVL}) because the feedstock and energy costs of EL-based process were higher despite larger production of GVL from EL-based process (490 t/d) compared to LA-based process (375 t/d, \$1.16/kg_{GVL}). The MSP for the EL-based process could be lower than that of LA-based process when feedstock and energy costs decrease by 30%.

Abstract

A platform is presented that enables systematic alternative generation and multiobjetive evaluation for designing biopharmaceutical drug product manufacturing processes. In the platform, the layers of product, unit operation, equipment technology, and operation are defined to assist generation of process alternatives as the combination of information at each layer. Multiple indicators are defined to evaluate economy, environment, supply, and product quality, which are aggregated to total score using weighting factors. A case study demonstrated that the developed platform can facilitate comprehensive process synthesis and multiobjective evaluation considering the novel disposable equipment technology for biopharmaceutical manufacturing known as single-use technology.

Keywords: Pharmaceuticals, Single-use technology, Process alternative generation, Multiobjective evaluation, Decision-making

1. Introduction

Pharmaceutical manufacturing is shifting from large-scale single-product production to small-scale and multiproduct production. In biopharmaceutical manufacturing, continuous technology or single-use technology (SUT) are developed as the new equipment technologies (Konstantinov and Cooney, 2015, Levine et al, 2012). SUT uses pre-sterilized and disposable resin-made equipment, which can substantially reduce changeover operations at the shop floor, e.g., cleaning and sterilization. The conventional technology to SUT is known as multi-use technology (MUT) that uses stainless steel equipment and requires cleaning and sterilization at every batch. The choice of these technologies can affect the entire process regarding various aspects.

Many authors investigated the process design considering SUT in drug substance and drug product manufacturing, e.g., Walther et al. (2015) and Shirahata et al. (2017a), respectively. In these previous works, the number of the considered process alternatives were limited due to the reliance on heuristics. Generation of process alternatives has been investigated for decades for commodity chemical manufacturing (Kirkwood et al., 1988), however, less attention has been paid to pharmaceutical manufacturing. In this work, we focus on biopharmaceutical drug product manufacturing, i.e., sterile filling of compounded drug solution into glass containers, and present a design platform for generating and evaluating process alternatives with considering novel equipment technologies such as SUT.

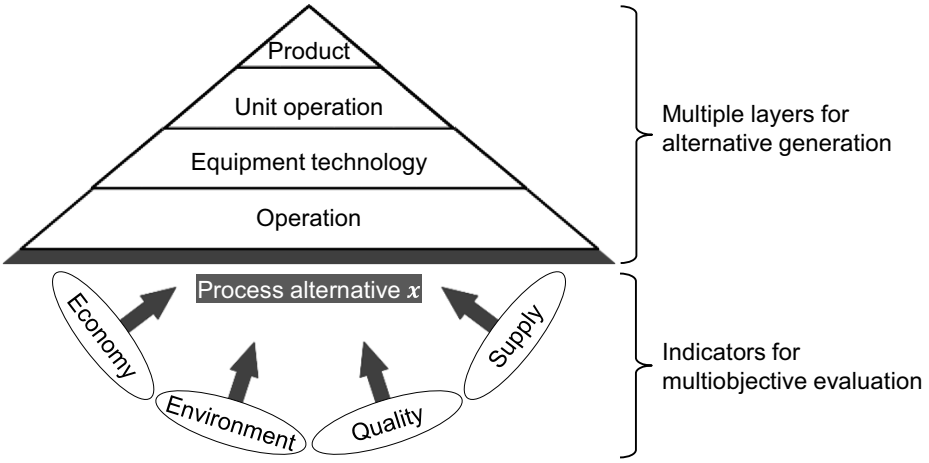

Figure 1. Hierarchical structure of the developed platform

2. Developed platform

Figure 1 shows the hierarchical structure of the developed platform with multiple layers for generating alternatives, and with the multiple indicators for evaluating alternatives.

2.1. Multiple layers for alternative generation

Four layers are defined to consider numerous candidate alternatives in a hierarchical manner. The first and the second layer, "product" and "unit operation", consider information on the product and the combinations of unit operations, respectively. The third layer, "equipment technology", is defined to incorporate novel equipment technologies, e.g., SUT, with considering materials, layout, and sizes of the equipment. The fourth layer, "operation", considers manufacturing conditions and scheduling. At each layer of "product", "unit operation", "equipment technology", and "operation", row vectors, $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$, and $\boldsymbol{d}$, are defined, respectively, as shown in Eqs.(1–4), which contain the elements corresponding to the layer.

$$\boldsymbol{a} = (\text{Production lifetime, Annual production amount, Dorsage form, } \dots) \quad (1)$$

$$\boldsymbol{b} = (\text{Sterilization method, Presence of freeze dry, } \dots) \quad (2)$$

$$\boldsymbol{c} = (\text{Equipment material, Layout, Shape, } \dots) \quad (3)$$

$$\boldsymbol{d} = (\text{Production sequence, Filling speed, Temperature, } \dots) \quad (4)$$

A process alternative $\boldsymbol{x}$ is defined by specifying the elements of the vectors $\boldsymbol{a}$ to $\boldsymbol{d}$ as values or discrete choices (Eq. (5)). The symbol $\oplus$ indicates an operation of the direct sum.

$$\boldsymbol{x} = \boldsymbol{a} \oplus \boldsymbol{b} \oplus \boldsymbol{c} \oplus \boldsymbol{d} \quad (5)$$

2.2. Indicators for multiobjective evaluation

Multiobjective evaluation of the generated alternative $\boldsymbol{x}$ is then performed as shown in Eq.(6) by evaluation indicator y_{obj} with evaluation model f_{obj} for each design objective *obj*. For example, net present value (NPV) is used as y_{obj} (*obj* = Economy) as shown in Eq.(7). Here, C_0 [USD], s [–], n_{tax} [–], t [–], i [–], n [–], C [USD], and m [–] stand for investment cost, salvage rate, taxation lifetime, taxation rate, interest rate, production lifetime, monthly expense, and number of month per year, respectively.

$$y_{obj} = f_{obj}(\boldsymbol{x}) \qquad \text{with } obj = \{\text{Economy, Environment, Supply, Quality}\} \tag{6}$$

$$\begin{aligned}\text{NPV(cost)}(\boldsymbol{x}) = C_0(\boldsymbol{x}) - \frac{(C_0(\boldsymbol{x}) - sC_0(\boldsymbol{x}))}{n_{\text{tax}}}\, t \sum_{j=1}^{n_{\text{tax}}} \frac{1}{(1+i)^j} - \frac{sC_0(\boldsymbol{x})}{(1+i)^n} \\ + mC(\boldsymbol{x}) \sum_{j=1}^{mn} \frac{1}{\left(1 + {}^{i}/_{m}\right)^j}\end{aligned} \tag{7}$$

Life cycle CO_2 emissions, impact of time delay in product supply, and impact of interaction between the product and the equipment material are used for *obj* = Environment, Supply, and Quality, respectively, with the models f_{obj} from Shirahata et al. (2017b). The general design problem is formulated as shown in Eq.(8), where total score T [–] is obtained by aggregating four y_{obj} for supporting the decision-maker by providing a single objective value. The parameters w_{obj} [–] and $\alpha^{interaction}$ [–] stand for the weighting factors for *obj* and for *interaction*, respectively. The suffix *interaction* [–] stands for the two types of the interaction between the drug solution and the equipment materials, which are resin-made (for SUT) or stainless steel (for MUT).

$$\begin{aligned}\min_{\boldsymbol{x}} T(\boldsymbol{x}) = w_{\text{Economy}} \frac{y_{\text{Economy}}(\boldsymbol{x})}{\max_{\boldsymbol{x}} y_{\text{Economy}}(\boldsymbol{x})} + w_{\text{Environment}} \frac{y_{\text{Environment}}(\boldsymbol{x})}{\max_{\boldsymbol{x}} y_{\text{Environment}}(\boldsymbol{x})} \\ + w_{\text{Supply}} \frac{y_{\text{Supply}}(\boldsymbol{x})}{\max_{\boldsymbol{x}} y_{\text{Supply}}(\boldsymbol{x})} \\ + w_{\text{Quality}} \sum_{interaction} \alpha^{interaction} \frac{y_{\text{Quality}}^{interaction}(\boldsymbol{x})}{\max_{\boldsymbol{x}} y_{\text{Quality}}^{interaction}(\boldsymbol{x})}\end{aligned} \tag{8}$$

s. t. $\quad 0 \le \alpha \le 1, 0 \le w \le 1, \sum \alpha = 1, \sum w = 1$

3. Case study

A case study was conducted in which the developed platform was applied to the design of a commercial production process of biopharmaceutical drug manufacturing.

3.1. Alternative generation at product, unit operation, and operation layers

At the "product" layer, two options for annual production amount, i.e., 10,000 or 250,000 L/year, and three options for production lifetime, i.e., 1, 10 or 20 year, were considered. At the "unit operation" layer, no option was considered but nine unit operations were set according to the industrial standard, which are partly shown in Figure 2. The "operation" layer considered two options for production sequence, i.e., alternating or campaign production. As for the remaining elements, typical values and choices were specified based on industrial expert information. The alternatives generated at these three layers are hereafter referred to as "production situation", i.e., in total twelve production situations (I–XII) are considered further in this work.

The specified elements for two production situations I and XII are shown in Eqs.(9) and (10) as the representative examples. The production situation I and XII describe a "short-

term, small-scale and multiproduct" production, and a "long-term, large-scale and single-product" production, respectively.

$$\boldsymbol{x}^{\mathbf{I}} = (\text{Production lifetime, Annual production amount, ..., Production sequence, ...}) \quad (9)$$

$$= (1\ \text{year}, 10{,}000\ \text{L/year}, \ldots, \text{Alternating production}, \ldots)$$

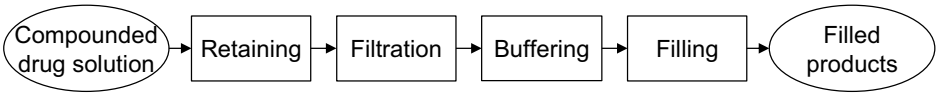
$$\boldsymbol{x}^{\mathbf{XII}} = (20\ \text{year}, 250{,}000\ \text{L/year}, \ldots, \text{Campaign production}, \ldots) \quad (10)$$

3.2. Alternative generation at equipment technology layer

The "equipment technology" layer considered the choice of resin-made and stainless steel equipment for each of the nine unit operations, except for the operation to send drug solution for filling glass containers. This operation can only be performed with resin-made tube because peristaltic pump is used for filling biopharmaceutical drug products. After considering all combinations, in total $2^8 = 256$ process alternatives were generated per product situation. Among all the alternatives, the one consisting only of the stainless steel options was named as "full-MUT"; the one with all resin-made equipment was named as "full-SUT"; the remaining 254 alternatives consisting of both materials were denoted as "hybrid (HYB)". Figure 2 shows four representative alternatives; the full-MUT, two HYBs, and the full-SUT, to which the IDs of 1, 128, 130, and 256 were assigned, respectively. For example, HYB-128 has a stainless steel mixing tank and resin-made equipment for the remaining, which is recognized as a typical hybrid process industrially. HYB-130 is introduced for a comparative purpose.

3.3. Multiobjective evaluation

The generated alternatives were evaluated under each production situation regarding economy, environment, supply, and quality, which were further aggregated to T. Figure 3 shows the evaluation results for all $\boldsymbol{x}$ in production situation XII using equal values for w and α, i.e., $w = 0.25$ and $\alpha = 0.5$. The objective function T is to be minimized, i.e., $\boldsymbol{x}^{\mathbf{XII}}_{\mathbf{130}}$ was the worst, and $\boldsymbol{x}^{\mathbf{XII}}_{\mathbf{256}}$ was the best. The alternative $\boldsymbol{x}^{\mathbf{XII}}_{\mathbf{130}}$ used resin-made mixing tank and filling needles, and stainless steel equipment for the remaining equipment. This combination made the manufacturing footprint the largest, which made the environmental evaluation the worst due to large energy consumption required for the heating, ventilation, and air conditioning (HVAC). In drug product manufacturing, HVAC is the technology to maintain the cleanliness of the production area, and known to be cost- and energy-intensive (Müller et al., 2014).



Equipment	Mixing tank	Filter housing	Buffer tank	Filling needle	Process alternative ID
Equipment material*	0	0	0	0	1 (Full-MUT)
	0	1	1	1	128 (HYB)
	1	0	0	1	130 (HYB)
	1	1	1	1	256 (Full-SUT)

*{0, 1}={Stainless-steel, Resin}

Figure 2. Process alternatives with combination of equipment material

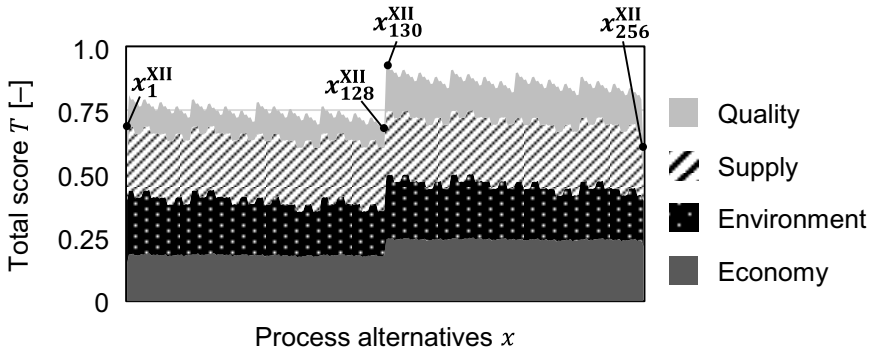


Figure 3. Total score T of 256 process alternatives under production situation XII (long-term, large-scale and single-product production) using equal values for the weighting factors w and α

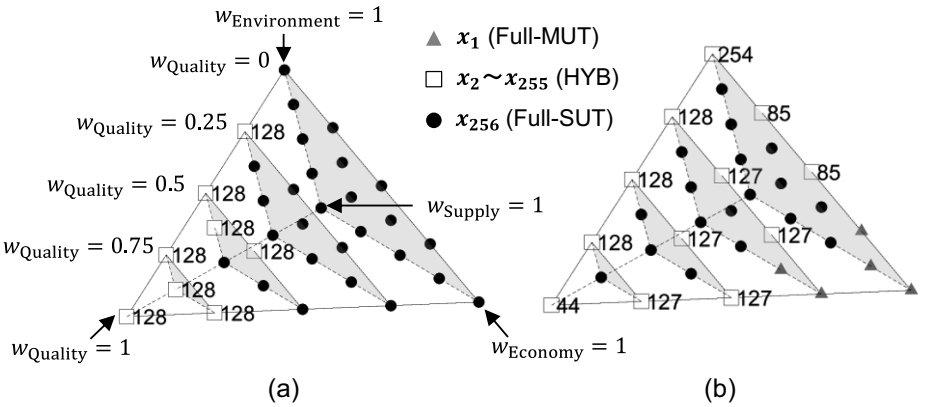

Figure 4. Sensitivity of weighting factor w to total score T at (a) production situation I (short-term, small-scale and multiproduct production) and (b) production situation XII (long-term, large-scale and single-product production)

3.4. Sensitivity analysis of weighting factor w

Sensitivity analysis on the factor w was performed, in order to investigate the impact of the priority of the design objectives on T. The tetrahedron representation in Figure 4 visualizes the sensitivity of the four weighting factors at one time (Shirahata et al., 2017b). The inner space corresponds to the possible range of w, where each vertex represents w = 1; at each point the alternative $\boldsymbol{x}$ with the smallest T is displayed. Figure 4 shows the result for production situations I (Figure 4(a)) and XII (Figure 4(b)), where full-SUT was commonly the best at the gravity point, i.e., w = 0.25. As for the area around the vertex with w_{Economy} = 1, full-SUT and full-MUT were the best in the case of (a) and (b), respectively. This disagreement is because full-MUT had large investment cost in (a), and full-SUT had small investment cost but large long-term operating expenses in (b). The area around the vertex of $w_{\text{Environment}}$ = 1 displayed the alternatives with the small footprint; the area around the vertex w_{Quality} = 1 displayed the hybrid alternatives that had lower impacts of interactions between the equipment material and the drug product than full-SUT or -MUT. Full-SUT was the best at the area around the vertex of w_{Supply} = 1 because

full-SUT showed longer but more importantly less frequent delay of product supply than full-MUT.

4. Conclusions and outlook

We presented a platform, which enabled systematic alternative generation and multiobjective evaluation for designing biopharmaceuticals drug product manufacturing processes. Multiple layers of the platform categorized the information on product, unit operation, equipment technology, and operation, which assisted hierarchical and comprehensive generation of alternatives. Especially, the "equipment technology" layer enabled to consider the novel equipment technology SUT by including the element of equipment material. The platform was demonstrated in a case study where 256 alternatives for the equipment technology under 12 production situations were evaluated considering economy, environment, supply, and quality. Under the production situations of a short-term, small-scale and multiproduct production, and a long-term, large-scale and single-product production, the full-SUT alternative resulted the best when the priorities of all indicators were the same. The sensitivity analysis on the weighting factors indicated that the best alternative could differ depending on the priority, i.e., when making decisions, the "mind-set" must be appropriately reflected in the weighting factors. The way of the systematic reflection is the future research subject; also we plan to extend the study boundary to cover drug substance manufacturing processes, and to include continuous technology as an option to be generated in the platform.

Abstract
A computational fluid dynamics (CFD) model for compact-type steam methane reformer (SMR) was proposed for highly-efficient hydrogen production from natural gas. The compact-type SMR included two domains: the combustor at the center for supplying the reaction heat demand and sleeve-shape reactor with a catalyst for steam methane reforming reactions. The $k-\varepsilon$ realizable turbulence model and discrete ordinates (DO) method of radiative transfer equation (RTE) were employed to the CFD model. A catalyst volume-based reactions mechanism from literatures was adopted for steam methane reforming reactions at the sleeve-shape porous catalyst zone. The CFD model results were validated with our experiment data and other studies on SMR in terms of the temperature profile, producer gas compositions, production rate, heating efficiency, and wall heat flux. Pressure, temperature, flow stream lines, producer gas compositions, and reaction rates were then analyzed. The present compact type SMR reactor showed a flatter heat flux profile than conventional reactor designs in literatures.
Keywords: Steam methane reformer; Combustion; Computational fluid dynamics; Radiation; Compact-type reactor design.

1. Introduction
The steam methane reforming (SMR) as a hydrocarbon fuel processing technology accounts for a significant proportion of worldwide hydrogen production (Kumar et al., 2016; Tran et al., 2017). The SMR process is an overall endothermic process in which the methane (natural gas) reacts with super-heated steam in the presence of a nickel-based catalyst to produce hydrogen, carbon dioxide, and carbon monoxide (Tran et al., 2017; Xu and Froment, 1989). The SMR unit has two main modules including a combustor and reactor. The combustor (or furnace) produces heat demand by reacting the methane with oxygen in the air, whereas the reactor consumes heat to produce the hydrogen from steam and natural gas (Seo et al., 2006). There are several configurations of the combustor such as top-fired, bottom-fired, side-fired, and terrace wall-fired reformers (Lao et al., 2016; Tran et al., 2017).
With the dramatic increase of computational power, computational fluid dynamics (CFD) has become a powerful tool for design and hydrodynamics evaluation of chemical processes (Ngo et al., 2015). CFD technology has been successfully applied to the

simulation of industrial furnaces (Han et al., 2007), SMR tube reactors (Behnam et al., 2012), and newly designed SMR reactors (Ngo et al., 2015). CFD models in combination with an equilibrium reaction kinetics (Xu and Froment, 1989) predicted the SMR performance for various reactor scales (Lao et al., 2016). Unfortunately, there is no rigorous three-dimensional (3D) CFD study on a compact SMR reactor, considering the effect of the sleeve between the combustor and reactor on heat transfer.

In this study, a 3D CFD model is developed to investigate hydrodynamics, heat transfer and producer gas compositions of a compact SMR reactor with an H_2 production rate of 2.5 Nm^3/hr (6 kg/day). The effect of a sleeve protecting the catalytic reactor against the hot combustion gas on heat transfer is rigorously examined. The realizable $k-\varepsilon$ turbulence model for gas mixtures and the radiative transfer equation (RTE) by a discrete ordinates (DO) method are incorporated into the CFD model. An equilibrium SMR reaction kinetic model (Xu and Froment, 1989) is employed to the catalyst-bed zone which was assumed as porous media. The CFD results are validated with experimental data in terms of axial temperatures, producer gas compositions, and thermal efficiency. The CFD model will provide a tool for improving the design and the thermal efficiency of the compact SMR reactor with the sleeve.

2. Compact steam methane reforming (SMR) process

A compact SMR process with a height of 460 mm and an outer diameter of 114 mm is shown in Figure 1. The compact SMR reactor is composed of two primary domains: (a) the fluid domain consists of the combustor and reactor, and (b) the solid domain covers walls between fluids. The heat is generated by combustion of CH_4 with air at the center, then transferred through the sleeve gap. The sleeve gap size is 3 mm. It is assumed that the combustion gas enters at 1,100 ºC and 1 atm. The feed gas (steam and NG) is injected by 16 nozzles through a porous heat carrier zone for pre-heating the mixture.

Material properties of solids (wall, heat carrier and catalyst), gas components, and fluid mixtures are listed in Table 1. The refractory wall has a low thermal conductivity. The metallic heat carrier with a high porosity (γ) of 0.95 shows a high density and conductivity. A Ni-based catalyst supported on Al_2O_3 was used in this experiment, which ensures a low-pressure drop in the tubular reactor (ReforMax, 2017). A high thermal conductivity of 235 W/m/K at an actual operating temperature of about 700 ºC was used for the catalyst, which is higher than typical catalysts (Palma et al., 2012). The incompressible ideal gas was used for the density of the gas mixture. The ideal gas mixing-law was applied for the specific heat capacity, thermal conductivity, and viscosity.

3. Modelling and simulation

A steady-state 3D simulation of the compact SMR process was performed using a commercial CFD code, ANSYS Fluent R17 (ANSYS Inc., USA). The gas phase was assumed to be incompressible. The CFD model included a realizable $k-\varepsilon$ turbulence model, discrete ordinates (DO) radiation method and a species transport model with SMR reactions.

Outer wall	Convection	9		300

An equilibrium chemical reaction model (R_n) of SMR on nickel-based catalyst pellets proposed by Xu and Froment (Xu and Froment, 1989), which was derived from the Langmuir-Hinshelwood mechanism, is used in this study. SMR boundary conditions at the inlet and outlet are listed in Table 2.

4. Results and discussions

The CFD model was solved using a finite volume-based solver, ANSYS Fluent R17 (ANSYS Inc., USA). The calculation was performed on a workstation with 24 cores (2.7

GHz CPU) and 128 GB RAM. The mesh independence test was first presented. Then the effectiveness factor function was introduced, and the CFD results were validated with experimental data. Finally, the performance criteria were analyzed for the reformer.

The producer gas composition (y_i, dry basis), H_2 production rate (F_P, $\mathrm{Nm^3/h}$), and lower heating value (LHV) efficiency (η_{LHV}) are compared for the CFD model, our experiment, pure kinetic model, and literature data of industrial-scale SMR processes. The wet-based producer gas compositions along the normalized catalyst length from the present CFD model are compared to the data from a 1D tube-segment mathematical model in an industrial-scale SMR process (Latham, 2008) in Fig. 2a. The gas compositions at the end of the normalized reactor length are almost the same for the two results. Fig. 2b shows the wall heat fluxes through sleeve wall ($q_{w,S}$, $\mathrm{kW/m^2}$) and catalyst outer wall ($q_{w,R}$, $\mathrm{kW/m^2}$) with respect to the normalized length of the reactor. The q_w has a symmetric shape along the reactor length due to a counter-current heat exchange through the sleeve. Whereas, the $q_{w,S}$ of Lao *et al*. (2016) decreases monotonically because of a co-current flow in a top-fired reactor. This SMR reactor with the sleeve leads to a flatter heat flux than the top-fired one. The mean value of $q_{w,S}$ of this study (=55 $\mathrm{kW/m^2}$) is lower than that (=75 $\mathrm{kW/m^2}$) of the industrial-scale SMR process (Lao et al., 2016). The flatter heat flux has a more advantage in operating and fixed costs (Ricca et al., 2017) and a lower risk in hot-spot phenomena (Palma et al., 2012).

Higher thermal efficiency was observed with a more uniform temperature distribution of the reformer. The sleeve used in this study helps to uniformly distribute the temperature of the wall of the reformer (or heat flux) over the axial direction, as mentioned earlier. The uniformity of heat flux was used to evaluate how much the heat flux at the inner wall of the catalyst reactor ($U_{q,R}$) and sleeve wall ($U_{q,S}$) are distributed evenly.

$$U_{q,R} = 1 - \frac{\int \left| q_{w,R} - \overline{q}_{w,R} \right| dA}{2\overline{q}_{w,R} A_{R,i}}, \quad \overline{q}_{w,R} = \frac{\int q_{w,R} dA}{A_{R,i}} \tag{1}$$

$$U_{q,S} = 1 - \frac{\int \left| q_{w,S} - \overline{q}_{w,S} \right| dA}{2\overline{q}_{w,S} A_{S,i}}, \quad \overline{q}_{w,S} = \frac{\int q_{w,S} dA}{A_{S,i}} \tag{2}$$

Where A is area, q is heat flux through reactor inner wall ($q_{w,R}$) and sleeve inner wall ($q_{w,S}$) for each computational face cell i.

Table 3 summaries the $U_{q,R}$ and $U_{q,S}$ for present CFD result and literature. Both of $U_{q,R}$ and $U_{q,S}$ are higher than a conventional top-fired SMR reactor (Lao *et al*., 2016). The CFD result proves the function of sleeve gap on flattening the heat flux in present SMR reactor design. The amount of heat flux through the inner wall of the catalyst reactor is around 3.4 times higher than the heat flux from the combustor to the inner wall of the sleeve because of the convection flow inside the sleeve gap. However, the direct heat transfers from combustor to sleeve gap through sleeve wall at the top part of sleeve is higher due to high temperature of the inlet, therefore the total heat flux through sleeve gap is smoothly distributed from the top to the bottom of reactor. As the result, the heat flux through reactor in presence of sleeve wall is more uniformly distributed than the conventional top-fired reactor design.

Table 3. Heat transfer coefficient and temperature uniformity of annulus SMR reactor

	$U_{q,R}$ (this study)	$U_{q,S}$ (this study)	$U_{q,R}$ (Lao *et al*., 2016)
Values	0.89	0.72	0.69

Characteristics of flow streamlines are illustrated in Fig. 3a. Figs. 3b and 3c show contours of absolute pressure and temperature on the symmetric plane. In the pressure contour, the pressure drops in the combustor and reactor are around 360 and 654 Pa, respectively. The pressure drop in the combustor is mainly caused by the sleeve gap, whereas that in the reactor is caused by the porous heat carrier and catalyst beds.

5. Conclusions

A three-dimensional computational fluid dynamics (CFD) model was developed for a compact type steam methane reforming (SMR) reactor to evaluate wall heat flux and to investigate the effect of a sleeve between the combustor and reactor on heat flux. The $k-\varepsilon$ realizable turbulence model and discrete ordinates (DO) method of radiative transfer equation were employed to the CFD model. The CFD results such as temperature profile, producer gas composition, production rate, heating efficiency, and wall heat flux were validated with experiment data and other studies in the literatures. Pressure, temperature, flow stream lines, and producer gas compositions inside the reactor were analysed. The compact-type SMR reactor showed flatter heat flux, compared to conventional top-fired SMR reactors.

Abstract

A gas-liquid Eulerian computational fluid dynamics (CFD) model coupled with a population balance equation (PBE) was presented to investigate hydrodynamics of a bubble column with hydrocracking reactions in H_2-vacuum residue oil system (H_2-VR) in terms of pressure drop, gas holdup, mean bubble size, and bubble surface area. The column had a height 1.9 m and 0.05 m in inner diameter. The column was initially filled with a vacuum residue (VR) and vacuum gas oil (VGO) mixture of a height of 1.9 m. The VR/VGO mixture with 80% VR and 20% VGO by weight, was injected at a velocity of 0.271 mm/s. The H_2 was injected through the gas distributor at a superficial gas velocity of 6.4 mm/s. The bubble column was operated at 160 bar, 430°C. For the H_2-VR system at the high pressure and temperature, the pressure drop, the total gas holdup, the mean bubble size and the specific bubble surface area were estimated to be 5,984 Pa/m, 8%, 3.2 mm and 150 m^2/m^3, respectively, using the CFD-PBE model. The compositions of the components were also calculated. This CFD study provides a potential to design the bubble column and to optimize the operating conditions.

Keywords: Bubble column, Computational fluid dynamics (CFD), Population balance equations (PBE), Specific surface area.

1. Introduction

Bubble column reactors are widely used in chemical, petrochemical, biochemical, and metallurgical industry for gas-liquid and gas-liquid-solid contacting or chemical reactions (Bhole et al., 2008; Liang et al., 2016). Because of the large interfacial area available, bubble columns offer excellent heat- and mass-transfer characteristics (Monahan et al., 2005).

The gas holdup and the bubble size are two important parameters in the bubble column design. The BSD determines gas holdup and gas-liquid interfacial area, which is of importance for mass transfer between the phases (Sharaf et al., 2016). The gas holdup is influenced by pressure, liquid and gas velocities, viscosity, surface tension, and liquid and gas densities.

Computational fluid dynamics (CFD) has emerged as a promising tool for the simulation of hydrodynamics in bubble columns (Bhole et al., 2008; Liang et al., 2016). Two approaches including the Euler-Lagrange (E-L) approach and the Euler-Euler (E-E) approach are primarily used (Liang et al., 2016; Ngo et al., 2015; Pham et al., 2015).

Since the E-L model is normally limited to a relatively small number of particles or bubbles because of computational expense (Bayraktar et al., 2013; Liang et al., 2016), the E-E approach is typically preferred for modeling the bubble column (Bhole et al., 2008).

The population balance equation (PBE) coupled with the flow equations is a promising approach to simulate gas-liquid dispersed flows (Bayraktar et al., 2013). The coupled model takes into account bubble breakup and coalescence, describing the gas holdup and the BSD (Liang et al., 2016).

Fluid dynamic studies on multiphase systems at high pressure and temperature remain scanty. Few researchers have addressed the effect of pressure on hydrodynamics of the bubble column, using the multiphase Eulerian CFD model with PBE.

This study investigated hydrodynamics of a bubble column reactor with chemical reaction at 160 bar and 430°C, using a multiphase Eulerian CFD model with PBE. Firstly, the gas–liquid Eulerian CFD model coupled with a turbulence and PBE is developed for a pilot-scale pressurized bubble column. The reaction model is also integrated into the CFD model. Finally, the hydrodynamic parameters and compositions of components are estimated in a H_2/vacuum residue system.

2. Geometry, physical properties and boundary condition

A pilot-scale bubble column with a height of 1.9 m and an inner diameter of 0.05 m was constructed to perform catalytic hydrocracking of heavy at 160 bar and 430°C. A perforated plate was used as the gas distributor.

2.1. Geometry and meshing of CFD calculation domain

The two dimensional (2D) symmetric geometry and the mesh structure of the bubble column are depicted in Fig. 1. In this study, two inlet boundary conditions were considered. One is the premixed inlet, where a premixed mixture of both gas and liquid is injected to the bottom of the bubble column. The other is the individual inlet, where gas and liquid enter the bubble column uniformly and individually. For the outlet boundary condition, a virtual outlet with an extended column is used to minimize the effect of the reverse flow at the exit on the composition of the liquid phase.

2.2. Physical properties and boundary conditions

The physical properties such as molecular weight (MW), density (ρ), viscosity (μ) and surface tension (σ) between the gas and liquid phases affect the bubble behavior (Bhole et al., 2008). Table 1 shows the physical properties of each component in the liquid and gas phases. All the species except H_2 are pseudo-components classified by the boiling point range. The boundary conditions of the CFD model are shown in Table 2.

3. Gas–liquid Eulerian CFD model couple with population balance model

The fluid flow was assumed to be incompressible and isothermal, and the gas was considered as a dispersed phase. A gas–liquid Eulerian CFD model was developed for the bubble column. The governing equation included the continuity equation for total mass conservation and the momentum equation with drag and non-drag forces. The modified Tomiyama model with a drag force correction factor was used (Liang et al., 2016). The k-ω turbulence equation, the population balance equation (PBE) and the reaction model were integrated into the CFD model.

Table 1. Physical properties of gas and liquid at 160 bar and 430°C.

Component	Phase	MW(kg/kmol)	ρ (kg/m^3)	μ (Pa·s)	σ (N/m)
Vacuum residue	Liquid	629.8	816.3	1.21×10^{-3}	20.23×10^{-3}
Vacuum gas oil	Liquid	377.9	685.9	2.07×10^{-4}	9.41×10^{-3}
Distillate	Liquid	195.6	577.5	5.30×10^{-5}	1.45×10^{-3}
Naphtha	Liquid	120.8	419.7	4.30×10^{-5}	5.40×10^{-5}

	Boundary conditions
Gas & liquid inlets	Incompressible gas, mass flow inlet. Gas load (H_2): U_G = 6.4 mm/s, P = 160 bar, T = 430°C. Liquid load (VR/VGO): U_L = 0.271 mm/s, P = 160 bar, T = 430°C.
Gas outlet	Degassing.
Liquid outlet	Pressure outlet.

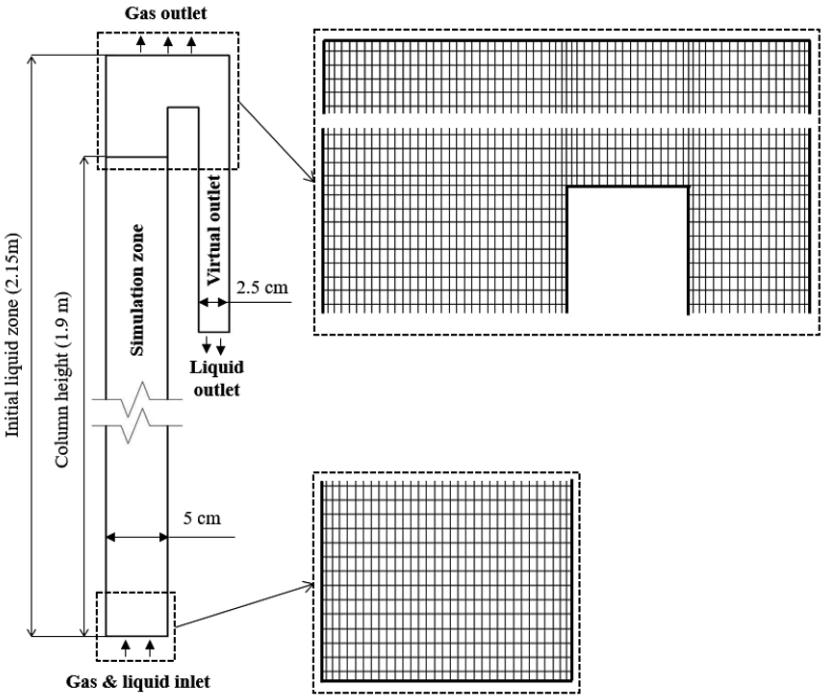

Fig. 1. Geometry and meshing of CFD calculation domain

4. CFD simulation results

The CFD-PBE model was first solved on different mesh numbers to examine their effect on hydrodynamics in the bubble column. Then, CFD results of the inlet boundary

conditions (individual and premixed inlets) were compared. Finally, the hydrodynamics and the composition of species after 80 minutes were estimated in the H_2/vacuum residue system.

4.1. Mesh independent test without chemical reaction

The effect of the mesh number is shown in Fig. 2 in terms of the specific pressure drop ($\Delta P/L$), the total gas holdup ($\overline{\alpha}_G$), the Sauter diameter (d_{32}) and the specific surface area (a_s) at 160 bar and 430°C. The specific pressure drop and gas holdup are almost the same in the case of medium and fine meshes. The Sauter diameter and specific surface area change with the number of cells. However, almost the same BSD shape is observed for medium and fine meshes (Fig. 3a). Thus, in this study, the medium mesh (30,000 cells) was selected to reduce the computational cost.

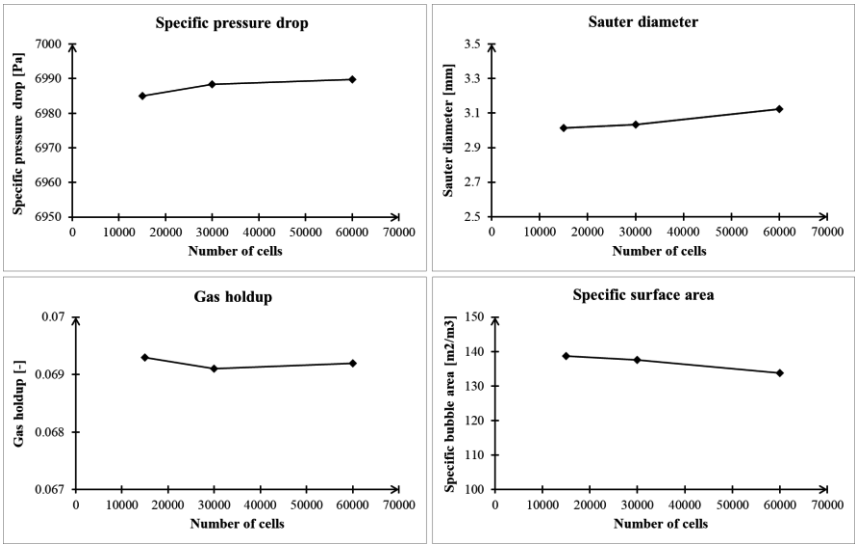

Fig. 2. Mesh independent test on coarse, medium and fine meshes with premixed inlet and virtual outlet with $N_b = 20$, $0.1 \leq d_b \leq 30$ mm at 160 bar and 430°C, $U_G = 6.4$ mm/s, $U_L = 0.271$ mm/s (time-averaged value).

4.2. Comparison of individual and premixed inlets without chemical reaction

The effect the inlet boundary condition on hydrodynamics of the bubble column was investigated. Fig 3b compares the BSD between the two cases. The BSD of individual inlet is a little narrower than that of the premixed inlet. Table 3 compares the hydrodynamic parameters of the two cases. The difference of the parameters does not exceed 5%. Thus, to simplify the geometry and reduce the calculation time, the premixed inlet was selected in this study.

4.3. Hydrodynamics and product composition after reaction

The gas holdup reaches a stable state after about 0.4 h, as shown in Fig. 4a. Fig. 4b shows the BSD at t = 80 min after the chemical reactions take place. The hydrodynamics at t = 80 min are reported in Table 4.

Table 3. Hydrodynamic parameters of individual and premixed inlets with N_b = 20, 0.1 ≤ d_b ≤ 30 mm at 160 bar and 430°C, U_G = 6.4 mm/s, U_L = 0.271 mm/s (time-averaged value).

	$\Delta P/\Delta L$ (Pa/m)	$\bar{\alpha}_G$	d_{32}	a_s (m^2/m^3)	Calculation time (h)
Premixed inlet	6,988	0.069	3.0	138	5
Individual inlet	6,821	0.068	3.1	132	6
Difference (%)	-2.4	-1.9	2.4	-4.2	20

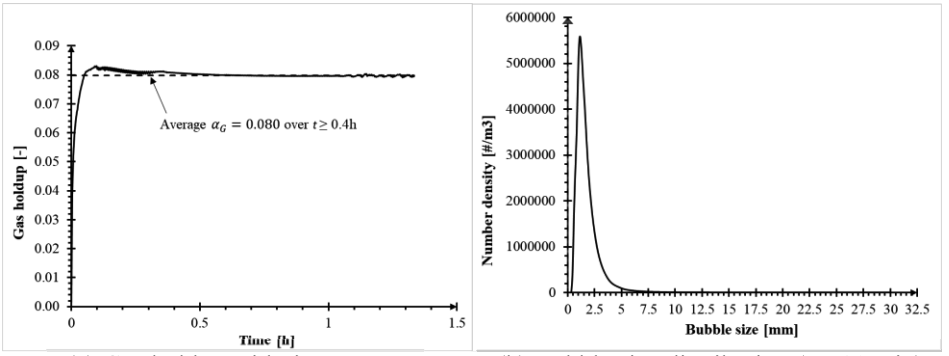
Fig. 3. BSD on coarse, medium, fine meshes of premixed inlet and comparison of BSD between individual inlet and premixed inlet with N_b = 20, 0.1 ≤ d_b ≤ 30 mm at 160 bar and 430°C, U_G = 6.4 mm/s, U_L = 0.271 mm/s (time-average value).



(a) Gas holdup with time

(b) Bubble size distribution (t = 80 min)

Fig. 4. Evolution of gas holdup with time and bubble size distribution (BSD).

Table 4. Hydrodynamic parameters of bubble column reactor with N_b = 20, 0.1 ≤ d_b ≤ 30 mm at 160 bar and 430°C, U_G = 6.4 mm/s, U_L = 0.271 mm/s, t = 80 min.

$\Delta P/\Delta L$ (Pa/m)	$\bar{\alpha}_G$	d_{32}	a_s (m^2/m^3)
5,984	0.080	3.2	150

After 80 min of reaction, the concentrations of vacuum residue, vacuum gas oil, distillate, naphtha and gas are about 52%, 39%, 3.4%, 4.7% and 0.9% by weight, respectively. All the species except gas approach monotonically a steady-state with time. Gas increases rapidly at the initial moment and decreases gradually toward a stable state. Fig. 5 shows the concentration of species at the exit of the reactor column with time.

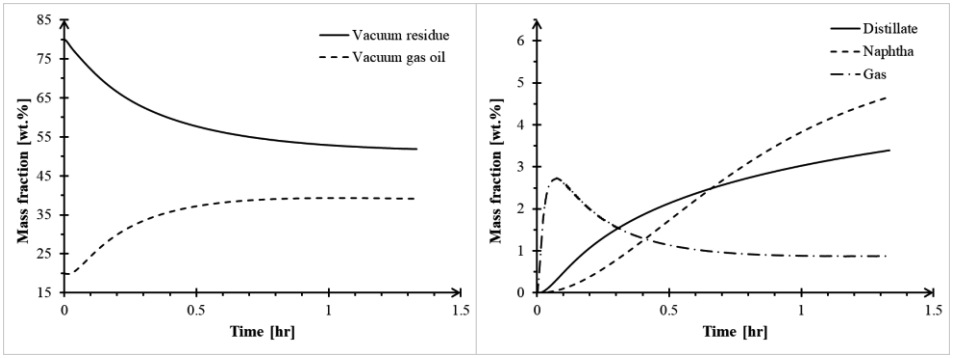


Fig. 5. Concentration of species with time at bubble column exit.

5. Conclusions

For a H_2/heavy oil system, the gas–liquid Eulerian CFD model coupled with a k-ω turbulence equation and a population balance equation (PBE) was developed to investigate hydrodynamics and the product composition of a bubble column reactor. The hydrodynamics were not sensitive to the gas-liquid mixing condition at the inlet. Thanks to the virtual outlet with an extended column, the reverse flow was avoided and the computational time was reduced. Future work should focus on the validation of the product composition with experimental data.

Abstract

Three-phase (air-oil-water) crude oil is separated using the gravity separator with internal structures such as coalescer, demister, and weir plate. The objective of this study is to develop a multiphase liquid/liquid/gas computational fluid dynamics (CFD) model and to predict hydrodynamics and separation performance under the ship motion. An Eulerian-Eulerian CFD model combined with the k-ε turbulence model and rotation matrix was used. The air-phase was considered continuous, while oil and water phases were assumed as mono-dispersed secondary-phases with an average diameter of 100 μm. The momentum equation included drag force, lift force and resistance of porous media. The exit pressures of oil and water were examined, which played an important role in determining the liquid level of oil and water in the separator. It was found that the exit pressures of water and oil were at 6.3 kPa and 5.1 kPa, respectively, which showed an effective separation of water and oil. The mean residence time for water and oil obtained from the CFD simulation was around 15 minutes. The vertical velocities of oil and water in the gravity direction along flow direction were analyzed at several liquid levels. The predicted oil separation efficiency (99.85%) were in line with experimental data (99.96 %). The CFD results also showed under the pitching motion. Three ship motions influenced significantly the separation performance in the separator.

Keywords: Separation efficiency, Liquid outlet pressure, Residence time, Three ship motions, Computational fluid dynamics (CFD)

1. Introduction

The separation processes of gas, oil and water are of importance in the petroleum industry. Currently, there are several available separation methods including filtration, membrane separation, gravity or centrifugal settling, chemical demulsification, pH adjustment, heat treatment, and electrostatic demulsification (Noik et al.; Roques-Carmes et al., 2014; Šećerov Sokolović et al., 2009; Zhao & Li, 2011; Zolfaghari et al., 2016). The gravity separation processes based on density differences of immiscible phases are often used in industry. However, the gravity settling approach requires a big equipment size to reach effective separation, which is not practical and economic, especially, not convenient with offshore conditions. Hence, the three-phase gravity separators are equipped with a different type of internals to enhance droplet coalescence and to optimize their length (Kharoua et al., 2013).

Recently, the experiments and CFD simulations have been used to study the effect of design and operating parameters on the separation efficiency. Speth et al. (2002) presented coalescence of secondary dispersions in fiber beds. Hernandez-Perez and Abdulkadir (2010) indicated a strong dependency of phase separation on the flow velocity and the droplet size. Sokolovic et al. (2010) investigated the effect of the coalescer geometry on steady-state bed coalescence by experiment. The effect of changing the position and size of baffles and modifying the thickness of liquid levels on separation performance were considered in Pourahmadi Laleh et al. (2013). The performance of internal structures on separation efficiency were investigated by Kharoua et al. (2012)

However, few researchers have addressed the effect of exit pressure of oil and water outlets. Moreover, limited studies examined the performance of separator under the off-shore condition. This study proposes a computational fluid dynamic (CFD) model to predict internal flow patterns and the effects of exit pressure and ship motions on separation efficiency.

2. Oil separation with coalescer

A three-phase separator includes some internal structures such as perforated plate, coalescer and demister. There are one inlet and three outlets. **Table 1** shows physical properties of three phase and the mass flow rates at the inlet. The operating pressure and temperature are set to 1 bar and 20°C, respectively.

Table 1 Physical properties of air, water and oil and inlet mass flow rate.

Component	Phase	Mass flow rate (kg/s)	ρ (kg/m^3)	μ (Pa.s)	σ (N/m) with air
Air	Gas	0.0444	1.2	$1.84\text{x}10^{-5}$	-
Water	Liquid	0.1067	998	$1.00\text{x}10^{-3}$	$72.8\text{x}10^{-3}$
Oil[a]	Liquid	0.0711	831	$7.21\text{x}10^{-3}$	$27.2\text{x}10^{-3}$

[a]Oil: synthetic oil

The geometry of the separator is shown in **Fig. 1**. The horizontal separator is 2.66 m long with a diameter of 0.78 m. Since the geometry is symmetric, a 3D symmetric geometry is used as the CFD domain. The polyhedral mesh is constructed and the number of cells is about 495,000.

3. CFD model

A 3D porous media CFD model was developed for the oil separator. The fluid flow was assumed to be incompressible, isothermal and Newtonian fluid. The unsteady turbulent multiphase flow was solved in a commercial CFD code, ANSYS Fluent 17.0. In the Eulerian-Eulerian model, the air-phase was considered continuous, while water and oil assume as mono-dispersed secondary phases. The two secondary phases were

represented as an average diameter of 100 μm. In this study, the momentum equations included drag force, lift force and resistance of porous media.

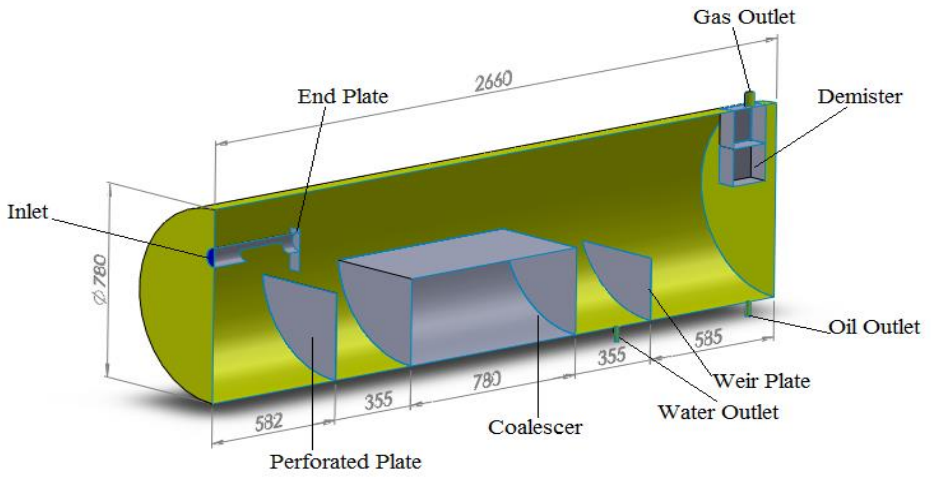

Fig. 1. Geometry of air-oil-water separator.

The phase-coupled SIMPLE method was chosen for pressure-velocity coupling. The first-order upwind and QUICK schemes were used for the spatial discretization of the momentum and volume fraction, respectively. The maximum number of iterations was limited to 50 at each time step, and the convergence tolerance was 1×10^{-3}. The calculation time was about 7 days with a flow time of 40 minutes.

The inlet and outlet boundary conditions were set to the velocity inlet (mass flow inlet) and the pressure outlet, respectively. The pressure at the gas outlet was atmospheric, while those at the liquid outlets were monitored to maintain the liquid levels and to ensure an overall phase mass balance. At the beginning of simulation, the separator is filled with gas (air) and liquid (water).

4. Results and discussions

The effect of exit pressure in water outlet and oil outlet on the liquid level were investigated. The oil separation efficiency predicted by CFD was compared with experiment data. Next, the dynamic behavior of mass flow rate in oil and water outlet under pitching motion was shown. Finally, the oil separation performance between vertical standing and pitching motion was compared.

4.1. Effect of exit pressure on separation efficiency

Table 2 shows the effect of exit pressure on oil separation efficiency. The oil outlet pressure was kept constant (P_O = 4.2 kPa), and the water outlet pressure was changed from 5.6 to 6.4 kPa. As the pressure at the water outlet increases, the level of the oil layer in the water side decreases, and the oil level in the oil side increases. Thus, increasing the water exit pressure decreases the oil separation efficiency. When P_o changes from 4.2 to 5.4 kPa at P_W=5.6 kPa, the oil content in the outlet water increases and the separation

efficiency decreases. Therefore, it is necessary to choose a proper range of outlet pressures of water and oil.

Table 2. Effect of exit pressures to separation efficiency

			P_O = 4.2 kPa			P_W = 5.6 kPa		
Pressure in outlet (kPa)			P_W = 5.6	P_W = 6.0	P_W = 6.4	P_O = 4.2	P_O = 4.7	P_O = 5.4
Volume fraction (%)	Outlet gas	water	6.0E-07	6.3E-07	8.8E-07	6.0E-07	9.2E-07	8.1E-07
		oil	4.4E-06	2.1E-06	2.9E-06	4.4E-06	8.6E-07	7.8E-07
		air	99.99	99.99	99.99	99.99	99.99	99.99
	Outlet oil	water	0.17	0.55	1.83	0.17	0.12	0.11
		oil	99.83	99.45	98.17	99.83	99.88	99.88
		air	4.7E-05	6.6E-05	2.6E-04	4.7E-05	6.4E-05	8.5E-05
	Outlet water	water	99.95	99.96	99.94	99.95	99.06	71.10
		oil	0.044	0.035	0.057	0.044	0.94	28.90
		air	1.5E-06	4.2E-07	2.5E-09	1.5E-06	4.9E-05	1.2E-04
Liquid level (cm)	Water side	Water	12.1	16.2	18.6	12.1	7.3	6.0
		Oil	12.9	8.8	6.4	12.9	17.7	19.0
	Oil side	Oil	4.2	5.9	11.5	4.2	11.5	19.9

In this study, the suitable water outlet pressure and oil outlet pressure were found to be P_W = 6.3 kPa and P_O = 5.1 kPa for effective separation. **Table 3** shows the separation efficiency obtained from the simulation and experimental data. The oil separation efficiency obtained from the CFD simulation agrees well with experimental data.

Table 3. Comparison of CFD results with experimental data.

		CFD results	Exp. data	Error (%)
Outlet gas	air	99.99	-	-
Outlet water	water	99.96	-	-
Outlet oil	oil	99.85	99.96	0.11

4.2. Effect of ship motion on separation efficiency

To investigate the effect of the pitching motion, the exit pressures in water and oil outlets kept constant at 6.3 kPa and 5.1 kPa, respectively. For the case of 3° pitching motion, there are some backflows (positive values), which is not realistic. The fluctuation amplitude of the mass flow rate is bigger than that of 1.5° in both the water and oil outlets, as shown in **Fig. 2**.

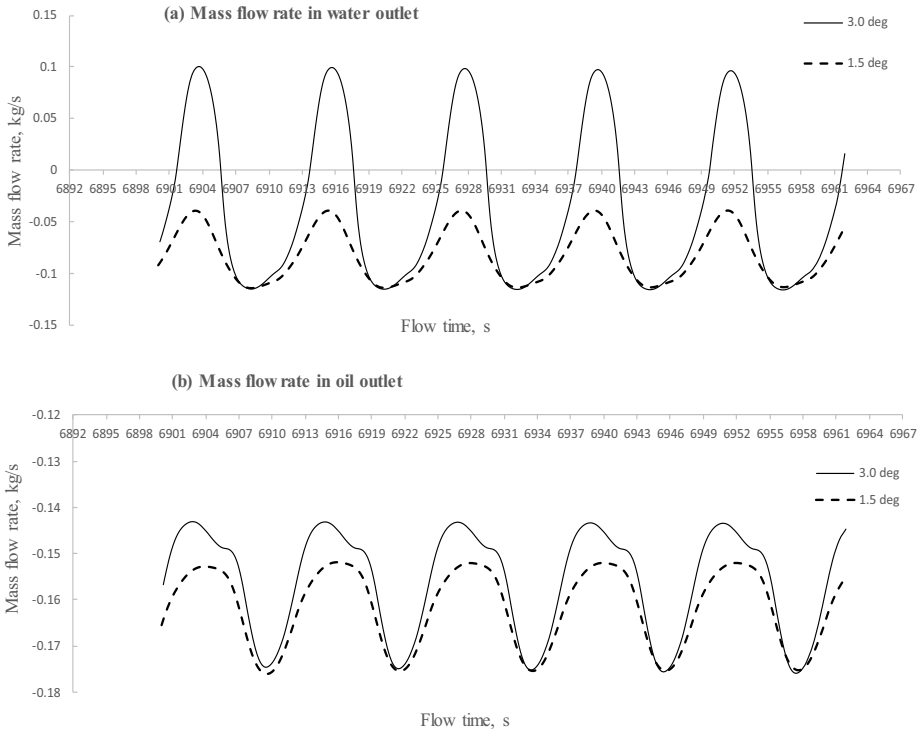

Fig. 2. Dynamic behavior of mass flow rate in water and oil outlets.

Table 4 summerizes the separation efficiency of vertical standing and pitching motion cases. The pitching motion decreases significantly the separation efficiency by 13.3% for the 1.5° and 17.0 % for 3° pitching motion. The separation efficiencies under pitching motion are low because of serious fluctuation caused by spurious backflows from the water outlet. These spurious backflows would be resolved by dynamic pressure control of the water and oil outlets.

Table 4. Comparison of separation efficiency for vertical standing and pitching motion.

	Vertical standing	Pitching motion									
Angular (degree)	0	1.5					3				
Time	0	0s	3s	6s	9s	mean	0s	3s	6s	9s	mean
Outlet gas	99.99	99.99	99.99	99.99	99.99	99.99	99.99	99.99	99.99	99.99	99.99
Outlet water	99.96	99.68	99.69	99.98	99.73	99.77	99.96	99.50	98.35	99.24	99.27
Outlet oil	99.87	87.26	86.52	85.70	86.88	86.59	83.56	83.38	81.66	82.79	82.85

5. Conclusions

A 3D CFD model for an air-water-oil separator with the perforated plate, coalescer and demister was built to identify hydrodynamics inside the three phase separator and to predict the oil separation efficiency under offshore operation.

The effect of exit pressures in water and oil outlets on the separation efficiency was investigated. It was found that the exit pressures at 6.3 kPa and 5.1 kPa for water and oil, respectively, were suitable for maintaining a liquid level of 25 cm with a good separation efficiency. The predicted oil separation efficiency (99.85%) agreed well with experimental data (99.96 %). The pitching motion decreased significantly on the separation efficiency by 13.3% for 1.5° and 17.0% for 3° pitching motion.

The CFD model proposed in this study did not include the population balance model (PBM) that accounts for the droplet size distribution, coalescence, and breakup phenomena of the secondary phases.

Abstract

A flexible first principles mathematical model of a counter-current moving-bed reactor has been developed and implemented in Pyomo as part of the Institute for the Design of Advanced Energy Systems (IDAES) process systems engineering framework. The model consists of a set of differential and algebraic equations obtained by applying the mass, energy, and pressure balances. The model is applied to the simulation of the reducer reactor for the chemical looping combustion of methane using an iron-based oxygen carrier. The effect of several system and operating parameters on the methane and oxygen carrier conversions are investigated to help assess the performance of the moving-bed reducer. The results show that nearly full methane conversion (95.75 %) can be attained in the counter-current moving-bed regime using relatively low oxygen carrier/methane mass flow ratios.

Keywords: chemical looping combustion, moving-bed reactor model, IDAES, Pyomo

1. Introduction

Chemical looping combustion (CLC) has emerged as a new high-efficiency, advanced energy technology that has the potential of outperforming conventional technologies for fossil fuel combustion with CO_2 capture. In CLC, oxygen is transferred from air to a fuel via oxidation-reduction cycling of a solid oxygen carrier (OC) between two reactors. In the reducer, the OC reacts with the fuel, generating CO_2 and water. In the oxidizer, the reduced OC is regenerated with air, producing a hot O_2-depleted air stream that can be used to produce steam for power production. Thus, CLC provides a means for oxy-combustion without an expensive air separation unit.

To date, many different fuels (syngas, natural gas, biogas, coal, and biomass) have been successfully combusted at small to intermediate scales using nickel-, iron-, copper-, manganese-, or calcium-based OCs, in different types of gas-solid contactors operating in circulating fluidized bed, bubbling fluidized bed, and moving-bed (MB) regimes. Given that the performance of a CLC process is determined by the properties and performance of the particles, the system configuration, and the reactor design, choosing the optimal combination of these factors for a specific process becomes very important for achieving a highly efficient, cost-effective process. Computational tools that rely on advanced multi-scale models provide a systematic approach to rapidly synthesize and

optimize processes, accelerating the development of new technologies like CLC to maturity (Miller et al., 2014). Important requirements of mathematical models that can be used to optimize complex, integrated processes while supporting scale up are that they should be flexible and accurate for the parameter and variable space under investigation (Miller et al., 2017) and have exact first and second derivatives. To facilitate the development of custom models that are not available in commercial simulators and enable advanced process systems engineering (PSE) capabilities that support optimization, control and uncertainty quantification, the U.S. Department of Energy (DOE) initiated the Institute for the Design of Advanced Energy Systems (IDAES). IDAES is developing a next generation PSE framework to enable the rapid modeling, design, and optimization of new, innovative advanced energy systems such as CLC. In this paper, we present the development of a detailed, flexible, hierarchical, first principles model of a MB reducer within the IDAES PSE framework. The model is implemented in Pyomo (Hart et al., 2017), a Python-based open-source software package. Due to its hierarchical, modular structure, the model can be applied to the simulation of different gas-solid processes in a straightforward manner, given sufficient reaction information. To demonstrate the capabilities of the model, the MB reducer is applied to the combustion of methane (CH_4) using an iron-based OC. Additionally, a series of case studies are presented that evaluate the effect of several design and operating parameters on the conversion of both the OC and CH_4. Ultimately, this model will be used to support optimization of integrated CLC systems.

2. Model formulation

Fresh OC (hematite, 45 % Fe_2O_3 on an alumina inert support) enters at the top of the MB reducer and counter-currently interacts with a CH_4 gas stream fed at the bottom. A CO_2 and H_2O gas stream leaves at the top of the reducer, while spent OC (magnetite) is retrieved at the bottom. The H_2O vapor can be condensed from the reducer exhaust gas, leaving a concentrated CO_2 stream ready for compression and utilization or storage. The spent OC is circulated to the oxidizer, where it is reconstituted to its oxidized state using air and then reintroduced to the reducer. The reduction reaction of iron oxide Fe_2O_3 with CH_4 is given by the endothermic reaction:

$$CH_{4(g)} + 12Fe_2O_{3(s)} \rightarrow CO_{2(g)} + 2H_2O_{(g)} + 8Fe_3O_{4(s)} \quad (1)$$

The overall performance of the process is determined by reduction reaction (1), because oxidation is fast and thermodynamically favored (Li et al., 2010). Therefore, studying and modeling the reducer reactor is essential for the design of an efficient CLC process. To date, several MB adsorber models have been proposed for carbon capture (Kim et al. 2013, 2016, and Mondino et al. 2017); however, MB reducer models are scarce. While Tong et al. (2013) and Kathe et al. (2016) have presented models based on idealized reactors in series, no previous studies have reported a first principles mathematical model of a MB reducer for CLC suitable for equation-oriented flowsheet optimization. In the following, the MB reducer model is presented.

The model is a 1-D, steady-state, non-isothermal, gas-solid counter-current MB reactor model, based on the following assumptions:

1. Radial concentration and temperature gradients within the bed are negligible.
2. Axial dispersion and thermal conduction along the axial direction are negligible.
3. The solids flow with uniform velocity and the reactor bed voidage is constant.
4. No channeling occurs.

Table 1. Mass and energy balance equations of the MB reducer model.

$0 = -\frac{d(u_g C_i)}{dz} - (1-\varepsilon)\rho_s \frac{\upsilon_i}{\upsilon_{Fe_2O_3}} r_{gen}$	(2)
$0 = \frac{d(u_s q_j)}{dz} - (1-\varepsilon)\rho_s MW_{s,j} \frac{\upsilon_j}{\upsilon_{Fe_2O_3}} r_{gen}$	(3)
$0 = -\rho_g C_{p,g} u_g \frac{dT_g}{dz} - (1-\varepsilon) h_f \frac{6}{d_p}(T_g - T_s) - h_w \frac{4}{D_r}(T_g - T_w)$	(4)
$0 = \rho_s C_{p,s} u_s \frac{dT_s}{dz} + (1-\varepsilon) h_f \frac{6}{d_p}(T_g - T_s) + (1-\varepsilon)\rho_s(-\Delta H_{rxn}) r_{gen}$	(5)
$0 = a_{w,in} h_w (T_g - T_w) - a_{w,out} U (T_w - T_\infty)$	(6)

5. The ideal gas law holds in the gas phase.
6. The pressure balance is given by the Ergun equation, using the slip velocity between the gas and the solid phases.

The mass and energy balance equations of the mathematical model are presented in Table 1. Eq. (2) and (3) are the gas and solid component mass balance, Eq. (4), (5) and (6) are the gas phase, solid phase and reactor wall energy balance equations. In addition to the balance equations, the MB model includes the Ergun equation and additional correlations used to compute gas and solid properties, heat transfer coefficients, etc.

In the balance equations, $C_i(z)$ (mol/m^3) is the gas phase concentration of component i, $q_j(z)$ (kg/m^3) the mass concentration of the solid component j, $T_g(z)$, $T_s(z)$, $T_w(z)$ and T_∞ (K) are the gas, solid, reactor wall and ambient temperatures, $u_g(z)$ and u_s (m/s) are the superficial gas and solid velocities, υ_i is the stoichiometric coefficient of component i, $MW_{s,j}$ (kg/mol) the molecular weight of the solid component j, $\Delta H_{rxn}(z)$ (kJ/mol) the heat of reaction, $h_f(z)$ and $h_w(z)$ (kW/m^2/K) are heat transfer coefficients between the gas and particles and gas and reactor wall, $U(z)$ (kW/m^2/K) is the overall heat transfer coefficient, $C_{p,g}(z)$ and $C_{p,s}(z)$ (kJ/kg/K) are the gas and solid heat capacities, $\rho_g(z)$ and ρ_s (kg/m^3) the gas and particle densities, and $a_{w,in}$ and $a_{w,out}$ (m^{-1}) are internal and external specific heat transfer areas.

For modeling the reaction kinetics, it is assumed that diffusion through the particle grain is the dominating resistance (Abad et al., 2007), resulting in the reaction rate expression given by Eq. (7). It is also assumed that CH_4 reforming is negligible. The kinetic parameters are from Abad et al. (2007), as shown in Table 2.

$$r_{gen} = \frac{x_{Fe_2O_3} a_{vol}}{MW_{s,Fe_2O_3}} \frac{3bkC_{CH_4}^n}{(\rho_m r_g)} (1 - X_s)^{2/3} \tag{7}$$

Eq. (7) is written on Fe_2O_3 basis, where r_{gen} (mol/kg$_{cat}$/s) is the reaction rate, $x_{Fe_2O_3}$ the mass fraction of Fe_2O_3, a_{vol} the available reaction volume per volume of OC, X_s the fractional conversion of Fe_2O_3, b the reaction stoichiometric coefficient of Fe_2O_3, and $k = k_0 \exp\left(-E/(RT_g)\right)$ the kinetic rate constant.

The MB reducer model is implemented in Pyomo, where the differential equations with appropriate boundary conditions are discretized on a non-uniform grid using the shifted Gauss-Radau roots orthogonal collocation method over 20 finite elements with 3 collocation points within each finite element, using the automatic discretization

Table 2. Kinetic model parameters, and MB reactor and particle parameters.

Kinetic model parameters		MB reactor and particle parameters	
Grain radius, r_g (m)	2.6×10^{-7}	Particle diameter, d_p (m)	1.5×10^{-3}
Molar density, ρ_m (mol/m^3)	32.8×10^3	Particle density, ρ_s (kg/m^3)	3251.75
n (-)	1.3	Reactor diameter, D_r (m)	6.5
k_0 (m$^{1.9}$/mol$^{0.3}$/s)	0.0008	Reactor height, H (m)	5
Activation energy, E (kJ/mol)	49	Reactor bed voidage, ε (-)	0.4

capability of pyomo.dae (Hart et al., 2017), and solved using IPOPT (Wächter and Biegler, 2005). An initialization scheme has been developed and implemented that sequentially activates the initially deactivated mass and energy balance equation terms and uses the solution obtained at the end of each step as the initial guess for the solution of the following step. The reaction model and properties of the gas and solid phases are computed in separate property modeling blocks, thus keeping the MB model general and easily applicable to other gas-solid CLC processes. Consistent with the IDAES modeling conventions, the model consists of a collection of modeling components that can be conveniently deactivated or activated as needed. This grants flexibility to the model and enables its straightforward application to the simulation of, for example, an isothermal model by simply deactivating the energy balance equations, or of a cold flow process (i.e., no reaction) by deactivating the terms corresponding to the reaction in both the mass and energy balances, or of an adiabatic process by deactivating the reactor wall energy balance Eq. (6) and the third term in Eq. (4). In the following section, results from the CH_4 CLC process obtained from adiabatic simulations are presented.

3. Results and discussion

To demonstrate the capabilities of the model, a conceptual 100 MW_{th} MB-based CLC reducer is simulated. For the given processing capacity of the fuel $C_{plant} = 100$ MW_{th}, the feed flow rate of CH_4 F_{CH_4}(mol/s) is calculated as $F_{CH_4} = C_{plant}/H_{CH_4}$ (Li et al., 2010), where $H_{CH_4} = 889$ kJ/mol HHV is the higher heating value of CH_4. Then, the inlet flow rate of the gas mixture is calculated to be 245.495 mol/s with the following composition: $y_{CH_4} = 0.458$, $y_{CO_2} = 0.499$, and $y_{H_2O} = 0.043$. The inlet molar fractions, inlet pressure (1.37 bara) and temperatures are referenced from NETL's CLC reference steam generation system (Keairns et al., 2014) and the Ohio State University's CLC technology (Kathe et al., 2016). The reactor dimensions are calculated such that the superficial gas velocity u_g does not exceed the minimum fluidization velocity of the OC particles at any point in the reactor. It is worth noting that the gas velocity can increase up to three-fold in the reducer. The reducer design parameter values and OC particle characteristics used in this study are listed in Table 2. These are not optimized values, as optimization of the CLC system is outside of the scope of this study.

The reducer performance under different gas and solid flow conditions is analyzed by quantifying their effect on the CH_4 and OC conversions. The operating parameters that are varied are the stoichiometric OC/fuel ratio, the gas and the solids inlet temperatures. The values of the different conditions considered are presented in Table 3, together with the steady state conversion of CH_4 and Fe_2O_3. The stoichiometric OC/fuel ratio for this system is 266.15, i.e. 266.15 kg of OC (of which 45% is Fe_2O_3) are needed for the combustion of 1 kg of CH_4, which gives an Fe_2O_3/CH_4 mass flow ratio of $\phi = 119.77$.

Table 3. Case study operating conditions and resulting CH_4 and Fe_2O_3 to Fe_3O_4 conversions.

Case	T_g (°C)	T_s (°C)	$M_{OC,in}$ (kg/s)	ϕ (-)	CH_4 conversion (%)	Fe_2O_3 conversion (%)
1	600	910	479.01	119.77	95.75	95.75
2	600	910	239.51	59.88	49.49	98.99
3	600	910	718.52	179.65	99.79	66.53
4	300	910	479.01	119.77	95.75	95.75
5	600	600	479.01	119.77	79.21	79.21

Case 1 tests the performance of the MB reducer under stoichiometric feed conditions. High conversions are attained: both CH_4 and Fe_2O_3 conversions are 95.75 %. Next, the Fe_2O_3/CH_4 mass flow ratio is decreased to $\phi = 59.88$ by decreasing the inlet OC flow to $M_{OC,in} = 239.54$ kg/s (half of the OC flow for Case 1). Operation at an OC/fuel ratio that is 50 % below the stoichiometric requirement leads to 98.99 % conversion of Fe_2O_3, while leaving 50.51 % uncombusted CH_4. For Case 3, the Fe_2O_3/CH_4 mass flow ratio is increased to ϕ =179.65, i.e. 50 % above the stoichiometric OC/fuel requirement. The excess amount of OC leads to near total (99.79 %) combustion of CH_4 with 33.47 % unconverted Fe_2O_3. In Case 4, the effect of a lower inlet gas temperature is investigated, with all other inlet and operating conditions being identical to the conditions of Case 1. Decreasing the inlet gas temperature has a negligible effect on the reactor performance, even though the decrease in the inlet gas temperature is significant (300 °C). This is because thermal equilibrium in the reducer is reached almost instantaneously, given the extremely rapid heat transfer between the gas and solid phases, and the much larger thermal mass of the solids. In Case 5, the inlet temperature of the solids is decreased by 300 °C, keeping all other conditions identical to the conditions of Case 1. The conversions of CH_4 and Fe_2O_3 drop by 16.54 percentage points compared to Case 1. The sensitivity of the Fe_2O_3 conversion to the investigated system conditions is shown in Figure 1 (a) along the normalized reactor bed length. The CH_4 concentration profiles depicted in Figure 1 (b) are consistent with the trends observed in the Fe_2O_3 conversion profiles. Finally, Figure 1 (c) shows the solid temperature profiles along the reactor bed for each of the studied cases.

The current version of the MB model can be used for the design and optimization of CLC reducers. Model validation, testing, and further development are ongoing, to improve the MB model's accuracy and establish its reliability and robustness under a wide range of applications (e.g. optimization and process flowsheeting).

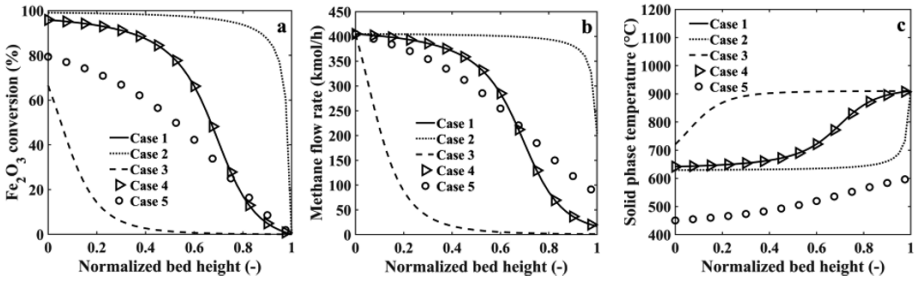

Figure 1. (a) Fe_2O_3 conversion, (b) CH_4 molar flow rate, and (c) solid temperature profiles along the normalized length of the reactor bed (gas inlet: $z = 0$, solids inlet: $z = 1$).

4. Conclusions

The development of a detailed first principles model of a gas-solid counter-current MB reducer has been presented and applied to the simulation of the CLC of methane using an iron-based oxygen carrier. The model is flexible and modular, enabling its straightforward adaptation for the simulation of different gas-solid processes. It is also suited for the design and optimization of CLC processes. The reducer has been designed to simulate a conceptual 100 MW_{th} MB-based CLC system, and the conversions of methane and oxygen carrier have been investigated under different simulation conditions. The conversions have been found to be determined by the oxygen carrier/fuel flow ratio and the solids inlet temperature. The gas inlet temperature has a negligible effect on the reducer performance. The main advantage of operating in the MB regime is the capability of attaining very high methane conversion (95.75 %) at solids circulation rates corresponding to the oxygen carrier/fuel stoichiometric ratio.

Abstract

A compact steam methane reforming (SMR) reactor for H_2 production from natural gas was investigated using a steady-state three-dimensional (3D) computational fluid dynamics (CFD) model with heat transfer and chemical reactions. The SMR reactor consisted of two main individual streams including combustion gas for reaction heat supply, and natural gas feed into a porous catalyst bed. The realizable k–epsilon turbulence model with enhanced wall treatment, the discrete ordinates (DO) radiation model, and the volumetric reactions in the species transport model were employed into the CFD model. A reaction kinetics model for SMR of Xu and Froment (1989) was applied to porous media as the catalyst bed. CFD model results for the temperature profile and producer gas composition were validated with experimental data. Optimum sleeve gap sizes between the burner and catalytic reaction zone for various velocities were determined, maximizing the H_2 production rate. The present CFD model showed a potential for the development of new design of the SMR reactor.

Keywords: Hydrogen production; Steam methane reforming (SMR); Computational fluid dynamics (CFD); Chemical reaction rate model; Optimum gap size.

1. Introduction

Hydrogen is one of the most important materials for many petroleum and chemical processes in manufacturing industry. In petroleum refineries, hydrogen is produced for many applications including the hydrotreating and hydrocracking processes. Additionally, in the field of energy, hydrogen is used to run fuel cells which convert hydrogen to electricity (Olivieri & Vegliò, 2008). One of the industrially established methods to effectively produce H_2 is steam methane reforming (SMR) (Chen et al., 2011). In this process, natural gas and steam are converted into hydrogen, carbon dioxide and carbon monoxide in the presence of a nickel-based catalyst under high pressure and high temperature (Olivieri & Vegliò, 2008; Zamaniyan et al., 2010).

The earliest model for SMR reactions was developed in the 1960s. The reaction model was applied to the design, optimization, and monitoring of SMR reactions (McGreavy, 1969). Currently, an SMR reaction kinetic model on nickel-alumina catalyst (Xu & Froment, 1989), which was derived from Langmuir-Hinshelwood mechanism, was often

accepted in academia as well as in industry (Lao et al., 2016; Lee et al., 2013; Seo et al., 2006; Tran et al., 2017).

Computational fluid dynamics (CFD) is a powerful tool for the identification of the intrinsic nature of chemical processes. Specifically, many CFD researches have realized successfully physical and chemical phenomena inside SMR tube reactors in microscopic-scale, bench-scale as well as industrial-scale (Dixon, 2014; Seo et al., 2006; Tran et al., 2017). However, little attention is paid to an annulus SMR reactor with a narrow sleeve.

In this study, a CFD model is developed for a compact SMR reactor involving two main zones: combustion and catalyst zones. The CFD model includes the turbulence equation, radiative heat transfer model, and chemical reaction kinetics for combustion and SMR reactions. The CFD results are validated by comparing with available data in our experiment and literatures. Finally, an optimum gap size of the sleeve showing the highest thermal efficiency is found.

2. SMR reactor

2.1. Geometry of SMR reactor

The geometry of the SMR reactor is illustrated in Fig. 1a The SMR reactor is divided into two main domains: the fluid and solid domains.

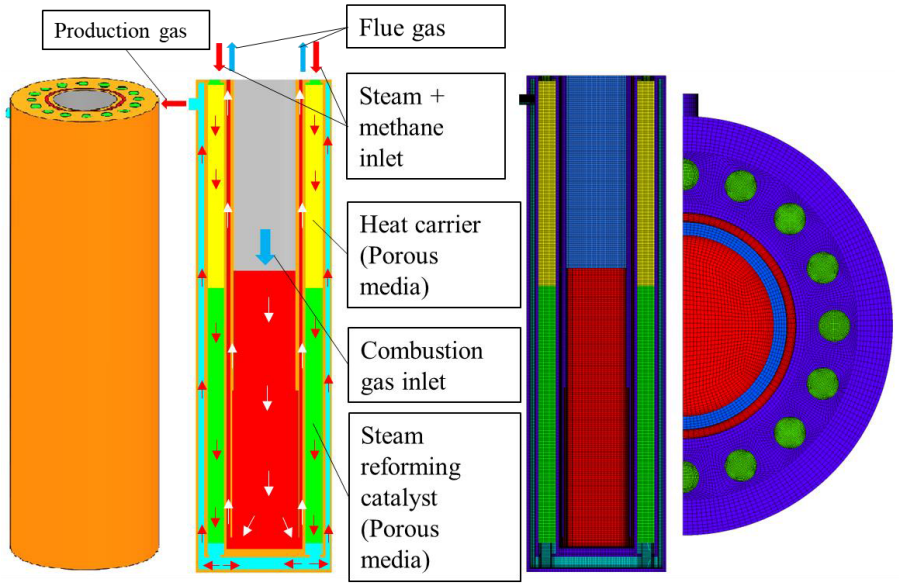

Fig. 1. Schematic diagram of SMR reactor and hexahedral mesh structure.

2.2. Meshing of CFD domain

The 3D symmetric CFD domain is shown in Fig. 1b, which was constructed in a meshing software, ICEM-CFD. The number of hexahedral cells is approximately 2.6 million with a minimum orthogonal quality of 0.52 and a maximum aspect ratio of 29.7.

3. CFD model with chemical reactions

3.1. CH_4 combustion model

The SMR reaction is a highly endothermic process. The heat required for the reforming reaction is supplied by the combustion gas via a gas burner. The air–methane mixture with an oxygen molar ratio to methane of 2.58 is injected into the combustion chamber and is completely oxidized to generate carbon dioxide, water and a large amount of thermal energy required for the SMR reaction. A simplified global kinetic model for the combustion of methane is adopted to reduce the computational time. A single-step combustion mechanism is given as follows:

$$CH_4 + 2O_2 \Rightarrow CO_2 + 2H_2O \quad (1)$$

The premixed combustion is resolved by using the eddy-dissipation (ED) model as the turbulence and chemistry interaction in the volumetric reaction.

3.2. SMR reaction model

The SMR reaction on nickel–based catalyst is expressed by the following reversible equations:

$$\begin{aligned} &CH_4 + H_2O \leftrightarrow CO + 3H_2 && \Delta H_{\circ 298} = 206\ \text{kJmol}^{-1} \\ &CO + H_2O \leftrightarrow CO_2 + H_2 && \Delta H_{\circ 298} = -41.1\ \text{kJmol}^{-1} \\ &CH_4 + 2H_2O \leftrightarrow CO_2 + 4H_2 && \Delta H_{\circ 298} = 164.9\ \text{kJmol}^{-1} \end{aligned} \quad (2)$$

The SMR reaction kinetics model is integrated into the CFD model by using user–defined functions.

3.3. Performance criteria of SMR reactor

The sleeve gap sizes of 2, 3, 4, 5, and 7 mm were tested at three velocities of 6, 7.5, and 9 m/s. The thermal heat efficiency (η) based on lower heating value (*LHV*) was used to find an optimal gap size.

$$\eta = \frac{F_{product,H2} \times LHV_{H2}}{(F_{CH4,burner} + F_{CH4,feed}) \times LHV_{CH4}} \times 100 \quad (3)$$

where F (Nm^3/h) is the volumetric flow rate.

4. Results and discussions

The CFD model with a gap size of 3 mm was solved at 7.5 m/s. The temperature and concentration profiles obtained from the CFD model were compared to experimental data and values published in literatures. The sleeve gap size maximizing the thermal efficiency was found at each feed velocity.

4.1. Validation of CFD model

Fig. 2 shows the temperature along the catalytic reactor length. The temperature profile from the CFD model with combustion reaction is higher than that without combustion reaction. The CFD results of temperature show a similar tendency to the experimental ones.

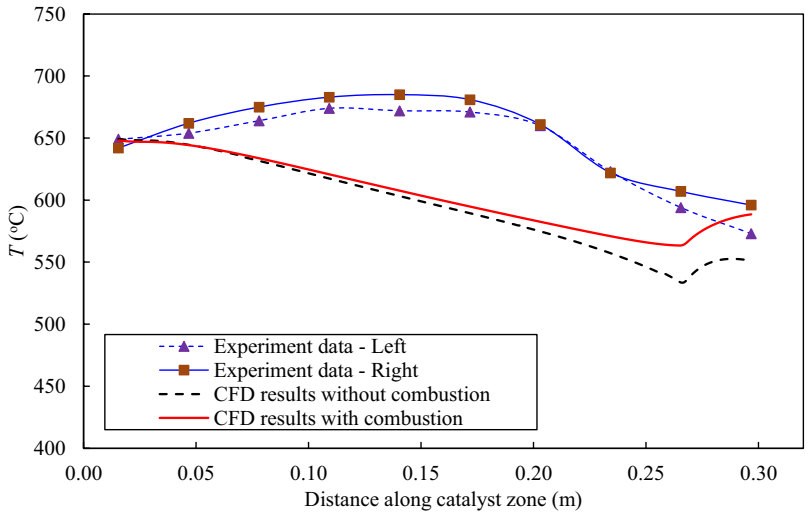

Fig. 2. Comparison of temperatures obtained from experimental data and CFD results with and without combustion reaction.

Fig. 3 depicts mole fractions of the producer gas along the normalized catalyst length. Two literature data are compared to the CFD results. The CFD results have a good agreement with the literature data. Table 1 reports the mole composition, H_2 production rate and *LHV* heat efficiency for this CFD study, experimental data, and the two literature data. The CFD results are in good agreement with the others.

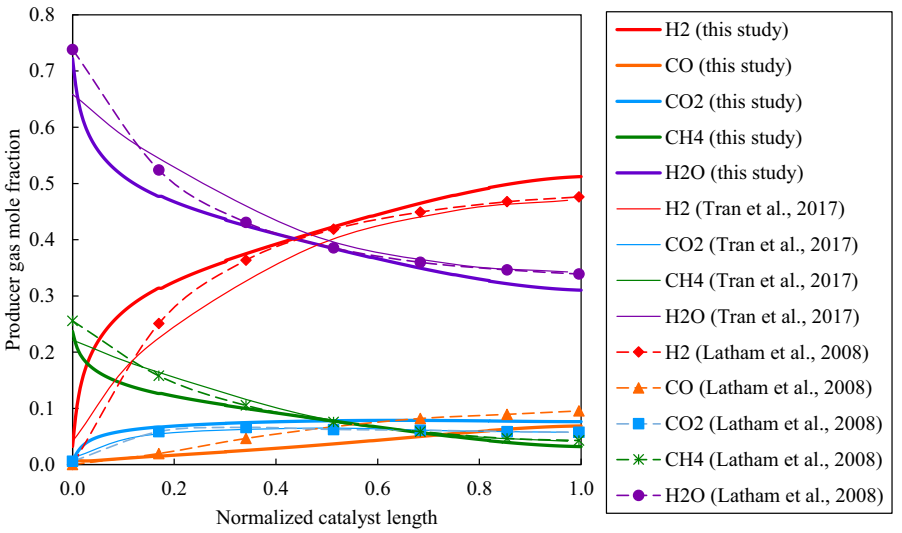

Fig. 3. Comparison of product gas composition along catalyst length with literature

Table 1. CFD model validation on producer gas composition

Parameter	CFD result w/o combustion	CFD result with combustion	Exp. Data 1	Exp. Data 2	(Xu & Froment, 1989)	(Latham, 2008)
H_2	0.7318	0.7266	0.727	0.7395	0.7206	0.71
CO	0.0902	0.0308	0.0665	0.08	0.1089	0.13
CH_4	0.0627	0.0841	0.0845	0.0615	0.0704	0.07
CO_2	0.1153	0.1585	0.122	0.119	0.1001	0.087
H_2 production rate (Nm^3/h)	2.64	2.57	2.73	2.56	2.51	2×10^5
LHV efficiency (%)	49.33	48.05	48	50.1	46.8	

4.2. Optimum sleeve gap size

Fig. 4 shows the thermal efficiency according to the sleeve gap size. The maximum heat efficiency is observed at each gas velocity inside the sleeve gap. As the velocity increases from 6 to 9 m/s, the optimum gap size decreases from 5 to 3 mm.

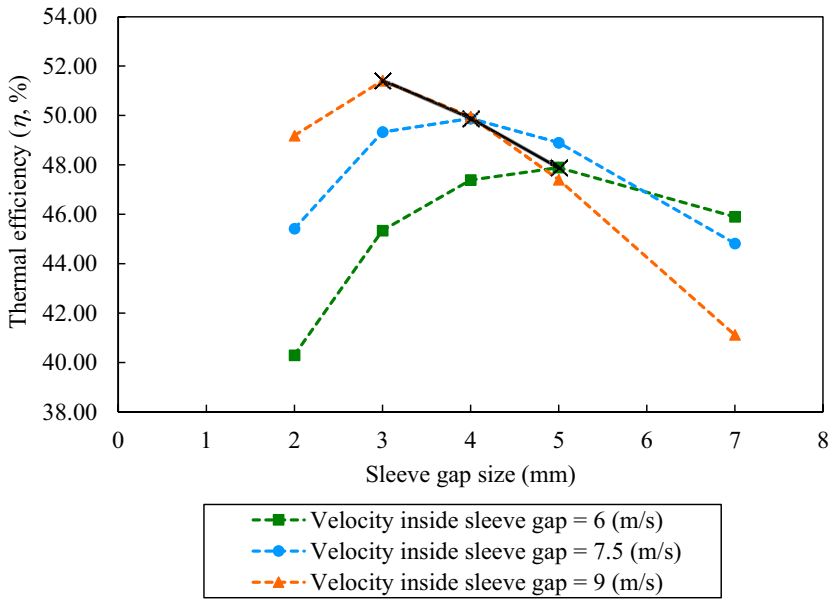

Fig. 4. Thermal efficiency with respect to sleeve gap size for each gas velocity inside sleeve gap.

5. Conclusions

A three-dimensional (3D) computational fluid dynamics (CFD) model was constructed for a steam methane reforming (SMR) reactor with catalyst in the reaction zone and porous media in the heat carrier zone. The CFD simulation including heat transfer, radiation and reaction models was performed at 2 bar and about 700 ºC. The coarse, medium and fine meshes were built for the mesh independent test and the medium mesh was selected for further study.

The CFD results agreed well with experimental data in terms of temperature and gas compositions. The optimum sleeve gap size was found at each velocity of the sleeve gap, maximizing the thermal efficiency.

Abstract

Biofuel production using carbohydrate rich brown seaweed is being intensely researched in the last few years as a viable replacement for 1st and 2nd generation biomass. Process design and simulation is generally used when evaluating technological and market capabilities of large scale, novel, fuel production processes. This study, for the first time, presents process design solution for a biorefinery, an integrated anaerobic digestion, and PHP (Pyrolysis, Heat and Power) process. The process utilizes 3rd generation biomass (marine macroalgae) and yields wide range of products: mixed alcohols, ethanol, biodiesel equivalent, biogas, and electricity. Technoeconomical assessment of the biorefinery is performed and compared to single conversion pathways (biochemical and thermochemical). It is highly expected that the synergistic effect of this integrated process should yield a more economically and environmentally viable biofuel production, compared to stand-alone pathways.

Keywords: Biofuel, Seaweed, Process simulation, Process integration

1. Introduction

The strain between energy supply and demand, is increasing, as the finite nature of fossil fuels is becoming ever more evident. Consequently, innovation and research in every part of the energy sector is increasing rapidly. Biofuels present a green alternative to crude oil derivatives, due to their inherit renewable nature and possibility of carbon neutrality. Since the biofuel boom of 2005[1] advocates against biofuels argue that the global usage of food crops for biofuel production will inevitably affect global food prices. Hence, research has shifted toward food crop residues such as corn stover[2], rice husk[3], seed shell[4], etc., as well as woody biomass and forest residues[5]. Biofuels derived from those materials are defined as second generation biofuels[6]. With valid management and supply chains second generation biofuels do present advantage over food crops. However, indisputably, second generation biofuels are still terrestrially derived, which means they do require land in some point of their lifecycle. Utilization of aquatic biomass, or third generation biofuels[7,8] present a number of advantages over terrestrial biomass. First and most obvious advantage is that marine biomass (microalgae and macroalgae) does not require land for cultivation. Secondly, they have inherent faster growth rates and better photosynthetic efficiency[9]. Finally, their physiology does not require lignin nor cellulose as support materials[10–12], which both present challenges in biofuel

production from woody biomass. On the other hand inherently high moisture, mineral content and its seasonal variation[13,14] presents new set of challenges for potential biofuel production processes. This means that well established conversion processes for biofuel production need to be modified and evaluated if this relatively new type of feedstock is to be effectively utilized. Hence, algae cultivation studies[15], as well as, standalone conversion processes which utilize marine macroalgae as feedstocks have been evaluated. Biochemical pathways such as anaerobic digestion[16], bioethanol and mixed alcohol processes[17,18] have been investigated. Thermochemical pathways such as gasification[19], pyrolysis[20] and liquefaction[21] have also been investigated on industrial scale. This work however, presents a conceptual study of an industrial integrated process combining biochemical and thermochemical pathway and which utilizes brown macroalgae as a feedstock. General aim of the study is to define beneficial economic and possibly environmental implications of combining two pathways into a seaweed based biorefinery.

2. Materials and methods

2.1. Biochemical Conversion Pathway

The biochemical conversion process simulation model, design and economics are based on published work by Fasahati et al.[22]. Main products of the process were ethanol and mixed alcohols, produced via hydrogenation of volatile fatty acids (VFAs). The VFAs were obtained by inhibitor controlled anaerobic digestion of brown seaweed *Saccharina japonica* as a feedstock. The process was designed and simulated in Aspen Plus on an industrial scale of 500,000 tonnes of dried seaweed (18 % wt. moisture) per year. Major product process streams and pricing is outlined in table 2. Combined mixed alcohol yield of the process compared to bone dry seaweed weight was 29 % wt., of which 75 % wt. was ethanol after separation. The process is highly water intensive and consumes 532 T/h. Solid residue of anaerobic digestion or digestate is produced at 41.5 T/h (35% wt. moisture) and at this process design is marketed as crop fertilizer. The total installed cost of the process was determined to be 85.9 mil USD, and the calculated minimum product selling prices (MPSPs) of ethanol and mixed alcohols were 0.589 USD/L, and 1.143 USD/L respectively.

2.2. Thermochemical Conversion Pathway

The thermochemical conversion process of algae to diesel equivalent fuel (Figure 1) was simulated in Aspen Plus at an industrial scale of 320,000 dry tonnes per year. Major product process streams and pricing is outlined in table 2 Experimental data for the simulation model was based on published works by Choi et al. [23,24] for fast pyrolysis of brown algae *Saccharina japonica* in a fluidized bed reactor. As received feed with water content of 35 wt. % and mineral content of 26 wt. % is pressed and dried to a water content of 5 wt. %. The seaweed is pyrolyzed in a fluidized bed reactor, after which pyrolysis vapors are separated from char in a cyclone and sent to phase separation section. Here, pyrolysis vapors are liquified, and organic pyrolysis liquid (biocrude) is separated from aqueous phase and non-condensable gasses. Biocrude is upgraded to a diesel equivalent fuel via catalytic hydrogenation. Required hydrogen is partly purchased (45 wt. %) while the rest can be obtained by recycling the gasses from hydrogenation section via pressure swing absorption (PSA). The yield of diesel upgraded fuel compared to dry seaweed (absent mineral content) was 14.5 wt. %. As a thermochemical process it is highly heat intensive and consumes 9.2 T/h of natural gas and produces 29.1 T/h of

aqueous phase. Net produced power in the heat and power section was 1.5 MW. Calculated total installed cost of the process was 56.9 mil USD and a MPSP of 1.257 USD/L was determined.

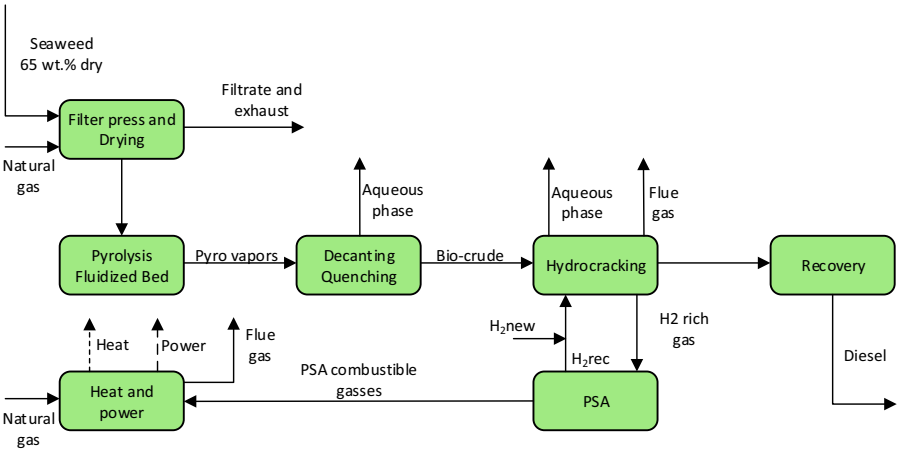

Figure 1. Block flow diagram of the fast pyrolysis route

2.3. Combined Process Key Integration Points

Integration design concept of biochemical and thermochemical pathways is illustrated in figure 2. The two pathways are integrated in three key points. Primarily, anaerobic digestate will now be utilized as a feedstock for fast pyrolysis process. This would accomplish two objectives, production of higher value-added product, as well as reducing the mineral content in the pyrolysis feedstock due to water washing during the fermentation. Secondly, both pathways require the same type of product upgrading, as well as hydrogen recycling, which presents the potential of lowering the total capital investment of combined process. Thirdly, utilization of produced aqueous phases in the pyrolysis section would reduce the water consumption of the biochemical conversion. Finally, the Heat and power production section of the pyrolysis section can provide most of the heat and power required for the combined process.

Table 1. Economics summary of standalone pathways and integrated process

USD / 2016	Thermal-pathway	Bio-pathway	Integrated
Inside battery limit (ISBL)	53,300,000	78,330,000	119,279,000
Total installed cost	56,880,000	85,926,000	122,858,000
Total direct costs	66,207,000	99,634,000	143,732,000
Total indirect costs	39,724,000	59,780,000	86,239,000

Ethanol	8420	MPSP			

3. Results and discussion

3.1. Technoeconomical Assessment of Integrated Process vs. Standalone Pathways

Economics summary of standalone pathways and integrated process are outlined in table 1. As it can be observed, on considered industrial scale, integrated process shows a reduction in capital investment by 15.2 % compared to combined two standalone pathways of the same scale. This reduction is accredited to shared equipment of hydrogen

recycling and upgrading sections, as well as single heat and power production section (Figure 3). Total utilities savings of integrated process was calculated at 6.33 mil USD per year of which the majority is due to the hydrogen savings (85 %), heat and power savings (14 %) and water usage savings (1%). Even though in sheer mass consumption per year water was significantly reduced compared to hydrogen, greater price of the latter affected a bigger ration in utilities savings.

3.2. Minimum Product Selling Price

Due to reduction in capital investment cost and utilities savings MPSPs of main products ethanol, mixed alcohols and diesel equivalent fuel were reduced by 5.6 % compared to product prices of standalone pathways, assuming equal percentage reduction of all product prices. If MPSP of diesel equivalent fuel remained equal to that of standalone pyrolysis process in the integrated process, the MPSPs of alcohols can be reduced by 7.5 %. Likewise, if MPSPs of alcohols remained fixed, the MPSP of diesel equivalent fuel can be reduced by as much as 21.9 % in the integrated process.

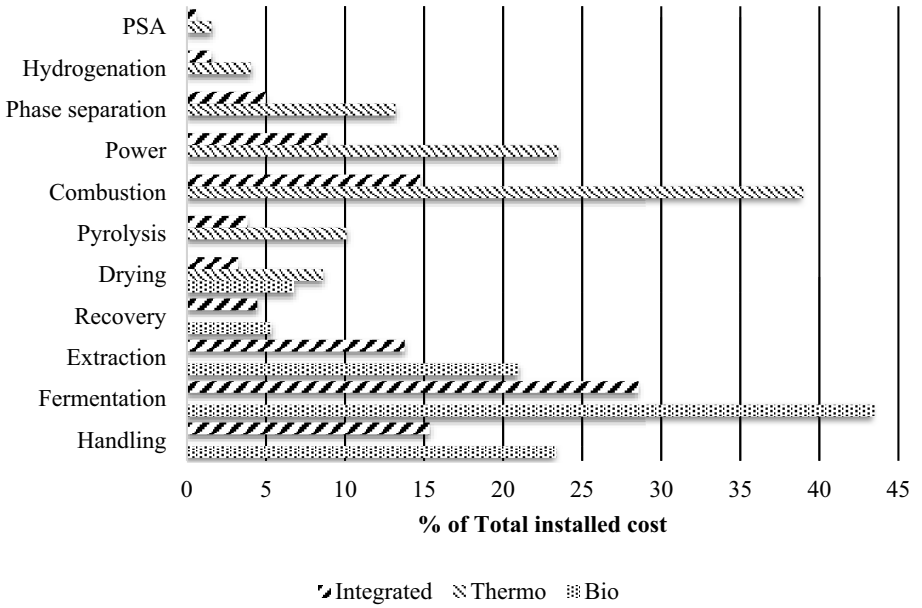

Figure 3. Capital cost breakdowns by process sections of standalone pathways and integrated process

4. Conclusions

In conclusion it was shown that seaweed based biorefinery consisting of mixed alcohol production and diesel fuel via biochemical and thermochemical pathway respectively has performed more favorably economically compared to standalone pathways of the same scale. This was shown through reduced total capital investment and annual utilities savings. More favorable economics also affected the reduction of minimum product selling prices of 5.6 % for all products equally or 7.5 % to 21.9 % when individual products are viewed.

Abstract

Steam biomass gasification has been receiving a lot of attentions as a green process to produce hydrogen rich fuels. In this process, biomass is converted into product gas, which consists of mainly H_2, CO, CH_4, and other combustible gases, at elevated temperatures and under presence of air and steam as oxidizing agents. The product gas can be used directly as a gaseous fuel or upgraded to syngas (i.e., H_2 + CO) for production of other liquid biofuels and chemicals. Fluidized bed reactor has been preferable for biomass gasification due to excellence gas-solid contact as well as heat and mass transfer. Conventional fluidized bed gasifier involves air and steam in a single reactor, which normally yields product gas consisting of nitrogen at a high concentration. Consequently, heating value of the product gas is dramatically reduces. In contract, a dual fluidized bed concept can produce nitrogen-free product gas, which is advantageous for process up-scaling.

In this study, a biomass gasification process with a dual fluidized bed technology is constructed in Aspen Plus software. Model validation is carried out using available experimental data. The model can provide in details the performance of the gasification process in terms of product gas distribution and heating value as well as the process efficiency.

Keywords: Biomass gasification; Dual fluidized bed gasifier, Process modeling.

1. Introduction

Biomass gasification has been receiving a lot of attentions as a green and clean process to produce hydrogen rich fuels with minimal environmental impacts (Farzad et al., 2016). In this process, biomass is converted into product gas, which consists of mainly H_2, CO, CH_4, and other combustible gases, at high temperatures and under a controlled oxidative atmosphere. The product gas can be used directly as a gaseous fuel (Cuéllar-Franca & Azapagic, 2015; Streimikiene, 2010) or upgraded to syngas for production of other liquid biofuels and chemicals (Alghurabie et al., 2013; Takeshita, 2011).

Among the gasifiers, fluidized bed reactor has been preferable for biomass gasification due to excellence gas-solid contact as well as heat and mass transfer. Conventional fluidized bed gasifier involves air and steam in a single reactor, which normally yields product gas consisting of nitrogen at a high concentration. Consequently, heating value of the product gas is dramatically reduces. A dual fluidized bed (DFB) reactor (Kern et al., 2013) can overcome this problem of steam biomass gasification by employing two separate fluidized bed reactors: a combustor and a gasifier. In the combustor, part of char is burnt with air to heat bed material (e.g., sand). The hot bed material is then

transferred to the gasifier, where steam is introduced as gasifying agent, for char gasification.

Although some studies have been conducted experimentally to understand the effect of the process parameters on the performance of DFB gasifier (Corella et al., 2007; Kern et al., 2013), current knowledge on the DFB technology is still limited due to limited experimental points. Process simulation can help increase the number of investigated points and provide more information about the technology.

In this study, a biomass gasification process with a dual fluidized bed technology is constructed in Aspen Plus software. Model validation is carried out using available experimental data. The model can provide in details the performance of the gasification process in terms of product gas distribution and heating value as well as the process efficiency.

2. Process simulation

2.1. Model description

The constructed gasification model in Aspen Plus is presented in Figure 1. The stream BIOMASS containing dried biomass is fed to the reactor PYRO, which simulates the decomposition of biomass at moderate temperature (i.e., pyrolysis) and converts the non-conventional component into conventional components. The block CHARSEP is used to split a portion of char, which is burnt at the COMBUST reactor to obtain the heat Q-COMB. The splitting ratio is set to a value that the heat from the char combustion can balance the heat required for the char gasification and decomposition. Other components after splitting char are fed to the NS reactor to convert nitrogen and sulfur in the biomass into NH_3 and H_2S, respectively. Thereafter, the two gases are separated from the main stream by the block NSSEP and mixed to the product gas later. Main gasification reactions occur at the GASIFIER block, where steam is introduced at 150 °C. After gasification, the stream OUTGASIF goes through the block H2OSEP to remove water from the product gas. Then the dry gas (stream DRY-GAS) is mixed with the stream NS-GAS2 containing NH_3 and H_2S in the MIX-GAS before cooled to room temperature by the HX-CG. The heater HX-NS is used to increase the temperature of the stream NS-GAS1 equal to that of the stream DRY-GAS.

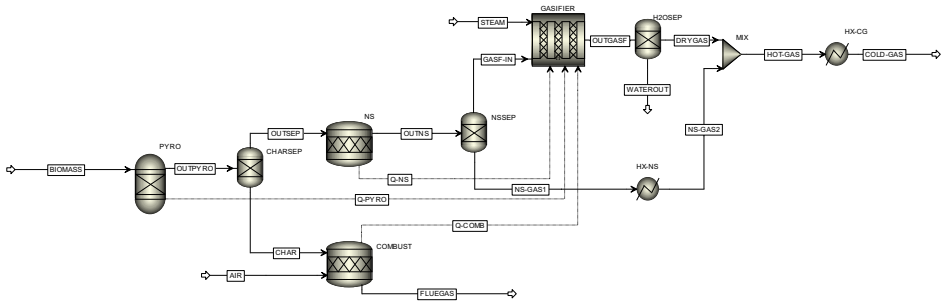

Figure 1. Biomass gasification model in Aspen Plus.

2.2. Assumptions

In order to simplify the process simulation, some common assumptions are made:

- The stream class used in the model is MIXCISLD, in which biomass are considered as non-conventional components.
- Char is 100 % carbon, and ash is an inert component.
- The properties method is Peng-Robinson with Boston-Mathias function (PR-BM), which is suitable for high temperature like gasification.
- All calculations are in steady-state.
- The system operates at atmospheric pressure and all pressure drops are neglected.
- Tar formation is neglected.
- Air consists of 79 % nitrogen and 21 % oxygen on molar basis.

2.3. Materials

In this study, Norway spruce from (Tapasvi et al., 2012) are chosen as feedstock for the gasification simulation. On the other hand hardwood chips, blended pellets and sewage pellets from an experimental DFB gasification study (Schmid et al., 2012) are chosen for model validation. The fuel properties of these materials are list in Table 1.

Table 1. Fuel proprieties of various biomass materials (on dry basis).

Feedstock	Proximate analysis			Ultimate analysis				
	Ash	VM	FC	C	H	N	S	O
Norway Spruce	0.23	86.34	13.43	49.94	6.34	0.07	0.05	43.38
Hardwood chips	1.0	84.0	15.0	48.8	5.9	0.15	0.05	44.1
Blended pellets	1.6	82.4	16.0	49.9	5.7	0.25	0.05	42.5
Sewage sludge pellets	41.5	55.4	3.1	29.7	3.7	3.90	1.00	20.2

3. Results and discussion

3.1. Model validation

Experimental data from a DFB gasification study (Schmid et al., 2012) was adopted for validation of the model in this work. The extracted data from the simulation were compared with the experimental values in the previous work. The product gas compositions from the experiments and simulations are presented in Figure 2, which shows good agreements between the modeled and experimental data. The validation indicates that the constructed model is appropriate for a variation of feedstock and could be employed for deeper investigations of different biomass gasification.

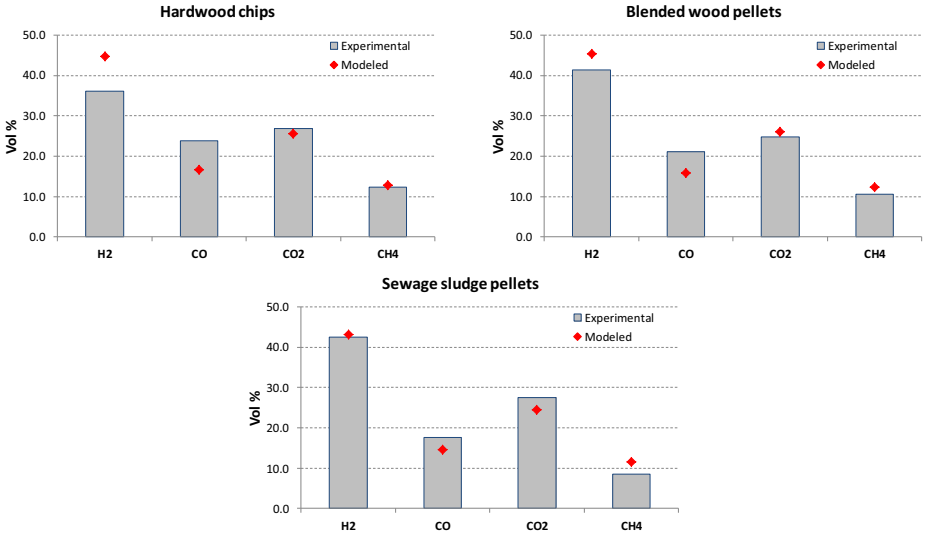

Figure 2. Validation of product gas composition from different feedstocks.

3.2. Effects of gasification temperature

Effects of temperature on the spruce gasification are presented in Figure 3. Figure 3A shows the composition of product gas at different temperature while Figure 3B demonstrates the LHV (lower heating value) of cold gas and the CGE (cold gas efficiency) with varying the temperature. It can be from Figure 3A that both the H_2 and CH_4 contents decrease slightly while CO content increases when temperature rises from 700 to 900 °C. On the other hand, CO_2 content shows a decrease with increasing temperature. In addition, the contributions of NH_3 and H_2S in the product gas are insignificant due to low nitrogen and sulfur contents in the biomass. Figure 3B reveals that the LHV of cold gas increases but the CGE decreases with increasing the gasification temperature. The increase of cold LHV with temperature is due to the reduction of CO_2 and the increase of CO. In addition, the decrease of CGE with temperature can be explained by that more char is split in order to balance for higher heat demand at the GASIFIER, thus less char is gasified and less gas yield is obtained at higher temperature.

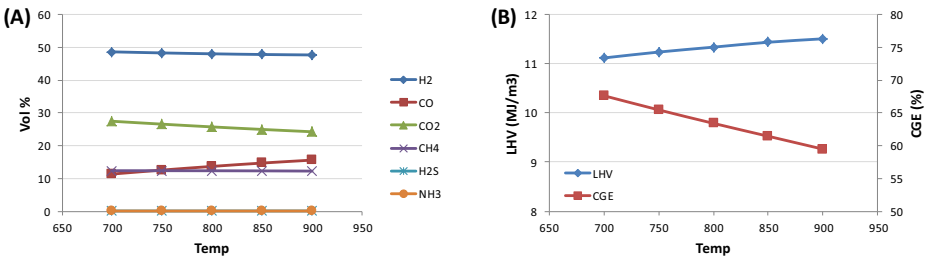

Figure 3. Effects of temperature in spruce gasification.

3.3. Effect of steam-to-biomass ratio

The changes in product gas composition with varying SBR (steam-to-biomass ratio) are presented in Figure 4A, which shows increasing trends for both the H_2 and CO_2 contents and decreasing trend for both the CO and CH_4 contents while increasing the SBR. In details, the contents of H_2 and CO_2 are increased respectively from 45.6 and 24.7 vol% to 50.2 and 26.5 vol%; whereas the contents of CO and CH_4 are decreased respectively from 15.8 and 13.7 vol% to 12.1 and 11.2 vol%. Due to the change in the composition, the LHV of cold gas decreases (from 11.8 to 10.9 MJ/m^3) but the CGE increases (from 62.2 to 64.2 %) with increasing the SBR, as shown in Figure 4B.

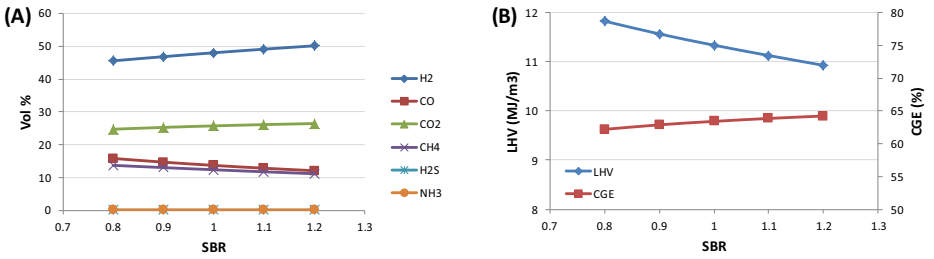

Figure 4. Effects of SBR in spruce gasification.

4. Conclusions

A model for biomass steam gasification with the DFB technology has been successfully constructed in the commercial Aspen Plus simulator, and validated using available experimental data. Simulation results from the model show that the H_2 and CO_2 contents in the product gas decreases with increasing temperature and decreasing SRB, while the CO and CH_4 contents show opposite trends. In addition, the cold gas LHV is enhanced with increasing gasification temperature and decreasing SBR. The CGE is, however, reduced when gasification temperature increases and SBR decreases.

Nomenclature

Abbreviation	Description
CGE	Cold gas efficiency
DFB	Dual fluidized bed
LHV	Lower heating value
SBR	Steam-to-biomass ratio

Abstract

In this paper, a general model-based methodology for chemical substitution, which takes into account different problem definitions depending on the objective for substitution, is presented. The associated property models and modeling tools are also described. The application of the methodology is shown through an example on substitution of a chemical from a chemical-based product. It is about finding a substitute for a non-biodegradable surfactant used in products from the cosmetics and personal care sector. Amino acid based surfactants are found to be particularly viable substitute candidates. However, this example requires the development of a set of new group contribution-based models for a number of useful properties of amino acids, which are also presented. Besides this, several other known substitution problems are solved using the developed methodology.

Keywords: Chemical Substitution, Model-based Methodology, Property Models.

1. Introduction

Chemical-based products, which could be structured product formulations, single molecule products or blends of molecules have brought substantial benefits for humans and have been a significant part of the world economy. Life may be difficult to imagine without these structured products. But like every coin has two sides, some chemicals constituting these products can be detrimental to us and the environment. This is primarily due to the hazardous environment-related properties that some of these chemicals possess. Besides, there are many more chemicals which have not been evaluated due to lack of resources for experiments and lack of rigorous estimation methods (Hukkerikar *et al.*, 2012). Hence, there is an urgent need to identify substitute chemicals that will not be dangerous to the environment, toxic to human health and harmful for the eco-systems.

The concerns about the environment and human well-being has given rise to the REACH regulation implemented by the European Chemical Agency (Echa.europa.eu, 2007), which compels companies operating in Europe to stop the use of hazardous substances and replace them with environmentally benign chemicals. Therefore, there is a need to develop a systematic, model-based methodology that can help to find substitutes to existing chemicals in order to improve the environmental impact, while still delivering the same or improved product functionality.

In this work, the objective of developing a chemical substitution methodology is to quickly and reliably identify promising candidates through model-based techniques and

only then proceed to conduct experiments in order to verify and evaluate their performance and applicability. In this way, the experimental resources are used for verification rather than the time-consuming, trial-and-error search. Besides, while seeking alternative substitutes for the undesirable chemicals, the trial and error based approach will have a very large search space. This is avoided by a reverse design approach (Gani, 2004) wherein, predictive property models are made use of. Here, alternative chemicals are found by matching the desired properties of the original product and avoiding the undesired properties of the 'compound to-be substituted'. The developed methodology can be used in systematically identifying, comparing and selecting safer and environmentally compatible alternatives to the chemicals of concern; and finally designing safe chemical product formulations with the same or better product performance.

2. Methodology for Property Model-based Chemical Substitution

2.1. Components of Methodology Development

The model-based methodology development first requires the following three components that need to be very comprehensive in order to solve a wide range of chemical substitution problems:

2.1.1. Environmental Health and Safety (EH&S) Property Criteria to select 'Objective for Substitution'

The EH&S properties enable us to determine whether the 'compound to-be substituted' is an environmental hazard or a human health hazard and what specific danger it has, if it is continued to be used. The criteria that aid in selecting the objective for substitution have been defined by making use of the 'substance classification and labelling' requirements under REACH regulations (Fisk, 2004).

2.1.2. Property Model Library

The property model library (Figure 1) consists of pure component, mixture and product performance property models for a variety of compounds. The product performance models are further classified according to the class of products i.e. blends of molecules, homogeneous liquid phase formulations, emulsions and devices.

2.1.3. Experimental Property Database

The experimental property database available at KT-Consortium contains 40 pure component properties of different types (primary, secondary and functional) and 9 mixture properties of more than 13,000 compounds classified into nine main categories according to molecular structure: normal fluid, polar associating, polar non-associating, multifunctional (with respect to groups), water, polymer, electrolyte, steroid and amino acid (Marrero and Gani, 2004). This database would be required either when the property prediction models are not available or when a developed property model needs to be verified.

2.2. A Model-based Methodology

Based on the regulatory needs along with the regulatory lists like Hazardous Substances Data Bank (HSDB) and REACH Substances of Very High Concern (SVHC) list, the 'compound to-be substituted' can be recognized, when the list of ingredients and their chemical composition in the product are available. In order to find a substitute for this compound, one can follow the Tasks 1 - 7 as outlined in Figure 2 and described below.

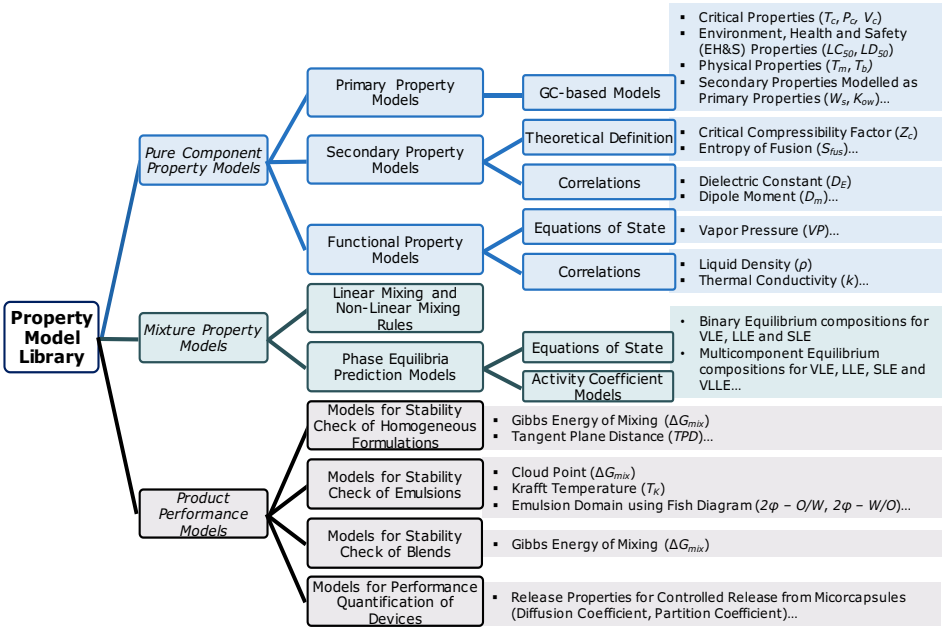

Figure 1: Classification of Properties in the Property Model Library

Task 1. Identification of Problem Type: Firstly, the function of the 'compound to-be substituted' in the original product and the 'objective for substitution' based on the 'EH&S property criteria' are identified. This sets the type of substitution problem that we have i.e. whether the compound to-be substituted is toxic to the aquatic environment, persistent in the environment, toxic on ingestion etc.

Task 2. Problem Definition: Next, the problem is mathematically formulated wherein, the desired and undesired needs of the substitute are recognized and converted to target pure component and mixture properties.

Task 3. Constraint Selection: Constraints on pure components and mixture properties are selected such that the performance and functional properties are as close as possible to the 'compound to-be substituted' while the EH&S properties are as far as possible.

Task 4. Identification / Generation of Substitute Candidates

Sub-Task 4A. Generation of Substitute Candidates: The substitute candidates are generated by Computer-Aided Molecular Design (CAMD), which makes use of property models.

Sub-Task 4B. Database Search: Alternatively, the substitute candidates can be identified by means of a database search after expanding the experimental database.

Task 5. Substitute Compound Verification: In-case it was chosen to generate substitute candidates by CAMD in Sub-Task 4A, but if some of the property models have known uncertainties, then these properties can be checked at the verification stage using an experimental property database or rigorous pure component property models.

Task 6. Final Product Verification: After the list of verified substitute candidates is obtained, it is required that it is tested to check it fits in the original mixture. This can be done by first screening the candidates based on mixture properties calculated through linear mixing rules, then by rigorous thermodynamic and property models and finally by checking the experimental mixture property database and/or conducting experiments. If at this stage, the verification fails, then the problem formulation needs to be changed,

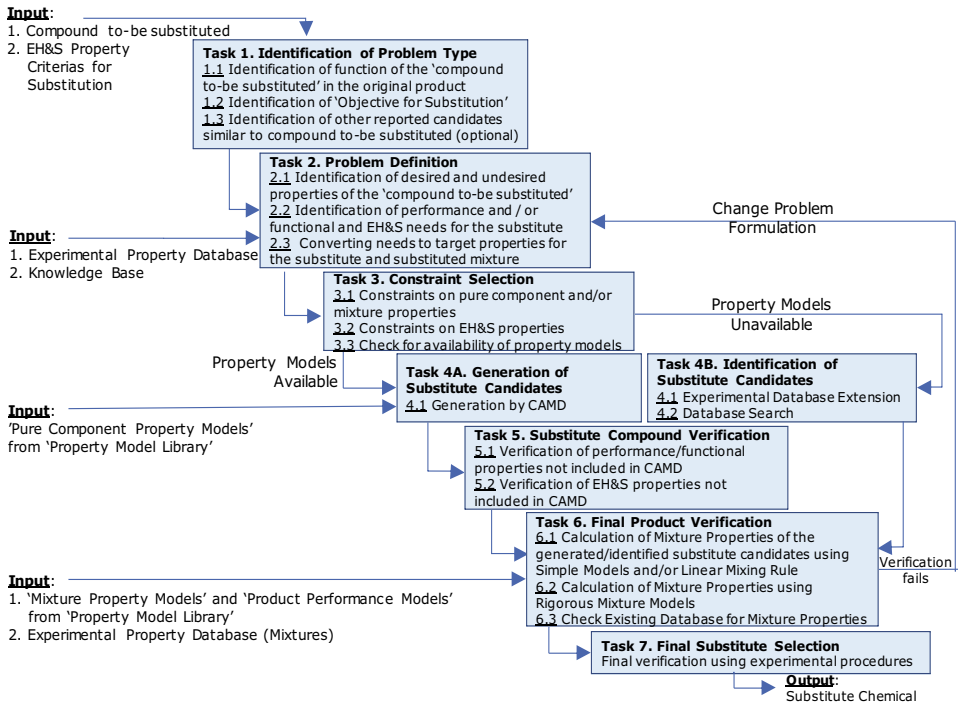

Figure 2: Methodology for Model-based Chemical Substitution

that is, some of the properties need to be compromised for other important ones or the constraints need to be relaxed.

Task 7. Final Substitute Selection: Finally, the substitute can be selected after all its properties have been checked through experimental procedures.

It should be noted that in case a needed GC property model is not available, the method cannot be applied. However, if sufficient data can be found for the selected target property, a GC model can quickly be developed through the property modelling tool-box in ProCAPD (Kalakul *et al.*, 2017) by regressing the group contribution parameters.

3. Practical Examples Employing the Developed Methodology

3.1. An Example: Substitution of Cetrimonium Bromide form a Hair Conditioner

Cetrimonium bromide is a conventional mono-quaternary ammonium cationic surfactant, used in the hair conditioner, 'Rejuvenol Keratin after Treatment Conditioner' (Whatsinproducts.com, 2001). However, it is persistent in the environment and toxic to freshwater crustaceans (Carlroth.com. 2006). In order to find a substitute for this surfactant, the desired and undesired needs are identified. These are then converted to target pure component and mixture properties as shown in Table 1 by making use of the knowledge base.

Two amino acid-based surfactants (Pérez *et al.*, 2002) are found to be viable substitutes with a biodegradation rate of greater than 60% and low toxicity to the aquatic environment. However, due to lack of GC-based models for EH&S properties and the surface-active properties for 'amino acids and their derivatives', the substitute candidate identification is carried out by means of a 'database search' (Sub-Task 4B).

Table 1: Needs, Target Properties and Constraints for Example

Need	Target Property	Target Property Constraints
Ability to form micelles / Solubilize dirt and oils	Critical Micelle Concentration (*CMC*)	$CMC < 0.02$ mol L^{-1}
Ability to lower surface tension	Surface Tension at CMC (σ_{CMC})	$\sigma_{CMC} < 40$ mN m^{-1}
Soluble in Water	Water solubility (log W_s)	$log\ W_s > 1.5$ log(mg L^{-1})
Non-toxic to aquatic environment	Immobilization Concentration (IC_{50})	$-log\ IC_{50} < 4.5$ log(mol m^{-3})
Biodegradable	Biodegradation Rate	> 60% in 28 days

A comparison of the properties of these two identified substitutes with cetrimonium bromide is shown in Table 2.

Table 2: Comparison of Target Properties of Cetrimonium Bromide with Substitute Candidates

Compound	CMC (mol L^{-1})	σ_{CMC} (mN m^{-1})	Log W_s log(mg L^{-1})	-Log IC_{50} log(mol m^{-3})	Biodegradation Rate (%)
Cetrimonium Bromide	0.0009	38.0	4.56	6.88	44
CAM (N_α-acyl-arginine methyl ester, n=8*)	0.0160	40.0	1.53	4.11	95
LKM (N_ε-acyl lysine methyl ester, n=10*)	0.0055	31.0	2.16	4.40	90

*The surfactant is the acyl derivative of an amino acid ester where *n* denotes the alkyl chain length

In order to solve the problem by making use of property models, the missing property models are first required to be developed. Therefore, GC-based models for the prediction of three physicochemical properties of amino acids and their derivatives (normal melting point, T_m, aqueous water solubility, W_s, octanol water partition coefficient, K_{ow}) are developed using the Marrero and Gani group contribution method (Jhamb *et al*., 2018). The performance of these models, determined using the statistical indicators namely, R-square and average absolute error, are summarized in Table 3.

Once GC-based models for the prediction of all the pure component properties necessary to solve this problem (Table 1) are available in the property model library, CAMD can be used to generate substitute candidates with the tool, ProCAMD in ICAS (Gani *et al.*, 1997). As a first input to the CAMD algorithm, the building blocks of amino acids can be provided as they are inherently known to be environmentally compatible and safe molecules.

Table 3: Model Performance Statistics of Developed GC-based Property Models for Amino acids

Property	Number of datapoints	R-square	Average Absolute Error	Maximum Average Absolute Error
T_m	239	0.94	10.81 *K*	42.82 *K*
Log W_s	211	0.94	0.19 *log(mg L^{-1})*	0.97 *log(mg L^{-1})*
Log K_{ow}	335	0.99	0.16	1.18

3.2. Other Examples Solved using the Developed Methodology

Besides the example discussed above, three others have been successfully solved using the developed methodology. Two out of these are well-known problems (ethylene glycol substitution from an engine coolant; methylene chloride substitution from a paint and epoxy remover), while the third one is to substitute an aromatic, toxic solvent used for the dissolution of UHMW-PE in its gel spinning process. It is to be noted however, that the final selection of the substitute for all the solved examples, does need experimental verification (Task 7).

4. Conclusion and Future Work

A systematic model-based methodology for chemical substitution has been developed and has been applied to substitute environmentally hazardous and/or unsafe chemicals in liquid phase product formulations from various industrial sectors. The challenges and opportunities for chemical substitution in devices, solid state products, polymers and plastics etc. still need to be evaluated. While some of the missing property models have been developed and validated, for instance, the group contribution models for predicting the physico-chemical properties of the amino acid class of compounds (Jhamb *et al*., 2018), the development of many more property models is necessary to expand the scope, significance and applicability of model-based methodologies like this.

Abstract

Presented in this manuscript is a novel technique for the exploitation of a unique feature of multipurpose batch plants, so called floating pumps. A MILP mathematical formulation is proposed to determine the optimal number and allocation of pumps within the batch plant while simultaneously synthesizing the plant and optimizing the batch production schedule with variable material transfer times. It was shown by way of an example that it is possible to decrease the number of pumps required for operation from seven to two. By using fewer pieces of equipment which are optimally allocated, equipment degradation due to nonuse can be reduced. It is, therefore, possible to reduce capital and maintenance costs by implementing the formulation while still achieving or improving on existing throughput.

Keywords: Pump, Batch, Synthesis, Multipurpose, Optimization

1. Introduction

Batch processes are commonly used to produce high value products in low volumes. Multipurpose batch plants afford great flexibility by producing a number of different products using the same equipment. This flexibility allows for improved equipment utilization while adapting to rapid market fluctuations. In the selection of batch equipment, the processing requirements and production material properties dictate the design. Most batch chemical plants, such as in the food, pharmaceutical and agrochemical industries, predominantly contain liquids that need to be transferred between processing units using pumps.

Batch plant optimization and scheduling have been studied since the 1970s and gained considerable attention in the field of mathematical modelling during the 1990s. The use of mathematical modelling has made it possible to determine the optimal processing time and material allotted to processing units in order to manage a batch plant efficiently. Sparrow et al. (1975) presented an initial formulation to address the general scheduling problem of multiproduct batch plants by looking at heuristic and branch and bound techniques. A large number of scheduling models based on various insights followed. Notably, within these scheduling models, mainly the major processing equipment of the batch plant, such as the reactors, separators, heaters and storage, were mathematically scheduled, yet focus has not been given to the optimal synthesis or scheduling of pumping equipment within multipurpose batch plants.

Loonkar and Robinson (1970) noted that the capital cost of a batch plant is also dependent on the rating of pumping equipment, heat exchanger duty and the size of the processing vessels. Hegyhati and Friedler (2011) noted that materials transfers are generally simplified to fixed durations when scheduling plant production, regardless of the batch size and costs associated with the transfers. Lee et al. (2015) considered fixed material transfer times in their work in order to allow for heat integration during the transfer, however, each transfer time was a fixed parameter which was independent of the amount of material transferred.

Barbosa-Póvoa and Macchietto (1994) stated that piping connections must be present between vessels in order to facilitate transfer of material and presented a general MILP model that allowed for transfers only if a relevant connection was available. Hegyháti et al. (2009) noted that many models overlooked the subtle transfer infeasibility that arose when various operational philosophies were employed. Specifically noted was that mathematical models inadvertently allowed material to be transferred to and from a processing unit at the same time, so called cross-transfer.

2. Motivation

In this manuscript, the concept of floating pumps is introduced. These floating pumps are not necessarily dedicated to particular units or sections in the plant, as shown in Figure 1(a) but can be reassigned to different processing units and sections as required. By using floating pumps, flexibility in the batch plant is increased. It is evident from Figure 1(b) that the proposed allocation of pumps would result in increased pumping equipment utilization, while reducing the total number of pumps required. This is favorable since prolonged disuse of pumps may increase maintenance costs due to clogging or blockages and structural degradation. Notably, this can be achieved while preserving or even improving the production throughput of cases where no flexible pump allocation is taken into consideration. This synthesis method can be applied for plant design where it is desirable to limit the number of equipment units required, in order to save on capital investment and optimally use available space. It can also be applied in retrofit design in order to eliminate unnecessary processing and pumping equipment in a plant, thereby saving on maintenance costs.

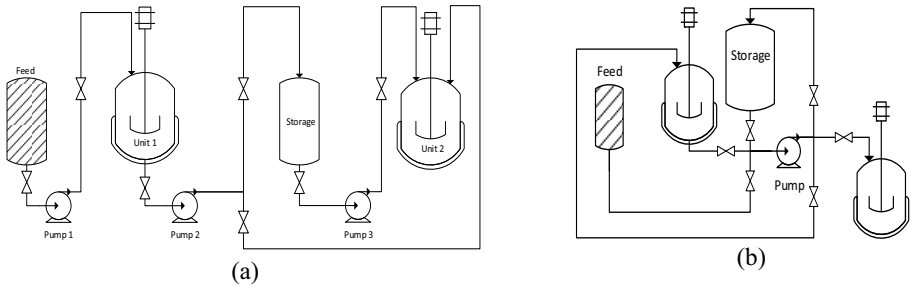

Figure 1 (a) Conventional pump allocation and (b) proposed pump allocation

3. Key Constraints

The key constraints that pertain to pump allocation are shown below. These constraints may be adapted into scheduling models. The scheduling model used in this manuscript is reformulated from the models presented by Seid and Majozi (2013) and Lee et al. (2015) to allow for pumping allocation and variable transfer times. In the formulation, v represents any vessel, j a processing unit, v_v a storage vessel, ζ a pump, v_s a source vessel, v_d a destination vessel, s a state, $s_{in,j}$ a task and p a time point.

Constraints (1) and (2) state that pumping (μ) may only occur if inlet (i) and outlet (o) piping connections are available.

$$\mu(v', v, \zeta, p) \leq i(\zeta, v') \tag{1}$$

$$\mu(v', v, \zeta, p) \leq o(v, \zeta) \tag{2}$$

Constraints (3) and (4) state that a pump may only pump to a single unit or from a single unit at a given time point, respectively. This may only occur if the pump exists.

$$\mu(j, v_s, \zeta, p) + \sum_{j'} \mu(j', v_s', \zeta, p) \leq e(\zeta) \tag{3}$$

$$\mu(v_d, j, \zeta, p) + \sum_{j'} \mu(v'_d, j', \zeta, p) \leq e(\zeta) \tag{4}$$

Constraint (5) states that a pump must be active between a receiving storage vessel and a unit in order to transfer material.

$$m^{in}(s, j, p) \leq V^U(v_v) \sum_{\zeta} \mu(v_v, j, \zeta, p) \tag{5}$$

Similarly, Constraint (6) states that a pump must be active between a receiving unit and a storage vessel to transfer material.

$$m^{out}(s, j, p) \leq V^U(v_v) \sum_{\zeta} \mu(j, v_v, \zeta, p) \tag{6}$$

Additionally, Constraint (7) states that a pump must be active between two different units to transfer material.

$$m_t(s, j, j', p) \leq V^U(j) \sum_{\zeta} \mu(j, j', \zeta, p) \tag{7}$$

Constraints (8) – (10) state that the transfer time is dependent on the respective material transfer and the rating of the pump used.

$$R(\zeta) m_t(s, j, j', p) - M\big(1 - \mu(j, j', \zeta, p)\big) \leq t_t(s, j, j', \zeta, p) \leq R(\zeta) m_t(s, j, j', p) + M\big(1 - \mu(j, j', \zeta, p)\big) \tag{8}$$

$$R(\zeta) m^{in}(s, j, p) - M\big(1 - \mu(v, j, \zeta, p)\big) \leq t_t(s, v, j, \zeta, p) \leq R(\zeta) m^{in}(s, j, p) + M\big(1 - \mu(v, j, \zeta, p)\big) \tag{9}$$

$$R(\zeta) m^{out}(s, j, p) - M\big(1 - \mu(j, v, \zeta, p)\big) \leq t_t(s, j, v, \zeta, p) \leq R(\zeta) m^{out}(s, j, p) + M\big(1 - \mu(j, v, \zeta, p)\big) \tag{10}$$

Constraint (11) states that there is no transfer time required to transfer material from a unit to itself.

$$t_t(s, j, j, \zeta, p) = 0 \tag{11}$$

Constraints (12) and (13) assign slots for pumping to the scheduling formulation and states that sufficient time for pumping into a task and out of a task must be given, respectively.

$$t^{in}_{dur}\big(s_{in,j}, p\big) \geq \sum_{v_S} t_t(s^{sc}, j, v_S, \zeta, p) \tag{12}$$

$$t^{out}_{dur}\big(s_{in,j}, p\big) \geq \sum_{v_v} t_t(s^{sp}, v_v, j, \zeta, p) \tag{13}$$

4. Illustrative Example

An illustrate example is presented based on the scenario given by Lin and Floudas (2001), which involves a multipurpose batch plant capable of performing 4 distinct tasks. Three major processing units are available to perform the processing tasks, along with a storage vessel that is available to store state 4 (S4). The recipe representation for the scenario is given in Figure 3. Data pertaining to the equipment may be found in Table 1 and economic data in Table 2, as adapted from Lin and Floudas (2001). The data pertaining to pumping rates for the various available pumps are given in Table 3. The illustrative pumping rates were calculated such that no pump will be active for more than five minutes when the pumps are placed conventionally with the plant operating at full capacity. A time horizon of 12 hours was considered.

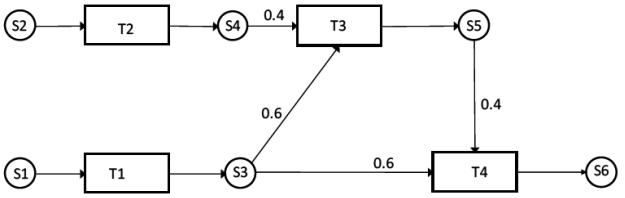

Figure 2 STN Representation for Illustrative Example

Figure 3 shows the typical flowsheet for the illustrative example and depicts the pumps which would conventionally be used to transfer material between different areas within the plant.

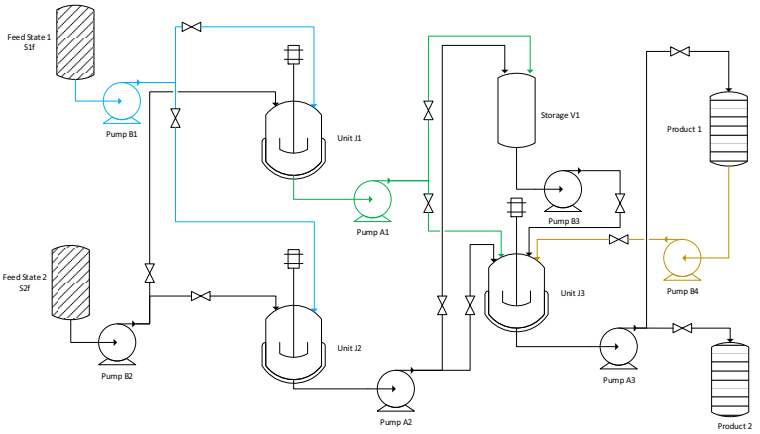

Figure 3 Conventional pump allocation and plant flowsheet

Table 1. Equipment data for the first illustrative example

Unit / Storage Vessel	Capacity	Suitability (Task/Storage)	Task Duration (Hours)	Cost (Cost Units)
Unit J1	50-150 mu	T1 T2	2 2	100
Unit J2	50-150 mu	T1 T2	2 2	150
Unit J3	50-200 mu	T3 T4	4 2	120
Vessel 4	100 mu	S4	-	15

Table 2. Economic data for the first illustrative example

Material/Equipment	Price (Cost units)
S1, S2	0.1 /mu
S5 (Product 1)	0.4 /mu
S6 (Product 2)	0.6 /mu
Pump base cost	10
Pump rating cost	0.001
Piping cost per connection	5

Table 3. Pump ratings for the first illustrative example

Pump	Pump Rating (seconds / unit material)	Pump	Pump Rating (seconds / unit material)
A1	2.00	**B1**	2.00
A2	2.00	**B2**	2.00
A3	1.50	**B3**	1.50
		B4	1.50

The MILP problem was solved using the CPLEX solver. The optimal pumping schedule may be found in Figure 4 and the optimal processing schedule in Figure 5. Figure 6 shows the resulting optimal plant pumping structure needed to cater for the example. By flexibly allocating pumps, the plant required two pumps to transfer material throughout the batch plant whereas seven pumps were required when flexible pump allocation was not considered. The synthesis results also show that a storage vessel is not required for S4. The problem was solved using four time points, yielding an objective value of 1.27×10^6 cost units in a CPU solution time of 2.45 seconds.

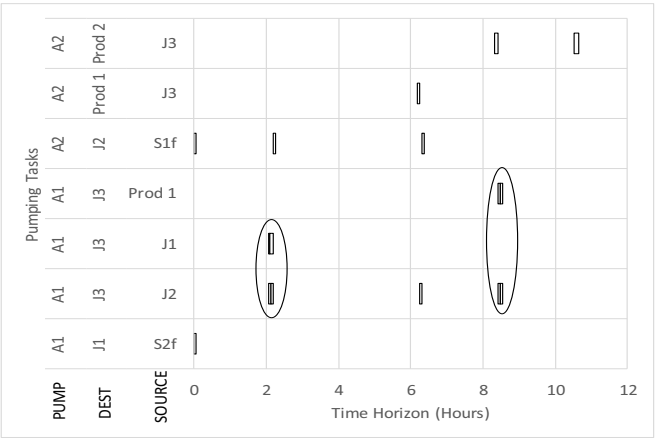

Figure 4 (a) Optimal pumping scheduling using floating pumps

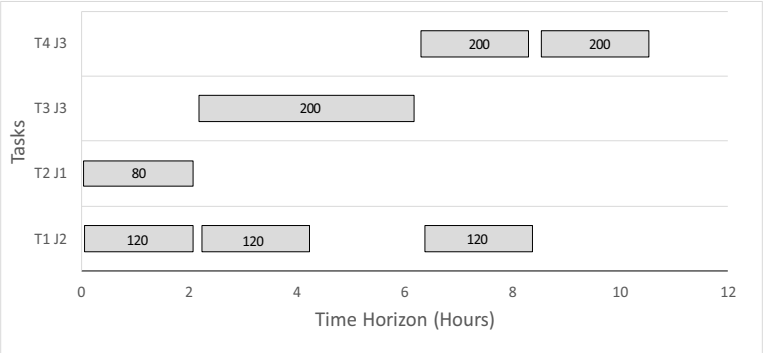

Figure 5 Optimal processing schedule using floating pumps

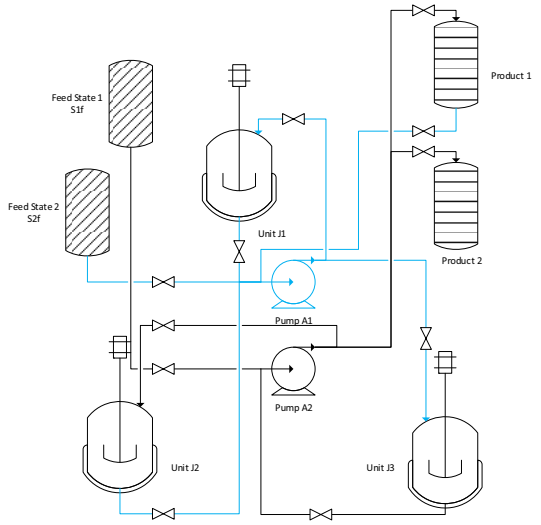

Figure 6 Optimal floating pump allocation and connections

5. Conclusions

A MILP mathematical formulation is introduced which is capable of synthesizing multipurpose batch chemical plants while flexibly allocating pumps to transfer different materials to units during the time horizon of interest. Previously, no consideration has been given to the pumping equipment in the synthesis and scheduling of batch plants. The illustrative example showed it is possible to decrease the total number of pumps required from seven to two pumps. Worthy of mention is that product integrity issues would have to be taken into consideration whenever the concept of roving pumps is introduced in a practical process. It is also evident that the roving pumps result in combinatorially complex operations that would ultimately require advanced control mechanisms in order to avoid cross contamination. These aspects will be the subject of future investigation.

Abstract

Addressing the need for comprehensive analysis of the potentials and characteristics of ethylene production via Oxidative Coupling of Methane (OCM) process was the main motivation of performing the current study. In this context, technical, environmental and economic characteristics of alternative OCM process design structures including the integrated OCM and ethane dehydrogenation process for the industrial plants with the annual capacity of one million t ethylene production were analyzed and compared by predicting their performances using Aspen-Plus simulation and Aspen Economic Process Analyzer. The performance of the reactor section, carbon dioxide separation section and adsorption section in this simulation were mapped and validated using the observed performances of the OCM miniplant scale experimental facility constructed in TU Berlin.

It was found that the operating cost in all cases is the main source of cost, so that even the one-year operating cost is estimated to be 3-4 times of the fixed cost. In the operating cost, the raw material cost stands for the major part of the cost to be around 750 million Euro annually. Most of the utility costs is needed for the energy-intense cryogenic distillation, which is avoided in the demethanizer section when adsorption unit is utilized. However, one percent loss of ethylene and significant increase on the fixed-cost are the main disadvantages of using adsorption technology. Yet, this process structure provides the fastest return of investments around 9 y based on the considered costs and the assumptions in this study. Using selective carbon dioxide membrane separation technology was also investigated and showed a marginal contribution specially by considering the expected 2% loss of ethylene in this case. If better membrane technologies for CO_2 separation or preferably for ethylene separation becomes available, it can be beneficial in the whole economy of the process and in this case the best observed total energy consumed can be improved beyond current 40-50 GJ/t ethylene. Beside trying to reduce the total cost, the amount of the generated CO_2 and the total energy consumed associated with production of one t of ethylene, potential of using bio-based materials for instance for producing the required adsorbents and also utilizing the whole OCM process for bio-based methane feedstocks were also taken into consideration. The technical challenges regarding the OCM catalyst and reactor operation should be addressed prior to any attempt for industrial scale operation of this process.

Keywords: OCM process, Economic evaluation, Ethylene adsorption, Process scale analysis.

1. Introduction

Ethane and naphtha cracking are the main stream mature technologies currently used for ethylene production in the scale of 160 million t/y as the third largest chemicals produced worldwide. Achieving around 60 percent conversion and 80 percent selectivity towards ethylene are the promising performance indicators of these processes. As an attempt for diversifying the feedstocks and replacing a cheaper and more available feedstock for producing ethylene from methane, Oxidative Coupling of Methane (OCM) process has been investigated for more than 35 years. OCM technology specifically is recommended for utilizing the remote and waste methane sources in the places where ethane or naphtha are not easily available in the quantity needed for the current and future capacity of the crackers. During the last four decades, different aspects of the OCM process such as catalysts' materials and characteristics, reactor concepts, process structures etc. have been investigated and their performances have been improved. However, the OCM process has not been so far implemented industrially mainly due to the fact that globally observing, ethylene production via cracking is preferred both technically and economically. To mention the technical reasons, it can be highlighted that a) the previous reported catalysts has not been enough selective towards ethylene and more importantly has not been enough stable, b) operation of the exothermic high temperature OCM reactor in large scale is a huge challenge, c) separation of the OCM products and unreacted reactants requires an energy/cost-efficient removal/purification system. Although, the challenges regarding OCM economic perspective and its catalytic performance remains, the progresses achieved in these areas in the last decade specially based on the extensive experiences achieved by our research group (Cluster of Excellence "Unifying Concepts in Catalysis" UniCat, www.unicat.tu-berlin.de) are the major motivations for re-evaluating the OCM process in this study. In this paper, the observed performances of the catalyst-reactor section, carbon dioxide removal and ethylene separation in the UniCat miniplant experimental facility are set as the base for the simulation-economic study of four alternative OCM plants targeting one million t/y ethylene production. The specifications and the assumptions associated with the performances of these sections will be reviewed here while the specifications of the experimental setup will be described later in this paper for each unit operation.

Figure 1 shows the schematic representation of the OCM process in which the unit operations and their interactions have been demonstrated.

Figure 1. Schematic representation of the OCM covering four process structures

1.1. Catalyst-Reactor Section

Among the selected tested OCM catalysts, the benchmark Mn-Na_2WO_4/SiO_2 catalyst has shown a promising performance in terms of the selectivity and stability, therefore it has been widely recommended for this process (Yildiz*, et al.* 2016). This catalyst has been

synthesized and tested in different-scales reactors in the UniCat miniplant (Sadjadi*, et al.* 2015, Godini*, et al.* 2014) resulted in one of the best so far observed OCM catalysts performances in membrane reactor (Godini*, et al.* 2014). It worth emphasizing that such reactor performance has been achieved under the set of operating conditions which are also practically relevant regarding the industrial-scale operation of this process. For instance, in the reactor section, the utilized level of the methane-to-oxygen feed ratio enabled securing the minimum level of methane conversion and ethylene yield respectively at 40% and 60% believed roughly to be the minimum values of these factors associated with potential economic OCM process in industrial scale. Moreover, the level of inert gas dilution, which will impose a significant cost in the downstream units to be separated, should be kept as low as possible. The observed reactor's product compositions are reported in Table 1. The utilized feed stream composed of methane, oxygen and nitrogen respectively to be 64%, 32% and 4%. The feed was introduced to the pre-heating section of the reactor with 600 ˚C and the products have been cooled down to 650 ˚C before utilizing further heat integration.

Table 1. OCM reactor performance indicators of 50% conversion and 23% C_2-yield; product composition observed experimentally and mapped in the performed model-based simulation for 4% N_2-diluted feed of methane-to-oxygen ratio 2

CH_4	H_2O	N_2	CO	CO_2	C_2H_4	C_2H_6	C_3H_6	C_3H_8	H_2
0.31	0.28	0.04	0.04	0.13	0.05	0.02	0.01	0.002	0.12

The experimentally observed performance of the OCM and EDH reactors were mapped in the Aspen Plus simulation to simulate the outlet compositions of the reactors and conducting the techno-economic analysis of the process scenarios using Aspen Economic Analyzer. The required amount of catalysts were calculated based on the productivities of these catalyst which later was resulted in determining the dimension of the reactor by considering the density of those catalyst and effective volume of the shell-tube reactors.

1-150 gr catalysts have been tested in the UniCat OCM reactors with the reactor diameter of 7-55 mm. In the cases of integrated reactors, the design of the reactor section has been considered as an integrated form of OCM and an endothermic ethane dehydrogenation (EDH) reaction system. The performance of the EDH section has been also considered to be around 56% ethane conversion with approximately 50% ethylene yield.

The assumptions related to this reactor section is that the catalyst is stable for 5 y, heat-integration is manageable, and the operating pressure is 10 bar. The reason for the last one is that in this case, carbon dioxide removal in the next section takes place efficiently under this pressure and any need for compressing the gas from the reactor section into the CO_2-removal section or other downstream units imposes a huge operating cost due to the need for special corrosive resistance material and relatively high compression duty there. Moreover, supplying methane-rich and oxygen-rich stream of 10 bar from the previous units is not complicated. In any case, the performance of the OCM reactor should be evaluated in the context of the whole OCM process.

1.2. Carbon Dioxide Removal Section

As mentioned earlier, since more than 40 percent of the converted methane appears in the form of carbon oxides, it is important to remove it from the reactor outlet gas stream as quickly and as efficiently as possible. This is achieved via different techniques. For instance, in the UniCat miniplant facility, the performance of the amine absorption unit and the polymer membrane module for this task were experimentally investigated.

1.2.1. Amine Absorption

Wide range of operating conditions and amine materials have been tested for carbon dioxide removal from the OCM reactor outlet stream. It was experimentally shown that Methyl diethanolamine (MDEA) solution under 10 bar pressure in the miniplant-scale absorption column with 40 mm diameter and 5 m length, under 30 ˚C, provides one of the best removal performances in terms of lowest energy consumption and ethylene lost. It was decided to keep the ethylene lost below 5% as ethylene lost more than that value is obviously is economically unjustified.

In the simulation, MDEA solution of 10% MDEA+ 88% H_2O + 2% Piperazin was used.

In HYSYS, thermodynamic equations method recommended for CO_2 Absorption "Acid gas" was used in an absorber-column with 48 stages under 10 bar pressure. For the stripping, a recoiled absorber with 15 stages under 1.5 bar has been used.

1.2.2. Membrane

Using polymer membrane especially cellulose acetate, polyimides or poly-(ethylene oxide) active layer have been tested in the UniCat miniplant-scale Flat sheet envelope type of membrane module (provided by Helmholtz-Zentrum Geesthacht) for CO_2 removal task for this application. It was shown that the hybrid separation via combination of membranes and absorption provides the best separation performance in terms of minimizing the required energy and ethylene lost. Further information in this regard are available elsewhere (Brinkmann, *et al.* 2015). A one-dimensional solution-diffusion model was developed to represent the performance of such membrane modules in the industrial scale techno-economic analysis.

1.3. Ethylene Separation Section

The limited range of methane conversion below 50% per pass and consequently the huge amount of the remaining unreacted methane which is needed to be separated from the rest of gaseous species is a major source of deficiency in the OCM process as this is usually done using the energy-intense cryogenic distillation.

1.3.1. Separating unreacted methane and other light gases via Demethanizer

Right after the carbon dioxide removal section, by providing around 33.5 bar pressure and condenser temperature of -111.9 ˚C, separation performance of this system for the industrial scale system was simulated using RadFrac column with 30 stages, Reflux ratio of 1.5 and distillate to feed ratio of 0.83 in a 8.5 m diameter, 30 m tall column which traces the methane in the C_2-rich stream by minimum ethylene loss of 0.27 %.

1.3.2. C_2-Splitter

Similar procedure was applied for separating ethane from ethylene in a 5.4 m diameter 18 m height RadFrac-column with 66 stages under 20 bar pressure and around -29 ˚C operating temperature with Reflux ratio of 5.3 and distillate to feed ratio of 0.648 to secure ethylene purity of 99.5 %.

1.3.3. Adsorption

As an alternative in the downstream of the OCM process, a pressure/temperature swing adsorber PSA/TSA system with 60 mm diameter and one-meter length was tested experimentally in the UniCat miniplant to separate the C_2-products after the reactor as quick and efficiently as possible. Improved Zeolite 13X was used as an efficient adsorbent for such task showing a significant adsorption capacity. Similar to the other unit operations, the experimentally observed performance of the adsorption unit in the miniplant scale was mapped for the large scale OCM plant and all operating aspects associated to it, such as considering 5 columns from which one is always in adsorption

cycle and three are in desorption cycle and one is used as by-pass for backup, were considered in the techno economic analysis and CO_2 was used as strip gas.

The selected four process scenarios and the results of their techno-economic analysis are listed in Table 2. Case 1 is the reference OCM process. Case 2 has an EDH reactor. Case 3 is similar to case 2 but utilizes a hybrid membrane absorption system. Case 4 is similar to case 2, but instead of demethanizer uses a PSA/TSA system for ethylene separation.

Table 2. Selected OCM process cases and their performance-cost items

case #	OCM Reactor	integrated potential	CO_2 removal		C_2 separation		C_2 splitter	P.O. Period [y]
		EDH	Amin absorption	Polymer membrane	Demethanizer	Adsorption		
case 1	44 [€/t C_2H_4]	-	21 [€/t C_2H_4]	-	127[€/t C_2H_4]	-	3.9 [€/t C_2H_4]	-
case 2	51 [€/t C_2H_4]		20 [€/t C_2H_4]	-	100[€/t C_2H_4]	-	5.9 [€/t C_2H_4]	9.52
case 3	51 [€/t C_2H_4]		17 [€/t C_2H_4]		100[€/t C_2H_4]	-	6.3 [€/t C_2H_4]	9.96
case 4	54 [€/t C_2H_4]		35 [€/t C_2H_4]	-	-	11 [€/t C_2H_4]	6.6 [€/t C_2H_4]	8.95

The reported costs here include the utility cost per t of ethylene in which the equipment cost has been depreciated and included (€/t C_2H_4).

The details of the costs associated with each task and section of these case-processes have been also shown in Table 2. As seen here, it is clear that by increasing the ethylene production capacity by integrating the EDH reactor, the separation costs per t of ethylene is reduced. It is also seen that the major part of the cost is associated with separation of the unreacted methane and light gases, when demethanizer is used. Using adsorption, demethanizer can be even completely avoided. Therefore, the operating cost for C_2-separation can be reduced significantly. It should be mentioned however, that these are the operating costs and in order to have a base for comparing the economy of these cases, fixed costs and pay-out period of these processes should be also taken into analysis. The results of the performed techno-economic analysis of these scenarios are reported in Table 3. For such analysis, the cost of raw materials, main and side products, utilities etc. have been collected for the same local and have been doubled checked with the industrial sources. For instance, one t of methane, ethylene, ethane and one Kcal generated HP-steam were respectively considered to cost 110 €, 900 €, 250 € and 6.45E-06 €.

Table 3. Results of the performed techno-economic analysis on the OCM process cases

	Case 1	**Case 2**	**Case 3**	**Case 4**
Ethylene Lost [%]	0.8	0.3	2.1	1.0
Operating Cost [€]	994,295,520	1,031,630,000	1,025,270,000	899,646,000
Utility Cost [€]	168,363,160	196,424,000	191,280,000	75,921,500
Raw Material Cost [€]	730,328,360	734,983,000	734,948,000	742,601,000
Fixed Cost	265,754,000	349,605,000	364,794,000	388,877,000
Total energy per t of Ethylene [GJ/t C_2H_4]	53.95	46.87	43.03	53.50
Total energy cost per t of Ethylene [€/t C_2H_4]	170.33	156.70	156.10	115.95
Total CO_2 Produced per t of Ethylene [t CO_2/t C_2H_4]	3.82	3.03	3.06	3.31

Table 3. Results of the performed techno-economic analysis on the OCM process cases (continued)

Utility cost per t of Ethylene with equipment cost depreciated included [€/t C_2H_4]				
Section of reaction	44.08	50.87	51.18	53.97
Section of CO_2 separation	21.10	20.23	16.75	34.79
Section of Demethanizer	126.92	100.22	100.28	0.00
section of C_2 splitter	3.89	5.89	6.33	6.56
Section of adsorption	0.00	0.00	0.00	11.05

2. Conclusions

The performance of the OCM reactor, carbon dioxide removal and C_2-separation sections have been analyzed in a miniplant scale experimental facility and their results have been mapped in the large scale OCM plants representing four different process-structures.

Recycling ethane back to the OCM-EDH reactor section securing significant ethane dehydrogenation and heat integration has a significant positive impact on the economy of the OCM process. Moreover, using a low-pressure adsorption unit enables one to even replace the cryogenic distillation used for demethanizer and its related required compression and cooling duties, which stand for the major portion of operating cost of the whole OCM process. Fixed-cost in this case will be increased however. Similarly, using polymer membrane reduces the required energy for CO_2 separation which is not a significant part of the whole OCM process cost though. All these conclusions are only valid when the remaining operating challenges for the OCM catalyst and reactor are addressed as assumed in this study.

Abstract

This paper presents a multi-objective modeling framework for simultaneous process-heat integration optimization with multistream heat exchangers (MHEXs). The trade-off between operating cost and heat integration of the process is considered. The proposed framework comprises heat recovery of MHEXs, thermodynamics, vapor-liquid equilibrium, and other unit operations of process. The MHEXs model takes advantage of the compact formulation of the multi-M approach (Hui, 2014) to improve solution efficiency. The model is formulated as a mixed-integer nonlinear programming (MINLP) model and applied to an industrial air separation unit (ASU) to demonstrate its effectiveness. Multi-objective optimization is performed to investigate the trade-off between heat recovery of MHEXs and energy consumption of air compressors.

Keywords: multistream heat exchanger, heat integration, process optimization, multi-objective optimization

1. Introduction

Multistream heat exchanger (MHEX) is a single unit process for simultaneous heat transfer between more than two streams. MHEXs find applications in a variety of energy intensive processes that includes, but are not limited to, air separation (Pattison and Baldea, 2015), food and pharmaceutical production (Galeazzo et al., 2006), hydrocarbon processing (Shah et al., 2000), hydrogen purification and liquefaction (Christopher and Dimitrios, 2012), liquefied natural gas (LNG) production (Kamath et al., 2012), power generation (Memmott et al., 2017), and refrigeration processes (Thonon, 2008).

Despite wide application, it is often challenging to simultaneously optimize MHEXs within process due to the restriction of temperature difference and occurrence of phase change. Further complicating the issue is the variable stream data, e.g. inlet and outlet temperatures and flow rates. Hasan et al (2009) applied the concept of superstructure (Yeomans and Grossmann, 1999) to simulate MHEX, and formulated an MINLP model to optimize heat recovery of MHEX. However, the complex superstructure is often computationally expensive, which brings greater difficulty to the simultaneous process and MHEX optimization. Kamath et al. (2012) presented a nonlinear programming (NLP) formulation of MHEX based on the concept of Pinch analysis (Kemp, 2011,Liang and Hui, 2016). The major challenge of the NLP formulation is the

nonlinear approximation of *max* function, which leads to errors in energy balance and numerical difficulties.

Therefore, an efficient modeling approach of MHEX is significant for the simultaneous MHEXs and process optimization. Moreover, existing methods rarely performed multi-objective optimization of processes with multiple MHEXs. In practice, however, multiple factors are considered in the design so that process can achieve balanced energy-economic performance. Thus, there is a growing interest to develop a rigorous and computationally efficient modeling framework and investigate the tradeoff between different factors (e.g. heat recovery and operating cost). Heat integration modeling approach (Hui, 2014) and multi-objective optimization method (Hwang and Masud, 1979) can be applied to the simultaneous MHEXs and process optimization.

The objective of this paper is to propose a framework for simultaneous MHEXs and processes optimization that addresses the modeling of MHEX and considers trade-off between operating cost and heat recovery. The proposed framework avoids discontinuous *max* function and nonlinear approximation when modeling the MHEX. The resulting optimization problem is formulated as a multi-objective MINLP model, which simultaneously maximizes heat recovery of MHEXs and minimize operating cost of process. The model subjects to the constraints of energy balance, constraints to enforce temperature difference of heat transfer in MHEXs, and constraints of the thermodynamics and other unit operations. We apply the model to an industrial air separation process with multiple MHEXs to demonstrate its effectiveness.

2. Model formulation

(MP1) summarizes the proposed framework for simultaneous MHEXs and process optimization. The model considers heat recovery of MHEXs, thermodynamics, and other unit operations. **(MP1)** is formulated as a multi-objective MINLP model for the nonlinear thermodynamics constraints and discrete nature of the multi-M formulation. For convenience, parameters are denoted by upper case letter, and variables by lower case letter in this paper.

Heat transfer of an MHEX can be regarded as heat integration of multiple process streams with no heating and cooling utilities. Therefore, the concept of Pinch analysis is applicable to model MHEXs. However, simultaneous MHEXs and process optimization usually requires nonlinear formulation or binary variables, which are computationally expensive. To enhance solution efficiency, we propose a method adapted from Hui's (2014) multi-M formulation that circumvents nonlinear formulation and minimizes the number of binary variables. The model assumes counter-current of hot and cold streams at the MHEXs. Additionally, the heat capacity of a stream is assumed temperature independent in liquid phase, vapor phase, and phase change. The stream data (e.g. inlet and outlet temperatures and flow rate) can be varied or fixed.

$$t_{j,e}^{p}=t_{i,e}^{in}\quad i\in H,j\in I,e\in E \tag{16}$$

$$t_{j,e}^{p}-\Delta T_{e}^{min}=t_{i,e}^{in}\quad i\in C,j\in I,e\in E \tag{17}$$

$$g(x,w)=0 \tag{18}$$

$$h(x,w)\leq 0 \tag{19}$$

H and C are the sets of hot streams and cold streams, respectively. I is a set of process streams ($I=H\cup C$). E is a set of MHEXs. $f_{i,e}$, $CP_{i,e}$, $t_{i,e}^{in}$ and $t_{i,e}^{out}$ are molar flow rate, heat capacity, inlet temperature, and outlet temperature of process streams, respectively. $tp_{i,j,e}^{in}$ and $tp_{i,j,e}^{out}$ respectively are pseudo inlet and outlet temperatures of stream i at MHEX e regarding pinch candidate j. $qsoa_{j,e}$ is enthalpy of hot streams above pinch candidate j, and $qsia_{j,e}$ is enthalpy of cold streams above pinch candidate j. $t_{j,e}^{p}$ is pinch candidate. $y_{i,j,e}^{in}$ is binary variables to determine the value of pseudo inlet temperatures. $M1_{i,j,e}^{in}$ and $M2_{i,j,e}^{in}$ are sufficiently large numbers. ΔT_{e}^{min} is the minimum temperature difference for heat transfer.

Eq. (1) is the objective function to maximize overall heat recovery of MHEXs. Eq. (2) is the objective function to minimize operating cost of process. Eq. (3) represents energy balance of MHEXs, in which heat recovery obeys the conservation of energy. Eqs. (4)-(17) guarantee feasible heat transfer between hot and cold streams with temperature differences greater than or equal to ΔT_{e}^{min}. Eq. (4) ensures heat surplus above all pinch candidates. Eqs. (5) and (6) calculate the enthalpy of hot and cold streams above $t_{j,e}^{p}$ using the pseudo temperatures, which are determined by the multi-M constraints (Eqs. (7)-(15)). Eqs. (16) and (17) calculates pinch candidate $t_{j,e}^{p}$. Eqs. (18) and (19) denote the constraints of thermodynamics and unit operations (e.g. compressors and valves).

Here we use the calculation of pseudo temperatures of hot streams (Eqs. (7)-(10), (13), and (14)) to illustrate the multi-M formulation. Pseudo inlet temperature $tp_{i,j,e}^{in}$ is calculated via Eqs. (7)-(10). For $t_{i,e}^{in}\geq t_{j,e}^{p}$, $y_{i,j,e}^{in}$ must be equal to 1, and hence Eq. (7) is

reduced to $tp_{i,j,e}^{in} \leq t_{i,e}^{in}$ whilst Eq. (9) is relaxed into $tp_{i,j,e}^{in} \leq t_{i,e}^{in} + M1_{i,j,e}^{in}$. Together with Eq. (8), there is $tp_{i,j,e}^{in} = t_{i,e}^{in}$. Similarly, for $t_{i,e}^{in} \leq t_{j,e}^{p}$, we have $tp_{i,j,e}^{in} = t_{j,e}^{p}$. Pseudo outlet temperature $tp_{i,j,e}^{out}$ is governed by Eqs. (13) and (14) without using binary variable. The constraints ensure the hot streams' enthalpy above $t_{j,e}^{p}$ is not overestimated. Distinct from previous methods, the multi-M formulation avoids nonlinear formulation and reduces the number of binary variables, which are crucial to improve efficiency of an MINLP model.

3. Illustrative example

We use an ASU process to demonstrate the proposed modeling framework. Figure 1 illustrates a simplified flowsheet of the MHEXs in an industrial ASU. The process involves 2 MHEXs, 3 hot streams, 4 cold streams, 2 water coolers, 2 air compressors, 1 expansion turbine, and 1 expansion valve. Cooling of the ASU is delivered by the compressors, and is recovered by the MHEXs. The thermodynamics of the process is modeled based on SRK method. Process streams data are listed in Table 1. Composition of the process streams are presented in Table 2. The operating conditions of the units are specified in Table 3. The minimum temperature difference ΔT_e^{min} is equal to 3 K. Multi-objective optimization is achieved by ε-constraint method (Hwang and Masud, 1979). The model is implemented on GAMS 27.4 and solved by BARON.

The optimal solutions of the example are listed in Table 4. 2 points of interest, namely the maximum heat recovery solution and minimum operating cost solution, are presented. The results suggest that increasing outlet temperature and flow rate of H2 can increase heat recovery. However, the increase flow rate of H2 results in greater energy consumption of the compressors, which leads to higher operating cost.

4. Conclusions

A modeling framework was developed for simultaneous MHEXs and process optimization. In this model, MHEXs were modeled effectively using the multi-M formulation (Hui, 2014) that allowed variable stream data, avoided nonlinear approximation, and reduced the number of binary variables. Moreover, the proposed framework can be integrated with rigorous thermodynamics method, which enables the framework to be compatible with various processes. The proposed framework was applied to a realistic ASU design problem with multiple MHEXs. The results showed that the framework successfully handled complex process optimization problem. Eventually the framework will be extended to the entire ASU flowsheet including distillation columns, which is able to consider trade-offs between compressor power consumption, oxygen purity, heat recovery, and investment of equipment.

Abstract

The separation of ternary mixture with azeotropes by distillation into three high-purity products is difficult due to the existence of distillation boundaries. However, combinations of pressure swing distillation (PSD) configurations and recycle streams can provide alternatives for feasible pathways to the separation of the mixtures. In this work, a two-step approach is proposed to the optimal design of pressure swing distillation system to separate azeotropic ternary mixtures. An example of separating a ternary mixture with azeotropes of C2H5OH/C4H8O-01/C4H8O-02 is used for illustrating and validating the proposed method.

Keywords: ternary mixture; binary azeotrope; PSD; optimization;

1. Introduction

Several methods in industry are used to separate mixtures with azeotropic, including extractive distillation, azeotropic distillation, pressure swing distillation and relatively new membrane separation and so on (Luyben, 2012 and Soto, M, 2011, Xia et al. 2012). Application of extractive distillation or azeotropic distillation in industry is relatively mature. PSD is first proposed by Lewis (Lewis,1928), however, the pressure swing distillation from then has been mainly applied for separations of binary azeotropes where the composition of azeotrope is sensitive to pressure change, such as 2-butanone (MEK)-cyclohexane. Studying the separation of binary mixture (ethanol-water) separation, Knapp (Knapp,1992) mentioned that when the two components are in different distillation zones and the azeotropes are insensitive to pressure changes, a distillation boundary line, one end of which is sensitive to the pressure change can be formed by addition of a new component. However, such studies have been mainly focused in on binary azeotropic mixtures (Li et al. 2014, Li and Xu, 2017), few workers have addressed PSD for azeotrope containing ternary mixture separations (Yang and Gao, 2010).

In this paper, a approach to the conceptual design of PSD for separating a kind of azeotropic ternary mixture is proposed. If binary minimum-boiling azeotrope(s) is/are formed in a ternary mixture, and the composition of a binary azeotrope is sensitive to pressure, a three-column PSD process combined with two recycle streams can be designed by the method proposed in the following sections. The separation process of C2H5OH/C4H8O-01/C4H8O-02 ternary mixture will be used as an example to illustrate the method.

2. Generation of PSD flowsheet

2.1 Residual curve analysis

The residual curve map (RCM) at 101.3 kPa of C2H5OH/C4H8O-01/C4H8O-02 mixture is shown in figure 1. Three binary minimum azeotropes by each two of the components result in two distillation boundary lines. Three pure components to be separated are divided into three different distillation regions (as shown in Figure 1). As shown in figure 2, the composition of the C2H5OH/C4H8O-01 azeotrope is pressure sensitive. And thus, if the feed composition of the ternary mixture falls in Zone 2, it seems that a right pressure could be found so that the feed composition is on the C-D line, as shown in figure 3, and a distillation column, say column T1, can be used to separate the ternary mixture into the product of C4H8O-02 at the bottom of T1 and the azeotrope of the other two components at the top. However, if the position of feed locates in the remaining two zones, no matter how the pressure changes, no a feasible distillation exists to separate the ternary mixture into a pure component and a binary azeotrope mixture, as shown by the D-E and B-F lines. So, our design method is valid only when the feed composition locates in Zone 2.

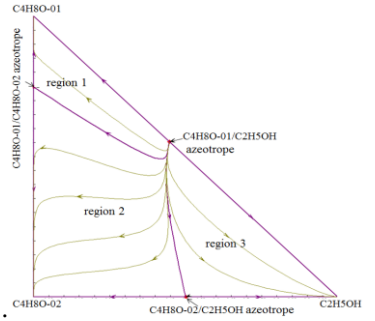

Fig. 1 RCM of the ternary mixture at 101.3 kPa

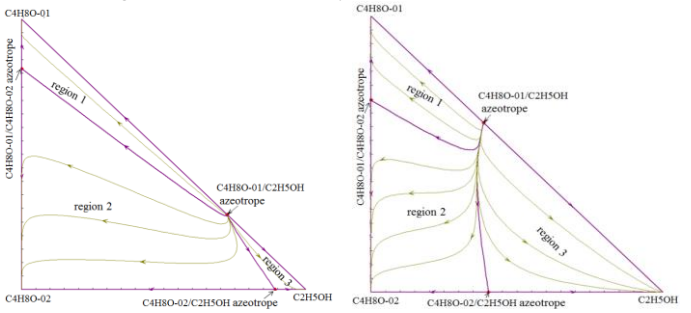

Fig. 2 RCMs of the mixture at different pressures: (a) 600 kPa; (b) 50 kPa

Figure 3 also implies that azeotrope composition at the opposite side of the triangle should be sensitive enough to pressure so that a C-D line can be found for a proper feed composition of the ternary mixture. Inspired by figure 3, we find that the top product can be introduced into a column, let say T2 that operates in a lower pressure so that the bottom product can be pure component B and at the top we can get an azeotrope with richer component A. This azeotrope can then be introduced to a column T3 with higher pressure to produce in the bottom the pure A and the top the azeotrope richer with B, which can be recycled to column T2. As a result, the ternary mixture is separated into three pure components by the three-column distillation system.

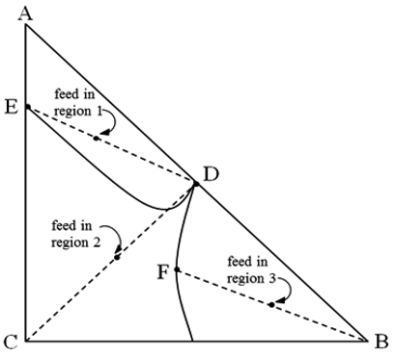

Fig. 3 Possible distillation separations for three kinds of feed compositions

2.2. Synthesis of three-column PSD process

Suppose that the feed flowrate is 10 kmol·h^{-1} with a temperature of 25 ˚C and a pressure of 101.3 kPa. The composition of feed and the product requirements are given in Table 1. It is found in our calculation that the cost of the distillation by column T1 depends on its pressure, and 600 kPa is found having the lowest cost by calculating its TAC and comparing with other four cases having different pressures of T1 column. The corresponding residue curve combination chart is shown in Figure 4. In this case, C2H5OH product (B2) should be added to the feed so that FEED moves to FEED1 that locates on the B1-D1 line as shown in Figure 4. The process chart of the three-column PSD obtained from Figure 4 is shown in Figure 5. The operating pressures for the three columns are 600 kPa, 50 kPa and 101.3 kPa, respectively. The feed stream needs to be pressurized to 600 kPa before mixed with part of C2H5OH product from T2.

Table 1 The composition of raw materials and product specifications

Components	Composition /%(mol)	Product specifications /%(mol)
C2H5OH	33	99
C4H8O-01	20	99
C4H8O-02	47	99

In this case, the corresponding distillation boundaries become the blue curves in Figure 4. The mixed feed stream FEED1 passes through T1 column, C4H8O-02 product is obtained at the bottom, i.e. B1 in Figure 4, and the C2H5OH/C4H8O-01 azeotrope (D1) is obtained at the top. After decompression to 50kpa, the stream of composition of D1 enters T2, the distillation boundaries after decompression becomes green line with in Figure 4. And D1 and C2H5OH product are in the same distillation zone, after separation in T2, the C2H5OH product is obtained at the bottom, i.e. B2 in Figure 4; Part of the product recycles back to form the feed to T1, and the rest is recovered as C2H5OH product. The top product of T2 of composition of D2 is introduced into T3 and separated at pressure 101.3 kPa into C2H5OH/C4H8O-01 azeotrope of composition D3 at the top of T3 and C4H8O-01 product at the bottom, and now, the corresponding distillation boundaries are red lines; then the D3 stream is depressurized to 50 kPa and then is recycled to column T2, to form the feed composition of FEED2 to column T2. Finally, the ternary mixture is effectively separated by three-column PSD process.

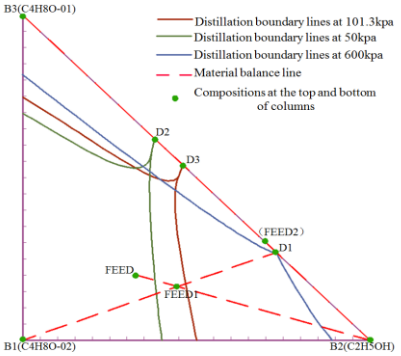

Fig. 4 Distillation boundaries at different operating pressures

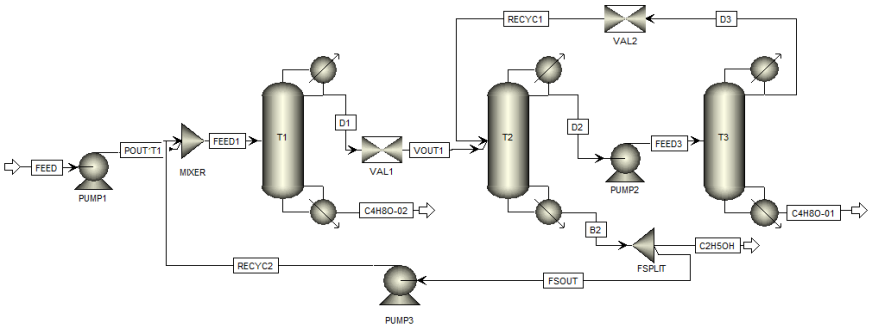

Fig. 5 PSD configuration for the ternary mixture separation

2.3 Selection of column pressures

The position of the original feed in the residue curve is changed by varying pressure of T1column and recycle flow rates of C2H5OH product, as shown in Figure 4 and then column T1 can separate C4H8O-02 product and C2H5OH/C4H8O-01 azeotrope. Figure 6 gives the corresponding distillation boundaries at 600 and 700 kPa respectively. And thus, the corresponding composition of the feed to T1 is FEED1 and FEED1*, respectively. In this way, six different pressures (P1=570, 600, 700, 800, 900 and 1000 kPa) for column T1 are tested to find the best one. It is found that when P1 is 600 kPa, the corresponding temperature of T1' bottom, 419K, attended the maximum temperature that can be provided by the medium-pressure steam used as the hot utility. To use less expensive cooling water as cold utility, P2 (pressure of T2) takes 50 kPa; the corresponding temperature of C2H5OH/C4H8O-01 azeotrope is 326 K. P3 (pressure of T3) is 101.3 kPa, meeting the conditions that the difference between azeotropic compositions at the top of T2 and T3 is greater than 5mol%.

3. Optimization results and discussion

In this paper, the total annual cost (TAC) as a criterion is estimated using the method suggested by Douglas (Douglas, 1988). In this section, column T1 at 600 kPa is optimized as an example to illustrate the optimization.

3.1 Optimization of the flow rate of RECYC2

Figure 7 gives the changes in purity of products at the top and bottom of column T1 with the recycle stream. It shows that when the flowrate of RECYC2 is 2.2 kmol•h^{-1}, the purity of C4H8O-02 product at the bottom of T1 reaches the maximum value.

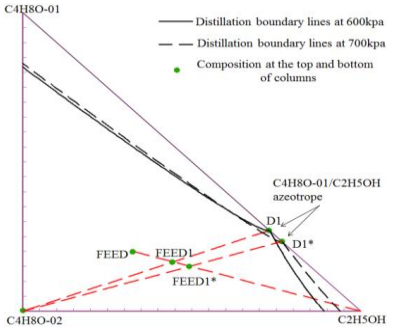

Fig. 6 RCMs of C2H5OH/C4H8O-01/C4H8O-02 at 600kpa and 700kpa

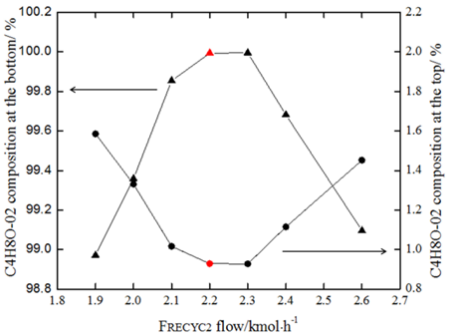

Fig. 7 The dependence of the T1 column product purities on the flow rate of RECYC2.

3.2 Optimization of T1 column

Figure 8 shows the relationship between the number of stages (NS1) in T1 and the reflux ratio (RR1). The value corresponding to where the number of column plates varies most significantly with the slope of reflux ratio curve is selected as the optimum number of theoretical stages, and the corresponding reflux ratio is taken as the optimum. As shown in Figure 8, NS1 is 97 and the corresponding RR1 is 28.6. As shown in Figure 9, the feed stage position (FS1) of T1 is 45.

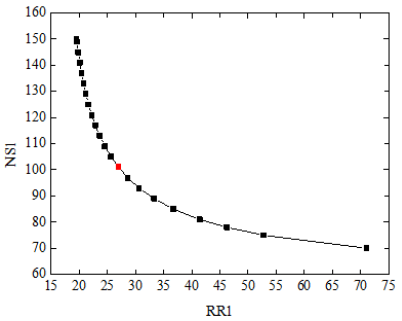

Fig. 8 Relationship of NS1and RR1 in T1column

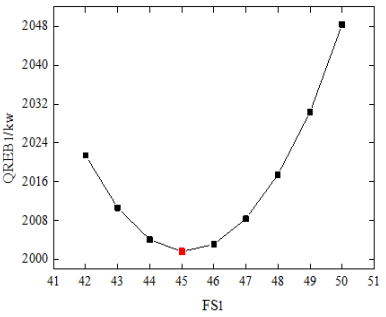

Fig. 9 The dependence of the reboiler heat duty on feed stage of T1 column

3.3 Optimization of columns T2 and T3

A method of sequential iterative optimization for T2 and T3 column is adopted in this paper. This method is widely used in many studies of optimization of PSD. Results of five case studies at different pressures of T1 are collected in Table 2. The heat duty of T1 is much greater than the sum of the heat duties of the other two columns, therefore, the difficulty in separating the mixture lies in the separation of C4H8O-02. It is found that when P1 is 600 kPa, the total annual cost (TAC) is 1025.2×103/$·y^{-1}, the lowest cost value, 6.27% lower than that when P1 is 800 kPa.

Table 2 Result of case studies at different pressures of column T1

Variables	**Case1**	**Case2**	**Case3**	**Case4**	**Case5**
P1/kPa	600	700	800	900	1000
NS1/ NS2/ NS3	97/45/50	102/43/50	95/55/67	104/54/60	95/55/55
FS1	45	79	71	80	70
FSD1/FSRECYC1	19/13	30/27	24/19	22/15	32/23
FS3	25	39	26	24	35

RR1/ RR2/ RR3	28.6/1/1.5	25.6/1.7/1.5	21.2/1.2/2	18.7/1.2/1.5	15.5/1.2/1.5
FRECYC1/kmol • h^{-1}	2.2	3.3	4.5	6.0	8.8
QREB1/kW	2002.1	2052.5	1944.6	1989. 8	2089.7
QREB2+QREB3/kW	650.9	641.2	660.2	629.4	576.0
TAC×10^3/$ • y^{-1}	1025.2	1094.0	1089.5	1102.7	1104.4

4. Conclusions

Using the residue curves under different pressures, a method to synthesis a PSD system separating a kind of ternary mixtures with azeotropes is proposed. Separation of mixture C2H5OH/C4H8O-01/C4H8O-02 is used to illustrate the method. If the feed composition falls in a distillation area containing C4H8O-02 product, separation of three components can be achieved. A three-column PSD process with two recycle streams has been proposed to have achieved effective separation of the mixture. Furthermore, the operating pressure of T1 not only determines the economy of the column itself, but also determines the flowrate of the RECYC2, thereby affecting the economy of the overall process. By choosing five cases with different pressures of T1, this paper has studied the influence of P1 on the economy, with the optimized calculation results shown in Table 2.

Abstract

Conceptual design of novel efficient hydrogen production processes is essential to realizing a future clean energy scenario. Traditional approaches to process design involve detailed modelling of unit operations followed by simulation and optimization steps. However, several implicit assumptions may be made in the detailed models and these limit the efficiency of the overall process. In addition, potentially efficient novel technologies may not be considered. In this paper, fundamental thermodynamic principles are used within the framework of the "G-H" methodology (G denotes Gibbs free energy and H denotes enthalpy) for synthesis of an efficient hydrogen production process. The optimal chemical route is determined and termed the "1-step reaction". However, the G-H methodology assumes complete conversion, which may not be optimal or even feasible for all reactions. Thus, this paper extends the G-H methodology to make it more realistic by including conversion as a variable. This methodology is then applied to a case study of flowsheet synthesis that uses separation and recycle to achieve 80% conversion. The flowsheet is simulated using Aspen HYSYS and an exergy analysis is performed. An overall exergetic efficiency of 81.8% is achieved and this represents an ideal target to motivate future technology improvements.

Keywords: Conceptual design, Hydrogen production, Process synthesis.

1. Introduction

Hydrogen is a clean fuel and is thus expected to play an important role as an energy carrier in a future decarbonized energy scenario. However, global hydrogen production currently is dominated by fossil-fuel based processes with significant inefficiencies. Conceptual design of novel efficient processes is essential to realizing a hydrogen-based energy economy. Traditional approaches to process design have focused on detailed modelling and optimization of unit operations (such as reactors, distillation columns and heat exchanger networks) followed by assembling these into a flowsheet. The interaction between the different units is not emphasized implying the overall flowsheet may be inefficient even with optimized individual unit operations. More recently, superstructures are generated of unit operation alternatives, followed by simulation and optimization using mathematical programming techniques. However, the optimal solution is only as good as the superstructure considered (Hildebrandt et al., 2015), and potentially efficient processes may be excluded. This is especially true for novel technologies since

superstructures tend to only include well-understood mature technologies. Furthermore, several implicit assumptions (such as chemical routes, temperature and pressure ranges) may be made in the detailed models of the individual unit operations and thus may limit the efficiency of the overall process.

An alternative approach is to use fundamental thermodynamic principles for process design through targeting and synthesis steps. Patel et al. (2007) developed a methodology based on mass, energy and entropy balance perspectives to target for the optimal chemical route while making as few assumptions as possible. Fox et al. (2013) developed the systematic "G-H" methodology, which uses information about the Gibbs free energy (G) and enthalpy (H) for process synthesis to derive the operating conditions (temperatures, pressures, stream flow rates) that result in highest thermodynamic efficiency. It is assumed that complete conversion can be achieved in all the equilibrium-limited reactions. Hildebrandt et al. (2015) illustrated the value of this methodology using a case study of a coal-to-liquids process. The key principle is to begin with a thermodynamically ideal process target and synthesize flowsheets that approach this target. Then, the unit operations of the flowsheet are mapped onto existing technologies. However, there are usually no existing technologies to achieve the ideal process target. In particular, it may not be optimal or even feasible to achieve complete conversion. Thus, this paper extends the G-H methodology to include conversion as a variable such that the resulting flowsheet is realistically achievable. No restrictions are made on the specific method used to achieve this conversion. The extended G-H methodology is then illustrated with a case study of flowsheet synthesis for a single-step hydrogen production process.

2. Methodology and Application to Hydrogen production process design

2.1. Chemical Route Targeting

The target of the overall process is to convert as much feed to useful product(s) as possible while satisfying material balance constraints. Patel et al. (2007) developed a methodology to determine the optimal chemical route that satisfies this target. The methodology is applied in this work to determine the best chemical route that converts a unit mole of methane to the maximum amount of hydrogen. Water and carbon dioxide are chosen as reacting species (Eq.(1)) and the material balance constraints are presented in Eq.(2).

Solving Eq.(2) gives the reaction presented in Eq.(3), hereafter referred to as the "1-step reaction" because it combines the well-known Steam-Methane Reforming (SMR), Water-Gas Shift (WGS) and steam generation processes. The technological feasibility of the 1-step reaction has been experimentally demonstrated by Malerød-Fjeld et al. (2017). A $BaZrO_3$-based proton-conducting electrolyte deposited as a dense film on a porous Ni composite electrode was used as the catalyst. Lee et al. (2007) also presented a process concept in which the SMR and WGS reactions were carried out in the same unit operation. The 1-step reaction requires heat and work in order to proceed. Thus, heat integration

$$1\mathrm{CH_4(g)} + \nu_1\mathrm{H_2O(l)} + \nu_2\mathrm{CO_2(g)} \rightleftharpoons \nu_3\mathrm{H_2(g)} \tag{1}$$

$$1 + \nu_2 = 0; \quad 4 + 2\nu_1 = 2\nu_3; \quad \nu_1 + 2\nu_2 = 0 \tag{2}$$

$$\mathrm{CH_4(g)} + 2\mathrm{H_2O(l)} \rightleftharpoons \mathrm{CO_2(g)} + 4\mathrm{H_2(g)} \quad (\Delta H_{1-step} = 252.95\,\mathrm{kJ/mol},\ \Delta G_{1-step} = 130.69\,\mathrm{kJ/mol}) \tag{3}$$

$$\begin{aligned} &CH_4(g) + 2O_2(g) \rightleftharpoons CO_2(g) + 2H_2O(g) \\ &(\Delta H_{comb} = -802.35\,\text{kJ/mol}, \Delta G_{comb} = -800.71\,\text{kJ/mol}) \end{aligned} \quad (4)$$

with an exothermic process is necessary. This heat could be provided by methane combustion (Eq.(4)) as is done in standard SMR processes today.

2.2. Thermodynamics of Chemical reactions

The G-H methodology uses the results (Eq.(5)) that a reaction's heat (Q) and work (W) requirements can be derived from the 1st and 2nd laws of thermodynamics. Work can be added by compression, separation or together with heat (Patel et al., 2010). In this paper, the reactor work requirements are supplied together with heat. For the work requirements to be exactly supplied together with heat, the reactor has to be run at a particular temperature called the "Carnot temperature", T_{Carnot} (Patel et al., 2010). Eq.(6) gives the relationship between a reaction's heat and work requirements and its Carnot temperature. Patel et al. (2010) demonstrated that reactors running at their Carnot temperature are reversible and hence are thermodynamically efficient. The Carnot temperatures of the 1-step reaction and the combustion reaction are 616.9 K and 145,866.3 K respectively.

$$Q = \Delta H_{reaction} \quad ; \quad W = \Delta G_{reaction} \quad (5)$$

$$W_{comb} = Q_{comb}\left(1 - \frac{T_0}{T_{Carnot}}\right) \quad (6)$$

The Carnot temperature of the combustion process is not technologically feasible, thus the process has to be run at a lower temperature. This deviation introduces irreversibilities implying that the methane combustion reaction is inherently inefficient. A lower operating temperature of 626.9 K is chosen such that the 1-step reactor can be placed inside the furnace with $\Delta T_{\min}$ of 10 K.

2.3. Integrating equilibrium-limited chemical reactions

In order to synthesize a process flowsheet, only the input and output parameters (or the transfer characteristics that relate the output to input parameters) of the different unit operations are relevant. In an equilibrium reactor, conversion is the relevant transfer function and thus an important variable. Equilibrium-limited reactions running at their Carnot temperatures do not necessarily achieve complete conversion. Approaches used to shift the equilibrium to the right include continual separation and removal of products using membrane reactors (Malerød-Fjeld et al., 2017) or sorption-enhanced reactors (Lee et al., 2007), and separation and recycle of unreacted feed. It is commonly not optimal or even technologically feasible to achieve complete conversion. Thus, the G-H methodology has to be extended to account for incomplete conversion as illustrated next.

For a stoichiometric feed, the change in the number of moles of each component is proportional to the stoichiometric coefficient; the extent of reaction (e) is the proportionality constant. Conversion (c) is the fraction of the stoichiometric feed that reacts. Thus, the extent of the reaction is given by: $e = f * c$. f is termed the "multiple of the stoichiometric feed" since the molar flow rate of each reacting component can be determined by multiplying f with the corresponding stoichiometric coefficient. The rationale for using f is to have a single number from which the feed flow rates can be

$$\begin{pmatrix} \Delta H_{overall} \\ \Delta G_{overall} \end{pmatrix} = \begin{pmatrix} \Delta H_{1-step} \\ \Delta G_{1-step} \end{pmatrix} \left(f_{1-step} * c_{1-step} \right) + \begin{pmatrix} \Delta H_{comb} \\ \Delta G_{comb} \end{pmatrix} \left(e_{comb} \right) \quad (7)$$

determined for flowsheet synthesis. With this definition, the overall process thermodynamics (Eq.(7)) can be determined by adding the heat and work requirements of each reaction scaled by the corresponding extent of reaction (with the substitution $f * c$ made for the equilibrium-limited 1-step reaction).

In the G-H methodology (Fox et al., 2013), design decisions are made to determine the unknowns in Eq.(7) ($\Delta H_{overall}, \Delta G_{overall}, f_{1-step}, c_{1-step}, e_{comb}$). These design decisions include: Requiring no wastage of methane (i.e. $e_{comb} = 1 - f_{1-step} * c_{1-step}$), requiring no loss of excess heat irreversibly to the environment (i.e. $\Delta H_{overall} = 0$), and assuming that a conversion target (c_{1-step}) of 0.8 is technologically feasible. Eq.(7) can be solved to give f_{1-step} of 0.95. The conversion target is a variable that can be set to any value. Determining the optimal conversion target requires insight into the specific conversion enhancement method and is as an important task for future work. The flow rates of all streams are derived from f_{1-step} and presented in Figure 1. $\Delta G_{overall}$ is -1.50 kJ/mol implying that the combined process is feasible. Reactor pressures are set such that all the available work can be extracted (Fox et al., 2013). The net work is the difference between the work supplied by expansion of products from the reactor pressure and the work required for compression of feed to reactor pressure. In this case study, no work is extracted since $\Delta G_{overall}$ is negligible thus the pressures of the two reactors are both 1 bar. The proposed flowsheet was simulated using Aspen HYSYS v9.0. Conversion of 80 % is achieved using separation and recycle of unreacted feed. The unreacted methane from the 1-step process is fed to the combustion process. An exergy analysis is then carried out to evaluate process performance.

3. Results and Discussion

Table 1 shows that the furnace destroys the most exergy as expected. The methane combustion reaction is inherently inefficient because its Carnot temperature is not practically achievable. This implies that future design efforts should focus on lowering the extent of the combustion reaction or eliminating it altogether by finding alternative heat sources. An interesting concept was suggested by Adams and Barton (2011) who proposed using the exothermic coal gasification process as a heat source. Other alternatives arise from novel process intensification technologies. For instance, the Protonic Membrane Reactor presented by Malerød-Fjeld et al. (2017) uses the heat generated from the galvanic operation of the membrane. The endothermic 1-step reaction and the exothermic processes are spatially coupled resulting in microscale heat integration. If the 1-step reactor is co-located with other industrial process systems, heat integration with background hot streams may also be possible. Herein lies one of the advantages of the 1-step reaction compared to the SMR or WGS reactions. The Carnot temperature of the 1-step process (616.9 K) is significantly lower than the Carnot temperatures of the SMR (960.8 K) or the WGS (974.7 K) reactions implying there is a greater chance of finding background process streams for heat integration.

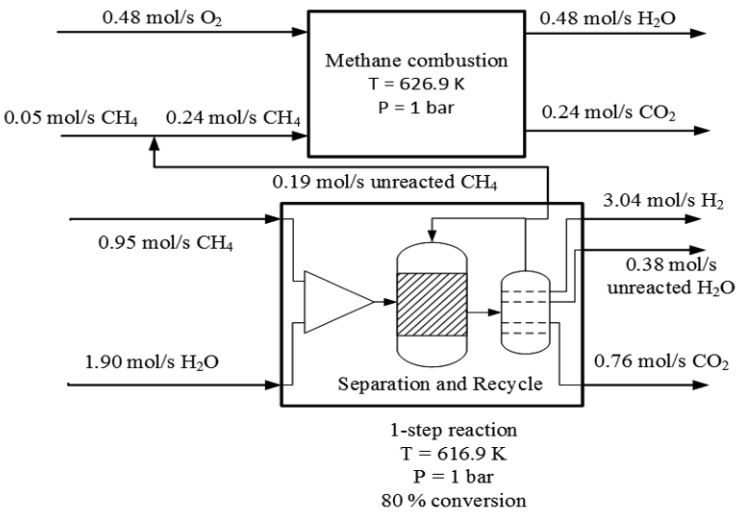

Figure 1: Flowsheet for hydrogen production using the 1-step reaction

Table 1: Exergy analysis of hydrogen production process

Component	Exergy Destruction (%)
Feed mixers	4.1
1-step reactor	6.3
Combustion furnace	65.6
Separation processes	24.0

The separation process, that includes both separation of the product stream into pure components and separation of the unreacted feed for recycle, also destroys a significant amount of exergy. Thus, there is a trade-off between the chosen conversion target and the exergetic efficiency: Larger amounts of exergy are destroyed in the separation process because of higher recycle to achieve a higher conversion. This implies an optimization step is essential to determine the conversion target.

The overall exergetic efficiency ($\frac{\text{Total Useful Exergy Out}}{\text{Total Exergy In}}$) is 81.79%. This represents the upper-bound attainable because of two reasons. First, while the flowsheet in Figure 1 is technologically feasible, it corresponds to the conceptual phase. Detailed modelling of the unit operations inevitably introduces irreversibilities resulting in lower exergetic efficiency (Anantharaman et al., 2013). Second, while the flowsheet represents a thermodynamically optimal process, it may not necessarily be economically optimal. Detailed modelling and optimization with respect to net present value may result in a different design with lower exergetic efficiency.

4. Conclusions

This paper extends the G-H methodology to make it more realistic by including conversion as a variable. This extended methodology is then applied to a case study of flowsheet synthesis for a hydrogen production process that uses separation and recycle as a conversion enhancement method. A conversion target of 0.8 was chosen but this could

be optimized. Determining the optimal conversion target is an important task that requires insight into the specific conversion enhancement technology. Current work by the authors focuses on developing a methodology to estimate the conversion achievable in a membrane reactor at the conceptual stage. The optimal chemical route, termed the 1-step reaction, is determined and validated by existing technologies. The 1-step reaction intensifies the SMR, WGS and the steam generation processes into a single unit operation, thus showing potential to lower capital and operating costs as well as to reduce the number of units. In addition, the 1-step reaction can be run efficiently at a lower temperature than the SMR or WGS reactions, thus increasing the chance of finding suitable background streams for heat integration. The methane combustion reaction destroys the most exergy, thus future design efforts should focus on utilizing alternative heat sources. Current work by the authors focuses on developing polygeneration strategies that include additional feedstocks with exothermic processing steps.

The key principle behind the extended G-H methodology is to begin with a thermodynamically ideal process target and synthesize a feasible flowsheet that approaches this target. Then, the unit operations of the flowsheet are mapped onto existing technologies. If there are no existing technologies, this highlights an improvement potential to motivate the development of novel technologies (Anantharaman et al. 2013). Thus, this approach uses fundamental thermodynamic principles applied at the systems level to influence where to focus technology development efforts rather than the opposite approach of generating a flowsheet based on existing technologies. Therefore, this paper presents a novel and more realistic thermodynamic approach to process synthesis and design.

Abstract

The design of optimal sustainable processes must be performed relying on systematic steps, which must guide the users to take the best decision in terms of given objectives. This study proposes and implements a framework consisting of organized steps combining methods and tools, using as a case study the separation and purification of the acetone-butanol-ethanol (ABE) mixture obtained from a fermentation broth. A feasible configuration to that end includes the use of liquid-liquid extraction (LLE) columns followed by conventional distillation columns. Thus, the framework includes a molecular design step to tailor-made the extractant agent employed in the LLE unit with the desired properties, the process design of the required equipment for the ABE separation, and finally an optimization step using a hybrid stochastic optimization method, differential evolution with taboo list. The results allowed to reduce the total annual cost by 67 % and the environmental impact by 72 % relying on the eco-indicator.

Keywords: ABE, Eco-Indicator, liquid-liquid extraction, molecular design, heptyl acetate.

1. Introduction

The lignocellulosic butanol has been identified as a potential biofuel since it has showed some advantages compared with bioethanol such as: better blending with gasolines, it has higher energy content, it is less hydrophilic, etc. The production of butanol relying on a fermentation process has been done employing bacteria from the genera Clostridia. The possible advantage of this fermentation is that the bacteria also produce simultaneously acetone and ethanol, which firstly make consider that this could be a multiproduction process (Morales-Rodriguez et al, 2014); however, the simultaneous acetone-butanol-ethanol (ABE) production increases the complexity in the separation of the products, specially, the butanol. This has originated that several studies have aimed to find the best separation and purification configuration, for example, employing conventional distillation, extractive distillation and hybrid processes including liquid-liquid extraction (LLE) and distillation columns (DC) configurations (Kraemer et al., 2010). Errico et al. (2015) proposed 9 alternative hybrid process configurations, which showed an interesting variety of technologies to achieve his separation, for instance, hybrid extraction, thermally coupled alternatives, intensified configurations, etc.

A literature survey allowed identifying the possible process candidates for the ABE separation and purification. Previous works focused on biobutanol purification process have shown some benefits in terms of cost and controllability (Errico et al., 2015). Nevertheless, the first step for the LLE is the identification of the extractant, which is commonly identified and selected employing an experimental trial and error approach; thus, generating some drawbacks for the efficient process design, making it expensive in term of time and economic aspects. Moreover, the process design task not necessarily would provide the optimal process configuration, therefore, an optimization effort is necessary to find the best process design. Thus, the use of a systematic methodology including diverse methods and computer-aided tools could assist to overcome those issues, thereby, the objective of this work is to propose a framework for optimal molecular and sustainable process design to separate and purify the acetone-butanol-ethanol mixture employing a LLE system and conventional DC.

2. Optimized sustainable molecular and process design framework: LLE and DC approach

The framework for optimized molecular and sustainable process design includes 7 steps: 1) the data collection and state of art analysis related with LLE; 2) the molecular design task, aiming to find the potential extracting agents with tailor-made characteristics, employing a computer-aided molecular design (CAMD) (Harper et al., 1999); 3) selection of the extractants based on the cost, market availability and toxicity, and the thermodynamic model suitable for the mixture to separate; 4) evaluation of extractant candidates in a simulation tool (Aspen plus, PRO II, etc); 5) comparison of the evaluated extracting agent with the base case (BC) in order to determine its performance and continue with the design of the subsequent equipment, whether the performance of the candidate is worse than the BC scenario in terms of selected criteria, it is possible to return to step number 3 to select another candidate, otherwise, just continue with the next step; 6) process design employing shortcut methods followed by a sensitivity analysis to refine the process specification, and finally, the selection of configurations with better performance based on product recovery, purity and operating cost; 7) multiobjective optimization employing differential evolution (DE) and taboo list (TL) methods, minimizing the total annual cost (TAC) and the environmental impact (EI) calculated with the Eco-indicator 99; and finally the selection of the best configuration based on a Pareto front.

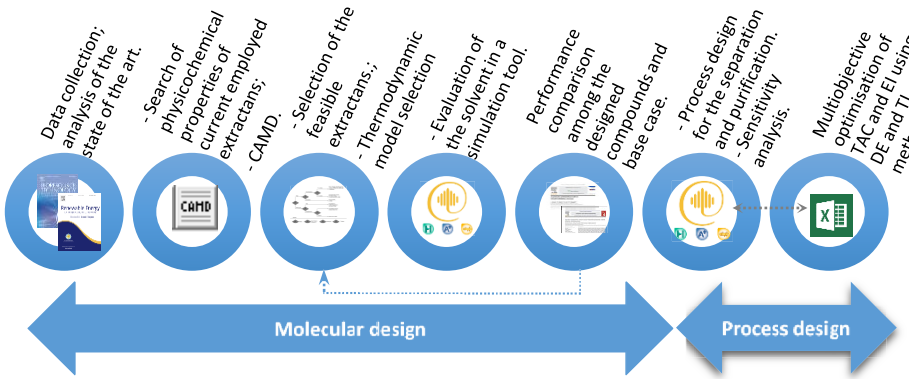

Figure 1. Optimized molecular and sustainable process design framework.

3. Implementation of systematic framework for molecular and sustainable process design: ABE separation from fermentation broth

The framework used as case study the separation of a fermentation broth containing ABE, water, carbon dioxide and hydrogen, since the residual sugars such as glucose and xylose are separated in distillation column before entering to the LLE unit.

3.1. Data collection and state of the art analysis

The implementation of LLE includes the selection of extractant agent. Kraemer et al. (2010) employed 1,3,5-trimetilbenzene (mesitylene). Moreover, Morales-Espinosa et al. (2017) employed hexyl acetate (HEX) as extractant agent having better results than using mesitylene. In any case, there is still necessary to search an environmentally friendlier and economic extractant agent substitute.

3.2. Computer-aided molecular design

The potential extractant agent can be designed relying on CAMD principles. Thus, it is necessary to list the desired characteristics of the reference extractant (mesitylene), such as, partition coefficient, water solubility, vapour pressure, not azeotrope formation with the present compounds, etc. That information is specified in the Pro-CAMD that is available in the Integrated Computer Aided System (ICAS). The Pro-CAMD designed a number of candidates that were reduced by manipulating the lower and upper limit values of the desired characteristics, ending with 846 compounds.

3.3. Selection of the potential candidate to be used as extractant and the thermodynamic model

The discrimination to determine the final list of potential candidates was obtained checking the existence or availability of the compound in the market, and also the commercial prices compared with the reference compound. The heptyl acetate (HEP) as well as the HEX (previously analysed by Morales-Espinosa et al., 2017) were found as the most promising substitutes for the mesitylene. Thus, in this study the HEP was chosen to be evaluated. Since all the involved compounds were known, the NRTL and Hayden O'Connell thermodynamic models were selected to describe the liquid-vapour equilibrium, respectively.

3.4. Evaluation of the potential extractant candidate

The HEP and mesitylene were tested in a LLE unit with the same number of stages (5), process conditions (T = 35 °C and P = 1 atm) and molar-based feeding ratio (1:0.84, mixture and extractant, respectively).

3.5. Comparison of the potential candidate vs base case extractant

The results employing HEP had similar ABE recovery. In addition, the commercial price of mesitylene compared with HEP was 2.62 times higher, thereby, finding the HEP as a better candidate in terms of economics and performance.

3.6. Process design for separation and purification.

The process configuration is shown in Figure 2, which was design relying in heuristic rules, then the equipment design was done using shortcut methods for the DC and a sensitivity analysis to improve the LLE design and the DC. Once, the design is gotten a rigorous simulation is performed using EXTRACT unit for LLE and RADFRAC for the three DC in Aspen plus (AP). The LLE unit (C-101) is employed to remove the water from the fermentation broth and the columns D-101 and D-102 are used to purify the HEP and butanol, respectively. The D-103 unit separates the acetone, hydrogen and carbon dioxide from the ethanol and water traces.

wCO_2	0.0058
wH_2	0.0001
wH_2O	0.6710
Flow rate (kmol/h)	299.091

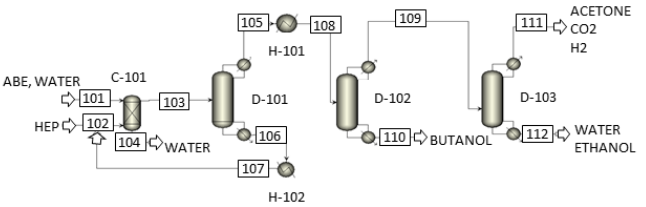

Figure 2. Process configuration for the ABE separation using HEP as extractant agent.

3.7. Multiobjective optimization

3.7.1. Objective Function

The objective function included the simultaneous minimization of the TAC and the eco indicator 99. The minimization of these objectives was subject to the required recoveries and purities in each product stream (see Equation 1).

$$Min\left(TAC, Eco\ 99\right) = f\left(N_{tn}, M_{in}, N_{fn}, R_{rn}, F_{rn}, D_{cn}\right),\ subject\ to\ y_m \geq x_m \tag{1}$$

where N_{tn} are total column stages in LLE column and DCs, M_{in} is the feeding flowrate of extractant to the LLE, N_{fn} is the feed stage of all streams in columns, R_{rn} is the reflux ratio, F_{rn} is the distillate fluxes and D_{cn} is the column diameter, y_m and x_m are vectors of obtained and required mass purities (95%, 99.5% and 83% for ABE) with the mass recoveries (98%) for the m components, respectively. This minimization implied the manipulation of 18 continuous and discrete variables. The TAC calculation was performed as it is shown in Equation 2.

$$TAC = \frac{Capital\ Cost}{Payback\ period} + Operative\ cost \tag{2}$$

On the other hand, the environmental indicator was measured through the eco-indicator 99 based on the methodology of the life cycle analysis (Geodkoop and Spriensma, 2001). In the eco-indicator 99 methodology, 11 impact categories were considered, aggregated into three major damages categories: (1) human health, (2) ecosystem quality, and (3) resources depletion.

3.7.2. Global stochastic optimization strategy

To optimize the process route for biobutanol production, a stochastic optimization method, Differential Evolution with Taboo List (DETL) was used, which have shown being robust to optimize intensified separation systems. Srinivas and Rangaiah (2007) showed that the use of some concepts of the metaheuristic taboo can improve the performance of DE algorithm. The implementation of this optimization approach was made using a hybrid platform where the DETL was coded using Microsoft Excel (ME) and the separation process was rigorously simulated using AP. The vector of decision variables (i.e., the design variables) is sent from ME to AP using DDE (Dynamic Data Exchange) through COM technology. For the optimization of process routes analysed in this study, the following parameters for DETL method were used: 200 individuals, 300 generations, a taboo list of 50% of total individuals, a taboo radius of 0.0000025, 0.80 and 0.6 for crossover and mutation fractions, respectively.

The results of the optimization are illustrated in Figure 3. There are various possible combinations that could be selected as optimal as it is shown inside the oval. For example, the optimal value could be the point (a). However, there are other combinations with lower TAC (point b and c), but higher eco-points. Comparing the eco-points values for point (a) with points (b) and (c), the differences are higher by 0.7%. and 1.21%, respectively; with a difference of 9,609 points/year for point (b) and 16,632 points/year for point (c) compared with the 1,353,369 points/year for point (a). In addition, the TAC was decreased by 5.5% when comparing point (a) and (b). Therefore, the optimal design is the point (b) with TAC = 4,481,469 US$/year and eco indicator = 1,362,978 points/year. The comparison between the optimal scenarios for TAC and eco-points with the base case (BC) scenario, indicated that the base case (point d) was 3 times higher for TAC and 3.6 for the eco-indicator, thereby, the optimization task undoubtedly achieved its objectives. Table 1 shows the optimal (Opt) specifications compared with the BC scenario. The results showed the D-101 and D-102 units are shorter, and the reflux ratio was highly decreased due to the optimization implementation; on the other hand, it was found for D-103 that it is more convenient having a larger unit operation, but whether the reflux ratios are compared, the BC is 11.72 times higher than optimal. For all the distillations columns, the reduction in the reflux ratio results in a reduction of the operation cost because of the heat duty decrease.

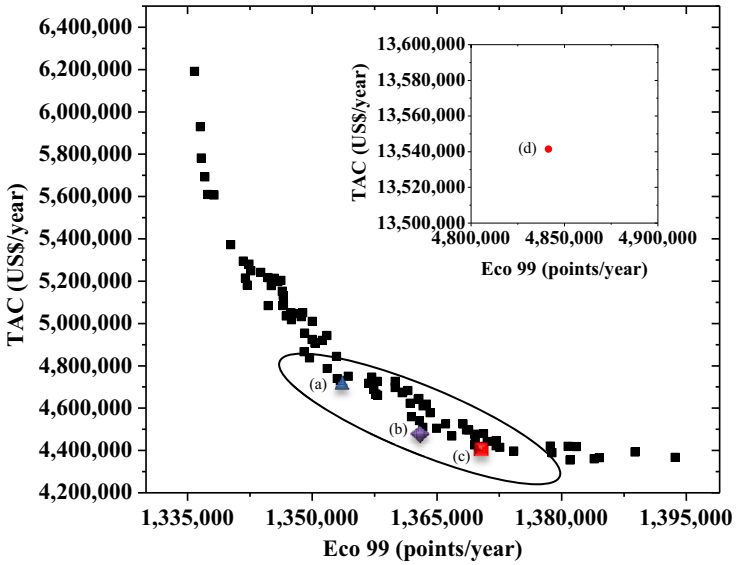

Figure 3. Pareto Chart for determining the optimal process design in terms of economic and environmental aspects.

4. Conclusions

This study proposed a framework for optimized molecular and sustainable purification process design, which was possible due to the combination of different methods and computer-aided tools. The results showed an improved design by reducing the TAC and the eco-indicator 67% and 72%, respectively. The enhancement was achieved due to the appropriate molecular design that provided a cheaper candidate with the similar

performance as some previous extractant agents; in addition with the improvement of the process design by finding the proper unit characteristics relying on the DETL method.

Table 1. Specifications of the unit operations included in the downstream section.

Unit	Base case	Optimal design

Abstract

Natural gas liquefaction is an energy intensive process with very small driving forces at cryogenic temperatures. Small temperature differences arise from the excessive exergy destruction that occurs from irreversible heat transfer at low temperatures. As a result, even a small change in driving forces in the low temperature region can propagate into large exergy losses that must be compensated by additional compression power. Along with the significant investments and operating costs associated with these processes, this demands a robust and accurate simulation tool. Nonsmooth simulation models for single mixed refrigerant processes already exist in the literature. However, these processes are relatively simple, and are normally only considered for small-scale production or floating operations. Other processes, such as dual mixed refrigerant processes, are therefore normally considered for large-scale production of LNG. It is necessary to investigate whether the nonsmooth flowsheeting strategy is capable of also handling these more complex liquefaction processes. This article describes a simulation model for a dual mixed refrigerant process. The model is solved for two cases using the Peng-Robinson equation of state, each solving for a different set of unknown variables. Both cases converged within a few iterations, showing nearly identical results to simulations run in Aspen Plus.

Keywords: LNG, DMR process, nonsmooth modelling, process simulation.

1. Introduction

Liquefied natural gas (LNG) plays an important role as an energy carrier in the shift towards green energy sources. It is considered a cleaner alternative to other fossil fuels such as coal and oil, particularly due to a low sulfur content, no particle emissions during combustion and lower specific CO_2 emissions. Moreover, LNG can be distributed to a global market unlike traditional pipeline gas that relies on pre-existing infrastructure. However, liquefaction of natural gas is a very energy intensive process that requires the natural gas to be cooled down to cryogenic temperatures. At these low temperatures, thermodynamic losses due to irreversible heat transfer become significant, thus motivating designs with small temperature differences particularly at the cold end of the heat exchangers. Temperature differences are minimized by using refrigerant cascades and/or refrigerant mixtures, as well as splitting of streams to provide cooling at different temperature levels. Multistream heat exchangers (MHEXs) thus represent critical unit operations in the liquefaction process. Besides from being very energy intensive, LNG processes also entail significant capital costs through investments in expensive and

proprietary equipment such as cryogenic heat exchangers and turbomachinery. Hwang et al. (2013) report that natural gas liquefaction represents about 30-40 % of the total cost in the LNG chain.

The high operating and capital costs motivate the need for optimization to develop energy-efficient designs. However, state-of-the-art process simulators such as Aspen Plus have significant limitations in their ability to model MHEXs. For instance, Aspen Plus lacks rigorous checks for avoiding temperature crossovers, instead requiring the user to rely on an iterative trial-and-error approach to LNG simulation. A multistream heat exchanger model that performs these checks, as well as area calculations for economic analysis has previously been developed using a nonsmooth approach (Watson et al., 2015). The model is formulated using a partially equation-oriented framework where the flash calculations are removed from the overall flowsheet and instead solved sequentially as nested subroutines (Watson et al., 2017a-b and Watson and Barton, 2017b). The results are a reduced model size and increased robustness compared to using a fully equation-oriented framework. The MHEX model was used to simulate successfully the PRICO process (Watson et al., 2017b) and three other single mixed refrigerant (SMR) processes of varying complexity (Vikse et al., 2017). The same processes were later optimized in an article by Watson et al. (2017c). However, single mixed refrigerant processes are normally considered only for small-scale or floating production units for which capital investment and space limitations are the main concerns. In the case of base-load plants, the high production volume and high operating costs advocate designs that are more efficient. One such design is the AP-DMR^{TM} (dual mixed refrigerant) process, which offers an attractive alternative for large-scale LNG production, due to its high efficiency and flexibility in design. However, the additional flexibility comes at a cost, as the AP-DMR^{TM} process is significantly more complex to model than the SMR processes. This paper models a version of the AP-DMR^{TM} process with single stage compression using the nonsmooth approach to flowsheet modelling (Watson et al., 2017b) and the MHEX model by Watson et al. (2015). Two case studies are presented and the results are validated using Aspen Plus.

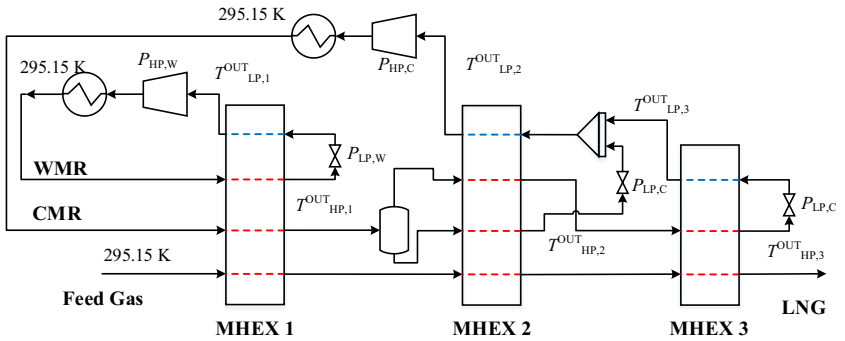

Figure 1: Flowsheet of the DMR process.

2. The DMR model

The flowsheet of the DMR process modelled in this paper is shown in Figure 1. The model, which is an extension of the hybrid process presented in Example 3 in Vikse et al. (2017), features three separate MHEXs. A warm mixed refrigerant (WMR) cycle is used

for precooling both the natural gas (NG) and the cold mixed refrigerant (CMR). An adiabatic phase separator is included after MHEX 1 to avoid freeze-out of heavier hydrocarbons as well as a high circulation rate in MHEX 3. The liquid product is subcooled and used for cooling in MHEX 2, whereas the vapour stream proceeds to MHEX 3 where it is condensed and subcooled to provide cooling at the cold end of the process.

The variables indicated in Figure 1 are as follows: $P_{\mathrm{HP,C/W}}$ and $P_{\mathrm{LP,C/W}}$ are the high (HP) and low pressure level (LP) of the CMR (C) or WMR (W), $T^{\mathrm{OUT}}_{\mathrm{HP,1/2/3}}$ and $T^{\mathrm{OUT}}_{\mathrm{LP,1/2/3}}$ are the temperatures of the HP and LP refrigerant streams out of MHEXs 1-3, whereas $F_{\mathrm{MR,C/W}}$ are the refrigerant flowrates. Moreover, the minimum approach temperature and heat exchanger conductance in the MHEXs are denoted as $\Delta T_{\mathrm{min,1/2/3}}$ and $UA_{\mathrm{1/2/3}}$, respectively. Two cases are considered for the DMR model, each solving for a different set of unknown variables:

- Case I – variable set: $T^{\mathrm{OUT}}_{\mathrm{HP,1}}$, $T^{\mathrm{OUT}}_{\mathrm{HP,2}}$, $T^{\mathrm{OUT}}_{\mathrm{LP,3}}$, $P_{\mathrm{LP,C}}$, $F_{\mathrm{MR,C}}$, $f_{\mathrm{W,ethane}}$, $\Delta T_{\mathrm{min,2}}$.
- Case II – variable set: $T^{\mathrm{OUT}}_{\mathrm{HP,1}}$, $T^{\mathrm{OUT}}_{\mathrm{HP,2}}$, $T^{\mathrm{OUT}}_{\mathrm{LP,3}}$, $P_{\mathrm{HP,C}}$, $P_{\mathrm{LP,W}}$, $P_{\mathrm{LP,C}}$, UA_3.

Here, $f_{\mathrm{W,ethane}}$ is the component molar flowrate of ethane in the WMR, which is used to solve for the mole fraction of ethane $z_{\mathrm{W,ethane}}$ from $f_{\mathrm{W,ethane}} = z_{\mathrm{W,ethane}} F_{\mathrm{MR,W}}$. The initial guesses for the unknown variables as well as the parameter values in the model are provided in Table 1. A heavy composition is used for the WMR consisting of 47.83 % ethane, 34.17 % propane and 18.00 % n-butane. The corresponding refrigerant composition for the CMR is 7.00 % nitrogen, 41.80 % methane, 33.20 % ethane and 18.00 % n-butane. An NG composition with 1 % nitrogen, 91.60% methane 4.93 % ethane, 1.71 % propane, 0.35 % n-butane, 0.40 % iso-butane and 0.01 % n-pentane is used in both cases. A natural gas molar flowrate of 1 kmol/s at 5.5 MPa pressure is used in the simulations. In addition, the outlet temperatures of the natural gas in the MHEXs are set equal to the temperatures of the high-pressure refrigerant streams.

The model subdivides the process streams into three sub-streams, corresponding to the two-phase, subcooled and superheated phase regions (Watson et al., 2017a). In addition, each sub-stream is further partitioned into stream segments with constant heat capacity flowrate to ensure accurate representation of the property models. In the simulations, five stream segments are used for both the subcooled and superheated regions in each MHEX, whereas 20 segments are used for representing the two-phase region. However, as the stream segments for the two-phase sub-stream are solved separately through nested flash routines, they do not affect the model size. Consequently, the model is represented by 95 unknown variables, 88 of which are intermediate temperatures of the superheated and subcooled stream segments in the MHEXs. These variables are initialized through an automatic initialization procedure that assumes a linear relationship between enthalpy and temperature. The model was solved with the Peng-Robinson equation of state with parameters taken from Aspen Plus, using the nonsmooth Newton solver described in more detail in Vikse et al. (2017).

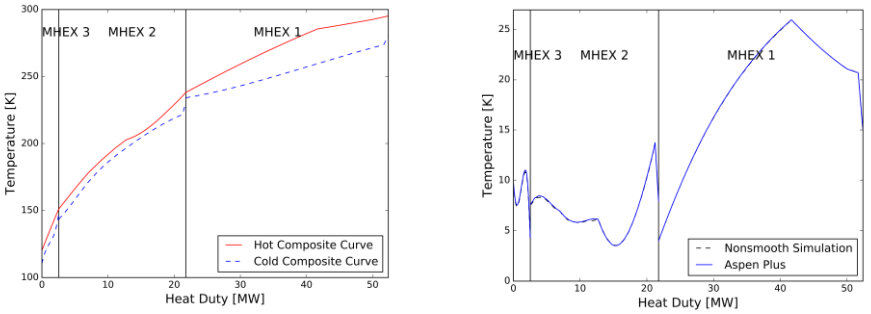
Table 1: MHEX and refrigerant stream data for the DMR model. The initial guesses for the unknown variables are placed in brackets.

Property	Case I	Case II	Property	Case I	Case II
$\Delta T_{\min,1}$ [K]	4.0	4.0	$P_{\mathrm{HP,W}}$ [MPa]	1.667	1.667
$\Delta T_{\min,2}$ [K]	[5.0]	5.0	$P_{\mathrm{LP,W}}$ [MPa]	0.420	[0.420]
$\Delta T_{\min,3}$ [K]	4.0	4.0	$T_{\mathrm{HP,1}}^{\mathrm{OUT}}$ [K]	[240.15]	[240.15]
UA_3 [MW/K]	0.3	[0.3]	$T_{\mathrm{LP,1}}^{\mathrm{OUT}}$ [K]	280.15	280.15
$F_{\mathrm{MR,C}}$ [kmol/s]	[1.45]	1.45	$T_{\mathrm{HP,2}}^{\mathrm{OUT}}$ [K]	[160.15]	[160.15]
$P_{\mathrm{HP,C}}$ [MPa]	4.850	[4.850]	$T_{\mathrm{LP,2}}^{\mathrm{OUT}}$ [K]	230.15	230.15
$P_{\mathrm{LP,C}}$ [MPa]	[0.250]	[0.250]	$T_{\mathrm{HP,3}}^{\mathrm{OUT}}$ [K]	120.15	120.15
$F_{\mathrm{MR,W}}$ [kmol/s]	[1.55]	1.55	$T_{\mathrm{LP,3}}^{\mathrm{OUT}}$ [K]	[145.15]	[145.15]

3. Results

3.1. Case I

A solution with $T_{\mathrm{HP,1}}^{\mathrm{OUT}} = 238.11$ K, $T_{\mathrm{HP,2}}^{\mathrm{OUT}} = 150.96$ K, $T_{\mathrm{LP,3}}^{\mathrm{OUT}} = 146.96$ K, $P_{\mathrm{LP,C}} = 0.310$ MPa, $F_{\mathrm{MR,C}} = 1.370$ kmol/s and $\Delta T_{\min,2} = 3.55$ K was obtained after three iterations. The new WMR composition consists of 50.16 % ethane, 32.64 % propane and 17.20 % n-butane. The molar flowrate of the WMR also changed to $F_{\mathrm{MR,W}} = 1.62$ kmol/s as a result of varying the component molar flowrate of ethane. Heat exchanger conductance values of MHEXs 1 and 2 were calculated to $UA_1 = 1.928$ MW/K and $UA_2 = 3.16$ MW/K during post-processing. The solution resulted in an isentropic compression power of 5.09 MW and 8.78 MW for the WMR and CMR, respectively.



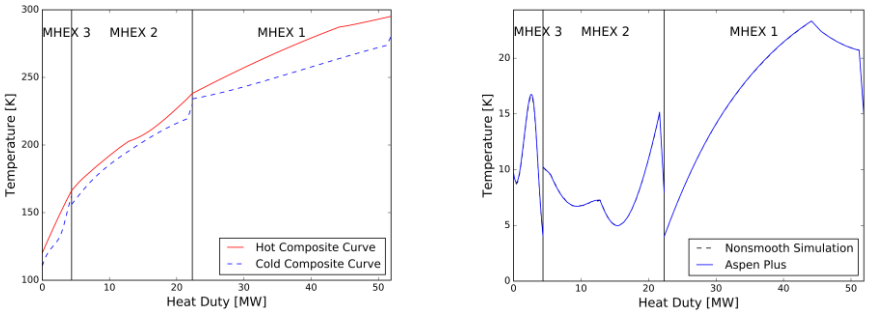
(a) (b)

Figure 2: (a.) Composite curves for Case I. (b.) Corresponding driving force plot.

Figure 2 presents the composite curves and the driving force plot for Case I. The driving force plot also includes results from simulations in Aspen Plus v9. As Aspen Plus can only solve for a single unknown variable in the MHEX modules, the above solution can only be obtained using a manual iterative procedure. Instead, the simulation was performed by using the solution from the nonsmooth model, only allowing the outlet temperatures of the LPR stream in each MHEX to vary. Aspen Plus and the nonsmooth model obtain the same driving force distribution at the solution. Moreover, the calculated isentropic compression power, UA_1 and UA_2 all lay within 1 % of the results of the nonsmooth model. The UA_3 -value deviates < 3.5 % of the nonsmooth model.

3.2. Case II

The second case converges after 5 iterations to a solution that requires 5.01 MW and 9.04 MW of isentropic compression power for the WMR and CMR, respectively. The composite curves and driving forces for the three MHEXs are presented in Figure 3. In addition, the solution in Aspen Plus is provided in Figure 3b. Again, the driving force curves are identical, indicating that Aspen Plus indeed obtains the same feasible solution. In addition, the isentropic compression power as well as heat conductance values for MHEX 1 and 2 are all within 1% of the nonsmooth model, whereas the deviation in UA_3 was calculated to < 2.5 % of the nonsmooth model.



(a) (b)

Figure 3: (a.) Composite curves for Case II. (b.) Corresponding driving force plot.

4. Conclusions

This article uses the nonsmooth flowsheeting strategy developed by Watson et al. (2017b) to model a dual mixed refrigerant process for LNG. Two simulation cases were analysed with the Peng-Robinson equation of state, employing a nonsmooth Newton solver for the system of equations. Both cases converged after a few iterations and the results correlate well with solutions obtained in Aspen Plus. In addition, the nonsmooth model contains additional degrees of freedom, making it easier to obtain feasible solutions without having to rely on a manual iterative procedure to avoid temperature crossovers in the MHEXs. The dual mixed refrigerant process is significantly more complex than the single mixed refrigerant processes previously studied by Vikse et al. (2017) and Watson et al. (2017b). Obtaining feasible solutions after just a few iterations demonstrate the model's capability of handling large and complex liquefaction processes. The next step will be to incorporate the model in an optimization framework.

Abstract

In this work, the preliminary synthesis of a fast pyrolysis plus catalytic hydrogenation process for the production of value added products from sunflower seed hulls will be presented at the conceptual stage. A General Disjunctive Programming (GDP) problem is solved, proposing a superstructure generated by the different ways of treating the raw material, posing different alternatives for the separation process and desired products. The Net Present Value is used as objective function. The solution of this problem allows for the identification of promising alternatives for the sensible and profitable use of residual biomass.

Keywords: Bioprocess, Mixed Integer Optimization, Sunflower Seed Hulls, Furfural, Furfuryl Alcohol.

1. Introduction

Residual biomass can be found in production processes or as an undesired component in the environment. As an example of the first, sunflower seed hulls are a residue from the edible oil industry, with thousands of tons a year, and as example of the latter, some types of algae present in water bodies. It is common practice to burn remnants of biomass in production processes as fuel for energy production, causing several environmental issues as the fumes and odor are very unpleasant. For this reason, there is a growing interest in using these biomass residues as feedstock for obtaining high value added (VAP) products. There are several technologies, which can be classified into three categories: thermochemical, physicochemical and biochemical. Thermochemical waste-to-energy (WTE) technologies are characterized for using high to very high temperatures to convert waste into energy or a VAP. Several thermochemical processes can be proposed for the conversion of biomass as feedstock as shown in Patel and Liu, (2017) for pyrolysis, gasification and Fischer-Tropsch synthesis, and Tozlu et al, (2016) also included incineration). Pyrolysis proved to be a high efficiency process, with an efficiency of nearly 80% for the production of energy, with a high potential to be used in large scale setups because of its promising characteristics for the production of VAPs (Higman and Tam, 2014). This is the reason pyrolysis was chosen as the first reaction process for the conversion of seed hulls into bio-oil in this work. Following this path, it is possible to obtain fuels from the bio-oil, bio char, syngas (Laird *et al*, 2009), and by separation from bio-oils, some other products as furfural and then, by hydrogenation, furfuryl alcohol. Studies have been performed lab and bench-scale to characterize the bio-oils and bio-char obtained (Sanchez *et al*, 2009). When residual biomass is used as feedstock, two objectives are met, solving an environmental issue and having added value products from

otherwise a residue, with the benefit of having a free raw material. Acid hydrolysis has been the traditional way of producing furfural (Quaker Oats patent) but it poses several environmental problems because of the very acidic waste produced, which is difficult to treat. In Argentina this has been the traditional route for obtaining furfural from wood.

For this work, several fast pyrolysis alternatives were developed at lab and bench scale by the research group (Casoni *et al*, 2015, 2017), which allowed the characterization of the raw material as well as the possible products following different process paths, with different catalysts and conditions. A preliminary flowsheet for the pyrolysis of sunflower seed hulls is presented at a conceptual stage in Casoni *et al* (2018) without evaluating all the alternatives for the different blocks of the process. It is desirable to scale up these processes so as to provide a solution for the treatment of the growing amount of residual biomass, and having a profit out of it. To the authors' knowledge, there is no industrial application reported using sunflower seed hulls with alternatives aligned with Green Chemistry principles so this work is a pioneer in the field.

2. Experimental

The production of furfural via fast pyrolysis and furfuryl alcohol via catalytic hydrogenation at laboratory scale were first studied. Details can be found elsewhere (Casoni *et al* 2015, 2018). The experimental results are used to predict the selectivity and conversion of the reactants considering different pretreatments of the sunflower seed hulls (SS) (untreated or pretreated using aqueous solutions with either 5% H_3PO_4. or 5% $ZnCl_2$). Results of SS characterization and pyrolysis yields are shown in tables 1 to 3. These results are used as a base to build the conceptual models for the pyrolysis and hydrogenation reactors, including mass and energy balances.

From the different biochars obtained post pyrolysis, catalysts are synthesized. The catalysts will be referred as Pd/BC, Pd/BC_{Ac} and Pd/BC_{Zn} for the catalyst prepared with Pd supported on biochar obtained from untreated hulls (BC); H_3PO_4 pretreated hulls (BC_{Ac}) and $ZnCl_2$ pretreated hulls (BC_{Zn}) respectively (Casoni *et al*, 2017). The catalysts are then used for the hydrogenation of furfural to furfuryl alcohol.

Table 1. Sunflower Seed Hulls (SS) characterization (Proximate Analysis and biomass contents).

	SS (untreated)	SS_{Ac} 5% H_3PO_4	SS_{Zn} 5% $ZnCl_2$
Moisture (%, dry basis)	6.1[a]	5.9	5.7
Volatile Matter (%, dry basis)	79.8[a]	83.8	83.1
Ashes (%, dry basis)	2.1[a]	2.3	1.9
Hemicellulose %	18.4	17.3	19.8
Cellulose %	39.1	33.8	36.7
Lignin %	20.4	16.9	18.7
Others [b] %	22.1	32.0	34.8

[a] Casoni *et al*., 2015. [b] Pectins, resins, extractives, etc.

Table 2. Yield to different products of pyrolysis

	SS (untreated)	SS_{Ac} 5% H_3PO_4	SS_{Zn} 5% $ZnCl_2$
Bio-oil % $_{ww}$	45	39	33
Bio-char % $_{ww}$	27	26	31
Gas % $_{ww}$	28	35	36

Regarding the yield to products, there are several subproducts present in the outlet stream of the reactor, depending on the pre-treatment of sunflower seed hulls used prior to the pyrolysis. A simplified account of products for the different conditions is shown in Table 3. A complete distribution of products in the bio-oil for several pretreatments can be found in Casoni et al (2015).

Table 3. Bio-oils chemical composition.

3. Model

A superstructure considering the different pretreatment stages (Untreated hulls, or pretreated with either H_3PO_4 or $ZnCl_2$), pyrolysis conditions, catalysts used and separation alternatives is presented in a very simplified way in figure 1. Models for the different processes are proposed using first principles and yields are used for the reactors.

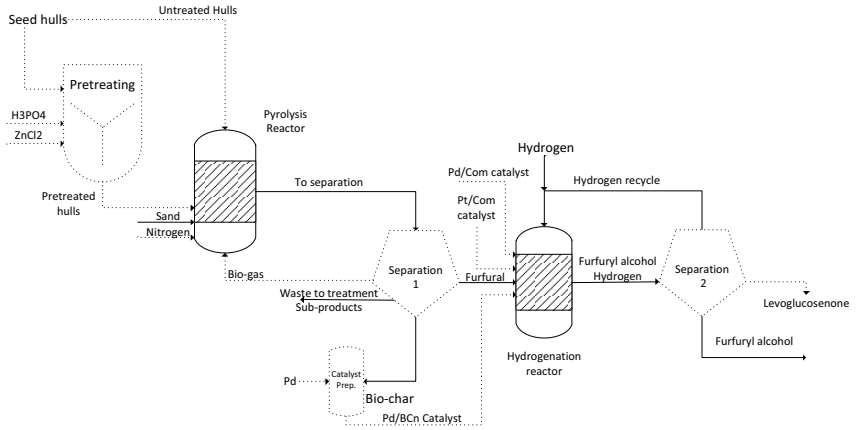

Figure 1: Simplified superstructure of the furfural and furfuryl alcohol production process. Equipment in dotted lines (together with associated streams) are represented by sets of logic propositions, each one represented by a Boolean variable. Separation sectors include several alternatives for the separation of products, being furfural, furfuryl alcohol and levoglucosenone (if applicable) the desired products.

3.1. Superstructure description

The sunflower seed hulls are transported to the facility and grounded using hammer mills. Only transportation costs are taken into account for the cost of the hulls, because they are a waste from sunflower edible oil industries. Hulls are stored in containers until transported to pyrolysis reactor or previously, to stirred tanks where they can be pretreated with either H_3PO_4 5% (880 u$s/ton H_3PO_4) or $ZnCl_2$ 5% (1950 u$s/ton $ZnCl_2$) if applicable. Diluted acid is previously prepared on site. Then, the liquid is discarded (Water and phosphoric acid can be disposed untreated, while diluted $ZnCl_2$ must be treated before disposal) and the wet solids need to be washed with water to eliminate the remaining acid and salts. The use of untreated sunflower seed hulls was also considered. Laboratory tests were performed to characterize the untreated hulls using these pretreatments, shown in Table 1.

The grounded (and pretreated if applicable) hulls must be dried before being sent to the pyrolysis step. For drying the hulls a flash drier is used.

The untreated or pretreated hulls are sent to the pyrolysis reactor, where they are mixed with hot sand (at temperatures from 650 to 700 °C) and fluidized with either the bio-gas from the reaction or nitrogen, where the proportions of sand/biomass should be between 10-20 and fluidization gas/biomass between 2-9. Type of reactor is circulating bed. The reactor is isothermic operating at 500 °C The product is sent to a series of cyclones where sand and bio-char are separated, and vapors are sent to a cooling system to condense the bio-oil with furfural. Biochar is either used for the preparation of the catalyst used in the subsequent hydrogenation step or burnt for energy generation.

A separation train (Separation 1) is then used for obtaining the liquid products from pyrolysis (bio-oil, furfural, levoglucosenone, acetic acid and water). Alternatives are: several single equilibrium stages or a single distillation unit with several side streams.

Furfural is sent to the second reaction step for hydrogenation, using the prepared catalyst (Catalyst prep). The possibility of using commercial Pd/Com and Pt/Com catalysts can also be included in the superstructure, Com standing for commercial catalyst support.

A final separation sector (Separation 2) is proposed to obtain all the products, evaluating the use of either distillation, single equilibrium steps, condensation or pervaporation membranes for obtaining high purity levoglucosenone. There is a huge interest in obtaining the latter because its selling price is 300 u$s/g. However, the separation steps required for attaining the high purity needed in the pharmaceutical industry are difficult and costly. With the model the feasibility of producing high purity LG will be evaluated at a preliminary level.

Treatment of residues is also proposed for all applicable cases and their costs taken into account.

3.2. Model formulation highlights

The problem is posed as a hybrid GDP using LOGMIP within GAMS. Due to the size of the problem it is not possible to include all the equations, so a few highlights are shown. The formulation of a hybrid GDP can be found in Vecchietti and Grossmann (1999)

Objective function is Net Present Value (*NPV*). The internal revenue rate (*IRR*) is also calculated as a way of evaluating the profitability of the project. *NPV* is calculated as:

$$NPV = -C_0 + \sum_{i=1}^{T} \frac{C_i}{(1+r)^i} \quad (1)$$

Where *Co* is the initial investment, C_i the cash flow in each year *i* (assumed to be annual *NB*), *T* is the lifespan (*T*=15 years) and r the discount rate (*r*=0.1).

Disjunctions are posed for the different equipment in each sector where alternatives can be used. For example, in the pretreatment sector, the unit will be present if pretreated hulls are selected by the model. Boolean variables Y_k are associated to untreated hulls, H_3PO_4 and $ZnCl_2$ and constraints on flow rates are written.

$$Y_{Untreated} \Rightarrow \neg Y_{Ac} \wedge \neg Y_{Zn} \tag{2}$$

$$Y_{Ac} \Rightarrow \neg Y_{Zn} \tag{3}$$

$$\begin{bmatrix} Y_{Untreated} \\ F_{Pyr} = F_{Hulls} \end{bmatrix} \vee \begin{bmatrix} \neg Y_{Untreated} \\ F_{Pyr} = F_{Hulls} + F_{Pret} \end{bmatrix} \tag{4}$$

$$\begin{bmatrix} Y_{Ac} \\ F_{Pret} = F_{H3PO4} \end{bmatrix} \vee \begin{bmatrix} \neg Y_{Ac} \\ F_{Pret} = F_{ZnCl2} \end{bmatrix} \tag{5}$$

Supported on-site prepared Pd catalyst used is linked to pretreatment, meaning for example that if untreated hulls are used, Pd/BC catalyst or any of the commercial catalysts will be used.

$$Y_i \Rightarrow Y_{Pd/i} \qquad i = Ac, Zn \tag{6}$$

$$Y_{Untreated} \Rightarrow Y_{Pd/Com} \wedge Y_{Pd/BC} \tag{7}$$

The preparation unit will be present only if Pd catalyst is used. This information will be used to define the yields in each reactor only, as conceptual models (based on laboratory test yields) for the reactors are posed. Volume is estimated using the residence time needed to complete the reaction for the different catalysts used (Casoni et al, 2018) so as to predict a preliminary reactor cost.

For separation sector 1 disjunction sets include a series of condensing stages or a distillation column with side streams. For separation sector 2, alternatives considered are single separation stages, distillation, pervaporation, or a hybrid distillation/pervaporation process. All the models are posed at a conceptual level using mass and energy balances, a shortcut model for the case of distillation and the membrane area for pervaporation is calculated using a correlation generated from a rigorous simulation.

For the scaling up of the reactors it was assumed that the same laboratory scale selectivity and conversion are reached in the industrial scale setup, which can provide a theoretical maximum. The desired product in the hydrogenation reactor is furfuryl alcohol > 80% $_{ww}$. Levoglucosenone 93% is obtained as subproduct if pretreated hulls are pyrolyzed. This can be further purified or sold at a low price to a producer who can purify it. Selling price of levoglucosenone <99.9% (pharma purity) is considered 1% of the selling price.

4. Results

Table 4 shows the most relevant results of the optimization problem. Riser temperature adopts the lower limit to decrease the pyrolysis cost. Combustion of bio-char provides enough energy to regenerate the sand. Levoglucosenone resulted to be the highest VAP obtained with this process, and so the pretreatment of seed hulls was selected, using H_3PO_4 because it does not need treatment for disposal, together with the preparation and use of catalyst Pd/BC_{Ac}. The purification stage of LG was not selected as the cost of

purification was anti-economic. This reduces the selling price of LG and then benefits are highly reduced. However, optimization results showed that the NPV of this process considering a lifespan of 15 years is 52 MMu$s with an IRR of 24%, making this a profitable project. A sensitivity analysis (Not shown) indicates that levoglucosenone selling price is key for the economics of the project.

Table 4. Optimization results for a production of 7000 t/y furfuryl alcohol with 3 pretreatment tanks and 3 condensing stages for separating furfural from bio-oil,

Sunflower seed hulls (ton/y)	20118	Hydrogen - fresh feed (Nm^3/h)	391.7
H_3PO_4 for pretreatment (kg/h)	1344	Residence time pyrolysis (s)	2
Riser temperature (°C)	500	Furfural produced (kg/h)	1130
Sand flow rate (kg/h)	40888	Total installation cost (MMu$s)	30.6
Bio-Char (kg/h)	393.9	Operating cost (MMu$s/y)	48.6
Bio Gas recycle (kg/h)	2775	NPV (MMu$s)	52
Bio-Oil (kg/h)	10177	IRR (%)	24

5. Conclusions

The preliminary synthesis of a novel waste to VAP industrial process based on pyrolysis of sunflower seed hulls and hydrogenation of furfural was presented, with the initial objective of producing furfuryl alcohol, but results suggested that the possibility of producing levoglucosenone as a subproduct should be considered. Provided that this is a conceptual stage study using simplified models including mass and energy balances, a rigorous design would be desirable to take account of more detailed instances of the process. For example, a nonlinear optimization programming technique would provide details on sizing and operating variables more accurately. Especially for LG purification stages this could dramatically increase the *NPV*, because a fine tuning of the separation process could lead to the decision of producing high purity LG, which is being studied.

Abstract

Work and heat are the two main forms of energy consumption in chemical processes. These work and heat requirements of the processes can be synergized to increase the overall energy efficiency. In this work, we simultaneously synthesize a network of work-exchange units (single-shaft-turbine-compressor) and heat exchange units (heat exchangers) to minimize the total annualized costs. The process streams are not pre-classified as high-pressure or low-pressure streams in work integration, or as hot or cold streams in heat integration. Furthermore, the model accommodates phase and pressure-temperature dependent properties, allowing liquid, vapor, and 2-phase streams. Finally, we illustrate the benefit of simultaneous work-heat integration through a case study of a propylene-propane separation process.

Keywords: work-heat integration, heat exchange network synthesis, work-heat exchange network synthesis, mixed-integer non-linear programming.

1. Introduction

The world's population is growing and fossil fuels, the main source of energy, are depleting. Moreover, the combustion of fossil fuels release greenhouse gases and contribute to global warming. These concerns are encouraging global efforts for increased energy efficiency and conservation. Heat integration is a well-established tool in process industries to reduce the overall utility consumption. Apart from heat, work is another form of energy consumption required for pressure changes. As pressure changes are often accompanied by temperature changes; compressors, turbines, and valves which bring about these pressure changes strongly interlink pressure (work) and temperature (heat). Thus, considerable energy savings can be achieved by simultaneously integrating both forms of energy requirements of the process streams.

The fundamental principles of heat exchange network synthesis can be extended to work-heat exchange network synthesis (WHENS). As heat exchanger transfers heat indirectly between two streams, a single-shaft-turbine-compressor (SSTC) can be used to transfer work between multiple streams on the same shaft. However, WHENS is a challenging problem as the required or generated work is a highly non-linear function of operating conditions. Wechsung et al. (2011) combined the pinch analysis, exergy analysis, and mathematical programming to minimize the external work/utilities or their costs. Razib et al. (2012) proposed an mixed-integer non-linear programming (MINLP) formulation for work exchange network (WEN) synthesis of SSTCs, ignoring heat integration among process streams. Onishi et al. (2014) presented an MINLP model for simultaneous heat and work exchange network synthesis; classifying streams as LP (low

pressure streams that undergo compression)/HP (high pressure streams that undergo expansion). They allowed multiple SSTCs and heat integration between WEN stages. Du et al. (2015) proposed a transshipment model to obtain the minimum utility consumption in WENs. Huang and Karimi (2016) presented a mathematical model for WHENS with a single SSTC and no pre-fixed end heater/coolers.

The existing literature uses predefined pressure manipulation routes or fixed identity of streams as LP/HP and hot/cold. However, in a real case such as refrigeration cycle, the same stream can undergo both compression and expansion. Furthermore, the existing models apply only to gaseous streams with constant thermo-physical properties such as heat capacity and Joule-Thomson (JT) coefficient. This limits the practicality of currently available models. We have developed a novel framework for work-heat integration in which the streams are not classified as HP or LP streams in the WHENS. This flexibility allows pressure change for streams with net zero pressure change. Additionally, the identities of the streams are not fixed a priori in heat integration. We optimize the design and operating variables to minimize the total annualized costs. To this end, we apply the developed MINLP model to study energy requirements of a C3 splitter column in various cases and exhibit the benefit of simultaneous work-heat integration.

2. Model

2.1. Problem Statement

Given S streams with known flow rates, inlet/outlet temperatures and pressures, we synthesize a work-heat exchange network (WHEN) with minimum total annualized cost (TAC) that may include 2-stream exchangers, utility heaters/coolers, Joule-Thomson (JT) expansion valves, SSTC with electric generator or motor.

2.2. Assumptions

- Pressure drops in pipes and exchanger are zero.
- Isothermal mixing of substreams in heat integration.
- Turbines, compressors, and valves are not operated in parallel.
- The cost of valves is zero compared to compressors and turbines.
- Only one zone of a stream (liquid, vapor, or 2-phase) can exist in an exchanger.

2.3. WHEN Framework

The WHEN employs two types of equipment. SSTC and Joule-Thomson (JT) expansion valves change stream pressures, hence are called pressure-changing (PC) equipment. 2-stream exchangers and heaters/coolers change stream temperatures without changing pressures, hence are called non-pressure changing (NPC) equipment. The NPC equipment together make up one single Heat Exchange Network (HEN). SSTC has one or more compressors or turbines. The turbines generate the work to run the compressor. If the turbine work is insufficient, then the SSTC has an electric motor that uses the deficit power from the grid. If the turbine work is in excess, then an electricity generator produces the power for the grid. A JT valve may be used to reduce a stream's pressure.

2.4. Superstructure

Each stream s $(s = 1,2,..,S)$ begins at initial conditions and passes through a series of N_s stages $(n = 1,2,\dots,N_s)$ to reach its final pressure. In every stage n, it first enters the

HEN for temperature adjustment and then, it passes through one PC equipment (either a valve or a compressor/turbine on the SSTC). During this pressure change, its temperature also changes. After exiting stage N_s, the stream enters the HEN for the last time, and leaves at outlet conditions. For a stream s that cannot change pressure in the WHEN, we set $N_s = 0$. Thus, each stream s enters the HEN $(N_s + 1)$ times, once in every stage n and then after stage N_s.

The HEN consists of K stages $(k = 1,2, \dots, K)$ of 2-stream exchangers. Each stage may have one or more parallel 2-stream counter-current exchangers that heat/cool process streams using other process streams. In the conventional HEN synthesis literature, streams are pre-classified as either hot or cold. In contrast, stream identities are unknown in this WHEN. The HEN involves heat exchange among all $S + \sum_s N_s$ streams. For simplicity, we assume isothermal mixing after each stage as proposed by Yee and Grossmann (1990) stagewise superstructure. Furthermore, a stream may use utility only before it exits the HEN.

2.5. Model formulation

We develop an MINLP model for minimizing the TAC of WHENs. In a stage, a stream can use any of the pressure-changing (PC) equipment. Furthermore, binary variables are used to define the identify of stream as hot or cold and to detect the liquid and vapor zones of a stream. These binary variables are also used for calculating zone-based heat transfer coefficients. The capital expense (CAPEX) for the WHEN includes the costs of SSTC, valves, heat exchangers, and utility heaters/coolers in the HEN. The operating expense (OPEX) includes the costs of running the helper motors, and the costs for heating/cooling utilities. The power generated by the SSTC provides the revenue. A stream s $(1 \leq s \leq S)$ with $N_s = 0$ uses no PC equipment and directly enters the final HEN. Thus, the same model can be used for synthesizing HEN, WEN and WHEN by changing the N_s and identity for each stream.

3. Propylene-Propane Separation

Propylene is one of the important starting product in petrochemical industry, due to its large use in manufacture of polypropylene. It is important to separate propane from propylene as the polypropylene process requires polymer-grade propylene (≥ 99.5 wt. % propylene). This separation is traditionally carried out in a distillation column, called C3 splitter, and is one of the most energy-intensive commercial distillation processes. Numerous studies have explored mechanical vapor recompression as an alternative for the traditional reboiler and condenser.

In this case study, we study various configurations for feed preheating, top vapor condensation and vaporization of bottom liquid for a fixed design of distillation column through WHENS and obtain the optimal configuration. The flowsheet for the process is as presented in Figure 1. There are 3 streams; the feed stream, top vapor stream and the bottom reboiling stream. We assume linear variation of enthalpies with pressure and temperature in different zones. We generate enthalpy, BPT, DPT data using Peng-Robinson in Aspen HYSYS, and regress them linearly. We used GAMS 24.8.5 for optimization with BARON as the MINLP solver with default parameters.

3.1. Case 1: Only heat integration

In the first case, we synthesize the heat exchange network with a minimum approach temperature of 5 K, ignoring the work exchange. Since the feed stream is changing

pressure from 2.1 MPa to 1.8 MPa, a valve is used to bring about this pressure change. We set $N_s = 0$ for all the streams and find the optimal heat integrated configuration. As can be seen in Figure 1(a), the heat integration is not economically attractive, and all the streams use utility for the desired enthalpy change. The temperature level of each stream prohibits heat exchange among them. Thus, the total annualized cost is 5.579 million \$/y with OPEX of 5.506 million \$/y as listed in Table 1.

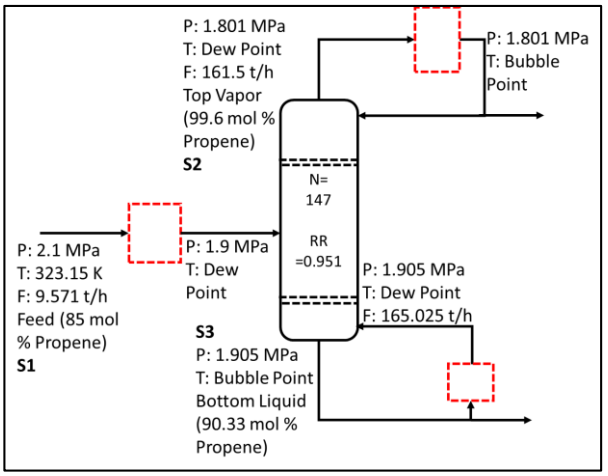

Figure 1. Flowsheet for the C3 splitter

3.2. Case 2: Work and heat integration with fixed identities

We use the same model to study work and heat integration done sequentially for mechanical vapor recompression process. In this case, there are 2 streams for pressure change (top vapor stream as HP and feed stream as LP) and 3 streams for temperature change (top vapor and feed stream as hot streams, and bottom liquid stream as cold stream). The outlet pressure and temperature of the top vapor stream are optimized to improve the heat integration, such that the total annualized cost is minimum. The identity of all the streams are fixed in heat and work integration. In this case, the optimal network is as shown in Figure 2 (b) with TAC of 1.228 million \$/y. The compressed top vapor is used to reboil the bottom liquid stream, thus drastically reducing both the hot and cold utility consumption and the OPEX associated with it.

3.3. Case 3: Simultaneous work and heat integration without pre-fixed identities.

We use the model for simultaneous WHENS with no pre-fixed identities for the top vapor and feed stream. Although this case considers the configurations from earlier two cases, the final optimal configuration as shown in Figure 2 (c) is different from the earlier two configurations. The top vapor stream changes identity several times. First, it is a cold stream which is heated before sending to a compressor where it acts as a LP stream. Later, it acts as a hot stream and subsequently as a HP stream. Although it is a stream with zero net pressure change, our model allows it to change pressure. In contrast to the intuition of cooling a stream before compression to reduce power consumption, the model preheats the compressor inlet stream. If this stream is not preheated, then a higher pressure-ratio is needed in the compressor to use the outlet stream as a hot stream and maintain the minimum approach temperature (MAT) in the reboiler. If the preheater is placed after the compressor, external hot utility is needed as

it is the highest temperature stream in the process. Thus, the current configuration is optimal, which the earlier two cases did not include. This affirms the benefit of simultaneous work-heat integration without prefixed identities.

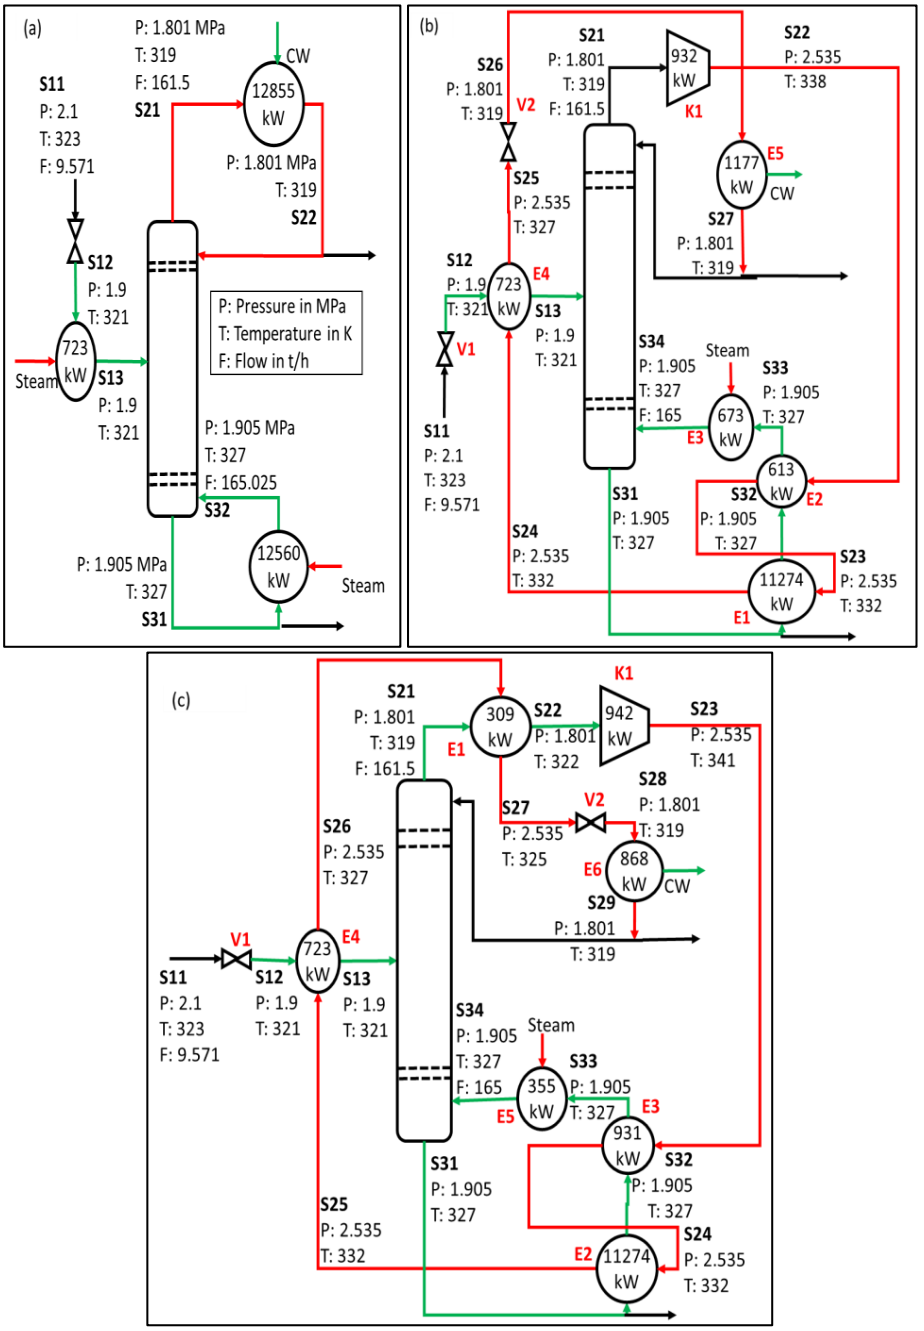

Figure 2. (a) Optimal configuration for Case 1, (b) Optimal configuration for Case 2, (c) Optimal configuration for Case 3

Table 1. Results for Case 1, Case 2, and Case 3.

	Case 1	Case 2	Case 3
Hot utility demand (kW)	12855	673	355
Cold utility demand (kW)	13284	1177	868
Power (kW)	0	932	942
CAPEX (million $)	0.275	1.881	2.015
OPEX (million $/y)	5.506	0.732	0.604
TAC (million $/y)	5.579	1.228	1.136

4. Conclusions

We have provided a general framework and developed an MINLP model for WHENS that does not pre-classify streams into hot/cold or HP/LP. We obtain the network of SSTCs, valves, and heat exchangers with the corresponding operating conditions and associated costs. The proposed model is generic and practical with a wide range of applications in process industries. We have illustrated its applicability through a case study on energy consumption in C3 separation process. Through this case study, we highlight the advantages of holistic energy integration through WHENS with unknown identity of streams over HENS and WHENS with fixed identity of streams.

Mechanical Energy Recovery through Work Exchanger Network Integration: Challenges and Opportunities

Aida Amini-Rankouhi, Yinlun Huang*

Department of Chemical Engineering and Materials Science, Wayne State University, Detroit, MI 48202, USA
yhuang@wayne.edu

Abstract

Heat and mass integration are two types of process integration technologies that have been practiced for improving energy and material efficiency in the process industries. Heat integration, frequently through integrating a heat exchanger network (HEN) into a process system, is for the recovery of thermal energy. However, recovery of mechanical energy, another form of energy, has not been fully explored. In this paper, we discuss the concept of work integration and its fundamentals. This will be followed by a general review of the frontier research on work exchanger network (WEN) synthesis, which is a system approach to implementing work integration. Challenges in WEN synthesis, such as energy targeting, equipment innovation and costing, and system configuration when heat integration is incorporated, are discussed. Preliminary studies on energy targeting, heat-incorporated WEN synthesis, and cost estimation are presented. Future research opportunities in WEN design and deployment are also discussed.

Keywords: Work integration, work exchange network, and mechanical energy recovery

1. Introduction

Process sustainability has become a main concern in industries, for which energy efficiency is a key indicator. Over the past decades, the chemical process industry has shown a great success in energy recovery in process systems through applying heat integration technologies. In chemical plants, thermal and mechanical energy are two common forms of energy. While the former can be effectively recovered by heat exchanger networks (HEN's), the recovery of the latter, however, has not drawn sufficient attention. Note that process work is more expensive than process heat, but recovery of mechanical energy is much more challenging.

From the thermodynamics point of view, heat flow where temperature is the state variable can be systematically managed to improve thermal energy efficiency, while work flow where pressure is the state variable must be carefully characterized so that opportunities for recovering mechanical energy can be identified. It is known that a large number of chemical plants have process streams to be pressurized, which require work for compression, or depressurized, which can produce work through expansion. Naturally, work exchange among process streams through synthesizing work exchanger network (WEN) should be a feasible approach for mechanical energy recovery.

In this paper, the state-of-the art research on work integration is reviewed, and some key challenges and opportunities of this area are discussed. We will then present a preliminary research on energy target setting and basic economic analysis that are necessary for synthesizing a cost-effective WEN. Furthermore, issues of heat integration

in WEN synthesis and evolution of current devices are also discussed.

2. WEN Synthesis-Progress Overview

It is recognized that the utilization of the mechanical energy available in a set of high-pressure streams for pressurizing a set of lower pressure streams in a process system may greatly reduce energy cost for compression operation. The pressure driven mechanical energy can be recovered using two types of work transfer units (WTU), the direct or indirect recovery devices. The former is called work exchanger (WE), which was first introduced for seawater reverse osmosis desalination systems (to replace energy-intensive pumps and turbines) by Cheng et al. (1967). The device was built using two displacement vessels configured in parallel that could simultaneously pressurize one fluid stream in one vessel and depressurize an equivalent volume of another stream in the other vessel in each operational cycle. Figure 1(a) is a sketch of one vessel, where the stream flows are controlled by four valves (Cheng et al., 1967). As a comparison, an indirect WTU, namely single-shaft-turbine-compressor (SSTC), is sketched in Fig. 1(b). This type of unit exchanges work in two steps: the pressure energy of a high-pressure stream is firstly converted to mechanical energy using an expander (turbine), and then to a compressor to pressurize a low-pressure stream (Chen and Wang, 2012). This type of device, however, has a low operational efficiency.

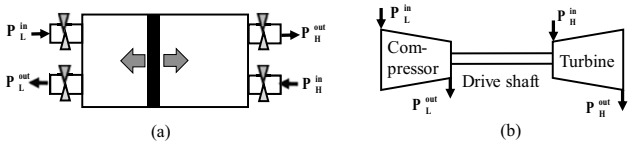

Figure 1. Sketch of work transfer units: (a) a (flow) WE and (b) a SSTC.

Inspired by the heat integration and methodological development for HEN synthesis, Huang and Fan (1996) introduced a notion of work integration through synthesizing WEN's. In their work, the similarities and differences between HEN and WEN synthesis were deliberated and the P-W (pressure-work) diagram was introduced to synthesize WEN.

A basic thermodynamic analysis on gas-gas work exchange was later conducted by Deng et al. (2010). Chen and Feng (2012) studied a design targeting issue for an ammonia synthesis example. Liu et al. (2014) proposed a graphical method using the P-W diagram. However, their method is somehow simplistic, and economic evaluation is restricted to the amount of energy recovered without counting capital cost. Amini-Rankouhi and Huang (2017) introduced a thermodynamic analysis method to evaluate rigorously the maximum amount of recoverable mechanical energy prior to WEN synthesis. Case studies showed that the energy efficiency was higher than the known studies. Du et al. (2017) presented a direct WEN synthesis using transhipment model under an isothermal condition, and the maximum energy recovery is not achieved. Razib et al. (2012) proposed a superstructure-based modelling approach using simple 2-stream SSTC units to design WEN with MINLP technique. Onishi et al. (2014) described a new MINLP model for WEN synthesis with hypothetic heat integration for optimal pressure recovery of process gaseous using SSTC units. Huang and Karimi (2016) included a HEN in a WEN system to minimize total annualized cost. In WEN synthesis, isentropic efficiency of both types of units has been considered. Heat and work integration has been also studied through placement of heat engines and heat

pumps (Townsend and Linnhoff, 1983), and compressors and expanders (Fu and Gundersen, 2016) during HEN synthesis.

3. Challenges and Opportunities

The known studies have shown that WEN synthesis is a new type of process integration technology, and WEN can be integrated into process systems to recover mechanical energy that is consumed by compressors, pumps, turbines, and other types of pressure vessels in the process industries.

There are various similarities between HEN and WEN syntheses, as fundamentally in each type of network, a set of high-potential streams (hot streams in HEN or high-pressure streams in WEN) transfer energy to a set of low-potential streams (cold or low-pressure streams) due to the existence of a driving force (ΔT in HEN and ΔP in WEN). In HEN, heat transfer units are easy to operate. By contrast, the compressors and expanders in WEN may operate in multiple stages, which could be under isothermal or non-isothermal condition. Thus, the shaft work either demanded for compression or provided by a work force may be significantly different. In addition, required compression and provided expansion energy is operating temperature dependent.

Methodologically, the Pinch Analysis technique successfully used in HEN synthesis cannot be directly used for WEN synthesis, because the basic notion of pinch point for heat exchange is not applicable for work exchange. As shown in the T-H diagram in Fig. 2(a), the temperature of the hot stream must be higher than that of the cold stream in the entire temperature range involved. However, this is not the case for work exchange between a high-pressure stream and a low-pressure stream as shown in the P-W diagram in Fig. 2(b). Therefore, the method for determining the maximum energy recovery by a HEN cannot be applied to a WEN problem. Besides, the basic formula for estimating the minimum number of heat transfer units in a HEN cannot be simply applied to the estimation of the minimum number of work transfer units in a WEN.

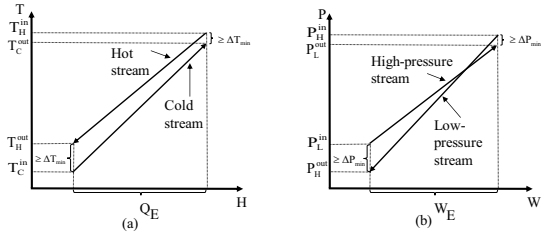

Figure 2. Comparison of (a) heat transfer in a HE and (b) work transfer in a WE.

It is noticed that WE, either direct or indirect, has only limited industrial applications. There is a serious lack of technological innovation in equipment design, especially for gas-gas or gas-liquid direct WE. This requires a more fundamental study on the designed operational behaviour of such a type of devices. Also note that if a WE involves a gas stream's pressurization or depressurization, the stream temperature can be changed considerably in operation. Therefore, such a WEN should be designed with heat integration technology incorporated; thereby leading to a hybrid exchange network.

WEN synthesis problems could be mathematically formulated and solved by MINLP techniques. Other type of synthesis methods could be also attractive, especially if a WEN design problem involves not too many high/low pressure streams, which is common. In such a case, heuristic based methods may demonstrate advantages, as a derived solution structure becomes explainable, which allows engineers to address some

practical design issues that could be difficult to formulate mathematically. Note that since heat-incorporated WEN system is structurally highly interacted, its operation could be sophisticated in terms of system dynamics, control, and process safety.

Energy Target Setting

For any chemical plant, a WEN is attractive if it is economically sound. Therefore, it is beneficial if the maximum amount of mechanical energy that can be feasibly recovered by a WEN can be determined prior to network design. This will facilitate justification of a need for WEN integration into an existing process.

Recently, we introduced a thermodynamic modelling and analysis method to accurately identify the maximum amount of recoverable mechanical energy of any process system of interest (Amini-Rankouhi and Huang, 2017). The energy targeting method includes four steps: (1) identification of all pressure intervals of known low-pressure streams for pressurization by given high-pressure streams, (2) evaluation of mechanical energy transfer from the high-pressure streams to the low-pressure streams, (3) determination of the minimum amount of external energy requirement, and (4) calculation of the maximum amount of recoverable mechanical energy. Each step is mathematically formulated, and a general computational procedure is developed for target setting of mechanical energy recovery of a WEN synthesis problem of any size. The detailed modelling and computational method is provided in Amini-Rankouhi and Huang (2017). By using that mathematical formulation, a WEN synthesis methodology is introduced, where heat integration is also incorporated to design a cost-effective hybrid network. A case study data in Razib et al. (2014) is used in this work to design a heat-incorporated WEN (HIWEN) by the introduced methodology. The synthesized network configuration is shown in Fig. 3. In this solution, a total of 61.35% mechanical energy of high-pressure streams and 49.91% energy for low-pressure streams are recovered. In addition, a total of 688 kW of thermal energy is recovered, too.

Table 1. Process Stream Data.

Stream No.	P^s (kPa)	P^t (kPa)	F (kg/s)	T^s (K)	T^t (K)	C_P (kJ/kg.k)
H_1	850	100	3	600	430	1.432
H_2	960	160	5	580	300	0.982
H_3	800	300	2	960	300	1.046
L_1	100	510	3	300	700	1.432
L_2	100	850	3	300	600	1.432

Basic Cost Analysis

The energy cost in a HIWEN can be readily estimated. Its capital cost of work transfer units, especially WE's, is determined by the number of units used, equipment structure, materials used, work transfer capacity, etc. Cheng and Fan (1968) studied the design of flow work exchanger for a desalination process, where the equipment structure and a basic equipment cost estimation were illustrated. We conducted a preliminary study on equipment design for gas-gas work exchange.

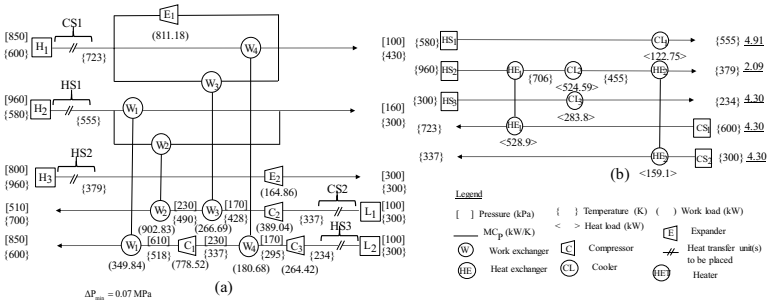

Figure 3. Flowsheet of heat-integrated work exchange network (a) WEN, and (b) HEN.

Similar to the cost estimation formula for heat transfer units, we propose the following formula: $C_B=\alpha S^{\beta}$, where S is the volume of a displacement vessel, and α and β are the parameters to be determined through experiment. As a case study, for one work exchanger unit, the cost data collected can be used to determine the parameters. Figure 4 gives the cost estimation of a WE based on the volume of the displacement vessel made by stainless steel, working in three different conditions with maximum pressure tolerance of the vessels and valves.

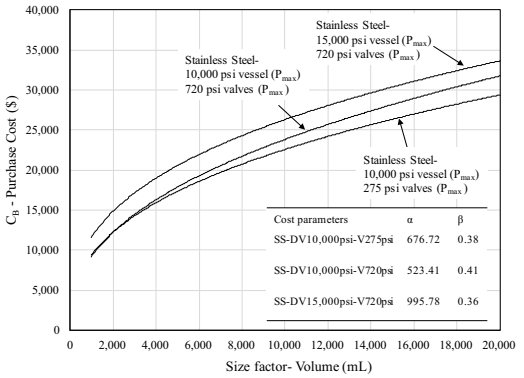

Figure 4. Cost estimation for one work exchanger unit.

Note that a comparison of the capital cost of a compressor or expander with a WE is mainly determined by equipment structure and capacity, materials used for the unit, process stream types, especially for gas-gas WE's, and operating condition. Thus, more reliable cost estimation methods are needed for WEN synthesis. Among different types of WE's, the Dual Work Exchange Energy Recovery Device (DWEER) has been widely used for seawater reverse osmosis (RO) desalination, which is one of the most efficient energy recovery systems developed to date (by Flowserve Corporation). This type of devices (dealing with liquid streams) has been reported to have low mixing and leakage losses, low maintenance cost, and self-adjustment capability to different flow rates and pressures. Despite that, WE's dealing with gas phase streams will demonstrate different operational characteristics. Note that operational safety related to leakage and mixing losses should be considered, especially when processing gas streams.

Another important concern is the operational performance of WE's, as the units may have a longer cycle time, depending on the operational mode, in comparison to compressors and expanders. Therefore, WEN dynamic control could be a challenge, as an effective operational coordination strategy is needed for operating different types of

units working in continuous or batch-like operational modes. This requires a more comprehensive study on system control design.

4. Conclusions

Improvement of energy efficiency in process systems has been always a key concern in the chemical process industry. However, the recovery of mechanical energy, as compared to thermal energy recovery, has not received sufficient attention. This renders a research need on work integration through designing WEN for chemical plants. In this work, a general review of the current research progress is provided, and the challenges and opportunities are presented. Preliminary studies have shown that WEN can be designed in a cost effective way. However, due to the special feature of work exchange, complexity in network design, and unique feature of work exchangers, WEN system design will be more sophisticated. In many cases, heat integration needs to be considered as well. It is expected that more systematic system design methodologies will be developed, and gas-to-gas work exchangers will be innovatively introduced in the near future.

Process Synthesis under Seasonal and Daily Variability: Application on Concentrating Solar Power

Xinyue Peng, Thatcher W. Root, Christos T. Maravelias[*]

Department of Chemical & Biological Engineering, University of Wisconsin-Madison, WI 53706, USA
christos.maravelias@wisc.edu

Abstract

We propose an optimization-based framework for the synthesis of systems that are subject to variability in two frequencies. We use "scenarios" and "modes" to represent seasonal and daily variability respectively. We construct a multimode superstructure to consider different flowsheets alternatives for each mode. We formulate the optimization problem as a two-stage multimode stochastic programming approach with embedded models in each scenario. We illustrate the applicability of our framework through the design of concentrating solar power (CSP) plants.

Keywords: stochastic programming, superstructure optimization, solar power.

1. Introduction

Process synthesis under variability remains an important problem in process system engineering, especially nowadays with the increasing emphasis on the design of energy systems with intermittent renewable sources availability. The common approach to handle variability is to specify multiple operating conditions and then formulate the synthesis problem as a multiscenario/ multiperiod optimization problem (Grossmann et al., 1983). However, this approach is applicable when variability is present in one timescale. Many processes involve resource variability (e.g., wind, solar irradiance, electricity demand) on multiple timescales. To date, no previous approach has been proposed to systematically handle process synthesis under two-frequency variability. The majority of research in the area of chemical process synthesis has focused on processes which operate on a single "mode" (i.e., steady state) during a day and also have reasonably small variability, which, in these settings, is considered through "deviations" from the nominal operation and it is assumed that its effects can be compensated by control variables (Rooney and Biegler, 2003). Existing methods cannot be applied when the variability is so large and persistent that large subsystems of the facility are basically operating in completely different "modes" during, for example, the course of a day.

Accordingly, the goal of this paper is to outline an optimization-based framework for process synthesis under variability in two frequencies. Two key components of the framework is the use of scenarios to represent low frequency variability (e.g., seasonal) and modes, embedded within each scenario and linked with each other, to represent high frequency variability (e.g., daily). The framework allows us to formulate relatively accurate but yet tractable mixed-integer nonlinear (MINLP) models for process synthesis.

2. Modeling framework

In this paper, we focus on seasonal and daily variability (see Fig. 1), but the framework can be applied to systems under variability in any two frequencies. To efficiently capture the two frequencies, we adopt *scenarios* and *modes* to represent seasonal and daily variability, respectively. Scenarios ($s \in \mathbf{S}$) are representative days, each with a frequency of occurrence (π_s) within a year. For example, a year can be represented by three scenarios: a typical winter (25%), summer (25%) and mid-season (50%) day. Modes ($m \in \mathbf{M}$) are time periods within a day in which values of the varying parameters are notably different. For example, day and night modes may be used to describe daily solar irradiance variation.

All scenarios have the same types of modes occurring in the same sequence, which preserves the temporal connections between consecutive modes, but, to represent seasonal variations, the duration of the models can vary across scenarios (e.g., the day mode of a summer day scenario has longer duration than the day mode of a winter day scenario). Operation is linked across modes, which allows material and energy being stored and used in other modes. The main motivation behind using modes to represent daily variability is to allow the employment of different designs and operation strategies during the course of a day. Another motivation for the employment of modes, instead of refined time steps, is computationally tractability, since we aim to employ relatively detailed unit models (e.g., reactor models with kinetics or equilibrium relationships) and even consider, simultaneously, heat integration (which plays a key role in the development of renewable energy systems).

The framework consists of three key steps (see Fig. 1). First, we generate "scenarios" and "modes" from parameter data over a year. Second, we construct a multimode superstructure that contains different alternatives for each mode. Third, we formulate an design optimization problem as a multimode stochastic programming model. The design and associated operational decisions are obtained from the solution of the model. In the following subsections, we present the three steps in detail.

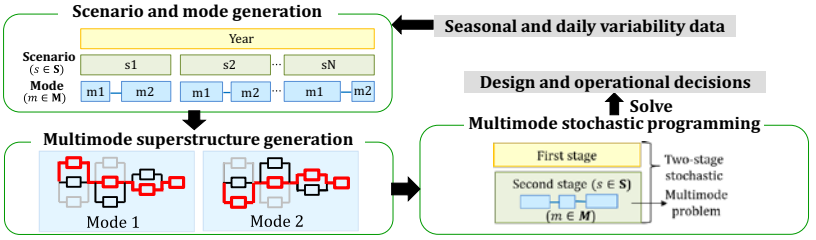

Figure 1. Overview of the proposed optimization framework.

2.1. Scenario and mode generation

The procedure of scenario and mode generation is shown in Fig. 2. We first identify M modes for each scenario based on patterns in daily profiles of varying parameters $\boldsymbol{\theta}$. For example, daily profiles of solar irradiance can be represented by day and night modes (see Fig. 3). Next, we develop a piecewise constant approximation to transform the actual daily profiles, into mode profiles, with $\boldsymbol{\theta}$ constant over M time intervals: for each model m and day l we have parameter $\boldsymbol{\theta}_{l,m}$ and duration $t_{l,m}$.

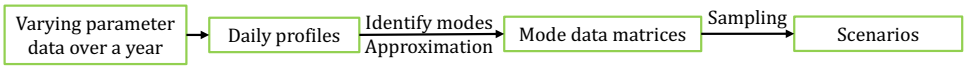

Figure 2. Scenario and mode generation procedure.

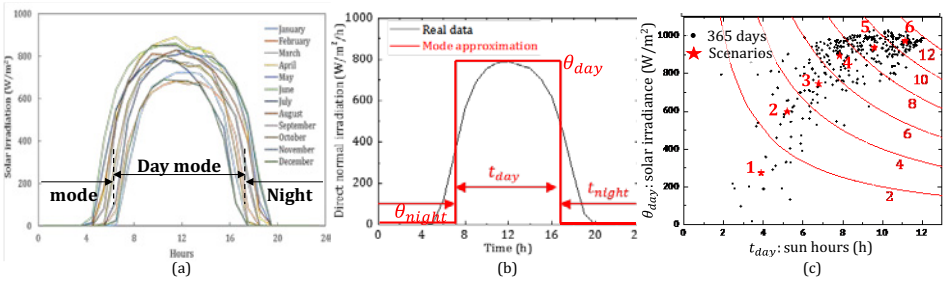

Figure 3. (a) Daily profiles of solar irradiance (b) mode-represented profiles from piecewise constant approximation and (c) 6 scenarios generated from 365 days.

For computational tractability, a small number (N) of representative days (i.e. scenarios) are selected to represent the low frequency variability (e.g., seasonal). This representation is reasonable because, in most cases, values of variability data over a year can be clustered into a small number of groups. For example, as shown in Fig. 3(c), solar conditions over 365 days (black dots) are divided into 6 groups based on the abundance of daily solar energy (energy abundance increases from bottom left to top right), and 6 scenarios are generated to represent these groups. The solar condition and occurrence frequency (π_s) of each scenario are then calculated as the average condition and the sum of occurrences of all days belonging to the corresponding group.

2.2. Multimode superstructure generation

Conventional superstructure optimization for process synthesis problems considers process alternatives at a *nominal* operating condition (Wu et al., 2016). This treatment is insufficient when the processes need to operate at different steady states as a result of variability. Accordingly, we propose a multimode superstructure that consists of different process flow sheets and unit alternatives for each mode.

To model the superstructure, we introduce three basic sets: (1) units $i \in \mathbf{I}$, (2) streams $j \in \mathbf{J}$, and (3) components $k \in \mathbf{K}$. Fig. 4 is the graphic representation of a general processing unit with all the relevant first and second stage variables.

Binary variables Z_i^d denote the selection of unit i for the overall design, while binary variables $Z_{i,m}^o$ denote the operational status (on/off) of unit i in mode m. If i is off in m ($Z_{i,m}^o = 0$), all component flows of its inlet ($j \in \mathbf{J}_{i,m}^{\mathbf{IN}}$) and outlet streams ($j' \in \mathbf{J}_{i,m}^{\mathbf{OUT}}$) are forced to zero. Streams are indexed over (i, m) because different streams can connect to the same unit in different modes. Unit i is installed if it is turned on in any mode.

$$Z_i^d \geq Z_{i,m}^o \quad i \in \mathbf{I}, m \in \mathbf{M} \tag{1}$$

The unit operation over scenarios and modes can then be formulated using a flow-based approach given as, in its general form, as,

$$(\boldsymbol{y}_{i,s,m}^{\mathbf{3}}, \boldsymbol{y}_{i,s,m}^{\mathbf{4}}) = f(\boldsymbol{y}_{i,s,m}^{\mathbf{1}}, \boldsymbol{y}_{i,s,m}^{\mathbf{2}}) \quad s \in \mathbf{S}, m \in \mathbf{M} \tag{2}$$

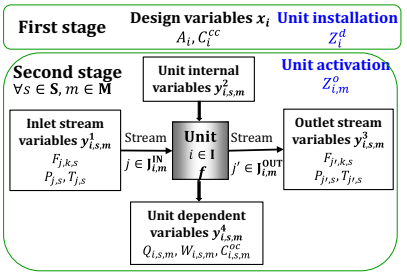

Figure 4. A general processing unit.

where $\boldsymbol{y_{i,s,m}^1}, \boldsymbol{y_{i,s,m}^2}$ are input operational variables and $\boldsymbol{y_{i,s,m}^3}, \boldsymbol{y_{i,s,m}^4}$ are output operational variables. Specifically, $\boldsymbol{y_{i,s,m}^1}$ are inlet stream variables (component flow rates $F_{j,k,s}$, stream temperatures $T_{j,s}$ and pressures $P_{j,s}$); $\boldsymbol{y_{i,s,m}^2}$ are unit internal variables (e.g. distillation reflux ratio); $\boldsymbol{y_{i,s,m}^3}$ are outlet stream variables ($F_{j',k,s}, T_{j',s}, P_{j',s}$); and $\boldsymbol{y_{i,s,m}^4}$ are unit dependent variables (e.g., heat duty $Q_{i,s,m}$, work $W_{i,s,m}$, operational cost $C_{i,s,m}^{oc}$).

While operational variables are different across modes and scenarios, design variables $\boldsymbol{x_i}$ (equipment size A_i, capital cost C_i^{cc}) are decided at the first stage, that is, remain fixed during operation. To guarantee operational feasibility, the equipment size is chosen as the maximum required size among all scenarios and modes:

$$A_i \geq f_i^{sizing}(\boldsymbol{y_{i,s,m}^1}, \boldsymbol{y_{i,s,m}^2}, t_{s,m}) \;\; i \in \mathbf{I}, s \in \mathbf{S}, m \in \mathbf{M} \tag{3}$$

where f_i^{sizing} is the unit sizing function, which carefully selected so that when unit inlet component flows are equal to zero, f_i^{sizing} is also forced to zero.

2.3. Multimode stochastic programming

The optimization problem is formulated as a two-stage stochastic programming approach with multimode subproblems inside each scenario, leading to a multimode stochastic programming model given as follows,

$$\begin{aligned}
&\min_{x} f^1(\boldsymbol{x}) + \textstyle\sum_s \pi_s \cdot Q_s\left(\boldsymbol{x}, \boldsymbol{\theta}_{s,m}, t_{s,m}\right) \\
&\quad \boldsymbol{x} = [\,\boldsymbol{x}^{\mathbb{B}}, \boldsymbol{x}^{\mathbb{C}}]^{\mathrm{T}}, \boldsymbol{x}^{\mathbb{B}} \in \{0,1\}^{n1}, \;\; \boldsymbol{x}^{\mathbb{C}} \in \mathbf{R}^{n2} \\
&\quad Q_s = \min_{\boldsymbol{y_{s,m}}} f^2(\boldsymbol{x}, \boldsymbol{y_{s,m}}, \boldsymbol{\theta}_{s,m}, t_{s,m}) \qquad \forall\, s \in \mathbf{S} \\
&\quad \text{s. t.} \left.\begin{array}{c} h_{s,m}(\boldsymbol{x}, \boldsymbol{y_{s,m}}, \boldsymbol{\theta}_{s,m}) = 0 \\ g_{s,m}(\boldsymbol{x}, \boldsymbol{y_{s,m}}, \boldsymbol{\theta}_{s,m}) \leq 0 \\ r_{s,m}(\boldsymbol{x}, \boldsymbol{y_{s,m}}, t_{s,m}, \boldsymbol{y_{s,m+1}}, t_{s,m+1}) = 0 \\ \boldsymbol{y_{s,m}} = \left[\,\boldsymbol{y_m^{\mathbb{B}}}, \boldsymbol{y_{s,m}^{\mathbb{C}}}\right]^{\mathrm{T}}, \boldsymbol{y_m^{\mathbb{B}}} \in \{0,1\}^{n1}, \boldsymbol{y_{s,m}^{\mathbb{C}}} \in \mathbf{R}^{n3} \end{array}\right\} \forall\, m \in \mathbf{M}
\end{aligned} \tag{4}$$

where $\boldsymbol{x}$ are design variables, including discrete $\boldsymbol{x}^{\mathbb{B}}$ (i.e. Z_i^d) and continuous $\boldsymbol{x}^{\mathbb{C}}$ (i.e. A_i, C_i^{cc}) decisions; $\boldsymbol{y_{s,m}}$ are operational variables, including discrete $\boldsymbol{y_m^{\mathbb{B}}}$ (i.e. $Z_{i,m}^o$) and continuous $\boldsymbol{y_{s,m}^{\mathbb{C}}}$ (i.e. $\boldsymbol{y_{i,s,m}^1}, \boldsymbol{y_{i,s,m}^2}, \boldsymbol{y_{i,s,m}^3}, \boldsymbol{y_{i,s,m}^4}$); $h_{s,m}$ are equality constraints (e.g. unit mass and energy balances); $g_{s,m}$ are inequality constraints including equipment sizing equations and design specifications; and $r_{s,m}$ are coupling constraints (e.g. storage or inventory level tracking) that connect the operation across modes.

3. Case study: Concentrating solar power plants

We apply the proposed framework to concentrating solar power (CSP) plants with thermochemical energy storage (TCES) (shown in Fig. 5). CSP converts concentrated sunlight to heat, which then drives a turbine to generate electricity. TCES stores the solar-heat for night power generation by reversibly converting it to chemical energy. The plant comprises four subsystems, the collector, receiver, TCES and turbine. Note that different process configurations are adopted in day and night modes.

In previous work by the authors, a deterministic optimization model for CSP+TCES processes operating at a nominal annual average solar condition has been developed (Peng et al., 2017). Building upon that work, we consider the seasonal and daily variability in solar irradiance (θ: direct normal irradiance W/m^2).

We chose Daggett in southern California as the CSP plant site and obtain its hourly solar irradiance data over 1-year from the National Solar Radiation Data Base. We generate six scenarios, each has two modes (shown in Fig. 3(c)).

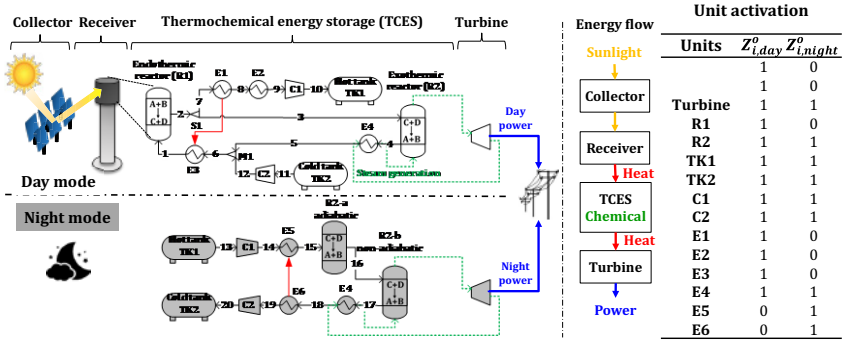

Figure 5. Process flow sheet of CSP plants with fluid phase TCES systems.

3.1. Model of CSP plants

Our goal is to simultaneously optimize design and operation to minimize the overall levelized cost of electricity (LCOE). The first-stage design variables ($\boldsymbol{x}$) include solar field area, receiver size and TCES equipment sizes. The second-stage operational variables ($\boldsymbol{y_{s,m}}$) include turbine output levels, stream flow rates and unit operating conditions. Equality constraints arise from the physical model of subsystems (i.e. collector, receiver and turbine), unit mass and energy balances, as well as cost calculations. Inequality constraints arise from equipment sizing and design specifications. Coupling constraints arise from material balances around storage tanks. We specify the plant nameplate capacity as 100 MW and generate bounds for all design and operational variables through a propagation algorithm.

3.2. Results

The resulting MINLP model has 1095 variables and 1461 constraints. It is formulated in GAMS (24.2.3) and solved using global optimization solver BARON (12.7.7) (Tawarmalani and Sahinidis, 2005) on an Intel® .

The design and LCOE obtained from the proposed stochastic approach based on six scenarios and the deterministic approach based on an annual average day are compared in Table 1. The stochastic design achieves a 0.5 $¢/kWh$ LCOE reduction over the

deterministic design (i.e., the value of stochastic solution). While the turbine capacity in both designs is fixed to 100 MW, the deterministic approach leads to a design where the other subsystems are larger (i.e., higher capital cost). This is because the average day assumption overestimates the plant performance. This *larger* (deterministic) design is inferior when the seasonal variability is considered.

Table 1: Comparison of stochastic and deterministic designs

Approach	LCOE (¢/kWh)	Capital cost (M$)				
		Total	Collector	Receiver	TCES	Turbine
Proposed	12.7	801	381	192	49	179
Deterministic	13.2	892	451	211	51	179

Power output levels and compression demand in all scenarios are shown in Fig. 6. In *sunny* scenarios 5 and 6, the plant maintains the full load for both day and night. In less sunny scenarios, the daytime production is high but night drops notably. The reason is that night power generation requires extra compression for reaction gas storage, the amount of which depends on both the night turbine output level and the night duration. Finally, in scenario 1, there is no night production because the total solar input is low.

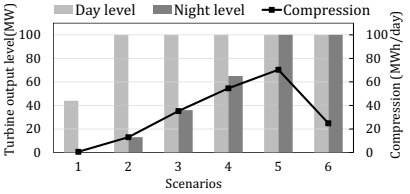

Figure 6. Turbine output levels and compression demand for storage in all scenarios

4. Conclusions

We developed a framework for process synthesis under seasonal and daily variability, represented by scenarios and modes respectively. A multimode superstructure is constructed to consider different process alternatives for each mode. The optimization design model was formulated as a multimode stochastic programming model. The proposed framework allows us to develop better designs of systems that are subject to two variability in two frequencies, notably, renewable energy systems converting solar energy to liquid fuels and power.

Abstract

This work describes a simple algorithm based on partial least square (PLS) to enable the construction of surrogate models using a single tuning parameter. The proposed algorithm is illustrated with the case study of a membrane module for natural gas sweetening, where a mechanistic model is used as data generator. The effect of the tuning parameter is analysed, and it is shown that this parameter captures the trade-off between the surrogates' accuracy and their complexity (number of terms). The algorithm performance is also compared with four different approaches from the literature, showing a similar performance.

Keywords: surrogate modelling, variable selection, optimization, natural gas sweetening.

1. Introduction

The development of efficient numerical methods alongside faster computers has triggered a step-change in the process synthesis area, where heuristic approaches are being replaced by superstructure optimization approaches, due to their better capacity to account for a large number of design alternatives (Henao and Maravelias, 2011). However, optimization-based process synthesis methods lead to complex mathematical programs, which even nowadays, prove difficult to solve when detailed, mechanistic models are used to represent each process in the superstructure. One approach to overcoming this computational burden is to replace these detailed models by simpler models (also called, surrogates, emulators or reduced-order models). The later can be fitted with data generated by the former, and thereby remain accurate in a certain operational region. Over the last decade, the use of these surrogate models in the area of process design and synthesis has been reported by a number of authors; see, e.g., Caballero and Grossmann (2008), Huang et al. (2012).

The surrogate-based optimization approach follows four basic steps: (i) a sample set of independent variables is taken within a certain operational region; (ii) the mechanistic model is simulated for this sample set; (iii) the surrogate is fitted using the input/output information provided by the mechanistic model; and (iv) optimization studies are conducted based on the surrogate, and the results are checked against the mechanistic model. Of course, the major issue faced by any surrogate modeling approach is making sure that the optima of both the surrogate and mechanistic models match. In other words, it is necessary to have a compromise between the possible underfit and overfit

that may occur during parameter estimation in step (iii). To overcome this problem, it is necessary to select a model that is flexible enough to fit the data, yet not too flexible to prevent over-fitting. The review paper by Bhosekar and Ierapetritou (2018) emphasize the importance of model selection in surrogate-based optimization, and lists a number of methods to perform this selection, including heuristics, integer programming, methods relying on model fitness, Bayesian variable selection, and methods based on correlation between input-output variables.

Special attention has been given to surrogates comprised of algebraic equations since they can easily be incorporated into optimization platforms such as GAMS and AMPL. There, a local or global optimization solver can be used to solve the MINLP problems resulting from the superstructure formulation. Recently, Cozad et al. (2014) proposed an algorithm for the proper construction of algebraic surrogates using a reformulated Akaike Information Criterion. The resulting MILP is solved a number of times, by increasing the total number of input variables until the information criterion gets worse. Boukouvala and Floudas (2017) presented an algorithm for global optimization based on surrogate models. In their approach the model selection step is performed by the Sure Independence Screening method (SIS) implemented in the R® language, which applies a ranking criterion to sort the input variables with respect to the vector of marginal correlations to the outputs, and then selects a suitable surrogate based on standard regularization methods for variable selection (Fan and Lv, 2008).

Of the alternatives to develop surrogates are algorithms for dimensionality reduction using partial least square (PLS). This family of methods analyzes the estimation problem in a projected space, performing the variable selection by adding informative variables to construct a new reduced model or by removing non-informative variables from a complete initial model. The goodness-of-fit may be assessed by cross-validation, which is a model validation technique used to estimate the model prediction capacity over an independent data set. The review paper by Mehood et al. (2012) on model selection methods using PLS cites a relatively large number of algorithms developed for this problem. In the present paper we describe a simple implementation of such model reduction algorithms in MatLab®, based on the standard *plsregress* function. This algorithm relies on the wrapper methods class presented by Mehmood et al. (2012) and presents the advantage of using a single tuning parameter as the stopping criterion. We compare our algorithm with four other alternatives implemented either in MatLab® and R®, using the case study of a membrane module for natural gas sweetening.

2. Problem Statement

Consider a vector of measured output variables $y \in \mathbb{R}^{n_{exp}}$, with n_{exp} the number of sampling points; and a set of input measurements $\boldsymbol{X} \in \mathbb{R}^{n_{exp} \times n_v}$, with n_v the number of possible combinations for the input variables (or basis functions such as polynomial, radial or exponential forms). The problem is to determine a compact surrogate model in the form of Eq.(1), where $\boldsymbol{X_s} \in \mathbb{R}^{n_{exp} \times n_s}$ is a subset of $\boldsymbol{X}$, $\beta \in \mathbb{R}^{n_s}$ is the vector of predicted parameters, $\varepsilon \in \mathbb{R}^{n_{exp}}$ is the vector of errors, and n_s is the number of selected terms from the initial model.

$$y = \boldsymbol{X_s}\beta + \varepsilon \tag{1}$$

The objective is to obtain a surrogate model comprising the least number of terms (or basis functions) n_s, as well as values for its parameters β, in order to: (i) minimize the

error vector ε (model underfit); and (ii) minimize the prediction error as estimated by cross-validation (model overfit). Another constraint in this problem is that the number of selected variables should remain lower than the number of experiments, $n_s < n_{exp}$, in order to avoid a direct interpolation of the available data by the selected surrogate.

3. An algorithm for model reduction based on standard PLS regression

The proposed algorithm is similar to the COVPROC algorithm proposed by Reinikainen and Höskuldsson (2003). There, the surrogate model is constructed variable by variable, until it reaches the stopping criterion that balances the quality of fit and prediction. Instead, we compute the stopping criterion herein based on the best-case scenario obtained with the complete model $\boldsymbol{X}$, which tends to overfit the set of measurements. Specifically, by using cross-validation, it is possible to obtain the minimum value of the objective function (mean square error of cross-validation, MSECV), which is used as the stopping criterion in turn. Basically, the algorithm proceeds in 6 steps:

Step 1: *Determine the stopping criterion value for the best-case scenario* – The best-case scenario for the PLS regression corresponds to the complete model $\boldsymbol{X}$, and entails determining the number of latent values which minimizes the MSECV. Figure 1 illustrates a typical MSECV profile with respect to the number of latent variables: the MSECV decreases with an increasing number of latent variables until a minimal value is reached (latent variable number 53), after which the MSECV starts to increase due to model overfitting. The stopping criterion is calculated as $sc = wcv - (wcv - bcv)t$, where wcv is the worst-case value (minimum number of latent variables), bcv is the best-case value (ideal number of latent variables), and $0 \leq t \leq 1$ is the tuning parameter accounting for the model accuracy. The best accuracy is obtained with $t = 1$, yet this comes at the price of a greater number of latent variables.

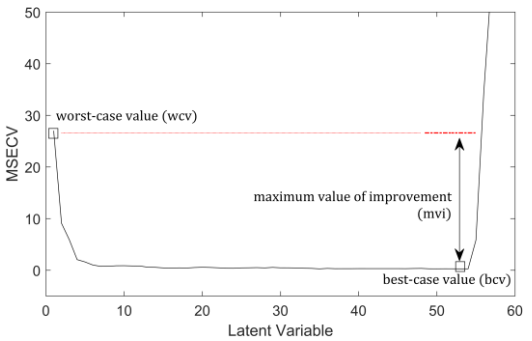

Figure 1. Illustrative example of a typical MSECV curve

Step 2: *Determine the initial number of latent variables* – This entails finding the minimum number of latent variables such that MSECV $\leq sc$. In Figure 1 for instance, if t is set as 0.95, the algorithm retains the first 6 latent variables (n_{LV}) as an initial guess.

Step 3: *Reduce the model* $\boldsymbol{X}$ *to a subset of selected variables* $\boldsymbol{X_s}$ *for the given* n_{LV} – We use the MatLab® function *plsregress* to compute the set of loading weights (w), as a measure of the importance for each model term on the latent variables (Mehmood et al., 2012). This information is used to select the model variable from $\boldsymbol{X}$ having the largest absolute value for each latent variable in order to build the reduced model $\boldsymbol{X_s}$.

Step 4: *Perform a PLS regression with the reduced model* $\boldsymbol{X_s}$ – A new curve of MSECV is computed with the reduced model.

Step 5: *Find a set of latent variables for the reduced model* $\boldsymbol{X_s}$ – The MSECV curve is analyzed with an increasing number of latent variables for finding the minimal number of components satisfying the stopping criterion MSECV$\leq sc$. If the latter stopping criterion is reached, the algorithm stops with a decision for $\boldsymbol{X_s}$ and the correspondent number of latent variables. Otherwise, it continues to Step 6.

Step 6: *Increase the surrogate dimensionality* n_{LV} – If the number of latent variables n_{LV} is less than the number of experiments n_{exp}, the algorithm sets $n_{LV} \leftarrow n_{LV} + 1$ and returns to Step 3. Otherwise, it stops and returns the best possible $\boldsymbol{X_s}$ for which the number of variables in the surrogate is less than the number of experiments $(n_s < n_{exp})$.

It is worth noting that the algorithm may be used to detect the need for more experimental data. When the algorithm terminates in step 6, and the reduced model does not present an acceptable level of adjustment, it would indeed be necessary to obtain more experimental data to properly fit the output variable y; one may also increase the complexity of the initial set of basis functions $\boldsymbol{X}$ to promote a better fit.

4. Case study

The proposed algorithm is compared with four different alternatives available in the literature. Table 1 lists these algorithms and summarizes their main features.

Table 1. List of algorithms for variable selection

Description	Reference
GA-PLS 1 (Matlab®) Genetic algorithm combined with PLS. In this class of algorithms, different subsets of input variables are used to fit the model. The selection occurs in the way that variables that show a better fit have a higher probability to continue in the sets of selected variables in the subsequent iterations.	(Leardi, 2000)
GA-PLS 2 (R®) Genetic algorithm combined with PLS. A different implementation of the genetic algorithm combined with PLS for variable selection.	(Hasegawa et al., 1997)
SIS (R®) Sure independent screening. This method proceeds in two main steps. First, the input set $\boldsymbol{X}$ is reduced to a number of input variables less than the number of experiments. Next, the algorithm uses a penalization method to refine the surrogate model.	(Fan and Lv, 2008)
MC-UVE-PLS – R® – Monte Carlo based uninformative variable elimination. In this approach, the input set $\boldsymbol{X}$ is augmented by noise variables. After that, the variables that have less "importance" than the artificial noise are eliminated from the model. This procedure is repeated until the prediction error get worse.	(Centner et al., 1996)

The input-output data used to fit the surrogates are generated from a detailed mechanistic model of a membrane module used in natural gas sweetening (Scholz et al., 2013). This model describes a number of non-ideal effects (concentration polarization, pressure loss, real gas behaviour and Joule-Thomson effect) and predicts the concentration of 5 species (CO_2, H_2S, CH_4, C_2H_6, and C_3H_8), resulting into a large and complex set of equations. In this particular case, the use of surrogate models to optimize

and/or integrate this system into a superstructure for membrane network design may be an attractive choice. The detailed model comprises 9 input variables (feed flow rate, temperature, pressure, composition and pressure of the permeate side) that are sampled within a given operational region using Latin Hypercubes Sampling to generate 60 experimental points. Then, the mechanistic model is used to simulate the corresponding set of output variables. The objective of the surrogate model presented hereafter is to predict the behaviour of the permeated stream temperature. Due to the presence of CO_2 and the large pressure drop across the membrane, the temperature of permeate stream decreases as a result of the Joule-Thomson effect, which modifies the membrane permeability and its overall separation performance in turn. The complete initial model $\boldsymbol{X}$ is given by a second-order polynomial model of the 9 input variables plus an artificial variable (membrane pressure drop), resulting in a complete model with a total of 65 basis functions (n_V). 80 percent of the set of input-output variables are used to select and calibrate the surrogate models, while the remaining 20% are used to evaluate the performance of the resulting surrogate models. Table 2 summarizes the results obtained with each approach.

Table 2 – Results obtained for different model reduction algorithms

Algorithm	Tuning factor	n_s	n_{LV}	r^2	RMSEV [°C]
This work	0.950	4	3	0.9454	1.1602
	0.980	5	4	0.9775	0.7329
	0.990	6	5	0.9817	0.6713
	0.995	8	7	0.9955	0.3322
	1.000	25	21	0.9981	0.2147
GA-PLS 1	n/a	27	10	0.9971	0.2665
GA-PLS 2	n/a	10	4	0.9965	0.2936
SIS	n/a	7	n/a	0.9986	0.1838
MCUVE-PLS	n/a	22	6	0.9967	0.2851

RMSEV – root mean square error of validation; r^2 – correlation factor

Increasing the tuning factor t up to 0.995 results in a moderate increase in the number of selected basis functions n_s, yet in a significant increase in the correlation factor r^2. Then, increasing t further from 0.995 to 1 results in a sharp increase in the number of selected variables, yet a small increase in r^2, which is consistent with the MSECV profile shown in Figure 1. It is difficult to determine the optimal value for the tuning parameter t a priori since the MSCEV profile is problem specific, but understanding this tuning parameter could be used as a means to evaluate the surrogate's accuracy with respect to the number of selected terms. The algorithms GA-PLS 1, GA-PLS 2 and MCUVE-PLS present a large variability in the resulting surrogates, changing the number and the selected basis functions to compose the final surrogate model. This behaviour may be partly attributed to the stochastic nature of these algorithms. However, this stochasticity is not necessarily seen as a problem here, as long as the algorithm is able to identify a compact surrogate model with good predictive capabilities, as observed for instance in the results of GA-PLS 2. It is worth noting that, for results obtaining errors less than 0.5°C, only three out six cases selected a number of basis functions lower than or equal to 10. In all the other cases, the number of selected basis functions is, at least, twice as large. The algorithm SIS presented the best result among the tested algorithms, since it provides the smallest surrogate model with the best prediction capacity within the validation set.

5. Conclusion

This paper has presented an algorithm for construction of surrogate models based on PLS techniques. This algorithm features a simplified term selection, by employing a single tuning parameter to capture the trade-off between accuracy and complexity of the candidate surrogate models. An application of this algorithm has been presented for the surrogate modelling of a membrane module used in natural gas sweetening. The results have been compared with four other approaches from the literature, showing that the proposed algorithm can exhibit a comparable performance to these existing approaches for suitable values of the tuning parameter. Naturally, it is not possible to decide which algorithm is better by analysing a single case study, but the approach is nonetheless useful to identify key features and limitations of the proposed algorithm. In practice, the variability in the algorithm outcomes, associated with their fast processing, suggests that several algorithms could be run concurrently, and only the best surrogate models would then be retained amongst the resulting candidates.

A Comprehensive Approach for the Design of Solvent-based Adhesive Products using Generalized Disjunctive Programming

Jingyue Cui[1], Suela Jonuzaj[1] and Claire S. Adjiman[1,*]

[1]*Centre for Process Systems Engineering, Department of Chemical Engineering, Imperial College London, London SW7 2AZ, U.K.*
c.adjiman@imperial.ac.uk

Abstract

In this work, we present a comprehensive and systematic methodology for the design of optimal adhesive products within the computer-aided product design (CAPD) framework. In the proposed approach, the optimal number, identities and compositions of active ingredients and solvents in the final product are determined simultaneously. Generalised Disjunctive Programming (GDP) is employed to formulate the main design decisions of the problem (i.e., how many ingredients should be included, which active ingredients and solvents compounds should be used and in what proportions). The design methodology has been applied to identifying cheap and environmentally friendly acrylic adhesives, which are commonly used in construction.

Keywords: Adhesives, Product design, CAPD, GDP.

1. Introduction

There has been growing interest in the chemical industry towards the manufacturing of improved adhesive products that meet specified target properties over the last decades. Adhesives are formulations that can join materials together when applied on their surfaces, and are widely used in consumer goods, paper and packaging industry, construction, and transportation [Kinloch, 1987; Ceresana Market Research, 2017]. Nearly 14 million tonnes of adhesives are used worldwide and market demand is expected to increase in the next decade, resulting in a substantial revenue increase of 3.6 % per year [Ceresana Market Research, 2017]. Therefore, the design of environmentally benign adhesive products at minimum cost and time is important to maintain sustainability in a highly competitive field.

Although extensive work has been conducted within the Computer-Aided Product Design (CAPD) framework [Gani, 2004] for designing commodity products, pharmaceuticals and agrochemicals [Conte et al., 2011; Mattei et al., 2014; Gani and Ng, 2015], only a few model-based studies have been reported in the literature for the design of adhesives, including dental adhesives [Abedin et al., 2017; Spencer et al., 2010] and die attach adhesives [Fung et al., 2016]. Product formulations contain blends of ingredients from different chemical categories (e.g., polymers, solvents or solvent mixtures and aromas) which are often challenging to determine simultaneously due to the combinatorial explosion of the problems (many possible combinations of chemicals), leading to hierarchical design methodologies where each type of ingredients is determined in sequential steps [Conte et al., 2011; Mattei et al., 2014]. Within the decomposition-based methods smaller sequential subproblems are usually posed and

solved, where the active ingredient is first determined, and then solvents or binary solvent mixtures and additives are identified.

In this work, we propose the first comprehensive CAPD formulation for the design of acrylic adhesives. We develop this within the framework of a generic methodology in which the number of components, their identities and compositions are optimized simultaneously to maximize performance [Jonuzaj et al., 2016; Jonuzaj and Adjiman, 2017]. The optimal active ingredient and solvent mixtures are selected from given lists of candidate compounds. The design methodology is applied successfully to the design of environmentally friendly solvent-based acrylic putty.

2. Adhesive product design

2.1. Problem definition

The CAPD problem involves the generic formulation of the product design problem where the optimal number of ingredients, the optimal identities of all components and their compositions are identified, such that all given specifications are satisfied and the performance objective is optimised. The adhesives to be designed consist of three main classes of chemicals, the active ingredient (AI), solvent mixtures and additives. AI (usually a polymer) is the most important substance that defines the main function of the product; the solvent mixtures are usually in high concentration and are used to dissolve the AI and additives; small quantities of additives are present in the formulation to enhance the product quality and attributes. Here, additives in small concentrations (traces) that may be included in the final product are not taken into account and are not included in the design formulation. In order to develop the formulations, we define several index sets. The first is the set of components in the formulation, $I=\{1,\ldots,N_c\}$, where N_c is the total number of product ingredients. $N=\{1,\ldots,N_{max}\}$ is the set of components to be determined, whereas the sets $A=\{1,\ldots,N_a\}$ and $S=\{1,\ldots,N_s\}$ define the lists of compounds from which the unknown active ingredients and solvent components must be chosen, respectively.

2.2. GDP formulations

GDP techniques and different solution strategies have recently been employed to formulate mixture design problems [Jonuzaj et al., 2016]. The GDP formulation of the generalized product design problem is given as follows:

$$\begin{aligned}
\min_{x,Y} \quad & f(x) \\
\text{s.t.} \quad & g(x) \le 0 \\
& \bigvee_{a \in A} \begin{bmatrix} \hat{Y}_{i,a} \\ r_{i,a}(x) \le 0 \end{bmatrix}, i \in I \\
& \bigvee_{s \in S} \begin{bmatrix} Y_{i,s} \\ h_{i,s}(x) \le 0 \end{bmatrix}, i \in I \\
& \bigvee_{n \in N} \begin{bmatrix} \tilde{Y}_n \\ \tilde{F}_n(x) \le 0 \\ x_i \ge x_i^L, i = 3, \ldots, n \\ x_i \ge 0, i = n+1, \ldots, N_c \end{bmatrix}
\end{aligned}$$

$$\Omega\left(\hat{Y}, Y, \tilde{Y}\right) = \text{True}$$
$$x \in [x^L, x^U] \subset \mathbb{R}^m$$
$$\hat{Y}, Y, \tilde{Y} \in \{\text{True}, \text{False}\} \qquad (GDP)$$

where *f* and *g* represent the objective function and general constraints that must hold regardless of the discrete choices, respectively. Three different disjunctive sets are included in the general model. The first two sets involve disjunctions for assigning an active ingredient *a* and a solvent *s* from the lists (*A* and *S*) to components *i* in the product formulation. Conditional constraints $r_{i,a}$ and $h_{i,s}$ are active when the corresponding Boolean variables $\hat{Y}_{i,a}$ and $Y_{i,s}$ are true, respectively. The third disjunction includes constraints, $\tilde{F}_n$, that depend on the number of product ingredients and are active when the Boolean variable $\tilde{Y}_n$ is true. The mole fraction, x_i, of a component i is greater than a user-specified threshold value x_i^L if the component is present in the product formulation and is zero otherwise. It is noted that the mole fraction of the AI and the first solvent component are always greater than zero (the AI and at least one solvent should be present in the formulation). Logic propositions $\Omega\left(\hat{Y}, Y, \tilde{Y}\right)$ are derived to avoid degenerate solutions and relate the Boolean variable for the identities and number of components. The GDP formulation is converted into an MINLP problem by replacing the Boolean variables with binary ones and converting the logic propositions into linear inequalities. Conditional constraints inside the disjunctions are formulated using the big-M approach. A detailed description of the logic relations and the resulting MINLP model is given in Jonuzaj et al. [2016].

3. Case study: the design of acrylic putty

3.1. Problem description

The objective of the design problem is to identify an optimal AI and solvents or solvent mixtures that participate in acrylic putty in order to minimise the toxicity of the product. The problem includes phase stability and phase equilibrium relations which increase the complexity of the models. In particular, the mixture problem consists of nonlinear and nonconvex solid-liquid equilibrium relations for calculating the solubility of the AI in solvent mixtures, and the miscibility function to ensure that the generated solvent mixtures are in one liquid phase, as shown in Table 1. The liquid phase activity coefficients are calculated with the UNIFAC model. Pure component and mixture properties, such as toxicity (τ), viscosity (η), surface tension (σ) and evaporation time (T^{90}), are evaluated using experimental values [Martin and Young, 2001] or group contribution methods and linear mixing rules (when no experimental property values exist). The optimal AI and solvent components are selected from lists of 4 and 8 candidates, respectively. The candidate polymers and solvents used in this case study have been selected based on the effectiveness of the chemicals to achieve product attributes, their cost, health-and-safety issues and environment impact. In the application of the proposed methodology, we consider two formulations: (i) a restricted problem (models P1-P5), where we fix the number of ingredients, and products with one AI and one, two, three, four or five solvents are determined (i.e., *N*=1-6); (ii) the generalized problem (P6), where the number of components is not fixed but bounded by a maximum N_{max}, which takes a value of 6 here (i.e., 1 AI and up to 5 solvents).

Table 1: Problem specifications.

Description	$N \leq 6$
Components in the mixture	1 active ingredient (a) and up to 5 solvents (s_1 - s_5)
Active ingredients (AI) [Warson, 1993]	3 units of methyl methacrylate (3MMA), 3 units of propyl methacrylate (3PMA), 4 units of butyl acrylate (4BA), 4 units of ethyl acrylate (4EA)
Candidate solvents [Ebnesajjad and Landrock, 2015]	ethyl acetate, butyl acetate, hexane, benzene, ethyl benzene, propyl benzene, toluene, xylene
Model equations [Conte et al., 2011; Martin and Young, 2001]	$\ln x_a + \ln \gamma_a = \frac{\Delta H_{fus,a}}{R}\left[\frac{1}{T_{m,a}} - \frac{1}{T}\right]$, $\frac{\partial \ln \gamma_i^{i,j}}{\partial x_i^{i,j}} + \frac{1}{x_i^{i,j}} \geq 0$, UNIFAC model, $0.6 \leq \eta \leq 0.9$, $26.5 \leq \sigma \leq 29.5$, $55 \leq T^{90} \leq 570$, linear mixing rule: $\xi = \sum_{i=1}^{N_c} \xi_i x_i$
Problem size	1,402 eqns., 819 continuous and 109 discrete vars.

3.2. Results and discussion

All models (P1-P6) were implemented and solved in GAMS version 24.8.3, running on a single core of a dual 6 core Intel Xeon E5-1660 machine at 3.30 GHz. SBB [Bussieck and Drud, 2001], a local branch-and-bound MINLP solver, was used to solve all problem cases presented. GAMS files for all MINLP models can be found at *https://zenodo.org/record/1163603* and the results are summarized in Table 2.

Table 2: Optimal product toxicity (τ), identities and composition (x_i) of AI and solvent mixtures, obtained when solving the restricted and generalised problems of the case study. The lower bound of solvent mole fractions in the mixture is set to $x_i^L = 0.01$.

Problem	τ	Ingredients	Components	x_i	CPU (s)	$N_{\equiv}^{o}$ of nodes
P1 (N=2)	4.114	a	3PMA	0.207	0.24	22
		s_1	Ethyl acetate	0.793		
P2 (N=3)	4.097	a	3PMA	0.100	0.50	48
		s_1	Toluene	0.853		
		s_2	Butyl acetate	0.047		
P3 (N=4)	4.018	a	3PMA	0.104	2.29	142
		s_1	Ethyl benzene	0.563		
		s_2	Ethyl acetate	0.219		
		s_3	Toluene	0.114		
P4 (N=5)	**3.976**	a	3PMA	0.100	22.60	716
		s_1	Ethyl benzene	0.447		
		s_2	Ethyl acetate	0.228		
		s_3	Toluene	0.187		
		s_4	Propyl benzene	0.038		
P5 (N=6)	3.980	a	3PMA	0.100	43.07	663
		s_1	Ethyl benzene	0.475		
		s_2	Ethyl acetate	0.229		
		s_3	Toluene	0.158		
		s_4	Propyl benzene	0.028		
		s_5	Butyl acetate	0.010		

P6 ($N \leq 6$)	**3.976**	a	3PMA	0.100	153.66	1034
		s_1	Ethyl benzene	0.447		
		s_2	Ethyl acetate	0.228		
		s_3	Toluene	0.187		
		s_4	Propyl benzene	0.038		

Overall, the optimal product with the lowest toxicity is found in models P4 and P6, and consists of a poly-propyl methacrylate (3PMA) and 4 solvents (ethyl benzene, propyl benzene, ethyl acetate and toluene). The use of a solvent mixture, rather than a single solvent, leads to a product with low toxicity yet acceptable AI content. In addition to the above formulations, the traditional decomposition-based problem, where the AI is first determined and then the optimal solvents are identified in smaller subproblems, was solved; different more toxic formulations were obtained with 3MMA being identified *a priori* as the optimal AI. CPU time increases with the number of product ingredients due to the increased size of the problems. In the studied example, the restricted models with fixed number of components require less computational time than the general problem. In practice, however, formulating a single generic problem (P6) requires less user input than formulating and solving a series of restricted problems. The smallest problem (P1), where one active ingredient and one solvent are determined, is also solved globally using BARON version 17.10.16 [Tawarmalani and Sahinidis, 2005] in 3.94 CPU seconds. The results verify the optimal solution obtained with the SBB MINLP solver. Convergence to global optimality was not reached in 100,000 CPU seconds when larger problems (P2-P6) were solved.

4. Conclusions

This study provides a general and comprehensive mathematical formulation for the design of optimal adhesive products based on a computer aided product design (CAPD) framework. Within this systematic generalized approach the number of product ingredients, the identities of the components (i.e., active ingredients and solvent compounds) and their compositions were determined simultaneously. The general formulation makes it possible to identify the best AI and the optimal solvent mixture at the same time, without specifying in sequential steps each type of chemicals which may lead to suboptimal solutions. The general methodology was applied successfully to the design of acrylic adhesives, where optimal blends with one active ingredient and up to 5 solvents were determined. The simultaneous design of the AI and solvent mixtures can lead to better results than the ones obtained when fixing the active ingredient in advance. The proposed approach could be used to generate a ranked list of promising designs by adding integer cuts and would thus serve as a guide to experiments. Further work is required to evaluate the impact of uncertainty in the property prediction models and the linear mixing rule used to calculate mixture properties. Furthermore, the development of suitable algorithms to achieve global solutions should be considered.

Abstract

Natural gas is a key resource for global energy supply and serves a feedstock for many processes. Each of the natural gas utilization or monetization routes, whether to value added products or use as fuel, is associated with certain emissions and cost. Therefore, the development of effective strategies for natural resource monetization is important for profitable resource utilization. However, the global community commitment to ambitious CO_2 emission reduction targets thus there is also a need to address the environmental concerns associated with natural gas monetization. Al-Mohannadi et al (2017) introduced a method that identifies efficient CO_2 reduction options in industrial parks with a natural gas allocation model. The approach produces natural gas and CO_2 networks for an industrial city that adheres for a given CO_2 target. While, the method aims at maximizing profitability of natural gas monetization, and reduces CO_2 through the use of carbon capture and utilization (CCUS) and the application of renewable energy, it does not consider the sustainability of the networks. This work will incorporate different indicators to understand the impact of the carbon constrained natural gas allocation networks on a natural gas central economy. This insight into sustainability performance will help better design for overall environmental protection and better use of natural resources. The aim of the method is to aid policymakers to quantify and understand the economic, environment and social impact of emission regulation.

Keywords: Natural gas monetization, CO_2 reduction, Sustainable process design, Optimization, Renewable Energy

1. Introduction

The demand for natural gas is increasing for its diversities and low footprint. Recent advances in hydraulic fracking have significantly boosted proven natural gas reserves and resulted in increased natural gas processing capacities in many parts of the world (American Petrolum Institute, 2015). Natural gas can be processed into a variety of products, prominent examples of which include liquid fuels, fertilizer and methanol (Al-Douri et al, 2017). This process of producing value added products out of natural gas, known as natural gas monetization, has become an important pillar of many economies. One natural gas centric economy is State of Qatar which is the leading exporter of Liquefied Natural Gas (LNG), and a major producer of fertilizer and other basic materials over the past two decades (U.S. Energy, 2015). In the meantime, 195 countries

adopted universal, legally binding global climate to avoid dangerous climate change by limiting global warming to well below 2°C in Paris Untied Nations Conference of Parties (COP 21). Thus, there is a need to averting climate change and still conitute to sustaible growth and development.

Research contributions focused reducing the carbon footprints of existing industrial complexes with process integration approaches such as the concept of CO_2 reuse between industrial processes for example Von der Assen et al (2016) look into CO_2 utilization potential through heuristics and metric system. Abdul Aziz et al (2017) created a pinch analysis graphical method for CO_2 reuse in an industrial city that takes into account heat and power demand of the industrial site. Other research was focused on identifying highly profitable natural gas utilization schemes such as Al-Sobhi and Elkamel (2015). The method does not consider carbon dioxide reduction effect on or possible carbon dioxide utilization options. Recenetly, Al-Mohannadi et al (2017) developed an apporach to identify the most promising configurations from a number of possible monetization alternatives and carbon management options that could be applied in the industrial cluster, that exploits synergies between natural gas conversion and CO_2 management.

While, Al-Mohannadi et al (2017) consider economic and environmental aspects, social aspect is not covered leading to incomplete assessment of the designs. Thus, including sustainable evaluation (economic, environmental and social elements) into the Al-Mohannadi et al, (2017) method could assist with the design and development of low carbon emission gas utilization strategies and would reduce the probability of overlooking solutions that could come from non-systematic trial-and-error approaches. This work aims to incorporate the three dimensions of sustainability into an existing optimization framework accounting for profitability, environmental impacts and evaluate social issues such as health as explained in the next section.

2. Method

This work aims to identify sustainable strategies for natural gas utilization in an industrial clusters. It builds on the approach and model proposed by Al-Mohannadi et al (2017; 2016). In Al-Mohannadi et al (2017) Mixed Integer Linear Program (MILP) formulation, the attention is limited to clusters that utilize natural gas as the primary feedstock for its plants, where the maximum supply of natural gas is limited.

The materials exchanged within the industrial cluster are natural gas (methane) and CO_2. Each plant receives natural gas supply from a common distribution infrastructure. Each plant is connected to the existing electricity grid for power export or import. Each plant is associated with emissions and contributes to the overall footprint of the cluster. Adjusting Al-Mohannadi et al, (2017) formulation to include each plant's associated with a waste emission substance that have environmental and social impacts measured using an appropriate corresponding factor.

Plants may convert natural gas to alternative products; convert or sequestrate CO_2 through carbon capture utilization and storage, produce power at reduced or eliminated specific natural gas requirements, which feeds directly into the electricity grid, e.g. wind, solar power, or other renewable power generation. The plants however, are assumed to not process other waste substances and thus the waste emission substances will be emitted to the atmosphere. The produced network is then optimized first for

given CO_2 target and second for sustainability defined target. An example is analysed in the next section and solving using WhatsBest solver (Lindo, 2006). Illustrated Example

In this work the integration and optimization is applied on a set industrial city with known processes and layout. The analysis is focused on economic performance and emissions to the air. The main optimization objective is to maximize the annual industrial city profit adhering to carbon dioxide target, which mean the economic and environmental metrics has been covered in the objective. Using the Tool for the Reduction and Assessment of Chemical and Other Environmental Impacts (TRACI) method (EPA, 2012), the social impact is quantified. TRACI is an environmental impact assessment software available with different characterization factors to assess life cycle assessment and sustainability metrics. Characterization factors measure the potential impacts following the equation below.

$$I^i = \sum_{xm} CF^i_{xm} * M_{xm} \quad (1)$$

Where:

I^i= The potential impact of all chemicals (x) for a specific impact category of concern (i)

CF^i_{xm}= The characterization factor of chemical (x) emitted for impact category (i)

M_{xm}= The mass of chemical (x) emitted

The TRACI software can be divided into four main groups: inventory of stressors, impact categories, characterization and overall effect. The impact categories studied in this work are Global Warming impact quantified using CO_2 emissions and the social metric Human Health effect quantified using particulate emissions.

3. 1. Industrial Cluster Information

The industrial cluster studied includes a set of plants, namely a Gas-to-Liquid (GTL) facility, a Cement plant, a Natural Gas Fired Power Plant, a Renewable Solar Photovoltaic Plant (PV), Enhanced Oil Recovery (EOR), Saline Storage, Methanol plant (both a standard (A), and a CO_2 -receiving plants(B)) and a Greenhouse. The plants main products and approach required information are adopted from Al-Mohannadi et al (2017) including the required plants economic information. Table 1 shows a summary of the most important parameters in addition to the sustainability metrics used for the natural gas consuming plants.

Table 1: Industrial city data

Plant	CO_2 Factor	NO_x Factor
Methanol (A)	0.50 t/t Methanol	6.3E-5kg/t Methanol
Cement	0.54 t/t Cement	2.1 kg/t Cement
Gas-to-Liquid	4.02 t / t GTL (total)	0.3 kg /t GTL
Natural gas fired power plant	0.40 t/MWh	0.5 kg/MWh

Nitrogen oxides (NO_x) data were obtained from Oryx (2015), Cochez et al (2010) and Seebregts et al (2010). Nitrogen oxide substance effect on human health is quantified in the TRACI method using the factor (0.7 PM2.5 eq/kg NO_x). While most plants in this city emit coarse particulate matter (PM10) from gas-fired turbine fine particulate matter (PM2.5) are also produced, which can cause severe human health risk (EPA, 2012).

3. 2. Results and Discussion

It was found that when the flow of methane in the city was restricted to 30E03 t/d and no CO_2 emission was imposed, the optimization selected Methanol, GTL and Cement plants to be operated to the full capacity of products. The city maintained a profit of 3E09 $/y. It was noticed that the natural gas fired power plant met the power requirement and exports by consuming natural gas. The optimization did not activate the renewable solar power option to satisfy the demand as burning methane as fuel was more profitable. Moreover, the network chose to re-use CO_2 from GTL plant to generate extra profit from the EOR sink. When a 20 % target reduction of CO_2 was imposed on the city, the network did not lose much of its profit, this was due to revenue generating CO_2 sink namely enhanced oil recovery and methanol. Both sinks were supplied by high purity CO_2 from GTL, which did not require further treatment. When the capture target was increased to 30% CO_2 reduction, the cement plant was shut off to reduce emissions and maximum PV capacity was activated. The profit reduced 2.9E09 $/y. When the network was set to maximum CO_2 reduction, the network cost was at 5.9E05 $/y. All CO_2 was allocated to EOR and Storage. All natural gas receiving plants were switched off, except the power plant as there is a constraint on the minimum power requirement needed to export outside the city.

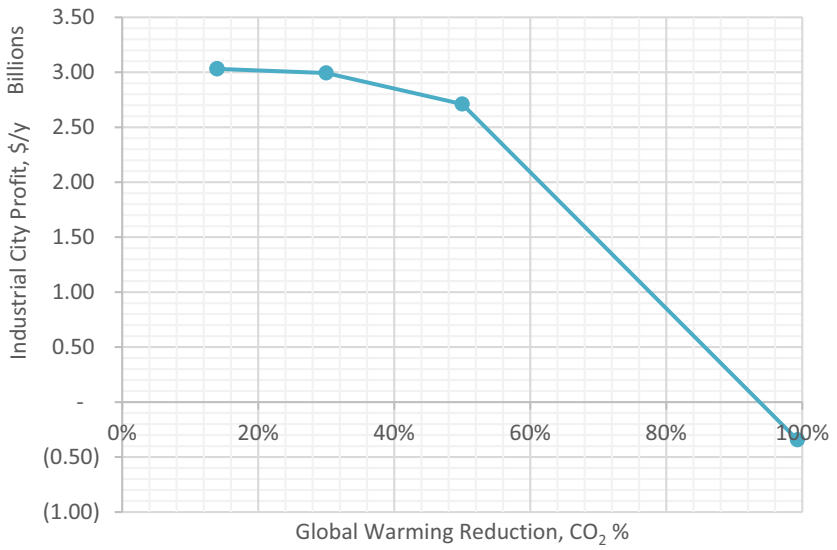

Figure 1: Industrial city's Profit vs. Global Warming Reduction

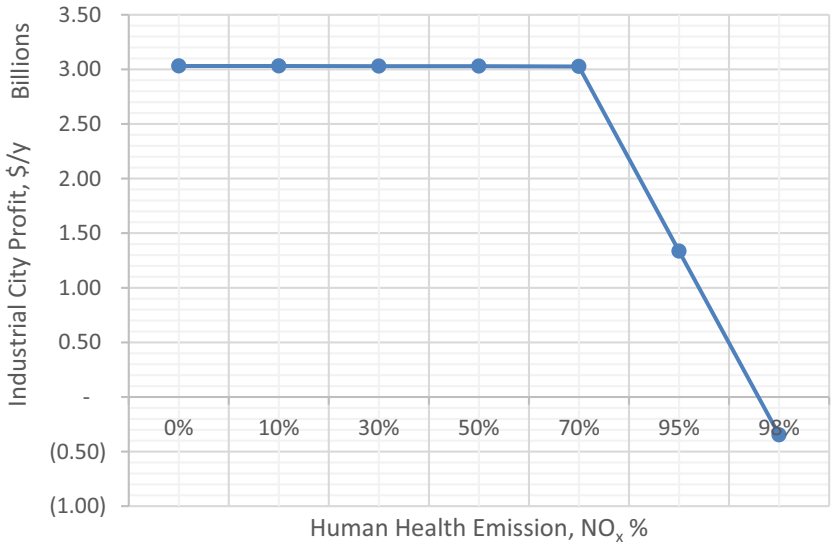

Figure 2: Industrial city's Profit vs. Negative Human Health Emission Reduction

The results of the analysis have been presented in form of a Pareto curve in Figure 1 elucidating the variation of CO_2 reduction target with the industrial city's profit. The network was also analysed to quantify the impact of human health of the city by varying the allowed NO_x emissions. The results of the analysis have been presented in form of a Pareto curve in Figure 2. When a target of 10 % reduction of NO_x emissions was set, the network allocated natural gas to maximize the capacity of the GTL and methanol plants while reducing the amount allocated to the cement plant, which was operated at 87%. When the target was increased to 30% reduction of NO_x emissions, the optimization reduced the cement output further and activated the renewable power option. When the network was solved to minimize NO_x emissions output, the network cost was -3.5E05 $/y. All natural gas plants where shut off, with the exception of the power plants due to the power export requirement.

The global warming impact and human health impact follow the same pattern when optimized against the industrial city profit. It was noticed when human health factor was reduced it also resulted in reducing CO_2 emissions. This shows that multi-objective optimization will give better insights into the trade-offs between the metrics. Furthermore, this study looked into emissions into air, the inclusion of water effluents would also enrich the assessment.

3. Conclusions

This paper introduced the concept of systematic screening of sustainable natural gas monetization in an industrial cluster. The resulting optimization-based approach can synthesize integrated natural gas, CO_2 and evaluate different defined sustainability metrics. An example is solved illustrating the applicability of the approach and showed that need to systematically screen options for different impacts in order before implementing a network design. Future work would look into multi-objective

optimization in order to get a more insightful network simultaneously instead of a stepwise approach.

Abstract

Even though the last decades have seen an explosion of simulation and optimization tools in Process Systems Engineering, this has not had a significant impact in the basic design of equipment such as heat exchangers, condensers, reboilers, distillation columns, absorption, adsorption columns, etc. To this date most mainstream textbooks advocate the use of trial and error procedures, while scattered work has been done using MINLP methods. In addition, these methods are most of the time local and/or do not converge if no good initial points are provided. We provide here alternatives to formulate global and robust rigorous models, sometimes linear. In this paper, we discuss the challenges that this quest is presenting.

Keywords: Process Equipment Basic Design, Optimization Models

1. Introduction

Practitioners employ computational tools for equipment design, but they are limited to analyze the behavior of proposed solution alternatives in a task that is highly dependent on the engineer experience. Despite the wide utilization of modern simulation tools, the rationale of the basic design procedure is usually based on trial-and-error procedures guided by heuristic rules and rarely search optimality. This philosophy is the established mainstream paradigm in design books for education and in many specialized texts. For example, in the area of heat exchanger design, the procedures recommended in current textbooks are based on the aforementioned trial-and-error schemes. These procedures contain rules of thumb or heuristic options that usually end when a solution unit performs the desired heat transfer task with an acceptable pressure drop, but without a focus on cost minimization. These procedures require the intervention of knowledgeable personnel to make good choices during the search. Heat exchanger rating software employ distributed models and up-to-date correlations, but the design solutions are obtained using simple search algorithms with several limitations. The same can be said about the design of separation vessels and distillation columns.

Advances of optimization models and mathematical programming algorithms have been made by the PSE community, but they are seldom used in the solution of equipment design problems in practice and remain difficult to solve in general. In the area of heat

exchangers is where MINLP models, in many cases difficult to solve, even locally, have proliferated.

This paper presents a discussion about the drawbacks that restrain the utilization of mathematical programming for the solution of design problems, such as: a) The utilization of simplified models obtained through analytical solutions; b) Convergence problems originated from nonlinear (MINLP) formulations. Aiming to circumvent these problems we propose some possible solutions involving: 1) The introduction of discrete variables, and reformulations to attain simpler models; 2) The need for models that represent transport properties as a function of local conditions expressed through state variables (temperature, pressure, concentration), as opposed to overall averages through the equipment. To illustrate the ideas, we show examples of simple MINLP models, MILP and IP models for the design of heat exchangers as compared to heuristics, and how global optimization can be implemented in the case where the resulting models cannot be completely and rigorously reformulated to be linear.

Finally, we clarify that the reformulations we are proposing are such that no approximations, linearizations by truncating Taylor series or other simplifications are made. In other words, the reformulated model is such that every solution of one model is feasible in the other, that is, no loss of rigor takes place.

2. Heuristic-based Trial and Error Procedures

Consider the case of the design of shell-and-tube heat exchangers. Heuristic procedures, presented in most design books (Towler and Sinnot, 2012, for example) and heat transfer books (Serth, 2007; Cao, 2010), are based on trial-and-error schemes, such as the set of steps presented below:

(1) Make initial specifications, such as fluid allocation (tube-side x shell-side), shell and head types, and heat exchanger configuration (e.g. number of tube and shell passes). Pick a combination of tube diameters, tube lengths, baffle spacing, etc; (2) Start estimating the area using some good estimate of the overall heat transfer coefficient (U^{est}), that is

$$A^{est} = \frac{\hat{Q}}{U^{est}\widehat{\Delta T}_{lm}F} \quad (1)$$

where $\hat{Q}$ and $\widehat{\Delta T}_{lm}$ are given according to the thermal task; (3) Pick a number of tubes, compatible shell diameter, such that the area matches closely to A^{est}; (4) Calculate heat transfer coefficients for the tube side and the shell side and with a recommended fouling coefficient, calculate a new overall heat transfer coefficient, and the pressure drops resulting from using the above geometric choices; (5) If the overdesign is acceptable, and the pressure drops are below recommended maximums, then the design is usually finished. Otherwise, some clever adjustments are made based on the analysis of the current trial, aiming at fixing the problems observed. After that, a new evaluation of the new solution candidate is executed (return to Step 4).

Little is said by these procedures, as to how the iteration is handled, when a new trial is needed, neither recommendations are given for the cases where the new calculated value of overall heat transfer coefficient is excessively larger that the value estimated. This is handled by somebody with expertise. One can see a similar approach for the case of designing vertical and horizontal flash-units, distillation column tray design, etc.

In conclusion: most recommended procedures do not incentivize iterative procedures, only trial and verification, that is they provide heuristics and require expertise to obtain a feasible answer, not an optimal one.

The limitations of the traditional design approaches present an opportunity for mathematical programming to contribute with solutions. Despite the number of papers published that tries to fill this gap, there are important limitations that hinder the utilization of such approaches for practical problems, as discussed in the next section.

3. Optimization Models

In the last few decades, several authors started to present different optimization approaches to the design of heat exchangers. Nowadays, the two main approaches employed are stochastic methods and mathematical programming. The utilization of mathematical programming efforts has been dominated by nonconvex formulations, encompassing older nonlinear programming approaches (Jegede and Polley, 1992) or more recent mixed-integer nonlinear programming solutions (Ravagnani and Caballero, 2007). Of all the above approaches, mathematical programming is only one that has any chance of achieving and guarantee globally optimal solutions.

A more detailed analysis of the literature about the utilization of mathematical programming techniques for solving the design problem of shell-and-tube heat exchangers indicates several aspects that limit the utilization of these approaches for practical applications:

a) The utilization of nonlinear formulations that are associated to convergence problems and multiple local optima with different values of objective function. The lack of robustness is an important barrier for the acceptance of this kind of tool by a broader audience, including practitioners;
b) Utilization of heat exchanger models based on analytical solutions where the heat transfer coefficients have a uniform value along the heat transfer area. This problem is particularly important for services with phase change (vaporization or condensation), where the conditions along the flow can change considerably.In the next sections, we discuss how these challenges have been addressed in our group.

4. Use of Discrete Variables

Our proposal is to use a set of discrete values for geometric variables, thus allowing a representation of the design solution closer to the engineering practice. Additionally, having the design variables in a discrete space allows reformulation to a linear form.

For example, heat exchanger tubes come in discrete options (3/4", 1", 1 ¼", 1 ½", 2") with different wall thickness dictated by pressure (BWG 12, 14, 16, etc.) and different discrete options for length. The same can be said for shell diameters and other geometric variables that have been standardized (TEMA). A similar case can be made for other equipment. Thus, the diameter is expressed in terms of discrete options as follows:

$$dti = \sum_{sd=1}^{sdmax} \widehat{pdti}_{sd}\, yd_{sd} \tag{2}$$

where yd_{sd} is a binary variable and $\widehat{pdti}_{sd}$ is the corresponding discrete value. The expression also requires to be accompanied by:

$$\sum_{sd=1}^{sdmax} yd_{sd} = 1 \tag{3}$$

Consider now for example the calculation of the heat transfer coefficient for the tube-side flow using the Dittus-Boelter correlation:

$$ht = \frac{0.023\, Ret^{0.8} \widehat{Prt}^{n}\, \widehat{kt}}{dti} \tag{4}$$

Assuming one tube-side pass, the expression of the Reynolds number in relation to the mass flow rate is:

$$Ret = \frac{dti\, v\, \widehat{\rho t}}{\widehat{\mu t}} = \frac{4\ \widehat{mt}}{Ntt\ \pi\ \widehat{\mu t}\ dti} \tag{5}$$

Thus, substituting, one obtains:

$$ht = \frac{0.023 \left(\frac{4\ \widehat{mt}}{\left[\sum_{sNtt=1}^{sNttmax} \widehat{pNtt}_{sNtt}\, yNtt_{sNtt}\right] \pi\ \hat{\mu}\ \sum_{sd=1}^{sdmax} \widehat{pdti}_{sd}\, yd_{sd}} \right)^{0.8} \widehat{Prt}^{n}\, \widehat{kt}}{\sum_{sd=1}^{sdmax} \widehat{pdti}_{sd}\, yd_{sd}} \tag{6}$$

Note that we replaced the total number of tubes by a sum of discrete options. The above expression is nonlinear in the binary variables and requires reformulation if it is run by most commercial MINLP.

5. Reformulation

We first realize that the product of summations elevated at a certain exponent, even negative, can be rewritten in form that contains products of integers, as follows:

$$[\sum_i \widehat{pd}_i\, yp_i]^{n1}\, [\sum_j \widehat{qd}_j\, yq_j]^{n2} \ldots [\sum_k \widehat{zd}_k\, yz_k]^{nm} = p^{n1} q^{n2} \cdots z^{nm} = \sum_{i,j,\ldots k} \widehat{pd}_i^{\,n1}\, \widehat{qd}_j^{\,n2} \ldots \widehat{qd}_k^{\,nm}\, yp_i\ yq_j \ldots yz_k \tag{7}$$

Thus Eq.(6) can be rewritten as follows:

$$ht = 0.023\, \widehat{Prt}^{n}\, \widehat{kt}\, \left[\frac{4\ \widehat{mt}}{\pi\ \hat{\mu}}\right]^{0.8} \sum_{sd=1}^{sdmax} \sum_{sNtt=1}^{sNttmax} \frac{yNtt_{sNtt} yd_{sd}}{\widehat{pdti}_{sd}^{\,1.8}\, \widehat{pNtt}_{sNtt}^{\,0.8}} \tag{8}$$

A generalized expression for this equation, valid for any number of tube passes, including the relations associated to the tube count in relation to the shell diameter can be find in Gonçalves et al. (2016). We emphasize again that we arrive at Eq.(8) by rigorous reformulation, that is without making any approximation of any sort.

In general, we expect, products of binaries and continuous variables as well as fractional terms, which we know can be easily and rigorously linearized (Williams, 2013). The resulting formulation can be MILP or even IP (Gonçalves et al., 2017). Now, we are exploring this approach for other alternatives of heat exchangers, such as double-pipe, air coolers, plate-and-frame, and plate-and-fin; there are also investigations using a similar approach to the design of the internals of distillation columns, flash units and separators.

Another alternative for representation of the discrete variables is the utilization of a table that contains all combinations of the discrete values, i.e. each row of the table is a solution candidate. Therefore, instead of using several sets of binary variables, this

formulation employs a single set, associated to the table rows. Numerical tests indicated that this approach can bring large reductions of the computational effort (Gonçalves et al., 2017).

6. Global Optimization

Sometimes, the resulting model contains continuous variables participating in non-linear terms that are not amenable to be discretized. We illustrate this with the case of an air cooler. Hitherto, we solved this problem using a fixed air flow rate, which yielded an IP problem (Souza et al., 2017). Now, we are exploring the case of variable air flow, which leads to a model that is nonlinear in only one continuous variable (the air flow rate). The air flow rate participates in several expressions used to calculate the Reynolds number and consequently the overall heat transfer coefficient. This can be solved using any global optimizer (we tried Baron, Antigone and Rysia (Faria and Bagajewicz, 2012)). One can think of just using different flow rates and solve the IP fixed flow problem repeatedly, by using several discrete values of flow, or incorporate such discretization to the model and reformulate. Both options are mathematically not rigorous, but practically sound.

We also find the same situation in the case of heat exchangers with fouling being modelled. Traditionally, the design of heat exchangers addresses the fouling problem using fixed values of fouling resistances. However, the literature presents fouling models that can be embedded in the design equations, thus allowing the problem of fouling mitigation to be inserted into the optimal design problem. Sometimes, it is possible to include the fouling model and still generate a linear problem (Lemos et al., 2017). However, in more complex systems, these models may bring to the problem continuous variables involved in nonlinear terms that cannot be eliminated (e.g. fouling layer thickness), which demands MINLP optimization algorithms.

7. Local models

One of the challenges ahead is to move away from simplified models based on analytical solutions (e.g. LMTD method) and address the optimization problem using discretized portions of the equipment where local properties are calculated using conservation equations. This issue becomes especially important for phase change services where the nature of the streams present a large variation along the flow path (e.g., in a total condenser, the inlet stream is saturated vapour and the outlet stream is saturated liquid). Instead of only use the end temperatures, the model will contain equations related to the set of temperatures distributed along the flow path.

8. Implications for Process Design/Retrofit

The current paradigm in PSE regarding process design and/or retrofit is one where one first use approximate models to determine structure and then eventually perform basic equipment design. The alternative is to incorporate detailed equipment models into the whole optimization. We believe that the PSE community needs to move in the latter direction and increasing computing power will render better designs/retrofits can be accomplished. For example, consider Heat Exchanger Network design/retrofit: With a few exceptions, all existing methods optimize using a-priori selected values of heat transfer coefficients. We believe that even structural changes can come from using

different values. The only chance address it is to include the detailed exchanger design into the modelling. This thought is extended to the whole process design.

9. Conclusions

PSE has been attained remarkable advances in the last decades, providing a myriad of computational tools to solve chemical engineering problems. For example, process simulators are widely employed to provide solutions in chemical process industries. However, despite the advances obtained in problem formulation and solution algorithms, the design problems are still solved in practice using the same trial-and-error approach.

Possible reasons that hinder the direct utilization of PSE tools to solve real design problems were discussed along this paper. The lack of robustness and the simplified physical modelling are two aspects that hinder the utilization of the optimization tools for solving design problems. We are trying to address the former issue using reformulation techniques to generate linear optimization problems and, when this approach is not sufficient, we suggest the utilization of global optimization solvers. We are also investigating solutions for the latter issue based on the adoption of discretized models for the formulation of the design problem, therefore overcoming the lack of accuracy of analytical solutions in certain situations (e.g. condensers and vaporizers).

Abstract

Block-based superstructure (Demirel et al., 2017; Li et al., 2017) offers advantages over classical unit operation-based process synthesis approaches as it leverages upon building blocks to represent different physicochemical phenomena, processing tasks and equipment configurations. In this work, we extend this approach to demonstrate that the same block superstructure representation can be used to perform simultaneous synthesis, integration and intensification in a unified framework. The block-based representation also enables automatic generation of intensified flowsheets without *a priori* postulation of connectivity. Moreover, it is generic enough to be reduced to various process integration network problems, such as heat exchanger networks, fuel gas networks, water networks, etc. A literature example is used to demonstrate the benefits of block superstructure for the particular case of flowsheet generation and heat exchanger network synthesis (HENS).

Keywords: Block Superstructure, Process Synthesis, Intensification, Integration.

1. Introduction

Optimization-based process synthesis provides a systematic pathway for identifying optimal process flowsheets from numerous alternatives. However, most synthesis methods are currently limited in scope for "out-of-the-box" design solutions as they require pre-postulated superstructures. This also prohibits innovative equipment design which plays a critical role in process intensification (Stankiewicz and Moulijn, 2000). To this end, we have proposed building block superstructure (Demirel et al., 2017; Li et al., 2017) which eliminates the need for pre-specified equipment types, and automates the search for intensified process alternatives.

In this work, further benefits of the building block superstructure are presented via extending the formulation to include simultaneous heat integration and to form a comprehensive framework for intensified conceptual process design. As the proposed superstructure automatically generates the flowsheet alternatives without any *a priori* information on the final flowsheet, position and the identity (i.e. hot/cold) of the integrated streams are not known beforehand. Accordingly, proposed formulation is for simultaneous process synthesis and heat integration network synthesis with unclassified process streams. This opens up the potential of utilizing the block superstructure as a general framework for process synthesis, heat integration and intensification. The benefits of the proposed approach is demonstrated via a literature example and it is shown that significant advantages can be obtained by utilizing building block superstructure in conceptual process design.

2. Block Superstructure in a Grid Formation

Block superstructure is shown in Figure 1. Here, each block can be used to represent different chemical phenomena, tasks, materials and equipment. A detailed discussion on how to use building blocks to represent various phenomena are given in Demirel et al. (2017). Each block is connected with neighbouring blocks via bidirectional inter-block streams. Bidirectional flow representation enables incorporation of the recycle connections into the superstructure. Furthermore, heater/cooler and expander/compressor equipment are positioned on each stream so as to quantify the utility requirements in the superstructure and to consider operating and capital costs for these equipment. Each block can also have feed and product streams to facilitate interaction with external environment.

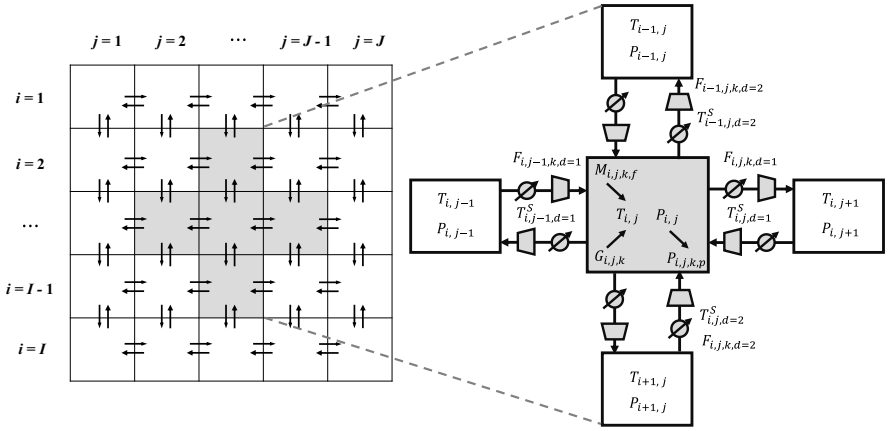

Figure 1. A schematic of the block superstructure.

With this representation, many process synthesis superstructures can be incorporated into the block superstructure. An example superstructure taken from literature (Kong et al., 2017) and its block superstructure representation are illustrated in Figure 2. Here, reactors are represented as single blocks while separators are represented via block boundaries between two blocks to indicate the position of the separated stream.

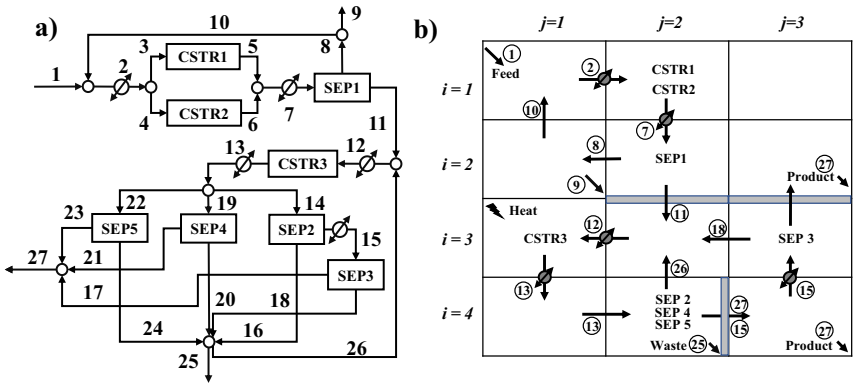

Figure 2. Superstructure representations (a) unit-operation based, (b) block based.

Different process integration networks can be also included in the same superstructure representation. Each stream contains a heater/cooler and the identity of the stream (i.e. hot or cold) and corresponding utility consumption can be determined via an energy balance around each stream. If the utility requirement of a hot and cold stream at two different positions are the same, then they can be integrated to each other. If no such stream available, then the heating/cooling requirement is satisfied via external utilities. This is illustrated in Figure 3a. Although each stream is allowed to match with any other stream in the superstructure, these matches can be restricted to certain positions to yield the same superstructure with the one given by Yee and Grossmann (1990), in which case, each column represents one stage. In Figure 3b, this is illustrated for 2 hot and 2 cold streams. Stream splitting can also be achieved via increasing the number of rows that a stream can go through. For instance, if all the streams in Figure 3b can go through splitting, then 8×5 superstructure with each stream occupying two rows would be used.

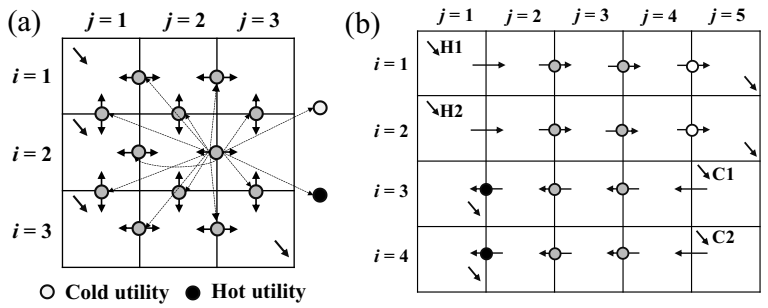

Figure 3. Heat exchanger network representation using block superstructure.

3. Superstructure Model for Synthesis, Heat Integration and Intensification

The overall model for process synthesis, integration and intensification is based on a single mixed integer nonlinear programming (MINLP) and summarized below. Model contains block superstructure constraints for generating the process flowsheet and HENS constraints for determining the corresponding HEN.

$$\min_{x,x\prime,z,z\prime,y,w} f(x,x',z,z') + h(y,w) \tag{1}$$

$$g_{i,j}(x,x') = 0 \quad i \in I, j \in J, \quad g'_{i,j,d}(x,x') = 0 \quad i \in I, j \in J, d \in D \tag{2}$$

$$q_{i,j}(z) \le 0 \quad i \in I, j \in J, \quad q'_{i,j,d}(z') \le 0 \quad i \in I, j \in J, d \in D \tag{3}$$

$$r_{i,j}(x,x',z) \le 0 \quad i \in I, j \in J, \quad r'_{i,j,d}(x,x',z') \le 0 \quad i \in I, j \in J, d \in D \tag{4}$$

$$G_{l,l\prime}(x',w) = 0 \quad l,l' \in L \; l < l' \tag{5}$$

$$Q_l(y) \le 0 \quad l \in L \tag{6}$$

$$R_{l,l\prime}(w,y) \le 0 \quad l,l' \in L \; l < l' \tag{7}$$

$$x'^L \le x' \le x'^U \quad x^L \le x \le x^U \quad w^L \le w \le w^U \quad x \in R^{I\times J}, x' \in R^{I\times J\times D}, w \in R^{L\times L}$$
$$z = \{0,1\}^{I\times J} \; z' = \{0,1\}^{I\times J\times D} \; y = \{0,1\}^{L\times L}$$

The overall superstructure model is comprised of objective function, Eq.(1), which minimizes the annualized cost while considering operating and capital cost for the process, i.e. $f(x, x', z, z')$, and corresponding heat exchanger network, i.e. $h(y, w)$, process related constraints Eqs.(2)-(4), and HENS model constraints Eqs.(5)-(7). Each block is designated with its position in the superstructure as $B_{i,j}$, in which $i = 1, \dots, I$ and $j = 1, \dots, J$ are row and column indices, respectively. There are mainly two type of variables in the superstructure model: block, i.e. x, z, and boundary, i.e. x', z', variables. Block variables, for instance, include $P_{i,j}$ and $T_{i,j}$ which stands for block pressure and temperature, respectively. Boundary variables, on the other hand, are defined to represent flow rate of the interblock streams, $F_{i,j,d}$, and stream temperatures, $T^s_{i,j,d}$ in which $d = \{1,2\}$ designates the orientation of the boundary variables as horizontal ($d = 1$) or vertical ($d = 2$). While block binary variables, z, are used to assign reaction related phenomena to the blocks, boundary binary variables, z', are used to assign separation related phenomena or operation to the boundaries in the superstructure. In process related constraints, Eqs.(2) indicate block material and energy balances and stream energy balances, Eqs.(3) designate logical constraints, and Eqs.(4) relate continuous and binary variables.

In the HENS model, block indices are mapped into a single index, $i, j, d \rightarrow l$ where $l = 1, \dots, L$ is an ordered set and contains all the streams in the superstructure, i.e. $L = 2 \times I \times J$. Note that, as the model is posed as a simultaneous synthesis and heat integration model, and the identity of the streams, i.e. hot/cold, in the superstructure are not known beforehand, binary variables are used to determine stream identities. Accordingly, HENS model is similar to the one proposed by Yee and Grossmann (1990) except that it is extended for unclassified process streams. While continuous variables,w, are used to represent the heat duty for each matching stream in the superstructure and determine approach temperatures for these matches, binary variables, y, are used to determine the stream matches within the superstructure, and classifying streams as hot or cold. In HENS model related constraints, Eq. (5) stands for heat balances for each stream, Eq. (6) designates logical constraints for determining the existence of a match and classification of a stream, and Eq. (7) relates HENS model binary variables with continuous variables.

4. Case Study

An example problem adapted from Kong et al. (2017) is used to demonstrate the use of block superstructure for automatic flowsheet generation first and, then for determining its corresponding HEN. The original superstructure given by Kong et al. (2017) and its block representation is given in Figure 2. There are four components in the process: A and B are used as raw materials to produce C (R1: A + B → C), which is further utilized in a second reaction to obtain the final product D (R2: C ↔ D). There are two isothermal reactor alternatives for R1: CSTR1 (500 K) and CSTR2 (400 K). R2 is an equilibrium reaction carried out in an isothermal equilibrium reactor: CSTR3 (330-400 K). There are five separator alternatives. While Sep1 (430 K) is used to separate C from R1 reactants, Sep2-5 are used to separate product D from C. Note that Sep1 and CSTR3 requires hot utility. The aim of the problem is to synthesize a process for maximizing the total annual profit considering product revenue, unit capital costs and utility costs. All the equipment parameters along with their cost parameters are taken from Kong et al. (2017). First, the problem is solved via fixing the binary variables related with the unit operations and flow directions, as shown in Figure 2 and the original superstructure

is obtained. When this fixed superstructure solved with ANTIGONE, it yields the global solution with an objective value of $14,004,425 in 152 CPU s.

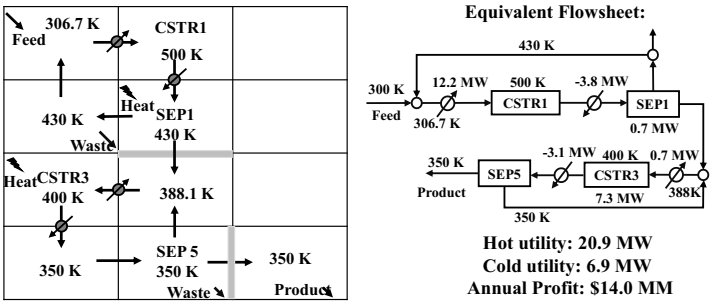

Figure 4. Solution obtained from the original superstructure.

Resulting block superstructure solution and its equivalent flowsheet are shown in Figure 4. Then, the same problem is solved for 22 h with ANTIGONE for automatic flowsheet generation without any fixing and with an initial solution provided by the strategy outlined by Li et al. (2018). The flowsheet identified by block superstructure has an annual profit of $14,171,800 which is $167,300 higher than the process flowsheet obtained via the original superstructure. This result is shown in Figure 5. The improvement is due to the change in the position of the unreacted recycle stream from Sep1. As Sep1 operates a lower temperature than the CSTR1, the recycle stream from top of the Sep1 needs to be heated before entering into CSTR1 (see Figure 4). However, recycling reactor outlet directly facilitates a higher mixing temperature at the feed mixer and decreases the cost associated with the recycle stream. Accordingly, flow rate of the recycle stream can be increased which contributes to higher overall conversion. Note that this structural alternative is not included in the original superstructure and block superstructure could identify this connection without pre-specifying its existence.
.

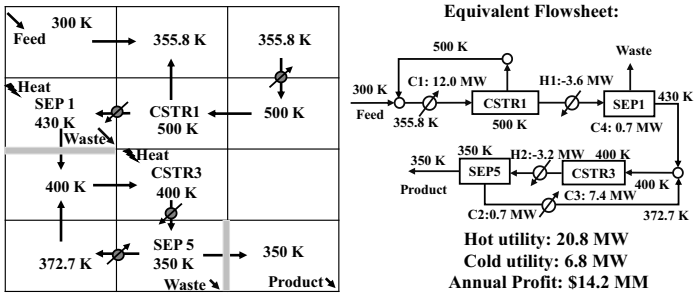

Figure 5. Final block superstructure result.

HEN for this result can also be addressed via block superstructure. The final flowsheet contains 4 cold streams (C1-C4 while C3 and C4 are isothermal) and 2 hot streams (H1 and H2). Accordingly, 6×7 block superstructure can be used to represent HEN superstructure as shown in Figure 6. Note that in Figure 6, the resultant block structure and only the matched streams are shown with a heater/cooler symbol. While first two rows are used for two hot streams, other rows are used for cold streams. First and last columns are used to represent hot and cold utility consuming heat exchangers,

respectively. Isothermal cold streams are handled with 1 K fictitious temperature difference. As the identity of the streams are known, binary variables associated with the stream classification are fixed accordingly. The objective is to synthesize a HEN with minimum annual cost while considering fixed and variable capital costs and operating costs. The optimal block superstructure result is obtained in 7 CPU s with ANTIGONE and corresponding HEN is also shown in Figure 6. Resulting network has a total annual cost of $1,566,440 and contains two heat exchangers (between C1-H1 and C1-H2), four heaters and one cooler. Since the heat content of the hot streams are low, three cold streams (C2, C3, and C4) could not be integrated and, they require hot utility.

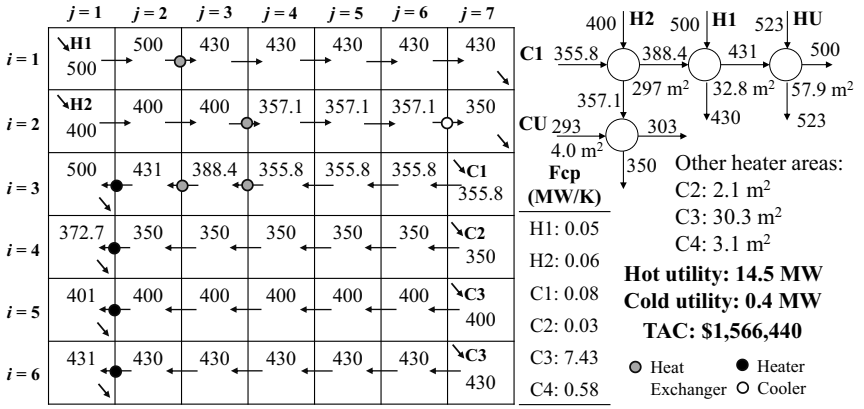

Figure 6. Optimized HEN for the generated flowsheet.

5. Conclusions

In this work, block superstructure model is extended to include simultaneous HENS. The use of the model is illustrated via a literature example first for automated flowsheet generation and then constructing the corresponding HEN. Note that superstructure model developed in this work is also applicable for simultaneous HENS. Future work will focus on utilizing the full model and demonstrating the capabilities of block superstructure for simultaneous process synthesis, heat integration and intensification.

Design and optimization of plate heat exchanger networks

Kexin Xu*, Robin Smith

Centre for Process Integration, School of Chemical Engineering and Analytical Science, The University of Manchester, M13 9PL, UK.
kexin.xu@manchester.ac.uk

Abstract

Heat transfer enhancement technologies have been widely used in heat exchanger network (HEN) retrofit due to its relatively low retrofit cost. However, for enhancement to be effective, one of the side film coefficients must be controlling on one of the side that presents a higher magnitude. Alternatively, plate heat exchangers (PHE) have relatively small minimum approach temperature and high heat transfer coefficient, and they do not rely on the differences between coefficients. Applying PHE into retrofit design of HEN is considered as an attractive option as it can enhance heat recovery and reduce energy consumption. The first part of this paper proposes an optimal design of two-stream multi-pass plate heat exchangers, including gasket plate heat exchangers and welded plate heat exchangers. An MINLP model is formulated to minimize the total area of a PHE by selecting the best plate geometries, chevron angle and flow arrangement. The second part of this paper presents a new cost-effective methodology of applying the optimized PHE model in HEN retrofit with a fixed network structure. Sensitivity analysis is used to identify the best heat exchangers to replace. A non-linear optimization based model is formulate to deal with downstream effect after replacement. A case study highlights the benefits of the new approach of applying PHE in HEN retrofit.
Keywords: plate heat exchanger, heat exchanger network, retrofit, optimization,

1. Introduction

With the growth of energy consumption and increase of environmental degradation, improving heat transfer efficiency became an important task. HENs retrofit is a cost-effective way to increase heat recovery based on the existing heat exchanger network in process industries. Adding additional heat transfer area and topology modifications are the two main methods to improve energy efficiency in retrofit over the past years. In practice, these conventional methods can lead to high cost retrofit due to amount of pipe work and shutdown time. Heat transfer enhancement is a relatively cost-effective technique for HENs retrofit as it can be applied during the maintenance period. However, for the enhancement to be effective, at least 50% of overall heat transfer resistance must be with either the tube-side film coefficient or shell-side coefficient. Besides, energy saving is restricted by the limitation of the heat transfer coefficient.

PHEs are one of the most efficient types of heat transfer equipment over other types of heat exchangers (Kakac et al. 2012). Compared with conventional shell-and-tube heat exchangers, PHEs could significantly increase energy efficiency with minimum approach temperatures as low as 2° C, decrease the possibility of fouling, reduce the fuel consumption and CO_2 emissions. PHEs are widely used in energy-intensive

process industries, such as food, pharmaceutical, petrochemical plants, and refineries. Based on these distinct advantages, applying PHEs in traditional shell-and-tube heat exchanger networks retrofit can be an attractive option as it allows high energy saving without the need of topology modifications and additional heat transfer area.

Plate geometry, chevron angle and flow arrangement are the three main factors that affect heat transfer in PHEs. However, most previous studies proposed different methods to investigate the effect of no more than two factors on heat transfer. Arsenyeva et al. (2011) proposed a relatively complete design method for plate heat exchangers. However, the method is time-consuming and more suitable for a rating problem by employing the ϵ-NTU method. Thus, this paper presents a computer aided approach to automatically optimize a single multi-pass plate heat exchanger by using logarithmic mean temperature difference (LMTD) method in thermal-hydraulic design to reduce computation time, with the consideration of various flow arrangement selections, plate pattern selection and pressure drop constraints.

Pinch analysis, mathematical programming and hybrid methods are the three main retrofit techniques in existing HENs. Sreepathi and Rangaiah (2014) presented a detailed review of different methods for HENs retrofit. Heat transfer enhancement is a relatively cost effective retrofit option compared to adding area or topology modifications as existing HENs structure can be maintained. A novel MILP based iterative method was proposed by Pan et al. (2014) to retrofit HENs with heat transfer enhancement. The work done by Akpomiemie and Smith (2015) extended this methodology to account for the downstream effects on the network after the application of heat transfer enhancement. However, for heat transfer enhancement to be effective, one of the film coefficients must be controlling. Besides, although heat transfer enhancement techniques can be performed during the normal shutdown time, the potential risk of damaging the heat exchangers when adding inserts or fins is unneglectable. Thus, to overcome these drawbacks, this work presents a new retrofit method that provides insights into the application of PHEs into HENs to reduce the network energy consumption and increase heat recovery with fixed network structure.

2. Methodology

2.1. Design a single plate heat exchanger

The proposed method aims to find the optimal design for a multi-pass plate heat exchanger with required process conditions. The variables include plate geometries, chevron angle, and the pass number of each stream. The objective is to minimize the total area of a single PHE since there is a direct proportion between heat transfer area and capital cost of a single plate heat exchanger. The heat load and pressure drop for both sides are the two main constrains.

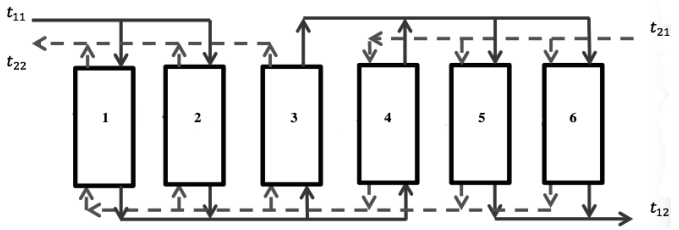

Figure 1. An example of multi-pass (X_1=3, X_2=2) flow arrangement with 6 blocks

Table 1. Geometrical parameters of Alfa Laval plates (Arsenyeva et al. 2011)

Plate type	δ,mm	d_e, mm	b, mm	A, m^2	D_p, mm	$f_{ch}\times10^3$, mm	L_p, mm
M3	2.4	4.8	100	0.03	36	0.240	320
M6	2.0	4.0	216	0.15	50	0.432	694
M6M	3.0	6.0	210	0.14	50	0.630	666
M10B	2.5	5.0	334	0.24	100	0.835	719
M15B	2.5	5.0	449	0.62	150	1.123	1381

*δ is the inter-plate gap, d_e is the equivalent diameter, b is the plate width, A is the plate area, D_p is the connection diameter, f_{ch} is the cross-section area, L_p is effective length.

Large number of plates give freedom for flow arrangement to achieve the required heat load within the specified pressure drop. For a two-stream multi-pass plate heat exchanger, plates can be separated into several parallel blocks and each block can be regarded as a one-pass PHE. For a X_1-X_2 PHE, the total number of blocks is $N = X1 \cdot X2$, where X_1 is the number of passes of hot stream and X_2 is the number of passes for cold stream. Figure 1 shows an example of 3-2 multi-pass flow arrangement. The LMTD method is employed for the thermal design of a single PHE. The key point for thermal design for a multi-pass PHE is to set up linear correlations of temperature among blocks. Each flow arrangement can be considered as a possible individual design. Enumeration technology is used to compare different flow arrangement.

Plate geometries and plate type are the other two main factors that affect heat transfer in plate heat exchangers. For practical consideration, standardized plate sizes from Alfa Laval are considered in this design. The detailed geometries are listed in Table 1. The plate selection problem is formulated as a mixed integer nonlinear programming (MINLP). To account for the effect of chevron angle on heat transfer efficiency, H, L and M type channel with different chevron angles are considered. The empirical correlation of three different channels and Nusselt number is stated in Eq.(1).

$$Nu = A \cdot Re^n \cdot Pr^{0.4} \cdot \left(\frac{\mu}{\mu_w}\right)^{0.14} \quad (1)$$

Where Pr is Prandtl number, μ and μ_w are the dynamic viscosities at stream and wall temperature respectively.

The values of the coefficient A and the exponent n under different plate geometries derived from many industrial manufacture plates are listed in Table 2. In total, there are five different plate types and three different chevron angles. To select plate type and chevron angle, binary variables are introduced to derive optimal solution automatically. Thus, a MINLP model is formulated in GAMS by using ANTIGONE solver to optimize a single multi-pass PHE unit.

2.2. Apply plate heat exchanger in HEN retrofit with fixed structure

This section presents the methodology of application of PHEs into retrofit design of an existing fixed structure HEN. The steps of methods, including identify the best candidate heat exchangers to replace, apply optimized single plate heat exchanger model and set up non-linear model to rebalance network, are detailed in this section.

2.2.1. Identification of heat exchanger candidates to replace

Utility path and sensitivity analysis are used to identify candidate heat exchangers and determine the rank of identified exchangers. To develop a cost effective retrofit method of an existing HEN without structure modifications and additional heat transfer area, the exchangers to be replaced must be on a utility path so that heat loads can be shifted along the path. For a simple network, utility paths can be specified by inspection. For a complex HEN, Incidence Matrix Approach is used to identify utility paths in the HEN. Sensitivity analysis is used to identify the best heat exchangers, which can bring the most energy saving among others. It also helps users to select the sequence of replacement.

2.2.2. Apply plate heat exchanger and optimization of HEN

After the best heat exchangers for replacement are identified, plate heat exchangers need to be applied in the replacement of selected shell-and-tube heat exchangers. The input process stream data are derived from candidate heat exchangers. The maximum heat transfer coefficient of the single plate heat exchanger can be derived from the optimization model in GAMS.

To rebalance the HEN, the heat loads of heat exchangers need to be relocated. The heat loads can be shifted through the utility paths. Application of PHEs can decrease energy consumption. However, the high installation cost of new heat exchanger is unneglectable. Thus, to propose a cost effective retrofit design, the objective of this optimization problem is to maximize retrofit profit. The total cost of retrofit including the implementation cost of bypass, the installation cost of plate heat exchangers, the cost of adding heat transfer area only if the heat exchangers are not on the utility path. Reaching target temperatures and maintaining the existing heat exchangers area are the two main constraints of the design.

Objective Function: *Maximize Retrofit Profit* = Profit from energy saving – Total cost of retrofit

Constraints: maintain the areas of existing heat exchanger (excluding the candidate heat exchanges) and reach target temperatures

Variables: heat load for all exchangers on a utility path
heat transfer coefficient for candidate heat exchanger

Table 3. The overall process data

	T_{in}	T_{out}	V	ρ	cp	λ	μ
Units	°C	°C	m^3/h	kg/m^3	kJ/(kg·K)	W/(m·K)	kg/(m·h)

Plate type	M6M	M6	M6M	M10B	M10B	M6	M6	M10B
Number of plates	39	30	39	24	84	32	36	32
Total area (m^2)	5.46	4.50	5.46	5.76	19.6	4.80	5.4	7.68

Table 4. The results of optimization a single plate heat exchanger

3. An example of single plate heat exchanger

An example from published literature (Arsenyeva et al. 2011) is studied to verify the effectiveness and accuracy of the new proposed design methodology. The overall process data are listed in Table 3. It can be clearly seen from Table 4 that the optimal solution is obtained for 2-3 flow arrangement with 30 plates (M6 plate type). The minimum total area of the plate heat exchanger is 4.50m^2. As a comparison, the minimal area from literature is 5.04 m^2 with 38 plates. Thus, it is possible to say that the proposed methodology can provide a solution with better heat transfer behavior and it significantly reduces the computation time for optimization a single PHE from several hours to 20 minutes.

4. Case study

A simplified crude preheat train is used to illustrate the benefit of application of plate heat exchanger into retrofit design of HEN in a fixed network structure. The existing structure of the network is shown in Figure 2. To quantify the retrofit profit, the operating time is fixed as one year.

5. Results and discussions

Incidence Matrix Approach is used to identify utility paths in the HEN. Only process heat exchanger 7 is not on the utility path. According to results from sensitivity analysis,

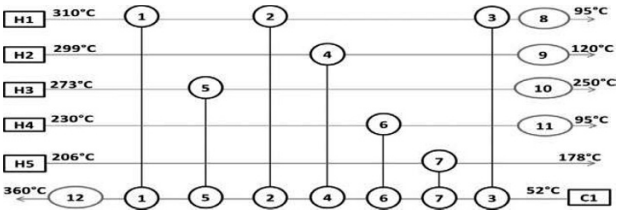

Figure 2. A simplified preheat train

	Parameter	Replacement	Enhancement
Retrofit Cost	Replacement	$76,630.58	$3,981.16
	Increasing Area	$0	$0
	Implementing By-pass	$15,000	$15,000
	Total Cost	$91,630.58	$18,981.16
Retrofit Profit	Utility Savings	$296,684.13	$237,252.68
	Net Saving	$205,053.55	$216,271.52

Table 5. A comparison between replacement and enhancement

heat exchanger 5 is the most sensitive exchanger. After replacing heat exchanger 5 by the optimized PHE, the optimization procedure is conducted to rebalance the network by using global solver on LINDO Systems What's Best!. The comparisons between applying PHEs and enhancement (Akpomiemie and Smith 2015) are highlighted in Table 5. The retrofit profit of replacement is a bit smaller than enhancement due to the high installation cost of plate heat exchanger. However, the replacement can save more energy than enhancement.

6. Conclusions

A design and optimization method for plate heat exchangers is proposed, which addresses plate pattern selection, determination of flow arrangement and pressure drop constraints. The computation time and total area are considerably decreased. Plate heat exchanger can be used as an alternative to heat transfer enhancement. The benefit of applying plate heat exchanger into retrofit design of HEN with fixed structure is highlighted by the case study.

Abstract

Water and energy are two of the important elements in ensuring sustainability in the process industry. In the past decade, the synthesis of heat-integrated water network has gained good attention among the research community of process system engineering. Various techniques ranging from pinch analysis and mathematical programming have been proposed to solve this problem. Note however that most works have only considered direct reuse/recycle scheme, where water sources are heated/cooled prior to their recovery to the water sinks. In this work, the placement of water interception units will be considered. Apart from direct water reuse/recycle, water sources may be subjected to partial purification with the interception unit, where impurity loads are to be removed prior to their recovery. This is commonly known as water regeneration. A hybrid approach consisting of superstructural and transshipment models is proposed for the solution strategy. Even though the approach is based on mathematical programming framework, it emphasizes the targeting philosophy of pinch analysis. A literature example is solved, with the objective being to minimize water flowrates and cost targets. It is shown that water regeneration cost is an important factor that dictates the overall water flowrates and costs.

Keywords: Process integration; simultaneous energy and water reduction; waste minimization; resource conservation; optimization.

1. Introduction

Energy and water are the key resources used in process industries. The need to conserve these resources has led to the development of heat integrated water regeneration networks (HIWRNs). Water consumption is reduced through the strategies of re-use, recycle and regeneration; while energy is conserved by maximum heat transfer. HIWRN synthesis has been carried out through various mathematical optimization models. One of such was a mixed integer non-linear programming (MINLP) formulation, where water allocation networks (WANs) were synthesized prior to the minimization of the total annual costs (TAC) by using sequential (Chen et al., 2010) or simultaneous techniques (Dong et al., 2008). Other formulations involved the minimization of total operating cost (TOC) as the first step through MINLP (Ibric et al., 2014) or used non-linear programming (NLP) formulations to set bounds (Ibric et al., 2016) followed by

the minimization of TAC using MINLP. Several sequential and simultaneous optimization strategies have been proposed and compared. However, their interchangeability has not been formally reported. The proposed model overcomes the drawbacks of simultaneous and sequential optimization techniques. The optimization problem was simplified to an NLP formulation (Ataei et al., 2009). The simplest form of the optimization problem was found to be an NLP formulation from a review on the heat integrated WANs (Ahmetović et al., 2015). This paper proposes a linear programming framework to synthesise HIWRN in a novel way for fixed flowrate problems.

2. Problem Definition

The essential parameters in the synthesis of HIWRN are flow rate, *F*, contaminant concentration, *C*, and temperature, *T*. For a fixed flow rate problem, the processes are divided into water-consuming (sink) and water-producing (source) processes. Water can be conserved through the recovery among water sources and sinks. Due to contaminant concentration constraint on the sinks, and/or water availability of the sources, fresh water may be used to supplement water requirement of the HIWRN. Energy consumption, on the other hand, can be minimized through heat recovery between hot and cold process streams. Hot and/or cold utilities are used to satisfy the unmet energy needs. A typical HIWRN is shown in Figure 1.

Subscripts *s* and *d* denote the source and sink. Subscripts *i*, *j*, *r*, *t*, *k*, *hu* and *cu* represent indices for source, sink, interception unit, contaminant, temperature level, hot utility, and cold utility. In this formulation, *i* and *j* equal to zero for a fresh water source and waste water. T_{d0} cannot exceed the discharge limit, but no limit is imposed on C_{d0}. *f* denotes the variable flow rate. There are *M* contaminants. *N* and *A* denote the number of units and unit cost. The transshipment model is used with *T*I temperature intervals (George et al., 2011). *H* and *G* are the amounts of heat supplied and gained by hot and cold streams, while *HS* and *HD* are the heat surplus and heat deficit. *Q* corresponds to the utility and *R* denotes the residual heat.

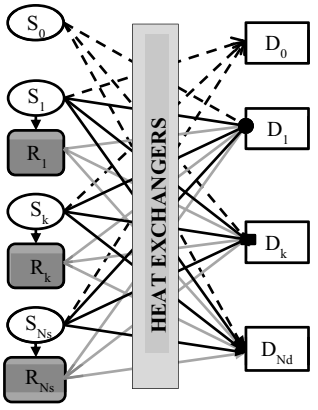

Figure 1 A typical HIWRN

Each water source is regenerated at its temperature, thereby requiring 1 to N_s interception units. Isothermal mixing of water sources and regenerated sources occurs at the sinks. Single pass interception units are considered for this model. The interception unit acts as a source (outlet), a sink (inlet) and is also classified into a fixed outlet and fixed removal ratio (RR) type (Foo, 2012). F_{Reg} is the amount of water regenerated. The contaminant concentrations leaving the fixed outlet and RR type interception units are denoted by $C_{out,t,}$ and $C_{rr,t}$. The removal ratio (*rr*) for an RR type of interception unit is the ratio of contaminant load removed to the amount of contaminant load entering it. As a result of no flow loss, the *rr* for each interception unit may be simplified as shown in Eq. (1).

$$rr_r = \frac{C_{rr,t} - C_{si,t}}{C_{si,t}} \quad \forall\, r = i,\ where\ r = 1\ to\ N_s \tag{1}$$

As the *rr* is specified and $C_{si,t}$ is a known quantity, $C_{rr,t}$ is fixed. The problem turns out to be the same as the fixed outlet type. Any methodology applicable to the fixed outlet type of interception unit can be used for the fixed RR type as well provided that the temperature of the interception unit equals the temperature of the source that is regenerated. Thus the problem is formulated for the fixed outlet interception unit.

3. Mathematical formulation

3.1. Fresh Water Minimization (M1)

The fresh water is minimized in Eq. (2) subjected to the flow balance constraints for sources, sinks and interception units expressed as Eqs. (3)-(5) and contaminant load constraint is given by Eq. (6).

$$Minimize\ F_{s0} = \sum_{j=1}^{N_d} f_{0j} \tag{2}$$

$$\text{Subject to: } \sum_{j=1}^{N_d} f_{ij} + f_{i0} + \sum_{r=1}^{N_r} f_{ir} = F_{si}\ \forall\ i\ \in \{1,2,\dots N_s\} \tag{3}$$

$$\sum_{i=1}^{N_s} f_{ij} + f_{0j} + \sum_{r=1}^{N_r} f_{rj} = F_{dj}\ \forall\ j \in \{1,2,\dots N_d\} \tag{4}$$

$$\sum_{r=1}^{N_r} f_{ir} = \begin{cases} \sum_{j=1}^{N_d} f_{rj} & if\ i = r \\ 0 & otherwise \end{cases} \qquad \forall\ r\ (1\ to\ N_s) \tag{5}$$

$$\sum_{i=1}^{N_s} f_{ij}\ C_{si,t} + f_{0j} C_{s0,t} + \sum_{r=1}^{N_r} f_{rj}\ C_{out,t} \le F_{dj} C_{dj,t}\ \ \forall\ j \in \{1,2,\dots N_d\}\ and\ t \in \{1,2,\dots M\} \tag{6}$$

3.2. Regeneration flowrate minimization (M2)

The regeneration, given in Eq. (7), is minimized subjected to either a fixed amount of fresh water or waste water expressed by Eqs. (8) and (9) respectively and Eqs. (2)-(6).

$$Minimize\ F_{Reg} = \sum_{r=1}^{N_r} \sum_{j=1}^{N_d} f_{rj} \tag{7}$$

$$\text{Subject to: } \sum_{j=1}^{N_d} f_{0j} = F_{s0} \tag{8}$$

$$\sum_{i=1}^{N_s} f_{i0} = F_{d0} \tag{9}$$

3.3. Utility minimization (M3)

The hot utility is minimized in Eq. (10) subject to the flow rates given in Eqs. (8), (9) and (11) and the regeneration contaminant concentrations. The other constraints are heat surplus, heat deficit, energy balance in each *TI*, the upper and lower limit of heat transfer and the non-negativity constraints expressed by Eqs. (12)-(16) respectively.

$$\text{Minimize } Q_{hu} = \sum_{k=1}^{TI} Q_{hu,k} \tag{10}$$

$$\text{Subject to: } \sum_{i=1}^{N_s} f_{ir} = \sum_{j=1}^{N_d} f_{rj} = F_{Reg} \qquad \forall\, re(1\ to\ N_s) \tag{11}$$

$$HS_k = \sum_{j=0}^{N_d}\sum_{i=0}^{N_s} H_{i,k,j} + \sum_{j=1}^{N_d}\sum_{r=1}^{N_r} H_{r,k,j} \quad \forall\, k \in \{1, 2, \ldots TI\} \tag{12}$$

$$HD_k = \sum_{j=0}^{N_d}\sum_{i=0}^{N_s} G_{i,k,j} + \sum_{j=1}^{N_d}\sum_{re=1}^{N_{re}} G_{re,k,j} \quad \forall\, k \in \{1, 2, \ldots TI\} \tag{13}$$

$$R_k - R_{k-1} - Q_{hu,k} + Q_{cu,k} = HS_k - HD_k \qquad \forall\, k \in \{1, 2, \ldots TI\} \tag{14}$$

$$R_0 = R_{TI+1} \tag{15}$$

$$R_k, HS_k, HD_k, Q_{hu,k}, Q_{cu,k} \geq 0 \qquad \forall\, k \in \{1, 2, \ldots TI\} \tag{16}$$

4. Solution Strategies

The mathematical models for the minimization of fresh water, regenerated water and utility are linear programming (LP) formulations. Simultaneous optimization and three-stage sequential strategy are proposed based on the above models.

4.1. Simultaneous strategy

The simultaneous optimization strategy involves the minimization of the TOC given in Eq. (17) subject to Eqs. (3)-(6) and Eqs. (12)-(16). A_{fw} and A_{ww} are the unit costs of fresh water and waste water respectively.

$$\begin{aligned} Minimize\ TOC = {} & A_{fw}\sum_{j=1}^{N_d} f_{0j} + A_{ww}\sum_{j=1}^{N_d} f_{i0} + A_r\sum_{r=1}^{N_r}\sum_{j=1}^{N_d} f_{rj} + \\ & A_{hu}\sum_{k=1}^{TI} Q_{hu,k} + A_{cu}\sum_{k=1}^{TI} Q_{cu,k} \end{aligned} \tag{17}$$

4.2. Three stage sequential strategy

Models M1, M2, and M3 are solved in each step of the three stage sequential strategy. In Eqs.(8) and (9), F_{s0} and F_{d0} values will be set to the minimum fresh water and waste water requirement obtained from M1 and in Eq.(11), the F_{Reg} value will be set to the amount of regeneration carried out by each interception achieved by solving M2.

5. Example for HIWRN synthesis

Table 1 represents the limiting water data (George et al., 2011) for the HIWRN synthesis. A single pass interception unit with fixed contaminant concentration of 80 ppm and without any constraint in its operating temperature is used. It is further assumed that the fresh water enters at 20 °C and the waste is to be discharged at 30 °C, while the specific heat capacity of water is taken as 4.2 kJ/kg °C. GAMS 24.2.2 software is used for solving the optimization models.

The three-stage sequential strategy was implemented. The fresh water (FW) and waste water (WW) flowrates resulting from M1 were found to be 52.5 kg/s. With constant FW requirement, the minimum regeneration flowrate was identified as 87.5 kg/s through M2. The flow rates, temperatures and contaminant concentrations of the regenerated streams obtained from M2 serve as an input to M3 along with the FW requirement from M1. The minimum hot ($Q_{H,\,min}$) and cold ($Q_{C,\,min}$) utility requirements are 6615 kW and

4410 kW. Without regeneration, the FW consumption of 77.28 kg/s and hot and cold utility of 10963.62 kW and 7717.78 kW is observed (George et al., 2011). The WAN and energy targeting results are shown in Tables 2 and 3. No flow occurs through the interception unit R2. As the temperature and outlet contaminant concentration is same for R1 and R3, they can be combined into a single interception unit, with the regeneration of 87.5 kg/s.

Table 1 Limiting process data for Example (George et al., 2011)

The costs of FW, regenerated water, WW, hot utility and cold utility are \$1/t, \$0.5/t, \$1/t, \$120/kW and \$ 10/kW. The FW requirement, WW discharge, amount of water regenerated, hot and cold utilities were found to be same from the simultaneous and three stage sequential strategy. The TOCs with and without regeneration were \$5.5 million/y and \$6.3 million/y. The WAN and energy targeting can be done for simultaneous optimization (results in two regeneration units). The regeneration cost is varied from \$0.5/t to \$2/t and its effect on water flow rates and utilities is depicted in

Figure 2. With the increase in the unit cost, the amount of regeneration decreases and the utilities increase; while the FW consumption first decreases and then increases. The energy cost increases with the increase in the unit cost (Figure 3). There is a decrease followed by an increase in the water and total costs. The proposed methodology is applicable to multiple contaminants problems (not demonstrated due to brevity).

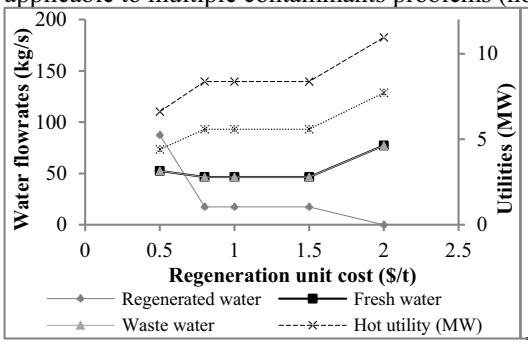

Figure 2 Effect of regeneration cost on flow rate and utilities

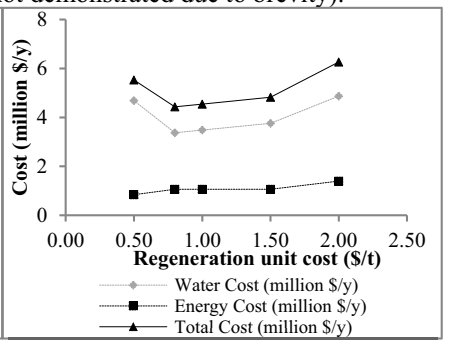

Figure 3 Effect of regeneration cost on water, utility and total cost

6. Conclusion

A simultaneous optimization approach with an objective to minimize the TOC is compared with a three stage sequential methodology, where the fresh water, regenerated water, and utility are minimized separately. Both the approaches are LPs and provide the same results, which implies that both methods can be used interchangeably. The effect of change in unit cost of regeneration on water flow rates, utilities, their respective costs and the total cost was studied. Due to the dependence of convergence efficiency on the number of variables, the three-stage sequential optimization formulation ensures better convergence efficiency as compared to the simultaneous technique in case of large data.

Abstract

Lactic acid (LA) is a compound with a considerable range of application in industry, where its use as precursor of diverse products is currently relevant. Thus, it is important to complement experimental efforts to investigate the design of the lactic acid production relying in computer-aided tools using a process system engineering approach. This work presents the implementation of a computer-aided processing platform and the analysis of a possible industrial production route of LA from the waste of sugar industry. The process configuration consisted on a pretreatment stage to extract the raw material from the residues. Subsequently, the LA fermentation is included using a more realistic design and analysis considering the combination of batch and continuous operations based on a scheduling plan. Finally, the separation and purification stages using reactive distillation are included, aiming to obtain an LA solution above 95 % mass fraction and a production of 14,448 kg/hr from 28,886 kg/h of sugarcane bagasse. The process was evaluated to determine its economic feasibility based on a price of 1.5 US/kg of LA. It was estimated that the process has a recovery time of 3.6 years.

Keywords: Lactic acid production; renewable materials; aspen plus; reactive distillation.

1. Introduction.

Currently important issues such as, environmental protection, sustainability and oil reserves decline have motivated the search of alternatives to produce some high value substances from renewable raw materials rather than fossil sources. Among the different basic chemicals, the lactic acid (2-hydroxypropionic acid, $CH_3CHOHCOOH$) is interesting due to its wide range of applications to produce and manufacture commodities, mainly in food industry, chemical products, cosmetics and pharmaceuticals sector. More recently, the interest to produce lactic acid has grown since it is the basis to produce

polylactic acid (PLA). PLA is a biodegradable polymer classified as bio-plastic and it can be used for different products due to their properties, for example: high tensile strength, high modulus, thermoplastic properties, biodegradability and bioenvironmental compatibility/absorbability, in addition with the application in the medicine area (Pérez-Cisneros et al., 2015). Therefore, LA is a strategic product to be manufacture in the near future since it can reduce our dependency on fossil raw materials. It has been estimated that the demand for lactic acid increases annually by 5-8 % (Yadav et al, 2011). The annual world market for lactic acid production was forecasted in a demand of 259,000 metric tons for the year 2012 (Martinez et al, 2013), and was expected to reach 367,300 metric tons in 2017.

The production of lactic acid can be achieved either by chemical synthesis or through fermentative production routes. Between the options, fermentative production offers advantages such as, the use of renewable and cheaper substrates, low production temperatures and low energy consumption. The fermentation-based production of lactic acid involves the typical sections of a lignocellulosic bio-based configuration: pretreatment to breakdown the lignocellulosic matrix (PT), enzymatic hydrolysis to release the glucose from cellulose (EH) and fermentation where glucose and xylose are converted to lactic acid (F) (Morales-Rodriguez et al., 2016). The produced fermentation broth contains diluted lactate, which must be treated in a downstream processing to obtain higher lactic acid concentration for the polymer production. For the separation and purification different procedures have been explored, for instance, electro-enhanced dialysis (Prado-Rubio et al., 2009), liquid-liquid extraction, ultrafiltration, osmosis, adsorption, reactive extraction and reactive distillation (Pérez-Cisneros et al., 2015). However, some technologies have shown some disadvantages, for example, ultrafiltration and osmosis are unviable for a large amount of raw material. Adsorption and reactive extraction have some problems regarding to species particle selectivity, capacity and regeneration. More importantly, all these methods suffer from low recovery of lactic acid (Prado-Rubio, et al., 2016). Due to these limitations, up to now, the most attractive method for the purification of lactic acid from fermentation broth is a two-stage reactive distillation process. There, the lactic acid is first reacted with an alcohol to form a more volatile ester that it can be purified by distillation. Subsequently, the pure lactic acid is recovered by hydrolysis of the ester. This method of purification cannot only handle a large capacity of raw material, but can also achieve a high recovery of lactic acid (Su et al, 2013).

Thus, the objective of this work is to present process design and simulation to investigate the lactic acid production from lignocellulosic materials, as well as analysing the techno-economic feasibility of the process using a computer-aided tool. The process configuration includes the PT, EH, F and downstream process relying on reactive distillation.

2. Computer-aided process design: lactic acid production

2.1. Simulation approach

The LA production process was implemented in Aspen plus process simulator allowing the design, and analysis of the proposed process feasibility. In order to perform the evaluation of the LA process production, the sugarcane bagasse was used as lignocellulosic raw material. This study considers a feeding flowrate of 28,886.6 kg/hr consisting of cellulose (68.22%), lignin (29.19%) and xylan (2.59%). According to the

involved compounds and process conditions, the thermodynamic models employed in the simulations were the NRTL and the Hayden-O'Connell models. The NRTL model parameters were obtained from the National Renewable Energy Laboratory (NREL) database (Wooley and Putsche, 1996).

The process topology was built relying on some previous work. For instance, the bioproduction that include the pretreatment, enzymatic hydrolysis and fermentation was taken from Morales-Rodriguez et al. (2016) and the downstream processes was based on the study proposed by Pérez-Cisneros et al. (2015).

2.2. Process description

The LA process configuration is illustrated in Figure 1, which consists of 6 sections: 1) pretreatment, 2) neutralization and nutrient production, 3) enzymatic hydrolysis, 4) inoculation, 5) LA fermentation and 6) separation and purification. The process starts mixing the bagasse (30 wt/wt%) with a sulfuric acid solution. This mixture is fed to reactor R-101 where the lignocellulosic matrix is broken-down breakdown while some glucose and xylose are also produced. The output stream of reactor R-101 is a mixture of solid, liquid and vapours, which is sent to separator F-201 to separate steam and liquid in two streams (201 and 202, respectively).

For the nutrient production, a fraction of the liquid phase (2% of total flow) is divided (S-201) and fed to reactor R-201 together with a stream of ammonia (207) to produce ammonium sulphate, which is used as nitrogen source for the microorganisms at stage 5. The reaction in R-201 is carried out at 1 atm, 50°C with a sulfuric acid conversion of 89%. For the neutralization process, the output stream of R-201 is mixed (M-202) with the rest of the vapour and liquid coming from the M-201 mixer. This stream passes through the heat exchanger H-201 to reach the temperature of 25°C and it is fed to the neutralization reactor (R-202) together with a stoichiometric flowrate stream of sodium hydroxide (211). As preparation for the hydrolysis, the neutralized stream (212) is mixed (M-301) with the stream of solids (203) from the separator F-201. The solid-liquid flow (302) enters the divider (S-301) to generate two flows, 10% of the flow (303) is sent to the inoculation section, while the remaining 90% (304) is sent to the enzymatic hydrolysis section. Before entering the enzymatic reactors, the stream temperature is raised to 50°C in the H-302 heat exchanger. Besides, a stream (307) of diluted enzyme is mixed with the stream leaving the exchanger in the M-302 and subsequently feeds the reactors (R-301-R-305). The feeding ratio of the enzyme should be 20 mg per 1 g of cellulose and the aqueous dilution should be 30% enzyme. The enzymatic reactors breakdown cellulose to produce glucose with a conversion of 66%. The stream 303 reaches a temperature of 37°C in an exchanger, then mixed with a diluted enzyme solution and directed to the inoculation reactors (R-401-R-406) to release glucose molecules from the solids. The enzyme/glucose ratio is the same as the hydrolysis section. The streams 417 and 320 are sent to solid-liquid separators (S-404 and S-402, respectively), where the liquid stream of both separators are mixed (M-404) and the mixture (420) is sent to the fermentation stage of lactic acid, while the solid phase (323) is available to be combustion and generate energy. The lactic acid fermentation reactors (R-501-R-506) are fed by stream 420 to carry out the conversion of glucose (80 %) and xylose (60%) into lactic acid as shown in the following reactions:

$$C_6H_{12}O_6 \rightarrow 2\ C_3H_6O_3 \quad (1)$$

$$3C_5H_{10}O_5 \rightarrow 5C_3H_6O_3 \quad (2)$$

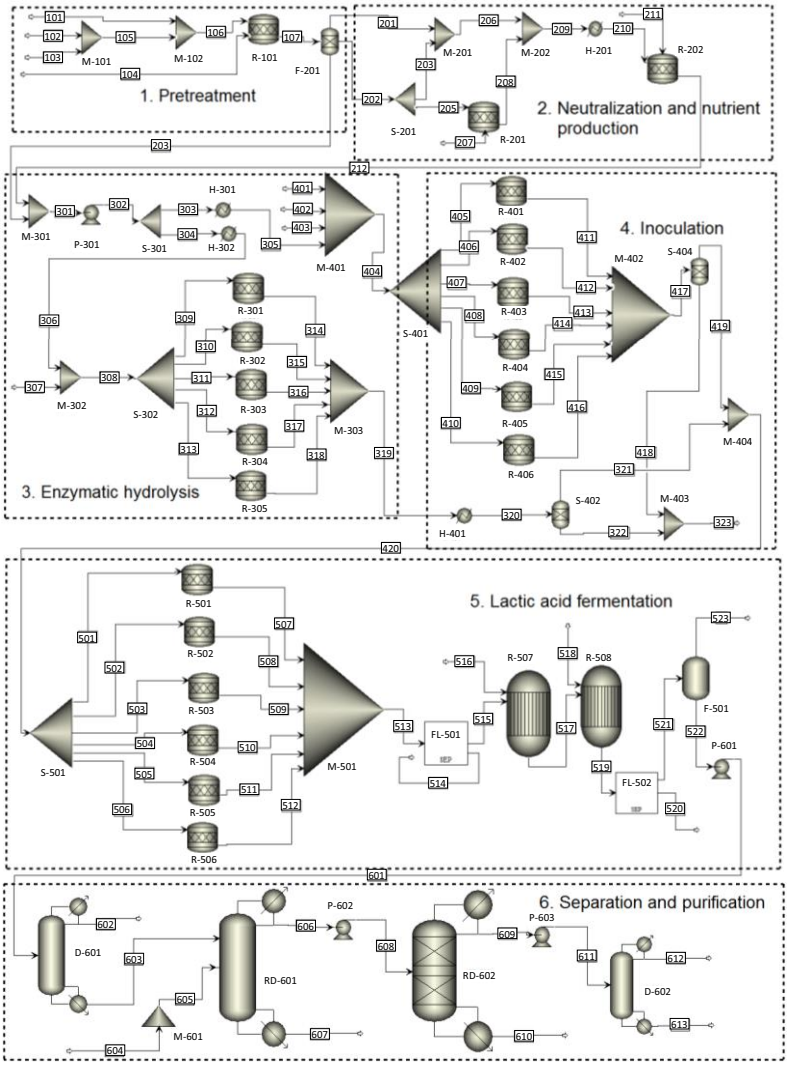

Figure 1. Process flowsheet for the acid lactic production

The lactic acid (515) is precipitated from the fermentation broth as calcium lactate in the reactor R-507 where a 15% mass fraction solution of calcium hydroxide (516) is also fed. Stream 517 feeds reactor R-508 together with a 15% mass fraction sulfuric acid solution to remove the calcium salt and to obtain lactic acid. The calcium sulphate is separated by filtration (FI-502), while the liquid mixture (521) is sent to a flash tank (F-501) to separate a large part of the water from the mixture. The reactions of R-507 and R-508 are presented below, respectively:

$$2C_3H_6O_3 + Ca(OH)_2 \rightarrow Ca(C_3H_6O_3)_2 + 2H_2O \quad (3)$$

$$Ca(C_3H_6O_3)_2 + H_2SO_4 \rightarrow 2C_3H_6O_3 + CaSO_4 \quad (4)$$

The purification section stars with stream 601, where this flow reaches a distillation column (D-601) to remove the largest amount of water (602) and send the flow of lactic

acid (603) to the first column of reactive distillation (RD-601) together with a stoichiometric flow of methanol (605) to carry out the esterification reaction (Eq. 5):

$$C_3H_6O_3 + CH_3OH \rightarrow C_4H_8O_3 + H_2O \quad (5)$$

The stream leaving the dome of the column (RD-601) is pumped (P-602) to the next reactive column (RD-602) where the hydrolysis (Eq. 6) is carried out to obtain lactic acid:

$$C_4H_8O_3 + H_2O \rightarrow C_3H_6O_3 + CH_3OH \quad (6)$$

The lactic acid is obtained from the RD-602 in the stream 610 with flowrate of 14,448.3 kg/hr and an acid mass fraction of 98%. On the other hand, the stream 609 is sent to another conventional distillation column (D-602) to recover the methanol from the process.

2.3. Scheduling for combining batch and continuous operation

The process configuration combined the continuous and batch operation modes. In order to perform a reliable analysis of the process, it is necessary to propose an operation scheduling, which must include the filling, reaction, drawing and idle that are repeated periodically. The schedule for enzymatic hydrolysis and seed (see left column) could be understood as following: for reactor number one the periodic operation last 60 hours. It starts with the loading of 12 h, followed by a reaction time (36 h) and finally it ends with 12 h of drawing/emptying the content of the reactor. Once the first cycle is completed the next cycle starts again by repeating the same schedule. The first lactic acid fermentation reactor starts after 48 h then following for a similar schedule 12, 48 and 12 h. There is a difference in the reaction time for the fermentation section, because this operation requires of 12 extra hours to reach the desired titter. In addition, it is necessary to add an extra fermentation unit to keep the same schedule.

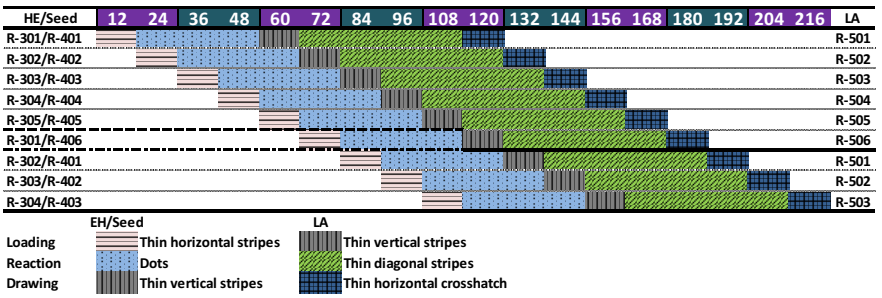

Figure 2. Process flowsheet for the acid lactic production

3. Findings using the computer-aided simulation

The computer-aided simulation allowed performing the economic evaluation of the process using Aspen Economic Analyzer, as well as the potential energy integration employing The Aspen Energy Analysis. The economic analysis consisted on performing a sensitivity analysis on the LA selling price. Table 1 illustrates the different evaluated prices and the economic evaluation. The results illustrates that it is possible to have competitive selling prices with still positive economic metrics. Considering a commercial price of 1.5 USD/kg, the result showed a short payback period (PBP) that allowed having a satisfactory net present value (NPV) in 10 years. The results also showed a great

opportunity for the use of agroindustrial residues in the production of LA, promoting the valorisation of the biomass.

Table 1. Economic analysis for lactic acid production

Selling price, [US$ kg^{-1}]	NPV [MUS$] at 10 years	PBP [years]
1.5 (Alibaba.com)	255.08	3.13
1.2	109.99	4.81
1.1	78.15	5.62

The energy integration analysis was also performed in this work, which allowed identifying that 60.46% of the energy could be integrated reducing the even more the utilities cost.

4. Conclusions

The development of the computer-aided simulation allowed the tecno-economical evaluation of LA bioproduction. The results illustrated that it is feasible to have LA production following a biotechnological route from lignocellulosic residues. This work gives the basis for the complete design of the lactic acid production plant and open the opportunity to have further comparison with different process technologies, such as membrane-based processes, liquid-liquid extraction and in situ product removal configurations.

Abstract

In this work, a systematic framework for a computer-aided mixture/blend design (CAM^{b}D) developed by Kalakul et al. (2017) is integrated into a computer-aided model-based tool for chemical product design and analysis called ProCAPD. Within the framework as implemented, a software architecture, database management, model development, design methodologies and design algorithms are integrated. The software employs a template approach, where each template follows the same common steps in the workflow for design of blended products, but has the option to employ different blend design solution approaches, product specific property models, data and calculation routines, when necessary. With the new additions, the software is able to support the design and analysis of a wide range of blended products, such as, jet-fuels, diesel fuels, gasoline fuels, solvent mixtures and lubricants. The decision making process is supported by dedicated property models and structured databases, specifically developed for each blend design problem scenario. Output from the software is a small set of most promising product candidates and a short list of recommended experiments that can validate and further fine-tune the product compositions. The application of the new feature is highlighted through case studies involving a diesel surrogate design and a tailor-made jet-fuel blend.

Keywords: Chemical product design, Computer-aided mixture/blend design (CAM^{b}D).

1. Introduction

Mixture/blend design problems are considered when single molecules are unable to satisfy all the desired product specifications. It has been widely accepted that use of computer-aided mixture/blend design (CAM^{b}D) methods helps speed up development times and reduce consumption of experimental resources. CAM^{b}D is defined as follows: given a set of chemicals and a set of property constraints, determine the optimal mixture and/or blend consisting of a sub-set of chemicals (Gani, 2004). CAM^{b}D problems are usually formulated and solved as Mixed Integer Non Linear Programming (MINLP) or Mixed Integer Linear Programming (MILP). The main efforts have been directed to the design of solvent mixtures (Jonuzaj et al., 2016), polymer blends and formulated liquid products (Conte et al., 2011). Different solution strategies have been employed to solve CAM^{b}D problems such as Artificial Neural Networks (ANN) and Analytical Hierarchy Process (AHP). Zhang et al. (2015) formulated and solved MINLP problems to design working fluid mixtures for Organic Rankine Cycles, while Jonuzaj et al. (2016) did the

same for solvent mixture design. Yunus et al. (2014) decomposed the overall MINLP problem into sub-problems to tailor-make gasoline and lubricant blends.

Even though many CAM^{b}D problems have been solved and different solution approaches have been proposed, due to the lack of the needed property models and data for the target properties, the currently available methods and tools can only solve a small percentage of blend design problems. Also, the process needs, inclusion of sustainability issues as well as product performance verification add to the complexity of the problem due to constraints that need to be satisfied. This is a challenging task requiring the integration of many tasks, such as, data acquisition, data testing, model development, and multi-scale modeling in a computer-aided framework. Therefore, the objective of this paper is to present a hybrid computer-aided framework for CAM^{b}D that is integrated with experimental verification options and is flexible, robust and versatile. The objective of the framework with its associated data, models, methods and tools is to provide the means to design, analyze and verify blended products in a fast, efficient and systematic manner. The application of the developed framework, implemented as a new option (template) in an extended version of the computer-aided tool for chemical product design called ProCAPD (Kalakul et al, 2017), is illustrated through two case studies. With respect to the CAM^{b}D template, more property models for fuel and lubricant blends (e.g. Cetane index, pour point, carbon dioxide emission from the combustion engines and friction coefficient) and more algorithms to solve CAM^{b}D problems are added. Thus, the software is able to solve wider ranges of CAM^{b}D problems in a fast and efficient way.

2. CAM^{b}D Template within ProCAPD

The framework (architecture) of the CAM^{b}D template in the ProCAPD software is highlighted in Figure 1 in terms of the main steps (workflow), the methods and tools employed in each step and the dataflow from one step to the next.

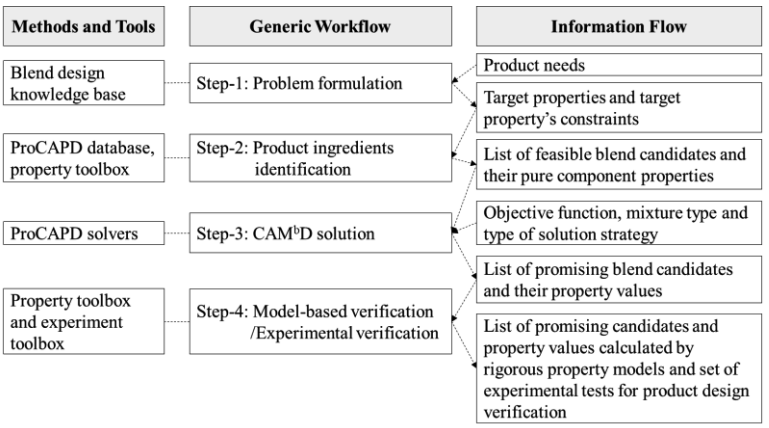

Figure 1: Architecture (framework) of the CAM^{b}D option in the ProCAPD software.

In Step-1, a product design problem is defined through the definition of needs and their translation to target properties for the desired products. Chemical products such as mixtures and blends are obtained by mixing several selected ingredients (chemicals) to obtain the desired product attributes (target properties). Therefore, in Step-2, the list of

feasible blend candidates (ingredients) is generated for the defined product. The fastest way to create this list is to simply search the available chemicals from a database. However, as databases are usually incomplete, another alternative is to employ CAMD to generate this list. CAMD methods such as "generate and test" (Harper et al., 2000) and mathematical optimization methods are commonly employed for the generation of ingredient lists. In Step-3, the mixture and blend design problems are formulated and solved. The blend design problem represents an MILP/MINLP model, depending on the specific property model used. In this paper, a two-step solution approach (Zhang et al., 2015) and a decomposition-based algorithm (Yunus et al., 2014) are employed to solve the MINLP problems. Finally, in Step-4, each feasible blend from Step-3 is verified by either rigorous model-based tests or experimental tests.

3. ProCAPD Application Examples

Two application examples involving the design of a diesel surrogate and a tailor made jet-fuel blend are illustrated through the use of the CAM^{b}D template in ProCAPD.

3.1 Design of a Diesel Surrogate

Conventional diesel fuels comprise of a large number of compounds that are extremely difficult to be simulated for better understanding of the fuel behavior in combustion engines. Therefore, the objective of this case study is to design a diesel surrogate that has fewer compounds and emulates certain important physicochemical properties of the conventional diesel.

Step-1: Problem Definition – The new diesel surrogate should have good fuel performance and meet requirements for the ASTM D975 standard as listed in Table 1.

Table 1. List of product needs and their corresponding target property constraints

Need	Property	Unit	Target Property	
			Diesel Surrogate	Tailor-made Jet-Fuel Blend
Ability to be burned	Reid vapor pressure	kPa	$RVP \leq 1.38$	$RVP \leq 1$
	ASTM distillation temp	°C	$T_{90} \leq 288$	$T_{10} \leq 205$
Flammability	Flash point	°C	$T_f \geq 52$	$T_f \geq 38$
Engine efficiency	Higher heating value	MJ/kg	$HHV > 35$	$HHV \geq 43$
	Density at 15 °C	g/mL	$0.79 \leq \rho \leq 0.87$	$0.77 \leq \rho \leq 0.84$
	Cetane Index	-	$50 \leq CI \leq 60$	
Consistency of fuel flow	Kinematic viscosity at 20°C	mm^2/s	$1.3 \leq V \leq 4.1$	
	Kinematic viscosity at -20°C	mm^2/s		$0 \leq V \leq 8$
	Melting point	°C		$T_m \leq -40$
Environmental impacts	$-log(LC_{50})$	mol/L	$-log(LC_{50}) < 5$	$-log(LC_{50}) \leq 4.58$
	CO_2 emission	kgCO_2/mile		$CO_2E \leq 25.36$

Step-2: Product Ingredients Identification – A set of chemicals (ingredients) that can be blended together in order to match the target properties is generated using the CAMD option provided in ProCAPD. 20 chemicals are generated according to the benchmark of the existing diesel fuel such as boiling point, type of chemicals, melting point and flash point. Pure compound and mixture property models of the chemicals are retrieved from the ProCAPD database. Missing properties are estimated through the property toolbox.

Step-3: CAMʰD Solution – The surrogate design problem is formulated as a MINLP problem using the decomposition approach, where ρ is maximized, subject to target properties. Initially, the software lists 20 chemicals as feasible candidates, which can formulate 15,504 quinary mixtures (5 different chemicals mixed together). Out of which, 2,713 mixtures are excluded due to their linear property constraints and a further 6,254 mixtures are excluded because they form immiscible blends. Subsequently, 6,537 mixtures are left which are evaluated to find the optimal mixture compositions that satisfy all constraints, linear as well as non-linear. The composition (in vol%) of the most promising surrogate consists of n-dodecane (15%), n-tetradecane (31%), cyclo-octane (44%), iso-cetane (9%) and toluene (1%). The properties of the diesel surrogate are listed in Table 2.

Step-4: Model-Based Verification/Experimental Verification – Rigorous property models for *V*, *CI* and ASTM distillation temperature (T_{10}, T_{50} and T_{90}) are applied in this step (see Table 2). The results predicted by ProCAPD are in good agreement with the experimentally measured data (Choudhury et al., 2017). For the engine performance analysis, net torques of the surrogate and the conventional diesel are similar. *CI* value of the surrogate (52) is lower than the conventional diesel (57) which leads to better complete combustion along with ignition delay characteristics. Therefore, the selected diesel surrogate satisfies all target properties and has similar combustion and emission characteristic as the conventional diesel.

Table 2. List of target property values of the diesel surrogate (*: Experiment)

RVP	*HHV*	*V*	*ρ*	*-logLC50*	T_f	T_{10}	T_{50}	T_{90}	*CI*
1.1	47	2.0	0.8	4.21	60	156	184	232	52
1.1*	47*	1.8*	0.8*	-	-	-	-	-	53*

3.2 Design of a Tailor-Made Jet-Fuel Blend

PK fuels (Paraffinic Kerosene) can be used as alternative fuels for commercial aviation. However, PK fuels lack certain chemical constituents, which although they are benign to the environment, offer a trade-off in performance when used in a jet-fuel engine. Therefore, the objective of this example is to improve properties of a GTL PK fuel by blending with feasible additives.

Step-1: Problem Definition – The tailor-made jet-fuel blend should have good fuel performance and meet or exceed stringent requirements for the ASTM D1655 standard as listed in Table 1.

Step-2: Product Ingredients Identification – The tailor-made jet-fuel blend needs to include the GTL PK fuel plus appropriate additives. The composition of the GTL PK fuel is obtained from GC analysis provided by the TEES Gas & Fuels Research Center, Texas A&M University at Qatar. 50 feasible additives are generated using the CAMD technique in ProCAPD according to the benchmark of the existing jet-fuel.

Step-3: CAMʰD Solution – The surrogate design problem is formulated as a MINLP problem using the decomposition approach and the two-step approach, where the composition of the GTL PK fuel is maximized, subject to target properties. In the two-step solution appraoch, 143 equations are generated with 30,099 continuous variables and

51 discrete variables. In the decomposition-based algorithm, initially, a total of 50 chemicals are selected as additives from which 1,225 binary mixtures can be formed, out of which 903 mixtures are excluded due to their linear property constraints. The remaining 332 ternary mixtures are all miscible and subsequently all 332 mixtures are evaluated to determine the optimal mixture compositions that satisfy all target property constraints, linear as well as non-linear. The most promising blends with the maximum GTL PK composition obtained from the decomposition-based algorithm and the two step solution approach are listed in Table 3. The calculated target properties of the promising blends are listed in Table 4.

Table 3. List of blends matching the jet-fuel target properties ((DC: the decomposition-base algorithm; TS: The two step solution approach))

ID	Composition (vol%)
1 (DC)	GTL PK (80.2) Decalin (8.3) Butylbenzene (11.5)
2 (DC)	GTL PK (78.6) Decalin (12.4) Pentylbenzene (9)
3 (DC)	GTL PK (77) Decalin (6) Hexylbenzene (17)
4 (TS)	GTL PK (77) Decalin (18) Hexylbenzene (5)

Table 4. List of blends matching the jet-fuel target properties and their properties

4	0.50	43.1	4.1	0.78	24	4.42	51	183	197	222		
GTL PK	0.64	47.6	4.0	0.756	23	4.58	58	184	204	228		
		47.0*	4.1*	0.752*			56*	181*	201*	223*	-49	0.712

Step-4: Model-Vased Verification/Experimental Verification – Rigorous property models to predict η and ASTM distillation temperatures are applied in this step (see Table 4). The results predicted by ProCAPD are in good agreement with the experimentally measured data. All blends satisfied the target properties constraints. Blending aromatics with the GTL PK fuel increases the freezing points along with the better pumpability of the blends. The large wear scar diameter (WSD) implies poor lubricity. The upper bound of WSD is 0.85 mm. Blend ID1 and Blend ID3 are promising candidates because they improve all target properties. In addition, the volumetric heating values of Blend ID1 (36.5 MJ/mL) and Blend ID3 (36.4 MJ/mL) are higher than the GTL PK (33.5 MJ/mL). Although the lubricity of Blend ID3 is better than Blend ID1, its gives higher aromatic content, this may generate more particulate matter (PM) during engine operation that reduce engine lifetime and can cause serious respiratory and cardiovascular health problems. Therefore, Blend ID1 is the best blend candidate.

4. Conclusions

A systematic framework for CAM^{b}D has been developed and implemented as the part of the CAM^{b}D template of the ProCAPD. The application of the CAM^{b}D template is

highlighted through examples involving the design of a diesel surrogate and a tailor-made jet-fuel blend. In order to save time and avoid combinatorial explosions within a very large search space of solving CAM^{b}D problems, the large mixed-integer non-linear problems of the three fuels are solved using the decomposition-based and the two step solution approach. The results from the case studies reveal the uncertainty of choosing the methods to solve CAM^{b}D problems. Both methods identify promising blends with familiar additives, however, the decomposition based algorithm tends to give better solutions. It helps to obtain the maximum GTL PK compositions with better target properties for the design of the jet-fuel blend. Both methods help to reduce the search space and provide promising chemical candidates that are competitive, and environmentally feasible, making it flexible and capable of solving a wide range of CAM^{b}D problems. Therefore, ProCAPD enhances the future development of chemical product design as huge amounts of data, models, knowledge, methodologies and algorithms are integrated and managed in a systematic and efficient way, increasing the possibility to capture past experiences and provide better guidelines for future chemical products (Gani, 2004).

Abstract

Due to increased concerns regarding environment, public health and safety through regulatory enforcements and growing competitiveness through globalization, there is an incentive and a quest for innovative designs that are efficient, profitable as well as sustainable. To generate a truly optimal process flowsheet a systematic method to identify the types of tasks-operations that need to be performed, the corresponding design of the operation-equipment, their configuration, mass-energy flows, environmental impacts, etc., need to be employed. In this case, development and use of a hybrid method that combines the best features of knowledge-based and optimization-based approaches into one method is an attractive option. This work focuses on the development of an integrated method and computer aided software tool capable of enumerating all feasible alternatives within the entire search space defined by a process synthesis problem. Solving this type of large and complex synthesis problems using mathematical formulations is usually cumbersome and difficult. In this work we integrated ProCAFD (computer-aided synthesis tool used for enumeration) with Super-O, which automates the mathematical formulation of the synthesis problem thereby leading to very quick and reliable solutions. An overview of the key concepts and the method is presented along with details of the developed computer-aided tool.

Keywords: Process synthesis, Mathematical programming, ProCAFD, Super-O.

1. Introduction

In process synthesis the objective is to find the best processing route that can convert a given set of raw materials to desired products. In recent years, diminishing natural resources and increasing environmental awareness has driven the process industry towards development of more sustainable and innovative processes. To generate truly innovative and optimal solutions it is imperative that one considers the entire search space of alternatives and solve the resulting superstructure based optimization problem. In this work a superstructure of all feasible alternatives is created using a technique similar to computer aided molecular design (CAMD) (Tula et al., 2015). According to this technique, chemical process flowsheets are synthesized in the same way as atoms or groups of atoms are combined to form molecules in CAMD techniques. The building blocks in the process flowsheet synthesis problem are called process-groups (PG), which represent a single or set of unit operations that are selected by employing a thermodynamic insights based method (Jaksland et al. 1995). These building blocks are then combined using connectivity rules to enumerate all feasible process flowsheet alternatives.

In general, two solution strategies are commonly employed to solve superstructure based synthesis problems: simultaneous approach and decomposition-based approach. In the simultaneous approach, the synthesis problem is solved by considering all the constraints and components of the process synthesis simultaneously. On the other hand, in the decomposition approach the synthesis problem is divided into a set of sub problems that are solved sequentially in a predefined order. Mathematical optimization methods are employed by the simultaneous approach to determine the best processing route from a superstructure of alternatives. Industrially relevant problems in general pose mathematical challenges due to their size and complexity in formulation. Consequently, the main focus of most of the research in this area has been related to the development of solution methods, aiming at solving progressively larger and more complex problems, while at the same time minimizing the computational power required. In this work we have integrated ProCAFD and Super-O, where ProCAFD was used to enumerate all the possible flowsheets while Super-O automates the mathematical formulation of the generated alternatives to solve the synthesis problem using a mathematical optimization approach.

2. Methodology and Dataflow

The developed synthesis, design, analysis and improvement method is based on the three-stage approach (Babi et al., 2015) for innovation as shown in Figure 1.

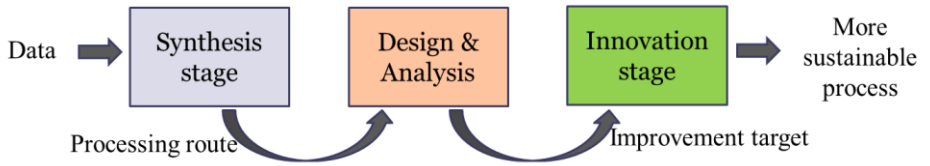

Figure 1: Three stage approach for sustainable synthesis, design, analysis of flowsheets

In stage 1, process synthesis is performed, and all the feasible alternatives are generated for a given synthesis problem. This superstructure of alternatives is solved to identify the best processing route based on process constraints and performance criteria. In stage 2 additional design details are added to the process tasks-operations so that simulations with rigorous process models can be performed. The simulation results serve as input for equipment sizing and utilities requirement calculations, which in turn serve as input for process analysis (economic, sustainability factors, LCA factors, etc.). Based on this analysis process hot-spots are identified, which are translated into design targets, that is, if satisfied, eliminates the process hot-spots and generates sustainable flowsheet alternatives. In stage 3, the optimal processing route is further improved by applying various synthesis-intensification methods to determine process alternatives that match the targets for improvement. Any match of the design targets corresponds to a more sustainable process alternative. In this paper, only stage 1 is discussed in detail as the methodology has been extended for this stage.

2.1. Synthesis Stage

The synthesis method consists of 6 steps: (1) problem definition; (2) problem analysis; (3) process-groups selection; (4) generation of flowsheets; (5) superstructure generation; and (6) selection of optimal flowsheet.

2.1.1. Problem Definition: The objective here is to define the synthesis problem, design constraints and the performance criteria based on which the generated alternatives are to be benchmarked. The structural description of the synthesis problem is defined through data on raw materials (input streams), desired products (outputs stream) and process specifications (for example, product purity, product recovery, etc.)

2.1.2. Problem Analysis: The objective of this very important step is to generate the information required for solving the synthesis problem. Analysis is performed to further define the synthesis problem by knowledge bases and physical insight based methods. First, reaction analysis is performed to identify reaction tasks needed to produce the desired product as defined in the previous step. A database search is performed to find the reaction mechanisms yielding the desired product. Next, pure component and mixture property analysis is performed for all the chemical species listed in the problem to generate data that can be used for identification of separation tasks and corresponding feasible separation techniques. Analysis of 22 pure component properties for the system chemicals is performed. Based on this analysis a table of property ratios is generated for all the binary pairs of chemicals. Mixture property analysis identifies the existence of possible azeotropes, eutectic points and the available driving forces for all identified binary pairs. Based on the mixture analysis and the property ratios feasible separation techniques are identified using the extended Jaksland et al. (1995) physical insights-based method.

2.1.3. Process-Groups Selection: Here, all the process-groups that are applicable for the synthesis problem are selected and initialized based on the problem definition and analysis steps. Information from the problem definition step is used to select and initialize the inlet and outlet process-groups with corresponding components. From the problem analysis step, corresponding reaction process-groups and separation process-groups are selected and initialized.

2.1.4. Generation of Flowsheets: In this step, the initialized process-groups are combined according to a set of rules and specifications to generate feasible flowsheet structures. This is achieved through the flowsheet generation method based on a PG-combinatorial algorithm, which is governed by a set of connectivity and logical rules that ensure the generation of only feasible solutions, thereby avoiding any combinatorial explosion.

2.1.5. Superstructure Generation: Based on all the generated process alternatives a superstructure is generated and represented in the form of a Processing Step-Interval Network (PSIN). Figure 2 represents an illustration of a superstructure linking raw materials and products using process intervals. Here process steps, which are represented as columns correspond to different sequences of processing tasks to convert raw materials to products. Process intervals represent different techniques to achieve the particular processing task. The main advantage of representing the superstructure in the form of PSIN is that a generic model (Quaglia et al., 2015) for the process interval can be used to perform optimization on the superstructure. The optimal processing route determined this way, also provides mass and energy balance results for each processing step. Through the generic model, each process interval of the superstructure is represented by a sequence of tasks (Figure 3): (1) mixing, (2) reaction, (3) waste separation, and (4) product separation. The model allows all the interval blocks to be defined by the same set of equations related to the tasks allowing simplified data flow and time effective formulation of large problems. The model is sufficiently flexible to allow multiple inlets to and outlets from the interval, including recycle streams from downstream intervals and bypasses.

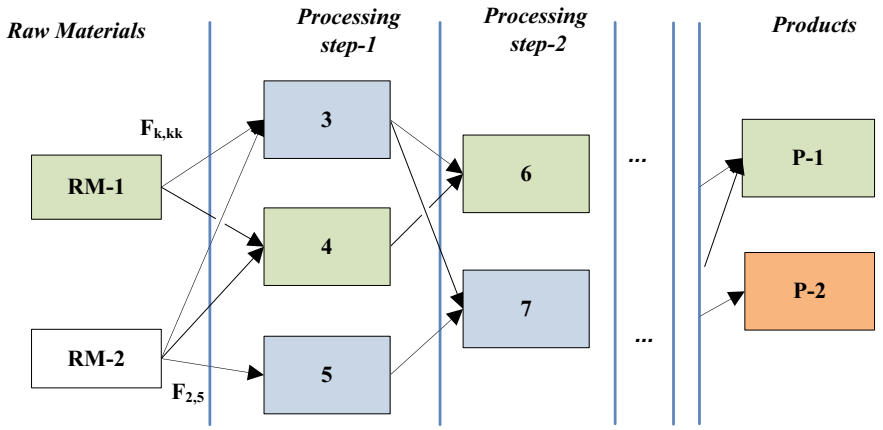

Figure 2: Generic superstructure representation (PSIN)

The model parameters required are given by the definition of the process-groups. The raw material compositions are obtained from the inlet process-groups, reaction process groups provide the conversion factors while the separation split factors are obtained from the separation process-groups. For instance, in the case of the distillation process-group, the recovery of the components lighter than the light key is set to 100% in the overhead product and the recovery of the components heavier than the heavy key is set to 100% in the bottom product. The recovery of the key components is greater than or equal to 99.5%. Similarly, separation factors based on different driving forces available for each process-group are defined.

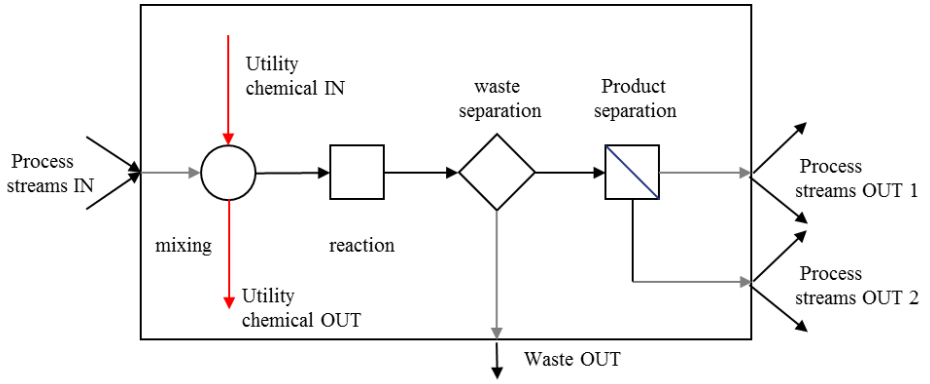

Figure 3: Generic model for process interval

2.1.6. Selection of Optimal Flowsheet: The optimization problem formulated in step 5 is solved by direct approach (that is, all the equations are solved simultaneously). The problem formulation is in the form of a MI(N)LP which is solved here with an appropriate solver (using GAMS). The solution gives the optimal process alternative to convert the given raw material to products.

3. Software implementation

ProCAFD (Tula et al., 2017) is a computer-aided software developed in C# based on the CAMD approach which uses decomposition strategy to solve the synthesis problem. However, in this work the scope of the software is further expanded to solve the synthesis problem in a simultaneous approach using mathematical programming. Figure 4 shows the schematic representation of the integrated software based on the developed method. ProCAFD is integrated with structured databases, methods, in-house tools and external simulation tools like Aspen Plus, PRO/II, which can be accessed through the main user interface, and interact to provide sufficient information to solve the synthesis-design problem.

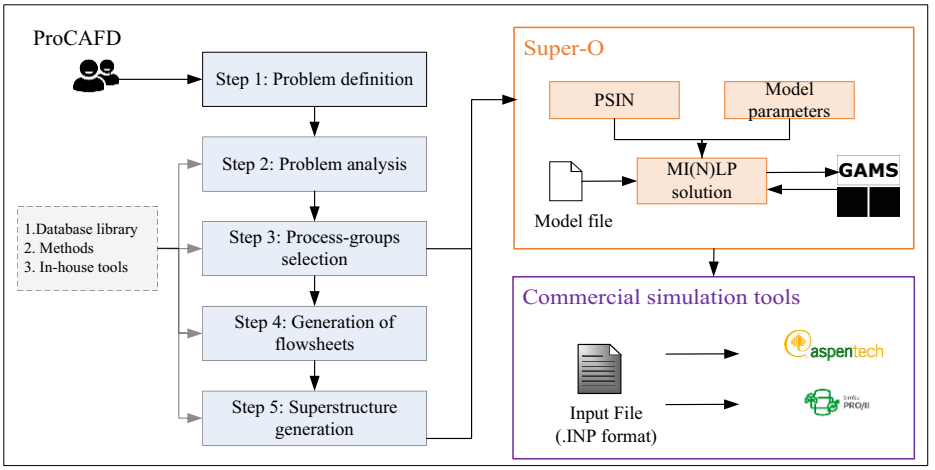

Figure 4: Schematic representation of integrated computer-aided tool for process synthesis

3.1. Software Workflow: In ProCAFD, the user defines the synthesis problem and all the necessary information is retrieved from the integrated database libraries. Based on the data provided, ProCAFD generates information to create the superstructure of all feasible alternatives using different methods and integrated in-house tools. The generated superstructure is represented in the form of Processing Step-Interval Network and sent to Super-O along with the model parameters. Based on this information Super-O generates a GAMS-readable file containing all problem data and generic equations using the generic model file. Super-O which is integrated with GAMS, directly calls the appropriate solver, to solve the optimization problem and generate an output file containing the results. ProCAFD is also integrated with commercial simulators to verify the design alternatives using rigorous models (stage 2). Based on the selected optimal flowsheet from Super-O, ProCAFD calculates the operational design parameters and an input file (.INP) is generated which can be accessed directly in commercial simulation packages like Aspen Plus or PRO/II.

3.2. Case Studies for Testing: This integrated tool has been tested by solving various synthesis problems. The problem size and model size of three cases solved using ProCAFD are listed in Table 1. More details on the solution can be obtained from the authors.

Table 1: List of case studies solved.

Case	NPI	NP	NC	NR	NEQ	NV(NDV)	TA
Hydrodealkylation of toluene	48	2	5	2	51978	50560(106)	340
DMC from propylene carbonate	31	2	4	2	20534	19763(72)	53
Cumene from benzene and propylene	56	2	5	2	68125	66488(122)	240

Abbreviations are as follows: NPI is the number of processing intervals; NP is the number of products; NC is the number of components; NR is the number of reactions; NEQ is the number of equations; NV is the number of variables; NDV is the number of discrete variables; TA is total number of alternatives.

4. Conclusions

In this work an integrated hybrid method is proposed for sustainable process synthesis which combines physical insights based methods with optimization based approach. While the physical insights methods make sure that all feasible flowsheet alternatives are generated, the optimization based approach ensures optimal solution from the generated superstructure. There is a limit on the number of flowsheets that can be handled (generated and analyzed) using a manual approach for synthesis methods. However, by application of a computer-aided software-tool, multiple flowsheet alternatives can be generated and screened efficiently and reliably. A computer-aided software-tool has been presented together with a software architecture that incorporates multiple methods, algorithms and computer-aided tools. Through the introduction of a generic model to represent process intervals, faster and systematic formulation of large synthesis-design problems, which are solved through different options in ProCAFD, are made possible. In this work the integration of ProCAFD with external simulation tools like Aspen Plus and PRO/II has been made, thereby enabling the user to perform rigorous simulations of any selected process alternative.

Abstract

Design and optimization of Heat Exchanger Networks (HENs) is well established and has been heavily applied in the process industries since its pioneering period in the 1970s and 1980s. While temperature and thermal energy (heat) obviously are key elements in process plants and power stations, pressure and mechanical energy (work) are equally important. By adding expanders and compressors as equipment and power as a utility to the classical HEN problem, the considerably more challenging Work and Heat Exchange Network (WHEN) problem has been formulated as a new and growing discipline within Process Systems Engineering (PSE). Considerable opportunities exist for improving energy efficiency in process plants and power stations by using the WHEN methodology. Recent applications include (I) design of LNG processes, (II) design of CO_2 capture processes, and (III) an industrial sensible heat pump. In fact, WHENs have strong similarities to Heat Pumps and Refrigeration Cycles, with the additional advantage of a PSE approach. Challenges in the graphical methodology for WHENs compared to HENs include (a) the shape of Composite and Grand Composite Curves will change with pressure manipulations, (b) the Pinch points may change, (c) the hot and cold utility demands will change, (d) the stream identity (hot or cold) may temporarily change, (e) process streams may be used as utilities, and (f) work and heat have different energy quality. To overcome the above challenges, the WHENs problem could be addressed by developing Optimization models using Total Annual Cost as the objective function. However, new challenges will appear if Mathematical Programming is used, such as (i) developing a sufficiently rich yet efficient superstructure, (ii) non-convexities in the model that may result in local optima, (iii) potentially a large number of binary variables that may give a combinatorial explosion, and (iv) discontinuities in the process models that will cause numerical problems and slow down convergence, unless recent developments in nonsmooth analysis can be adopted for these problems.

Keywords: Work and Heat Exchange Networks, Process Integration, Optimization

1. Introduction

The objectives of this paper are (i) to introduce the new research field WHENs to the PSE community, (ii) to provide a brief review of this research area, and (iii) to discuss challenges and opportunities. The main contributions of the paper are thus (ii) and (iii).

In the process industry, a significant amount of energy can be saved by Process Integration. Heat exchange between heat sources and heat sinks to reduce hot and cold utility consumption is the key idea of heat integration, which has been a successful

application of process integration. The Heat Exchanger Networks (HENs) problem has been well defined and studied since the 1970s (Gundersen and Naess, 1988). In the process industry, pressure is also an important parameter. It is obvious that work exchange between high and low-pressure streams will reduce work consumption (shaft work or electricity), which is another example of Process Integration (Huang and Fan, 1996). Razib et al. (2012) developed a superstructure for Work Exchange Network (WEN) configurations minimizing total annualized cost. Significant energy savings verified the efficacy of the model. Thus, WENs aiming at reducing work consumption is emerging in Process System Engineering. If HENs and WENs are considered simultaneously, energy efficiency can be further improved by considering heating from compression and cooling from expansion in the heat recovery problem. This gives rise to a new problem referred to as Work and Heat Exchange Networks (WHENs).

Aspelund et al. (2007) proposed a graphical design methodology based on Pinch Analysis referred to as ExPAnD. Their study considers the pressure change of process streams and extends the heat integration methodology to the WHENs problem. The key contribution from their work is that compression (expansion) adds heating (cooling) and should be done above (below) the process Pinch. Fu and Gundersen (2015a) presented a systematic graphical design procedure based on four theorems for integration of compressors in HENs above ambient temperature. Similarly, four theorems were proposed to integrate compressors into heat exchanger networks below ambient temperature (Fu and Gundersen, 2015b). The integration of expanders into heat exchanger networks above and below ambient temperature are also investigated (Fu and Gundersen, 2015c,d). It is concluded that compression/expansion above/below ambient temperature should start at distinct temperatures, such as Pinch, ambient or hot/cold utility depending on the actual case. No other temperatures will give lower exergy consumption. Later, a systematic methodology was developed by Fu and Gundersen (2016a) to integrate both compressors and expanders into heat exchanger networks above ambient temperature. Fu and Gundersen (2016b) summarized the fundamental thermodynamic insights and applied them to three carbon capture processes. Considerable energy savings have been achieved by heat and work integration based on these thermodynamic insights. However, there are still many challenges in WHENs. This paper mainly focuses on the realized and potential applications of WHENs and the challenges in this field.

2. Problem definition

The WHENs problem in its most general form can be stated as follows: “Given a set of process streams with fixed supply and target states (pressure and temperature), as well as utilities for heating, cooling and power; design a Work and Heat Exchange Network consisting of heat transfer equipment such as heat exchangers, heaters and coolers, as well as pressure changing equipment such as compressors, expanders, pumps and valves, in such a way that Exergy consumption or Total Annual Cost is minimized.”

What makes WHENs different from HENs is that the thermodynamic path from supply to target state depends on the sequence and the extent of changes in pressure and temperature. As a result, the shape of the Composite and Grand Composite Curves will change, and the design problem becomes considerably more difficult. In addition, the identity of streams (hot/cold) may temporarily change. Even a stream with constant pressure could temporarily have its pressure changed by compression and expansion. In that way streams would act as a utility, which is often done below ambient temperature.

The WHENs problem has a lot in common with heat pumps and refrigeration cycles, however, one important difference is that WHENs offer a systematic and systems-oriented approach to solving the design problem. Heat pumps and refrigeration cycles have been addressed as standalone units with the exception that economizers are used in refrigeration cycles, i.e. an integration of heat between the cycle and the background process. Another difference is that the WHENs methodology also considers compressors and expanders that are not part of cycles.

3. Opportunities for Work and Heat Exchange Networks

There are many possible applications of WHENs in the process industry. These opportunities arise in both above and below ambient temperature processes. WHENs become more important below ambient temperature due to the fact that refrigeration is obtained by compression/expansion. In this section, some realized and potential applications of WHENs will be presented by examples.

3.1. Offshore LNG process

Aspelund and Gundersen (2009) proposed a novel energy and cost-effective transport chain for stranded natural gas. Using liquefied N_2 and CO_2 as carriers of cold exergy, natural gas is liquefied and transported by ship to an onshore power plant using oxy-combustion for CO_2 capture. Figure 1 shows the process streams that take part in the offshore process WHEN design. Wechsung et al. (2011) combined models for Pinch operator, exergy operator and pressure operator to synthesize the WHEN in the offshore LNG process. The results show that pressure manipulation can significantly reduce the irreversibilities of the system. Huang and Karimi (2016) also applied their WHENs model to synthesize the off-shore LNG process. However, they treat natural gas and nitrogen as simplified streams with constant heat capacity flowrate, which is a rather crude assumption. Onishi et al. (2015) also developed a mathematical model for the retrofit of WHENs and verified the model by this offshore LNG process. Considerable energy savings from work and heat integration are reported in these studies.

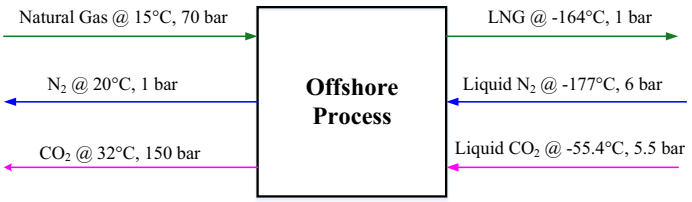

Figure 1 WHENs problem in an offshore LNG process (Aspelund and Gundersen, 2009)

3.2. Post-combustion carbon capture processes

Carbon capture and storage is a competitive alternative to reduce CO_2 emissions. Zhao et al. (2010) proposed a post-combustion carbon capture process using multistage CO_2/N_2 gas separation membranes. There are two membranes in this process. The retentate from both membranes at 8 bar can be expanded to 1 bar to recover shaft work. If the retentate streams are integrated with flue gas and air in the air preheater, more expansion work can be recovered. Fu and Gundersen (2016b) applied the

thermodynamic insights for WHENs to this carbon capture process. Work and heat integration can reduce the specific work consumption by 12.9%.

3.3. Sensible heat pump for industrial heat recovery

Recently, Fu and Gundersen (2016c) proposed a novel sensible heat pump based on a reversed Brayton cycle. Their study is an extension of the appropriate placement concept for compressors and expanders by Fu and Gundersen (2016a). In order to recover the compression heat and expansion work efficiently, a sensible heat pump is developed based on work and heat integration. The sensible heat pump is more competitive for cases where there is no sharp Pinch point on the Grand Composite Curve (GCC), the temperature range is large, and energy saving is a primary concern.

Holiastos and Manousiouthakis (2002) also applied a heat and work integration methodology to crude oil pre-heat train successfully. Their methodology is, however, limited to the integration of heat engines and heat pumps, thus it does not address heat integration opportunities from pressure changes to process streams. The above-mentioned studies are successful applications of WHEN methodologies. There is still a large number of potential applications of WHENs in the process industry, such as cascade refrigeration cycles in ethylene plants (Dinh et al., 2015) and low-temperature waste heat recovery by organic Rankine cycles in oil refineries (Yu et al., 2017).

4. Challenges in Work and Heat Exchange Networks

Although the WHENs problem has received increasing attention in the last decade and some methodologies have been developed, there are still considerable challenges. These challenges exist in practical issues, Pinch Analysis based methodologies, optimization based approaches, and selecting the appropriate objective function.

In realistic applications, more issues need to be considered, which are not addressed in the majority of current research: Multiple hot/cold utilities, gliding temperature utilities, multi-stage compression/expansion, phase change of the process streams, pressure ratio determination, and design issues related to operating compressors and expanders at high and low temperatures, respectively.

The methodologies based on Pinch Analysis rely on Composite Curves (CCs) and the GCC. Even though CCs and the GCC are powerful and reliable tools for HENs, they cannot be easily applied to WHENs for the following reasons: Pressure manipulations may change the identity (hot/cold) of the process streams and the CCs and GCC will definitely change after pressure manipulation. Consequently, the Pinch point may change correspondingly. Thermodynamic insights proposed by Fu and Gundersen (2016a) actually solve the issue of Pinch changes, however, their work mainly focuses on one or two pressure changing streams and single stage pressure manipulation. If multiple pressure manipulating streams are considered or the Pinch point changes after pressure change, the manual procedure will be very tedious for design of WHENs.

To overcome the above challenges, the WHENs problem could be addressed by optimization. Mathematical programming can deal with multiple streams, multiple thermal utilities and multiple stages of pressure manipulation, in most cases based on the idea of superstructures. However, new challenges will appear if mathematical programming is used. The models are commonly highly nonconvex nonlinear programming (NLP) or mixed integer nonlinear programming (MINLP) problems. The formulation and solution of MINLP optimization problems are not likely to reach the

same stage of maturity and reliability as linear and mixed integer programming. To the extent that integer (binary) variables are required to formulate the design problem, this represents another major challenge in optimization based models. The problem size and search tree in a Branch and Bound approach grow exponentially with the number of such discrete variables. A superstructure should be rich enough to consider all possible configurations, but this makes the problem difficult to solve efficiently. Therefore, a rich yet efficient superstructure is urgently needed for WHENs. It is not trivial to propose a superstructure that can take into account all the factors concerning operating cost, equipment cost, operability and flexibility. A few superstructures tailor made for WHENs have been proposed, however, a detailed discussion of these is beyond the scope of this paper. A new more general representation using fundamental building blocks aiming at process integration and intensification presented by Demirel et al. (2017) could have the potential to be used as a superstructure for WHEN synthesis. As far as discontinuities are concerned, it is hoped that recent developments in nonsmooth analysis can be adopted to solve these problems (Watson et al., 2015).

Since both heat and work are involved in WHENs, it is challenging to set up an appropriate objective function. There are generally two categories of objective functions; energy-related objective functions and economic indicators. Exergy is increasingly adopted as the energy-related objective function. Exergy can provide a unified treatment of different energy forms, such as work and heat. Equipment cost varies constantly and has large uncertainties. Thermodynamics will give sound and reliable criteria for process design. However, the exergy of heat is calculated based on reversible processes (i.e. the Carnot cycle), which results in an overestimation of the quality of heat. Valves are favorable because of their negligible capital cost compared with turbines, however, if exergy is the objective function, valves are not likely to be selected due to the exergy destruction in such units. To overcome the limitations of energy-related objective functions, a techno-economic objective function can be used in order to balance energy cost and equipment cost. However, accurate equipment cost correlations are not easy to get. Correlations for equipment cost in the literature are simplified, which may lead to unreliable results. A detailed economic analysis is still a challenge when techno-economic optimization is performed.

5. Conclusions

Work and Heat Exchange Networks (WHENs) is an emerging new topic in Process System Engineering. There have been some promising applications that illustrate the significant energy savings that can be obtained by synergizing work and heat integration. However, the methodology for WHENs is still under development and many challenges need to be addressed and overcome. Due to the respective disadvantages of Pinch based methods and Mathematical Programming, it is better to combine these methods taking advantage of the merit of each approach. The Pinch based methods can provide fundamental thermodynamic insights, which can help in developing more efficient superstructures and as a result, the size of the mathematical model can be reduced and make it easier to find optimal solutions. In addition, practical issues should also be taken into account in the future work.

Abstract

The effect of evaporation on the output of literature dynamic models for hydrotreating trickle-bed reactors was examined. The model system, presented by Mederos & Ancheyta (2007), was applied to a given oil treating case. In order to account for evaporation, Pro/II flash calculations were implemented over the length of the reactor in cocurrent operation. It was found that, given the model and the chosen reaction network, the heat of reaction would result in a large fraction of the liquid feed evaporating in the reactor. It was also found that the reaction rate of the feed influenced the effect of the evaporation. A higher reaction rate was found to widen the range of outputs attainable between high and low mass transfer rates.

Keywords: Hydrotreating, trickle-bed reactor, evaporation, adiabatic model, Pro/II

1. Introduction

Trickle-bed reactors (TBR) are catalytic reactors used to convert sulfur, nitrogen and aromatic compounds in hydrocarbon fuels. In the reactor, hydrogen is contacted with the fuel over the catalytic particles at high pressures resulting in highly exothermic reactions. In order to properly design and control TBRs, representative, rate-based, adiabatic and dynamic models are appreciated. Such a model was presented by Mederos & Ancheyta (2007). The model assumes that only normal gases (H_2, H_2S and NH_3) are subject to transfer between the gas and liquid phase, where they may be dissolved. This means that evaporation of the fuel is completely neglected from the mass and energy balances. A high level of evaporation, could cause incomplete wetting of the catalyst as well as reactor hot spots resulting in catalyst degradation. Rigorous modeling of rate-based evaporation and phase equilibria is deemed to add a very high level of complexity to the model, but neglecting it may be a serious deficiency. Therefore, in order to examine the potential effects of evaporation on the aforementioned model, it was combined with process simulation software to calculate the equilibrium compositions of the phases. This is based on the novel concept presented by Ramírez-Castelán et al. (2017). The inclusion of flash calculations was used to compare the model outputs at different rates of mass transfer with the output neglecting evaporation.

2. Methodology

The model presented by Mederos & Ancheyta is a first-principle partial differential equation system. The model was, in this work, modified by taking into account the change in gas velocity as demonstrated by Alvarez & Ancheyta (2012). The model equations are

given in Eq. (1) to (6) with the gas velocity derivative given in Eq. (7). The differential equation system was discretized in the axial direction using a backwards finite-difference method with 100 space steps.

$$\frac{\varepsilon_G}{R\,T_G}\frac{\partial p_j}{\partial t} = -\frac{1}{R\,T_G}\frac{\partial(u_G\,p_j)}{\partial z} - k_j^{GL}\,a_{GL}\left(\frac{p_j}{H_j} - c_j^L\right) \tag{1}$$

$$\varepsilon_L\frac{\partial c_j^L}{\partial t} = -u_L\frac{\partial c_j^L}{\partial z} + k_j^{GL}a_{GL}\left(\frac{p_j}{H_j} - c_j^L\right) - k_j^{LS}a_{LS}\left(c_j^L - c_j^S\right) \tag{2}$$

$$(1-\epsilon)\,\varepsilon_p\frac{\partial c_j^S}{\partial t} = k_j^{LS}a_{LS}\left(c_j^L - c_j^S\right) + \rho_B(\eta\,r)_j \tag{3}$$

$$\varepsilon_G\rho_G c_{pG}\frac{\partial T_G}{\partial t} = -u_G\rho_G c_{pG}\frac{\partial\,T_G}{\partial z} - U_{GL}a_{GL}(T_G - T_L) \tag{4}$$

$$\varepsilon_L\rho_L c_{pL}\frac{\partial T_L}{\partial t} = -u_L\rho_L c_{pL}\frac{\partial T_L}{\partial z} + U_{GL}a_{GL}(T_G - T_L) - U_{LS}a_{LS}\,(T_L - T_S) \tag{5}$$

$$(1-\epsilon)\rho_S c_{pS}\frac{\partial T_S}{\partial t} = U_{LS}a_{LS}(T_L - T_S) + \textstyle\sum_i \rho_B(\eta\,r)_i(-\Delta H_i) \tag{6}$$

$$\frac{\partial u_G}{\partial z} = \frac{RT_G}{P}\left(\frac{\varepsilon_G P}{RT_G^2}\frac{\partial T_G}{\partial t} - \textstyle\sum_j k_j^{GL}a_{GL}\left(\frac{p_j}{H_j} - c_j^L\right)\right) + \frac{u_G}{T_G}\frac{\partial T_G}{\partial z} \tag{7}$$

Table 1 Nomenclature

ε_k	Volumetric holdup in phase k	k	Mass transfer coefficient
ϵ	Void fraction of particle bed	a	Interfacial area
ε_p	Particle porosity	ρ_k	Density of phase k
c_j^k	Concentration of compound j in phase k	$c_{p,k}$	Specific heat of phase k
p_j	Partial pressure of compound j	U	Heat transfer coefficient
u_k	Superficial velocity of fluid phase k	T_k	Temperature of phase k
H_j	Henry's coefficient of compound j	P	Reactor pressure
ΔH_i	Reaction enthalpy of reaction i	ρ_b	Bulk density of particle bed
$(\eta\,r)_j$	Apparent reaction rate of compound j	$(\eta\,r)_i$	Apparent reaction rate of reaction i

The specific oil treating case considered is given by De La Paz-Zavala et al. (2013), which gives a boiling point curve found in Table 2. Their study uses a simplified reaction scheme to describe the combined reactions of sulfur and aromatic compounds. Here, the conversion of a sulfur-compound molecule results in the creation of a polyaromatic molecule, which can react to form a monoaromatic molecule, etc. The representative compounds are divided into regular compounds and methylated analogues as defined in Table 3. The methylated compounds react slower, and thus by changing the ratio of methylation, the reaction rate can be altered. The reaction network and its true rate

expressions have been documented by Vanrysselberghe et al. (1996,1998). Diffusion limitations in the catalyst particles were accounted for using a method presented by Chacon et al. (2012) utilizing the catalyst properties given by Mederos & Ancheyta. The vapor-liquid equilibrium of saturated species was included using a pseudo-component stream defined in Pro/II with the boiling point curve as given by De La Paz-Zavala et al. The gas-phase was assumed ideal and Pro/II library models were used for the liquid.

Table 2 ASMT D86-boiling point curve for the fuel considered in the simulations with specific gravity and molar mass (De La Paz-Zavala et al. (2013)).

Distilled fraction [vol.-%]	Temperature [˚C]
IBP	278.1
10	293.9
20	300.1
30	305.3
50	315.6
70	327.3
80	334.3
90	343.4
FBP	358.3
Specific gravity at 20 ˚C / 4 ˚C	0.8676
Molar mass [g / mol]	260

Table 3 Real components in the feed as used in the simulations (De La Paz-Zavala et al. (2013)).

Compound group	Representative compound	Methylated analogue	Total content [wt.%]
Sulfur	Dibenzothiophene	4,6'-dimethyl dibenzothiophene	1.96
Polyaromatic	Biphenyl	3,3'-dimethyl biphenyl	13.4
Monoaromatic	Cyclohexyl benzene	3'-methyl cyclohexyl toluene	20.1

The model was applied in two different scenarios. Only cocurrent operation was considered. Firstly, the model was run to a steady state at different degrees of methylation. Isothermal flashes were calculated over the reactor to record the vapor recovery of fuel species. Secondly, flash calculations were implemented at regular increments in order to take into account the effect of the fuel species evaporation on the process. One isothermal flash was set in the inlet, meaning the feed streams enter the reactor at equilibrium. The in-reactor flashes were adiabatic. The methylation of the feed was altered. Also, the number of flashes was altered between no flashes in the reactor and a high number of flashes throughout the reactor. This allowed examining the possible range of model outputs compared to the model without evaporation over the range of possible mass transfer rates.

3. Results

The simulations were performed using a feed inlet temperature of 643.15 K and a pressure of 7.8 MPa. The results for the potential vapor recoveries are illustrated in Fig. 1. Generally, the aromatic components are estimated to be more volatile than the fuel mixture. With decreasing methylation, the vapor recovery increases greatly as the reaction rate is higher, thus developing heat faster. At 25 wt.-% methylated feed, the vapor recovery increases with more than 30 mol-% over the reactor profile. Thus, implementing evaporation in the model would have a significant effect on the

composition of the liquid phase in the reactor. The flash calculations were implemented in the model at steady state using 19 in-reactor flashes. The temperature profiles are found in Fig. 2. For low mass transfer, the temperature is lower, caused by displacement of the substrates to the gas phase. For the high mass transfer cases, the temperature increase is slower. However, depending on the feed, the end temperature is either the same or higher than when neglecting evaporation. Thus, the potential conversion is higher for the case with evaporation than for the one without.

Calculating the molar flow profiles for the simulations, the effect of the mass transfer on the individual component conversions can be estimated. The sulfur molar flow is seen in Fig. 3. The low mass transfer cases have remaining sulfur in the gas phase while the other cases have complete conversion. For the high mass transfer cases, the flow profiles are very similar to the case without evaporation suggesting the high reaction rate diminishes the effect of evaporation. The molar flow profiles for the polyaromatic components are found in Fig. 4. For both degrees of methylation at high mass transfer, the reaction rates are lower than the no-evaporation case, but, over the length of the reactor, the molar flow becomes lower. This suggest the attainable conversion is higher when including mass transfer. The reason seems to be that evaporation of monoaromatics decreases the product inhibition of polyaromatic reactions. The highly methylated feed has a higher conversion than the low methylated feed in this case. This is an effect of the temperature difference

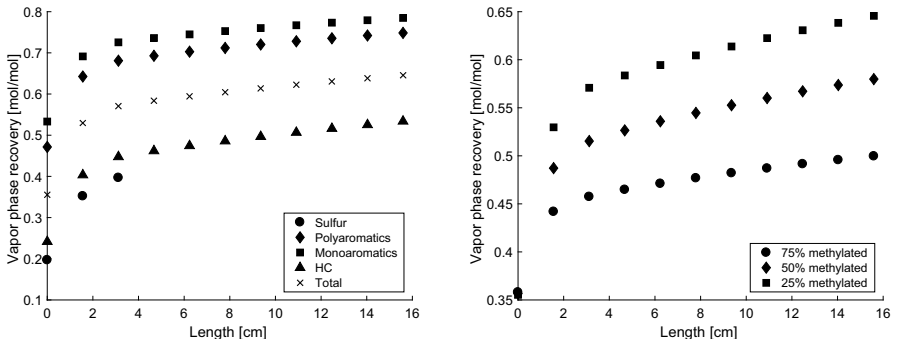

Figure 1 Calculated vapor recovery profiles of oil species in simulations neglecting evaporation. The plots present an overview of the individual species at 25 wt.-% methylated feed (left) and the recovery of oil species at different levels of methylation (right).

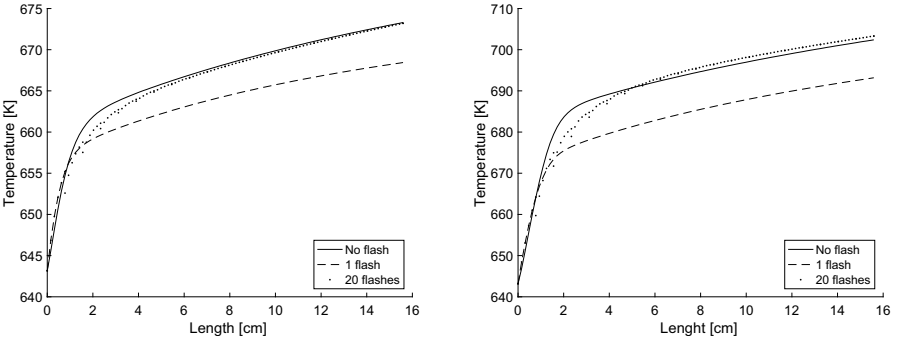

Figure 2 Liquid temperature profiles with or without flashes. The plots present the feed with 75 wt.-% (left) and 25 wt.-% methylated substrate (right).

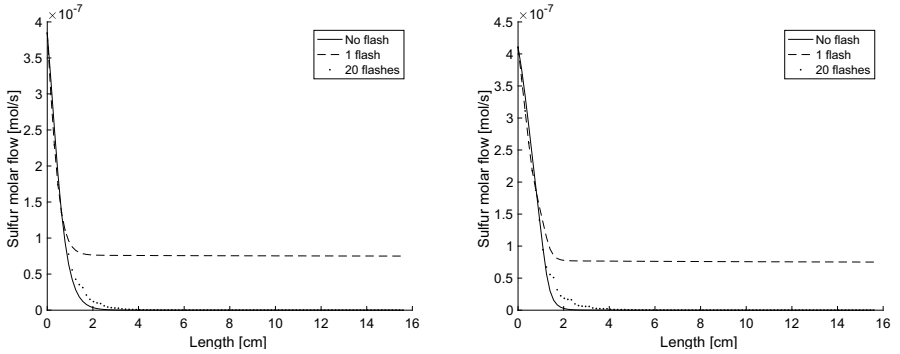

Figure 3 Molar flow profile of sulfur compounds with or without flashes. The plots present the feed with 75 wt.-% (left) and 25 wt.-% methylated substrate (right).

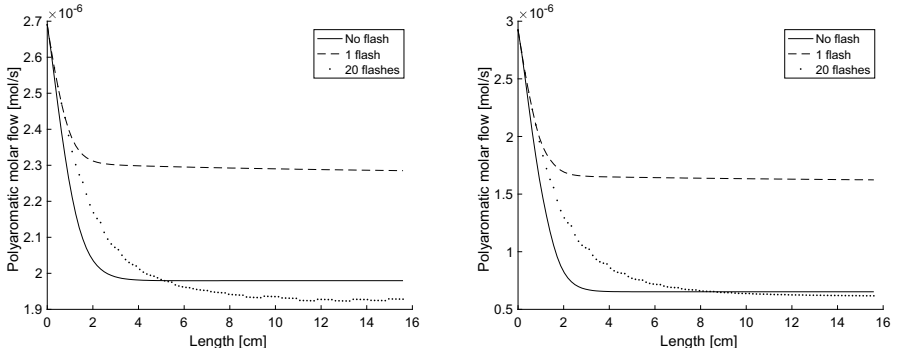

Figure 4 Molar flow profile of polyaromatic compounds with or without flashes. The plots present the feed with 75 wt.-% (left) and 25 wt.-% methylated substrate (right).

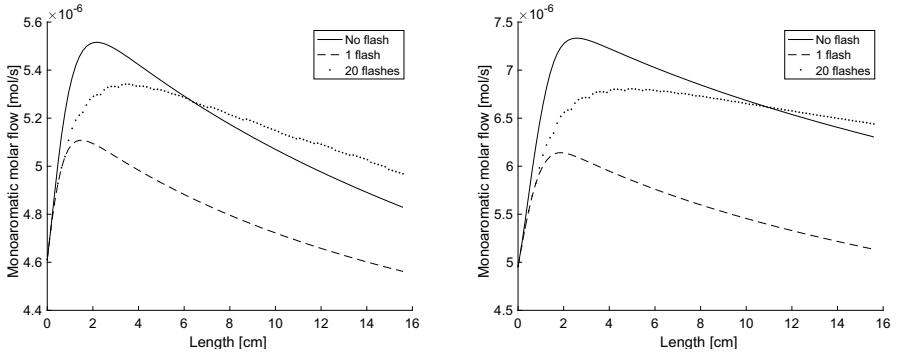

Figure 5 Molar flow profile of monoaromatics with or without flashes. The plots present the inlet with 75 wt.-% (left) and 25 wt.-% methylated inlet (right).

causing a lower substrate displacement in the case of lower reaction rates. The molar flow profiles for the monoaromatic compounds are given in Fig. 5. Generally, when including evaporation, the reaction rate and conversion is lower caused by the displacement of monoaromatics to the vapor. Comparing the different feeds, the high mass transfer case has a higher outlet flow corresponding to the higher conversion rate of the polyaromatics. Overall, it is seen that the inclusion of evaporation has a significant effect on the reaction

rate and conversion of the fuel, especially for the species which have slower reaction rates or are equilibrium limited. The presented approach therefore has value in showing the presence of these effect at the limits of mass transfer, even if it cannot predict the actual mass transfer rates of the oil species.

4. Conclusion

Using Pro/II to make flash calculations for the literature model, it was found that using the conditions given by De La Paz-Zavala et al. (2013) the equilibrium vapor recovery of fuel species is overall high. Implementing flashes over the length of the reactor, the mass transfer of fuel species was simulated, at either high or low mass transfer rates. It was found that the reaction rate of the fuel has a significant influence on the effect of the oil species mass transfer. At lower reaction rates, the high mass transfer simulation generally approximates the reactor profiles for temperature, sulfur and polyaromatic components assuming no evaporation. Monoaromatic component profiles differ significantly from this because of the high volatility of the defined monoaromatic species. For polyaromatic species at higher reaction and mass transfer rates, the conversion generally exceeds that of the simulations neglecting evaporation. The reason is likely that the evaporation of monoaromatics decreases product inhibition. In these same cases, the conversion of monoaromatics is lower because of substrate displacement.

Generally, it was found that the evaporation has little effect on fast reactions, like the sulfur reactions, and a significant effect on reactions that are limited by equilibrium, like the polyaromatic reactions. The range of reactor profiles assuming evaporation depends on the reaction rate with higher reaction rates resulting in a wider range of possible profiles. It was found that the approach could be useful in elucidating effects of evaporation on TBR models while it has little value in predicting experimental results.

Research on faulty antibody library of dynamic artificial immune system for fault diagnosis of chemical process

Yiyang Dai*, Yi Qiu, Ziyun Feng

[a]*College of Chemistry and Chemical Engineering, Southwest Petroleum University, Chengdu, China*
daiyiyang1984@163.com

Abstract

Fault diagnosis is one of the most important methods to ensure the safety of chemical process. With the development of artificial intelligences, many new methods have been introduced into the research of process fault diagnosis in chemical devices. Dynamic artificial immune system (DAIS) is one of the artificial intelligence methodologies with strong ability of self-learning and self-adaptability. However, in traditional AIS-based fault diagnosis strategies, key variables used in antibody cloning phase like total number of antibodies and mutation parameters are determined by experience. In this paper, we propose an approach for faulty antibody library construction in DAIS. Fault antibodies were classified into different types by different fault mechanism, and the size of antibody and mutation parameters of each faulty type were optimized individually. The performance of the modified DAIS-based fault diagnosis strategies is illustrated through the benchmarked Tennessee Eastman process.

Keywords: fault diagnosis, chemical process, artificial immune system, faulty antibody library,

1. Introduction

In recent years, the concept of “smart manufacturing” is gradually accepted by the public as the fourth industrial revolution is about to take place right now. For the chemical process industry, the goal of Smart Manufacturing should not only maximize economic competitiveness, but also significantly reduce safety incidents (Dai et al., 2016). Fault diagnosis is one of the effective methods to control and mitigate process risk. Venkatasubramanian et al. (2003) classified fault diagnosis methods into three general categories including quantitative model-based methods, qualitative model-based methods, and process history based (data-based) methods. With the development of automation technology, large amounts of data could be easily recorded and collected. Meanwhile, a significant progress has been made in the data-mining and processing area, which can provide new technologies for the utilization of process fault diagnosis in past decades (Ge et al., 2013).

Among the data-based techniques, the multivariate statistical process monitoring (PSPM) techniques are widely used in the last few years, such as principal component analysis (PCA), independent component analysis (ICA), support vector machines (SVM), partial least square (PLS), among others. Recently, artificial intelligent technologies are developed rapidly, a variety of new approaches have been recently proposed in addition to traditional statistical methods, such as deep belief network

(DBN), convolutional neural network (CNN), hidden Markov model (HMM), and artificial immune system (AIS), et al. To adapt to fault diagnosis of complex chemical process, dynamic artificial immune system (DAIS), was proposed (Dai & Zhao, 2011; Zhao et al., 2014). In DAIS-based fault diagnosis strategy, fault antibodies generated from the cloning of historical fault samples are used to diagnose the fault type. However, traditional antibody cloning algorithm mostly depends on experience, while the total number of antibodies and mutation parameters would affect the performance of fault diagnosis directly.

In this paper, we propose a modified approach for faulty antibody library construction, and apply it to fault diagnosis based on DAIS with modified antibodies (MA). The rest of the paper is organized as follows. A brief introduction of DIAS is reviewed in section 2. Section 3 introduces our proposed approach of faulty antibody library construction. The results and analysis of case study on Tennessee Eastman process are reported in Section 4. Finally, we conclude the paper and presents some future work in section 5.

2. Dynamic Artificial Immune System

AIS is developed through the application of techniques such as mathematical and computational modeling of immunology, abstraction from those models into algorithm (and system) design and implementation in the context of engineering (Timmis et al., 2008). To apply AIS in fault diagnosis of chemical processes, Dai and Zhao (2011) integrated the clonal selection algorithm of AIS with dynamic time warping (DTW) and afterwards used the DAIS in an online fault diagnosis strategy for full operating cycles of chemical processes (Zhao et al., 2014).

Different from traditional AIS technique, antigens and antibodies in DAIS are represented by matrices of time-sampled data to reflect the dynamic trends of process. While antigens are created by real-time samples and antibodies are created by historical samples with mutation during cloning phase. The system diagnoses faults by calculating and analyzing the affinity between antigens and antibodies. Eq.(1) and Eq.(2) show the composition of antigen and antibody.

$$Ag^{l\times n} = [Ag(1), Ag(2), ..., Ag(k), ..., Ag(l)] \tag{1}$$

$Ag(k)$ represents the variable vector of selected s at the (l-k)th sampling time before now. n is the number of selected variables and l is the length of the antigen.

$$Ab_{fault}^{m\times n} = [Ab_{fault}(1), Ab_{fault}(2), ..., Ab_{fault}(k), ..., Ab_{fault}(m)] \tag{2}$$

$Ab_{fault}(k)$ represents the vector of selected variables at the kth sampling time after the fault encountered. n is the number of selected variables and m is the length of the antibody.

The main steps of DAIS-based fault diagnosis stagey can be described as below.

1) Initialization. Generate original antibodies from historical samples. Then clone these antibodies with mutation to construct antibody library. Also, threshold of each fault type is calculated in this step.
2) Fault detection. Generate antigen from the test data and calculate the difference between the antigen and each antibody in the normal antibody library. If all of the differences are greater than the normal threshold, then a fault is detected.

3) Fault diagnosis. After detecting a fault, the differences between the antigen and each antibody in faulty antibody library of each type are calculated. If there exist fault antibodies in only one of the faulty antibody libraries that have smaller difference degrees than the threshold of the faulty antibody library, the fault is recognized of the fault type of the corresponding faulty antibody library.
4) Self-learning. After the fault diagnosis of DAIS, a manual diagnosis should be conducted to double check the diagnosis results by DAIS. According to the manual diagnosis result, a new original fault antibody is then generated and stored into the faulty antibody library of the fault type of the manual diagnosis result.

To improve the performance of DAIS in fault diagnosis, lots of work have been down. Causal inference method (Shu & Zhao, 2015) and genetic algorithm based fault antibody feature selection optimization (FAFSO) algorithm (Liang & Zhao, 2017) were proposed for the selection of variables to generate antibodies and antigens. To overcome limitation of the scarcity of fault samples in DAIS-based fault diagnosis, vaccine transplant approach has been proposed (Shu & Zhao, 2016). In the next section, the issue of faulty antibody libraries construction will be discussed.

3. Faulty Antibody Libraries

In DAIS-based fault diagnosis strategy, original antibodies are generated by historical samples with normalization at first. After the original antibodies generated, mutation is employed to create new antibodies during the clone phase.

Let X_1 and X_2 represent the two randomly selected original antibodies and C represents a normal historical sample. Calculate the difference matrix φ_1 between X_1 and C and φ_2 between X_2 and C separately. A new difference matrix φ^* can be obtained with mutation of $\varphi 1$ and $\varphi 2$. Than randomly select a matrix X_N of the same length with X_1 from C, a new cloning antibody X^* is generated based on shown in Eq.(3):

$$X^* = X_N + \varphi^* = X_N + a\varphi_1 + b\left(\varphi_1 - \varphi_2\right) \tag{3}$$

where a is a random number between 0.5 and 2, b is a random number between -1 and 1.

However, in traditional mutation algorithm, the total number of antibodies and the mutation parameters like a and b are all determined by reference. A modified approach for faulty antibody library construction is proposed in this section. For each type of faults, the fault diagnosis rate (FDR) and false positive rate (FPR) defined as below are used for antibody construction. p_i is the count of type i samples that are classified to type i, $q_{i,j}$ is the count of type i samples that are classified to type j.

$$\mathrm{FDR}(i) = \frac{p_i}{\text{total count of type } i \text{ samples}} \tag{4}$$

$$\mathrm{FPR}(i,j) = \frac{q_{i,j}}{\text{total count of type j samples}} \tag{5}$$

The main steps of DAIS-based fault diagnosis stagey can be described as below.

The main steps of the modified approach can be described as below.

Step1: For each fault type, randomly divide original antibodies into two groups. The bigger group contains about three quarters of the original antibodies, and the smaller one contains other one quarter of them. And we name the antibodies in the bigger group as initial antibodies, and which in the smaller group as revision antibodies.

Step 2: Then set the range of parameters a as [0.5,2], b as [-1, 1]. And the total number of initial cloning antibodies is twice that of the original antibodies. Create cloning antibodies using initial antibodies with mutation using Eq.(3).

Step 3: For each fault type, use revision antibodies of every fault type to test the cloning antibodies. Let ε represents criteria. For fault type i, if there was a type j let FPR(i,j)>ε, remove the antibodies, whose distance with antigen type j is smaller than threshold, from fault i antibody library. If FDR(i)<1-ε, change the range of parameters a, b to twice of which in last step.

Step 4: Check all fault type, if there was any fault type i let FPR(i,j)>ε or FDR(i)<1-ε, repeat step 2 and 3 to revise fault i antibody library.

Compared with traditional procedure, original antibodies are divided into two groups. Revision antibodies can be used to optimize the cloning parameters a and b, while FPR and FDR are used as optimization basis. Also the total number will not be confirmed, until cloning procedure is finished. All the optimizations are set to improve the performance of the diagnosis result.

4. Case Study

4.1. Process description

The TE process is the benchmark of fault detection and diagnosis. A revised model was proposed (Bathelt et al., 2015) which exploded more variables and more types of faults (available at http://depts.washington.edu/control/LARRY/TE/download.html.). In this paper, the process data are simulated by this revised model (Fig. 1).

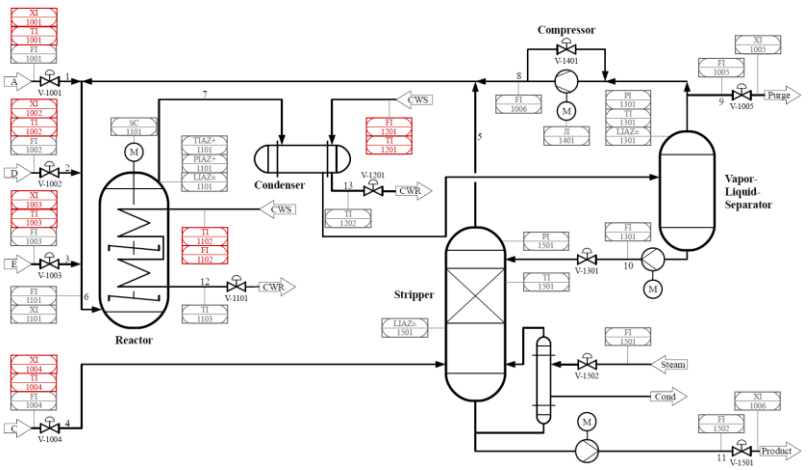

Fig. 1 P&ID of the revised TE process model;

The revised TE process model consists of 53 measured variables, including 22 process measurements, 19 composition measurements and 12 manipulated variables. For our case study, all variables are sampled at every 3 min and included in analysis. Only faults of step type, as faults 1-7 (see Table 1), are considered in this case study. Each type of fault is simulated for 12 times with different initial states, and the simulation time is set to 24 hours. The training dataset of each faulty antibody library consists of 4800 samples of that fault. The validation dataset has 480 samples of every fault. The training process is tended to construct the faulty antibody library based on AIS algorithm using the training dataset that has the best diagnostic performance on the validation dataset.

Table 1 Faults 1-7 defined in the TE process (Downs & Vogel, 1993).

Fault ID	Description	Type
IDV1	A/C Feed ratio, B Composition constant (stream 4)	Step
IDV2	B Composition, A/C Ratio constant (stream 4)	Step
IDV3	D Feed temperature (stream 2)	Step
IDV4	Reactor cooling water inlet temperature	Step
IDV5	Condenser cooling water inlet temperature	Step
IDV6	A Feed loss (stream 1)	Step
IDV7	C Header pressure loss – reduced availability (Stream 4)	Step

4.2. Diagnosis results

The FAFSO algorithm proposed by Liang and Zhao (2017) is used to select the fault antibodies' variables and optimize the faulty antibody libraries' thresholds. Then, antibody libraries are constructed with training dataset using proposed approach in section 3. While, 4000 samples are selected as initial data and 800 as revision data. After that, antigens are generated by validation dataset, and the differences between antigens and antibodies are calculated for fault diagnosis.

The fault diagnosis results of faults 1-7 are shown in Table 2 and the average testing FDR is 98.6%. Compared with fault diagnosis model in literatures (see Table 2), the performance of our proposed methods is improved significantly.

Table 2 Diagnosis performance comparison of different methods. (a) optimized variable selection based PCA (Ghosh et al., 2014); (b) supervised local neural network (Rad & Yazdanpanah, 2015); (c) Bayesian method (Jiang & Huang, 2016); (d) DBN based model (Zhang & Zhao, 2017); (e) AIS-FAFSO (Liang & Zhao, 2017); (f) DAIS-MA (proposed in this paper).

FDR/%	(a)	(b)	(c)	(d)	(e)	(f)
IDV1	99.87	96.37	100	100	100	100
IDV2	97.87	97.62	99	99	100	100
IDV3	2.37	20.62	6	95	93.7	94.3

IDV7	100	100	100	100	100	100
Average	85.64	84.76	86.42	96.9	97.7	98.6

5. Conclusions

With the development of artificial intelligences and automation of chemical plant, many new data-based methods draw much attention from the chemical process fault diagnosis research. have been introduced into the research of process fault diagnosis in chemical

devices. Dynamic artificial immune system (DAIS) is one of the new artificial intelligence methodologies with strong ability of self-learning and self-adaptability. However, the construction of faulty antibody library is rarely studied. In this paper, an approach of faulty antibody libraries construction in DAIS is proposed. According to different performance of process data and fault mechanism, fault antibodies were classified into different types, and the size of antibody and mutation parameters of each faulty type were optimized individually. A case study on TE process is performed to show the improvement of DAIS when our faulty antibody construction approach is used.

Abstract

We recently developed (Curitiba Marcellos et al., 2017) a model predictive control (MPC) design for batch enantiomer crystallization that determines an optimal temperature profile in a crystallizer during crystallization of a single desired enantiomer from a solution of two enantiomers of a racemic compound forming system in solvent. This article analyzes that MPC design to highlight important features and assumptions of the constraints to generalize the underlying principles of their design.

Keywords: Racemic compound forming systems, Crystallization, Predictive Control.

1. Introduction

Crystallization can be used to separate enantiomers classified as racemic compound forming systems in the range of conditions (e.g., temperature and composition (Jacques et al., 1981; Kaspereit, 2006)) within which a single pure enantiomer can exist in equilibrium with a liquid solution containing both enantiomers and solvent according to solution thermodynamics. Our prior work (Curitiba Marcellos et al., 2017) utilized a mandelic acid (MA) in water example to motivate an operation and control (with MPC) strategy for a batch crystallizer for a racemic compound forming system that utilized a ternary diagram for the control formulation development. The motivation for this individual analysis of racemic compound forming systems in the framework of MPC for crystallization is that their specific thermodynamic properties impact MPC design for such systems. Because this work therefore had a strong focus on the underlying thermodynamics of a system for the MPC model and constraint design, there are underlying themes in the MPC development that should be interpreted as having broad implications for batch crystallization of systems with various thermodynamic properties, which this work seeks to analyze.

2. Mandelic acid in water example: ternary diagrams and MPC

We begin by revisiting the example from Curitiba Marcellos et al. (2017), which considers an MA in water system. Fig. 1 denotes the range of compositions of the desired and undesired enantiomers (denoted by *R* and *S*, respectively) which correspond to a saturated liquid in equilibrium with crystals of pure *R*. The triangles **BER**, **B₁E₁R**, and **B₂E₂R** represent the range of initial liquid compositions at temperatures T_0, T_1, and T_2, respectively, from which pure *R* crystals and a saturated liquid solution would be obtained if thermodynamic equilibrium were attained. This data indicates that a mixture with initial composition **P** can be cooled until it reaches the boundary of the two-phase region at a lower temperature (which would be **E₂** in the figure). After that temperature is reached, further cooling will produce a racemic compound (which is a solid containing both the *R* and *S* enantiomers), which we consider is undesirable.

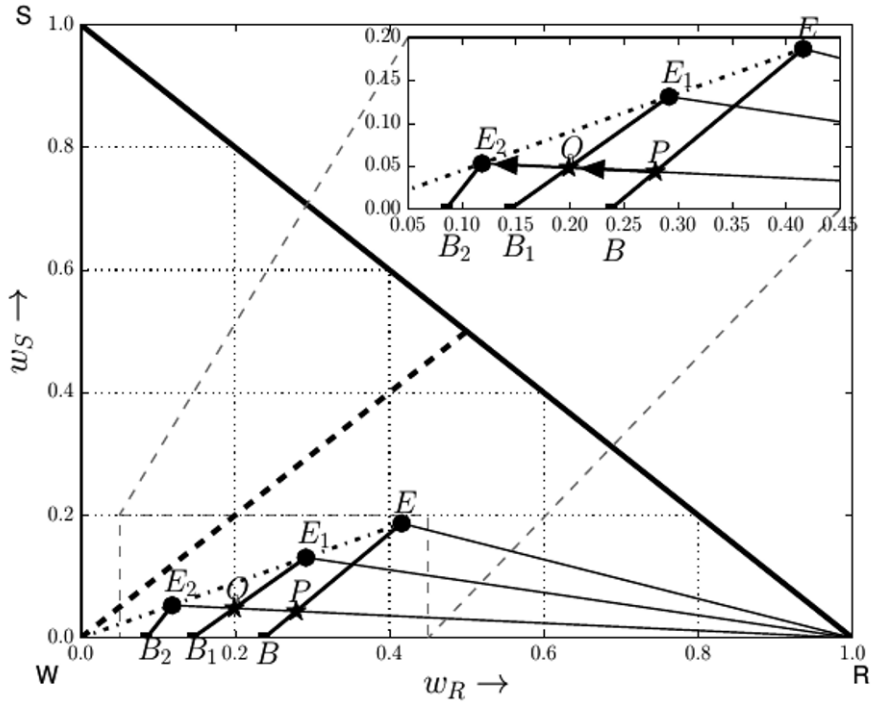

Figure 1: Right triangle ternary diagram for MA in water.

The batch crystallization process is modeled as a closed system containing two tanks (a well-mixed crystallizer and a well-mixed fines dissolution tank) between which the suspension in the crystallizer flows. The fines dissolution tank dissolves all crystals that enter it. A filter selective to smaller crystals is placed between the crystallizer output and the fines dissolution tank to prevent large crystals from entering the fines dissolution tank and dissolving. The motivation for including this fines dissolution loop is that it is desired to produce a greater mass of crystals from seeds than nuclei.

The population balance for the crystals, where the particle size distribution (PSD) $n = n(t, l)$ represents the number of crystals in the crystallizer of characteristic size l at time t per mass of solvent in the crystallizer (m_W), is as follows:

$$\frac{\partial n}{\partial t} = -\frac{\partial (Gn)}{\partial l} + B_0 \delta(l - l_0) - n\frac{d}{dt}\ln m_W + \left(\frac{1}{m_W}\right)\left(n_{in}\dot{m}_{W,in} - n_{out}\dot{m}_{W,out}\right) \quad (1)$$

where G is the crystal growth rate, B_0 is the nucleation rate (where nucleation occurs only at the crystal size $l_0 = 0$ m as enforced in Eq.(1) through the Dirac delta function), and n_{in}, n_{out}, $\dot{m}_{W,in}$, and $\dot{m}_{W,out}$ represent the population balances in the streams flowing into the crystallizer (from the fines dissolution tank) and out of the crystallizer (to the fines dissolution tank), as well as the mass flow rates of solvent into and out of the crystallizer, respectively. This equation is derived from a volume-integrated population balance equation for a well-mixed system (Randolph and Larson, 1988), in which the PSD was developed in terms of volume rather than solvent mass. An appropriate substitution for the volume-based PSD term (and related terms for the nucleation rate and also of the PSD's and flow rates into and out of the crystallizer) by terms based on solvent mass and required variables such as m_W and volume, and applying the chain rule and canceling terms, gives Eq.(1). In addition to the population balance equation, the mass balance on *R* in the crystallizer and fines dissolution tank and the temperature in the crystallizer were also modeled.

The resulting dynamic model was then incorporated within an MPC with the form:

$$\underset{\Delta T_{jkt,k}}{\text{minimize}} \quad J\left(T_{jkt,k}\right) := \frac{\mu_3^n(t_f)}{\mu_3^s(t_f)} \quad (2a)$$

$$\text{Process Model} \quad (2b)$$

$$\Delta T_{jkt,k} \leq 0, k = k_{it}, \ldots, k_{N_t - 1} \quad (2c)$$

$$T_{min} \leq T\left(t_f\right) \leq T_{max} \quad (2d)$$

$$\frac{P^i - P^e}{P^i(1 - P^e)} = 0.4435 \quad (2e)$$

where $T_{jkt,k}$ is the value of the cooling jacket temperature (manipulated input for the crystallizer) at the k-th sampling period, $\mu_3^i(t_f)$, $i = n, v$, represents the third moment (tied to crystal mass) of the PSD at the final batch time t_f for crystals derived from nuclei ($i = n$) or seeds ($i = s$), and $k_{it}, \ldots, k_{N_t - 1}$ represent the indices of the sampling periods in the prediction horizon. The values T_{min} and T_{max} represent the bounds on the temperature T at t_f, and the terms P^i and P^e represent the purities of the liquid in the crystallizer at the initial and eutectic compositions (where the purity is a ratio of the mass fraction of the *R* enantiomer to the sum of the mass fractions of the *R* and *S* enantiomers).

3. Analyzing MPC formulation for MA in water

We now seek to elucidate some of the implications of Eq.(2) for MPC for crystallization for other multicomponent systems, crystallizer designs, and operating objectives. First,

the formulation of the objective function of Eq.(2) reflects a desire to minimize, for the MA in water process, the ratio of the mass of crystals from nuclei to the mass from seeds. The constraint of Eq.(2b) is the model for the system (PSD and mass/energy balances), and the constraint of Eq.(2e) was derived as the maximum yield thermodynamically achievable for a batch crystallization process for MA in water with no fines dissolution loop. This constraint was utilized for simulations without and with the fines dissolution loop in Curitiba Marcellos et al. (2017) for consistency; however, the derivation of this equation in reference to yield is for the case with no fines trap. For the case with no fines trap, a thermodynamic analysis allowed the constraint of Eq.(2e) to be selected in combination with the objective function and Eq.(2b). Without a thermodynamic analysis, Eq.(2e) might be chosen as the objective function of the MPC to be maximized. However, for the MA in water process, there are multiple desired properties for the crystal product besides yield alone, such as the greater mass and number of crystals from seeds compared to nuclei. One method for attempting to account for all these considerations is by developing an objective function containing the various terms and weighting each of them. Another method, and that which is utilized in Eq.(2) for the case with no fines trap, is to examine the desired properties and to recognize that some of the desired properties are thermodynamically limited, meaning that they can be written as a constraint. In addition, changing the process design may help to improve some of the properties (which was the motivation in Curitiba Marcellos et al. (2017) for simulating the MA in water process with the fines dissolution loop after analyzing the number of crystals obtained from nuclei without it). Therefore, care should be taken in formulating an objective function when there are multiple desired operating goals to ensure that a consideration that can be accounted for in a constraint or in the process design is not being incorporated into the objective function. Furthermore, changes to the design may affect the meaning of constraints (e.g., the process design for which the constraint of Eq.(2e) was derived to represent the yield was changed to explore the benefits of a fines dissolution tank), and therefore care should be taken in ensuring that all constraints enforced in a batch crystallization process meaningfully apply to the design at hand and/or will not cause the crystallization process to proceed beyond the point at which crystals of a single desired species are formed.

Another principle exemplified by the development of Eq.(2) is that a visual representation of thermodynamics data such as ternary diagrams may help in developing thermodynamically-based equations for the process model. For example, in Eq.(2), the population balance model includes the saturation composition as a function of temperature within the growth and nucleation rate models that appear in Eq.(1). The saturation composition was modeled through a procedure that took advantage of work in Kaspereit (2006) involving the analysis of thermodynamic data available in an equilateral triangle ternary diagram for MA in water indicating that for various temperatures, the solubility curve can be approximated by a line between the eutectic and binary saturation compositions.

Visual displays of thermodynamic data like the ternary diagram can also be helpful for selecting thermodynamic constraints. For example, the ternary diagram makes the eutectic composition restriction visually apparent. However, because this is an equilibrium composition, if a constraint required that the solution in the crystallizer always be above that composition, it is possible that the solution would become cooled too much, depending on the rate of cooling computed by the MPC and the speed with which thermodynamic equilibrium is set up. The ternary diagram reveals that temperature

is another variable that is associated with the equilibrium condition and may be more effectively constrained. In general, care should be taken when working with thermodynamic data in defining MPC constraints, because thermodynamic equilibrium is a limiting condition and setting constraints that depend on any mass transfer-limited properties such as composition may not be appropriate.

Though the constraints in Eq.(2) allow control actions to be computed that drive the state to the limits of pure *R* crystallization in the yield and temperature constraints, MPC design for crystallization processes should consider that disturbances and plant-model mismatch are likely to occur, and even if control actions computed by the MPC cause thermodynamic constraints to be satisfied within the controller, they may not be satisfied by the actual process. Furthermore, the design in Eq.(2) considers that the final time of batch operation is included within the prediction horizon. Depending on the final batch time, this may be computationally prohibitive. However, the yield constraint as defined relies on this because the objective function and constraints both include the final time. For example, for the case with no fines dissolution loop, Eq.(2e) requires the process to produce the optimal yield by the end of the batch. If it is desired not to include the entire prediction horizon due to computation time reasons, one solution may be to adjust the objective function to allow it to also include the yield. However, a short prediction horizon may not allow the MPC to achieve as optimal of a cooling profile as including the entire batch time within the prediction horizon.

For any industrial crystallization process under MPC, all effects on the population balance that are significant should be accounted for (for example, Zhang et al. (2010) indicates that cooling rate may affect the crystallization growth rate) because unlike alternative operating policies such as a linear cooling profile in the crystallizer, it is difficult to know, a priori, what cooling profile an MPC will compute for a batch operation, even in the absence of disturbances, without performing closed-loop simulations. When disturbances occur, it may compute a different input trajectory than would be simulated without the disturbances. Therefore, it is not possible with MPC to assume that factors which may affect the crystallization process will be negligible, and they must be accounted for in the model.

The design in Eq.(2) considers that a feasible solution to the optimization problem exists. Due to the hard constraint on yield, a feasible solution is not guaranteed to exist within the batch time t_f chosen. Because this is a thermodynamic constraint, given a sufficiently large final batch time and no disturbances, it should be able to be met. However, in the presence of disturbances/plant-model mismatch, it is possible that the constraint may become infeasible due to t_f not being large enough or disturbances perturbing the equilibrium state.

The design in Eq.(2) does not operate a process at a steady-state in a traditional sense because a batch, rather than continuous, process is considered. Thus, stabilizing control designs like classical proportional-integral-derivative (PID) control or Lyapunov-based control would not apply, and optimization-based control will be an effective means for controlling the process. The MPC considered also does not enforce stabilization in a region around a steady-state (though stabilizing designs comprise a large portion of the MPC literature). However, if a thermodynamic equilibrium-based constraint, like that of Eq.(2e) for the case with no fines dissolution loop, is included, then at the end of the batch, the MPC may seek to stabilize the temperature in the crystallizer at the value corresponding to the equilibrium condition. Still, classical control designs that treat the

thermodynamic condition at the end of the batch as a steady-state and seek to drive the state to this condition are unable to ensure that critical thermodynamic constraints are respected or to optimize product characteristics during the crystallization process. Developing an MPC design for a continuous crystallization process (Kaspereit, 2006) would be fundamentally different than developing an MPC for a batch process.

Finally, the sampling period may be important. Increasing the sampling period length (reducing the number of sampling periods) can improve computation time, which may be beneficial, especially in the case in which the final time of the batch is important in developing a constraint as in Eq.(2e). However, to see the impact of reducing the number of sampling periods in the prediction horizon, consider a single sampling period in Eq.(2) in the case with no fines dissolution tank. In that case, to cause the constraint of Eq.(2e) to be satisfied at the end of the batch, the jacket temperature would need to drop to that at which the temperature in the crystallizer becomes fixed at the temperature corresponding to the eutectic purity for the given initial purity. This mode of operation then effectively drives the input to a steady-state value corresponding to the thermodynamic equilibrium condition at the end of the batch. It does not allow the trajectory along the way to this equilibrium condition to be optimized. If more sampling periods are utilized, the MPC has more flexibility to optimize the approach to thermodynamic equilibrium.

4. Conclusions

This article analyzed methods for MPC design for crystallization processes that take operating objectives as well as thermodynamic limitations into account.

Abstract

In this paper, two different model predictive control (MPC) methodologies that can account for process operational safety are compared. Specifically, we first develop the Safeness Index, which represents the relative safeness of the process state in state-space, and is used to form a state constraint in MPC to guarantee process safety. Then, a Control Lyapunov-Barrier Function-based economic model predictive controller (CLBF-EMPC) is developed to account for the unsafe region in the design of the Control Lyapunov-Barrier Function (CLBF), and thus ensures closed-loop stability and safety simultaneously.

Keywords: Process operational safety; Model predictive control; Safeness Index; Control Lyapunov-Barrier Functions

1. Introduction

Process operational safety plays an important role in operating chemical processes in an economically-optimal manner. Recently, the U.S. Chemical Safety Board released a report of over 20 chemical incidents occurring in the United States since 2013 that caused severe consequences (Completed Investigations of Chemical Incidents, 2016). The catastrophic consequences remind us of the significance of process operational safety, especially in the design of process control systems. In particular, recent work (Leveson and Stephanopoulos, 2014) has described process safety as a problem with respect to multi-variable interactions of process variables instead of individual variables violating bounds. Motivated by the above considerations, the Safeness Index (Albalawi et al., 2017) was first constructed using first-principles modeling information and past operating data, which can coordinate the control system design with process safety. A control system associated with a constraint on the Safeness Index can enhance the process safety and guarantee closed-loop stability. On the other hand, an intriguing control method accounting for both stability and safety termed Control Lyapunov-Barrier Function-based control has been developed (Romdlony and Jayawardhana,

2016). Since unsafe state-space regions could be open and bounded sets in the operating region, it is promising to incorporate CLBFs, which inherit nice properties of Control Lyapunov Functions and Control Barrier Functions, respectively, into MPC design to guarantee closed-loop stability and safety simultaneously. In the present work, we describe similarities and differences between these two approaches in the context of economic MPC and demonstrate their application to a chemical process example.

2. Preliminaries

2.1. Notations

The notation $|\cdot|$ is used to signify the Euclidean norm of a vector, the notation $|\cdot|_Q$ denotes a weighted Euclidean norm of a vector (i.e., $|x|_Q = x^T Q x$ where Q is a positive definite matrix). x^T denotes the transpose of x. The notation $L_f V(x)$ denotes the standard Lie derivative. Set subtraction is denoted by "\", i.e., $A \setminus B := \{x \in \mathbf{R}^n \mid x \in A, x \notin B\}$. The function $f(\cdot)$ is of class $\mathcal{C}^1$ if it is continuously differentiable.

2.2. Class of Nonlinear Process Systems

The class of continuous-time nonlinear systems considered is described by the following state-space form:

$$\dot{x} = f(x) + g(x)u + h(x)w, x(t_0) = x_0 \tag{1}$$

where $x \in \mathbf{R}^n$ is the state vector, $u \in \mathbf{R}^m$ is the manipulated input vector, and $w \in \mathbf{W}$ is the disturbance vector, where $\mathbf{W} := \{w \in \mathbf{R}^q \mid |w| \le \theta, \theta \ge 0\}$. The control action constraint is defined by $u \in U := \{u^{\min} \le u \le u^{\max}\} \subset \mathbf{R}^m$. $f(\cdot), g(\cdot), h(\cdot)$ are sufficiently smooth vector and matrix functions of dimension $n \times 1$, $n \times m$, and $n \times q$, respectively. Without loss of generality, the initial time t_0 is taken to be zero ($t_0 = 0$), and it is assumed that $f(0) = 0$ and $g(0) = 0$, and thus, the origin is a steady-state of the nominal system of Eq.(1) with $w(t) \equiv 0$, (i.e., $(x_s^*, u_s^*) = (0,0)$).

3. Safeness Index-Based Control

In this section, we first present the Lyapunov-based controller assumption. Then, the process Safeness Index is introduced into the formulation of Lyapunov-based economic model predictive control (LEMPC), under which the closed-loop system can always be driven into the safe operating region.

3.1. Lyapunov-based Controller Assumption

Consider the nominal system of Eq.(1) with $w(t) \equiv 0$. We assume that there exists a feedback control law $\Phi(x)$ for the nominal closed-loop system (i.e., $w(t) \equiv 0$) of Eq.(1) that renders the origin of the nominal system asymptotically stable for all x in an open neighborhood of the origin, when applied continuously, in the sense that there exists a positive definite $\mathcal{C}^1$ control Lyapunov function V and class $\mathcal{K}$ functions $\alpha_i(\cdot), i = 1,2,3,4$ that satisfy the following inequalities:

$$\begin{aligned}
&\alpha_1(|x|) \le V(x) \le \alpha_2(|x|) \\
&\frac{\partial V(x)}{\partial x}(f(x) + g(x)\Phi(x)) \le -\alpha_3(|x|), \Phi(x) \in U \\
&\left|\frac{\partial V(x)}{\partial x}\right| \le \alpha_4(|x|)
\end{aligned} \tag{2}$$

The set of initial conditions under the feedback control law, from which the origin of the nominal system of Eq.(1) can be rendered asymptotically stable, is characterized as the set $\phi_s := \{x \in \mathbf{R}^n \mid \dot{V} + \kappa V(x) \le 0, u = \Phi(x) \in U, \kappa > 0\}$. The stability region is defined as a level set of the Lyapunov function (i.e., $\Omega_\rho := \{x \in \phi_s \mid V(x) \le \rho\}$).

3.2. Safeness Index-Based LEMPC Formulation

Since the process operational safety of a chemical plant results from multivariable interactions and interactions between units, it is desirable to integrate the process control system and process safety by designing a function of the process states (i.e., Safeness Index) that indicates the level of safety of a given state. The methods of determining the functional form of $S(x)$ include first-principles process models or systematic safety analysis tools such as HAZOP.

Based on the functional form of $S(x)$, the closed-loop state predictions can be required to be maintained within a safe region (where $S(x)$ is below the threshold on the Safeness Index S_{TH}) by using the index within the process control design. The safety systems can be triggered whenever the threshold S_{TH} is sufficiently exceeded, which represents the overall system state becoming unsafe.

A straightforward method for incorporating the Safeness Index into the process control system is to set it as a constraint in model predictive control. Therefore, the Safeness Index-Based LEMPC is formulated as follows:

$$\max_{u \in S(\Delta)} \int_{t_k}^{t_{k+N}} L_e(\tilde{x}(\tau), u(\tau)) d\tau \tag{3a}$$

$$\text{s.t. } \dot{\tilde{x}}(t) = f(\tilde{x}(t)) + g(\tilde{x}(t))u(t) \tag{3b}$$

$$\tilde{x}(t_k) = x(t_k) \tag{3c}$$

$$u(t) \in U, \forall t \in [t_k, t_{k+N}) \tag{3d}$$

$$V(\tilde{x}(t)) \le \rho_e, \forall t \in [t_k, t_{k+N}), \text{ if } x(t_k) \in \Omega_{\rho_e} \tag{3e}$$

$$S(\tilde{x}(t)) \le S_{TH}, \forall t \in [t_k, t_{k+N}) \text{ if } S(x(t_k)) \le S_{TH} \tag{3f}$$

$$\dot{V}(x(t_k), u(t_k)) \le \dot{V}(x(t_k), \Phi(x(t_k))), \text{ if } x(t_k) \in \Omega_\rho / \Omega_{\rho_e}, \text{ or } S(x(t_k)) > S_{TH} \tag{3g}$$

where $\tilde{x}(t)$ is the predicted state trajectory, $S(\Delta)$ is the set of piecewise constant functions with period Δ, and N is the number of sampling periods in the prediction horizon. The optimization problem of Eq.(3) optimizes the cost function $L_e(x(t), u(t))$ of Eq.(3a) subject to the nominal process model of Eq.(3b). Eq.(3c) defines the initial condition for the optimization problem of Eq.(3) using the measurement of the process state at the current time t_k. Eq.(3d) defines the input constraints applied during the prediction horizon. Under the Mode 1 constraint of Eq.(3e), the LEMPC optimizes the time integral of $L_e(x(t), u(t))$ in a time-varying fashion while maintaining the predicted closed-loop state within the set $\Omega_{\rho_e} := \{x \in \phi_s \mid V(x) \le \rho_e, \rho_e < \rho\}$ defined to make Ω_ρ a forward invariant set. The constraint of Eq.(3f) maintains the closed-loop state within the safe operating region if the current state is inside it. Under the Mode 2 constraint of Eq.(3g), the contractive constraint is activated only in the first sampling period to decrease the value of the Lyapunov function. The LEMPC is implemented in a sample-and-hold fashion, and only the first step of the optimized input trajectory will be applied over the next sampling period. It should be noted that the optimization problem of Eq.(3) may not be feasible sometimes due to the constraint of Eq.(3f). In this case, the explicit stabilizing controller $\Phi(x)$ will be applied in sample-and-hold over the next sampling period to guarantee closed-loop stability.

The theorem below states that under sample-and-hold implementation of the Safeness Index-Based LEMPC of Eq.(3), closed-loop stability is maintained in the sense that the state of the closed-loop system of Eq.(1) is always bounded in Ω_ρ, and process operational safety is enhanced in the sense that the state will enter the safe region in finite time if it exits this region. The proof is presented in Albalawi et al., 2017.

Theorem 1 *Consider the closed-loop nominal system of Eq.(1) with* $w(t) \equiv 0$ *under the implementation strategy of the Safeness Index-based LEMPC of Eq.(3). Given any initial state* $x_0 \in \Omega_\rho$, *it is guaranteed that* $x(t) \in \Omega_\rho, \forall t \geq 0$, *and* $x(t)$ *will enter the safe region in finite time.*

4. CLBF-Based EMPC

In this section, we first introduce the definition of the constrained Control Lyapunov-Barrier Function (CLBF), and then develop the CLBF-EMPC to attain guaranteed closed-loop stability and process operational safety.

4.1. Definition of constrained CLBF

Based on the original Control Lyapunov-Barrier Function (Romdlony and Jayawardhana, 2016) that was developed for the nominal system of Eq.(1) with $w(t) \equiv 0$, in this manuscript, we propose a constrained CLBF that accounts for the presence of input constraints in the system of Eq.(1). Specifically, the definition of a constrained CLBF is as follows:

Definition 1 *Given a set of unsafe points in state-space* $\mathcal{D}$, *a proper, lower-bounded and* $\mathcal{C}^1$ *function* $W_c(x): \mathbf{R}^n \to \mathbf{R}$ *is a constrained CLBF if it satisfies the following properties:*

$$W_c(x) > \rho_c, \quad \forall x \in \mathcal{D} \subset \phi_{uc} \tag{4a}$$

$$\left|\frac{\partial W_c(x)}{\partial x}\right| \leq r(|x|) \tag{4b}$$

$$L_f W_c(x) < 0, \forall x \in \{x \in \phi_{uc} \setminus (\mathcal{D} \cup \{0\}) \mid L_g W_c(x) = 0\} \tag{4c}$$

$$\mathcal{U}_{\rho_c} := \{x \in \phi_{uc} \mid W_c(x) \leq \rho_c\} \neq \varnothing \tag{4d}$$

where $\rho_c \in \mathbf{R}$ and $r(\cdot)$ is a class $\mathcal{K}$ function. Similar to Safeness Index-based control, we also assume that there exists a stabilizing control law $u = \Phi(x) \in U$ (e.g., the control law in Lin and Sontag, 1991) such that the origin of the nominal system of Eq.(1) can be rendered asymptotically stable. ϕ_{uc} is defined to be the union of the origin and the set where the time-derivative of $W_c(x)$ is negative with constrained input:

$$\phi_{uc} = \{x \in \mathbf{R}^n \mid \dot{W}_c(x(t), u(t)) = L_f W_c + L_g W_c u < -\alpha |W_c(x)|, u = \Phi(x) \in U\} \cup \{0\}$$

where α is a positive real number. The set of initial conditions is characterized as a level set $\mathcal{U}_{\rho_c}$ of $W_c(x)$ in Eq.(4d), from which it can be proved that the origin of the nominal system of Eq.(1) with $w(t) \equiv 0$ can be rendered asymptotically stable while maintaining the state in a safe region at all times.

4.2. CLBF-based EMPC formulation

The CLBF-EMPC design is represented by the following optimization problem:

$$\max_{u \in S(\Delta)} \int_{t_k}^{t_{k+N}} L_e(\tilde{x}(\tau), u(\tau)) d\tau \tag{5a}$$

$$\text{s.t. } \dot{\tilde{x}}(t) = f(\tilde{x}(t)) + g(\tilde{x}(t))u(t) \tag{5b}$$

$$\tilde{x}(t_k) = x(t_k) \tag{5c}$$

$$u(t) \in U, \forall t \in [t_k, t_{k+N}) \tag{5d}$$

$$W_c(\tilde{x}) \le \rho_e, \text{ if } x(t_k) \in \mathcal{U}_{\rho_e},\ \forall t \in [t_k, t_{k+N}) \tag{5e}$$
$$\dot{W}_c(x(t_k), u(t_k)) \le \dot{W}_c(x(t_k), \Phi(x(t_k))), \text{ if } x(t_k) \in \mathcal{U}_\rho \setminus \mathcal{U}_{\rho_e} \tag{5f}$$

where the notation and constraints of Eqs.(5a)-(5d) follow the notation and constraints of Eqs.(3a)-(3d), and $\mathcal{U}_\rho$ is a safe region which has no intersection with the unsafe region $\mathcal{D}$. Similarly, if the state at $t = t_k$ is inside $\mathcal{U}_{\rho_e}$, the Mode 1 constraint of Eq.(5e) is applied to maintain the predicted closed-loop state within the set $\mathcal{U}_{\rho_e} \subset \mathcal{U}_\rho$, which is designed to make the safe operating region $\mathcal{U}_\rho$ a forward invariant set. Under the Mode 2 constraint of Eq.(5f), the contractive constraint is activated only for the first sampling step to decrease the value of $W_c(x)$, such that the closed-loop state will move back into $\mathcal{U}_{\rho_e}$ within finite sampling steps. Based on the CLBF-EMPC of Eq.(5), the following theorem establishes that under the sample-and-hold implementation of the CLBF-EMPC of Eq.(5), the optimization problem is recursively feasible. Additionally, closed-loop stability and safety are guaranteed in the sense that the closed-loop state is always bounded in $\mathcal{U}_\rho$. Again, the proof is omitted for brevity.

Theorem 2 *Consider the closed-loop nominal system of Eq.(1) (i.e., $w(t) \equiv 0$) with a constrained CLBF $W_c(x): \mathbf{R}^n \to \mathbf{R}$ that has its minimum at the origin. Given any initial state $x_0 \in \mathcal{U}_\rho$, it is guaranteed that under the CLBF-EMPC of Eq.(5), $x(t) \in \mathcal{U}_\rho$, $\forall t \ge 0$ where $\mathcal{U}_\rho \subset \mathcal{U}_{\rho_e}$ and $\mathcal{U}_\rho \cap \mathcal{D} = \varnothing$.*

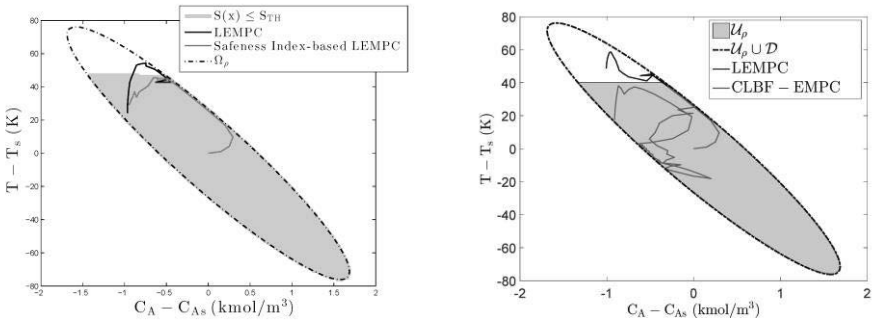
5. Application to a Chemical Process Example

A chemical process example is provided to illustrate the applications of the Safeness Index-based LEMPC and CLBF-EMPC to maintain the closed-loop state within the safety region defined by the Safeness Index function. Specifically, a well-mixed, non-isothermal continuous stirred tank reactor (CSTR) where an irreversible second-order exothermic reaction takes place is considered. The reaction transforms a reactant A to a product B ($A \to B$). The inlet concentration of A, the inlet temperature and feed volumetric flow rate of the reactor are C_{A0}, T_0 and F, respectively. The CSTR is equipped with a heating jacket that supplies/removes the heat at the rate Q. Based on material and energy balances, the CSTR dynamic model is of the following form:

$$\frac{dC_A}{dt} = \frac{F}{V}(C_{A0} - C_A) - k_0 e^{\frac{-E}{RT}} C_A^2 \tag{6a}$$
$$\frac{dT}{dt} = \frac{F}{V}(T_0 - T) + \frac{-\Delta H}{\rho_L C_p} k_0 e^{\frac{-E}{RT}} C_A^2 + \frac{Q}{\rho_L C_p V} \tag{6b}$$

where ΔH, k_0, E, and R represent the enthalpy of reaction, pre-exponential constant, activation energy, and ideal gas constant, respectively. The volume of the reacting liquid in the reactor V, heat capacity C_p, and fluid density ρ_L are assumed constant (process parameter values are in Albalawi et al., 2017). Additionally, a material constraint is introduced to make the averaged reactant material available over a given operating period $t_p = 1.0hr$ to be 0 (in deviation from the steady-state value, C_{A0s}). The explicit Euler method with an integration time step of $h_c = 10^{-5} hr$ is utilized to integrate numerically the dynamic model of Eq.(6). The states in the form of deviation variables are the concentration and temperature in the reactor and the manipulated inputs are the inlet concentration and heat rate, respectively (i.e., $x^T = [C_A - C_{As}\ T - T_s]$, $u^T = [C_{A0} - C_{A0s}\ Q - Q_s]$). The state-space profiles of the closed-loop system of Eq.(6) under the Safeness Index-based LEMPC of Eq.(3) and the CLBF-EMPC of Eq.(5) are shown in Fig. 1, where it is demonstrated that both the Safeness Index-based LEMPC

and CLBF-EMPC can maintain the state of the closed-loop system of Eq.(6) within the safe region (i.e., $S(x) \leq S_{TH}$, or $\mathcal{U}_\rho$); while under the standard LEMPC, the closed-loop states are only guaranteed to be bounded in the stability region (i.e., Ω_ρ, or $\mathcal{U}_\rho \cup \mathcal{D}$), but not within the safe (gray) regions. Additionally, the economic benefits under steady-state operation, Safeness Index-based LEMPC, and CLBF-EMPC are 13.9, 17.1, and 16.2, respectively, from which it is demonstrated that the proposed control schemes both economically outperform the tracking MPC (steady-state operation) and ensure process operational safety as well.



(a) Safeness Index-based LEMPC (b) CLBF-EMPC

Figure 1: The state-space profiles for the closed-loop CSTR under LEMPC (black trajectory) in both (a) and (b), and under the Safeness Index-based LEMPC of Eq.(3) (gray trajectory in (a)), and under the CLBF-EMPC of Eq.(5) (gray trajectory in (b)) for an initial condition (0,0).

6. Conclusion

In this work, we developed two MPC methodologies to deal with the process operational safety associated with economic model predictive control. Specifically, the problem of avoiding the unsafe region in state-space was first addressed with the notion of the Safeness Index and setting constraints within LEMPC using Safeness Index-defined regions. Then, we proposed a CLBF-based EMPC, which utilizes the constrained CLBF to design constraints in CLBF-EMPC, such that closed-loop stability, process safety, and the recursive feasibility are achieved simultaneously.

Abstract

In this work, we focus on the development of a multiscale computational fluid dynamics (CFD) model for plasma-enhanced chemical vapor deposition (PECVD) systems, and a corresponding run-to-run control framework with the purpose of improving product quality in the deposition of amorphous silicon thin film layers. A reactor scale model is linked with a microscopic, thin film growth model based on a hybrid kinetic Monte Carlo algorithm. Initially, open-loop operation suggests a product offset of greater than 8$\%$ from the set-point of 300 nm thickness. Application of the run-to-run control system, built around an exponentially-weighted moving average (EWMA) algorithm, is shown to reduce the thin film thickness non-uniformity to within 1$\%$ of the product set-point in less than 10 batches of operation.

Keywords: Multiscale modeling, computational fluid dynamics, run-to-run control.

1. Introduction

Uniform deposition of thin film layers remains a challenge in silicon processing industries due to the lack of in situ measurements and drift in the plasma composition caused by fouling (Gabriel et al., 2014). Specifically, in plasma-enhanced chemical vapor deposition (PECVD) of amorphous silicon (*a*-Si:H), growth rate non-uniformities greater than 20% across the surface of the wafer are common (Crose et al., 2016), which may lead to inefficient solar cells and microelectronics of poor quality. Process operators typically avoid this issue by preconditioning the reaction chamber and manually adjusting deposition conditions such that thickness non-uniformities may be reduced. Recently, Crose et al. (2016) developed a run-to-run (R2R) based, offline control scheme which has been demonstrated to reduce the offset in product thickness from 5% to less than 1% within ten batches of operation. While these results are promising, the multiscale model used relies on a first principles approach to solving the continuous mass, momentum and energy balances; however, recent advances in parallel computation strategies have made possible the application of multiscale computational fluid dynamics (CFD) to the modeling of PECVD (Crose et al., 2017).

Consequently, we propose the application of the newly developed run-to-run control strategy to the simulated deposition of amorphous silicon (*a*-Si:H) thin films using a

transient, multiscale CFD model. The two-dimensional axisymmetric model recently developed by Crose et al. (Crose et al., 2017) has been shown to accurately capture the complex behavior of the PECVD reactor and to reproduce experimentally observed non-uniformities with respect to the film thickness and porosity, and will be used throughout this work (Note: Fig. 3 demonstrates typical non-uniformity present in the process gas composition which leads to the aforementioned quality issues). A computationally efficient parallel processing scheme allows for the application of the R2R algorithm to 15 serial batch simulations which are shown to reduce the product offset from the 300 nm thickness set-point. It is important to clarify here that within each batch simulation 8 independent microscopic simulations are conducted which correspond to incremental radial wafer locations. Specifically, at each of $r = 0$, $r = 1$, ..., $r = 7$ cm, a kinetic Monte Carlo (kMC) algorithm is applied in order to capture both the exchange of mass and energy, as well as the character of the *a*-Si:H thin-film. The resulting multiscale model suggests that product offset from the desired thin-film thickness may be reduced to <1% for all zones.

The structure of this paper is as follows: first, the multiscale CFD model will briefly be presented including both the macroscopic reactor scale, as well as the microscopic thin film domain. Next, steady-state results will be discussed which motivate the use of an offline R2R control strategy. Finally, fifteen transient simulations demonstrate that the product quality, in terms of thin film thickness uniformity, may be greatly improved via the implementation of post-batch temperature control.

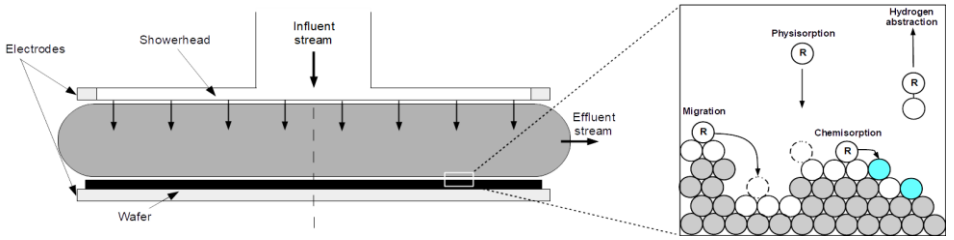

Figure 1. Macroscopic (left) and microscopic (right) PECVD simulation regimes.

2. Multiscale model

The PECVD process is inherently multiscale in that the macroscopic domain, which is defined as the gas phase contained within the reactor geometry, exchanges mass and energy with growing thin film layers which constitute the microscopic domain (see Fig. 1). As such, accurate modeling of PECVD processes requires the development of multiscale models which capture not only both domains, but the communication between these domains via a dynamic boundary. Recently, Crose et al. (Crose et al., 2017) demonstrated that multiscale models of this type are capable of reproducing accurate reactor operation and thin film growth; specifically, the spatial distribution of key deposition species such as SiH_3 and H are well characterized and highlight the need for batch-to-batch control strategies. The following subsections briefly present the development of the macro- and microscopic simulation domains; for a more in-depth discussion please refer to Crose et al. (Crose et al., 2016, 2017).

2.1. Macroscopic domain

In this work we utilize a two-dimensional, axisymmetric approximation of a typical chambered PECVD reactor (see Fig. 2). While the exact interior dimensions of PECVD

systems vary between manufactures, the dimensions shown here represent typical reactor geometries and may be considered as a representative base case. Additionally, the choice to use a two-dimensional (2D) axisymmetric approximation is motivated by both the axial symmetry of the cylindrical reactor as well as the desire to reduce computational demands. The results presented in the latter half of this work suggest a good agreement between the observed plasma characteristics and those reported experimentally; consequently, no additional geometries are explored.

In order to discretize a given geometry for use in CFD simulations, two general meshing strategies have emerged: (1) a collection of quadrilateral cells in a specific, repeating pattern is known as a structured mesh, and (2) unstructured meshes are characterized by a collection of polygons in an irregular pattern. Geometries lacking curvature or otherwise complex shapes benefit from the use of a structured mesh as they provide higher quality (e.g., orthogonality and aspect ratio) when compared to an unstructured mesh of equal cell count. Given the rectangular nature of the 2D axisymmetric geometry, a structured mesh composed of 120,000 cells is employed. It is important to note that throughout this work, ANSYS software is utilized for the creation of the geometric mesh (specifically, ICEM meshing) and as a solver for the partial differential equations which capture the gas phase mass, momentum and energy balances. An in-depth discussion of the finite volume methods used can be found in the ANSYS user manual (Ansys Inc., 2013).

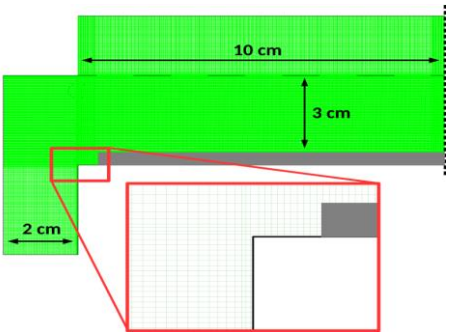

Figure 2. 2D axisymmetric geometry after discretization using a structured mesh containing 120,000 cells.

Three key user defined functions (UDFs) operate within the Fluent framework in order to tailor the solver to batch PECVD processing: the first involves a set of volumetric reactions which define the gas phase chemistry, the second details an electron density profile which enables plasma phase reactions, and the final UDF of considerable complexity allows for microscopic simulations (e.g., kinetic Monte Carlo algorithms) to operate in parallel to the macroscopic domain. Details on the various UDFs are available in the recent work of Crose et al. (Crose et al., 2017), while the UDF which defines the microscopic domain will be discussed in the following subsection.

2.2. Microscopic domain

Growth of amorphous silicon (*a*-Si:H) thin film layers along the surface of the wafer substrate (grey region in Fig. 2) defines the microscopic domain. Although tracking each individual particle which contributes to deposition remains a computationally infeasible task, growth of the lattice microstructure may be achieved using discrete kinetic Monte Carlo (kMC) algorithms. Specifically, at discrete locations along the

surface of the wafer from r = 0 cm to r = 8 cm, independent kMC simulations are conducted each of which utilize a triangular lattice of width 1200 particles (see Fig. 1, right). Regions along the wafer surface which are not explicitly contained within a kMC domain are assigned growth rates via interpolation between the known locations. In this manner, thin film layers may be grown along the complete span of the wafer substrate, and, of equal importance, the cells which border the wafer are provided with a dynamic boundary. Due to space limitations, the development of the kMC algorithm will not be provided here; however, a complete listing, including the relevant rate equations, may be found in Crose et al. (Crose et al., 2016). The transient boundary conditions of the multiscale model are of particular importance and are discussed in detail in the following subsection.

2.3. Multiscale workflow

Before the relevant steady-state and transient results can be discussed, it is important to clarify the methodology of the multiscale simulation presented here. At the start of a simulation, t = 0, the first time step for the macroscopic CFD domain is calculated within each cell of the reactor mesh using the ANSYS Fluent as discussed previously. Once the end of the first time step has been reached, $t = t_1$, species concentration, temperature and pressure information along the substrate boundary is fed to the microscopic domain. Discrete kMC simulations along the wafer surface are initialized using this information, and growth of the *a*-Si:H thin film begins. After the microscopic simulations have caught up to t_1, the boundary conditions for cells bordering the microscopic domain are updated based on the transfer of mass and energy to thin film growth. The macroscopic PDEs are once again solved such that the time progresses to $t = t_2$, and the cycle continues. The multiscale simulation progresses in this manner until the thin film product has reached its desired batch deposition time, t_{batch}.

3. Results

3.1. Steady-state species distribution

Once the reactor startup period has completed (i.e., after roughly the first three seconds of transient operation), distinct spatial non-uniformity becomes apparent in the concentration of SiH_3, and this non-uniform distribution persists throughout the remainder of the batch simulation. This phenomena is of particular importance in the red highlighted region of Fig. 3. Radial non-uniformity in the deposition species above the wafer substrate is the primary factor affecting the thickness profile of the thin film product. When operated in an open-loop fashion, without the use of batch-to-batch monitoring and control, the resulting thickness of the thin film layer near the edge of the wafer will undershoot the product specification of 300 nm by more than 8% (e.g., Fig. 4). At this time, there exists no direct means by which the species distribution within the PECVD reactor may be controlled; fortunately, run-to-run based algorithms have been shown to be effective in predicting optimal substrate temperatures which may reduce the thickness non-uniformity of amorphous silicon products (Crose et al., 2016).

3.2. Run-to-run control via EWMA

Given that the concentration and distribution of the deposition species (e.g., SiH_3) cannot be directly controlled, an alternative manipulated variable must be chosen in order to drive the thin film product to the desired set-point of 300 nm thickness. Recently, Crose et al. (Crose et al., 2016) demonstrated that the growth rates of *a*-Si:H thin film layers are a linear function of the substrate temperature in the neighborhood of

the nominal deposition condition of T = 475 K, for fixed species concentrations (namely, x_{SiH3} and x_H). Hence, a run-to-run control strategy is utilized in this work which requires only post-batch measurements of the product thickness in order to update the wafer temperature.

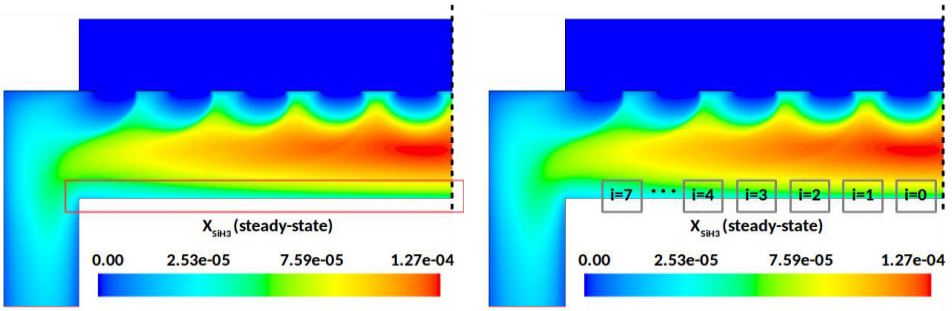

Figure 3. (left) Steady-state SiH$_3$ concentration within PECVD reactor. (right) Defined reactor zones which contain independent EWMA control algorithms.

Specifically, within each of the eight defined wafer zones (see Fig. 3, right) an exponentially-weighted moving average (EWMA) algorithm is applied in order to iteratively update the substrate temperature such that the *a*-Si:H thin film product may be driven to the desired thickness of 300 nm. The proposed EWMA algorithm is of the form:

$$\varepsilon_{k+1}^{i} = (1-\lambda)\varepsilon_{k+1}^{i} + \lambda(\tau_{s.p.} - \tau_{meas.}^{i}) \tag{1}$$

where ε^{i}_{k+1} is the parameter correction for the $k+1$ batch in zone i, λ is the learning factor, $\tau_{s.p.}$ is the thickness set-point and $\tau^{i}_{meas.}$ is the thickness measurement for zone i. The substrate temperature setting for each consecutive batch is then calculated via:

$$T_{k+1}^{i} = T_{k}^{i} + \varepsilon_{k+1}^{i}/(\alpha^{i} \cdot t_{batch}) \tag{2}$$

where T^{i}_{k+1} and T^{i}_{k} are the temperatures in zone i for the next and pervious batches, respectively, and α_i is a product of the growth rate linearization. Due to space limitations, further details on the development of the EWMA algorithm will not be provided here; please refer to Crose et al. (Crose et al., 2016).

3.3. Batch-to-batch operation

Fifteen data sets are shown in Fig. 4; each of which contains eight data points which correspond to the radial wafer zones. In the first data set (i.e., batch 1), all zones were maintained at the nominal deposition temperature, T = 475 K. The resulting thickness of the *a*-Si:H thin film demonstrates significant non-uniformity, most apparent in zones 6 and 7 which lie near the edge of the wafer substrate. This result is expected due to the observed loss in SiH_3 density near the outlet ports of the PECVD reactor (e.g., Fig. 4).

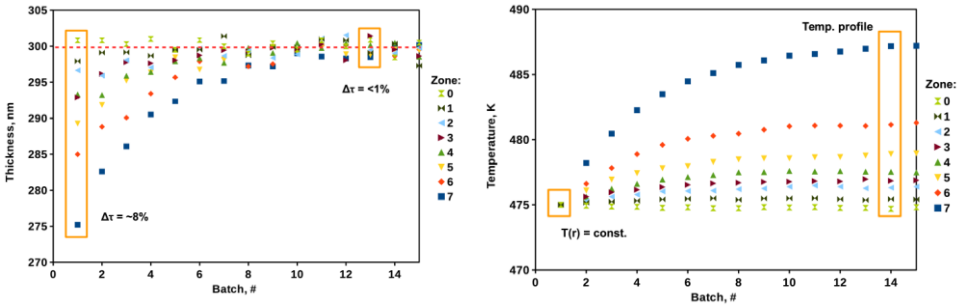

Figure 4. (left) Batch-to-batch thin film thickness. (right) Temperature profile developed via EWMA algorithm.

As the transient simulation progresses and additional batch deposition cycles complete, the EWMA algorithm begins to adjust the substrate temperature profile; see batches 2-15 in Fig. 4, right. Zone 0 maintains a near constant 475 K as its position is in the center of the reactor and receives the highest concentration of SiH_3. Conversely, the temperature of zone 7 is set to ~487 K by the R2R controller in an effort to drive the thin film thickness near the edge of the substrate to the set-point of 300 nm. By batch 8, all zones are within 1% of the product set-point and are maintained inside this margin thereafter.

4. Conclusions

A run-to-run control framework has been applied to batch deposition of amorphous silicon layers via PECVD. A multiscale CFD simulation which coordinates communication amongst the macroscopic, reactor scale model and the microscopic thin film growth domains has allowed for accurate growth of *a*-Si:H layers on a 16 cm wafer substrate. Radial concentration gradients in the deposition species, in particular SiH_3, have been shown to affect the uniformity of the thin film product. Through the application of the offline R2R control strategy which predicts optimized substrate temperatures, thickness offset in the product has been shown to be reduced from ~8% to less than 1% within 10 batches of operation.

Abstract

The objective of this work is to implement a sequential distributed model predictive control (MPC) for a process with infrequent and delayed primary measurements in presence of disturbances in the system. The overall system comprises of multiple units. A centralized state estimator based on Kalman filter is used to estimate states for the entire system. The estimator uses sampled state augmentation approach for fusing the delayed information from primary measurements with the frequent secondary measurements to obtain better estimates for output feedback control. Distributed MPC is developed that uses these estimates, as well as selective information transfer, based on process knowledge, between different units of the system. An example of a reactor separator system is considered to demonstrate the applicability of the control formulation. This system also has a plant-model mismatch of some parameter values and a disturbance model framework is incorporated.

Keywords: Distributed MPC; Sampled-state augmentation; Centralized control; Disturbance modelling

1. Introduction

Large process plants generally comprise of various interconnected sub-units. Overall control of the entire plant, when accomplished by control of individual units, is known as decentralized control. However, the performance of decentralized controller deteriorates as the interaction between various sub-units becomes stronger. Best control performance can, in principle, be achieved in a centralized control framework which has the knowledge about all interactions and disturbances affecting the plant. However, difficulty in obtaining a combined model for the system as well as computational challenges make the task of establishing a robust centralized control intractable. Hence, distributed control, which establishes frequent exchange of process- and control-related information across various controllers in tune with the actual plant interaction, has been proposed (Venkat et al., 2005). Parallel computation of localized controller targets reduces the computational complexity and unit level distributed structure reduces the associated modelling rigor compared to its overall plant level control. Christofides et al. (2013) provide the conceptual base and exhaustive review of distributed MPC. The local controller structure is based on physical sub-units in the system, though automatic partitioning into local sub-controllers has been proposed (Rocha et al., 2016).

Some earlier works discuss the distributed control application for systems with delayed multirate measurements. Liu et al. (2010 and 2012) address this issue with a sequential and an iterative DMPC framework, respectively. However, they considered full state feedback, which may occur in an asynchronous manner. Furthermore, framework for

systems with parameter mismatch or plant disturbances is missing in literature. Multi-unit systems require inferential control of a process variable of one unit using the estimates obtained through the measurements from other interconnected subsystems. While this inferential control of a single process unit in presence of disturbance has been well studied (Padhiyar et al. 2006; Prasad et al. 2002), it is challenging to extend the notion to a distributed architecture.

The objective of this work is to implement a distributed control framework when primary variable of one or more units in the system is measured infrequently and measurements are available after some delay. The control variables are inferred from secondary measurements when the primary measurements are unavailable. When these measurements arrive with a delay, state augmentation formulation (Gopalakrishnan et al., 2011) is used to fuse them in centralized estimator framework. This method is more efficient than filter recalculation, and is appicable for varying time-delays and for nonlinear systems. The control structure based on linear models thus developed is illustrated using a reactor-separator system. The observability of the plant ensures the inferential control of the parameter till the arrival of the delayed measurements.

The rest of the paper is organized as follows. Next section introduces the Kalman filter based centralized estimator formulation using sampled state-augmentation for fusing delayed primary measurement (Gopalakrishnan et al. 2011). Subsequently, distributed MPC framework is described. The proposed approach is implemented on a reactor-separator system in the next section. Results are presented for distributed control with and without delayed primary measurements, followed by conclusions of this work.

2. State Estimator Formulation

2.1. Model Formulation

Most chemical process systems follow a nonlinear relationship between variables, which is represented as:

$$\dot{x} = f(x,u) \tag{1}$$

$$y = g(x) + \lambda \tag{2}$$

where $x \in \Re^n, u \in \Re^p, y \in \Re^m$; and λ represents the measurement noise associated with the sensor. The control formulation in this work is developed for a linear model, which is obtained by linearizing around the steady state of the plant. The discrete-time state-space model is given by:

$$x_{k+1} = Ax_k + Bu_k \tag{3}$$

$$y_{k+1} = Cx_{k+1} + \nu_{k+1} \tag{4}$$

The sensor noise, ν, is assumed to be additive Gaussian white noise with $N(0,\sigma^2)$ and uncorrelated with the states, and model-plant mismatch is considered. Specifically, we use state-space matrices (A^P, B^P, C^P) to distinguish the "plant" from the model used for computing the MPC control actions. The latter "model" is used in the state estimator as well as in the controller design.

2.2. Input Disturbance Model

Disturbances can enter the system as unmeasured disturbances or through errors in the model parameters. The latter case is considered in the subsequent case study. The

disturbance models are constructed by augmenting disturbance states and estimating the same through state estimation techniques. Muske & Badgwell 2002 provide a detailed account of various disturbance modelling techniques and necessary conditions in choosing the disturbance states. Load disturbances are commonly added to compensate for model plant mismatch. Based on the Hautus condition for detectability, the number of disturbance states augmented should be less than or equal to measurements (Muske & Badgwell 2002). Since the number of measured variables during minor and major instances are different in multi-rate estimation, considering a predefined number of disturbance states will create observability issues. Hence, to account for bias due to parameter mismatch, integrating white noise disturbance is assumed to propagate through the inputs, i.e., $u_k^* = u_k + d_k$ (Padhiyar et al. 2006). The disturbance model,

$$x_{k+1} = Ax_k + Bu_k + Bd_k \tag{5}$$

can be written in the standard form by defining augmented state $z_k \triangleq [x_k^T \quad d_k^T]^T$ and

$$z_{k+1} = \tilde{A}z_k + \tilde{B}u_k + \tilde{B}_{\mathrm{d}}\varepsilon_k \tag{6}$$

$$y_{k+1} = \tilde{C}z_{k+1} + \nu_{k+1} \tag{7}$$

$$\tilde{A} = \begin{bmatrix} A & B \\ 0 & I \end{bmatrix}, \qquad \tilde{B} = \begin{bmatrix} B \\ 0 \end{bmatrix}, \qquad \tilde{B}_{\mathrm{d}} = \begin{bmatrix} 0 \\ I \end{bmatrix}, \qquad \tilde{C} = [C \quad 0] \tag{8}$$

The number of augmented disturbance states will be equal to the number of inputs.

2.3. Measurement Delays

The primary measurements (composition or quality variables) are sampled at a slower rate and are available after a fixed time delay (n_D) from its sampling instance. At minor instances, when only secondary measurements are available,

$$y_k^s = C^{\mathrm{s}}x_k + \nu_k^{\mathrm{s}} \tag{9}$$

At major instances when delayed primary measurements also arrive:

$$\begin{bmatrix} y_k^{\mathrm{s}} \\ y_k^{\mathrm{p}} \end{bmatrix} = \begin{bmatrix} C^{\mathrm{s}}x_k \\ C^{\mathrm{p}}x_{k-n_D} \end{bmatrix} + \begin{bmatrix} \nu_k^{\mathrm{s}} \\ \nu_{k-n_D}^{\mathrm{p}} \end{bmatrix} \tag{10}$$

where, "s" and "p" represent secondary and primary measurements, respectively. As in Eq. (8), we define $\tilde{C}^{\mathrm{s}} = [C^{\mathrm{s}} \quad 0]$ and $\tilde{C}^{\mathrm{p}} = [C^{\mathrm{p}} \quad 0]$.

Multi-rate state estimation will be implemented using the sampled-state augmentation method to fuse the delayed measurements when they arrive. As we show later, this method offers some computational advantage over other available methods for state estimation with delayed measurements (Gopalakrishnan et al. 2011). Prior to sampling of the primary variable, Kalman filter is implemented with just the frequent secondary measurement. At the time instance when the primary variable is sampled, the state vector is augmented with the states at the same instance (sampling). The augmented state estimate and the covariance matrix is given by

$$\hat{Z}_{(s|s)} = \begin{bmatrix} \hat{z}_{(s|s)} \\ \hat{z}_{(s|s)} \end{bmatrix}, \qquad P_{(s|s)}^{\mathrm{a}} = \begin{bmatrix} P_{(s|s)} & P_{(s|s)} \\ P_{(s|s)} & P_{(s|s)} \end{bmatrix} \tag{11}$$

and the state space transition matrices are given by

$$\Phi = \begin{bmatrix} \tilde{A} & 0 \\ 0 & I \end{bmatrix}, \qquad \Gamma = \begin{bmatrix} \tilde{B} \\ 0 \end{bmatrix}, \qquad \Psi = \begin{bmatrix} \tilde{B}_d \\ I \end{bmatrix}, \qquad \Xi = \begin{bmatrix} \tilde{C}^{\mathrm{s}} & 0 \\ 0 & \tilde{C}^{\mathrm{p}} \end{bmatrix} \tag{12}$$

During minor instances, only the first row of Ξ is used since y^{P} have not arrived. Once the primary measurement arrives, the measurements are fused using Kalman filter and augmented state is un-augmented back to its original form. The improved state estimates thus obtained are considered for MPC predictions in the controller block.

3. Distributed MPC: Output Feedback

Distributed control system is a modification to the decentralized structure with added model information regarding interaction from the neighboring subunits. Figure 1(b) shows the architecture of distributed MPC with output feedback. Let x^i represent the state vectors for the i^{th} subunit. Thus, $x = [x^1 \quad x^2 \quad \ldots \quad x^n]^T$

Two subunits in the system interact with each other. This interaction is accounted for by sharing information between the controllers of various subunits. Let x^{ij} ($x^{ij} \subset x^j$) represent the states of subunit *j* that are required in prediction of subunit *i*. The general form of the interacting model (Venkat et al. 2005) is given by

$$x_{k+1}^i = A_i x_k^i + B_i u_k^i + \sum_{j \neq i} \left(A_{ij} x_k^{ij} + B_{ij} u_k^{ij} \right) \tag{13}$$

$$y_{k+1}^i = C^i x_{k+1}^i + v_{k+1}^i \tag{14}$$

We further assume that the interaction between sub-units is uni-directional. Thus, an upstream unit affects a downstream unit, but not vice versa. In our future work, we will relax this assumption. This assumption allows us to calculate the control actions of upstream units first, followed by downstream ones in a sequential manner.

3.1. Case study: Reactor-separator system

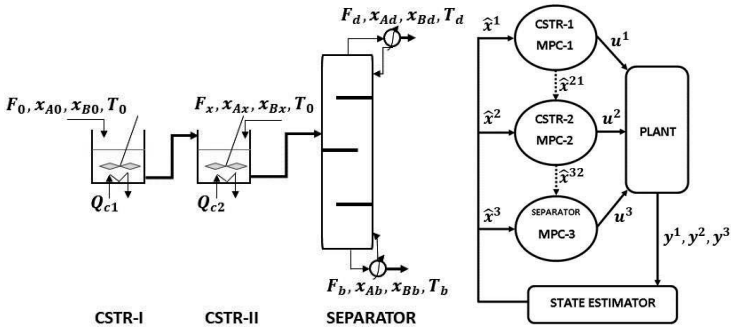

Figure 1: (a) Schematic of the reactor-separator system considered; (b) DMPC architecture

The case study of the two-reactor-separator system (Figure 1(a)) is considered for the implementation of the proposed distributed control formulation. Table 1 lists the key variables of the system. Since we have at least 3 measurements at each sampling instance, the number of disturbance states are always less than or equal to number of measurements thus satisfying the detectability condition for offset free control. Parameter mismatch is assumed between the linearized model and plant (in form of different values of heat transfer coefficients in CSTRs and relative volatility in separator). The sampling time is assumed to be 3 min; primary variables are sampled every 30 min and arrive with a delay of 15 min.

3.2. DMPC Algorithm

For the process in Figure 1, the distributed MPC formulation reduces to

$$x_{k+1}^{i} = \left(A_i x_k^i + B_i u_k^i\right) + A_{il} x_k^{il}, \qquad i = 1, 2, 3, \qquad 1 \le (l = i - 1) \le 2 \tag{15}$$

In other words, there is sequential transfer of information due to material transport across the three sub-units and the manipulated inputs of any sub-unit do not directly affect any other sub-unit. A future extension of this work is to compare the performance in presence of two-way interactions between the sub-units; for example, in presence of recycle from the separator to a reactor. Non-negativity constraints are used for mole fractions, and manipulated variables have both input magnitude and rate constraints. The proposed approach is implemented in MATLAB.

Table 1: List of variables of interest in the case-study

Variables	**CSTR-1**	**CSTR-2**	**Separator**
State Variables	x_A, x_B, T_1, T_{c1}	x_A, x_B, T_2, T_{c2}	x_{Ai}, x_{Bi} $(1 \le i \le 5)$
Controlled Variables	T_1	T_2	x_{B1}
Manipulated Variables	Q_{c1}	Q_{c2}	F_b
Measured (Frequent)	T_1	T_2	T_f
Measured (Infrequent)	–	–	x_{A1}, x_{B1}

4. Results and Discussion

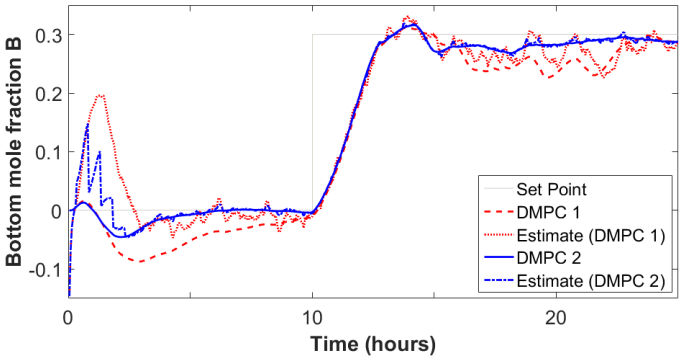

Figure 2: Comparison of DMPC with and without delayed primary measurements, DMPC 1 represents distributed MPC without primary measurements (secondary measurements only) and DMPC 2 includes delayed primary measurements.

Figure 2 and Figure 3 show the results of implementing the proposed approach on the reactor-separator system. For the sake of brevity, only the control of bottoms mole fraction of B (x_{Bb}) is discussed. This is chosen because x_{Bb} forms the delayed primary measurement in the third sub-unit; whereas the controlled variables T_1, T_2 for the CSTRs are available frequently and without delay. The thick solid line (blue color in online version of both figures) represents the values for distributed MPC with infrequent and delayed primary measurements. As can be seen from Figure 2, the performance of distributed MPC improves significantly when the primary measurements are used. A more meaningful comparison is that of distributed with centralized MPC in presence of delayed primary measurements. Figure 3 shows that the performance of distributed

MPC is close to that of the centralized control for controlling the bottoms mole fraction. Since measurements of the CSTRs are available without any delay, the distributed and centralized controllers match closely (results not shown). We compared this approach with distributed MPC using filter recalculation, and found our approach yields the same results, but with a slightly lower simulation time.

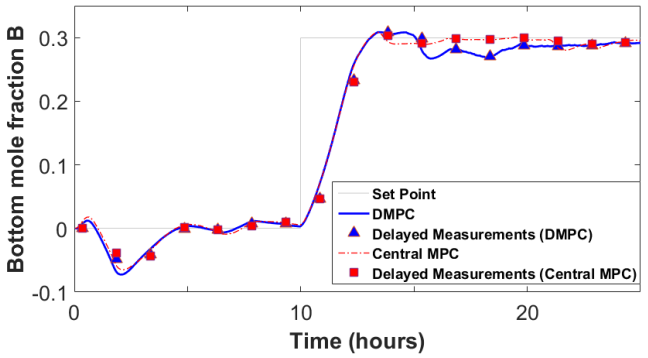

Figure 3: Comparison between centralized and distributed MPC (with primary variable sampled at 90 min). Markers represent the values of primary variables plotted at the arrival time.

5. Conclusions

The performance of distributed MPC with multi-rate estimation of primary variables was shown to be comparable to that of centralized control. Distributed MPC relies on seamless transfer of information across multiple controllers based on interactions in the physical plant. Fusing the infrequent and delayed primary measurements was important, as the improved state estimates provide better prediction of the control trajectory and hence improved control performance. Multi-rate estimation using augmentation of the sampled state is promising for distributed MPC and has potential scope for online implementation. This work will be extended to nonlinear system.

On-line Bayesian-based Model-set Management Method with Case Study of Steam Reforming Prediction under Various Feed Compositions

Jia Li[a*], Mingheng Li[a]

[a]*Cal Poly Pomona, 3801 W Temple Ave, Pomona, CA 91768, USA*
jiali@cpp.edu

Abstract

Steam reforming is the most widespread process for the generation of hydrogen-rich synthesis gas from light carbohydrates. One of the operation and design challenges is that the feed materials are various from natural gas, shale gas, to liquid gas, or naphtha. The optimal operating conditions identified under one type of feed may not be functional well under another one. Even within the same type feed, the compositions may vary large enough in continuous operation that requires online operating conditions tuning. Currently, two types of control strategies are applied to address the issue: one is feedforward control that the feed composition is measured in advance so that the operating conditions could be set accordingly. However, the performance would rely on the accuracy of the process model, and may not be robust on feed composition disturbances. The other is simple PID feedback control that the conditions are adjusted by the product composition feedback. However, the complexity of the multi-input multi-output (MIMO) steam reforming may bring challenges to the PID controller design. In this paper, a Bayesian-based model-set management method is introduced for constructing a statistically superior model set for online model-based control application. First, a number of steam reforming models are developed on various feed types or compositions. Then the optimal operating conditions are identified on the weighted model predictions. During online application, the measured product compositions are feedback to adjust the weights by a Bayesian-based statistical method. A repeated use of the method keeps the weights updated constantly based on the newly available system data, which makes the model-set-based prediction more precise, robust, and adaptive to various feeds automatically. The efficiency of the method is demonstrated by studying a steam reforming system with different feeds.

Keywords: Bayesian method, online model-based control, steam reforming

1. Introduction

Steam reforming is the most widely used method for producing hydrogen, carbon monoxide, or other useful products from hydrocarbon fuels such as natural gas. The severe operating conditions and rapid system dynamics necessitate advanced model-based control or optimization. Great efforts have been made to develop reaction kinetics and heat/mass transfer models for various feeds and catalysts (Hou and Hughes, 2001; Abbas et al., 2017). However, during online applications, the process is typically under various fluctuations and disturbances such as feed composition change, which make it a great challenge to ensure the accuracy and robustness of model prediction.

To address the challenge, a Bayesian-based model-set management method is introduced for constructing a statistically superior model set for online model-based control application. The efficiency of the method is demonstrated by a steam reforming case study showing a superior prediction performance under various process feeds.

2. Multiple-Model-based Process Control with Bayesian-based Weight Adjustment

The presented system diagram with model online evaluation is shown in Figure 1. Instead of having only one model, the presented scheme has a model base including N models (m_1, m_2, …, m_N). Each model has the same type of inputs, $\boldsymbol{X}$, and outputs, $\widehat{\boldsymbol{Y}}$. However, each model may present a certain scenario of the process, or has different model structures. For example, the models could be developed under various feeds, catalyst types, or catalyst age. The model itself could be empirical, first-principle, neural network-based, or hybrid model. Compared to the one-model-based control system, it is expected that the model set could provide more robust predictions by covering the entire process scenarios. The model set could also minimize the necessity of online measurements (e.g. feed composition) by including those variables into modeling.

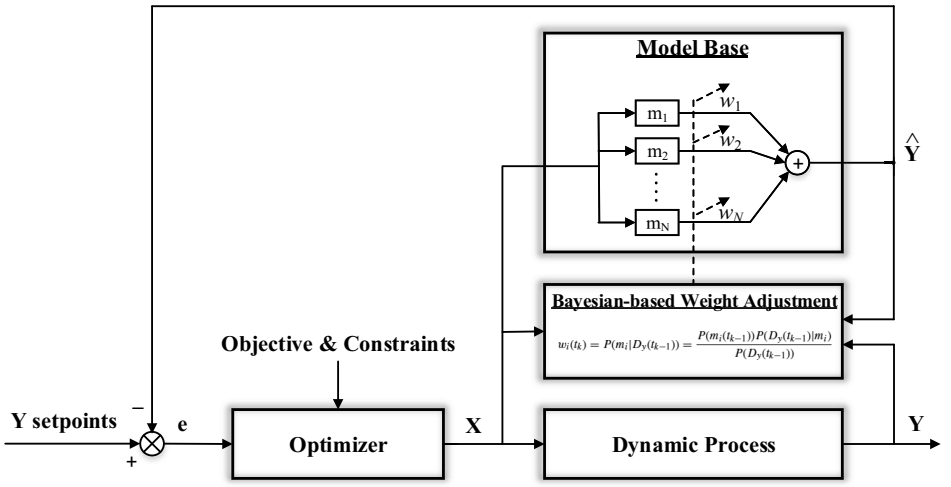

Figure 1 Bayesian-based model evaluation in the model based control diagram

The model prediction of model i at time t_k is presented as:

$$\hat{Y}_i(t_k) = m_i\big(X(t_k)\big) \qquad i = 1, 2, \dots, N \tag{1}$$

The model set prediction is the weighted average of all $\hat{Y}_i(t_k)$ with weights w_i:

$$\hat{Y}(t_k) = \sum_{i=1}^{N} w_i(t_k)\hat{Y}_i(t_k) \tag{2}$$

Having the weighted average model prediction, the control system could compare it to the output setpoint trajectory and identify the optimal manipulated variables in $\boldsymbol{X}$ to maximize (or minimize) the objective function under constraints.

When the process undergoes changes and the measured outputs deviate from the model prediction, a Bayesian-based model-set management method is introduced for constructing a statistically superior model set. In Bayesian equation, the posterior probability is constructed to evaluate the model accuracy by the product of prior probability and likelihood:

$$P(m|D) = \frac{P(m)P(D|m)}{P(D)} \tag{3}$$

Note that D is the newly available data set for evaluating model m. Prior probability $P(m)$ contains the prior knowledge about the applicability of model m. Posterior probability $P(m|D)$ is evaluated based on the past information about the model and the new process information. The model with a large posterior probability should be more desirable in model selection.

The presented weight adjustment system applies the posterior probability as the weights of each model. Assuming that the system information is available at time t_{k-1}, and the input and output data are contained, respectively. Then the Bayesian expression can be extended to time-variant as follows:

$$w_i(t_k) = P\big(m_i|Y(t_{k-1})\big) = \frac{P\big(m_i(t_{k-1})\big)P(Y(t_{k-1})|m_i)}{P\big(Y(t_{k-1})\big)} \tag{4}$$

The prior probability $P\big(m_i(t_{k-1})\big)$ presents the preference of model m_i before re-evaluation. Initially, all the models have the same preference. Then the posterior probability (or weight) of the previous time step can be set as the current prior probability. This should be valid based on such an analysis that a model showing a better prediction performance in the past may have a better chance to perform well in the current time step. Assuming the prediction error has a normal distribution with zero mean and deviation σ_j (j accounts for output variables), the likelihood $P(Y(t_{k-1})|m_i)$ is determined by the model prediction error probability. After equation derivation (Li and Huang, 2006), weight ω_i for model m_i at time t_k can be expressed of model predictions, measured outputs and preferred deviation:

$$w_i(t_k) = \begin{cases} \dfrac{\exp\left[-\frac{1}{2}\sum_j\left(\frac{y_j(t_{k-1})-\hat{y}_j(t_{k-1})}{\sigma_j}\right)^2\right]}{\sum_{i=1}^{N}\exp\left[-\frac{1}{2}\sum_j\left(\frac{y_j(t_{k-1})-\hat{y}_j(t_{k-1})}{\sigma_j}\right)^2\right]} & k=1 \\ \dfrac{w_i(t_{k-1})\exp\left[-\frac{1}{2}\sum_j\left(\frac{y_j(t_{k-1})-\hat{y}_j(t_{k-1})}{\sigma_j}\right)^2\right]}{\sum_{i=1}^{N}w_i(t_{k-1})\exp\left[-\frac{1}{2}\sum_j\left(\frac{y_j(t_{k-1})-\hat{y}_j(t_{k-1})}{\sigma_j}\right)^2\right]} & k>1 \end{cases} \tag{5}$$

where i is for model number, j is for output variables, k is for sampling time.

The Bayesian-based weight determination method can be used to evaluate periodically the degree of applicability of the models in the model set and to create a weighted average

prediction for system characterization. The method can be embedded in the following procedure for automatic, continuous management of the model set.

Step 1. Generate model set M that contains N process models. The models can be structurally or parametrically different.

Step 2. Initialize weights ω_i to $1/N$ and $k = 1$. Set deviation σ_j of the prediction error of each output variable. Calculate the initial model prediction sets $\hat{Y}_i(t_0)$.

Step 3. Obtain the real process outputs measurement values $Y(t_{k-1})$.

Step 4. Generate model prediction error $Y(t_{k-1}) - \hat{Y}_i(t_{k-1})$ for each model.

Step 5. Calculate the weights $w_i(t_k)$ using Eq. (5).

Step 6. Generate new model-based prediction $\hat{Y}(t_k)$ using Eq. (1) and (2).

Step 7. Return to Step 3 for the next time instant.

Note that after each update of the model weights, the model prediction $\hat{Y}(t_k)$ can be used for model-based control/optimization in the period before the next weight re-evaluation.

3. Steam Reforming Case Study

To show the efficiency of the presented method, the steam reforming process is applied which consists of three major reactions as below:

$$\text{Reaction 1: } CH_4 + H_2O \longleftrightarrow 3H_2 + CO$$

$$\text{Reaction 2: } CO + H_2O \longleftrightarrow H_2 + CO_2$$

$$\text{Reaction 3: } CH_4 + 2H_2O \longleftrightarrow 4H_2 + CO_2$$

According to Xu and Froment (1989a, 1989b), the kinetic models are developed as below:

$$r_1 = \frac{k_1}{P_{H_2}^{2.5}} \times \left(P_{CH_4} P_{H_2O} - \frac{P_{H_2}^3 P_{CO}}{K_1} \right) / \Omega^2 \tag{6}$$

$$r_2 = \frac{k_2}{P_{H_2}} \times \left(P_{CO} P_{H_2O} - \frac{P_{H_2} P_{CO_2}}{K_2} \right) / \Omega^2 \tag{7}$$

$$r_3 = \frac{k_3}{P_{H_2}^{3.5}} \times \left(P_{CH_4} P_{H_2O}^2 - \frac{P_{H_2}^4 P_{CO_2}}{K_3} \right) / \Omega^2 \tag{8}$$

$$\Omega = 1 + K_{CO} P_{CO} + K_{H_2} P_{H_2} + K_{CH_4} P_{CH_4} + K_{H_2O} P_{H_2O} / P_{H_2} \tag{9}$$

Where k_1, k_2, k_3, K_{CO}, K_{H2}, K_{CH4}, K_{H2O} are functions of temperature. The function parameters could be obtained by experimental data regression.

A model set with five steam reforming models are developed under different scenarios. The inputs are feed temperature and tube wall temperature, while outputs are product compositions and temperature. The model prediction error is defined as the sum of normalized outputs error to the real process. The set-point error is defined as the sum of normalized outputs error to the product composite set-points. Table 1 shows the model description. In the simulation test, the base case model 3 is applied as the pseudo real process for the first 30 sampling times and model 4 is set to the real process afterwards.

Table 1 Description of the Steam Reforming Models

Model #	**Description**
Model 1	Change the tube heat transfer coefficient from 50 to 70 [W/m2/K]
Model 2	Increase k_1 by 1.5%
Model 3	Base case model
Model 4	Change the steam to methane ratio from 1.75 to 1.96
Model 5	Increase K_{CH4} by 0.5%.

Figure 2 shows each model has different prediction error. Since the model 3 is assumed to be the real process at the first 30 sampling data, its prediction error keeps zero. With Bayesian-based method, the prediction error of the weighted model could approach to near zero quickly. After 30 data, the feed changes the steam to methane ratio and the model 4 becomes the pseudo real process. It can be seen that the prediction error of the weighted model could approach the minimal value as well in an automatic way.

A better model prediction performance could enhance the control performance as well. Figure 3 shows the error of the output compositions to the set-points. For the first 30 data, since the base case model 3 is also set as the real process, the model-based control could keep the setpoint error to the minimal value within the operation window. However, after the feed changes, the model 3 could not provide a good prediction and the setpoint error keeps high. As comparison, the Bayesian-based model could approach the same minimal setpoint error in several sampling times and adapt to the new scenario as well. It is shown that when the feed changes, the setpoint error does not change until ~60 sampling times when the weighted model gives new optimal inputs (the feed T and the tube wall T). To expedite the process, the deviation σ of the prediction error could be tuned as a trade-off between the quick response and the robust disturbance rejection.

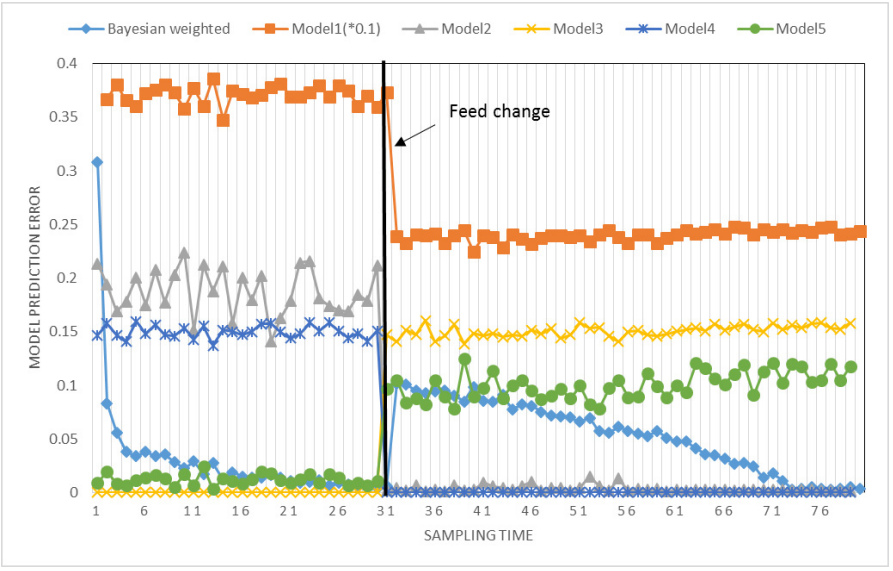

Figure 2. Model prediction error with feed change

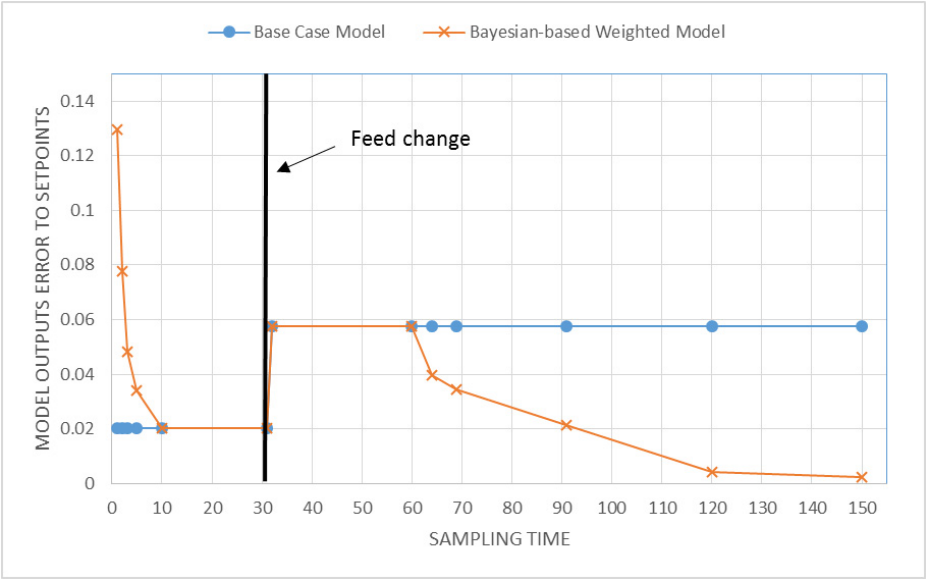

Figure 3. Model set-point error with feed change

4. Conclusions

In this paper, a Bayesian-based weight adjustment method is introduced in online applications. The periodic update of model-set weights by the model-set management procedure can be automated, which can ensure high-precision predictions, even if the process system undergoes disturbances and fluctuations. The steam reforming case study has demonstrated its attractiveness by shown a superior prediction performance under various process feeds. Also the presented method is generic and applicable for any model-based online applications.

Abstract

The original Tennessee Eastman (TE) process which contains vapor-liquid phase is a single time scale simplified model. Dynamic equations associated with the vapor phase mass are usually ignored and treated as quasi-steady state, leading to the pressure completely depending on temperature. In this paper, to restore the true dynamic characteristics of the pressure, the inadequacy of single time scale and quasi-steady state model are firstly analyzed, and then a full dynamic modeling method for whole process of the TE process is proposed and full dynamic model is built. Finally, the simulation results of pressure and temperature between full dynamic model and quasi-steady state model only on the basis of mass balance control (pressure open-loop) are compared and analyzed to validate the effectiveness of dynamic modeling method.

Keywords: systems engineering; dual-time scale; Tennessee Eastman process

1. Introduction

Nowadays, more and more people are engaged in the study of Tennessee Eastman (TE) process, the TE process benchmark based on the FORTRAN language was proposed by Downs and Vogel (1993). It consists of several chemical devices of vapor-liquid coexistence, in these devices, pressure related to vapor phase and temperature related to liquid phase cannot be observed in the same time scale because of the large differences of vapor-liquid phase physical characteristics. The TE process is not only a multivariable large system with cycle stream, but also a typical dual-time scale system.

In order to make the TE process closer to the chemical engineering theory, since the day the TE process was put forward, the modeling and simulation are developing. The simple mechanism model only composed of mass balance equations was established (Ricker and Lee, 1995). Next, energy balance equations for reactor, flash tank and stripper were increased (Jockenhövel et al., 2003), but the equations of each device are still algebraic. Then, the TE process for study on distributed control strategy of large systems was identified on Matlab (Liu et al., 2013). In recent years, more and more experts put forward a variety of fault diagnosis methods (Bo et al., 2008; Chebel-Morello et al., 2016) and problems related to control (Antelo et al., 2008), and use the TE process as the test object.

However, above models are still single time scale simplified models, there is no independent dynamic change of pressure. Furthermore, mass balance control is essential in chemical process control, mass balance control is controlling the pressure and level, however, the pressure cannot be strictly controlled, and the mass balance control in the true sense cannot be achieved. To reflect the real dynamic characteristics of pressure, Luo et al. (2015) established the full order model of flash tank through increasing the

dynamic mass balance equation of pressure based on dynamic modeling principle of chemical process.

In this paper, for the original TE process, the inadequacy of single time scale and quasi-steady state model and the necessity of full dynamic modeling are firstly analyzed. Then, to make the TE process closer to chemical engineering theory, a full dynamic modeling method for the whole process of TE process is proposed and full dynamic model is built. Based on above analyses, finally, through simulation comparison to validate the effectiveness of dynamic modeling method.

2. Evaluation of the original TE process

According to the original model, dynamic equations associated with the vapor phase mass are ignored and treated as quasi-steady state. They are as follows.

The pressure equations of components are as Eq.(1). The temperature equation after unification of vapor-liquid phase is as Eq.(2).

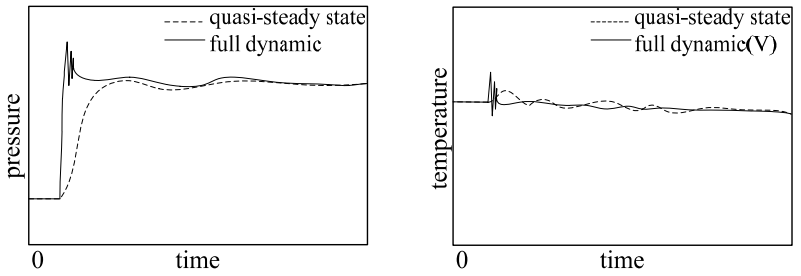
$$P_i = \frac{N_i \mathrm{R} T}{V^{\mathrm{V}}},\ i = \mathrm{A,B,C};\ P_i = x_i P_i^0,\ i = \mathrm{D,E,F,G,H};\ P = \sum_{\mathrm{i=A}}^{\mathrm{H}} P_i \tag{1}$$

$$\frac{\mathrm{d}T}{\mathrm{d}t} = \frac{F_{\mathrm{in}} h_{\mathrm{in}} - F_{\mathrm{vo}} h^{\mathrm{V}} - F_{\mathrm{lo}} h^{\mathrm{L}} + Q}{\rho^{\mathrm{L}} c_{\mathrm{p}} V^{\mathrm{L}}} \tag{2}$$

A-C – non-condensable components; D-H – condensable components; R – gas constant, V^V and V^L – vapor and liquid phase volume, m^3; P_i^0 – the saturated vapor pressure of component i, kPa; F_{in}, F_{vo}, F_{lo} – flow rate of inlet, vapor outlet and liquid outlet respectively, kmol·h^{-1}; h_{in}, h^V, h^L – enthalpy of inlet, vapor outlet and liquid outlet respectively, kJ·kmol^{-1}; Q – transfer heat, kJ·h^{-1}; ρ^L – liquid density, kmol·m^{-3}; c_p – liquid specific heat, kJ·kmol^{-1}·K^{-1}.

According to the above equations, the pressure is obtained by the temperature through the ideal gas equation of state directly in the modeling process, there is no independent dynamic change of pressure and the temperature within the whole device is represented by liquid temperature. When step signal is applied to the system ($\mathrm{d}T/\mathrm{d}t \neq 0$), the temperature is transferred from the original steady state value to a new steady state value, the value of each step in the transition is obtained by Eq.(2), and in every moment, the pressure is obtained by the temperature, as shown in Eq.(1). The transition process of temperature is over and pressure is end too until $\mathrm{d}T/\mathrm{d}t = 0$. In this case, process variables of vapor-liquid phase will change in the same time scale, as shown in Figure 1(a) and (b) by dotted line. As known to all, in the actual chemical engineering process, the changing rate of vapor pressure is much faster than that of liquid phase, if the difference between model and actual process is too large, then the real dynamic process will not be reflected and all simulation tests will lose their guiding significance to the actual process. The system analysis and synthesis results obtained by the simplified model are difficult to be applied to practice and this is true of the original TE process.

Therefore, restoring the dynamic characteristics of the TE process is especially important. Then, we assume that if the dynamic change of pressure and vapor temperature is restored, the pressure and vapor temperature are fast variables and liquid temperature is slow variables, at this moment, the dual-time scale characteristics are restored, as shown in Figure 1(a) and (b) by solid line.



(a) Dynamic response of pressure (b) Dynamic response of temperature

Figure 1. Dynamic response in quasi-steady state model and dynamic model

3. Fast dynamic pressure based full dynamic modeling

3.1. Principle of full dynamic modeling

In order to restore the true dynamic characteristics of vapor phase, this paper proposes a full dynamic modeling method. The full dynamic modeling method is shown in Figure 2, it represents the relationship between mass and energy variables after the vapor-liquid equilibrium. The vapor temperature is obtained from vapor phase mass balance equation and energy balance equation. The liquid temperature is obtained from the liquid phase mass balance equation and energy balance equation. The pressure is obtained from the vapor-liquid phase mass balance equation and vapor phase energy balance equation. The level is obtained from liquid phase mass balance equation, and the pressure will have an effect on the level, because the vapor-liquid phase coexists in the same device. The dynamic change of the pressure is associated with the change of vapor phase mass, vapor temperature and liquid level in full dynamic modeling. It shows that the pressure has the independent characteristic and is no longer completely dependent on the change of temperature.

3.2. Full dynamic modeling of operation units

The units of TE process are divided into four parts, namely, a mixing zone, a reactor, a stripper and a flash tank, wherein the flash tank portion includes a condenser, a separator and a circulating gas compressor. However, modeling schematic drawing is not fully in accordance with the TE process.

According to the proposed principle of full dynamic modeling, we take the reactor as an example to model and explain in detail. The modeling process of the other three parts is similar to that of reactor.

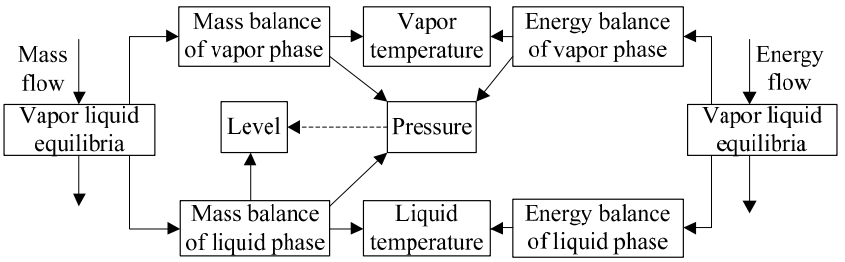


Figure 2. Schematic of full dynamic modeling

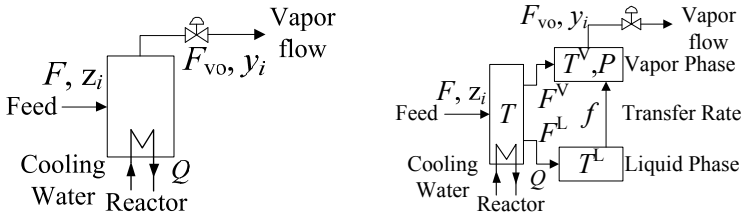

(a) Quasi-steady state modeling (b) Full dynamic modeling

Figure 3. Schematic of quasi-steady state and full dynamic modeling in reactor

F – feed flow rate; z_i – feed components; F_{vo} – vapor flow rate; y_i – vapor components; F^V, F^L – vapor-liquid flow rate of separation after reaction; f – transfer rate from liquid to vapor; P – pressure; T^V, T^L – vapor-liquid phase temperature; Q – heat exchange of cooling water.

The process of reactor with only vapor phase mass outlet: the vapor reactants are fed to the reactor and react. The products leave the reactor as vapors along with the unreacted feeds. The flow out of the vapor phase is determined by differential pressures and valve position of control valve. The reactor has an internal cooling bundle for removing the heat of the reaction. Quasi-steady state modeling in reactor is carried out according to the above, as shown in Figure 3(a). Full dynamic modeling is according to the schematic that transforms Figure 3(a) into Figure 3(b).

As shown in Figure 3(b), this paper considers the reactions are completing instantaneously and obtain vapor and liquid phase. Liquid flow comes into a virtual liquid tank, the liquid temperature and level are calculated in it. Vapor flow comes into a virtual vapor tank, the pressure and vapor temperature are calculated in it. The liquid phase enters the vapor phase in flash form. The reactor is satisfied the vapor-liquid equilibrium in whole process. And in whole process, in fact, there are three time scale, including reactions in reactor itself, liquid phase in virtual liquid tank and vapor phase in virtual vapor tank. Because the reactions are completing instantaneously, only considering the time scale of two virtual tanks.

After full dynamic modeling, the independent dynamic characteristic of pressure is restored, as shown in Eq.(3); and the temperature of vapor-liquid phase is calculated separately, as shown in Eq.(4).

$$V^{\mathrm{V}}\frac{\mathrm{d}P}{\mathrm{d}t}=\mathrm{R}T^{\mathrm{V}}\frac{\mathrm{d}N}{\mathrm{d}t}+N\mathrm{R}\frac{\mathrm{d}T^{\mathrm{V}}}{\mathrm{d}t}+P\mathrm{A}\frac{\mathrm{d}L}{\mathrm{d}t} \tag{3}$$

$$N\frac{\mathrm{d}T^{\mathrm{V}}}{\mathrm{d}t}=\frac{C_{\mathrm{p}}\left(F^{\mathrm{V}}+f\right)T-C_{\mathrm{pv}}F_7T^{\mathrm{V}}}{C_{\mathrm{pv}}}-T^{\mathrm{V}}\frac{\mathrm{d}N}{\mathrm{d}t};\ L\frac{\mathrm{d}T^{\mathrm{L}}}{\mathrm{d}t}=\frac{C_{\mathrm{p}}F^{\mathrm{L}}T-C_{\mathrm{pl}}fT^{\mathrm{L}}}{C_{\mathrm{pl}}\rho^{\mathrm{L}}\mathrm{A}}-T^{\mathrm{L}}\frac{\mathrm{d}L}{\mathrm{d}t} \tag{4}$$

V^V – vapor phase volume, m^3; P – pressure, kPa; R – gas constant, $J\cdot mol^{-1}\cdot K^{-1}$; T^V and T^L – vapor and liquid phase temperature, °C; N – amount of vapor phase substance, kmol; L – liquid level, m; A – cross-sectional area, m^2; C_p, C_{pv} and C_{pl} – molar heat capacity of mixed flow after reaction, vapor outlet flow and transfer flow from liquid phase to vapor phase respectively, $kJ\cdot kmol^{-1}\cdot K^{-1}$; F^V, F^L, F_{lv} and F_7 – vapor flow rate of separation, liquid flow rate of separation, the transfer flow rate from liquid phase to vapor phase and flow rate of outlet respectively, $kmol\cdot h^{-1}$.

Through the comparison between Eq.(1) and Eq.(3), Eq.(2) and Eq.(4), the main difference between the quasi-steady state model and the full dynamic model is whether

the pressure equation is dynamic or not, the pressure is not completely depending on temperature and it has an independent dynamic process. The other difference is temperature equation, the vapor and liquid temperature are calculated separately, and they both have their dynamic process.

Finally, full dynamic model of the whole process is connecting each unit device according to process to form a complete chemical engineering process. The connection between units is mainly through the pipeline, valves and pumps.

4. Simulation comparison

After full dynamic modeling, to verify our conjecture in section 1, the quasi-steady state model and the full dynamic model on the basis of mass balance control (level closed-loop and pressure open-loop) are simulated by gPROMS software, and the dynamic characteristics of the pressure and temperature are observed and compared.

4.1. Pressure

When the feed stream 1 changes, the simulation results of pressure are shown in Figure 4, it shows that when the independent dynamic change of pressure is restored, the dynamic characteristic of pressure under full dynamic model presents the fast change, and then the performance is consistent with that under quasi-steady state after the fast change is over. The dynamic response time of all variables will be influenced due to the control, but it will not change the dynamic characteristic of each variable.

4.2. Temperature

As shown in Figure 5, compared with quasi-steady state model, full dynamic model makes vapor and liquid phase temperature calculated separately, leading to two temperature curves. The change of vapor phase temperature is similar to that of pressure under full dynamic model; the change of vapor phase temperature is much faster than that of liquid phase temperature after applying step signal to the system, after that, the variation trend is consistent with that under quasi-steady state.

The section 4 indicates that full dynamic modeling method restores real dynamic characteristics of pressure and vapor phase temperature, the change of pressure is no longer completely dependent on temperature, vapor and liquid phase temperature also have their respective trends. Variables of vapor phase change fast and variables of liquid phase change slowly, they change in different time scale, namely, the dual-time scale characteristic of TE process is restored. It is consistent with our conjecture in section 1.

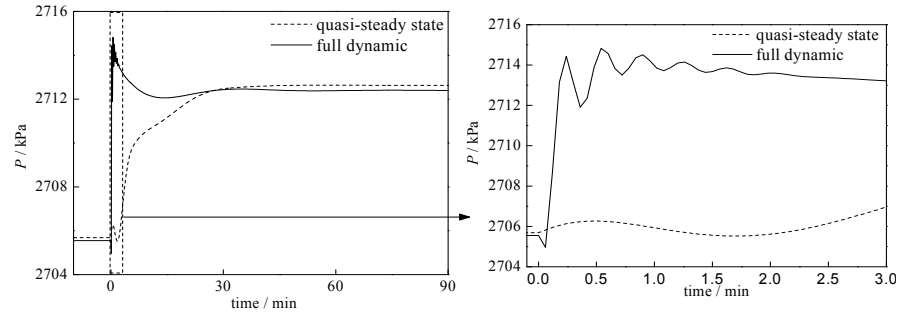

Figure 4. Dynamic response of reactor in quasi-steady state and full dynamic model

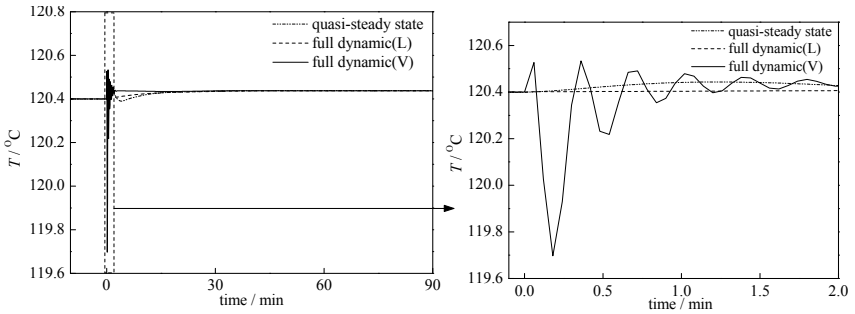

Figure 5. Dynamic response of reactor in quasi-steady state and full dynamic model

5. Conclusions

This paper aims at proposing a full dynamic modeling method and restoring the independent dynamic characteristic of pressure. Under quasi-steady state model, the pressure is completely controlled by temperature, and vapor and liquid phase temperature are unified, it is impossible to reflect the real dynamic process of vapor phase. The comparison of equations and simulation results indicate that full dynamic model can reflect the real dynamic characteristics of pressure and vapor phase temperature. Full dynamic model is closer to the chemical engineering theory and it will improve the quality of control algorithms and have guiding significance in optimization, nonlinear control, predictive control etc.

A Bilevel Programming Approach for the Dynamic Optimization of Cyanobacterial C-phycocyanin Production under Uncertainty

Dongda Zhang[a], Ehecatl A. del Rio-Chanona[a*]

[a]*Centre for Process Systems Engineering, Imperial College London, SW7 2AZ, UK*
a.del-rio-chanona@imperial.ac.uk

Abstract

C-phycocyanin is a high-value bioproduct synthesized by cyanobacterium *Arthrospira platensis* with a significant global market demand given its applications in the pharmaceutical, food and colorant industries. Unfortunately, its biosynthesis is currently characterized by low productivity and large uncertainty during the production process. High variability and unreliable expectations on product yields substantially hinder the industrialization of microorganism derived biochemicals as they present a risk to the profitability and safety of the underlying systems. Therefore, in this work, we propose a robust optimization approach to determine the lower and upper product yield expectations for the sustainable production of C-phycocyanin. Kinetic modeling is adopted in this study as a tool for fast prototyping, prediction and optimization of chemical and biochemical processes. On the upside, parameters in bioprocess kinetic models are used as a simplification of the complex metabolic networks to enable the simulation, design and control of the process. On the downside, this conglomeration of parameters may result in significant model uncertainty. To address this challenge, we formulate a bilevel max-min optimization problem to obtain the worst-case scenario of our system given the uncertainty on the model parameters. By constructing parameter confidence ellipsoids, we determined the feasible region along which the parameters can minimize the system's performance, while nutrient and light controls are used to maximize the biorenewable production. The inner minimization problem is embedded by means of the optimality conditions into the upper maximization problem and hence both are solved simultaneously. Through this approach, we determined pessimistic and optimistic scenarios for the bioproduction of C-phycocyanin and hence compute reliable expectations on the yield and profit of the process.

Keywords: uncertain dynamic systems, optimal control, bilevel programming, bioprocess optimization.

1. Introduction

C-phycocyanin is a blue antenna pigment used to enhance the photosynthetic efficiency of cyanobacteria and red algae (Eriksen 2008). It has been recognized as a high-value bioproduct with great potential in the pharmaceutical industry (Chen et al. 2013; Kuddus et al. 2013). Currently, extensive research has been conducted to identify the metabolic mechanisms of C-phycocyanin synthesis in cyanobacterium *A. platensis*. It has been demonstrated that nitrate concentration and illumination intensity are the most important factors determining both the content and the productivity of phycocyanin (Xie et al. 2015; del Rio-Chanona et al. 2015). Meanwhile, to accomplish the

industrialization of phycocyanin production, two requirements must be satisfied. First, it is necessary to identify the optimal operating conditions for phycocyanin synthesis and biomass growth so that the process efficiency can be maximized. Second, a final phycocyanin content higher than 10 % of cell dry weight must be guaranteed; otherwise the cost of the pigment downstream separation will be significantly increased.

To address the two requirements, mathematical models have become an indispensable tool to determine the process optimal operating conditions for long-term biomass cultivation and phycocyanin production. Recently, a kinetic model capable of simulating cyanobacterial biomass growth and phycocyanin production under different light intensities and nitrate concentrations has been proposed (del Rio-Chanona et al. 2015). However, as a kinetic model is a simplification of a highly complex metabolic network which involves a significant amount of metabolic reactions, the uncertainty of a kinetic model is in general large and the process optimization results heavily rely on the accuracy of the model. As a result, it is essential to consider the effects of model uncertainty on the process prediction and optimal control. Therefore, in this study a bilevel programming framework is designed to optimize C-phycocyanin production with uncertainty under a fed-batch long-term operation system.

2. Cyanobacterial C-phycocyanin production system

The *A. platensis* biomass growth and C-phycocyanin production model in (del Rio-Chanona et al. 2015) is adopted in the current study, and the reader is directed to the original source for details on the model. The dynamic equation system is:

$$\frac{dx}{dt} = r_M x - u_d x \quad (1), \quad \frac{dn}{dt} = -Y_{NO} r_M x + F_N \cdot N_{in} \quad (2), \quad \frac{dq}{dt} = kx - \frac{k_d q}{n + K_{Np}} \quad (3)$$

$$r_M = u_0 \frac{n}{n + K_n} \quad (4), \quad I(z) = I_0\left[\exp\left(-\left(\varpi x + K_a\right)z\right) + \exp\left(-\left(\varpi x + K_a\right)\left(L - z\right)\right)\right] \quad (5)$$

$$u_0 = u_m \frac{I(z)}{I(z) + k_s + I(z)^2 / k_i} \quad (6), \quad k = k_m \frac{I(z)}{I(z) + k_{sp} + I(z)^2 / k_{ip}} \quad (7)$$

Given the fact that nitrate inflow rate (F_N) is a control in this study, while the model was originally designed to simulate a batch process, a new term, $F_N \cdot N_{in}$ is added on the right-hand-side of Eq. (2) so that the model can be used to simulate the fixed-volume fed-batch process. The influent nitrate concentration (N_{in}) is assumed to be 500 mM. To maximize the production of C-phycocyanin, a 16-day fed-batch process was selected as the production mode for operation, and dynamic equations were modified accordingly. This would allow to treat the nitrate inlet flow and the light intensity as control variables, and hence we can formulate an optimal control problem. To maintain this scenario as close to reality as possible, controls were only allowed to vary once per day during a 16 day computational experiment.

3. Parameter estimation and confidence ellipsoids

3.1. Parameter estimation

Here we outline the procedure to estimate the parameters in Eq. (8) for Eqs. (1) - (7) using the data provided in the original article. To estimate these parameters, a nonlinear

least-squares optimization problem is formulated as Eq. (9). The output variables once the DAE system is solved are labelled y, while the experimental data is labelled $\hat{y}$, p_{lb} and p_{ub} are the upper and lower bounds of parameters, and Λ is the inverse of the covariance matrix estimated by the experimental measurement error. As the parameter estimation problem is nonconvex, and to avoid shallow local minima, a multi-start framework was implemented. One hundred initial starting points were generated by a Sobol sequence and the estimated parameters that produced the least objective function was chosen.

$$p = (u_m, K_N, u_d, Y_{NO_3}, k_d, K_{N_p}, k_m, k_s, k_i, k_{sp}, k_{ip}, \tau, K_a) \tag{8}$$

$$\min_p \sum_{i=1}^{N} \left(\hat{y}_i - y(t_i, p)\right)^T \Lambda_i \left(\hat{y}_i - y(t_i, p)\right)$$

$$\begin{aligned} s.t. \quad & \frac{dx}{dt} = f(x(t), p) \\ & p_{lb} \le p \le p_{lb}, \quad x(0) = x_0, \quad t_0 \le t \le t_f \end{aligned} \tag{9}$$

3.2 Confidence Ellipsoids

Joint confidence regions were determined by considering all simultaneous linear combinations of the parameters, computed by Eq. (10) where p^* is the optimal parameter solution determined by Eq. (9), and the right-hand side is the standard value for the Chi-square test given the number of parameters and a 95 % level of confidence.

$$\left(p - p^*\right)^T \Lambda \left(p - p^*\right) \le \chi^2_{1-\alpha, NP} \tag{10}$$

4. Optimization of process production

An optimal control problem was formulated to optimize the production of C-phycocyanin in a fed-batch operation mode. To maximize the process production, two control variables were used: light intensity and nitrogen inflow rate. The resulting dynamic optimization problem is the following:

$$\max_{Fin(t), L(t)} q(t_f)$$

$$\begin{aligned} s.t. \quad & \frac{dx}{dt} = f(x(t)) \\ & x(0) = x_0, \quad t_0 \le t \le t_f \\ & Fin^{\min} \le Fin(t) \le Fin^{\max}, \quad L^{\min} \le L(t) \le L^{\max} \end{aligned} \tag{11}$$

The solution of Eq. (11) would result in the optimal control sequences for *Fin*(*t*) and *L*(*t*). Problem (11) is discretized through orthogonal collocation over finite elements, where the collocation points are placed according to a fifth order Radau quadrature.

5. Worst-case scenario optimization

5.1. Bilevel programming approach

A bilevel max-min approach enables us to formulate a problem that would yield the worst-case scenario of the dynamic optimization in the system. In this case, given that we have no strict bound or inequality constraints that our system is likely to violate, the

worst-case is the scenario with the lowest product production even when the system is optimized. For this, we maximize the production of C-phycocyanin by using light and nitrate inlet as control parameters. Furthermore, we assume the system will select the worst possible set of parameters that are within the 95 % confidence intervals computed by (3). This bilevel optimization problem is the following:

$$
\begin{aligned}
&\max_{Fin(t),L(t)} \; q(t_f) \\
&s.t. \quad \frac{dx}{dt} = f(x(t)) \\
&\quad Fin^{\min} \le Fin(t) \le Fin^{\max}, \quad L^{\min} \le L(t) \le L^{\max} \\
&\quad x(0) = x_0, \quad t_0 \le t \le t_f \\
&\quad \min_{p} \; q(t_f) \\
&\quad s.t. \quad (p - p^*)^T \Lambda (p - p^*) \le \chi^2_{1-\alpha,NP}
\end{aligned}
\tag{12}
$$

Problem (12) can be reformulated by embedding the necessary and sufficient conditions for optimality of the inner minimization problem into the outer optimization problem. This formulation of a bilevel problem is referred as mathematical programs with complementarity constraints (MPCC). MPCC have a less complicated structure than the original Bilevel problems, particularly, the feasible sets are always closed (Allende & Still 2013). This reformulation yields the following single-level problem (13), where μ is the Lagrange multiplier for the constraint on the parameters feasible region, delimited by the confidence ellipsoid $G = (p - p^*)^T \Lambda (p - p^*) - \chi^2_{1-\alpha,NP}$ and $F = q(t_f)$.

$$
\begin{aligned}
&\max_{Fin(t),L(t)} \; q(t_f) \\
&s.t. \quad \frac{dx}{dt} = f(x(t)) \\
&\quad Fin^{\min} \le Fin(t) \le Fin^{\max}, \quad L^{\min} \le L(t) \le L^{\max} \\
&\quad x(0) = x_0, \quad t_0 \le t \le t_f \\
&\quad \nabla_p L(p^*) = \nabla_p F(p^*) - \mu \nabla_p G(p^*) = 0, \quad \mu G(p^*) = 0 \\
&\quad \mu \ge 0, \quad \nabla^2_{pp} L(p^*) \succeq 0
\end{aligned}
\tag{13}
$$

When embedding the lower bilevel problem into the upper problem by the conditions of optimality, it is advisable to use the Fritz-John (FJ) necessary conditions (Allende & Still 2013). However, as we do not have equality constraints for the lower problem, the Karush-Kuhn-Tucker (KKT) and the FJ necessary conditions are the same. Moreover, we consider the smoothing approach (Allende & Still 2013) where we replace the complementary equation $\mu G(p^*) = 0$ by $\mu G(p^*) = \varepsilon$, $\varepsilon > 0$ a small perturbation parameter. Finally, let us note that Eq. (3) is only twice differentiable for parameters k_{sp}, k_{ip}, K_a, T, and K_{Np}, so they are the only parameters considered as optimization variables.

6. Implementation

Optimization problems in this work were implemented in a Python programming environment, using Pyomo as an interface for the optimization solver IPOPT (Wächter & Biegler 2006). The value of ε vas set to be 10^{-6}. Furthermore, solving Eq. (13)

directly was found difficult due to inadequate starting points for the optimization problem. Thus, Eq. (11) was first solved to obtain preliminary initialization points. To ameliorate convergence issues, expressions which contain bilinear and trilinear terms were substituted by their linearized form (Adjiman et al. 1998). Subsequently, linearized expressions of (14) were introduced one-at-a-time for each parameter to update the initial guesses for the optimizer. Finally, (14) and (15) were re-introduced in the overall problem, and an optimal solution to (13) was attained.

$$\nabla_p L(p^*) = \nabla_p F(p^*) + \mu \nabla_p G(p^*) = 0 \tag{14}$$

$$\mu G(p^*) = \varepsilon \tag{15}$$

7. Results and discussion

To obtain an optimistic scenario of the process optimization, Eq. (11) is solved, however, parameters in Eq. (8) were also assigned as optimization variables, hence helping the maximization of the bioproduct. On the other hand, solutions obtained by Eq. (13) represent the worst-case scenario for the current process.

Table 1: Model parameters and optimization results.

Parameter	Pessimistic	Optimistic			Pessimistic	Optimistic
k_{sp}	37.328	11.323		Biomass	7.5 g/L	4.8 g/L
k_{ip}	197.78	800.0		conc., g/L		
K_a	3.799	0.0		Phycocyanin	533.9	773.2
τ	73.381	48.382		production,	mg/L	mg/L
K_{NP}	18.372	16.892		mg/L		

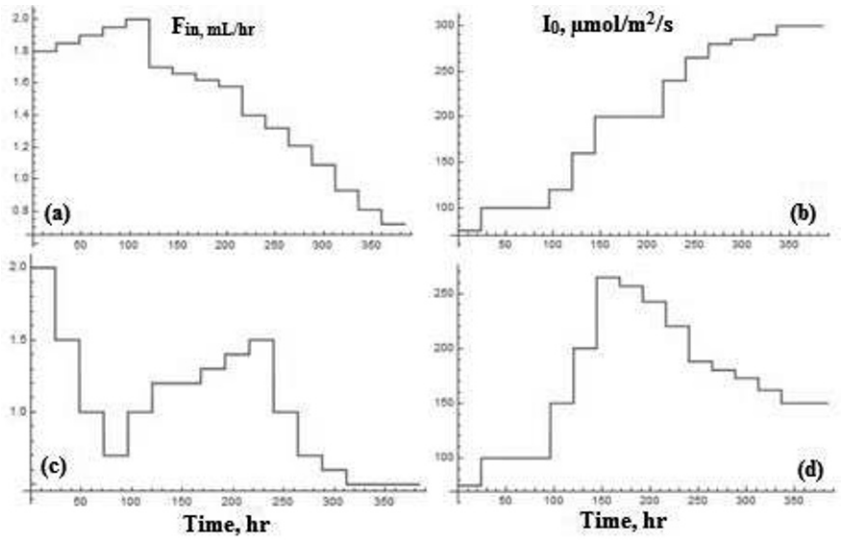

Figure 1: Optimal control actions under different scenarios. (a) and (b), (c) and (d): nitrate inflow rate and light intensity in the optimistic and pessimistic case, respectively.

The parameter values for both scenarios are listed in Table 1. By comparing the different results in Table 1, there is a significant change in the potential production on the process. This highlights the fact that an incorrect estimation of the best and worst production yields can severely endanger the safety and economics of the process. Furthermore, it is also worth noticing that there is a significant difference between the optimal control inputs for light and nutrient supply (Fig. 1), depending on the dynamic model parameters chosen. This means, that as expected, different parameter sets will result in different optimal control inputs to maximize the bioproduct.

In Table 1 we can see that k_{sp}, which is the light saturation term, is higher in the pessimistic scenario than it in the optimistic scenario. A system with a higher light saturation term is not able to use light to produce phycocyanin as efficiently as one that has a lower light saturation term. Moreover, the light inhibition term (k_{ip}) is higher in the optimistic scenario, which means that when there is a high light intensity, light will not inhibit the production of phycocyanin as much as that in a system with a lower value of k_{ip}, such as the pessimistic scenario. K_a and τ regulate how much the culture scatters and absorbs light. In both cases the pessimistic scenario has a higher value, which diminished the amount of light that can be utilized for phycocyanin production. Furthermore, K_{Np} can be seen to have practically the same value in both cases, reflecting its low sensitivity to phycocyanin production, and that other parameters can inhibit the systems performance more severely. Thus, it is important to identify the correct value of other parameters through model-based experimental design method in future study.

8. Conclusions

In this study, a bilevel max-min optimization framework was proposed to resolve the challenge on cyanobacterial C-phycocyanin production under uncertainty. Through this framework, phycocyanin production was predicted, and upper and lower bounds on productivity identified. Furthermore, given the wide confidence intervals, more experimental measurements are needed to narrow the varying range of the controls. This also highlights the need for an online identification and optimization strategy to be put in place (*e.g.* MPC, EMPC) so that the process optimization can be performed effectively.

Abstract

The decoupling control scheme is beneficial for controlling multivariable systems with strong interactions. This paper presents a novel control design approach where the concept of decoupling control is incorporated into the model predictive control design. We developed the decoupling dynamic matrix control that enables achieving effective decoupling control without adding any decouplers. Simulation study confirms the effectiveness of the proposed control design.

Keywords: model predictive control, dynamic matrix control, decoupling control.

1. Introduction

Most industrial and chemical processes are multivariable systems which often present undesirable couplings (interactions) between the controlled and manipulated variables. A multivariable system with strong interactions can be much more difficult to control. In this case, the decoupling control by using a decoupler is an effective control strategy to address the process interactions. However, the ideal decouplers are not always physically realizable, and the main problem of this decoupling approach is that the complexity of decoupler elements and apparent decoupled processes increases for high-dimensional multivariable systems (Garrido et al., 2012). Model predictive control (MPC) has become the standard method in several process industries to solve difficult multivariable control problems (Qin and Badgwell, 2003). MPC is a kind of multivariable control that can take process interactions into account. However, unlike the typical decoupler design, the conventional MPC design does not target explicitly on the ideal compensation of process interactions so that satisfactory decoupling control performance is not necessarily attained.

In this study, we propose a novel MPC design that enables achieving the condition of decoupling control without adding any decouplers. We term this control technique as decoupling dynamic matrix control (DDMC) as the step-response models are used for prediction. This novel design method conceptually decomposes each control signal into several constituent components for DDMC calculation. One of the components is used to drive a controlled variable to its reference signal, and the other components are used to eliminate the effects from other manipulated variables on this controlled variable. An additional term is then included in the DDMC cost function to penalize the incomplete compensation of process interactions. By tuning the constant weighting matrices, it is possible to deal with the trade-off among decoupling performance, tracking performance, and control efforts. Simulation study shows that the proposed DDMC design provides considerably improved decoupling control performance compared with the conventional DMC.

2. Dynamic matrix control

Dynamic matrix control (DMC) has achieved a great deal of success in the petroleum refining and petrochemicals industries. In this section, the conventional DMC algorithm, which uses the step-response model for output prediction, is briefly introduced.

Consider a general multivariable process involving r inputs, $\mathbf{u} = [u_1 \ u_2 \ ... \ u_r]^T$, and n outputs, $\mathbf{y} = [y_1 \ y_2 \ ... \ y_n]^T$. Let $\{s_{ij,1} \ s_{ij,2} \ ... s_{ij,N}\}$ be the N step-response coefficients for the model relating y_i and u_j. Assume that the initial condition is zero for simplicity. The p-step ahead prediction for the output y_i made at time instant t can be written as

$$\hat{y}_{i,t+p} = \sum_{j=1}^{r}\left(\sum_{h=1}^{N-1} s_{ij,h}\Delta u_{j,t+p-h} + s_{ij,N}u_{j,t+p-N}\right) = \sum_{j=1}^{r}\left(\sum_{h=1}^{p} s_{ij,h}\Delta u_{j,t+p-h}\right) + \hat{y}^{o}_{i,t+p} \tag{1}$$

where $\Delta u_{j,t} = u_{j,t} - u_{j,t-1}$ denotes the control move at time instant t, and $\hat{y}^{o}_{i,t+p}$ denotes the predicted unforced response obtained when $\Delta u_{j,t+h} = 0$ for $h \geq 0$.

Define vectors of predicted responses and predicted unforced response for the next P sampling instants, and control moves for the next M sampling instants as

$$\hat{\mathbf{Y}}_{t+1} = \begin{bmatrix} \hat{\mathbf{y}}_{t+1} \\ \hat{\mathbf{y}}_{t+2} \\ \vdots \\ \hat{\mathbf{y}}_{t+P} \end{bmatrix}; \qquad \hat{\mathbf{Y}}^{o}_{t+1} = \begin{bmatrix} \hat{\mathbf{y}}^{o}_{t+1} \\ \hat{\mathbf{y}}^{o}_{t+2} \\ \vdots \\ \hat{\mathbf{y}}^{o}_{t+P} \end{bmatrix}; \qquad \Delta\mathbf{U}_t = \begin{bmatrix} \Delta\mathbf{u}_t \\ \Delta\mathbf{u}_{t+1} \\ \vdots \\ \Delta\mathbf{u}_{t+M-1} \end{bmatrix} \tag{2}$$

where P is the prediction horizon and M is the control horizon, and we usually require $N \geq P \geq M$. The future output predictions of the model are written as

$$\hat{\mathbf{Y}}_{t+1} = \mathbf{S}\Delta\mathbf{U}_t + \hat{\mathbf{Y}}^{o}_{t+1} \tag{3}$$

where $\mathbf{S}$ is the dynamic matrix:

$$\mathbf{S} = \begin{bmatrix} \mathbf{S}_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{S}_2 & \mathbf{S}_1 & \mathbf{0} & \vdots \\ \vdots & \vdots & \ddots & \mathbf{0} \\ \mathbf{S}_M & \mathbf{S}_{M-1} & \cdots & \mathbf{S}_1 \\ \mathbf{S}_{M+1} & \mathbf{S}_M & \cdots & \mathbf{S}_2 \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{S}_P & \mathbf{S}_{P-1} & \cdots & \mathbf{S}_{P-M+1} \end{bmatrix}_{nP\times rM}; \qquad \mathbf{S}_h = \begin{bmatrix} s_{11,h} & s_{12,h} & \cdots & s_{1r,h} \\ s_{21,h} & s_{22,h} & \cdots & s_{2r,h} \\ \vdots & \vdots & \ddots & \vdots \\ s_{n1,h} & S_{n2,h} & \cdots & s_{nr,h} \end{bmatrix}_{n\times r} \tag{4}$$

Because there are uncertainties that cause output prediction error, we need to correct the future output predictions through output feedback. A typical approach is to add a bias correction to the predictions, which provides a vector of corrected predictions as

$$\tilde{\mathbf{Y}}_{t+1} = \hat{\mathbf{Y}}_{t+1} + \mathbf{\Phi}\left(\mathbf{y}_t - \hat{\mathbf{y}}_t\right) = \mathbf{S}\Delta\mathbf{U}_t + \hat{\mathbf{Y}}^{o}_{t+1} + \mathbf{\Phi}\left(\mathbf{y}_t - \hat{\mathbf{y}}_t\right) = \mathbf{S}\Delta\mathbf{U}_t + \tilde{\mathbf{Y}}^{o}_{t+1} \tag{5}$$

where $\tilde{\mathbf{Y}}^{o}_{t+1}$ is the corrected prediction for the unforced case, and $\mathbf{\Phi}$ is defined as

$$\mathbf{\Phi} = \begin{bmatrix} \mathbf{I}_n & \mathbf{I}_n & \cdots & \mathbf{I}_n \end{bmatrix}^T_{nP\times n}; \quad \mathbf{I}_n : n\times n \text{ identity matrix} \tag{6}$$

The general objective of the DMC control calculation is to determine $\Delta\mathbf{U}_t$ so that the following quadratic cost function is minimized:

$$\min_{\Delta \mathbf{U}_t} J_{\mathrm{DMC}} = \left(\mathbf{Y}_{t+1}^r - \tilde{\mathbf{Y}}_{t+1} \right)^T \mathbf{Q} \left(\mathbf{Y}_{t+1}^r - \tilde{\mathbf{Y}}_{t+1} \right) + \Delta \mathbf{U}_t^T \mathbf{R} \, \Delta \mathbf{U}_t \tag{7}$$

where $\mathbf{Y}_{t+1}^r$ is the reference trajectory over the prediction horizon, **Q** is the weighting matrix for predicted errors, and **R** is the weighting matrix for control moves. The DMC control law that minimizes the cost function in Eq.(7) can be calculated analytically. In the conventional DMC algorithm, the objective function is based on minimizing the predicted tracking errors and the control moves. However, the decoupling control performance is not *explicitly* considered in DMC design so that the conventional DMC does not necessarily provide an effective decoupling control. In the following, a novel DMC algorithm that enables the control design to achieve enhanced decoupling control performance is presented.

3. Decoupling design of dynamic matrix control

3.1. Condition for decoupling control

For a $n \times r$ multivariable process **G**(*s*), the typical decoupling control scheme is depicted in Figure 1, where **D**(*s*) is the decoupler and **C**(*s*) is the decentralized controller. To compensate the interactions among loops, the decoupler **D**(*s*) is designed such that the decoupled process matrix (**GD**) is a diagonal matrix. Namely, the process output y_i depends only on the controller output v_i, and the other controller outputs v_j ($j \neq i$) have no effect on y_i. In this case of ideal decoupling, a set-point change for one controlled variable has no effect on the other controlled variables, which is an important benefit of the decoupling control. In Figure 1, each decoupler output (process input) u_j comprises n components (u_{jk}, $k = 1, \cdots, n$) and is given by

$$u_j = \sum_{k=1}^{n} u_{jk} = \sum_{k=1}^{n} d_{jk} v_k \; ; \quad j = 1, 2, \cdots, r \tag{8}$$

where u_{jk} depends only on v_k. The process output can be written as

$$y_i = \sum_{j=1}^{r} g_{ij} u_j = \sum_{j=1}^{r} g_{ij} u_{ji} + \sum_{j=1}^{r} \left(g_{ij} \sum_{k=1, k \neq i}^{n} u_{jk} \right); \quad i = 1, 2, \cdots, n \tag{9}$$

As mentioned, the ideal decoupling is achieved when the process output y_i depends only on the controller output v_i, or equivalently depends only on u_{ji}. Therefore, according to Eq.(9), the condition for ideal decoupling is given by

$$\sum_{j=1}^{r} \left(g_{ij} \, u_{jk} \right) = 0; \quad \text{for all } \; k = 1, \cdots, i-1, i+1, \cdots, n \; \text{ and } \; i = 1, 2, \cdots, n \tag{10}$$

Development of the DDMC algorithm is based on the decoupling condition in Eq.(10).

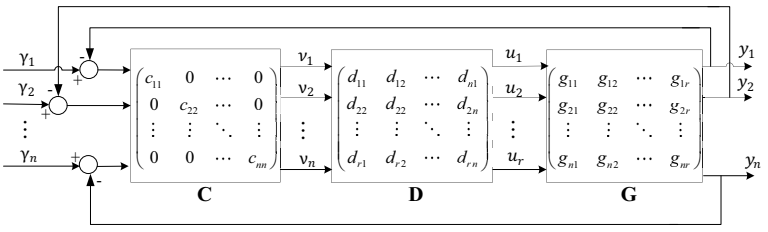

Figure 1. Decoupling control system for a $n \times r$ multivariable process.

3.2. Design of decoupling dynamic matrix control (DDMC)

Let $y_{ijk} = g_{ij}\, u_{jk}$ be the constituent components of y_i and $\hat{y}_{ijk,t+p}$ be the p-step ahead prediction for y_{ijk}. To achieve effective decoupling control, a new cost function is proposed for DMC control calculation as follows:

$$J_{\text{DDMC}} = \left(\mathbf{Y}^r_{t+1} - \tilde{\mathbf{Y}}_{t+1}\right)^T \mathbf{Q}\left(\mathbf{Y}^r_{t+1} - \tilde{\mathbf{Y}}_{t+1}\right) + \Delta\mathbf{U}_t{}^T \mathbf{R}\, \Delta\mathbf{U}_t + \sum_{i=1}^{n}\left[\sum_{k=1,k\neq i}^{n}\left[\left(\sum_{j=1}^{r}\hat{\mathbf{Y}}_{ijk,t+1}\right)^T \mathbf{W}_{ik}\left(\sum_{j=1}^{r}\hat{\mathbf{Y}}_{ijk,t+1}\right)\right]\right] \tag{11}$$

where $\hat{\mathbf{Y}}_{ijk,t+1} = [\hat{y}_{ijk,t+1}\ \ \hat{y}_{ijk,t+2}\ \cdots\ \hat{y}_{ijk,t+P_d}]^T$. The third term in J_{DDMC} is an additional penalty for the incomplete compensation of process interactions (the deviation of condition in Eq.(10)). Here, P_d is the decoupling horizon and $\mathbf{W}_{ik}$ is the weighting matrix for decoupling performance.

To calculate the predicted output component $\hat{y}_{ijk,t+p}$, each manipulated variable and control move is decomposed into n components in a similar manner given in Eq.(8):

$$u_j = \sum_{k=1}^{n} u_{jk}\ ; \quad \Delta u_j = \sum_{k=1}^{n} \Delta u_{jk}\ ; \quad j = 1,2,\cdots,r \tag{12}$$

Notably, such a decomposition is *conceptual* since a decoupler does not exist. The component Δu_{ji} is used to drive the output y_i to its reference signal, and the other components Δu_{jk} ($k \neq i$) are used to eliminate the effects from other manipulated variables on y_i. Define vectors of all decomposed control moves at time instant t and for the next M sampling instants as

$$\Delta\bar{\mathbf{u}}_t = \left[\Delta u_{11,t} \ \cdots\ \Delta u_{r1,t}\ \ \Delta u_{12,t}\ \cdots\ \Delta u_{r2,t}\ \cdots\ \Delta u_{1n,t}\ \cdots\ \Delta u_{rn,t}\right]^T \tag{13}$$

$$\Delta\bar{\mathbf{U}}_t = \left[\Delta\bar{\mathbf{u}}_t{}^T \ \ \Delta\bar{\mathbf{u}}_{t+1}{}^T \ \cdots\ \Delta\bar{\mathbf{u}}_{t+M-1}{}^T\right]^T_{rnM\times 1} \tag{14}$$

We have $\Delta u_{jk,t} = \mathbf{1}_{j+(k-1)n}\Delta\bar{\mathbf{u}}_t$, where $\mathbf{1}_{j+(k-1)n}$ denotes a $1\times rn$ row vector whose $[j+(k-1)n]$-th element is one and all other elements are zero. Also, a vector of decomposed control moves for the next M sampling instants can be expressed as

$$\Delta\mathbf{U}_{jk,t} = \left[\Delta u_{jk,t} \ \ \Delta u_{jk,t+1} \ \cdots\ \Delta u_{jk,t+M-1}\right]^T = \mathbf{\Pi}_{jk}\Delta\bar{\mathbf{U}}_t \tag{15}$$

where

$$\mathbf{\Pi}_{jk} = blockdiag\left[\mathbf{1}_{j+(k-1)n} \ \ \mathbf{1}_{j+(k-1)n} \ \cdots\ \mathbf{1}_{j+(k-1)n}\right]_{M\times rnM} \tag{16}$$

Therefore, the future predictions for the constituent components of output are written as

$$\hat{\mathbf{Y}}_{ijk,t+1} = \mathbf{S}_{ij}\Delta\mathbf{U}_{jk,t} + \hat{\mathbf{Y}}^o_{ijk,t+1} = \bar{\mathbf{S}}_{ijk}\Delta\bar{\mathbf{U}}_t + \hat{\mathbf{Y}}^o_{ijk,t+1}; \qquad \bar{\mathbf{S}}_{ijk} \triangleq \mathbf{S}_{ij}\mathbf{\Pi}_{jk} \tag{17}$$

where $\hat{\mathbf{Y}}^o_{ijk,t+1} = [\hat{y}^o_{ijk,t+1}\ \ \hat{y}^o_{ijk,t+2}\ \cdots\ \hat{y}^o_{ijk,t+P_d}]^T$ and $\mathbf{S}_{ij}$ is the $P_d \times m$ dynamic matrix for the SISO model between y_i and u_j.

The control moves for the next M sampling instants can be expressed as

$$\Delta\mathbf{U}_t = \mathbf{\Pi}\Delta\bar{\mathbf{U}}_t \tag{18}$$

where

$$\mathbf{\Pi} = blockdiag\left[\mathbf{\Omega} \ \ \mathbf{\Omega} \ \cdots\ \mathbf{\Omega}\right]_{rM\times rnM}; \quad \mathbf{\Omega} = \left[\mathbf{I}_r \ \cdots\ \mathbf{I}_r\right]_{r\times rn} \tag{19}$$

The corrected predictions of future outputs given in Eq.(5) can be written as

$$\tilde{\mathbf{Y}}_{t+1} = \bar{\mathbf{S}}\Delta\bar{\mathbf{U}}_t + \tilde{\mathbf{Y}}^o_{t+1}\ ; \qquad \bar{\mathbf{S}} = \mathbf{S}\boldsymbol{\Pi} \tag{20}$$

Substituting Eqs.(20), (18), and (17) into Eq.(11), the cost function for DDMC becomes

$$\begin{aligned} J_{\text{DDMC}} = &\left(\mathbf{Y}^r_{t+1} - \bar{\mathbf{S}}\Delta\bar{\mathbf{U}}_t - \tilde{\mathbf{Y}}^o_{t+1}\right)^T \mathbf{Q}\left(\mathbf{Y}^r_{t+1} - \bar{\mathbf{S}}\Delta\bar{\mathbf{U}}_t - \tilde{\mathbf{Y}}^o_{t+1}\right) + \Delta\bar{\mathbf{U}}_t{}^T\left(\boldsymbol{\Pi}^T\mathbf{R}\boldsymbol{\Pi}\right)\Delta\bar{\mathbf{U}}_t \\ &+ \sum_{i=1}^{n}\left[\sum_{k=1,k\neq i}^{n}\left[\left(\bar{\mathbf{S}}_{ik}\Delta\bar{\mathbf{U}}_t + \sum_{j=1}^{r}\hat{\mathbf{Y}}^o_{ijk,t+1}\right)^T \mathbf{W}_{ik}\left(\bar{\mathbf{S}}_{ik}\Delta\bar{\mathbf{U}}_t + \sum_{j=1}^{r}\hat{\mathbf{Y}}^o_{ijk,t+1}\right)\right]\right] \end{aligned} \tag{21}$$

where $\bar{\mathbf{S}}_{ik} = \sum_{j=1}^{r}\bar{\mathbf{S}}_{ijk}$. The cost function is now written in terms of $\Delta\bar{\mathbf{U}}_t$ so that the control design problem is transformed into the determination of $\Delta\bar{\mathbf{U}}_t$, instead of $\Delta\mathbf{U}_t$. Therefore, the DDMC control calculation is based on

$$\min_{\Delta\bar{\mathbf{U}}_t} J_{\text{DDMC}} \tag{22}$$

In the unconstrained case, the DDMC control law can be calculated analytically:

$$\Delta\bar{\mathbf{U}}_t = \mathbf{K}_T\left(\mathbf{Y}^r_{t+1} - \tilde{\mathbf{Y}}^o_{t+1}\right) - \sum_{i=1}^{n}\sum_{k=1,k\neq i}^{n}\left(\mathbf{K}_{D,ik}\sum_{j=1}^{r}\hat{\mathbf{Y}}^o_{ijk,t+1}\right) \tag{23}$$

where the gain matrices are given by

$$\begin{aligned} \mathbf{K}_T &= \left(\bar{\mathbf{S}}^T\mathbf{Q}\bar{\mathbf{S}} + \boldsymbol{\Pi}^T\mathbf{R}\boldsymbol{\Pi} + \sum_{i=1}^{n}\sum_{k=1,k\neq i}^{n}\left(\bar{\mathbf{S}}_{ik}{}^T\mathbf{W}_{ik}\bar{\mathbf{S}}_{ik}\right)\right)^{-1}\bar{\mathbf{S}}^T\mathbf{Q} \\ \mathbf{K}_{D,ik} &= \left(\bar{\mathbf{S}}^T\mathbf{Q}\bar{\mathbf{S}} + \boldsymbol{\Pi}^T\mathbf{R}\boldsymbol{\Pi} + \sum_{i=1}^{n}\sum_{k=1,k\neq i}^{n}\left(\bar{\mathbf{S}}_{ik}{}^T\mathbf{W}_{ik}\bar{\mathbf{S}}_{ik}\right)\right)^{-1}\bar{\mathbf{S}}_{ik}{}^T\mathbf{W}_{ik} \end{aligned} \tag{24}$$

Based on the receding horizon approach, only the first control move $\Delta\mathbf{u}_t$, which is obtained from $\Delta\mathbf{u}_t = \boldsymbol{\Omega}\Delta\bar{\mathbf{u}}_t$, is actually implemented and then a new set of control moves is calculated at the next sampling instant. Inequality constraints for process inputs and outputs can be included in the control calculation. In the constrained case, the control moves can be calculated by the programming techniques.

The extra design parameters in the DDMC design are the decoupling horizon P_d and the weighting matrix $\mathbf{W}_{ik}$, which provide more degrees for improved decoupling control performance. Increasing the value of $\mathbf{W}_{ik}$ generally improves the decoupling control performance, at the expense of the speed of tracking response. As P_d increases, the decoupling control performance tends to be improved. However, the decoupling control performance may become worse when a too large value of P_d is chosen. Our simulation study reveals that $P_d = P$ is a reasonable choice.

4. Illustrative example

Consider the Wood-Berry (Wood and Berry, 1973) binary distillation column process:

$$\begin{bmatrix} y_1(s) \\ y_2(s) \end{bmatrix} = \begin{bmatrix} \dfrac{-12.8e^{-s}}{16.7s+1} & \dfrac{-18.9e^{-3s}}{21s+1} \\ \dfrac{6.6e^{-7s}}{10.9s+1} & \dfrac{-19.4e^{-3s}}{14.4s+1} \end{bmatrix} \begin{bmatrix} u_1(s) \\ u_2(s) \end{bmatrix} \tag{25}$$

We compare the proposed DDMC design with the conventional DMC design. The tuning parameters used in the two designs are the same with $P = 15$, $M = 3$, and

$$\begin{aligned} \mathbf{Q} &= blockdiag\left[\mathbf{Q}_1, \mathbf{Q}_2, \cdots, \mathbf{Q}_P\right]; \quad \mathbf{Q}_i = diag\left[1 \quad 1\right]; \; i = 1, 2, \ldots, P \\ \mathbf{R} &= blockdiag\left[\mathbf{R}_1, \mathbf{R}_2, \cdots, \mathbf{R}_M\right]; \quad \mathbf{R}_i = diag\left[0.1 \quad 0.1\right]; \; i = 1, 2, \ldots, M \end{aligned} \tag{26}$$

For the DDMC design, the additional tuning parameters are set as $P_d = 15$ and

$$\mathbf{W}_{12} = \mathbf{W}_{21} = diag\left[W_1, W_2, \cdots, W_{P_d}\right]; \; W_i = 100; \; i = 1, 2, \ldots, P_d \tag{27}$$

Figure 2 shows the system responses for a unit step set-point change. The proposed DDMC gives superior decoupling performance because a set-point change for one controlled variable has negligible effect on the other controlled variables. The speed of tracking response for DDMC is slower compared to DMC. Nevertheless, when the speed of tracking response for DMC is slowed down (similar to that for DDMC) by setting R_i = 15, the DMC still cannot provide effective decoupling control. The result clearly demonstrates the effectiveness of the proposed DDMC design for improved decoupling control performance.

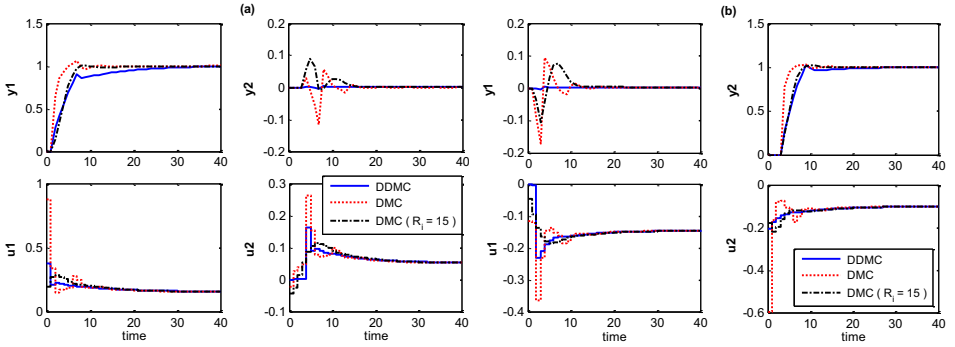

Figure 2. Closed-loop responses. (a) y_1 set-point change; (b) y_2 set-point change.

5. Conclusions

A novel design of DDMC controller for enhanced decoupling control has been proposed. The DDMC controller can provide an effective decoupling control without adding decouplers and without real-time adjustment of the design parameters. The effectiveness of the DDMC controller is validated through simulation studies. The DDMC design is expected to be a promising technology for the multivariable control systems where decoupling control performance is highly desirable.

Abstract

Time-variable energy prices motivate large energy consumers, such as the chemical industry, to adjust their electricity consumption to market signals, i.e., to perform demand side management (DSM). To maximize benefit, the processes must be able to perform large and fast load changes. In this paper, we apply dynamic optimization using a rigorous nonlinear model for offline computation of optimal load change trajectories. Considering characteristic load changes of an industrial-scale air separation unit (ASU) as a case study, we show that transition periods can be reduced by up to 50 % compared to solely using linear plant models to track load changes. Furthermore, we demonstrate that offline-computed optimal trajectories can be tracked efficiently by linearizing model predictive control in the presence of unknown temperature disturbances without violating the severe purity constraints. Hence, our results indicate a high potential of nonlinear model predictive control strategies for industrial DSM.

Keywords: Dynamic Optimization, Nonlinear Model Predictive Control, Cryogenic Air Separation

1. Introduction

Over the last decades, the share of power generation from intermittent renewable sources, in particular wind turbines and photovoltaics, has significantly increased. This leads to volatile electricity markets, where spot market prices differ substantially within few hours (EPEX SPOT SE, 2017). This price volatility motivates large energy consumers, e.g., the chemical/process industry, to perform demand side management (DSM), i.e., to adjust the electricity consumption and hence the production to market signals (e.g., Ghobeity and Mitsos, 2010).

In this context, the flexible operation of cryogenic air separation units (ASUs) has attracted interest due to their high energy consumption. Some ASU plants allow storing energy in times of low electricity prices in form of cryogenic liquid products that can be either sold to the market or re-vaporized to satisfy the demand for gaseous products in times of load reductions due to high energy prices. Most related works focus on the economic optimization of the production schedule by applying quasi-stationary models and identifying the optimal operation point as a function of current energy prices (e.g., Zhang et al., 2016 or Adamson et al., 2017). Recent work of Pattison et al. (2017) additionally includes process dynamics in economic optimization by using low-dimensional dynamic surrogate models.

However, previous works do not focus on the process control system. As industrial air separation comprises severe purity constraints, it is of paramount importance to satisfy these constraints while performing a load change and to reject unmeasured disturbances. For this purpose, we design a two-layer advanced process control system (APCS). The optimal trajectory for a desired load change is computed offline. Then, a linearizing online controller calculates base layer set-points for tracking the optimal trajectory. We compare the load-change performance of the proposed APCS to the industrial benchmark that uses only linear models. Furthermore, we evaluate disturbance rejection capacity for two load changes that enable energy market participation.

2. Methodology

2.1. Dynamic ASU Model

The flowsheet of the ASU considered in this work is depicted in Figure 1 (a). The ASU processes 135,000 Nm^3/h of fresh air. The vapor fraction of the incoming cooled air (HPF) enters the high-pressure column (HPC) in the bottom stage. On top of the HPC, a highly pure gaseous nitrogen stream is drawn off (HPGAN). Besides, after passing the condenser, a liquid nitrogen stream (LIN) is drawn off. The bottom product of the HPC is fed to the low-pressure column (LPC). In addition, the liquid fraction of the incoming air (LPF) and a fraction of the LIN-product are fed to the LPC. On top of the LPC, highly pure gaseous nitrogen is produced (LPGAN), while at the bottom, highly pure liquid (LOX) as well as gaseous oxygen (GOX) is produced. Besides, a gaseous stream is purged at an intermediate stage, drawing off the major part of the incoming argon. The condensing nitrogen of the HPC provides the required heat stream for the reboiler of the LPC.

A rigorous model of the described ASU is implemented in gPROMS version 4.2 (Process Systems Enterprise Ltd.) using the package Multiflash version 4.3 (KBC Advanced Technologies Ltd.) for physical property calculations. Values for pure compound as well as binary interaction parameters of the applied NRTL model are retrieved from the Aspen Plus database version 8.8 (Aspen Technology, Inc.). We assume that all streams entering the columns are either saturated liquid or vapor. The column stages are modelled with dynamic MESH-equations using the following assumptions (Huang et al., 2009 and Cao et al., 2016): (i) negligible vapor hold up, (ii) fast temperature dynamics, (iii) a constant pressure difference between neighboring stages and (iv) a linear relation for stage hydraulics. The HPC consists of 40 theoretical equilibrium stages, the LPC of 80. The respective pressures are 5.8 – 6.0 bar and 1.2 – 1.6 bar. A base layer control using PI controllers as depicted in Figure 1 (a) further extends the model. In total, the ASU process is represented by a differential-algebraic equation system (DAE) comprising 374 differential equations (in particular dynamic mass and component balances at each stage) and 1,885 algebraic equations, e.g., flash-calculations, pseudo steady-state energy balances to calculate the vapor streams within the column (c.f., Cao et al., 2016) and control laws of the PI controllers.

2.2. Advanced Process Control System

The APCS (Figure 1 (b)) is implemented using the in-house software OptoEcon Toolbox (Elixmann et al., 2014). Set-points of the base layer (PI) control are considered manipulated variables for the APCS that are used for realizing load changes, except for the liquid level in the reboiler, which is kept constant at its maximum value to ensure a complete covering of the integrated condenser. Product purities are considered controlled variables. Due to the high computational effort for nonlinear dynamic optimizations of

large-scale distillation models, the APCS is divided into a computationally intensive offline part for trajectory optimization and an online part for disturbance rejection, as suggested by Huang et al. (2009). First, an optimal trajectory is computed once for a pre-calculated load change (for instance, from quasi-stationary optimization of operating points) by solving the optimal control problem given below (see, White et al., 1996).

$$\min_{SP_i(t)} \sum_i \int_0^{t_f} \left(\frac{SP_i(t) - SP_i^*}{SP_i^*} \right)^2 dt \tag{1}$$

$$s.t.\ SP_i(t_f) = SP_i^* \qquad \forall\, i \tag{2}$$

$$\boldsymbol{h}(\boldsymbol{SP}(t)) \leq 0 \qquad \forall\, t \tag{3}$$

The objective is to minimize the quadratic relative difference between the current set-point $SP_i(t)$ of controller i and the set-point in the pre-calculated new operating point SP_i^* (Eq.(1)). End-point constraints in Eq.(2) ensure reaching the new operating point at final time t_f. The nonlinear function $\boldsymbol{h}(\boldsymbol{SP}(t))$ in Eq.(3), which is defined by the DAE model described above and relates controller set-points and purities, forces constraint satisfaction for all time points (10 ppm impurity for nitrogen and 0.5 % for oxygen). Dynamic optimizations are performed using gPROMS' built-in sequential NLPSQP solver (NL DO in Figure 1 (b)). A piecewise constant control vector parametrization is applied using a fixed grid with equally distributed control intervals. The set-point change between consecutive control intervals is further limited by an upper bound.

Second, a built-in block from the OptoEcon Toolbox for a linear time-invariant model predictive controller (LTI-MPC) calculates set-points for the base layer control to track the optimal trajectory while satisfying purity constraints. The LTI-MPC uses a linear state-space model that is obtained by linearizing the DAE once at nominal operating conditions. A prediction horizon of 16 sampling times is used, the control horizon is set to 12. Calculated set-points are provided to the plant surrogate via an OPC interface. We assume that all system states are estimated from measured outputs, i.e., state feedback, but add zero-mean white noise to simulate measurement errors. In the industrial benchmark APCS, the NL DO in Figure 1 (b) is dropped. Instead, ramps with maximum control action are applied as reference.

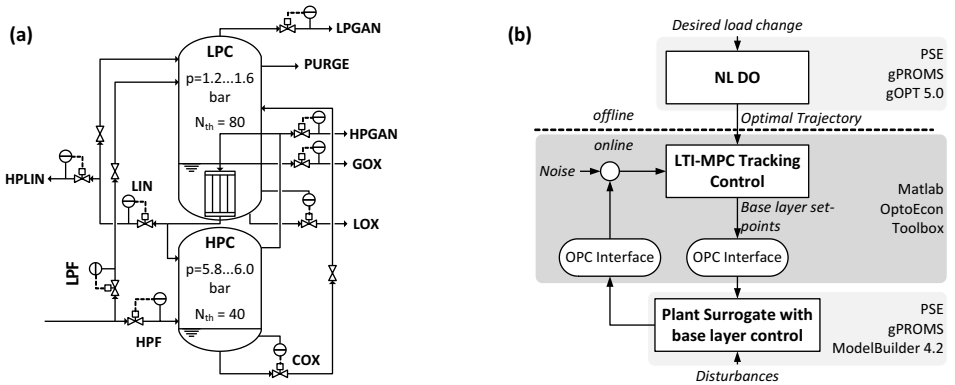

Figure 1: (a) Flowsheet of the ASU considered in this work. (b) Two-layer APCS incorporating offline nonlinear dynamic trajectory optimizations (NL DO) and online tracking control using a linear time-invariant model predictive controller (LTI-MPC).

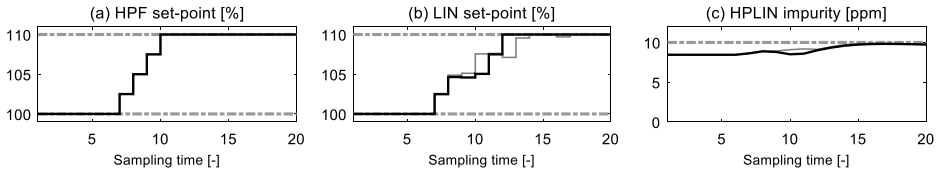

Figure 2: Temporal course of relevant process variables for a 10 % load increase of the ASU without disturbances. Solid black lines show optimal trajectories from NL DO. Thin grey lines show results of the industrial benchmark (without NL DO). Dashed-dotted grey lines show constraints.

3. Computational Case Studies and Discussion

3.1. Case Study A: Load Increase

First, we consider an operating scenario, where the ASU produces only liquids (HPLIN and LOX) that can be stored and discontinuously sold to off-site customers. The ASU can hence freely participate in the energy markets, i.e., if electricity is cheap, the load is increased in order to produce more. Likewise, if electricity is expensive, the load is decreased. For case study A, we consider a load increase by 10 % to be realized by the APCS. The comparison of the offline-optimized trajectories from NL DO solving Eq.(1) – (3) to the industrial LTI-MPC strategy (without NL DO) is given in Figure 2. In both cases, the HPF is increased with maximum allowed controller action per sampling time. If the LIN withdrawal was increased evenly, the limiting HPLIN purity constraint (Figure 2 (c)) would be violated, which requires corrective control actions. In both cases, constraint satisfaction is achieved by slower increasing the LIN withdrawal, which corresponds to a temporal reduction of the distillate-to-feed ratio that enhances the separation capacity of the column. By using the LIN trajectory from NL DO, the total transition period is reduced by 50% compared to the industrial benchmark.

In order to evaluate the disturbance rejection capacity of the proposed two-layer APCS, an unmeasured shift in HPF temperature (e.g., due to changing ambient temperature), that causes a partial condensation of the feed and that thus substantially disturbs the energy input to the column, is applied as disturbance scenario (Figure 3 (a)). We further assume zero-mean white noise on process states. Without using additional tracking control, the disturbances lead to a substantial violation of purity constraints during the load change (thin grey line in Figure 3 (c)), if the offline-optimized trajectories are applied. Using a LTI-MPC tracking control, this violation is circumvented by adjusting the distillate-to-feed ratio through temporal reductions of the LIN withdrawal compared to the offline-optimized trajectory (Figure 3 (b)) that keep the HPLIN impurity below its maximum allowed value (Figure 3 (c)).

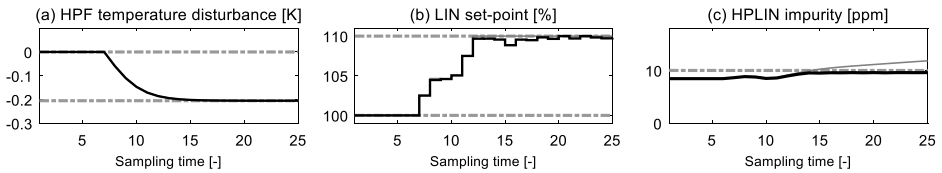

Figure 3: Temporal course of relevant process variables for a 10 % load increase of the ASU considering disturbances. Solid black lines show the simulation using the two-layer APCS. Thin grey lines show the results without tracking control. Dashed-dotted grey lines show constraints

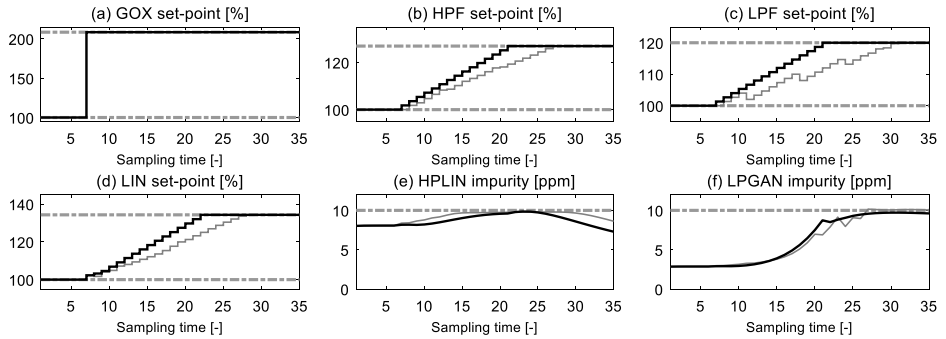

Figure 4: Temporal course of relevant process variables for a change of product mix of the ASU without disturbances. Solid black lines show optimal trajectories from NL DO. Thin grey lines show results of the industrial benchmark (without NL DO). Dashed-dotted grey lines show constraints.

3.2. Case Study B: Change of Product Mix

In the second operating scenario, an ASU with all possible products is considered. This kind of ASU has to ensure the supply of on-site customers with gaseous products. The fulfilment of supply agreements is the main objective. The ability of the ASU to participate in energy markets is thus limited to the liquid production. For case study B, we consider an instantaneous increase in GOX demand of an on-site customer (e.g., a steel mill). The increased oxygen production would lead to purity constraint violation without further measure. Thus, the operating point, in particular the liquid production, of the ASU is adjusted. We compare offline-optimized trajectories from NL DO to the industrial LTI-MPC strategy (Figure 4). Both the HPLIN impurity (Figure 4 (e)) and the LPGAN impurity (Figure 4 (f)) constraint are limiting and require corrective control actions. Similar to case study A, constraint satisfaction is ensured by temporal variations of the distillate-to-feed ratios now of both columns. We find that by applying input trajectories from the NL DO (Figure 4 (b) – (d)), transition periods are again substantially reduced by 37.5 % compared to the industrial benchmark.

Disturbance rejection capacity of the APCS is evaluated for this load change as well by introducing a shift in HPF temperature (Figure 5 (a)) and zero-mean white noise on process states. Similar to case study A, severe violations of both impurity constraints in case of missing tracking control can be avoided using a LTI-MPC (Figures 5 (e) and (f)), which in particular adjusts the LIN withdrawal from the HPC (Figure 5 (d)).

4. Conclusion

A two-layer APCS is proposed for an industrial-scale ASU. Load-change performance of the APCS is evaluated in two case studies using the in-house software OptoEcon-Toolbox. We show that by applying offline-computed trajectories from dynamic optimization of a nonlinear process model, transition periods for characteristic load changes can be significantly shortened, increasing the plant's agility. We further demonstrate that offline-optimized trajectories can be tracked in the presence of unknown disturbances without violating severe purity requirements by using industrial LTI-MPC controllers. Our results indicate a high potential of nonlinear model predictive control (NMPC) for industrial DSM, as quicker but still safe load changes are enabled. This is desirable in order to benefit from volatile energy markets, in particular from short-term spot market price peaks, such as negative electricity prices, that are expected to become more frequent. Future research should focus on the integration of economic objectives

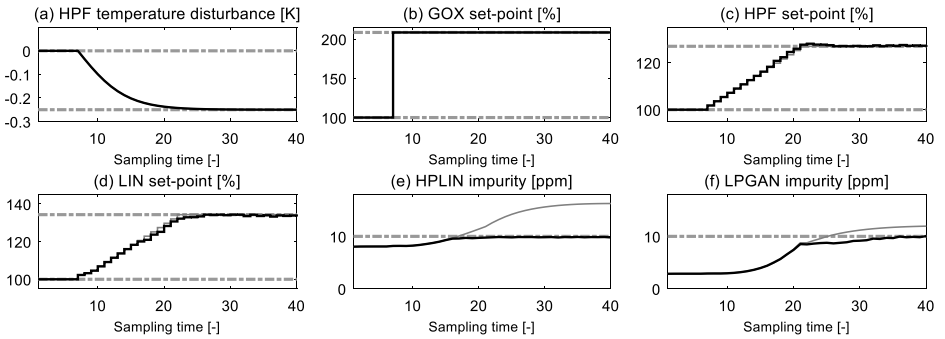

Figure 5: Temporal course of relevant process variables for a change of product mix of the ASU considering disturbances. Solid black lines show the simulation using the two-layer APCS. Thin grey lines show the results without tracking control. Dashed-dotted grey lines show constraints.

into the trajectory optimization to allow for a closed-loop economic NMPC. Particularly, this includes the incorporation and validation of reduced dynamic models for the distillation columns, such as, e.g., collocation-based models as suggested by Cao et al. (2016), in order to reduce the high computational demand of solving the NL DO problem.

Abstract

With recent advances in industrial automation, data acquisition, and successful applications of Machine Learning methods to real-life problems, data-based methods can be expected to grow in use within the process control community in the near future. Model-based control methods rely on accurate models of the process to be effective. However, such models may be laborious to obtain and, even when available, the optimization problem underlying the online control problem may be too computationally demanding. Furthermore, the process degradation with time imposes that the model should be periodically updated to stay reliable. One way to address these drawbacks is through the merging of Reinforcement Learning (RL) techniques into the classical process control framework. In this work, a methodology to tackle the control of nonlinear chemical processes with RL techniques is proposed and tested on the well-known benchmark problem of the non-isothermal CSTR with the Van de Vusse reaction. The controller proposed herein is based on the implementation of a policy that associates each state of the process to a certain control action. This policy is directly deduced from a measure of the expected performance gain, given by a value function dependent on the states and actions. In other words, in a given state, the action that provides the highest expected performance gain is chosen and implemented. The value function is approximated by a neural network that can be trained with pre-simulated data and adapted online with the continuous inclusion of new process data through the implementation of an RL algorithm. The results show that the proposed adaptive RL-based controller successfully manages to control and optimize the Van de Vusse reactor against unmeasured disturbances.

Keywords: Reinforcement Learning; Model Predictive Control; Adaptive Control.

1. Introduction

In the past few decades the process industry has experienced a large increase in automation and data acquisition systems, and as acquiring good quality and reliable data becomes easier and cheaper, data-based methodologies become more susceptible to application. Machine Learning and Data Science methods have grown in importance

outside of the process community, driven by successful applications in real-life problems. It is important for the process industry to explore the application of data-based methods, and incorporate the most successful ideas to the traditional process control framework.

Another incentive for the application of data-based methods arises from the drawbacks of classical model-based control. Most model predictive control (MPC) methods still rely on the assumption of linearity, which is not true for the majority of chemical processes. Nonlinear MPC (NMPC) methods may be applied, but they require a nonlinear process model that may be laborious to obtain. In addition, solving the NMPC optimization problem may be too computationally demanding for online applications.

In order to tackle some of the aforementioned problems, a control approach based on model-free learning may be used. In the process control community model-free control strategies have been proposed since the early 1960s, while in the artificial intelligence community the field of reinforcement learning (RL) was developed during the 1980s, focusing on the design of control algorithms that work solely based on data (Busoniu *et al.*, 2010). There is not yet a vast literature on the application of RL techniques to the control of chemical processes, as evidenced by Syafiie *et al.* (2008), but a few authors proposed general purpose model-free controllers in the past. Stenman (1999) proposed a partially model-free approach combining MPC with adaptive techniques that estimate linear models online, called model-on-demand. Lee and Wong (2010) proposed a modification to the stochastic MPC framework based on approximate dynamic programming (ADP), and explored different aspects of the problem such as parametric vs. nonparametric value function approximators, and batch vs. continuous learning. Morinelly and Ydstie (2016) formulated an adaptive optimal control algorithm for systems with uncertain dynamics, called RL dual MPC (RLdMPC), in which an exploratory component is embedded in the objective function of the MPC and the competing results of the optimal solution and the cost function approximation provide a balance in exploration and exploitation.

Focusing on the application of RL techniques to chemical processes, Hoskins and Himmelblau (1992) proposed a neural network (NN) based control, in which two different NN models are used to predict the control performance measure and the control action/policy. Martinez (2000) proposed a sampling strategy (sequential experiment design) based on RL for optimization of batch processes, where the RL solution is used to systematically shrink the region of interest for the optimization. Syafiie *et al.* (2008) proposed a model-free learning control method based directly on RL techniques, more specifically on Q-learning with finite-discrete action space. Although easy to implement, the discrete version of Q-learning may not be the most appropriate for chemical processes, in which states and actions are continuous and must be discretized to obtain a good representation. Shah and Gopal (2016) proposed a model-free predictive control, employing a fuzzy inference system to approximate the value function. While the fuzzy model may account for uncertainties, it is still subject to the curse of dimensionality and requires tuning of many localized parameters.

In the present work, an adaptive controller based on an RL algorithm with value function approximation via NN is proposed and tested for the control of a nonlinear non-isothermal CSTR with the Van de Vusse reaction. We aim to assess the application of the RL algorithm to a chemical process, while addressing aspects such as continuous representation of states, combined optimization and control, and comparison with linear MPC.

2. Methodology

The problem addressed by RL is that of decision-making. An agent (a controller in our case) receives information about the state x of the system (process) and implements a policy, a mapping from the states into actions, which defines which action the controller has to take based on the actual state of the process. This policy is derived from the so-called action-value function $Q_{(x,u)}$, computed from data by an RL algorithm, that assigns an expected performance gain or return value G over time to every possible state-action pair. In our work, a multilayer perceptron (MLP) NN is employed to approximate $Q_{(x,u)}$ in order to use a continuous representation of the states.

A policy iteration algorithm is used to compute the policy used by our controller. Iteratively, the action-value function for the actual policy is evaluated using the Monte Carlo policy evaluation and the policy is then improved using the well-known *ε-greedy* algorithm (Busoniu *et al.*, 2010), in which the action that leads to the maximum value function is chosen with a $1-\varepsilon$ probability. Otherwise, a random action is taken to help guaranteeing that all the actions are considered in the optimization of the return value in a given state. The NN is trained taking into account the states and actions as inputs and the expected return value as output.

Different configurations of the controller are tested in this work:

(i) Pre-trained non-adaptive RL-based Controller (RL-C): the NN is only trained with pre-simulated data corresponding to different initial steady-state conditions randomly selected.

(ii) Untrained adaptive RL-C: the NN is only trained with the process data acquired online. In this case, a step control is used to take into account the difference e_{k-1} between the predicted reward from the NN model and the actual reward obtained in the last step. The control action is limited when the NN model is not capable to correctly predict the outcome, as it is shown in Eq. (1), where a_k^P is the action predicted by the NN and a_k^R the action really taken by the controller.

$$a_k^R = a_k^P\left(1 - 0.95 \cdot 1/(1 + e^{|e_{k-1}|})\right) \quad (1)$$

(iii) Pre-trained adaptive RL-C: the NN is pre-trained and continues to be trained online. Two hidden layers of seventy neurons are used by the NN model. The hidden layers use logistic functions and the output layer a linear one. The NN training is performed using MATLAB NN toolbox, which provides batch and online algorithms. 80% of the available data were used for training, 10% for validation and 10% for testing.

3. Results

3.1. Process description

The performance of the proposed controller is tested through the simulation of the control of a non-isothermal CSTR, with the Van de Vusse reaction, as described by Klatt and Engel (1998). The reaction consists in the synthesis of cyclopentenol (B) from cyclopentadiene (A) by acid-catalyzed electrophilic addition of water in a dilute solution. Due to the strong reactivity of both A and B, dicyclopentadiene (D) is produced by the Diels-Alder reaction as a side product, and cyclopentanediol (C) as a consecutive product by addition of another water molecule. It is usually desirable to maximize the production of component B, while minimizing the production of C and D. The reaction is presented in Eq. (2), and the mass and energy balances in Eq. (3) to (5), where $C_{i,in}$ and C_i are the inlet and outlet concentration of the i-th component, $k_{j(T)}$ is

the reaction rate parameter for reaction j (according to Arrhenius law), ΔH_{R_j} is the constant heat of reaction j, T_k is the jacket temperature, and other parameters are as defined in classical notation. The parameters values can be found in Klatt and Engel (1998).

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \qquad 2A \xrightarrow{k_3} D \tag{2}$$

$$\frac{dC_A}{dt} = \frac{F}{V}\left(C_{A,in} - C_A\right) - k_1(T)C_A - k_3(T)C_A^2 \tag{3}$$

$$\frac{dC_B}{dt} = \frac{F}{V}\left(C_{B,in} - C_B\right) + k_1(T)C_A - k_2(T)C_B \tag{4}$$

$$\frac{dT}{dt} = \frac{1}{\rho \cdot C_p}\left[k_1(T)C_A\left(-\Delta H_{R_1}\right) + k_2(T)C_B\left(-\Delta H_{R_2}\right) + k_3(T)C_A^2\left(-\Delta H_{R_3}\right)\right] + \frac{F}{V}(T_{in} - T) + \frac{K_w A_R}{\rho\, C_p\, V}(T_k - T) \tag{5}$$

This process was chosen due to its nonlinear characteristics, the most important of those being the gain inversion of the product concentration C_B with respect to inlet flow F. The location of the gain inversion depends on the reactor temperature T, which in turn is controlled by manipulating the cooling jacket temperature T_k.

3.2. Controller definition

The actions vector u includes the manipulated variables inlet flow F and cooling jacket temperature T_k increments. The state vector x includes the outlet concentrations C_A and C_B, the reactor temperature T, and the manipulated variables F and T_k. The control objective is to track a certain F_B ($F.C_B$) while maximizing C_B. The corresponding instantaneous reward R is defined in Eq. (6), where F_B^{SP} is the setpoint for F_B and the subscript k corresponds to the time instant. The proposed reward function prioritizes the set-point tracking of F_B (the sigmoidal function used goes to 1 when the difference between F_B and its set-point is large). Then, when F_B is close to the set-point, the reward starts to focus on the optimization of C_B. The weight w is used as a tuning factor. The return G, or accumulated reward, is simply defined as the discounted sum of rewards, as shown in Eq. (7), where $\gamma \in [0,1]$ is the discount factor, a measure of how "far-sighted" the controller is in considering its rewards.

$$R(k) = |F_B(k-1) - F_B^{SP}| - |F_B(k) - F_B^{SP}| + w \cdot [C_B(k) - C_B(k-1)]\left\{1 - 1\Big/\left(1 + e^{\left|\frac{F_B(k) - F_B^{SP}}{F_B^{SP}}\right|}\right)\right\} \tag{6}$$

$$G(\hat{k}) = \sum_{k=0}^{\hat{k}} \gamma^k R(k) \tag{7}$$

3.3. Initial Conditions

The initial conditions used for the NN model training in different episodes are random steady states for different values of F and T_k, with $C_{A,in} = 5.1$ mol/L, $C_{B,in} = 0$ mol/L and T_{in} = 110 °C. The initial steady state considered for the following results is defined by $F = 1000$ L/h and $T_k = 100$ °C, with the same conditions for $C_{A,in}$, $C_{B,in}$ and T_{in} as for training. The F_B set-point was set to 2000 mol/h. The time step used for all simulations was 0.01 h.

3.4. Process Control/Optimization without disturbances

In this section, the performance of the pre-trained non adaptive RL-C, the untrained adaptive RL-C, the linear MPC controller and the nonlinear MPC (NMPC) are compared when changes in the operating conditions take place and no disturbances enter the system. The model of the MPC is obtained from the linearization of the nonlinear model defined in Section 3.1 at the initial condition, when disturbance steps of ±10% are applied to the manipulated variables. The NMPC uses the complete model of the system.

The results in Figure 1 show that the linear MPC is not able to maintain F_B at the desired set-point. This system presents a gain inversion of C_B with respect to the manipulated variables, which means the available model given to the MPC is no longer accurate. The NMPC is the first to achieve the desired set-point of F_B, but takes more time than the pre-trained RL-C to reach the maximum of C_B. The pre-trained non adaptive RL-C, having been trained with data from different initial conditions, quickly manages to bring F_B to its set-point while maximizing C_B. Lastly, the untrained adaptive RL-C expresses a behavior that is initially similar to the linear MPC strategy, but then manages to change its course employing actions that are more similar to the pre-trained NN model. In addition, it is possible to verify that the untrained adaptive RL-C first takes actions that brings F_B to its set-point, and then starts to make changes in the system to optimize C_B (the control strategy "walks" in the F_B set-point curve).

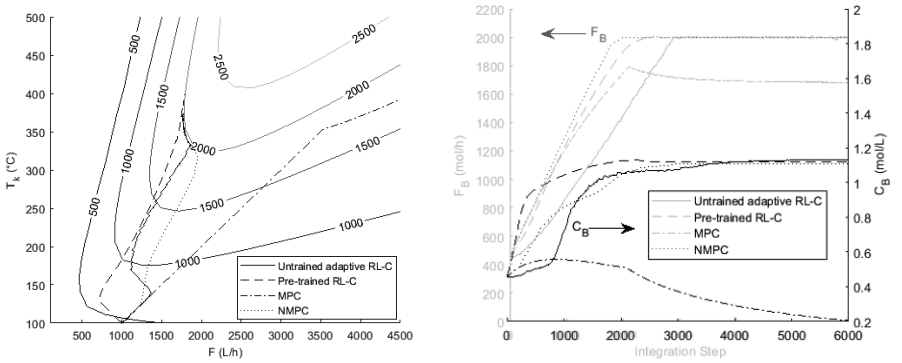

Figure 1. Simulation results without unmeasured disturbances

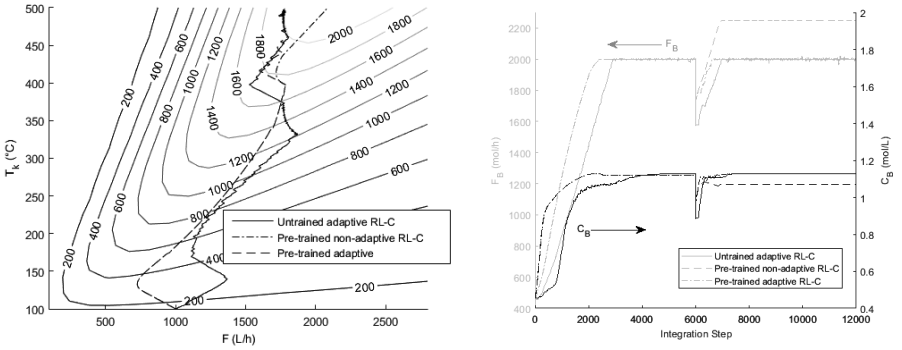

Figure 2. Simulation results with unmeasured disturbance

3.5. Process Control/Optimization with unmeasured disturbances

In this section, the performances of the three configurations of the RL-C defined in the methodology section are compared when an unmeasured disturbance occurs (the inlet temperature T_{in} changes from 110 ºC to 90 ºC at time step 6000). The results in Figure 2 show that both pre-trained strategies have the same behavior when the system is not disturbed. However, as expected, after the unmeasured disturbance occurs, only the pre-trained adaptive RL-C is able to bring the system back to the F_B set-point and to adapt to the new process conditions that are different from the ones used for training. In addition, the untrained adaptive RL-C also manages to bring F_B back to its set-point and to optimize C_B before and after the unmeasured occurs, although in a less efficient way, showing that the previous knowledge from the data can enhance its performance.

4. Conclusions

In this work a continuous RL algorithm was applied to the problem of adaptive control of chemical processes, in particular of chemical reactors with nonlinear response and gain inversion. A MLP neural network model was used to represent the action value function in terms of the continuous states and actions, which could be initially trained with a batch of pre-simulated process data. The results show that the adaptive RL-based controller successfully manages to control and optimize the Van de Vusse reactor against unmeasured disturbances and verify that the use of previous data from the system can help the NN model to adapt in a better way to changes in the system's behavior.

Abstract

Key polymer properties are substantially based on the polymer molecular weight distribution (MWD). Modeling polymerization processes using kinetic-based approach involves the mass balances for all chain types and for all possible chain lengths. These models exhibit the nature of large-scale dynamic system. The numerical solution is computationally expensive and is challenging when applied for optimization problems. In this work, we proposed a reduced order model of MWD in dynamic systems. The basic idea is to reformulate the population balances to decompose the coupling in the chain lengths. We present a kind of model reformulation based on null-space projection method. The reformulation separates the fast equilibrium of living chains and the accumulative dead chains. Moreover, the coupling in the living chain lengths is decomposed by further derivation. Thus, the calculation of all possible chains is avoided. The large-scale MWD model is reduced to a much smaller scale one. Simulation results show that the computational cost is significantly reduced without essentially affecting the accuracy performance of the model. The model is also applied to a grade transition case study, which provides the prospection of dynamic optimization, state estimation and model predictive control based on MWD.

Keywords: Molecular weight distribution, Model order reduction, Dynamic optimization, Polymerization

1. Introduction

Research on polymer modeling is essential in precisely tuning the properties of polymers produced. The polymer model plays an important role in polymerization process monitoring, optimization and control. Modeling of a polymerization process for optimization depends on what kind of quality index is considered. Key polymer properties are substantially related to the polymer molecular weight distribution (MWD) (Soares et al. 2012). Modeling polymerization processes using kinetic-based approach involves the mass balances for all chain types and for all possible chain lengths. These balances, the so-called “population balances” can then be simultaneously solved to obtain the properties of each individual chain, which can derive the full MWD or average molecular weight (AMW). However, theoretically this requires simultaneously solving an infinite number of equations. For most macro quality indices, such as AMW, one can reformulate the population balances via moment method (Mastan et al. 2015). But for microstructural indices such as MWD, population balances are still necessary in many cases. Though the Flory distribution is applied in many steady state situations, it does not apply for dynamic processes. In general, it is not possible to find an analytical solution of the MWD in non-steady state. One can solve the population balances directly or cumulate the instantaneous

MWDs using pseudo steady state assumption (Soares et al. 2012; Weng et al. 2015). Either of the two approaches involves solving a large-scale dynamic system. Therefore, model reduction is required to improve the computational efficiency, particularly for the sake of process optimization and real-time applications, such as state estimation and model predictive control.

There are generally two types of methodologies of model reduction. One is the black-box approach, which generates surrogate models using data-driven techniques. The other is the physics-based approach, which manipulates the structure and equations of the rigorous model to find a lower dimensional approximation. In polymerization processes, the kinetic are highly nonlinear and the MWDs are high-dimensional output. It is difficult and expensive to surrogate the MWD or even the polymerization process (Kang et al. 2017). Research efforts have been made to reduce the computational expenses for MWD models. Saliakas et al. (2007) employed collation method and fixed pivot to calculate the dynamic MWD. Weng et al. (2015) speeded up dynamic simulation of MWD by multi-thread parallel computation. In this work, the model reformulation approaches are investigated to reduce the dynamic MWD model.

In this paper, we proposed a reduced order model of MWD in dynamic systems. The basic idea is to reformulate the population balances to decompose the coupling in the chain lengths. A reformulated MWD model based on null-space projection method (Nie et al. 2013) is presented. The reformulation separates the fast equilibrium of living chains and the accumulative dead chains. Moreover, it is worth to note that the coupling in the living chains are decomposed. Thus, the calculation of all possible chains are avoided. The MWD model is significantly reduced without essentially loss of model information. This benefits computational efficiency for on-line monitoring, dynamic optimization and control for polymerization processes based on MWD.

2. Dynamic Molecular Weight Distribution Models

Population balance is widely accepted to model the polymerization process. The mass balances for all chain types and for all possible chain lengths are derived in this method. These balances can be simultaneously solved to obtain the molecule fraction of each individual chain. MWD is derived based on the information of each chain calculated. Taking the high-density polyethylene (HDPE) process as an example, population balances for the living and dead chains in the reactor can be derived using the kinetic mechanism in Kang et al. (2017).

By assuming that the polymerization happens in a CSTR, the following population balances are applied to monomer-free active sites $P_0(j)$, living chains with length r $P_r(j)$, and dead chains with length r $D_r(j)$:

$$\frac{dP_0(j)}{dt} = k_{aA}(j)C_p(j)A - k_p(j)MP_0(j) + \left(k_{tH}(j)H_2 + k_{tA}(j)A + k_t(j)\right)\sum_{r=1}^{N_T} P_r(j) - k_d(j)P_0(j) \quad (1a)$$

$$\frac{dP_r(j)}{dt} = -k_p(j)M\left(P_r(j) - P_{r-1}(j)\right) - \left(k_{tH}(j)H_2 + k_{tA}(j)A + k_t(j)\right)P_r(j) \quad (1b)$$

$$\frac{dD_r(j)}{dt} = \left(k_{tH}(j)H_2 + k_{tA}(j)A + k_t(j)\right)P_r(j) \quad (1c)$$

where $j \in \{1, 2, \dots, N_s\}$ is the active site and N_T is the maximum length of chain considered, which could be 100000 or more.

The mass balances of monomer *M*, hydrogen H_2, catalyst $C_p(j)$ and cocatalyst *A* are:

$$\frac{dM}{dt} = -\sum_{j=1}^{N_s}\sum_{r=0}^{N_T}(k_p(j) + k_{tM}(j))MP_r(j) \quad (1d)$$

$$\frac{dH_2}{dt} = -\sum_{j=1}^{N_s}\sum_{r=1}^{N_T} k_{tH}(j)H_2P_r(j) \quad (1e)$$

$$\frac{dC_p(j)}{dt} = -k_{aA}(j)C_p(j)A \quad (1f)$$

$$\frac{dA}{dt} = -\sum_{j=1}^{N_s} k_{aA}(j)C_p(j)A \quad (1g)$$

Eqs. (1a)-(1g) is a 0-DOF system which contains $2N_TN_s + 2N_s + 3$ differential equations and $2N_TN_s + 2N_s + 3$ variables. The dynamic MWD is calculated by

$$w_r(t) = \frac{\sum_{j=1}^{N_s} r(P_r(j)+D_r(j))}{\sum_{r=1}^{N_T}\sum_{i}^{Ns} r(P_r(j)+D_r(j))} \quad (2)$$

The dynamic MWD model above is computational expensive due to the extremely large scale nature. The population balances can be reduced to a much smaller set of equations by applying moment method. However, the information about individual chains is sacrificed, thus it is not able to predict the full MWD. Though the Flory distribution can be derived at steady-state, it is only valid instantaneously. The conventional method for the dynamic MWD simulation accumulates the instantaneous distribution in short time intervals (see Soares et al. 2012). This integration process is also time consuming and some parallel computation techniques can help speed up (Weng et al. 2015). Moreover, this cumulative MWD method is not applied for dynamic optimization problems because of its nested calculation nature. To overcome these computational difficulties, we propose a reformulated population balance for dynamic MWD.

3. Dynamic Reduced Order Models

In this section, we present a kind of model reformulation based on null-space projection method. Among the polymerization reactions, the propagation rates $k_p$are significantly higher than those of the other rates. Thus, the living chains and dead chains showed quite different behaviors. The living polymer chains are fast consuming, and the life time is in the order of seconds. The dead polymer chains are slowly cumulative, and the life time can be long as the resistance time of the polymerization. The population model consequently leads to a two-time scale model and incurs numerical calculation issues. Given that the dynamic MWD is determine by the dead polymer chains, it is reasonable to separate the two-time scale behaviors.

The population balances in Eq (1) can be described by the following equation:

$$\dot{x} = \mathrm{A}r(x) \quad (3)$$

where $x \in R^{n_x}$ is the vector of component concentrations or populations, $r(x) \in R^{n_r}$ is the vector of reaction rates, A is the coefficient matrix. By partitioning the fast rate reactions, the following system is obtained:

$$\dot{x} = [A_1 \ A_2][r_1(x) \ \sigma r_2(x)]^T \quad (4)$$

where $\sigma r_2(x)$ represents the fast reaction rates, and σ is a large positive number that can approach infinity. A nullspace matrix Z is introduced such that $Z^TA_2 = 0$, and a corresponding matrix Y is also defined ensuring $[Y \ Z]$ to be nonsingular. Multiplying $[Y \ Z]^T$ to both sides of Eq. (4) gives

$$Y^T\dot{x} = Y^T A_1 r_1(x) + \sigma Y^T A_2 r_2(x) \tag{5a}$$

$$Z^T\dot{x} = Z^T A_1 r_1(x) \tag{5b}$$

Eq. (5b) does not include the fast reaction rates and is kept as part of the reformulation system. The matrices in Eq. (5a) is partitioned and arranged:

$$[Y_a^T \;\; Y_b^T]^T\dot{x} = [Y_a^T \;\; Y_b^T]^T A_1 r_1(x) + [0 \;\; \sigma f(x)]^T \tag{6}$$

where $f(x)$ is the non-zero elements in $Y^T A_2 r_2(x)$.

When $\sigma \to \infty$, $f(x) = 0$ is required to maintain the equation unaffected. This condition sketches the fast equilibrium manifold of the reaction system and contributes to part of the reformulated system. Finally, the reformulated system is derived:

$$Y_a^T\dot{x} = Y_a^T A_1 r_1(x) \tag{7a}$$

$$f(x) = 0 \tag{7b}$$

$$Z^T\dot{x} = Z^T A_1 r_1(x) \tag{7c}$$

By applying the nullspace projection method, the reformulated model of Eq. (1) can be derived after a sequence of matric operations. The reformulated mass balance that corresponds to Eq. (7a) are the monomer free sites:

$$\frac{dP_0(j)}{dt} = k_{aA}(j)C_p(j)A - k_d(j)P_0(j) \tag{8}$$

The fast equilibrium that corresponds to Eq (7b) are the living polymer chains, which can be

$$k_p(j)MP_0(j) - \big(k_{tH}(j)H_2 + k_{tA}(j)A + k_t(j)\big)Y(j) = 0 \tag{9}$$

$$k_p(j)M\big(P_r(j) - P_{r-1}(j)\big) - \big(k_{tH}(j)H_2 + k_{tA}(j)A + k_t(j)\big)P_r(j) = 0 \tag{10}$$

where $Y(j) = \sum_{r=1}^{N_T} P_r\,(j)$ is introduced as a new component.

The remained population balances that corresponds to Eq. (7c) are the slow cumulative dead polymer chains and the rest of the reactants. These balances remain the same by

substituting the $Y(j) = \sum_{r=1}^{N_T} P_r\,(j)$ definition into Eqs. (1c)-(1g).

The original population balance containing $2N_TN_s + 2N_s + 3$ equations in Eq. (1) is reduced to a DAE with $N_TN_s + 2N_s + 3$ differential equations and $N_TN_s + N_s$ algebraic equations. Moreover, it is worth to note that the decomposition of coupling in living chain lengths is accomplished by further substitution of Eq. (10):

$$P_r(j) = \left(\frac{k_p(j)M}{k_p(j)M + k_{tH}(j)H_2 + k_{tA}(j)A + k_t(j)}\right)^r P_0(j) \tag{11}$$

The dynamic MWD is calculated by adding another differential equation

$$\frac{dC}{dt} = \sum_{j=1}^{N_s}(k_p(j) + k_{tM}(j)MY \tag{12a}$$

$$w_r(t) = \frac{\sum_j^{N_s} rD_r(j)}{C} \tag{12b}$$

By combining the reformulated population balances Eqs. (1c)-(1g), (8), (9), (11) and (12), a chain-decoupling model is obtained. This model provides the property of discretized sampling in large chain intervals. One does not need to calculate all the chains to obtain a MWD profile. Thus, the reformulated model can figure out a MWD profile using $2\delta N_T N_s + \delta N_T + 3N_s + 4$ equations compared to the original model with $2N_T N_s + N_T + 2N_s + 3$ equations, where δN_T can be less than 100 but N_T can be 100000 or more.

4. Numerical Results

In this section, the proposed dynamic MWD model is validated by comparing with the conventional method in Weng et al. (2015). The conventional method accumulates the instantaneous Flory distribution in short intervals by applying pseudo steady state assumption. On the other hand, the proposed dynamic MWD model is transcript from DAEs to NLP and IPOPT is employed as the solver. The simulation for a grade transition process is presented. The number of active sites N_s is 5 in this case. The dynamic MWDs along time calculated by the two methods are compared in Figure 1.

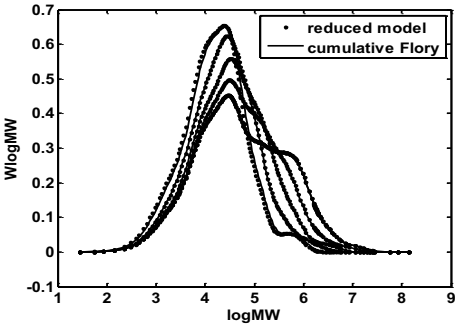

Figure 1. Dynamic MWDs along time with reduced model and cumulative Flory method

In the simulation case, the number of chains calculated in the reduced model were set as 40, i. e. $\delta N_T = 40$. These chains can be sampled very flexibly. In this case, the chain lengths are discretized evenly in logarithm scale. It indicates that the reduced model is predictive without essentially affects the performance. It achieved the same prediction performance as that of cumulative Flory method, which calculates over 50000 chains.
The model scale and computational efficiency of the reduced order model and cumulative Flory methods are further investigated. Despite the traditional serial computation of cumulative Flory method, parallel cumulative Flory method (Weng et al. 2015) is also tested for comparison.

Table 1. Model scale of the reduced order model and cumulative Flory method

Index	Chain calculated	Population balances	Moments	MWD equations
Reduced order model	40	213	-	41
Serial cumulative Flory method	50000	13	30	100000
Parallel cumulative method	50000	13	30	100000

Table 1. presents the equations that are solved in the reduce order model and cumulative Flory method. The reduced order model has the capability to solve a manageable number of population balances to derive the dynamic MWD. However, the cumulative Flory

method cannot deal with the large-scale population balances, and spends most of the computational efforts in MWD equations.

Table 2. presents the computational efficiency of reduced order model, serial cumulative Flory method, and parallel cumulative Flory method. Among the three methods, the reduced order model is the most efficient with a total cost of 12.1 s. It significantly reduced the time cost by more than 90% compared to the serial cumulative Flory method

Table 2. Computational efficiency of the three methods

Index	Thread	Moments (s)	MWD in sites (s)	Total (s)
Reduced order model	1	-	-	12.1
Serial cumulative Flory method	1	40.7	86.2	126.9
Parallel cumulative method	5	40.7	20.4	70.3

5. Conclusions

In this paper, a reduced order model is proposed for predicting MWD in dynamic systems. The original population balances are reformulated by applying null-space projection method. The fast equilibrium for living chains and slowly accumulative dead polymer chains are separated. Moreover, the coupling in chain lengths of the living polymers are decomposed. This decomposition significantly reduced the scale of necessary population balances to obtain the MWD. Numerical results indicate that the reduced model is predictive without essentially affects the performance. It significantly improves the computational efficiency and provides the prospective of real-time applications. Future work will focus on the on-line monitoring and optimal control based on MWD.

Abstract

Batch crystallization is still one of the most commonly used processes in the pharmaceutical industry. Indeed, due to the flexibility of the process and the possibility of changing the product specification, the batch process is still the main choice. However, crystallization is a highly non-linear process and therefore difficult to model and simulate. Moreover, uncertainty in physical parameters and uncertainty propagation from previous process outputs has an important and critical influence on the process risk and therefore the control strategy needed to achieve robust process performance.

To this end, a two dimensional population balance model of ibuprofen batch crystallization is developed and used to analyse and study the operability space, where uncertainty is included. The uncertainty comes from previous synthesis steps and from reported uncertainty in the process parameters, described in the literature. A nonlinear control strategy is then applied, comparing different radial basis functions (quadratic, cubic, Gaussian…), in order to achieve the desired mean size by manipulating and updating the cooling profile of the same process.

The resulting three operation strategies are benchmarked with respect to key performance metrics (reference trajectory, deviation and input variation): open-loop, open-loop strategy under process uncertainties, and closed loop operation subject to process uncertainties. The final mean crystal size (MCS) is reported as a confidence interval, in order to be used for further downstream processing.

Keywords: modelling, Ibuprofen crystallization, process control, process uncertainty

1. Introduction

For traditional pharmaceutical industry, separation processes and strict time schedules are two common discussed topics. The former topic usually takes place in the form of batch units, mainly composed by distillations, filtrations and crystallizations amongst others. These operations are rather complex, expensive, and generate waste (such as solvents). Moreover, some of these steps might propagate deviations/disturbances for the next consecutive process unit, commonly referred as uncertainty in the process variables. New strategies are needed to the process understanding and drug development, such as the as the usage of principles of chemistry, engineering, material science, and quality control (Escotet-Espinoza et al. 2015). In addition, as encouraged by the U.S. Food and Drugs Administration (FDA), the use of Process Analytical Technology (PAT) tools to certify and control the end product quality and requirements

is of major importance for the whole process risk assessment. This leads to a necessity of implementing fast, reliable and easy to use control strategies and online monitoring, that takes into account or counters previous uncertainty. This is especially important when moving from lab-scale to mini-plant or pilot-plant, where time schedules are tight, and every day before a patent expiration is important, and valuable.

In this work, a control-strategy based on Radial Basis Functions Networks (Orr, 1996) is applied to a population balance Ibuprofen crystallization unit. This cooling crystallization operates in discontinuous mode, and the modelling parameters are adapted from available literature. The model construction and simulation is based in a Matlab/Simulink interface (The MathWorks®, Natick, MA), and the outputs are used to simulate the control strategy, that uses a reference trajectory of the mean size crystal to predict and actuate on the temperature profile, over the simulation time. The mean size is predicted using different Radial Basis Functions, evaluating them, and then re-simulate the system, with uncertainty in different parameters. We note that the objective of this work is not to provide the optimal control, but a fast and reliable method for upscaling processes when data is uncertain or missing.

2. Nomenclature

Symbol	Description	Units
C_{sat}	Saturation concentration	$g_{Sol}/g_{Solvent}$
k_{gx}	Growth rate constant in x direction	$\mu m/min.(g_{Sol}/g_{Solvent})$
G_x	Linear growth rate	μm/min
ρ_c	Crystal density	kg/m^3
ρ_w	Water density	kg/m^3
x_w	Water mass fraction	$g_{Water}/g_{Solvent}$
T_w	Serpentine water temperature	Celsius
$T_{w,in}$	Water Inlet temperature	Celsius
T_{cryst}	Crystallizer temperature	Celsius
C_{ibu}	Ibuprofen concentration	$g_{ibu}/g_{solvent}$
S_{sat}	Supersaturation	$g_{sol}/g_{solvent}$
$C_{p,i}$	Heat capacity	kJ/kg/K
ΔH_c	Heat of formation of crystal	kJ/kg
$V_{form,crystal}$	Volume of formed crystal	m^3
U	Heat transfer coefficient	$W/(m^2.K)$
A	Cooling area	m^2
$F_{w,in}$	Cooling water flow	m^3/s

3. Methodology

3.1. Model development

The population balance crystallization model is built using the method of classes, for two dimensions:

$$\frac{dN_{i,j}}{dt} + f_{i,j} - f_{i,j}^{"} = B_{nuc} \tag{1}$$

Where $f_{i,j}$ represents the inlet or outlet flux of crystals from nearby classes. For an inlet flux, for example:

$$f_{i,j} = \frac{G_{x,i-1}N_{i-1,j}}{2C_{x(i-1)}} + \frac{G_{y,j-1}N_{i,j-1}}{2C_{y(j-1)}} \tag{2}$$

Where C_x and C_y represent the discretization space, or the classes. Fort this population balance model (PBM), the linear growth rate described in the literature (Rashid et al. 2010). For instance, for the growth along the x characteristic length

$$G_x = k_x {S_{sat}}^n \tag{3}$$

$$S_{sat} = \max(0, \frac{C_{ibu} - C_{sat}}{C_{sat}}) \tag{4}$$

$$C_{sat} = 0.495 + 0.001026 {T_{cryst}}^2 \tag{5}$$

$$\frac{dT_{cryst}}{dt} = \frac{-\Delta H_c \rho_c V_{form,cryst} - UA(T_{cryst} - T_w)}{\rho_{magma} V c_{p,magma}} \tag{6}$$

$$\frac{dT_w}{dt} = \frac{F_{w,in}\rho_{water}C_{p,water}(T_{w,in} - T_w) + UA(T_{cryst} - T_w)}{\rho_{water}V_{water}c_{p,water}} \tag{7}$$

The birth rates were adapted from literature (Rashid et al. 2011), as well as the saturation profile for Ibuprofen in an ethanol/aqueous solution. Parameters for equation 6 were adapted from literature (Nayhouse et al. 2015)

3.2. Simulation

The assembled model is simulated with two cooling profiles: an initial linear decrease of temperature from 32 to 28 degrees (30 minutes), followed by an exponential decrease as stated in equation 9, until 12 degrees:

$$T_{w,in:t>30m} = 28 - (28 - 12)(\frac{(t - 30)}{Time_{simulation\ end} - 30})^{1.5} \tag{8}$$

This profile avoids secondary nucleation, while keeping the supersaturation levels high enough for a steady crystal growth. The resulting evolution of the mean crystal size is used for reference for the rest of this work.

3.3. RBF implementation

Radial Basis Functions (RBF) uses a series of basis functions that are symmetric and centered at each sampling point. The main feature of these functions is that their response decreases, or increases, monotonically with distance from a central point. The centre, the distance scale and the precise shape of the radial function are parameters of the model (Jin et al. 2002). Three different basis functions are tested for the RBF

network: Inverse Multiquadratic (IMQ), Thin Plate Spine (TPS) and Biharmonic (BH) (Jekabsons, 2009). Equation 9 represents the radial basis function node of TPS:

$$\Phi(dist) = dist\ \ln(dist) \tag{9}$$

3.4. Simulation with uncertainty

Selecting one of the different basis functions, the system is then simulated with different uncertainties (or disturbances in the initial conditions and parameters). The reference mean size of the crystal trajectory is the same as the undisturbed case study, in order to determine if the control system is able to detect and actuate on different conditions.

4. Results and discussion

The simulation of the crystallization of ibuprofen starts by providing the initial seed attributes, such as the mean size in both characteristic lengths, and the deviation The final obtained PSD has been used has reference trajectory for the RBF network (figure 1). The hidden layer of the RBF trains itself within the first half an hour of the process assuming a time delay of 3 minutes (enough time to sample and analyse the mean size of the crystals). Different RBF functions were tested and the results are shown in figure 2. From the observed results, the BH function is able to predict quite well the behaviour of the stem, and actuate on the temperature of the cooling profile in order to minimize the difference between the simulated and the reference mean size of the crystal. The early fluctuation is due to a small amount of training data, and the prediction is not as accurate as for the end of the simulation. By this time, the data available for training the RBF is vast (100 data points, assuming a 3 minute delay).

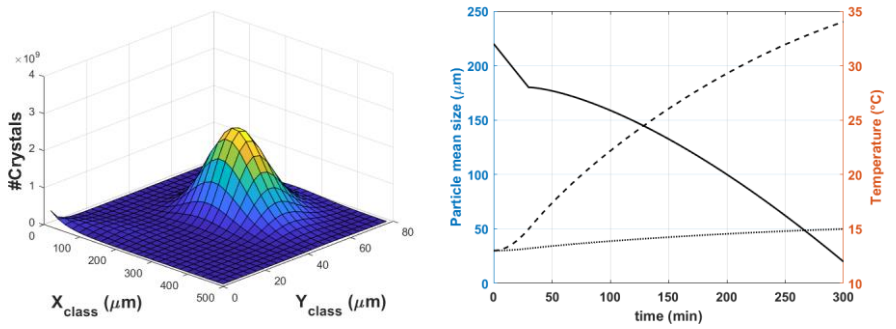

Figure 1- Final particle size distribution, at 5 hours of crystallization (left). Dynamic temperature profile over the process (full line, right), and the evolution of the mean sizes (dashed, right).

Using the BH RBF strategy, different simulations with deviations in process parameters (water content, initial seed mass) and uncertain parameters (k_g, k_b) were performed. Table 1 contains the results obtained for the 8 different simulations with uncertainty. Although the best approach to analyse the influence of this uncertainty would be to sample with Monte Carlo and propagate and quantify the uncertainty in the output (Sin et al 2009 et al), the results show that the RBH control is capable of reducing the off-spec MCS. For the example of the growth constant, figure 3 shows that by the end of the crystallization, the final mean size of the crystal is contained within the off-spec crystal in the open-loop simulation.

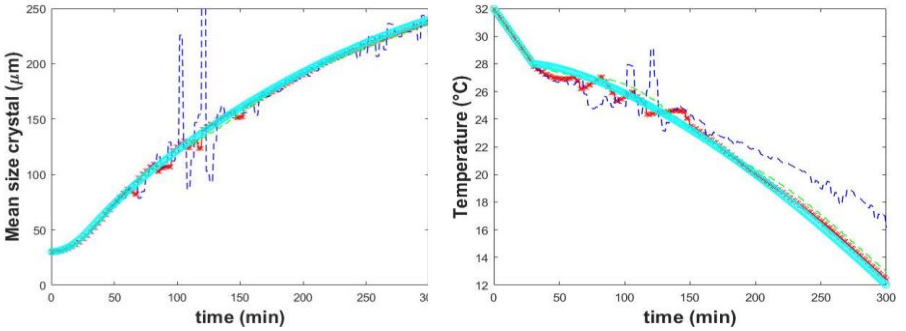

Figure 2- Mean particle size (left) and temperature profile predictions (right) of the different RBFs. (full: reference trajectory and temperature, dashed: IMQ RBF, remaining lines are similar to the reference trajectory)

Table1: Deviation from the mean size reference over time, due to uncertainty input

Input	Uncertainty	Mean size difference from ref. (μm)					Secondary nucleation
		t=1 h	t=2	t=3	t=4h	t=5h	
Water content	+50 %	0.80	-0.33	6.00	-2.86	1.25	no
	-50 %	-0.85	0.78	0.88	-0.85	0.21	no
Initial seed	+10%	-0.52	-2.93	-0.59	-1.61	-3.04	no
	-10%	0.58	4.51	8.01	1.43	-0.13	no
k_g	+20%	1.26	-5.25	1.49	-2.17	1.21	no
	-20%	-2.64	13.14	14.02	-6.14	0.34	yes
k_b	+65%	-0.21	-0.35	2.81	-1.47	<0.01	yes
	-65%	0.40	1.52	2.12	-0.40	0.39	no

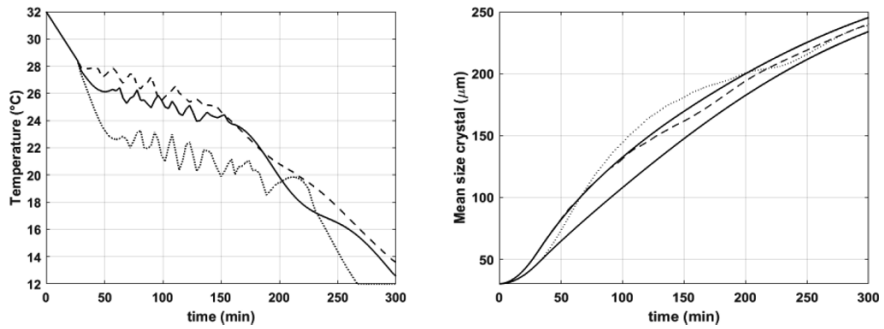

Figure 3- Temperature profiles (left) in closed loop for uncertainty in crystal growth (dashed: +20%, dotted: -20%, full: no disturbances) and the mean size evolution of crystals (right) under disturbance when in open-loop and closed loop (full: open loop for +20% and -20%, dashed:+20%, dotted: -20%,).

However, the problem was not posed to contain or avoid secondary nucleation. It is assumed that this data is unknown when moving from lab-scale to mini-plant. For the simulation, however, it was adapted from the literature (Rashid et al, 2010).

5. Conclusions

A control strategy using RBF network has been in an Ibuprofen crystallization model. It was shown that this is a reliable method to quickly move from smaller scales to mini-plant or micro-plant, when measurement (PAT) tools are available. The results show a good rejection of the disturbances made to the system, in the form of initial conditions of the batch and uncertain in critical parameters. The uncertainty contained in certain parameters replicates the case when available data from laboratory is not enough to have a good understanding of the process. Nevertheless, it is important to refer that this is not the optimal control strategy, as RBF is not trained on process input and output data generated from an optimal control (such as nonlinear model predictive control). The objective here is to show the ability of the RBF based control concept which can be trained using online measurements and which does not need a model to calculate control actions. Further work and development includes training of RBF to replace NMPC and laboratory validation of the control on a crystallisation unit.

Abstract

This paper presents a novel coordination scheme for distributed MPCs using a dynamic real-time optimization (DRTO) formulation with closed-loop prediction and a nonlinear dynamic plant model. The DRTO formulation generates the predicted closed-loop response of a nonlinear plant under the action of constrained distributed MPC for computing optimal set-point trajectories based on an economic or target-tracking performance objective. The performance of the formulation is assessed through evaluation on a nonlinear case study, with comparisons made between distributed, centralized and decentralized configurations.

Keywords: dynamic real-time optimization, economic optimization, distributed MPCs, coordination, nonlinear.

1. Introduction

Model predictive control (MPC) utilizes a dynamic model to predict the future response of a plant, and computes the optimal control action as the solution of a suitably formulated optimization problem. The inputs corresponding to the first control interval are implemented, and the process repeated with a correction based on the most recent plant measurement. Due to its constraint-handling ability and flexibility, MPC has been widely adopted in the process industry as well as other industrial sectors. However, application of a single MPC system to a large industrial plant presents challenges that include multiple time scales, and reliability considerations of having all plant sections reliant on a single advanced controller. MPC is consequently typically implemented in a distributed manner in large industrial plants, which has motivated research studies on paradigms and algorithms for a distributed MPC architecture, recent reviews of which are given in Pannocchia (2013) and Christofides et al. (2013).

The approach in this paper utilizes a hierarchical dynamic real-time optimization (DRTO) approach in which the DRTO layer provides economically optimal set-point trajectories to an underlying MPC system, as proposed by Jamaludin and Swartz (2017b) for centralized MPC. A key feature of the approach is that the DRTO calculation is based on the predicted closed-loop response of the plant and its associated MPC system. This results in a multilevel optimization problem that is solved by replacing the MPC optimization subproblems by algebraic constraints corresponding to their first-order optimality conditions. More recently, the formulation has been extended to coordination of multiple distributed MPCs (Li and Swartz, 2017), using linear dynamic plant models for both the MPC and DRTO formulations. In this work, we extend our earlier approach

by using a nonlinear dynamic plant model at the DRTO level so that the plant response generated can more accurately reflect the true plant dynamics. In the DRTO formulation, the interaction between distributed MPCs and process plant is fully captured and predicted in a rigorous fashion, and set-point trajectories are generated for each MPC subsystem. The performance demonstrated by the nonlinear DRTO formulation shows significant improvement compared to that of the linearized counterpart. The formulation is also versatile in that it can be utilized for the purpose of both target tracking and economic optimization. The formulation of the DRTO problem is described, and the performance of the method is illustrated through application to a reactor-separator case study.

2. Problem Formulation

The general architecture of the two-layer coordination scheme for distributed MPCs is shown in Figure 1. A nonlinear dynamic plant model is embedded in the upper layer as a surrogate model to generate the plant response. Along the DRTO prediction horizon, a series of MPC optimization subproblems are embedded and generate the control actions applied to the nonlinear dynamic model at each time instance. This sequential closed-loop prediction is thus optimized under a typically economic objective function, and generates set-point trajectories for lower level distributed MPCs to perform subsequent control tracking.

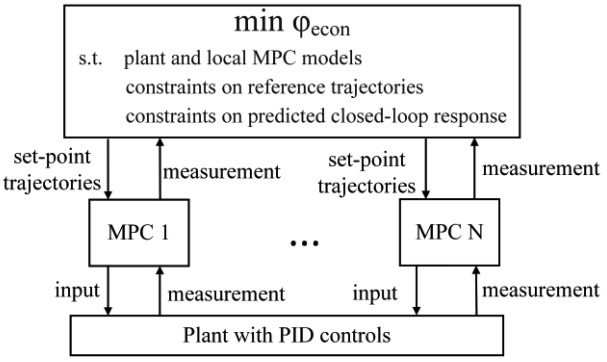

Figure 1: The control architecture for coordination of distributed MPCs with closed loop DRTO approach.

2.1. Model Discretization

Consider the nonlinear dynamic behaviour of the process plant to be accurately captured by a set of ODEs in the following form:

$$\begin{aligned} \dot{\mathbf{x}}^{\mathrm{DRTO}}(t) &= \mathbf{f}^{\mathrm{DRTO}}(\mathbf{x}^{\mathrm{DRTO}}(t), \mathbf{u}^{\mathrm{DRTO}}(t)) \\ \mathbf{y}^{\mathrm{DRTO}}(t) &= C\mathbf{x}^{\mathrm{DRTO}}(t) \\ \mathbf{x}^{\mathrm{DRTO}}(0) &= \mathbf{x}_0, \qquad \text{for } t \in [0, t_f] \end{aligned} \tag{1}$$

where $\mathbf{x}^{\mathrm{DRTO}}(t) \in R^{n_x}$ denotes the differential state vector, $\mathbf{x}^{\mathrm{DRTO}}(0) \in R^{n_x}$ the initial state vector, and $\mathbf{u}^{\mathrm{DRTO}}(t) \in R^{n_u}$ the input vector. t_f represents the duration of the DRTO prediction horizon. To solve the ODE system in the DRTO formulation, the system is discretized using an implicit Euler approximation. The controller sample time is assumed to be consistent with the finite element interval Δt_j and the piecewise constant inputs are applied to each finite element along the DRTO prediction horizon. There are various other discretization techniques available to achieve the same effect, such as orthogonal collocation on finite elements. However, implicit Euler integration is demonstrated to be sufficiently accurate to reflect the dynamic behaviour generated by the actual plant for

the case study considered. The plant is partitioned into subsystems $i \in O$, each of which is controlled by a local MPC based on a linear (or linearized) model of the form $\mathbf{x}_{k+1}^{(i)} = A_{ii}\mathbf{x}_k^{(i)} + B_{ii}\mathbf{u}_k^{(i)}$, $\mathbf{y}_k^{(i)} = C_{ii}\mathbf{x}_k^{(i)}$.

2.2. State and Disturbance Estimation for Nonlinear Plant Model

Prior to each DRTO execution, the current state estimate $\hat{\mathbf{x}}_j$ is first calculated based on the discretized model with previous state estimate $\hat{\mathbf{x}}_{j-1}$and the most recently implemented control action $\mathbf{u}_{j-1}^{\mathrm{MPC}}$. The predicted state estimate $\hat{\mathbf{x}}_j$ serves as the initial condition $\mathbf{x}_0$ for the DRTO model in the upper level. The disturbance added to the DRTO model is calculated by taking the difference between the current measured outputs and predicted outputs and assumed constant over the horizon:

$$\begin{aligned} \frac{\hat{\mathbf{x}}_j - \hat{\mathbf{x}}_{j-1}}{\Delta t_j} &= \mathbf{f}^{\mathrm{DRTO}}(\hat{\mathbf{x}}_j, \mathbf{u}_{j-1}^{\mathrm{MPC}}) \\ \mathbf{d}_j^{\mathrm{DRTO}} &= \mathbf{y}^{\mathrm{m}} - C\hat{\mathbf{x}}_j \\ \mathbf{x}_0 &= \hat{\mathbf{x}}_j \end{aligned} \tag{2}$$

2.3. Optimization Formulation

The dynamic models for the primary optimization problem and MPC optimization subproblems are embedded in the DRTO formulation as Eq.(3):

$$\begin{aligned} \min_{\mathbf{y}^{\mathrm{ref}},\mathbf{u}^{\mathrm{ref}}} \quad & \phi^{\mathrm{econ}}(\mathbf{x}^{\mathrm{DRTO}}, \mathbf{y}^{\mathrm{DRTO}}, \mathbf{u}^{\mathrm{DRTO}}) \\ \text{s.t.} \quad & \frac{\mathbf{x}_j^{\mathrm{DRTO}} - \mathbf{x}_{j-1}^{\mathrm{DRTO}}}{\Delta t_j} = \mathbf{f}^{\mathrm{DRTO}}(\mathbf{x}_j^{\mathrm{DRTO}}, \mathbf{u}_{j-1}^{\mathrm{DRTO}}), \quad j = 1, \ldots, N \\ & \mathbf{y}_j^{\mathrm{DRTO}} = C\mathbf{x}_j^{\mathrm{DRTO}} + \mathbf{d}_j^{\mathrm{DRTO}}, \quad j = 1, \ldots, N \\ & \mathbf{g}^{\mathrm{DRTO}}(\mathbf{x}^{\mathrm{DRTO}}, \mathbf{y}^{\mathrm{DRTO}}) \geq \mathbf{0} \\ & \mathbf{h}_i^{\mathrm{ref}}(\mathbf{y}^{\mathrm{ref}}, \mathbf{u}^{\mathrm{ref}}, \mathbf{y}^{\mathrm{sp}(i)}, \mathbf{u}^{\mathrm{sp}(i)}) = \mathbf{0}, \quad i \in O \\ & \mathbf{g}^{\mathrm{ref}}(\mathbf{y}^{\mathrm{ref}}, \mathbf{u}^{\mathrm{ref}}) \geq \mathbf{0} \\ & \mathbf{u}_j^{\mathrm{DRTO}(i)} = \mathbf{u}_{j,0}^{(i)}, \quad j = 0, \ldots, N-1 \\ & \left.\begin{aligned} & \mathbf{u}_{j,0}^{(i)} \in \arg \min_{\mathbf{u}_{j,k}^{(i)}} \phi_j^{\mathrm{MPC(i)}}(\mathbf{y}_{j,k}^{(i)}, \mathbf{y}_{j,k}^{\mathrm{sp}(i)}, \mathbf{u}_{j,k}^{(i)}, \mathbf{u}_{j,k}^{\mathrm{sp}(i)}) \\ & \text{s.t.} \quad \mathbf{x}_{j,k+1}^{(i)} = A_{ii}\mathbf{x}_{j,k}^{(i)} + B_{ii}\mathbf{u}_{j,k}^{(i)}, \quad k = 0, \ldots, m-1 \\ & \qquad \mathbf{x}_{j,k+1}^{(i)} = A_{ii}\mathbf{x}_{j,k}^{(i)} + B_{ii}\mathbf{u}_{j,m-1}^{(i)}, \quad k = m, \ldots, p-1 \\ & \qquad \mathbf{y}_{j,k}^{(i)} = C_{ii}\mathbf{x}_{j,k}^{(i)} + \mathbf{d}_{j,k}^{(i)}, \quad k = 1, \ldots, p \\ & \qquad \mathbf{d}_{0,k}^{(i)} = \mathbf{y}^{\mathrm{m}(i)} - C_{ii}\mathbf{x}_0^{(i)}, \quad k = 1, \ldots, p \\ & \qquad \mathbf{d}_{j,k}^{(i)} = \mathbf{y}_j^{\mathrm{DRTO}(i)} - C_{ii}\mathbf{x}_{j-1,1}^{(i)}, \quad k = 1, \ldots, p, \; j > 0 \\ & \qquad \mathbf{u}_{\min}^{(i)} \leq \mathbf{u}_{j,k}^{(i)} \leq \mathbf{u}_{\max}^{(i)}, \quad k = 0, \ldots, m-1 \end{aligned}\right\} \begin{array}{l} \text{MPC subproblems} \\ \text{subproblem } i \in O \\ j = 0, \ldots, N-1 \end{array} \end{aligned} \tag{3}$$

The closed-loop DRTO formulation consists of a primary optimization problem based on the nonlinear dynamic system to predict closed-loop response, and inner MPC optimization subproblems based on linear models of the plant subsystems to compute control actions. ϕ^{econ} denotes the objective function that captures the performance

criterion to be optimized. The main decision variables for the primary optimization problem are reference trajectories $\mathbf{y}^{\text{ref}}$ and $\mathbf{u}^{\text{ref}}$, from which the set-point trajectories for distributed MPCs $\mathbf{y}_{j,k}^{\text{sp}(i)}$and $\mathbf{u}_{j,k}^{\text{sp}(i)}$are extracted, while the decision variables in the inner MPC optimization subproblems are the control actions $\mathbf{u}_{j,k}^{(i)}$. $\mathbf{h}_i^{\text{ref}}$ represents the mapping of the DRTO reference trajectories to the MPC set-point trajectories, and can be used to enforce the trajectories to be constant within each DRTO interval over the DRTO prediction horizon, which can be explicitly represented as:

$$\begin{aligned} \mathbf{y}_{j,k}^{\text{sp(i)}} &= E_y^{(i)}\mathbf{y}_{j+k}^{\text{ref}}, \quad k=1,\ldots,p \\ \mathbf{u}_{j,k}^{\text{sp(i)}} &= E_u^{(i)}\mathbf{u}_{j+k}^{\text{ref}}, \quad k=0,\ldots,m-1 \end{aligned} \tag{4}$$

where $E_y^{(i)} \in R^{n_y^{(i)}\times n_y}$ and $E_u^{(i)} \in R^{n_u^{(i)}\times n_u}$ are matrices that map the full plant outputs and inputs to the subsystems. $\mathbf{g}^{\text{ref}}$ represents the upper and lower bounds of the trajectories. $\mathbf{x}^{\text{DRTO}}$, $\mathbf{y}^{\text{DRTO}}$, and $\mathbf{u}^{\text{DRTO}}$ are composite vectors of $\mathbf{x}_j^{\text{DRTO}}$, $\mathbf{y}_j^{\text{DRTO}}$, and $\mathbf{u}_j^{\text{DRTO}}$ respectively over the DRTO horizon. $\mathbf{u}_j^{\text{DRTO(i)}}$and $\mathbf{y}_j^{\text{DRTO(i)}}$ are subvectors of $\mathbf{u}_j^{\text{DRTO}}$and $\mathbf{y}_j^{\text{DRTO}}$ corresponding to the inputs and outputs of MPC subsystem i. A quadratic MPC objective function is used to yield a QDMC formulation as proposed in Garcia and Morshedi (1986) (see also Maciejowski (2002)). The disturbance estimate $\mathbf{d}_{j,k}^{(i)}$ is determined as proposed in Cutler and Ramaker (1980) and Garcia and Morshedi (1986), and utilizes the plant measurement $\mathbf{y}^{\text{m}(i)}$ for the first set of MPC subproblems, and the DRTO model output, $\mathbf{y}_j^{\text{DRTO(i)}}$, for subsequent time steps in the DRTO horizon, where $\mathbf{y}^{\text{m}(i)}$ is a subvector of the plant measurements corresponding to MPC subsystem i.

The multi-level optimization formulation of the closed-loop DRTO problem can be transformed into a single-level optimization problem by reformulating the MPC quadratic programming subproblems as a set of constraints using the Karush-Kuhn-Tucker (KKT) optimality conditions, as proposed by Baker and Swartz (2008). This correspondence for a general convex quadratic programming problem is:

$$\begin{array}{ll} \text{QP} & \text{KKT conditions} \\ \min_{\mathbf{z}} \ \frac{1}{2}\mathbf{z}^T H\mathbf{z} + g^T\mathbf{z} & H\mathbf{z}+\mathbf{g}-A^T\nu-\eta=\mathbf{0} \\ \text{s.t.} \quad A\mathbf{z}=\mathbf{b}, \quad \mathbf{z}\geq\mathbf{0} & A\mathbf{z}=\mathbf{b}, \quad z_i\eta_i=0, \quad (\mathbf{z},\eta)\geq\mathbf{0} \end{array} \tag{5}$$

where variable $\mathbf{z}$ denotes a generalized variable within the QP problem. The presence of the complementarity constraints in the reformulated problem may be effectively handled through an exact penalty formulation in which they are included as a penalty term in the objective function (Ralph and Wright, 2004; Jamaludin and Swartz, 2017a). The DRTO formulation are solved using AMPL with the IPOPT solver, and the lower-level control calculations and continuous plant simulation are implemented in MATLAB using the ode15s integrator.

3. Case Study

We consider a reactor-separator network studied by Baldea and Daoutidis (2007). A zero order reaction converts component A to component B in the reactor, and the product is then fed to the separator. The mole transfer rate between the vapour and liquid for component $i \in \{A,B,I\}$ in the vessel is modelled with the rate expression $N_j = K_j\alpha(y_j - P_j^s/P_c)x_j)(M_L/\rho_L)$. The differential equations used for this system are given below,

where M_R, M_V, M_L denote the molar holdup in the reactor, condenser vapour and liquid phase, and $N = N_A + N_B + N_I$. For simplicity, the molar hold-ups are assumed to be perfectly controlled.

$$\begin{aligned}
\dot{y}_{A,R} &= \tfrac{1}{M_R}[F_o(y_{A,o} - y_{A,R}) + R(y_A - y_{A,R}) - k_1 M_R y_{A,R}] & \dot{y}_I &= \tfrac{1}{M_V}[F(y_{I,R} - y_I) - N_I + y_I N] \\
\dot{y}_{I,R} &= \tfrac{1}{M_R}[F_o(y_{I,o} - y_{I,R}) + R(y_I - y_{I,R})] & \dot{x}_A &= \tfrac{1}{M_L}[N_A + x_A N] \\
\dot{y}_A &= \tfrac{1}{M_V}[F(y_{A,R} - y_A) - N_A + y_A N] & \dot{x}_I &= \tfrac{1}{M_L}[N_I + x_I N]
\end{aligned} \tag{6}$$

The nominal values for all process parameters are summarized in Baldea and Daoutidis (2007). The manipulated and control variables selected for the reactor are raw feed F_o and vapor composition of component A, $y_{A,R}$, respectively. The manipulated and controlled variables selected for the separator are condenser pressure P_c and liquid composition of component A, x_A, respectively. The tuning parameters for distributed MPCs and the DRTO formulation are summarized in Table 1. It is noted that the first move suppression weight value is small due to the small nominal value of the condenser pressure (0.338 MPa compared to feed flow rate 100 mol/min). In this case study, the system is given pre-determined targets for two outputs that are required to be tracked; the DRTO objective function is consequently formulated in a least-squares fashion. However, other forms of linear or nonlinear objective function can be readily used. The system is regulated separately for both centralized and decentralized MPC. For each case, the associated DRTO formulation is added to generate set-point trajectories for those MPCs. The performance is quantified using the sum-squared-errors (SSE) between the plant dynamics and final target values. The performance loss is defined as the percentange increase of SSEs with respect to the case with the lowest SSE value. Figure 2 shows the set-point trajectories and response of the continuous process dynamics for distributed cases using linear and nonlinear DRTO formulations. While the difference between the nonlinear and linear DRTO implementations appears slight, numerical results confirm the superior performance of the nonlinear approach. Table 2 summarizes the performance for several configurations: centralized and distributed DRTO with a nonlinear DRTO plant model, centralized and distributed DRTO with a linear DRTO plant model, and decentralized MPC with constant set-point trajectories corresponding to the set-point targets. From the results it can be seen that the nonlinear DRTO formulation outperforms the linear counterpart, which aligns with expectation since the DRTO formulation can generate a more accurate plant response based on the nonlinear model. The table also shows that the distributed cases experience only a slight performance drop when compared to the centralized counterparts due to the ability of DRTO formulation to predict the plant behavior based on a complete plant model that is not available to distributed MPCs. The performance drop can be justified by the additional flexibility and reliability offered by the distributed architecture over the centrazlied counterpart.

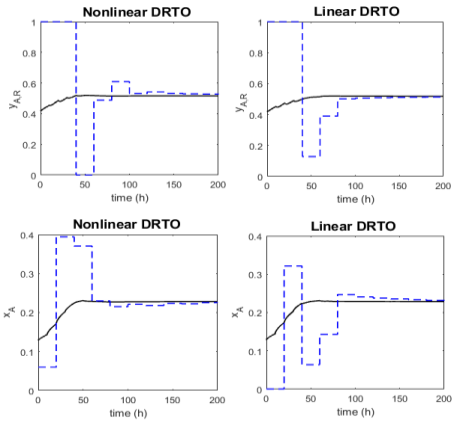

Figure 2: Set-points and output response for distributed MPC cases

Table 1: DRTO and MPC parameters for the process

Parameter	Description	Value (MPC1 & MPC2)
Δt_{DRTO}	DRTO sample time	20
Δt_{MPC}	MPC sample time	10
N	Optimization horizon	10
P	Prediction Horizon	5
M	Control Horizon	3
Q	Output tracking weight	10 & 2
R	Move suppression weight	10^{-4} & 5
y_{min}, y_{max}	Output and setpoint bounds	[0 1] & [0 1]
u_{min}, u_{max}	Input bounds	[0 250] & [0 1]

Table 2: The summary of performance under different configurations

Configuration	Control architecture	$\sum SSE$	performance loss
centralized	nonlinear DRTO + MPC	2.473	0%
distributed	nonlinear DRTO + MPC	2.556	3.36 %
centralized	linear DRTO + MPC	2.743	10.91%
distributed	linear DRTO + MPC	2.790	12.82%
decentralized	MPC	6.61	167.29%

4. Conclusion

The DRTO formulation is able to capture and predict the closed-loop behaviour of the plant response. Based on previous work of using a linear plant model in the DRTO formulation to generate plant responses, this paper demonstrates that the performance can be further improved when a nonlinear dynamic plant model is included in the DRTO formulation. The plant response is more accurate than that using a linear model, and consequently the set-point trajectories generated by the nonlinear DRTO strategy offer better target tracking capabilities for the lower-level distributed MPCs.

Abstract

In this paper, the optimization and low-level control design for Reactive Batch Distillation Columns (RBD) including startup operation are investigated. This is a complex problem involving control of heat and mass transfer phenomena over a wide operating window. A new model for the startup operation of an RBD column is proposed. Using this model, an offline optimization problem is solved to minimize the start-up time. Additionally, the classical low-level controllers for RBD columns are reformulated, and a new cascade control strategy with decouplers is proposed. This control structure allows reducing the strong interaction among the input-output variables of the RBD. Finally, the model, the optimal startup, and the proposed controllers are tested on simulation on a polyesterification process.

Keywords: Reactive Batch Distillation Columns, Start-up, Low-Level Control, Optimal operation.

1. Introduction

Reactive distillation is a process in which a chemical reaction and distillation occur simultaneously in one single installation. A typical process operation of reactive distillation columns is batch since batch distillation is used in the chemical industry for the production of small amounts of products with high added value. Reactive batch distillation has gained a growing interest in both academic research and industrial applications since process limitations can be circumvented and investment and operational costs can be reduced by combining the reaction and separation processes.

There are basically three low-level control strategies for RBD: one-point bottom control, one-point column control and two-point control (Sørensen and Skogestad, 1994). In one-point bottom control strategy, the main objective is to maintain the reactor temperature close to the boiling point of the mixture (set-point). However, this set-point value may be difficult to know a priori, mostly in multi-component systems. In two-point control strategy (control of both reactor temperature and distillate composition), the strong interactions among the main variables (temperature and concentration) are the main drawback, and the reactor temperature has to be specified close to the boiling point. Last but not least, the one-point column control strategy (controlling the temperature on a tray in the column) gives a good performance for the RBD columns. However, this control strategy is controlling indirectly the most important variables of the process, and it is very sensitive to measurement delays and noise.

An important fact to be considered in the control design and optimization of the RBD columns is the start-up of the process. The start-up of batch distillation columns is a difficult operation in the chemical industry since it takes a long period leading to off-spec products and energy costs (Elgue et al., 2004). In general, modeling start-up phase where the thermodynamic equilibrium is not yet achieved is challenging. Few rigorous models for distillation columns start-up are available in the literature, and these models generally require a lot of parameters (Wozny and Li, 2004). Therefore, the inclusion of the startup in the classic control strategies is still a big challenge.

This paper is organized as follows: In Section 2 a new model for the startup operation for an RBD column is proposed. Using this model, in Section 3 the startup time is minimized by solving an offline optimization problem. In Section 4 the classical low-level controllers for RBD are reformulated, and a new decoupled-cascade control strategy is proposed. In Section 5, the model, the optimal startup, and the proposed controllers are tested on simulation on a polyesterification process. Finally, in Section 6 the conclusions are presented.

2. Modelling of RBD including the Start-up

2.1. Dynamic Modelling

Consider an RBD column with N_c species, R reactions and N_T stages where the reboiler stage (bottom) is the reactor. Three basic assumptions are applied in the formulation of the model: Perfect mixing and equilibrium between vapor and liquid on all stages, the accumulation of moles in the vapor phase is considered negligible, and chemical reactions in the vapor phase are neglected. A general mathematical model of the RBD is given by the following equations,

$$\frac{dn_{i,j}}{dt} = L_{i-1}x_{i-1,j} - L_i x_{i,j} - \xi_{i,j} + \xi_{i+1,j} + n_{Ti} r_{i,j},\ x_{i,j} = \frac{n_{i,j}}{n_{Ti}},\ n_{Ti} = \sum_{j=1}^{N_c} n_{i,j} \qquad (1)$$

$$\frac{d\left(n_{Ti}H_i\right)}{dt} = L_{i-1}H_{L_{i-1}} - L_i H_{L_i} - \xi_i H_{v_i} + \xi_{i+1}H_{v_{i+1}} + n_{Ti}\sum_{j=1}^{N_c}\left(-\Delta H_j\right)r_{i,j} + Q_{ext} \qquad (2)$$

$\forall i = 1,2,\cdots,N_T, \forall j = 1,2,\cdots,N_C$. In the model $y_{i,j}$, $\xi_{i,j}$, H_i, and H_{V_i} are given by:

$$\xi_{i,j} = V_i\, y_{i,j},\ y_{i,j} = \frac{\gamma_{i,j}P_{i,j}^{sat}(T_i)x_{i,j}}{\sum_{j=1}^{N_c}\gamma_{i,j}P_{i,j}^{sat}x_{i,j}},\ \xi_i = \sum_{j=1}^{N_c}\xi_{i,j},\ H_i = C_{p_i}T_i, H_{V_i} = C_{p_i}T_i + \lambda_{Vi}$$

Table 1: Boundary conditions of the RBD

	L_{i-1}	L_i	$\xi_{i,j}$	$\xi_{i+1,j}$	$r_{i,j}$	Q_{ext}	$x_{i-1,j}$
$i=1$	L_D	0	0	0	0	0	$x_{i+1,j}$
$i=N_T$	L_{i-1}	0	$V_i y_{i,j}$	0	$r_{i,j}$	Q_{ext}	$x_{i-1,j}$

The model given by (1)-(2) are subject to the boundary conditions in Table 1. To highlight that, the initial conditions of the model (1)-(2) assume an amount of vapor due to the equilibrium relationship $\xi_{i,j}$. This term depends on the concentration in the liquid phase. Therefore, this model is representative just for the case when the system has reached the VLE. Also, the boiling temperature of the mixture can be calculated solving the following

equation for the boiling temperature T_{B_i}, where $P_{i,j}^{sat}(T_{B_i})$ is given by the Antoine equation: $f_{T_{B_i}}(T_{B_i}) = \sum_{j=1}^{N_C} \gamma_{i,j} x_{i,j} P_{i,j}^{sat}(T_{B_i}) - P_i = 0$

2.2. Modelling of the start-up operation

In modelling of the start-up operation, the vapor flow behavior before and during the VLE must be understood. In general terms, the vapor flow has a kind of switch behavior, i.e., before the VLE it is zero, and after, it takes a value. First, the calculation of the vapor flow can be done assuming the temperature in steady state during the VLE condition. Hence the vapor flow can be calculated from the energy balance using the following equation,

$$V_i = H_{v_i}^{-1}\left(L_{i-1}H_{L_{i-1}} - L_i H_{L_i} + H_{v_{i+1}}V_{i+1} + n_{Ti}\sum_{j=1}^{N_c}\left(-\Delta H_j\right) r_{i,j} + Q_{ext} \right), \forall i = 1,\ldots,N_T \quad (3)$$

To include the switching behavior in the vapor flow, the next sigmoidal functions are used: $S(\alpha,\beta) = \left(1 + e^{-\alpha(x_i-\beta)}\right)^{-1}$. With such function in the Eq.(3), the vapor flow can be calculated using the following equation,

$$V_i = \omega_{V_i} H_{v_i}^{-1}\left(\omega_{L_i} L_{i-1}H_{L_{i-1}} - L_i H_{L_i} + H_{v_{i+1}}V_{i+1} + n_{Ti}\sum_{j=1}^{N_c}\left(-\Delta H_j\right) r_{i,j} + Q_{ext} \right), \forall i = 1,\ldots,N_T \quad (4)$$

Where $\omega_{V_i} = S(\alpha_{T_{B_i}}, T_{B_i})$, and $\omega_{L_i} = S(\alpha_{T_i}, T_{i-1})$ are switch functions with $\alpha_{T_{B_i}} > 0$ and $\alpha_{T_i} < 0$. The function ω_{V_i} activates the vapor flow when the temperature of the *i*-th tray reaches the boiling point and ω_{L_i} is not active when the temperature of the *i*-th tray reach the temperature of the (*i-1*)-th tray. Also, a switch function $\omega_{n_i} = S(\alpha_{n_i}, \varepsilon_i)$, $\alpha_{n_i} < 0$ is included in the calculation of the mole fraction $x_{i,j}$ because during the start-up $n_{T_i} = 0$, therefore, the switch is not active when $n_{T_i} \geq \varepsilon_i$. Finally, the model that is given by Eq. (1) and Eq. (2) can be written including the start-up as follows,

$$\frac{dn_{i,j}}{dt} = L_{i-1}x_{i-1,j} - L_i x_{i,j} - \xi_{i,j} + \xi_{i+1,j} + n_{Ti} r_{i,j},\ x_{i,j} = \frac{n_{i,j}}{\bar{n}_{Ti}},\ \bar{n}_{Ti} = n_{Ti} + \omega_{n_i} n^* \quad (5)$$

$$\frac{d\left(\bar{n}_{Ti} H_i\right)}{dt} = L_{i-1}H_{L_{i-1}} - L_i H_{L_i} - \xi_i H_{v_i} + \xi_{i+1} H_{v_{i+1}} + n_{Ti}\sum_{j=1}^{N_c}\left(-\Delta H_j\right) r_{i,j} + Q_{ext} \quad (6)$$

Remark 1: It is important to note that the inclusion of the switch variables does not affect the interpretation of the solution of the differential equations. These functions avoid singularities and eliminate to use if-then statements in modelling.

3. Optimal Operation and Start-up

Several cost functions have been proposed for the optimal operation of RBD columns (Sørensen et al. 1996). However, none of these objective functions have considered the start-up explicitly. To find the optimal operation trajectory of the process including the start-up, the following dynamic nonlinear optimization problem is proposed:

$$\min_u \phi(x,u) = \int_{t_0}^{t_f} \left(\underbrace{-X}_{Conversion} + \underbrace{\left\| T_{N_T} - T_{B_{N_T}} \right\|_S^2}_{start-up} \right) dt,\ \text{s.t: Eq(5), (6)},\ x \in \mathbf{X},\ u \in \mathbf{U} \quad (7)$$

In the selection of the cost function we have considered maximizing the conversion. This means more volatile are being produced and these components must be removed immediately to enhance the forward reactions. To this end, the temperature of the reactor (T) must be kept close to the boiling point of the mixture (T_b). Thus, by maximising the conversion and maintaining T close T_b, we reduce the start-up time. Finally, the optimisation problem (7) has been solved by parametrizing u and converting (7) into an NLP.

4. Low-Level Control Design including the Start-up

4.1. Classical low-level controllers for RBD including the start-up

We summarize the main characteristics of the classical control strategies in Table 2. Anyone of these control strategies can be found implemented in the industry. However, none of them have considered the start-up.

Table 2: Classical low-level controllers for RBD

	One-point bottom control	**One-point column control**	**Two-point Control**	
			LV-configuration	**DV-configuration**
Controlled variable	T_{N_T}	$T_i, \forall i \neq N_T$	$h_c, x_{1,j}, T_{N_T}$	$h_c, x_{1,j}, T_{N_T}$
Manipulated Variable	$L_2, Q_{ext} = Q_{\max}$	$L_2, Q_{ext} = Q_{\max}$	L_D, L_2, Q_{ext}	L_2, L_D, Q_{ext}

To include the start-up in the classical low-level controllers for RBD, the level of the condenser drum plays a key role. During the start-up, and before the level reaches the set-point $h_{c,ref}$, L_2 and L_D should be equal to zero. After that, the flows should satisfy $V_3 = L_2 + L_D$, reducing the manipulated variables to just one: the reflux ratio R. Therefore, to take into account this effect in the classic control strategies, the following equations are proposed for the liquid flows L_2 and L_D in terms of R : $L_2 = \omega_{tp} R V_3$, $L_D = \omega_{tp}(1-R)V_3$, with $\omega_{tp} = S(\alpha_{tp}, h_{c,ref}), \alpha_{tp} > 0$. In this case, a switch function is included to maintain the flows equal to zero before the start-up and manipulate just one variable after the condenser drum reaches the set-point. Based on this approach, the LV-configuration is the same DV-configuration. Finally, Table 3 summarizes the classic low-level controller for RBD including the start-up.

Table 3: Classical low-level controllers for RBD with the start-up

	One-point bottom control	**One-point column control**	**Two-point Control**
Controlled variable	T_{N_T}	$T_i, \forall i \neq N_T$	$h_c, x_{1,j}, T_{N_T}$
Manipulated Variable	$R, Q_{ext} = Q_{\max}, L_2 = \omega_{tp} R V_3$ $L_D = \omega_{tp}(1-R)V_3$	$R, Q_{ext} = Q_{\max}, L_2 = \omega_{tp} R V_3$ $L_D = \omega_{tp}(1-R)V_3$	$R, Q_{ext}, L_2 = \omega_{tp} R V_3$ $L_D = \omega_{tp}(1-R)V_3$

4.2. Cascade control strategy with decouplers

We have proposed a cascade control strategy with decouplers to improve the performance of the low-level controllers. This is motivated by the fact that the vapor flow generated in the reactor V_{N_T} is a function of the heat flow Q_{ext} (see Eq.4), and at the same time, the vapor flow can be considered a disturbance for the condenser drum level and the concentration of the accumulator. Based on these observations, the main characteristics of this control strategy are presented in Figure 1. To this end, we decouple the effect of the vapor flow on the concentration in the accumulator, and the effect of the reflux ratio on the reactor. Due to space limitations, the mathematical development of the decouplers has not been presented.

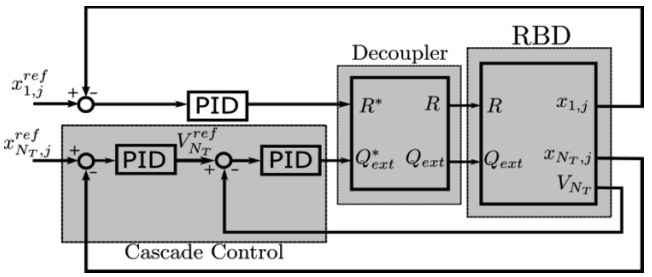

Figure 1: Cascade control structure with decouplers for the RBD

5. Case Study: Polyesterification Process

Consider a reactive batch distillation process of a polyesterification reaction with six stages ($N_T = 6$). The chemical process has 14 species ($N_c = 14$) with 17 reactions. Despite the multiple sub-reactions, a general reaction scheme is described by:

$$\text{Maleic Anhydride+Propylene Glycol} \rightleftarrows \text{Water+Polymer}$$

The control objective of this case study is to remove the water from the reactor to maximize the production of the polymer. To this end, fixed set-points $x_{1,\mathrm{H_2O}}^{ref} = 1$ and $T_{N_T}^{ref} = 450\,\mathrm{K}$ are selected for the local controllers. The simulations results of the control strategies and their comparison with the optimal trajectory are shown in Figure 2. In this Figure, it is possible to observe that, the one-point column control and the decoupled strategy have the better performance to remove the water. Besides, the concentration of water in the accumulator is close to the 80%

6. Conclusions

In this paper, a new model for the startup operation for an RBD column is proposed. Based on this model, an offline optimization problem is proposed in to minimize the start-up time. Additionally, the classical low-level controllers for RBD are reformulated, and a new cascade control strategy with decouplers is developed. Finally, the model, the optimal startup, and the proposed controllers are tested in simulation on a polyesterification process.

Abstract

This work presents a general sequential parameter-and-state estimation structure based on extents transformations for non-isothermal homogeneous reaction systems. The extents transformations allow for the development of a Linear Parameter-Varying (LPV) representation with a diagonal state matrix. The particular structure of the LVP system matrices and the physical interpretation of its parameters are used to propose an asymptotic estimator. The main advantage of this estimator is that its implementation does not depend on the chemical kinetic parameters. Based on the information given by the asymptotic estimators, two additional estimators are proposed: an adaptive estimator, and a Recursive Least Squares (RLS) estimator. The first one is used to estimate the chemical reaction rate, while the second to estimate the kinetic parameters. Convergence and tuning properties of the final structure are analyzed and tested on a CSTR example.

Keywords: State and parameter estimation, Extents transformations, Linear Parameter Varying (LPV) Systems, Non-isothermal Homogeneous Reaction Systems.

1. Introduction

The need for real-time information on the evolution of chemical reactions is critical for process control and fault detection. Additionally, the unavailability of specialized instruments motivates the development of state and parameter estimators for chemical processes. Estimators based on rigorous models are the first option for such purposes. However, most industrial processes are described by nonlinear differential algebraic equations, which are in general inconvenient for online parameter-and-state estimation. An alternative is to find different representations of rigorous models using state transformation such as projection methods, state space decomposition, or the inclusion of empirical linear models. Nevertheless, this type of approaches presents several disadvantages such as the loss of physical interpretation of the transformed variables. An attractive alternative is to use the concept of extent transformations (Amrhein et al. 2010) that allows the calculation of the contribution of every phenomenon in the process independently. Moreover, from the estimation perspective, the extents transformations allow for the development of a Linear Parameter-Varying (LPV) representation. The particular structure of the LVP system matrices and the physical interpretation of its parameters are used to propose a general structure for online estimation of non-isothermal homogeneous reaction systems.

There are many approaches for parameter and state estimation, however, due to the extent transformation, and the LPV representation, two well-known approaches for online parameter-and-state estimation are addressed in this paper: simultaneous and sequential. In the simultaneous approach, a set of differential equations that describe the

dynamics of the parameters are lumped to the original model of the system. The parameters are then assumed as a new set of extra states with no dynamics, and the parameter-and-state estimation problem is transformed into a single state estimation problem (Dochain, 2003). This approach has some notable drawbacks such as the selection of the models for the parameters, and the observability conditions of the system with the extended set of states. To tackle these issues, the sequential approach in a cascade structure has been proposed by Dochain, 2003. The main idea of sequential estimation is to solve two estimation problems: one for the states and one for the parameters. Typically, adaptive estimators (Bastin and Dochain, 1990) and least squares formulations have been suggested for parameter estimation. Nevertheless, specific characteristics such as convergence of the cascade structure, and models for the parameters (observer-based estimators) are still open issues. In this paper, the advantages of the LPV representation of non-isothermal homogeneous reaction systems are combined with the sequential estimation structure, to propose a general estimation structure with convergence guarantee.

This paper is organized as follows: In Section 2, the nonlinear model of the system is transformed into a Linear Parameter-Varying (LPV) system using the extent transformations. Based on the LPV model, In Section 3, an asymptotic estimator is proposed to estimate the states, and based on this information two additional estimators are proposed: an adaptive, and a Recursive Least Squares (RLS) estimators. In the same section, convergence and tuning properties of the final structure are analyzed. In section 4 the estimation structure is tested on a simulation of a CSTR. Finally, in Section 5 the conclusions are presented.

2. Extent-Based LPV Representations for Non-isothermal Homogeneous Reaction Systems

2.1. Extent of Reaction and Inlet Flow

Consider the mole balance equation for a homogeneous reaction system with *S* species, R_I independent reactions, *p* independent inlet flows and one outlet flow, given by:

$$\begin{aligned} \dot{n} &= VN^T r + W_{in}u_{in} - \theta n,\ n(0) = n_0 \\ \dot{T} &= -\theta T + \underbrace{\frac{C_{p_{in}}T_{in}}{mC_{p_{mix}}}}_{\alpha\in\mathbb{R}^{1\times p}} u_{in} - \underbrace{\frac{\Delta H_f N^T}{mC_{p_{mix}}}}_{\beta\in\mathbb{R}^{1\times R_I}} Vr + \underbrace{\frac{1}{mC_{p_{mix}}}}_{\gamma} Q_{in},\ T(0) = T_0 \end{aligned} \tag{1}$$

Where $n \in \mathbb{R}^S$ is the number of moles, V is the reaction mixture volume, $r \in \mathbb{R}^{R_I}$ is the reaction rate vector, and $u_{in} \in \mathbb{R}^p$ and $u_{out} \in \mathbb{R}^1$ are the inlet and outlet mass flows; $\theta = m^{-1}u_{out}$, where m is the reacting mixture mass; $N \in \mathbb{R}^{R_I \times S}$ is the stoichiometric coefficient matrix and $W_{in} \in \mathbb{R}^{S\times p}$ is the inlet composition matrix defined as $W_{in} = M_w^{-1}w_{in}$; $M_w \in \mathbb{R}^{S\times S}$ is the diagonal molecular weight matrix and $w_{in} \in \mathbb{R}^{S\times p}$ the matrix of weight fraction. In this work, the parameters α, β and γ are considered constant. To this end, a local controller for the total mass m is assumed. Based on the work of Amrhein et al. 2010, it is possible to find a linear transformation T_e such that the system (1) can be expressed in the following form:

$$\begin{bmatrix}\dot{x}_r\\ \dot{x}_{in}\\ \dot{\lambda}\\ \dot{T}\end{bmatrix}=\begin{bmatrix}-\theta I_{R_I} & 0 & 0 & 0\\ 0 & -\theta I_p & 0 & 0\\ 0 & 0 & -\theta & 0\\ 0 & 0 & 0 & -\theta\end{bmatrix}\begin{bmatrix}x_r\\ x_{in}\\ \lambda\\ T\end{bmatrix}+\begin{bmatrix}0 & 0\\ I_p & 0\\ 0 & 0\\ \alpha & \gamma\end{bmatrix}\begin{bmatrix}u_{in}\\ Q_{in}\end{bmatrix}+\begin{bmatrix}I_{R_I}\\ 0\\ 0\\ \beta\end{bmatrix}Vr \tag{2}$$

$$n = N^T x_r(t) + W_{in} x_{in}(t) + n_0 \lambda(t)$$

Where $x_r \in \mathbb{R}^{R_I}$ is the extent of reaction, $x_{in} \in \mathbb{R}^p$ is the extent of inlet flow, and $\lambda \in \mathbb{R}^1$ is the initial conditions discounting factor. The matrix T_e is calculated using a singular value decomposition of N^T and W_{in}. Details about this procedure can be found in Amrhein et al. 2010. With the representation Eq.(2) of the Eq.(1), the independent evolution of the reaction, the inlet flow, and outlet flow can be easily accounted.

2.2. LPV Representations for Homogeneous Reaction Systems

Let us assume the reaction rate r as an unmeasured disturbance, and the number of moles and the temperature as the outputs of the system, such that the equations (2) can be written as: $\dot{x} = A(\theta)x + Bu + Dd$, $y = Cx$, with $x \in \mathbb{R}^{R_I+p+2}$, $u \in \mathbb{R}^{p+1}$, $y \in \mathbb{R}^{S+1}$ and $d \in \mathbb{R}^{R_I}$. In this paper, it is assumed that the scheduling parameter θ is measured. Based on the LPV system (2), the state and parameter estimation based on extent transformations is developed.

2.2.1. Elimination of the reaction rate

To design asymptotic estimators, the reaction rate r must be eliminated from Eq. (2). Let us define a change of variable $z = \beta x_r + T$. Taking derivatives of both sides of the equation concerning time, and only considering time-varying the variables x_r and T, we obtain : $\dot{z} = -\theta z + \alpha u_{in} + \gamma Q_{in}$. The resulting overall dynamics become,

$$\begin{bmatrix}\dot{x}_{in}\\ \dot{\lambda}\\ \dot{z}\end{bmatrix}=\begin{bmatrix}-\theta I_p & 0 & 0\\ 0 & -\theta & 0\\ 0 & 0 & -\theta\end{bmatrix}\begin{bmatrix}x_{in}\\ \lambda\\ z\end{bmatrix}+\begin{bmatrix}I_p & 0\\ 0 & 0\\ \alpha & \gamma\end{bmatrix}\begin{bmatrix}u_{in}\\ Q_{in}\end{bmatrix}$$

$$y=\begin{bmatrix}W_{in}\left|C_N Z^{\dagger}\right.\\ 0\end{bmatrix}x+\begin{bmatrix}n_0\\ 0\end{bmatrix}\lambda + C_N q_z,\ C_N=\begin{bmatrix}N^T & 0\\ 0 & 1\end{bmatrix} \tag{3}$$

The system (6) can be seen as the following LPV system: $\dot{x} = A(\theta)x + Bu$ with $x \in \mathbb{R}^{p+1}$, $u \in \mathbb{R}^{p+1}$, $y \in \mathbb{R}^{S+1}$, where $q_z \in \mathrm{Ker(Z)}$ and $\mathrm{Z} = \begin{bmatrix}\beta & 1\end{bmatrix}$.

3. State and Parameter Estimation of Extent-Based LPV systems

In this section, the state and parameter estimation of Extent-Based LPV systems is addressed. First, let us define the measured and unmeasured variables of the system. In this paper, the temperature T and the number of moles of S_m components $n_m \in \mathbb{R}^{S_m}$, $\forall S_m \leq S$ are assumed as measured variables. Based on this, the number of moles are partitioned in measured $n_m \in \mathbb{R}^{S_m}$ and unmeasured $n_{um} \in \mathbb{R}^{S-S_m}$ variables. Also, the equation of the number of moles can be divided as:

$$\begin{bmatrix}n_{um}\\ n_m\end{bmatrix}=\begin{bmatrix}N_{um}^T\\ N_m^T\end{bmatrix}x_r+\begin{bmatrix}W_{in,um}\\ W_{in,m}\end{bmatrix}x_{in}+\begin{bmatrix}n_{0,um}\\ n_{0,m}\end{bmatrix}\lambda(t) \tag{4}$$

Where $N_{um} \in \mathbb{R}^{R_I \times (S-S_m)}$, $N_m \in \mathbb{R}^{R_I \times S_m}$, $W_{in,um}^T \in \mathbb{R}^{p \times (S-S_m)}$ and $W_{in,m}^T \in \mathbb{R}^{p \times S_m}$. Figure 1 shows the estimation structure proposed in this paper.

Theorem 1: *Consider the homogeneous reaction system given by the set of Eq. (2), where the reaction rate r is assumed as a bounded disturbance $r \in \Delta$, with Δ convex and compact. Then, if $rank([N_m^T \quad W_{in,m} \quad n_{0,m}]) = R_I + p + 1$, and $\theta \neq 0$ the system (2) is always observable.*

The proof of this theorem is omitted due to the space limitations.

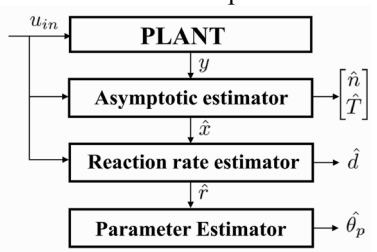

Figure 1. State and parameter estimation structure of Extent-Based LPV systems

3.1. Asymptotic estimator

In Table 1, the model, and the mathematical formulation of the asymptotic estimator are presented.

Table 1. Mathematical formulation of the asymptotic estimator

Model	Asymptotic Estimator
$\dot{x} = A(\theta)x + Bu$	Eq.(3)
$y_m = \begin{bmatrix} n_m^T & T \end{bmatrix}^T = C_m y$	$\hat{x}_r = \beta^{\dagger}(\hat{z} - T) + q_r,\ q_r \in \mathrm{Ker}(\beta)$
$y = C_z x + C_\lambda \lambda + C_N q_z$	$\hat{n} = N^{\intercal}\hat{x}_r(t) + W_{in}\hat{x}_{in}(t) + n_0\hat{\lambda}(t)$

The main advantage of this estimator is that its implementation does not depend on the chemical reaction rate r. The estimation of the extents of reaction depends on the variable $q_r \in \mathrm{Ker}(\beta)$. The calculation of this variable depends on the measured number of moles n_m, and this fact is stated in the following theorem.

Theorem 2. *Consider the asymptotic estimator presented in Table 2, where the estimation of the extents of reaction $\hat{x}_r$ is given by $\hat{x}_r = \beta^{\dagger}(\hat{z} - T) + q_r$ with $rank(\beta) = 1$ and $q_r \neq 0$. If $rank(N_m) = R_I$, then, the null space vectors q_r can be estimated using the following equation:*

$$q_r = \begin{bmatrix} (N_m)^{\dagger} & \beta^{\dagger} \end{bmatrix} \begin{bmatrix} n_m - W_{in,m}x_{in} - n_{0,m}\lambda \\ T - \hat{z} \end{bmatrix}$$

Also, the minimal number of species that need to be measured is $S_m \geq R_I$.

The proof of this theorem is omitted due to the space limitations. As it was stated in Bastin and Dochain (1990), the asymptotic observer is stable and convergent if $\theta > 0$. To satisfy such condition, in this paper, it is assumed that u_{out} does not remain equal to zero for too long.

3.2. Reaction rate estimation

In Table 2, the model, and the mathematical formulation of the reaction rate estimator is presented. For this purpose, the model given by Eq. (4) is used.

Table 2. Reaction rate estimation.

Model	Estimator
$\dot{x} = A(\theta)x + Bu + Dd$ $\dot{d} = -\theta d$ $y_m = y = Cx$	$\dot{\hat{x}}_e = A_e(\theta)\hat{x}_e + B_e u + L(\theta)(y - \hat{y}),\ \hat{y} = C_e\hat{x}_e$ $x_e = [x^T\ d^T]^T,\ A_e(\theta) = \begin{bmatrix} A(\theta) & D \\ 0 & -\theta \end{bmatrix},\ B_e = \begin{bmatrix} B \\ 0 \end{bmatrix},\ C_e = [C\ 0]$

This estimator is known in the literature as an adaptive estimator, and basically, it considers the unknown disturbances as unmeasured states with its dynamics equal to zero. However, in this paper, the disturbance is assumed with the dynamic of the extents of reaction because these variables are strongly related. Note that, this estimator uses as measured variables the temperature and the number of moles of all components. This information is taken directly from the asymptotic estimator. Due to the cascade nature of the states and parameter estimation structure, the convergence of the reaction rate estimator should be faster than the convergence of the asymptotic estimator. This can be achieved by the correct tuning of the matrix $L(\theta)$. However, the selection of this matrix has some limitation which are stated in the following theorem,

Theorem 3. *Consider the LPV model of Table 3. If C is a full row rank matrix, then, there exists a parametric observer gain $L(\theta)$ given by $L(\theta) = -(\theta + \vartheta)I_n C^{\dagger}$ where $\vartheta = \text{eig}\left(A_e(\theta) - L(\theta)C_e\right)$, such that $\theta \le \vartheta$.*
The proof of this theorem is omitted due to the space limitations.

3.3. Recursive Least Squares (RLS)

The final step in the estimation structure is the estimation of the kinetic parameters. To this end, a Recursive Least Squares method is used. First, the reaction rate r is typically parametrized as: $r_k = k_0 \prod_{i=1}^{S_r} C_{i,k}^{\mu_i}$. This equation can be written as $\overline{r}_k = P_k\theta_p + e_k$, where $\theta_p = \left[\ln(k_0), \mu_1, \cdots, \mu_n\right]^{\mathrm{T}}$, $\overline{r}_k = \ln(r)$ and $P_k = \left[1, \ln(C_{1,k}), \cdots, \ln(C_{n,k})\right]$. Finally, the estimation of the kinetic parameters contained in θ_p can be calculated using the following optimization problem: $\hat{\theta}_{p,k} = \arg\min_{\theta_p} \sum_{j=1}^{k} \left\| e_j \right\|_S^2$ .The solution of this problem is given by $\hat{\theta}_{p,k+1} = \hat{\theta}_{p,k} + L_{\theta_p}(\overline{r}_k - P_k\hat{\theta}_{p,k})$, where L_{θ_p} is the Kalman gain, and it can be calculated by the solution of the discrete-time Riccati equation.

4. Example

Let us consider a non-isothermal CSTR where a reversible reaction $A + B \leftrightarrows C + D$ takes place. The system has four species, one independent reaction, and two constant and independent inlets of *A* and *B*. The reaction rate is given by $r = k_f C_A C_B - k_r C_C C_D$, with $k_{f,r} = k_{o_{f,r}} \exp\left(\frac{-E_{a_{f,r}}}{RT}\right)$, where, $k_{o_f} = 6.06 \times 10^5\ \text{m}^3\text{kmol}^{-1}\text{h}^{-1}$, $k_{o_r} = 9.84 \times 10^6\ \text{m}^3\text{kmol}^{-1}\text{h}^{-1}$, $E_{a_f} = 63800\ \text{kJ kmol}^{-1}$, $E_{a_r} = 71710\ \text{kJ kmol}^{-1}$. The matrices N and W_{in} are given by: $N = \begin{bmatrix} -1 & -1 & 1 & 1 \end{bmatrix}$, $W_{in} = \begin{bmatrix} 0.01665 & 0 & 0 & 0 \\ 0 & 0.03121 & 0 & 0 \end{bmatrix}^{\mathrm{T}}$. The initial conditions are

$n_0 = [0.5,1,0.5,0]^T$ kmol, and $T_0 = 373$ K. Figure 2 shows the profiles of simulated and estimated variables including random measurement noise in the temperature T and outlet flow u_{out} (θ). These pictures are obtained in open loop performing step changes in the inlet flows and the initial condition of T. The performance of the estimation structure is quite good, even under noise in θ, however, at the beginning of the simulation, $\hat{n}_D$ is taking negative values, which is not desired. This problem can be corrected assuming perfect measurement of the outlet flow or by an appropriate selection of the desired poles.

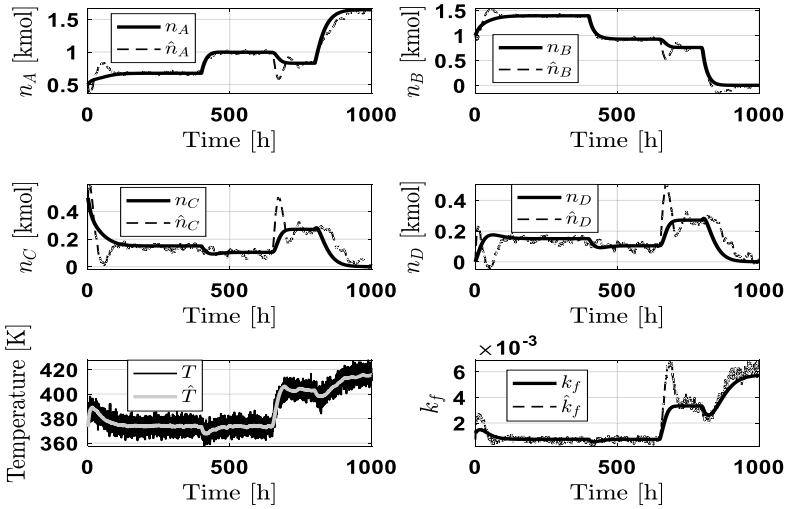

Figure 2. Trajectories of n_A, n_B, n_C, n_D, T and k_f : Simulated (—), Estimated (---)

5. Conclusions

In this paper, a general sequential parameter-and-state estimation structure based on extents-based LPV models for homogeneous and non-isothermal reaction systems is proposed. First, an asymptotic estimator is proposed based on an LPV model and without information of the chemical reaction rate. With the information given by the asymptotic estimator two estimators have been proposed: an adaptive estimator, and a Recursive Least Squares (RLS) estimator. Also, convergence and tuning properties of the final structure are analyzed. The estimation structure is tested on a simulation of a CSTR.

Abstract

In this study, a framework for efficiently detecting faults, and isolating fault causes with the integrated use of Markov Random Fields (MRF) and the graphical lasso, is proposed. MRFs are capable of expressing any subtle relationship that appears within a process without any a priori knowledge, and can compute the joint probabilities of the variables, taking in the nonlinearity of chemical processes. The graphical lasso, a regularization algorithm for inducing the sparse precision matrix and learning the structure of a graphical model, mitigates the high computational complexity of learning and inferencing a MRF. Also, by splitting the process variables into inter-relevant groups, it enables quick identification of the fault variable, and fault propagation path detection.

The proposed algorithm was applied to the Tennessee Eastman benchmark process (TEP), to test its performance. The 28 fault cases within the TEP model were tested with the new monitoring method, and the results were compared to that of the conventional methods. The proposed method showed high accuracy and efficient fault identification performance, even with the tricky fault cases 4 and 9.

Keywords: Process Monitoring, Fault Isolation, Graphical Models, Graphical Lasso

1. Introduction

Process monitoring is an essential part of safe plant operation, and has been studied in various angles over the past few decades. Among the various methods, conventional data-driven monitoring methods, such as PCA, FDA, and ICA have been used and improved extensively. However, these methods are inherently limited in that they are not capable of taking in nonlinearity, and various data processing methods have been implemented to resolve this problem.

Yan et al. (2016) used the two variant autoencoders, the contractive autoencoder (CAE) and the denoising autoencoder (DAE) to develop a nonlinear process monitoring model. They developed the monitoring statistics H^2 and SPE using the outputs of the autoencoders, and applied their method to the 20 fault cases of the TEP. Their results clearly show that due to the nonlinear nature of the activation function, the autoencoder monitoring framework greatly increases the fault detection rate. The limitation of their work is that, monitoring accuracy decreases greatly when the fault is related to highly interacting group of variables. Also, since the hidden layer of nodes containing dimensionally altered form of variables cannot provide knowledge about the individual contribution of the variables to the fault, fault identification is almost impossible.

The work by Gonzalez et al. (2015) implement the use of Bayesian networks to process monitoring. Using the kernel density estimation (KDE) method to fit conditional and joint probabilities, they take advantage of the causal nature of Bayesian networks to dissect the process monitoring problem into a series of probability inference problems. However, these works are limited in that they require a priori knowledge of the variable causal structure to fully use the Bayesian network monitoring system.

In this study, a monitoring framework that resolves the limitations of the previous methods is proposed. Since the TEP has been used as the benchmark problem for testing out various monitoring algorithms, the proposed algorithm is tested out on the 28 faults provided within the TEP. Such work involving TEP include the papers by Wang and Melo (2016), where they used the Bayesian treed Gaussian process methods for process monitoring, and the paper by Rato and Reis (2017), where they apply the sensitivity enhancing transformation (SET) for data pre-processing prior to process monitoring for improved fault diagnosis.

2. Methodology

The proposed methodology consists of the integrated use of two theories: Markov random fields (MRF), and the graphical lasso.

MRFs serve as the basis for modelling the relationships of variables, often vaguely represented within process data. By modelling the chemical process as a MRF, subtle relationships as well as cyclic relationships can be expressed, unlike Bayesian networks. Since cyclic relationships are abundant within a process, such as in distillation columns, it is more expressive to model a process as a MRF. When modelling process variables into a MRF, it is assumed that the variables form a multivariate Gaussian distribution. Thus by obtaining a covariance matrix among the variables a MRF is defined. After running the graphical lasso and obtaining a structure of the grouped variables, the MRF is trained to obtain a covariance matrix for each group. MRFs can be trained by obtaining the maximum log-likelihood of the data:

$$\mathrm{l}(\Theta) = \log det\Theta - \mathrm{tr}(S\Theta) \tag{1}$$

$$\Theta^{-1} - \mathrm{S} - \Gamma = 0 \tag{2}$$

The term Θ represents the precision matrix, inverse of the covariance matrix, S represents the empirical covariane matrx, and Γ is a matrix of Lagrange parameters, having the value zero for existing edges. The detailed description of the equations are given in Hastie et al. (2010). The separate MRFs can be trained using the iterative proportional fitting (IPF) algorithm. After all MRFs are trained, the $(1-\alpha)$ trust region is used to obtain the monitoring limit of the normal data. A typical value of $\alpha = 0.95$ is used in this work.

The graphical lasso is the extension of the lasso regularization to graphical models, where the algorithm seeks to find the sparse form of the precision matrix, using L1 regularization. Lasso itself is often used as a variable selection technique, and implementing it to graphical models allows it to reduce the model to a more sparse form. Thus, it can be used to learn the structure of the MRF. The essence of graphical lasso is obtaining the maximum of equation (3), where ρ is the regularization parameter making the precision matrix sparse. The details are given in Friedman et al. (2007).

$$\mathrm{l}(\Theta) = \log det\Theta - \mathrm{tr}(S\Theta) - \rho\|\Theta\|_1 \quad (3)$$

This process is an essential step of the proposed methodology, serving two purposes. One is that it allows efficient process monitoring and quick fault identification. As a result of the graphical lasso, the entire set of variables are segmented into groups, each group consisting of variables that are highly interrelated with each other. This leads to natural scale-down of the process monitoring dimension, enabling the process monitoring method to more effectively monitor faults and isolate them. Another important outcome of the graphical lasso is that it greatly mitigates the computational complexity when dealing with MRFs. MRFs typically require the partition function when learning its parameters or performing inference, which is a factor that greatly increases the computational complexity. By dissecting the graph into groups and dismissing irrelevant edges, the computational complexity related to MRF can be greatly reduced, making the monitoring process tractable. Since a single run of the graphical lasso results in a small graph while the rest of the variables are singled out, an iterative approach is applied, so that all of the variables can be grouped together for monitoring.

The overall methodology is implemented in the order shown in Figure 1. First, all of the process variables subject to monitoring are considered to be in a form of fully connected graph. Then the entire graph is input to the graphical lasso algorithm, to find the initial group of nodes. Since the main purpose of graphical lasso is to divide the graph into different sections for monitoring, a large enough lasso parameter is used to achieve this

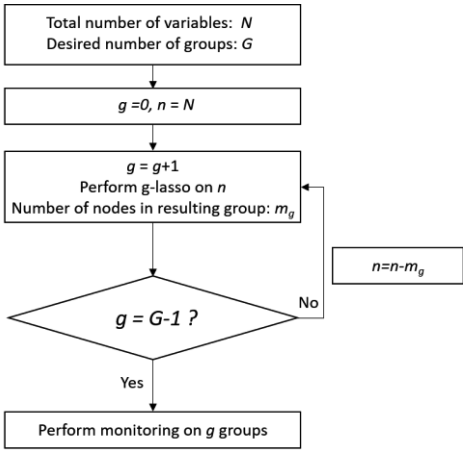

Figure 1. Proposed process monitoring framework

purpose. Usually this results in one small group of nodes, and all of the other nodes are isolated. For this reason, the graphical lasso is iteratively implemented on the rest of the results, to obtain multiple groups. An appropriate lasso parameter is selected empirically for each of the iterations. Afterwards, the grouped nodes are separately implemented into the MRF monitoring framework. Potential function and parameters of the MRFs are learned using IPF.

3. Results and Discussion

The proposed method is applied to the widely used Tennessee Eastman process (TEP), to verify its performance compared to that of conventional monitoring methods. For extensive analysis, rather than the original version by Downs and Vogel (1993), a revised version of the TEP, published by Bathelt et al. (2014) as a MATLAB Simulink model, was used to test out the monitoring framework. Compared to the original model, a more rigorous control structure was implemented in the Simulink model, and 8 extra faults were added, totalling up to 28 faults. The fault detection and isolation method was applied to each of the faults and the results were compared to that of the previous studies.

3.1. Grouping the process variables using graphical lasso

Prior to process monitoring, the 41 measurement variables of the TEP are divided into 6 groups, using the graphical lasso. After five dissections, the remaining nodes are gathered to form a final group. This process is shown in Figure 2.

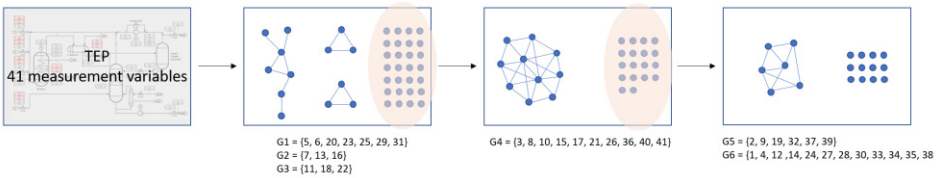

Figure 2. Performing iterative graphical lasso on 41 TEP variables

3.2. Monitoring: Improved fault detection performance

To emphasize the performance of the proposed method, the results of the faults 4 and 9 are presented in this paper, since they are usually deemed as the faults that are the most difficult to detect. Fault 1 is included as well as a representative case. Comparing with the monitoring results of fault 1 with the conventional PCA scheme, our framework shows an improvement in detection time by 1.5 hours. This is a significant improvement since 1.5 hours can be a critical time when dealing with process faults.

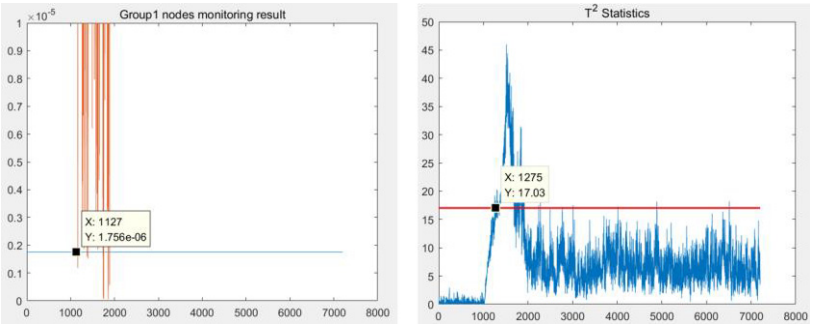

Figure 3. Monitoring results comparison of the proposed method and PCA

3.3. Fault propagation

To emphasize the effect of graphical lasso, it is tested out with the most recent, autoencoder monitoring framework. Due to the use of graphical lasso, process variables are monitored locally, and thus the fault propagation path can be detected. Considering

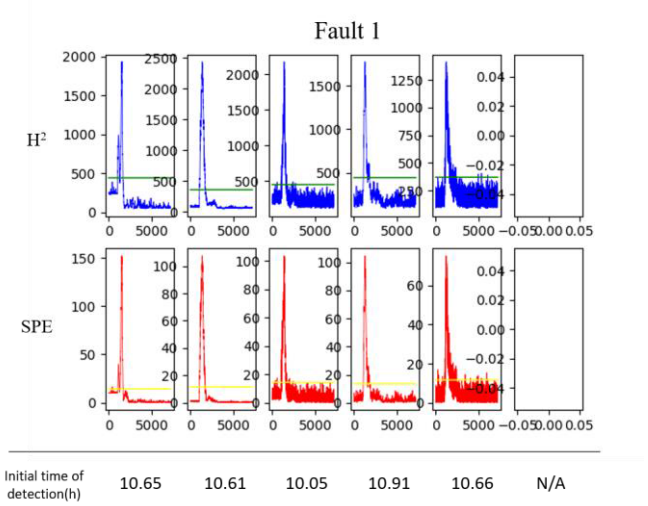

Figure 4. Fault propagation detection for fault 1

the fault detection results shown in Figure 4, the time in which fault is first detected within each group differs, suggesting a fault propagation path. The initial fault detection time of each group and the variables included in each group is given in Figure 4. The fault propagation among groups is evident from the initial detection time. Also, by analyzing the relevant variables within each group, it is possible to get a clear idea of the fault propagation path.

3.4. Fault isolation

A very important result of the proposed algorithm is the high efficiency in isolating a fault variable. For sensitive faults such as the first fault of the TEP, the process variable causing the fault can be isolated by investigating the group that is quickest in detecting the fault. However, the greatest strength of the proposed framework is revealed when dealing with complicated faults, such as the fourth and ninth fault of the TEP. Process

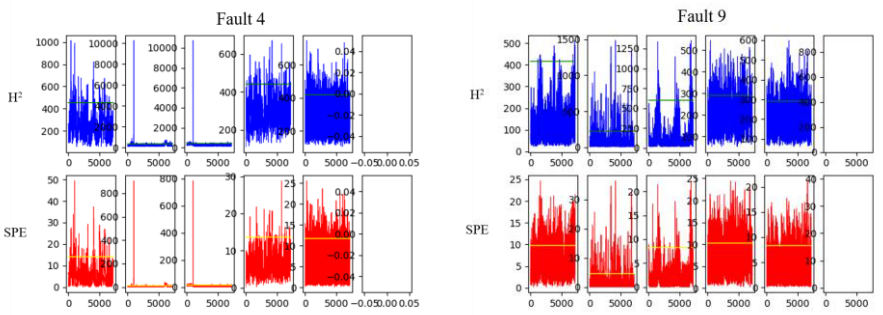

Figure 5. Fault isolation results for faults 4 and 9 of the TEP model

monitoring results of the two faults are given in Figure 5. Results from the recent process monitoring papers show that their methods detect only 30% of the faults, meaning it's almost impossible to get an idea of the location of the fault. However, as it can be seen from Figure 5, it is possible to restrict the region of fault variable and observe the trends for different groups when using this framework. The monitoring graph for fault 4 shows that groups number 2 and 3 are the only relevant regions for process monitoring. The benefit of the proposed framework is more evidently shown in the monitoring result for fault 9. When using only the autoencoder monitoring framework, one cannot even see whether a fault occurred at $t = 1000$, where in our case, group 3 clearly shows a change in value at that time, while all of the other groups are showing random noisy results. Considering the fact that fault number 9 is a random variation in D feed temperature, the results of our framework is consistent since group 3 contains variables 11, 18, and 22, all of them temperature variables. This suggests that, even without the knowledge of the fault such as in actual plants, it is possible to get evidence of the fault and start evaluating related variables.

4. Conclusions and Future Work

In this study, a framework for efficient process monitoring and fault isolation is proposed, via integrated use of the MRF learning and the graphical lasso. The proposed methodology was applied to the widely used TEP to test its performance. The results proved that the proposed method show great monitoring and fault isolation performance. These results show that with a simple application of the pre-processing method of graphical lasso to group the process variables, and using the remaining graph structure to perform MRF monitoring can not only enhance monitoring performance, but also provide process isolation and fault propagation results, allowing quick and accurate detection of process faults. This algorithm can be extended to industry-scale systems by simply adjusting the lasso parameter. This is to be included in future work.

Abstract

Reactive distillation columns with external recycle between the top and bottom (RDCs-TBER) have a better steady-state performance as compared with conventional reactive distillation columns (CRDCs) for the separations of reacting mixtures featuring the most unfavourable ranking of relative volatilities (i.e., the reactants are the lightest and heaviest components with the generated products in between). In this article, their dynamics and control are studied in great detail with special attention given to the influences of external recycle on process dynamics and controllability. Because of the totally reboiled operation mode plus a large reboiler, the CRDC is generally characterized by severe under-dampness between the intermediate-product compositions and the reboiler heat duty and long transient time. With external recycle between the top and bottom of the RDC-TBER, the suppression of the under-dampness between the intermediate-product compositions and the reboiler heat duty and relatively short transient time is attained, thereby presenting favourable influences to process dynamics and controllability. In additional, the supplementary manipulated variable (i.e., the flow rate of the external recycle) can be used to improve the process operation. A reactive distillation system, executing a hypothetical reversible reaction, A + B ↔ C + D ($\alpha_A > \alpha_C > \alpha_D > \alpha_B$), is employed to inspect the dynamics and controllability of the RDC-TBER and CRDC. The CRDC figures rather sluggish tracking responses because the under-damped behaviour and slow inventory control. The RDC-TBER, on the other hand, shows greatly improved tracking performance with even enhanced disturbance rejection capabilities.

Keywords: reactive distillation column, external recycle, total reboiled operation, process dynamics, process controllability.

1. Introduction

For the separation of reacting mixtures featuring the most unfavorable ranking of relative volatilities (i.e., the reactants are the lightest and heaviest components with the generated products in between), it is difficult to achieved high product purities via conventional reactive distillation columns (termed as CRDCs, hereinafter) with side draw and operating at total reboiled and total refluxed modes simultaneously (Chen et al., 2013). To deal this issue, Tung and Yu (2007) proposed a kind of reactive distillation columns with two reactive sections at the top and bottom (RDC-TRS). Despite the RDC-TRS can acquire high product purity, huge energy consumption should be applied. In order to overcome this difficulty, we proposed to utilizing feed splitting technology and/or adding external recycle between the top and bottom and thus derived five kinds of process alternatives with feed splitting and/or external recycle

(Chen et al, 2016): (i) reactive distillation columns with two reactive sections and feed splitting (termed as RDC-TRS-FS, hereinafter); (ii) RDC-TRS-FS with external recycle (termed as RDC-TRS-FS-ER, hereinafter); (iii) reactive distillation columns with two reactive sections and external recycle (termed as RDC-TRS-ER, hereinafter); (iv) reactive distillation columns with a top-bottom external recycle (termed as RDC-TBER, hereinafter); (iii) RDC-TBER with feed splitting (termed as RDC-TBER-FS, hereinafter). The results showed that adding a top-bottom external recycle and/or utilizing feed splitting technology to the reactive distillation column can largely improve the steady-state system performance as compared with the RDC-TRS and the CRDC for the separations of reacting mixtures featuring the most unfavorable ranking of relative volatilities. Although the steady state researches on the two methods employed showed that they have great advantages on enhancing process thermodynamics efficiency, their dynamics and controllability are needed to be studied.

In terms of the dynamics and control of RDC-TRS-FS for separating a two-stage consecutive reacting mixture ($A + B \leftrightarrow C + D$, $C + B \leftrightarrow E + D$ with $\alpha_D > \alpha_B > \alpha_C > \alpha_A > \alpha_E$), Kaymak et al. (2017) provided four types of control structures including a temperature inferential control, a direct composition control, and two hybrid temperature and composition control and concluded that the last two control schemes can achieve effective control performance with little steady state deviations. Lately, Cao et al. (2017) found that deliberate arrangement and control of feed splitting can give great favorable effects on process dynamics and control. As for the dynamics and control of RDC-TBER (c.f. Figure 1b), few papers can be found to the best of our knowledge, even though it has comparable (or even better) steady state performance than RDC-TRS-FS in some reaction systems. The RDC-TBER have more manipulating valuable (i.e., the flow rate of external recycle) than the CRDC because of the process retrofitting, which means that the RDC-TBER might have improved dynamic performance than the CRDC with the operation of the flow rate of external recycle even though the former represents much stronger internal mass integration and internal heat integration than the latter. Therefore, researches on the effects of external recycle to process operation and control are necessary.

The main purpose of the current article is to gain insights into the dynamic behaviors of the RDC-TBER and develop effective control systems. Detailed comparisons are made between the three control systems for the RDC-TBER and that for the CRDC. The separations of a hypothetical ideal quaternary reaction is employed as illustrative example to evaluate the impact of external recycle on process dynamics and control. After a brief discussion of the obtained outcomes, the article ends with the conclusions that can be drawn.

2. Dynamics and control of RDC-TBER

As sketched in Figure 1a, the CRDC for the separation of the most unfavorable reacting mixtures is configured in such a way that the reactive section is arranged deliberately at the bottom (which include not only the reboiler but also some stages in the lower section divided by the stage for withdrawing the reaction products) for the separation of an exothermic reaction. The lightest reactant A and the heaviest reactant B are fed, respectively, into the reboiler and at the top of the reactive section with the light product C and the heavy product D withdrawn together as an intermediate product above the reactive section. It is noted that this arrangement leaves the CRDC in a totally refluxed and totally reboiled operation mode. The reflux flow rate and reboiler heat duty are used

to maintain the inventories of the condenser and reboiler, respectively, and the compositions of the intermediate product are controlled by side draw flow rate. The very unusual process configuration and operation mechanism actually lend the CRDC very unique process dynamics that can have profound influences on process controllability.

First, the regulation path is to be analyzed. Varying the side draw flow rate could not directly affect the compositions of the intermediate product. Its variation should do this job though the bottom inventory control loop. The variation of the side draw flow rate will affect the level of the bottom, then the reboiler heat duty would be adjusted, and the compositions of the intermediate product will change indirectly. Actually it has two routines to affect the C and D compositions of the intermediate product. Once a change occurs in the reboiler heat duty, it arouses an immediate variation in the vapor flow rate and has its first impact on the C and D compositions of the intermediate product. After the change moves upward and enters into the condenser, the totally refluxed operation mode transfers it completely into a perturbation in the liquid flow rate. After it reaches the stage for withdrawing the intermediate product, the perturbed liquid flow rate then presents the second impact on the C and D product compositions. It is noted that the first and second impacts are along opposite directions, and their net effect is the occurrence of an open-loop, under-damped behavior. Apparently, the unique phenomenon is closely related to the totally refluxed operation mode; more specifically, when the inventory in the condenser is larger, the degree of under-dampness becomes more severe, which presents definitely detrimental influences to process controllability. Apart from the intensification of interaction with the other control loop (i.e., the stoichiometric-balance control loop), the under-damped behavior of the CRDC also poses additional restrictions to tightening controller tuning. Second, the disturbance path is to be analyzed. The primary disturbance essentially originates from the A feed flow rate (and this assumes implicitly that it is taken as the production rate handle). Because of the totally reboiled operation mode, the open-loop under-damped behavior should still prevail despite that the reboiler heat duty is supposed to regulate the reboiler inventory here. Nonetheless, the severity of the under-dampness should be alleviated substantially. With the adoption of external recycle in process revamp, the exploited degrees of freedom can generally lead to a great improvement in the steady-state performance of the RDC-TBER. As sketched in Figure 1b, an external recycle is now added from top to bottom to enhance the possibility of contacting between the lightest reactant A and the heaviest reactant B. Relatively low vapor and liquid heat loads are now solicited by the RDC-TBER than CRDC because of improved reaction conversion. The including of external recycle can also improve the process controllability. In the regulation path, the impact to the intermediate product compositions of C and D is considerably suppressed because of total reflux operation mode is changed into partial one. Therefore, the severity of open-loop under-dampness should be greatly abated in the RDC-TBER. In the disturbance path, the alleviation of the open-loop under-dampness behavior can still be expected. The improvement of open loop process dynamics will certainly present favorable influences to the tight control of the C and D compositions in the intermediate product.

In the following, two reactive distillation systems, including the separations of a hypothetical reversible reaction, $A + B \leftrightarrow C + D$ ($\alpha_A > \alpha_C > \alpha_D > \alpha_B$) is used to examine the insights on the dynamics and controllability of the CRDC and RDC-TBER.

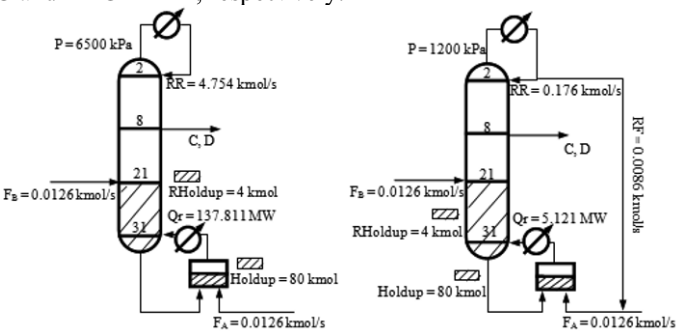
3. An illustrative example: A hypothetical ideal exothermic reaction

3.1. Process Studied

As shown in Figure 1, the two reactive distillation systems, i.e., the CRDC and RDC-TBER, are taken from Chen et al. (2013), which separate a hypothetical reversible reaction.

$$A + B \leftrightarrow C + D \quad (1)$$

To save the space, the main physicochemical properties, and other relevant information are omitted and one can found them in the relevant reference. The commercial software Mathematica is used in process simulation. In comparison with the CRDC, the RDC-TBER reduces the reboiler heat duty largely, highlighting the great potential of external recycle in process revamp. In this article, the solid and dashed lines stand for the outputs of the CRDC and RDC-TBER, respectively.



(a) (b)

Figure 1. Process synthesis and design. (a) CRDC, (b) RDC-TBER

3.2. Open-Loop Dynamic Characters

Figure 2 depicts the open-loop responses of the CRDC and RDC-TBER after they encounter ±5% impulse disturbances in the reboiler heat duty, separately. For both the positive and the negative perturbations, the CRDC shows seriously under-damped responses in the C and D compositions of the intermediate product. It is noted that the C composition of the intermediate product competes intensively with the D composition of the intermediate product, giving rise to quite similar responses but with opposite changing directions. For the RDC-TBER, external recycle makes it exhibit a degree of under-dampness that is considerably reduced as compared with that in the CRDC, implying a favorable influence on process dynamics by such a process revamp.

Figure 3 depicts the open-loop responses of the CRDC and RDC-TBER after ±5% impulse changes are introduced, separately, into the A feed flow rate. With the adoption of external recycle, the under-damped behaviors are subdued in the RDC-TBER, implying again a favorable influence on process dynamics by such a process revamp.

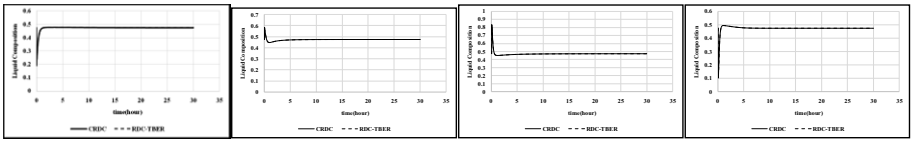


Figure 2. The open-loop responses of the CRDC and RDC-TBER after ±5% impulse disturbances in the reboiler heat duty

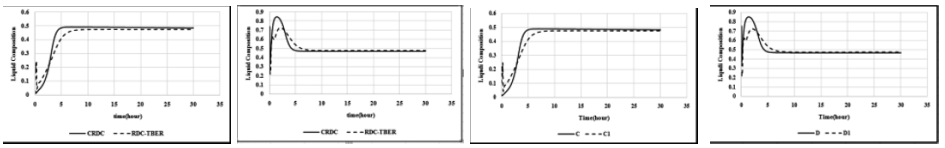

Figure 3. The open-loop responses of the CRDC and RDC-TBER after ±5% impulse disturbances in the A feed flow rate

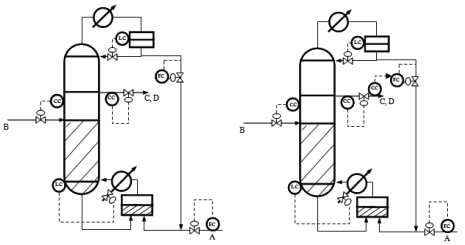
3.3. Closed-Loop Operation



(a) (b)

Figure 4. Control systems of RDC-TBER, (a) CS1, (b) CS2

Direct composition control schemes are employed here as shown in Figure 4. Column pressure is regulated with the condenser heat removal, and the inventories of the reflux drum and reboiler are regulated with the reflux and reboiler heat duty, respectively, via a P-only controller. The product compositions are controlled with two methods. One is that the C composition of the intermediate product is regulated by the intermediate product flow rate via a PI controller, leaving the D composition of the intermediate product uncontrolled (c.f. Figure 4a); and the other is that the C composition of the intermediate product is regulated by the intermediate product flow rate and the D composition of the intermediate product is regulated by external recycle flow rate (c.f. Figure 4b). The B feed flow rate is employed to control the composition of B on stage 5 in the CRDC and on stage 10 in the RDC-TBER since the composition variation is the largest, serving to keep the stoichiometric ratio between the lightest reactant A and the heaviest reactant B. Although a P-only composition controller or a PI composition controller can be used here, for the sake of simplicity, the former option is chosen. The A feed flow rate is flow-controlled and works as the production rate handle. The composition controllers, designed in-line with the Tyreus− Luyben tuning rule. Composition measurement devices are assumed to act like a first order process with a 3 min time constant, and control valves are all set at the half-open position in the nominal steady state.

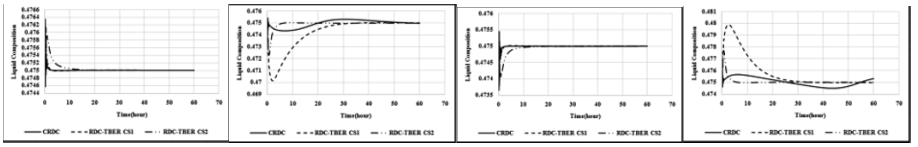


Figure 5. The regulatory responses of the CRDC and RDC-TBER after ±5% step changes are introduced into the A feed flow rate

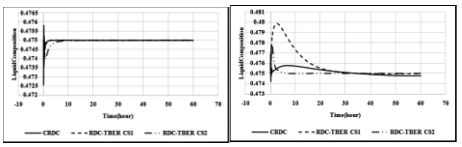

Figure 6. The regulatory responses of the CRDC and RDC-TBER after ±5% step changes are introduced into the A feed composition

The regulatory responses of the CRDC and RDC-TBER are illustrated in Figure 5 and 6, after ±5% step changes are introduced into the A feed flow rate and the A feed composition, respectively. Note that with the manipulating of external recycle, RDC-TBER (CS2) is found to be advantageous over the CRDC in this situation.

4. Conclusions

The unusual process configuration and operation mechanism, i.e., the totally refluxed and totally reboiled operation mode plus an intermediate-product withdrawal, lend the CRDC very unique process dynamics. In the regulation and disturbance path, seriously under-damped behaviours could occur between the light or heavy product compositions of the intermediate product and the side draw flow rate. These dynamic characteristics are likely to pose great difficulties for the tight quality control of the intermediate product. With the adoption of external recycle in the RDC-TBER, the reaction conversion is carefully coordinated, and this leads to not only the enhancement of steady-state performance but also the suppression of those unfavourable dynamic characteristics aroused by the totally refluxed and the totally reboiled operation mode plus an intermediate-product withdrawal. The reactive distillation system carrying out a hypothetical reversible reaction has been employed to scrutinize the dynamics and control of the CRDC and RDC-TBER. Two control systems of the RDC-TBER are developed. All of the obtained results have confirmed that with the adoption of external recycle the RDC-TBER helps to substantially alleviate the inherent drawbacks and therefore presents favourable influences to process dynamics and controllability.

Abstract

In this work, a new systematic methodology to address multivariable control structure (MCS) design for heat exchange networks (HENs) is proposed. This methodology is based on recent developments presented by Braccia et al. (2017) where the MCS design for medium/large-scale processes is performed based on a mixed-integer quadratic programming (MIQP) formulation. This methodology is based on an equation-oriented superstructure which addresses simultaneously: the selection of controlled variables (CVs) and manipulated variables (MVs), the input-output pairing definition, the controller topology, the initial heuristics considerations, and the stability test by using steady-state information only. Usually, in the HENs cases, all the outputs variables need to be controlled, i.e. there are no uncontrolled variables. In this context, the MCS design procedure presented in Braccia et al. (2017) requires a reformulation to quantify the manipulated variables instead of the uncontrolled variables. Furthermore, some modifications of the original MIQP algorithm related to the augmented functional cost are analyzed. The performance of different controller topologies, i.e. decentralized, sparse, and full, are evaluated. Two examples are given in this work to illustrate the potential of the proposed methodology and to support the final conclusions.

Keywords: Heat exchanger network synthesis, Multivariable controller design, Mixed-integer quadratic programming.

1. Introduction

The control structure design of heat exchange networks (HENs) is one of the most studied problems in the last decades. The aim of the control structure is to accommodate set-point changes and reject load disturbances in the network. Several approaches are proposed in the literature to ensure an appropriate control structure. Mathisen, et al. (1994) provided a heuristic method for bypass placement. Yang et al. (2001) and Escobar and Trierweiler (2009) proposed a retrofit HEN strategy with optimal bypass placement based on a simplified model for disturbance propagation and control. Morever, the pairing is based on the partial relative gain array (RGA), which is defined similar to the regular RGA.

In this work, a new MCS design formulation for heat exchange networks is proposed. The methodology of Braccia et al. (2017), which is based on the sum of squared deviations (SSD) and the net load evaluation (NLE) indexes, is considered as a starting point. A

reformulation of this methodology is made to quantify the manipulated variables instead of the uncontrolled variables, since control structure design problems for HENs require all the output variables to be controlled. Different controller topologies, i.e. decentralized, sparse, and full, are designed and analyzed.

2. Control Structure Design.

The proposed approach is based on an equation-oriented superstructure which addresses simultaneously: the selection of controlled variables (CVs) and manipulated variables (MVs), the input-output pairing definition, the controller design, the initial heuristic considerations, and the stability test by using only steady-state information. Given the transfer function matrix representation of a stable or stabilized plant, it can be partitioned as:

$$\begin{bmatrix} \boldsymbol{y}_s(s) \\ \boldsymbol{y}_r(s) \end{bmatrix} = \begin{bmatrix} \boldsymbol{G}_s(s) & \boldsymbol{G}_s^*(s) \\ \boldsymbol{G}_r(s) & \boldsymbol{G}_r^*(s) \end{bmatrix} \cdot \begin{bmatrix} \boldsymbol{u}_s(s) \\ \boldsymbol{u}_r(s) \end{bmatrix} + \begin{bmatrix} \boldsymbol{D}_s(s) \\ \boldsymbol{D}_r(s) \end{bmatrix} \cdot \boldsymbol{d}^*(s) \tag{1}$$

where $\boldsymbol{y}_s(s)$ and $\boldsymbol{y}_r(s)$ are the selected controlled variables (CVs) and the uncontrolled variables, respectively, $\boldsymbol{u}_s(s)$ are the selected manipulated variables (MVs) to control the subprocess $\boldsymbol{G}_s(s)$, and $\boldsymbol{u}_r(s) = 0$. Besides, $\boldsymbol{d}^*(s)$ are the disturbance variables (DVs). In Braccia et al. (2017), the process partitioning is done in the mixed-integer quadratic programming (MIQP) formulation by constraining specific entries in the inputs ($\boldsymbol{u}$) and the outputs ($\boldsymbol{y}$). The main idea is to minimize two indexes, i.e. SSD and NLE, which quantify the deviation of some specific process variables from their nominal operating point when set-point changes and disturbances occur individually. Obviously, the best solution depends on the CVs, MVs, and controller structure selection. The major contribution of this formulation is to translate the selection criteria based on the process matrices (G and D) to the input-output process variables (u and y). For this purpose, binary variable vectors to select the input and output variables ($\mathrm{z^I}$ and $\mathrm{z^O}$, respectively) and matrices to select the input-output pairing definition and controller design ($\mathrm{z^n}$ and $\mathrm{z^{nd}}$, respectively) are used. Using these binary variables, for each set-point and disturbance change the output and input variables are quantified by solving a system of equations, and the squared deviations are added up into the cost function.

In the proposed work, the control structure of the HEN is designed by only selecting the MVs, since all the process output variables (output temperatures) need to be controlled. In this sense, for a given HEN design ($\boldsymbol{G} = [g_{k,l}], \boldsymbol{D} = [\mathrm{d}_{k,j}]$), where $\mathrm{N_H}$ hot streams and $\mathrm{N_C}$ cold streams are integrated, the MIQP formulation presented in Braccia et al. (2017) is reformulated as follows:

$$\min_{\boldsymbol{u},\boldsymbol{y},\boldsymbol{z}} \mathrm{SSD} + \mathrm{NLE} = \sum_{i=1}^{m}\sum_{l=1}^{n} (u_{l,i}^{c})^2 + \sum_{j=1}^{d}\sum_{l=1}^{n} (u_{l,j}^{d})^2 + \sum_{i=1}^{m}\sum_{k=1}^{m} (y_{i,k}^{nc})^2 + \sum_{j=1}^{d}\sum_{k=1}^{m} (y_{j,k}^{nd})^2 \tag{2}$$

$$\text{subject to } \sum_{l=1}^{n} g_{k,l}\, u_{l,i}^{\mathrm{c}} - \phi_{k,i} = 0, \forall i,k \tag{3}$$

$$\sum_{l=1}^{n} g_{k,l}\, u_{l,j}^{\mathrm{d}} - \mathrm{d}_{k,j} = 0, \forall j,k \tag{4}$$

$$-\mathrm{M}\, z_l^{\mathrm{I}} \le u_{l,i}^{\mathrm{c}} \le \mathrm{M}\, z_l^{\mathrm{I}}, \forall i, l \tag{5}$$

$$-\mathrm{M}\, z_l^{\mathrm{I}} \le u_{l,j}^{\mathrm{d}} \le \mathrm{M}\, z_l^{\mathrm{I}}, \forall j, l \tag{6}$$

$$\sum_{l=1}^{n} z_l^{\mathrm{I}} = \mathrm{N_H} + \mathrm{N_C} \tag{7}$$

$$-\mathrm{M}\left(1 - z_{k,l}^{\mathrm{n}}\right) \le u_{i,k,l}^{\mathrm{nc}} - u_{l,i}^{\mathrm{c}} \le \mathrm{M}\left(1 - z_{k,l}^{\mathrm{n}}\right), \forall i, k, l \tag{8}$$

$$-\mathrm{M}\left(1 - z_{k,l}^{\mathrm{n}}\right) \le u_{j,k,l}^{\mathrm{nd}} - u_{l,j}^{\mathrm{d}} \le \mathrm{M}\left(1 - z_{k,l}^{\mathrm{n}}\right), \forall j, k, l \tag{9}$$

$$-\mathrm{M}\, z_{k,l}^{\mathrm{n}} \le u_{i,k,l}^{\mathrm{nc}} \le \mathrm{M}\, z_{k,l}^{\mathrm{n}}, \forall i, k, l \tag{10}$$

$$-\mathrm{M}\, z_{k,l}^{\mathrm{n}} \le u_{j,k,l}^{\mathrm{nd}} \le \mathrm{M}\, z_{k,l}^{\mathrm{n}}, \forall j, k, l \tag{11}$$

$$y_{i,k}^{\mathrm{nc}} + \sum_{l=1}^{n} g_{k,l}\, u_{i,k,l}^{\mathrm{nc}} - \phi_{k,i} = 0, \forall i, k \tag{12}$$

$$y_{j,k}^{\mathrm{nd}} + \sum_{l=1}^{n} g_{k,l}\, u_{j,k,l}^{\mathrm{nd}} = 0, \forall j, k \tag{13}$$

$$z_{k,l}^{\mathrm{n}} \le z_l^{\mathrm{I}}, \forall l, k, \quad z_l^{\mathrm{I}} \le \sum_{k=1}^{m} z_{k,l}^{\mathrm{n}}, \forall l, \quad z_{k,l}^{\mathrm{nd}} \le z_{k,l}^{\mathrm{n}}, \forall k, l \tag{14}$$

$$z_l^{\mathrm{I}} \le \sum_{k=1}^{m} z_{k,l}^{\mathrm{nd}}, \forall l, \quad 1 = \sum_{l=1}^{n} z_{k,l}^{\mathrm{nd}}, \forall k \tag{15}$$

$$-\mathrm{M}\left(1 - z_{i,l}^{\mathrm{nd}}\right) \le y_{i,l}^{\mathrm{r}} - g_{i,l}\, u_{l,i}^{\mathrm{c}} \le \mathrm{M}\left(1 - z_{i,l}^{\mathrm{nd}}\right), \forall i, l \tag{16}$$

$$\delta_1 z_{i,l}^{\mathrm{nd}} \le y_{i,l}^{\mathrm{r}} \le \delta_2 z_{i,l}^{\mathrm{nd}}, \forall i, l \tag{17}$$

$$\sum_{i=1}^{m} (1 - y_{i,i}^{\mathrm{nc}}) \ge \delta \tag{18}$$

In the proposed reformulation model, the SSD subproblem is addressed by eqs. (3) to (6). The variable $\boldsymbol{u}_i^c = \left[u_{l,i}^{\mathrm{c}}\right]$ and $\boldsymbol{u}_j^d = \left[u_{l,j}^{\mathrm{d}}\right]$ are the complete input vectors (including selected and not selected MVs) for the *i*-th set-point change and *j*-th disturbance effect, respectively. The unitary vectors $\phi_{\mathrm{i}} = \left[\phi_{\mathrm{k,i}}\right]$ generate the (normalized) change of set point i and the binary vector variable $\mathrm{z^I} = \left[\mathrm{z_l^I}\right]$ is used to select the MVs in the big-M formulation. The eq. (7) guarantees that the number of CVs and MVs are the same (square control structure). Note that, in this equation the number of CVs is equal to the total

number of currents in the network $(N_H + N_C)$ since all the process output variables (output temperatures) need to be controlled.

Moreover, the NLE subproblem is addressed by eqs. (8) to (13). The big-M inequalities given in eqs. (8) to (11) define the input response ($u_i^{nc} = [u_{i,k,l}^{nc}]$ and $u_j^{nd} = [u_{j,k,l}^{nd}]$) associated to the controller structure selected in z^n for each type of change. In this subproblem $y_i^{nc} = [y_{i,k}^{nc}]$ and $y_j^{nd} = [y_{i,k}^{nd}]$ are the complete net load effect vectors associated with control structure selection for ith set-point change and jth disturbance effect. The constraints in eqs. (14) and (15) are structural constraints. On the one hand, they guarantee that the controller structure z^n has only entries in allowed positions defined by the selection of CVs and MCs. In the other hand, they ensure that at least a decentralized policy is used. The selection of the decentralized control structure is represented with z^{nd}. This binary vector variable is used into a big-M constraint (eq. 16) to perform the RGA ($y^r = [y_{i,l}^r]$) matrix. The eq. (17) is used to guarantee a feasible and useful input-output pairing according to scalar parameters δ_1 and δ_2 fixed by the user. Finally an alternative stability/robustness test is include in the formulation in eq. (18), where a small positive lower bound δ is considered. A detailed description of SSD and NLE indexes, the perform of the RGA matrix or the stability criterion is not included here on account of the available space, but can be found in Braccia et al. (2017).

3. Case Study

In this section, a structure HEN02 studied in Escobar et al. (2009) are used to illustrate the application of the proposed MCS design procedure. In table 1 the design data are presented.

Table 1. Case study problem data

Stream	Tin (°C)	Tout (°C)	Flow Capacity ($kW°C^{-1}$)	Heat transfer coefficient ($kW°C^{-1}m^{-2}$)
H1	270	160	18	1
H2	220	60	22	1
C1	50	210	20	1
C2	160	210	50	1
CU	15	20		1
HU	250	250		1

On the one hand, the system input variables are the exchanger bypass on hot (and cold) side and the utility flow rate. On the other hand, the inlet temperature and flow rate of stream are the disturbance variables. The HEN02 configurations are composed by 11 inputs (where u_9, u_{10}, and u_{11} are associated with the flow rate of utilities), 4 outputs, and 8 disturbances. The disturbance propagation and control model presented in Yang et al. (2001) is used to obtain the steady-state gain of the process matrices (***G*** and ***D***). Since this model does not consider the hot and cold utilities, it is modified to: (a) incorporate these utilities as new heat exchangers and (b) include new process streams. In this sense, the hot and cold utilities are also characterized by the resulting steady-state gain matrices. Finally, the implementation utilizes an interface between MATLAB and GAMS, in which MATLAB generates the necessary data for each problem while GAMS solves the MIQP formulations. The state-of-the-art solver CPLEX 12.6 has been used to solve the MIQP problem.

3.1. RGA-based Input-Output Pairing.

We first analyse the results obtained by the proposed MIQP approach considering several alternatives for the interaction range $[\delta_1, \delta_2]$, which are presented in Table 2. It is important to recall that all results are associated to different decentralized control structures for HEN02. According to the discussion in Braccia et al. (2017), the parameter δ_1 is the most important limit, since it represents the minimum acceptable interaction.

In table 2, it can be observed that the performance index (SSD+NLE) increases if the interaction range is tighter. It is clear that a smaller lower bound for the interaction, i.e. $\delta_1 = 0.1$, allows the RGA matrix to include smaller elements. In this sense, the value of the RGA number (RGAn) increases.

Table 2. HEN02 decentralized results – Alternative interaction ranges $[\delta_1, \delta_2]$

$[\delta_1, \delta_2]$	SSD+NLE	Optimization Time [s]	RGA Number
$[0.1 , 1\times10^{5}]$	66574.60	16.02	2.18
$[0.2 , 1\times10^{4}]$	66574.60	14.57	2.18
$[0.5 , 1\times10^{3}]$	69171.23	32.64	1.82
$[0.9 , 1\times10^{2}]$	81975.06	11.12	0
$[1 , 1\times10^{1}]$	81975.06	20.90	0

3.2. Multivariable Control Structure Design

In this section different controller structures, i.e. descentralized, sparse and full, for HEN02 configurations are analyzed. Figures 1 show the optimal MCS designs obtained using the MIQP formulation for each configuration and controller type. These figures display the input-output pairing and plant-model mismatch obtained (which are marked using black and gray background, respectively).
Furthermore, in order to quantify and compare the performance of the solutions, three indexes are calculated and reported in Table 3: the performance index (SSD+NLE), the RGAn, and condition number (ρ). In this sense, this table shows that for HEN02 configuration the sparse structure has the best SSD+NLE index.

4. Conclusions

In this work, a new systematic methodology to address the multivariable control structure (MCS) design of heat exchanger networks based on a mixed-integer quadratic programming (MIQP) formulation is proposed. The optimal solutions of the proposed formulation can be obtained using state-of-the-art solvers such as CPLEX in GAMS. On the one hand, several alternatives for the interaction range were considered to evaluate their impacts on MCS design. On the other hand, the proposed approach has been successfully tested on HEN02 configuration. Three types of MCS based on three different controller topologies were designed. The results show that the optimal sparse controllers have the best performance. However, the improvement in the SSD+NLE indexes produced by this controller topology requires adding several control loops. In future work the integration between process control and process synthesis and design will be analyzed. In particular, an appropriate MCS design to guarantee a suitable HEN operation over a specified range of expected variations in the inlet temperatures of the process streams will be developed.

Abstract

In this work, a novel design methodology based on the control allocation (CA) approach is presented. The CA structure allows to explicitly handle the input constraints (e.g. actuator position limits) as well as the secondary control objectives (e.g. minimization of the control energy). In addition, it can manage actuator saturations (and faults) without performing a reconfiguration of the control structure. The proposed architecture involves two levels: (i) a high-level decentralized structure implemented with conventional PI controllers and (ii) a CA module based on a weighted least-squares formulation which utilizes an active set method algorithm. The complete procedure only requires a steady-state model of the process for the structure design. Several dynamic simulations demonstrate the performance of the suggested strategy.

Keywords: plantwide control design, control allocation, heat exchange networks

1. Introduction

The control of heat exchanger networks (HEN) represents an important problem in chemical engineering. On the one hand, HEN are commonly responsible of managing much of the process energy recovery, which significantly impacts on the global operating costs. On the other hand, HEN typically introduce important interactions among the process variables, complicating the control structure design and the controllers tuning.

In this work, the control allocation (CA) philosophy (Johansen and Fossen, 2013) is considered in order to design control structures (CS) for HEN. Commonly, CS can be distinguished depending on their degree of centralization, where decentralized and centralized are the common control policies. Traditional decentralized architectures based on multi-loop PID controllers present a significant drawback: they are not able to handle actuator constraints. While centralized strategies, such as MPC-based control systems, present several advantages over multi-loop structures, most contributions in the literature propose decentralized CS for HEN. The main reasons lie in the costs associated with the model identification task, the commissioning/maintenance, and the typical computational burden of the MPC systems.

This work proposes CS for HEN based on a novel architecture. This alternative design presents two hierarchical levels: (i) a high-level control (HLC) strategy consisting of

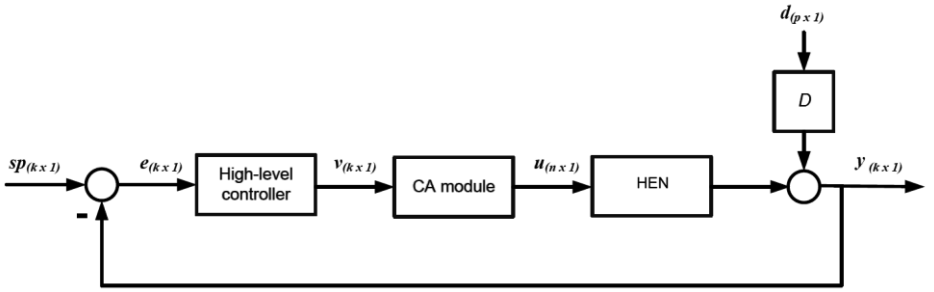

Figure 1: CA-based control structure

multi-loop PID controllers for computing a vector of virtual inputs and (ii) a control allocation module for mapping the vector of virtual inputs on the manipulated variables vector. This modular architecture allows to design the HLC by taking into account minimum information about the CA block. In addition, the CA module can handle the actuator constraints by itself. Another advantage is that it has the ability to accommodate actuator saturations and/or faults due to the automatic reutilization of the manipulated variables (redistribution of the manipulated energy).

The CS design procedure begins with the partition of the HEN model. The objective is to isolate the HLC design task from the CA module configuration. The next stage focuses on the HLC design, which is based on the well-known methodology presented by Braccia et al. (2017). In addition, a weighted least-squares formulation based on an active set method (Harkegard, 2002) is adopted for solving the CA problem due to its reduced computational load. The performance of the proposed CA-based CS design is evaluated through simulation of a HEN dynamic model, and it is compared against a conventional decentralized control structure.

2. Control structure design methodology

Consider a stabilized process with *n* inputs, *m* outputs and *p* disturbances expressed as:

$$y(s) = G(s)u(s) + D(s)d(s) \tag{1}$$

where *y(s)*, *u(s)*, and *d(s)* correspond to column vectors of dimension *(m x 1)*, *(n x 1)*, and *(p x 1)*, respectively. *G(s)* and *D(s)* are transfer function matrices which relate the inputs-outputs and disturbances-outputs, respectively, with dimension *(m x n)* and *(m x p)*. As illustrated in Fig. 1, a control allocation architecture is based on a high-level control (HLC) strategy and a control allocation (CA) module (Johansen and Fossen, 2013). The HLC strategy must compute a (column) vector of *k* virtual variables *v(s)*, which are usually defined based on the main process objectives. In addition, the CA module deals with the optimal management of the manipulated variables *u(s)* in order to satisfy:

$$v = M\,u, \quad u \in C \tag{2}$$

where *M* is a *(k x n)* matrix (commonly called control effectiveness matrix) and *C* represents the control constraints. Typically, the number of manipulated variables is greater than the number of outputs to be controlled (i.e. $n > k$). This allows to formulate

the CA problem as an optimization problem, where secondary control objectives can be easily included.
For the *(m x n)* matrix *G*, the singular value decomposition is defined as:

$$G = USV^T = [U_1 \quad U_2]\begin{bmatrix} S_1 & 0 \\ 0 & S_2 \end{bmatrix}\begin{bmatrix} V_1^T \\ V_2^T \end{bmatrix} \tag{3}$$

where *U* and *V* are *(m x m)* and *(n x n)* unitary matrices and the *(m x n)* matrix *S* contains real non-negative singular values arranged in descending order along its main diagonal. In Eq.(3), S_1 contains the *k* largest singular values. If the remaining (relatively small) singular values contained in S_2 are forced to zero, then an approximate representation of *G* is produced:

$$G \cong U_1 S_1 V_1^T \tag{4}$$

where U_1, S_1 and V_1 have dimension *(m x k)*, *(k x k)* and *(n x k)*. By discarding the smallest singular values of *S*, the least effective control directions of the plant are not taken into account. Note that Eq.(4) can be expressed as:

$$G \cong G_1 G_2 \quad with \quad G_1 = U_1 \quad and \quad G_2 = S_1 V_1^T \tag{5}$$

Assuming that the problem of Eq.(2) (unconstrained case) is based on $M = G_2$ and that G_2 has full rank, then it is simple to demonstrate that the transfer function which links *y* with *v* is U_1. Inversely, assuming that *y* and *v* are related via $G_1=U_1$ and that the pseudo-inverse of *G* from Eq.(4) is $G^+=V_1(S_1)^{-1}(U_1)^T$, then it is easy to show that:

$$u = V_1 S_1^{-1} v \tag{6}$$

i.e. the CA problem is based on $M = G_2$. In this framework, the proposal is to utilize the matrix $G_1=U_1$ for the HLC structure design and $G_2=S_1(V_1)^T$ for configuring the CA module. Note that the *(m x k)* matrix U_1 directly defines *k* virtual variables which are linked to the process outputs. Thus, it is possible to apply any know design methodology such as Braccia et al. (2017) for developing a decentralized (diagonal) HLC structure from $G_1=U_1$ and *D*.
Concerning the CA problem, the weighted least-squares (WLS) formulation proposed by Harkegard (2002) is considered here:

$$\min_u \left\| W_u(u - u_p) \right\| + \gamma \| W_v(G_2 u - v) \| \quad s.t. \quad \underline{u} \le u \le \overline{u} \tag{7}$$

where u_p corresponds to the nominal control input, W_u and W_v are weighting matrices which affect the control distribution among the actuators and the virtual variables, respectively, and gamma (γ) is a weighting parameter for relatively prioritizing the minimization of the control allocation error and the actuators movement. In addition, the constraints of Eq.(7) represent the position and/or the rate actuator limits. In this work, the active set based solver proposed by Harkegard (2002) is utilized to obtain the optimal solution of the CA problem. Such algorithm is very efficient for CA because a good estimate of the optimal active set is available from the previous sampling period. Moreover, active set methods are simple to implement with low computational burden.

3. Application example: HEN system

In this section it is considered the HEN studied in Braccia et al. (2015). It consists of two cold streams C_1 and C_2, one hot stream H_1, three heat exchangers (E_{111}, E_{121}, E_{122}), and one cooling utility (CU_1). The objective is to keep the outlet temperatures of hot and cold streams at their reference values (i.e. $Thout_1$ = 318 K, $Tcout_1$ = 393 K, $Tcout_2$ = 393 K) through the manipulation of the heat exchangers, rejecting flow and temperature disturbances at the inlet streams. In the following, uh_{ijk} (and uc_{ijk}) represent the exchanger bypass of hot (and cold) side between hot stream i and cold stream j at stage k, and fcu_1 represents the cooling utility flow, which constitute 7 system input variables (uh_{111}, uh_{121}, uh_{122}, uc_{111}, uc_{121}, uc_{122}, fcu_1). In addition, $Thin_i$ (and $Tcin_i$) correspond to the inlet temperature of hot (and cold) stream i, and fh_i (and fc_i) represent the flow capacity of hot (and cold) stream i, which constitute 6 system disturbance variables ($Thin_1$, $fhin_1$, $Tcin_1$, $fcin_1$, $Tcin_2$, $fcin_2$). The normalized steady-state gain matrices G and D corresponding to the nominal operating point presented in Braccia et al. (2015) are considered here for the CS design. The associated inputs, outputs and disturbances are: $u = [uh_{111}, uh_{121}, uh_{122}, uc_{111}, uc_{121}, uc_{122}, fcu_1]^T$, $y = [Thout_1, Tcout_1, Tcout_2]^T$ and $d = [Thin_1, fhin_1, Tcin_1, fcin_1, Tcin_2, fcin_2]^T$.

3.1. High-level control

In order to satisfy the HEN requirements, all outputs $Thout_1$, $Tcout_1$ and $Tcout_2$ must be controlled. Thus from Eq.(3), k = 3 must be configured. Taking into account the RGA-number minimization procedure proposed by Kariwala and Cao (2010), the obtained pairings between the virtual and controlled variables are: v_1-$Thout_1$, v_2-$Tcout_2$ and v_3-$Tcout_1$, which correspond to a decentralized (diagonal) CS implemented with 3 PI loops. The corresponding tuning parameters are: Kc_1 = 70, Ti_1 = 3.4, Kc_2 = 110, Ti_2 = 0.45, and Kc_3 = -43.3, Ti_3 = 1.25, which were obtained through the IMC method proposed by Garcia and Morari (1985).

3.2. Control allocation module

The proposed CA algorithm is based on the active set method for the weighted least-squares (WLS) formulation presented in section 2. In the following, the dynamic performance and timing properties of the CA are evaluated taking into account different simulation scenarios. On the one hand, the tuning of the gamma (γ) parameter as well as the control weighting matrix W_u are considered to show the CA ability for handling secondary control objectives (i.e. the control energy). On the other hand, an adjusted version of the nominal constraint set is proposed to demonstrate the advantages of the WLS algorithm.

Table 1: simulation scenarios

Scenario	Time [s]	Event	Variable	Type	Magnitude
Sc1	10	SP change	$Thout_1$	Step	+1.0 K
	500	"	$Tcout_1$	"	-1.0 K
	1000	"	$Tcout_2$	"	-1.0 K
Sc2	10	DV change	$Thin_1$	"	+2.5 K

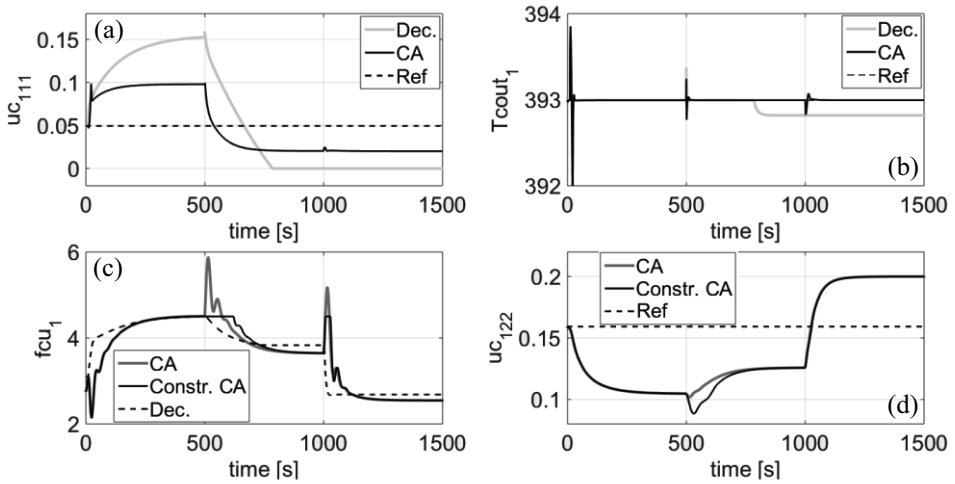

Figure 2: Dynamic responses

3.3. Results

In this section, several simulations of the complete system involving the dynamic model of the HEN controlled with the high-level controller plus the CA module are presented. In this context, different scenarios characterized by alternative CA configurations, constraints sets, setpoint (SP) changes and disturbances (DV) are considered, see Table 1. Also, a conventional decentralized CS for the HEN system which is composed of 3 control loops was developed for the sake of comparison. It was obtained taking into account the methodology proposed by Braccia et al. (2017). The selected manipulated variables and the corresponding pairings are: fcu_1-$Thout_1$, uc_{111}-$Tcout_1$ and uc_{122}- $Tcout_2$. The associated tuning parameters are: Kc_1 = -0.28, Ti_1 = 0.5, Kc_2 = -0.07, Ti_2 = 0.0097, and Kc_3 = -0.058, Ti_3 = 0.0089, respectively. In order to quantify and compare the performance of the solutions, three well-know indexes are utilized: the integral absolute error (IAE), the error improvement percent (EIP) and the control energy (E_u).

The first analysis corresponds to a performance comparison considering alternative gamma (γ) values for the WLS algorithm, taking into account the scenario *Sc2* superimposed with the scenario *Sc3* (i.e. a new scenario named here as *Sc4*). A gamma value of γ = 1000 was considered as a reasonable tuning because it provides an acceptable trade-off between control energy and dynamic performance, see Eq.(7). In this regard, for γ = 1000 all outputs reduce the IAE (up to a 60 %) with respect to a configuration with γ = 100, subject to a higher control energy requirement (which is less than 10% for all manipulated variables).

Unlike the obtained conventional decentralized CS, the CA-based system (with γ = 1000) meets all the control requirements for all the simulation scenarios, namely: *Sc1*, *Sc2*, *Sc3* and *Sc4*, and also for a critical version of *Sc4* where the disturbance $fhin_1$ changes its direction (i.e. a step of -0.3 $kWC^{-1}m^{-2}$ with respect to the nominal value). This is illustrated in Fig. 2 (a) and (b), where the evolution of the manipulated variable uc_{111} and the output $Tcout_1$ are compared taking into account both control strategies, subject to the commented critical scenario. As can be seen, the conventional decentralized CS is not able to regulate the output temperature due to the saturation of uc_{111}. Contrarily, the CA-based CS takes optimal advantage of all available degrees of

freedom, with a remarkable reduction of the control energy (up to a 81 %) for uc_{111}, uc_{122} and fcu_1.
The second analysis corresponds to the tuning of the control weighting matrix W_u in order to reduce the cooling utility flow (fcu_1). The considered test scenario was *Sc3*. For this purpose, the default W_u (i.e. an identity matrix) was replaced by W_u = *diag*([1,1,1,1,1,1,5]). With this configuration, the cooling utility flow was reduced 1.2% with respect to the nominal tuning, and 0.8% when compared against the decentralized CS, without affecting the dynamic performance of the system outputs.
Finally, the ability of the CA-based CS design for constraint handling was evaluated. To this end, a position high limit for the cooling utility flow (fcu_1) was defined (equal to 4.5) in order to remove some fcu_1 consumption peaks, see Fig. 2 (c). It can be noted that during the activation of the fcu_1 position high limit, the WLS algorithm further manipulates the remaining degrees of freedom so as to enhance the system performance. This effect is illustrated in Fig. 2 (d) where the control energy requirement is a 7% higher for uc_{122}. In addition, Fig. 2 (c) shows how the CA-based approach reduces 1.5 % the cooling utility flow (fcu_1) with respect to the decentralized CS, which does not consider explicitly the constraint.

4. Conclusions

The proposed CA-based CS design presents several interesting characteristics such as the management of secondary control objectives and constraint handling, which are usually provided by more complex controllers like MPC. Note that the design of the overall structure can be addressed considering only a steady-state model of the HEN process. In addition, the weighted least-squares (WLS) formulation was selected due to the good trade-off between the obtained dynamic performance and computational burden. In fact, the maximum computation time per sample was less than 10 milliseconds taking into account a compiled version (C-language) of the WLS solver. In this context, the WLS algorithm can be considered as an interesting option for real-time industrial implementations.

Abstract

The catalytic reforming process in the fuel cell based APU system is effective in supplying the fuel cell with a hydrogen-rich gas stream. Of several reforming technologies, autothermal reforming (ATR) is regarded as the most reliable for transportation applications, due to its durability during long-lasting operation and independence of heat sources. As autothermal reforming is a thermally neutral process involving exothermic and endothermic reactions, the analysis of the reaction coupled with transport phenomena inside the reformer is needed for obtaining operating conditions with respect to a specific fuel source. Such analysis ensures that the reformate gas enter the fuel cell at suitable composition and temperature. Thus, this study proposes a dynamic model of ATR of diesel, while considering the heat transfer phenomena involved with the kinetics of the Ni-based catalyst. For rate parameters for the Ni-based catalyst, model-based parameter estimation is performed in gPROMS Process Builder with micro-reactor experimental data. The established kinetics is then incorporated into the one-dimensional homogeneous model that accounts for heat transfer phenomena inside the monolithic reformer. The developed model shows good agreement with the corresponding experiment of the 1kW-class diesel ATR reactor conducted with step changes in the operating conditions.

Keywords: autothermal reforming, diesel reforming, dynamic modelling, fuel cell based auxiliary power unit system

1. Introduction

In efforts to reduce the greenhouse gas emissions, particularly carbon dioxide, a global movement toward more efficient and cleaner energy resource utilization has expanded and developed. For a clean and sustainable energy, a fuel reforming process has received much attention as it converts fossil fuel including diesel, coal, and natural gas to hydrogen-rich gas, providing a source for the fuel cell based auxiliary power unit (FC-APU) to generate electric power. APUs are commonly installed on heavy-duty vehicles, aircrafts, and other mobile systems for environmental purposes. Specifically, SOFC-APU on-board heavy-duty trucks enable to reduce unfavorable gas emission, noise during idling, and fuel consumption and idling time of primary engine (Xu et al., 2013).

As a primary part of the FC-APU system, reforming process has been investigated by a number of studies on the effects of fuel source, catalyst type, catalyst material, and reformer type on the reforming efficiency. A commercial FC-APU application widely uses autothermal reforming among several reforming technologies. ATR is a combination of exothermic partial oxidation and endothermic steam reforming reactions. The ATR occurs independently of external heat sources while achieving a high hydrogen yield. Since the reformer efficiency determines the SOFC performance and subsequently the overall output power, the reforming performance is of high importance and therefore is controlled in operation. The fuel source of the reformer also largely contributes in determining the efficiency and operation conditions. When operated with methane or light hydrocarbons as the fuel source, the reformer may show a complete conversion and stable operation (Hoang, 2004). However, the kinetic studies on diesel or heavy hydrocarbon reforming are hardly reported for its complex characteristics. The analysis of heavy hydrocarbon fuel reforming is challenging mainly due to its large carbon contents, which may cause coke formation and potential catalyst failure (Xu et al., 2013). The conventional ATR reactions may be inadequate to represent the complexity of diesel reformation such as decomposition of heavy hydrocarbons.

Thus, this study proposes a comprehensive mathematical model that describes ATR of diesel over the Ni-based catalyst. The ATR reaction kinetics regarding diesel reforming is refined to reflect the dynamic behaviour of an actual conversion process. We examine the kinetic model developed with model-based parameter estimation, followed by the dynamic model construction and simulation.

2. Model Development

2.1. Reaction kinetics

The autothermal reformer in the SOFC-APU system is implemented with a monolithic type catalyst. To examine the Ni-based catalyst performance in the monolith, a preliminary experiment has been performed at a micro-reactor scale. Experiments are carried out with varying input conditions such as steam-to-carbon ratio (SCR) of 1.5, 2.0, 2.5, 3.0, oxygen-to-carbon ratio (OCR) of 0.6, 0.8, 1.0, and temperature of 800, 850, 900 ^{o}C. The commercial-grade diesel is injected with an ultrasonic fuel injector. The composition of reformate gases is analyzed with a gas chromatograph. When compared to the thermodynamic equilibrium simulation based on adiabatic condition in Aspen Plus, a significant difference in product composition is noticed: two main components entering the SOFC stack, hydrogen and carbon monoxide, are produced 26 % and 33 % less than ideal. These differences suggest that an accurate prediction of the product composition requires an appropriate kinetic model of the reactios with the Ni-based catalyst.

Conventional autothermal reforming process comprises three main reactions: partial oxidation (POX), steam reforming (SR), and water-gas shift (WGS) reactions. Many of previous studies report that it is difficult to obtain the kinetics of POX for the heavy hydrocarbons due to the operation at high temperature and short contact time (Parmar et al., 2010). This difficulty may be solved by replacing POX with total oxidation (TOX) reaction in the ATR process. In the ATR operation condition where steam is supplied to the reactor in excess, Parmar et al. has suggested that the TOX may be regarded as a combination of POX, WGS, and hydrogen oxidation reactions.

The overall ATR reaction including TOX instead of POX is then compared with a stoichiometric balance of the experimental data, to confirm our assumption about

components and reactions. It is shown that when methane production is neglected as in the conventional ATR reactions, the overall reaction is not able to represent the practical behavior inside the reformer. Therefore, the reaction set has been refined based on the least squares method, minimizing the production and consumption difference between theoretical predictions and experimental data. Four key reactions are selected among the theoretically possible reactions (Xu et al. 2013): TOX, pre-reforming (PR), SR and WGS reactions (Table 1).

For the specific rate parameters for the Ni-based catalyst, the model-based parameter estimation is performed in gPROMS Process Builder with the data obtained with the commercial diesel. For each reaction, eight rate parameters of pre-exponential factors and activation energies are optimally determined by using the method of Maximum Likelihood Estimation. The assumptions used in the estimation are:

1. Ideal gas behavior
2. Fully developed laminar flow
3. Channels in the monolith assumed as one single channel
4. Reactor assumed as an isothermal plug flow reactor with mass balance of

$$\frac{dF_i}{dV} = \sum_j v_{ij} r_j \tag{10}$$

where F_i is the molar flow rate of species, V is the control volume, v_{ij} is the stoichiometry of species i in j^{th} reaction and r_j is the j^{th} reaction rate.

5. Rate law expression with powers of one
6. Reformate gas: H_2, CO, CO_2, O2, N_2, H_2O, CH_4 and light hydrocarbons (C_{2+}).

2.2. Mass and heat balances

To enhance the understanding of process dynamic behavior of the reformer, heat transfer phenomena inside the monolithic reformer are associated with the kinetics. As the main components pass through the monolith channels, they react on the catalyst-coated walls. Based on the assumptions used in the kinetic modeling as well as the following, the governing equations and accompanying boundary conditions for our reformer model are defined in Table 2.

Table 1. List of refined autothermal reactions with corresponding reaction rate expressions

Refined ATR reaction set selected (C_nH_m: diesel surrogate)		ΔH_{298} (kJ/mol)	
TOX	$C_nH_m + \left(n + \frac{m}{4}\right) O_2 \rightarrow nCO_2 + \frac{m}{2} H_2O$	-7513	(1)

PR	$C_nH_m + \left(\mathrm{n} - \frac{m}{4}\right) H_2O \rightarrow \left(\frac{n}{2} - \frac{m}{8}\right) CO_2 + \left(\frac{n}{2} + \frac{m}{8}\right) CH_4$	-92.67	(3)
	$r_{PR} = \boldsymbol{k_{PR}} y_{fuel} y_{H_2O}$		(4)
SR	$C_nH_m + nH_2O \rightarrow nCO + \left(n + \frac{m}{2}\right) H_2$	1928	(5)
	$r_{SR} = \boldsymbol{k_{SR}} y_{fuel} y_{H_2O}$		(6)
WGS	$CO + H_2O \leftrightarrow CO_2 + H_2$	-41.20	(7)
	$r_{WGS} = \boldsymbol{k_{WGS}} \left(y_{CO} y_{H_2O} - y_{CO_2} y_{H_2} / K_{eq}\right)$		(8)
	where $\boldsymbol{k_i} = k_{0,i}\, exp\left(-\frac{E_{A,i}}{RT}\right)$, and $K_{eq} = \exp\left(\frac{4577.8}{T} - 4.33\right)$ (Creaser et al., 2011)		(9)

Table 2. Governing equations for ATR reactor with corresponding boundary conditions

Mass balance for gas phase	$\frac{\partial \rho_g x_i}{\partial t} + \frac{\partial (u x_i)}{\partial z} = MW_i \sum_j \nu_{ij} r_j$	(11)
Energy balance for gas phase	$\rho_g C_{p,g} \frac{\partial T_g}{\partial t} + \rho_g C_{p,g} u \frac{\partial T_g}{\partial z} + \hat{a}_s u_{Overall}(T_g - T_s) = \sum_j (-\Delta H_j) r_j$	(12)
Energy balance for solid phase	$\rho_s C_{p,s} \frac{\partial (T_s)}{\partial t} = \hat{a}_s u_{Overall}(T_g - T_s) - \hat{a}_{out} h_{out}(T_s - 298.15)$	(13)
	where $\frac{1}{u_{Overall}} = \frac{1}{h_g} + \frac{w_s}{k_s}$	(14)
Boundary conditions	At reformer inlet ($z = 0$), $x_k = x_{k0}$, $T_g = T_{g0}$	

Table 3. Heat transfer correlations applied in the dynamic model

Heat transfer between gas and solid (Hoang, 2004)

$$j_{H,ln} = \frac{Nu_{ln}}{RePr^{1/3}} = \frac{h_{ln}}{\langle \rho v \rangle \hat{C}_p} \left(\frac{C_p \mu}{k}\right)^{2/3} = \frac{h_{ln} S}{\omega \hat{C}_p} \left(\frac{C_p \mu}{k}\right)^{2/3} \quad (15)$$

$$j_D = j_H = 0.91 Re_j^{-0.51} S_f \quad for\ Re_j < 50 \quad (16)$$

$$j_D = j_H = 0.61 Re_j^{-0.41} S_f \quad for\ Re_j > 50 \quad (17)$$

Natural convection from the solid (Bird, 1960)

$$Ra_L = Gr_L Pr = \frac{g\beta(T_s - T_\infty)L^3}{\nu\alpha} \quad (18)$$

$$\overline{Nu}_D = \left\{0.60 + \frac{0.387 Ra_D^{1/6}}{[1 + (0.559/Pr)^{9/16}]^{8/27}}\right\}^2 \quad for\ Ra_D \le 10^{12} \quad (19)$$

1. One-dimensional homogeneous system
2. Negligible pressure drop
3. Neglected heat transfer among channels
4. Neglected radiation and diffusion

This mathematical model is simulated in gPROMS Process Builder with thermodynamic physical properties obtained from Multiflash, database provided in gPROMS Process Builder. The partial differential equations in the balance equations are solved with the backward finite difference method. The heat transfer coefficient between the gas and solid phases are determined from the Chilton-Colburn factor (Bird, 1960). The heat loss to the air is considered as natural convection from the wall and the corresponding correlations are employed in the model (Table 3).

3. Results and Discussion

3.1. Kinetic model

The estimated rate parameters for the reactions are presented in Table 4. The activation energies for SR and WGS are roughly compared to the literature, despite variations in reaction mechanism for different catalysts (Creaser et al., 2011). The order of magnitude for each reaction is consistent with the reported value. For validation, the outlet molar flowrates of H_2 and CO in the micro-reactor experiment are compared with the kinetic model (Figure 1).

Table 4. Estimated rate parameters for refined reaction set

	Pre-exponential factor (mol/kg$_{cat}$/s)	Activation Energy (kJ/mol)	
	Estimated	Estimated	Literature
TOX	2.212×10^{7}	31.54	
PR	2.339×10^{11}	196.6	
SR	5.847×10^{12}	201.6	116.9
WGS	6.791×10^{2}	43.56	54.07

The kinetic model describes the measured data with a significantly improved accuracy as all data points fall within 15% error range. From Figure 2, we could observe the predicted behavior inside the reformer. The total oxidation reaction immediately occurs at the initial stages of the reformer, consuming the entire oxygen source. Steam reforming gradually takes place with the remaining fuel and generates hydrogen throughout the reformer.

3.2. Dynamic model

The simulation presents the dynamic response of the reforming process of diesel over the Ni-based catalyst. The predictions are validated with the experimental data at the reformer exit (Figure 3). To examine the effect of input conditions, step changes of SCR and OCR are imposed on the simulation that has been initially set with OCR of 0.7 and SCR of 2.5. We have varied SCR in ±0.3 and OCR in ±0.05.

One critical aspect to be concerned in the dynamic simulation is heat transfer. The total oxidation releases a large amount of heat near the initial stage of the reformer. As it is strongly exothermic, the mode to control the temperature inside the channel is necessary. Without considering any heat transfer phenomena, case 1 simulation response shows only the heat generated from the reactions and the outlet temperature is approximately 100 K higher than the experimental data. This temperature gap can be controlled by heat transfer correlations between the gas in the channel and the wall, as well as between the wall and ambient air. Case 2 simulation accounts for the heat transfer between the gas and the wall. Its response exhibits a reasonable time delay due to the heat transfer in every step sequence since the wall begins to hold the heat transferred from the gas. In the simulation considering all the reactions and the heat transfer correlations, the dynamic response follows the experiment trend closely.

8	2.2	

Figure 3. Temperature profile at reformer exit compared with experimental results in the sequence of step changes. Adiabatic simulation results (dotted line) and non-adiabatic simulation results (solid line). Step change details are listed in the table.

4. Conclusions

A comprehensive model for ATR of diesel over Ni-based catalyst has been suggested in this paper. The characteristics of Ni-based catalyst in the ATR has been studied and defined by model-based parameter estimation by using the method of MLE, which determined the optimal rate parameter values that minimize the differences with the given experimental data. The validation of the micro-reactor experimental data confirmed that the developed kinetics predicts the actual diesel reforming conversion quite well. The dynamic model has been developed considering the established kinetics, as well as heat transfer phenomena between the channels and the surroundings. Given varying operating conditions in step sequences, the dynamic simulation showed a good agreement with the corresponding experimental data.

The developed model ensures the prediction of the diesel reforming performance by including the hydrocarbon decomposition in the kinetics. The diesel ATR should be carefully modelled and analysed given the complexity in diesel compositions and the uncertainty in the inputs during reforming. It is found from the simulation that the efficiency of the diesel reforming is sensitive to the input variables and temperature. The optimal operation and control strategy will be developed with the aid of sensitivity analysis with respect to operating conditions in our future study.

Abstract

This study develops a mathematical model that predicts the dynamics of the temperature and pressure distributions, and phase changes in a Liquefied Natural Gas (LNG) fuel tank during the fuelling process. Using the Computational Fluid Dynamics (CFD) simulation results, it is shown that the LNG tank exhibits a vertical temperature distribution over the vapor phase during fuelling. Reflecting this insight from the CFD simulation, the developed model is a one-dimensional model for the vapor phase and a well-mixed model for the liquid phase. The developed model uses a moving boundary method to track the vapor-liquid interphase, reflecting the changing volume in a fixed discretised domain. Therefore, conservation equations are re-derived in order to account for the volume of the vapor phase that changes with the LNG injection. In addition, the model includes the interphase mass transfer, which reflects the phase change due to the pressure drop and heat transfer. The developed mathematical model was simulated using *gPROMS*^{TM} and the results were validated with the CFD results.

Keywords: Moving boundary, Bunkering, LNG, LNG fuel vessel, CFD

1. Introduction

With tightening of environmental regulations on ship fuel, LNG is expected to replace Heavy Fuel Oil (HFO) as the main fuel. However, the current state of vessel design for LNG bunkering lacks established standards and needs significant research efforts.

Most LNG storage tanks operate at ambient pressure. Consequently, as fuel is injected into the Liquid Fuel Vessel (LFV), the tank is depressurized to the ambient state. The pressure drop in the LFV tank causes the formation of Boil-Off Gas (BOG) from the remaining LNG. The LFV tanks are relatively small in volume compared to the tanks used in the past to store LNG. Also, the fuelling in this case is a much faster process due to the requirement of a short charge time. These factors lead to a sudden pressure drop and the BOG generation inside the tank. Temperature of the fuel entering the LFV tank during the bunkering process is lower than the temperature of the fuel remaining inside. The inflow of cold LNG can act to suppress the phase change in the tank. The system can be further stabilized by controlling the LNG feed for a gradual pressure drop.

It is not possible to predict and analyse the above phenomenon by modeling it as a flash drum, as often done in the past. Since LNG tanks in vessels are relatively large in size and cannot be assumed to be in equilibrium, a full dynamic model should be employed. It should be possible to use the computational fluid dynamics (CFD) to simulate the

situation where the liquid and vapor phases are clearly separated and external influences cause a phase change. The simulation results can be used to analyse the flow patterns inside the tank, which can be useful in developing a reduced-order mathematical model.

To this end, in this study, we propose a new LNG tank simulation model. The structure of the proposed model is based on CFD results: The liquid phase is assumed to be well mixed and the vapor phase is described by a one-dimensional model, to express vertical distributions of temperature and pressure. In order to reflect volume changes in the phases due to the fuel injection, it is necessary to implement a moving vapor-liquid interphase. The moving boundary method helps to track the changing domain in an efficient manner [Robalo, et al, 2005]. The multi-phase model enables the prediction of detailed heat and mass transfer based on the two-film resistance model. The designed mathematical model is simulated using the commercial software of *gPROMS*^{TM}, where thermal physical properties are calculated using the *Multiflash*^{TM} package.

2. CFD simulation

2.1. CFD Model description

This study involves an independent cylindrical tank of type C to be used in small to medium sized vessels (in Figure 1). The NG outlet is located in the dome at the top of the tank, and the inlet is designed to allow a horizontal injection from the bottom side of the dome. The volume is about 900 m^3 and the mesh number is about 700,000 in total.

LNG and NG coexist in the tank. Fuel is separated as liquid and vapor phase. We have simulated a situation where cooled LNG fuel (stored at lower pressure) is injected and the NG is discharged to ambient pressure. At this time, the incoming LNG and the leaving NG may constitute a multiphase fluid with a distinct phase boundary. Therefore, we simulated the flow and heat transfer of LNG and NG by using the Volume of Fluid (VOF) model. The *k-epsilon* model is used to predict the turbulence flow caused by the fast LNG injection and NG emissions. The NG outlet is modelled using a user defined function (UDF) to allow the fuel to be released by a choked valve, as in equation (1), where $\dot{m}$ is the mass flowrate in, C_d is the dimensionless discharge coefficient, A is the discharge hole cross-sectional area in m^2, γ is c_p/c_v, ρ is the gas density in kg m^{-3}, P is the gas pressure in Pa (Perry, et al, 2007). The CFD simulation is conducted to focus only on the convective phenomena without considering the phase change, due to the computational difficulty associated with introducing a phase change into the CFD simulation code. The detailed operating conditions for the simulation are shown in table 1.

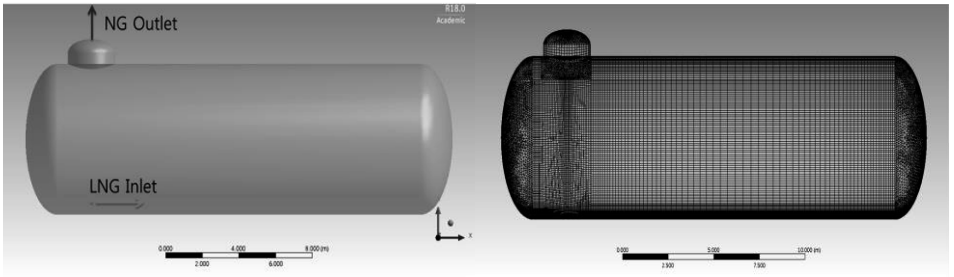

Figure 1. Geometry and mesh of a LNG tank

Table 1. Initial, boundary, and operating conditions for a simulation.

Initial condition		Gauge Pressure 3 bar Gas Temperature 183 K Liquid Temperature 131 K LNG Volume Fraction 0.1	Wall condition	Thermal	Temperature : 298.15 K U : 0.067 $Wm^{-2}K^{-1}$
Boundary condition	Inlet	Mass flow inlet T : 111.6 K LNG : 130 kg/s		Material	ρ: 1200 kg/m3 Cp : 1800 J/kg K k : 0.025 W/m K
	Outlet	Velocity inlet Using UDF (choked flow equation [Perry, et al, 2007]) $\dot{m} = C_d A \sqrt{\gamma \rho P \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma+1}{\gamma-1}}}$ (1)	Materials	NG	CH_4 vapor (Single component)
				LNG	CH_4 liquid (Single component)

2.2. CFD simulation result

From the CFD analysis, we can expect that the vapor phase will be dominated by the vertical flow and the liquid phase will be well mixed. Figure 2 a) shows the vertical temperature distribution, due to the vertical pressure drop, external heat input, and heat exchange in the interphase. The liquid temperature appears to be constant throughout the liquid phase. Figure 2 b) suggests that the liquid phase exhibit turbulent flow due to the fuel injection and the tank structure. CFD results can provide physical properties which cannot be computed in a simple process unit model. For example, variables using dimensionless numbers that include slip velocity can be predicted only if two or more dimensions of the multiphase fluid are simulated in a same domain. Therefore, the heat transfer coefficients of the interphase and the heat flux of the wall required for the heat transfer simulation in a process unit model are calculated from the CFD results as shown in Eq.(2).

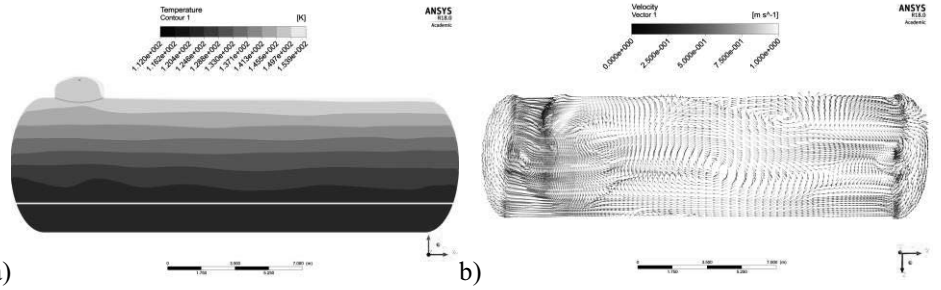
$$q_w \cong 11\ Wm^{-2},\ \ h_l \cong 99.5\ Wm^{-2}K^{-1},\ \ h_v \cong 21.4\ Wm^{-2}K^{-1} \quad (2)$$

, where q_w is heat flux from ambient, h_l and h_v are heat transfer coefficient of liquid and vapor at interphase.

3. LNG tank Model

3.1. Conceptual design for modeling (moving boundary method)

The model structure derived from the CFD simulation result is shown in Figure 3. Liquid phase is modeled as a well-mixed lumped parameter system. The vapor phase is modeled as a distributed system in one dimension to reflect the distinct vertical temperature



a) b)

Figure 2. CFD result of a LNG tank in a pseudo-steady state, a) temperature, b) velocity.

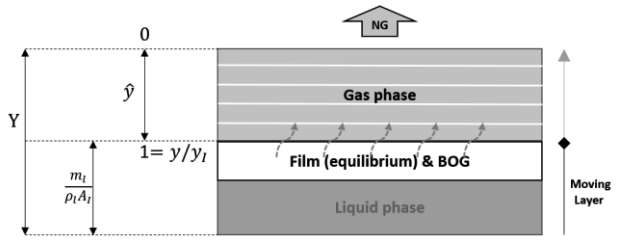


Figure 3. Conceptual design of a process unit model

distribution. It is assumed that there is a virtual film at the interphase between the vapor phase and the liquid phase. The film is always in vapor-liquid equilibrium, and the vapor phase and liquid phase exchange mass and heat with the film. The film follows the liquid level change tracked by the moving boundary method and the domain of the vapor phase is changed as the film is moving, as shown in Figure 3.

3.2. Model description

The moving boundary method uses a dimensionless domain scaled to reflect a moving boundary system. The boundary of a domain is usually calculated by a physical equation. Tracking the boundary point and reflecting it in the first principles equations using a dimensionless domain can make them appear as if a fixed domain is moving. The Eq.(3) represents the dimensionless domain, and Eq.(4) represents the induction formulas for reconstructing the first principles equations in the dimensionless domain.

$$\hat{y}(t) = \frac{y}{\mathrm{y}_I(t)} \tag{3}$$

$$\frac{\partial \phi}{\partial y} = \frac{1}{\mathrm{y}_I}\frac{\partial \phi}{\partial \hat{y}}, \qquad \frac{\partial^2 \phi}{\partial y^2} = \frac{1}{\mathrm{y}_I^2}\frac{\partial^2 \phi}{\partial \hat{y}^2}, \qquad \frac{\partial \phi}{\partial t} = \frac{\partial \phi}{\partial t} + \frac{\partial \phi}{\partial \hat{y}}\left(\frac{-\hat{y}}{\mathrm{y}_I}\frac{\partial \mathrm{y}_I}{\partial t}\right) \tag{4}$$

, where $\hat{y}$ is dimensionless domain, y is real domain, y_I is interface for tracking domain.

Equations (5) to (7) are conservation equations for the liquid phase. Equation (5) is the mass balance, Equation (7) is the energy balance, and Equation (6) calculates the interface location from the liquid level, y_I.

$$\frac{\partial m_l}{\partial t} = \dot{\mathrm{m}}_{in} - \mathrm{F} \cdot A_I \tag{5}$$

$$\mathrm{y}_I = \mathrm{Y} - \frac{m_l}{\rho_l A_I} \tag{6}$$

$$\frac{\partial m_l H_l}{\partial t} = \dot{\mathrm{m}}_{in} \cdot H_{l,in} - \mathrm{Q}_l \cdot A_I + q_w \cdot A_{l,w} \tag{7}$$

, where m_l is the mass of liquid in kg, F is the mass flux from liquid to vapour due to phase change in kg m^{-2} s^{-1}, A_I is the interphase area in m^2, Y is the tank height in m, ρ_l is the liquid density in kg m^{-3}, H_l is the liquid enthalpy in J kg^{-1}, Q_l is the heat flux from liquid to vapour in J m^{-2} s^{-1}, and $A_{l,w}$ is the heat transfer area of the liquid space wall in m^2.

Equations (8) to (10) are the newly derived conservation equations in the dimensionless domain, representing mass, momentum, and energy balances, respectively.

$$\frac{\partial \rho_v}{\partial \hat{y}}\left(\frac{-\hat{y}}{y_I}\cdot\frac{\partial y_I}{\partial t}\right) + \frac{\partial \rho_v}{\partial t} = -\frac{1}{y_I}\cdot\frac{\partial u_v \cdot \rho_v}{\partial \hat{y}} \tag{8}$$

$$\rho_v \frac{\partial u_v}{\partial \hat{y}}\left(\frac{-\hat{y}}{y_I}\cdot\frac{\partial y_I}{\partial t}\right) + \rho_v \frac{\partial u_v}{\partial t} = -\rho_v \cdot u_v \frac{1}{y_I}\cdot\frac{\partial u_v}{\partial \hat{y}} - \frac{1}{y_I}\cdot\frac{\partial P_v}{\partial \hat{y}} + \mu \frac{1}{y_I^2}\frac{\partial^2 u_v}{\partial \hat{y}^2} \tag{9}$$

$$\frac{\partial \rho_v E_v}{\partial \hat{y}}\left(\frac{-\hat{y}}{y_l}\cdot\frac{\partial y_l}{\partial t}\right)+\frac{\partial \rho_v E_v}{\partial t}=-\frac{1}{y_l}\cdot\frac{\partial u_v(\rho_v E_v+P_v)}{\partial \hat{y}}+\mathrm{k}_v\frac{1}{y_l^2}\frac{\partial^2 T_v}{\partial \hat{y}^2}+\mathrm{q}_w\cdot A_{v,w} \tag{10}$$

,where ρ_v is the vapor density in kg m^{-3}, u_v is the vapor velocity in m s^{-1}, E_v is the total vapor energy in J kg^{-1}, P_v is the vapor pressure in Pa, T_v is the vapor temperature in K, $A_{v,w}$ is the heat transfer area of the vapor space wall in m^2, and μ is the vapor viscosity in Pa.s.

Equations (11) and (12) express the heat flux the phase change by heat transfer and pressure change as a two-resistance model. As a general method of expressing heat transfer, the two-resistance model considers a separate heat transfer process with different heat transfer coefficients in the interphase.

$$\mathrm{Q}_l=h_l\cdot(T_{sat}(\mathrm{P}_v)-T_l)-F\cdot H_{l,s}=h_v\cdot(T_v-T_{sat}(\mathrm{P}_v))-F\cdot H_{v,s}=\mathrm{Q}_v \tag{11}$$

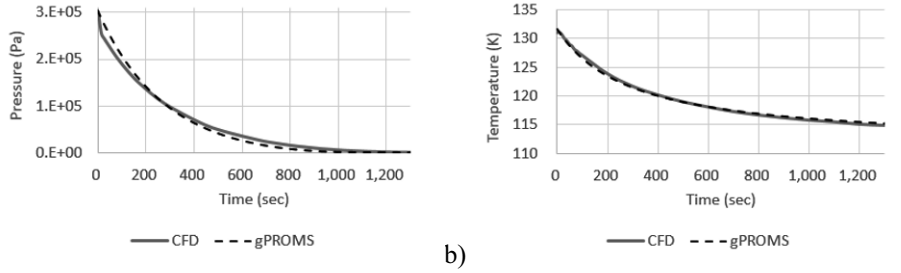
$$\begin{aligned} &IF\ F\geq 0\ (\text{'}evaporation\text{'}),\ H_{l,s}=H_l(T_l),\ H_{v,s}=H_v(T_{sat}(\mathrm{P}_v)) \\ &\text{Else}\quad (\text{'}condensation\text{'}),\ H_{l,s}=H_l(T_{sat}(\mathrm{P}_v)),\ H_{v,s}=H_v(T_v) \end{aligned} \tag{12}$$

, where, $T_{sat}(\mathrm{P}_v)$ is the saturated temperature for pressure P_v and T_l is the liquid temperature in K, $H_{l,s}$ and $H_{v,s}$ are liquid and vapor saturation enthalpies for phase change in J kg^{-1}, and Q_v heat flux for vapor from phase change in J m^{-2} s^{-1}.

3.3. Simulation result

To verify the results, we simulated the above one-dimensional mathematical model under the same condition as the CFD simulation. As shown in Figure 4 below, the pressure profile for the outlet and the temperature profile of the liquid phase were quite similar to those of the CFD simulation. The error range was within 0.03 Pa for the pressure, and 0.1 K for the liquid temperature. It took about 1200 seconds to reach the pseudo steady state after pressure and temperature drops. We confirmed that this transient behavior was consistent with the CFD result.

We simulated a control situation in which the choked valve and fuel injection were simultaneously considered. Unlike in the CFD simulation, the process unit model accounted for the phase change. The model reflects geometrical characteristics of a cylindrical tank: An increase in water level decreases the interfacial area representing the interphase. The height of the tank is 7 m, and we confirmed that the interface area showed a concave trend with a maximum at 3.5 m (as shown in Figure 5 a)). Figure 5 b) examines the mass flux by phase change. Evaporation occurs briefly during the initial phase of simulation. Immediately, the mass flux is reversed by condensation. After that, the evaporation starts again at about 756 seconds, and the inside of the tank starts to stabilize. Evaporation continues until the fuelling is completed. Temperatures of the vapor, liquid, and saturated temperature (film) in contact with the interphase can help explain the phenomenon more clearly (as shown in Figure 5 c)). The liquid temperature



a) b)

Figure 4. Comparison of CFD and gPROMS simulation results, a) outlet pressure, b) liquid temperature

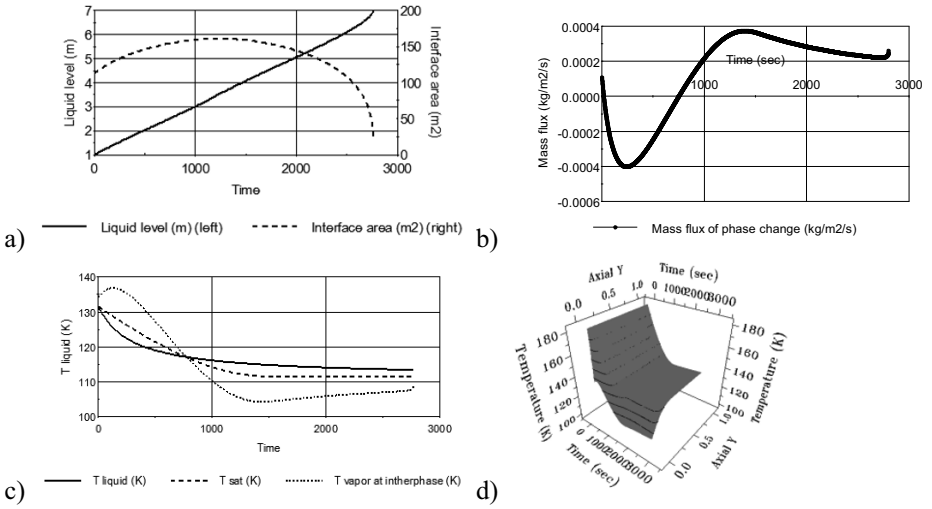


Figure 5. Dynamic simulation results of developed LNG tank model, a) interphase tracking, b) mass flux of phase change, c) interphase temperatures, d) vapor temperature profile in a tank

decreases depending on LNG fuelling, and the saturated temperature decreases depending on the pressure drop due to the NG emission. The vapor temperature is sensitive to the heat generated by the phase change. The condensation occurrs due to heat transfer by the liquid phase rather than energy released by pressure drop until 756 seconds. At about 240 seconds, the vapor temperature reaches a maximum. This is a consequence of the convective motion, which is predicted to occur at about the time it takes for the pressure drop to affect the vapor at interphase. After 756 seconds, the pressure drop causes the bubble point to be lower than the liquid phase, and evaporation occurs. The temperature change inside the tank reflecting these phenomena can be observed with time transient and vertical dimension (as shown in figure 5 d)).

4. Conclusions

The proposed LNG fuel tank model uses a dimensionless domain that can track the moving boundary based on total mass change of the liquid. All conservation equations have been rewritten in this domain. The proposed model includes a virtual film to enable the prediction of phase change and heat transfer between the phases. To demonstrate the use of the developed LNG tank model, a simple choked valve is implemented to predict the closed-loop dynamic response. The result shows the potential of using the model to develop an effective operation strategy. Our further study aims to improve the developed model to consider a multi-component fuel. The model also is expected to contribute to the establishment of a control strategy that optimizes the overall bunkering process with detailed control devices.

Abstract

Nonlinear model predictive control (NMPC) is an effective method for optimal operation of batch processes. Most dynamic models however contain significant uncertainties. It is therefore important to take these uncertainties into account in the formulation of the open-loop MPC problem to prevent infeasibilities or worse performance. An issue of such formulations is the disregard of feedback in the predictions, which leads to overly conservative control actions. The introduction of feedback through parametrized control policies is one way to solve this issue. In this work we compare the performance of affine feedback policies against more complex policies given by radial basis function networks. We incorporate these feedback policies into a polynomial chaos based stochastic NMPC algorithm to gauge their efficiency. The parameters of the feedback policies are either determined online by the NMPC algorithm or are pre-computed offline.

Keywords: Nonlinear model-based control, Polynomial chaos, Closed-loop policies, Chemical process control, Uncertain dynamic system

1. Introduction

Batch processes are used in many chemical sectors due to their inherent flexibility. These are operated at unsteady state and are often highly nonlinear, which motivates the application of nonlinear model predictive control (NMPC) (Nagy and Braatz, 2003). Many dynamic models however have limited accuracy due to various uncertainties. This can lead to constraint violations and worse control performance, which can be circumvented by incorporating these uncertainties in the NMPC algorithm (Mesbah, 2016). If we assume the uncertainties to be described by known probability density functions (pdfs), then the inclusion of the uncertainties in the NMPC algorithm leads to stochastic NMPC (SNMPC) formulations. In SNMPC constraints are addressed probabilistically, which allows for the systematic trade-off of constraint violation in probability with the conservativeness of the MPC solution (Mesbah, 2016). SNMPC methods include successive linearization (Cannon et al., 2009), sample-average NMPC (Bradford and Imsland, 2017), unscented sampling NMPC (Bradford and Imsland, 2017) and polynomial chaos expansion (PCE) NMPC (Fagiano and Khammash, 2012). A well-known problem of MPC under uncertainty is the fact that open-loop control actions are exceedingly conservative. To ensure reasonable predictions of the uncertainty, feedback needs to be considered. One way to achieve this is to optimize over parametrized feedback policies (Goulart et al., 2006). For linear stochastic MPC it is common to either evaluate a feedback matrix offline for pre-stabilization (Cannon et al., 2011) or by determining the parameters of the feedback control law online as decision variables (Hokayem et al., 2012). For SNMPC this problem is often ignored as in the PCE based SNMPC paper by

(Mesbah et al., 2014) or heuristics are applied as in Bradford and Imsland (2017). In this paper we focus on parametrized feedback policies for batch processes. For the SNMPC algorithm we use PCE due to its accuracy. We compare two different approaches to determine the parameters of the feedback policies: online optimization in the SNMPC algorithm or pre-computation offline. The first approach allows for revaluation of the feedback policy with knowledge of the new measurements, while the second allows for more complex feedback policies to be used. In addition, we consider three different parametrizations: affine time invariant, affine time varying and lastly radial basis function networks. In particular, radial basis function networks allow us to consider arbitrarily complex parametrizations. The various constellations were compared on a semi batch reactor case study via closed-loop simulations.

2. SNMPC with feedback policies

The aim of SNMPC is to control a discrete-time stochastic nonlinear system:

$$\mathbf{x}_{k+1} = \mathbf{f}(\mathbf{x}_k, \mathbf{u}_k, \boldsymbol{\theta}) \tag{1}$$

where k represents the discrete time, $\mathbf{x} \in \mathbb{R}^{n_\mathbf{x}}$ are the system states, $\mathbf{u} \in \mathbb{R}^{n_\mathbf{u}}$ are the control inputs, $\boldsymbol{\theta} \in \mathbb{R}^{n_\boldsymbol{\theta}}$ are uncertain parameters and $\mathbf{f}(\mathbf{x}_k, \mathbf{u}_k, \boldsymbol{\theta})$ denotes the system dynamics. We assume $\boldsymbol{\theta}$ to be independent Gaussian distributed random variables. The components have known mean μ_i and standard deviation σ_i. We can then formulate a general SNMPC problem with parametric feedback policies as follows:

$$\underset{\boldsymbol{\mathcal{u}}_N}{\text{minimize}}\ \mathbb{E}\big(J(N, \mathbf{x}(\mathrm{n}), \boldsymbol{\mathcal{u}}_N, \boldsymbol{\theta})\big)$$

subject to:

$$\begin{aligned}
&\mathbf{x}_{k+1} = \mathbf{f}(\mathbf{x}_k, \mathbf{u}_k, \boldsymbol{\theta}) && \forall k \in \{0, \dots, N-1\} \\
&\mathbb{P}\big(g_j^{(k)}(\mathbf{x}_k, \mathbf{u}_k, \boldsymbol{\theta}) \le 0\big) \ge 1 - p_j^{(k)} && \forall k \in \{1, \dots, N\} \times \left\{1, \dots, n_g^{(k)}\right\} \\
&\mathbf{u}_k = \boldsymbol{\varphi}\big(\boldsymbol{\nu}_k + \boldsymbol{\kappa}(\mathbf{x}_k, \boldsymbol{\gamma}_k)\big) && \forall k \in \{0, \dots, N-1\} \\
&\mathbf{x}_0 = \mathbf{x}(\mathrm{n})
\end{aligned} \tag{2}$$

where the objective function is the expectation of $J(N, \mathbf{x}(n), \boldsymbol{\mathcal{u}}_N, \boldsymbol{\theta})$, $g_j^{(k)}(\mathbf{x}_k, \mathbf{u}_k, \boldsymbol{\theta})$ are individual chance constraints, $p_j^{(k)} \in (0,1) \subset \mathbb{R}$ is the probability of constraint violation, $\boldsymbol{\mathcal{u}}_N = \{\boldsymbol{\nu}_0, \dots, \boldsymbol{\nu}_{N-1}, \boldsymbol{\gamma}_0, \dots, \boldsymbol{\gamma}_{N-1}\}$ is the set of decision variables, $\boldsymbol{\varphi}(\cdot)$ is a saturation function, $\boldsymbol{\kappa}(\cdot)$ is the feedback policy employed, $\boldsymbol{\nu}_k$ are the feed-forward control inputs, $\mathbf{x}(n)$ is the known initial state at time step n and N is the time horizon.

The saturation function in this report was defined to be individual sigmoid functions for each control input to introduce implicit constraints on $\mathbf{u}_k$: $\boldsymbol{\varphi}\big(\boldsymbol{\nu}_k + \boldsymbol{\kappa}(\mathbf{x}_k, \boldsymbol{\gamma}_k)\big) = \left[\frac{u_{max,1} - u_{min,1}}{1+\exp(-[\boldsymbol{\nu}_k + \boldsymbol{\kappa}(\mathbf{x}_k, \boldsymbol{\gamma}_k)]_1)} + u_{min,1}, \dots, \frac{u_{max,n_\mathbf{u}} - u_{min,n_\mathbf{u}}}{1+\exp(-[\boldsymbol{\nu}_k + \boldsymbol{\kappa}(\mathbf{x}_k, \boldsymbol{\gamma}_k)]_{n_\mathbf{u}})} + u_{min,n_\mathbf{u}}\right]^T$, i.e. $u_{min,i} \le u_{k,i} \le u_{max,i}\ \forall i \in \{1, \dots, n_\mathbf{u}\}$.

Three different parametrizations of feedback control laws were considered:

1) Affine time invariant (ATI)

$$\boldsymbol{\kappa}(\mathbf{x}_k, \boldsymbol{\gamma}) = \mathbf{K}\mathbf{x} \tag{3}$$

where $\mathbf{K} = \begin{bmatrix} \gamma_1 & \cdots & \gamma_{n_\mathbf{x}} \\ \vdots & \ddots & \vdots \\ \gamma_{n_\mathbf{u}} & \cdots & \gamma_{n_\mathbf{u} \times n_\mathbf{x}} \end{bmatrix}$, Number of parameters: $n_\mathbf{u} \times n_\mathbf{x}$

2) Affine time varying (ATV)

$$\boldsymbol{\kappa}(\mathbf{x}_k, \boldsymbol{\gamma}_k) = \mathbf{K}_k \mathbf{x} \tag{4}$$

where $\mathbf{K}_k = \begin{bmatrix} \gamma_{k,1} & \cdots & \gamma_{k,n_\mathbf{x}} \\ \vdots & \ddots & \vdots \\ \gamma_{k,n_\mathbf{u}} & \cdots & \gamma_{k,n_\mathbf{u} \times n_\mathbf{x}} \end{bmatrix}$, Number of parameters: $n_\mathbf{u} \times n_\mathbf{x} \times (n_k - 1)$

3) Radial basis function network time invariant (RBFN-n_{RBF})

$$\kappa_i(\mathbf{x}_k, \boldsymbol{\gamma}) = \sum_{j=1}^{n_{RBF}} \omega_j \phi_j(\mathbf{x}_k) \tag{5}$$

$$\phi_j(\mathbf{x}_k) = \exp\left(-0.5\left(\mathbf{x}_k - \boldsymbol{\mu}_j\right)^T \mathrm{diag}\left(\boldsymbol{\lambda}_j\right)\left(\mathbf{x}_k - \boldsymbol{\mu}_j\right)\right) \tag{6}$$

where n_{RBF} is the number of radial basis functions with parameters $\left[\omega_j, \boldsymbol{\mu}_j, \boldsymbol{\lambda}_j\right]^T = \boldsymbol{\gamma}_{(j-1)(1+2n_\mathbf{x})+1:j(1+2n_\mathbf{x})}$, Number of parameters: $n_\mathbf{u} \times n_{RBF}(1 + 2n_\mathbf{x})$

The open-loop case is given by $\boldsymbol{\kappa}(\cdot) = \mathbf{0}$. The nonlinear radial basis function network parametrization was taken from Deisenroth and Rasmussen (2011) and allows for arbitrarily complex feedback policies by adjusting the number of radial basis functions.

3. PCE based SNMPC

The problem defined in Eq.(2) is intractable, since it involves probability and expectations on nonlinear functions of $\boldsymbol{\theta}$. PCE can be used to solve this efficiently. Assume we are given a nonlinear transformation of independent standard normal variables $\zeta(\mathbf{z})$ with finite second order moments. According to PCE theory $\zeta(\mathbf{z})$ can be approximated by a truncated orthogonal polynomial basis (Owen et al., 2017):

$$\zeta(\mathbf{z}) \approx \sum_{0 \le |\boldsymbol{\alpha}| \le p} a_{\boldsymbol{\alpha}} He_{\boldsymbol{\alpha}}(\mathbf{z}) = \mathbf{a}^T \boldsymbol{\Phi}(\mathbf{z}) \tag{7}$$

where $\mathbf{z} \in \mathbb{R}^{n_\boldsymbol{\theta}}$ is a vector of standard normal variables with components $z_i \sim \mathcal{N}(0,1)$, $a_{\boldsymbol{\alpha}}$ are unknown expansion coefficients, $|\boldsymbol{\alpha}| = \sum_{j=1}^{n_\boldsymbol{\theta}} \alpha_j$, p is the order of truncation, $\mathbf{a}$ is a vector of coefficients $a_{\boldsymbol{\alpha}}$ and $\boldsymbol{\Phi}(\mathbf{z})$ contains $L = \frac{(n_\boldsymbol{\theta}+p)!}{n_\boldsymbol{\theta}! p!}$ polynomial elements $He_{\boldsymbol{\alpha}}(\mathbf{z})$ of the truncated expansion. $He_{\boldsymbol{\alpha}}(\mathbf{z})$ are known multivariate Hermite polynomials defined by a tensor product of univariate Hermite polynomials: $He_{\boldsymbol{\alpha}}(\mathbf{z}) = He_{\alpha_1}^{(1)}(z_1) \times \ldots \times He_{\alpha_{n_\boldsymbol{\theta}}}^{(n_\boldsymbol{\theta})}\left(z_{n_\boldsymbol{\theta}}\right)$, where $He_j^{(i)}$ is the univariate Hermite polynomial of order j in terms of the i[th] component of $\mathbf{z}$. Univariate Hermite polynomial can be found in look-up tables.

We now need to find values for the coefficients $a_{\boldsymbol{\alpha}}$ to obtain a good approximation to $\zeta(\mathbf{z})$, which is done by using observations of $\zeta(\mathbf{z})$ at different values of $\mathbf{z}$. In this report we used a Sobol quasi random design to determine the sample points and transform it to follow a Gaussian distribution by using the inverse cumulative normal distribution function. We will refer to this design as $\mathcal{Z} = \left\{\mathbf{z}^{(0)}, \ldots, \mathbf{z}^{(n_s-1)}\right\}$, which contains n_s sampling points. We then obtain a response for each sample, which gives us $\mathbf{Y} = \left[\zeta\left(\mathbf{z}^{(0)}\right), \ldots, \zeta\left(\mathbf{z}^{(n_s-1)}\right)\right]^T$. The coefficients can be found by least-squares estimation:

$$\hat{\mathbf{a}} = (\boldsymbol{\Psi}^T \boldsymbol{\Psi})^{-1} \boldsymbol{\Psi}^T \mathbf{Y} \tag{8}$$

where $\Psi_{ij} = He_{\boldsymbol{\alpha}_j}\left(\mathbf{z}^{(i)}\right)\ i = 0, \dots, n_s - 1, j = 1, \dots, L$ is a data matrix containing the polynomial terms in Eq.(7) and $He_{\boldsymbol{\alpha}_j}$ is the j[th] Hermite polynomial in the series expansion.

The variance and mean of $\zeta(\mathbf{z})$ are approximately given by (Mesbah et al., 2014):

$$\mathbb{E}\left(\zeta(\mathbf{z})\right) \approx \hat{a}_1, \quad \mathrm{Var}\left(\zeta(\mathbf{z})\right) \approx \sum_{j=2}^{L} \hat{a}_j^2\, \mathbb{E}\left(He_{\boldsymbol{\alpha}_j}^{\ 2}(\mathbf{z})\right) \tag{9}$$

Using PCEs the problem in Eq.(2) can be simplified as follows:

$$\underset{\boldsymbol{u}_N}{\text{minimize}}\ \mathbb{E}\left(\xi_J\right)$$

subject to:

$$\mathbf{x}_{k+1}^{(i)} = \mathbf{f}\left(\mathbf{x}_k^{(i)}, \mathbf{u}_k, \boldsymbol{\theta}^{(i)}\right) \quad \forall (k,i)\ \in\ \{0, \dots, N-1\}\ \times \{0, \dots, n_s - 1\} \tag{10}$$

$$\sqrt{\mathrm{Var}\left(\zeta_{g_{jk}}\right)\left(1 - p_j^{(k)}\right)/p_j^{(k)}} + \mathbb{E}\left(\zeta_{g_{jk}}\right) \le 0 \quad \forall k\ \in\ \{1, \dots, N\} \times \left\{1, \dots, n_g^{(k)}\right\}$$

$$\hat{\mathbf{a}}_J = (\boldsymbol{\Psi}^T\boldsymbol{\Psi})^{-1}\boldsymbol{\Psi}^T\mathbf{Y}_J, \qquad \hat{\mathbf{a}}_{g_{jk}} = (\boldsymbol{\Psi}^T\boldsymbol{\Psi})^{-1}\boldsymbol{\Psi}^T\mathbf{Y}_{g_{jk}}$$

$$\mathbb{E}\left(\xi_J\right) = \hat{a}_{J,1}, \qquad \mathbb{E}\left(\zeta_{g_{jk}}\right) = \hat{a}_{g_{jk},1}$$

$$\mathrm{Var}\left(\zeta_{g_{jk}}\right) = \sum_{m=2}^{L} \hat{a}_{g_{jk},m}^2\, \mathbb{E}\left(He_{\boldsymbol{\alpha}_m}^{\ 2}(\mathbf{z})\right)$$

$$\mathbf{u}_k^{(i)} = \boldsymbol{\varphi}\left(\boldsymbol{\nu}_k + \boldsymbol{\kappa}\left(\mathbf{x}_k^{(i)}, \boldsymbol{\gamma}_k\right)\right) \qquad \forall k\ \in\ \{0, \dots, N-1\}$$

$$\mathbf{x}_0^{(i)} = \mathbf{x}(\mathrm{n}) \qquad \forall i\ \in\ \{0, \dots, n_s - 1\}$$

where $\theta_l^{(i)} = \sigma_l z_l^{(i)} + \mu_l$, $\mathbf{x}^{(i)}$ represents the state vector of scenario i with uncertain parameter $\boldsymbol{\theta}^{(i)}$, $\mathbf{Y}_J = \left[J\left(N, \mathbf{x}(\mathrm{n}), \boldsymbol{u}_N, \boldsymbol{\theta}^{(0)}\right), \dots, J\left(N, \mathbf{x}(\mathrm{n}), \boldsymbol{u}_N, \boldsymbol{\theta}^{(n_s-1)}\right)\right]^T$ *and* $\mathbf{Y}_{g_{jk}} = \left[g_j^{(k)}\left(\mathbf{x}_k^{(i)}, \mathbf{u}_k^{(i)}, \boldsymbol{\theta}^{(0)}\right), \dots, g_j^{(k)}\left(\mathbf{x}_k^{(i)}, \mathbf{u}_k^{(i)}, \boldsymbol{\theta}^{(n_s-1)}\right)\right]$ are data matrices to determine the required coefficients**.** It should be pointed out that while $\mathbf{Y}_J$ and $\mathbf{Y}_{g_{jk}}$ change each iteration of the optimization algorithm**,** the sample design $\mathcal{Z}$ remains constant, such that $(\boldsymbol{\Psi}^T\boldsymbol{\Psi})^{-1}\boldsymbol{\Psi}^T$ and the $\mathbb{E}\left(He_{\boldsymbol{\alpha}_m}^{\ 2}(\mathbf{z})\right)$ can be calculated offline. The probability constraints were approximated robustly using Chebyshev inequality, for more information see (Mesbah et al., 2014).

4. Case study

The case study involves an isothermal semi batch reactor with a second-order exothermic reaction taking place; A + B → C. The exact differential equation for the case study can be found in Lucia and Paulen (2014). The control input is the feed rate u and the state vector is $\mathbf{x} = [C_A, C_B, C_C, V]^T$, where C_i are the concentrations of species i and V is the reactor volume. The flow rate u can be adjusted between 0 and 0.4. The initial conditions were set to $[C_{A0}, C_{B0}, C_{C0}, V_0] = [3,0,0,0.7]$ and the temperature is kept at 70°C. The semi batch reactor is controlled by a shrinking horizon implementation of Eq.(10). The objective of the SNMPC problem was set to maximize the average amount of C at the end of the batch, while keeping the adiabatic temperature below 85°C to prevent uncontrollable behaviour and the concentration of B at the final time below $0.5\mathrm{mol dm}^{-3}$.

The probability of constraint violation for both was set to 0.05. The resulting OCP was solved employing direct collocation with 10 control intervals and a final time of 1h utilizing CasADi in Python (Andersson et al., 2012).

To gauge the performance of the various feedback policy methods, we ran 100 simulations based on a Sobol design for 5 different constellations with 4 computed online: Open-loop without feedback, ATI, ATV and RBFN with a single radial basis function referred to as RBFN-1. A more complex RBFN was computed offline with 10 radial basis functions referred to as RBFN-10. In Fig.1 a box-plot is shown of the attained amount of product C and hence the higher the amount of C, the better the closed-loop performance. In Tab.1 the corresponding average computational times are shown with the number of decision variables of the optimization problem. We can see that the open-loop approach has the lowest median and the fastest computational time, which is expected since it is the most conservative and has the least number of decision variables. ATI and RBFN-1 perform slightly better than open-loop implementation but, due their simplicity, they are worse than the others. In particular, RBFN-1 is a poor choice, since it leads to the same performance as ATI with larger computational times. ATV on the other hand has the highest median production rate, yet it requires also the highest computational time due to its large number of decision variables. RBFN-10 is only marginally worse, however has a computational time that is significantly lower than the other feedback policy approaches. It does however take twice as long as the open-loop approach.

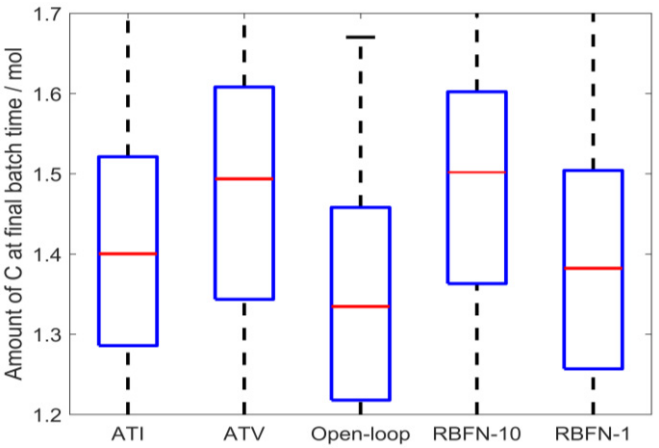

Figure 1 Box-plot of amount of product for 100 Sobol design points using different feedback policy approaches

Table 1 Comparison between number of decision variables evaluated online and average evaluation time of a single NMPC control step of the feedback policies

Feedback policy	No. decision variables	Evaluation time (s)
ATI	14	5.9
ATV	46	11.6
Open-loop	10	0.87
RBFN-10	10	1.87
RBFN-1	19	9.58

5. Conclusions

In conclusion, we investigated different approaches to introduce feedback into a SNMPC algorithm. In general, feedback always improves the performance of the otherwise open-loop algorithm. For the feedback policies evaluated online it could be shown that ATI and RBFN-1 were outperformed by the more complex ATV, however ATV carries the largest computational time due to the number of decision variables it introduces. On the other hand, the pre-computed RBFN-10 managed to perform only marginally worse while

being significantly faster in terms of computational time. We therefore conclude that the use of pre-computed complex feedback control parametrizations is an interesting approach to obtain good closed-loop performance without introducing a too heavy computational load.

Abstract

This paper focuses on the prediction of persistent disturbances based on their past measurements using two versions of the *k*-nearest neighbours method: an unweighted and a weighted version. Results of tests on data from a refinery show that the two methods can predict the future trend of a disturbance. They also show that the weighted version is more robust against the choice of the number of nearest neighbours used. The method opens up the possibility of model-free feedforward control without the constraint of causality based on the whole history of a measurement.

Keywords: Plantwide disturbance, time series prediction, nearest neighbours, process control

1. Introduction

In process plants, a disturbance is an undesired, transitory deviation of a process variable from its desired set point. Such disturbances can affect the quality of the product, or they can cause a malfunction of the site machinery and accelerate its wear (Yuan & Qin, 2014). Further, a disturbance originating from one unit can propagate to other units because of material, energy or information and control interconnections.

Control systems have a role in propagating a disturbance. A controller compensates the effect of the disturbance on the controlled variable by adjusting the manipulated variable. However, the manipulated variable can be an external disturbance for another plant unit. In this way, the plantwide disturbance continues to propagate. Various disturbances, each characterised by its own time trend, can affect a plant over time. Therefore, there should be an optimal control action for each disturbance. For this, it would be useful for the control algorithm to be able to detect that a disturbance is occurring and to predict the future evolution of the disturbance.

This paper focuses on disturbance prediction. Being able to predict the future evolution of a disturbance can improve the performance of a controller. In process systems, feedforward control is used routinely to compensate for measured disturbances when they are detected (Liptak 2005; Camacho and Bordons 2008), but the standard implementation of feedforward control does not include a prediction of the future evolution of the disturbance. Koerber & King (2013), and Mehra *et al.* (1997) have described how previewing a disturbance improved the control action with applications in wind turbines and automotive industries. However, modelling and predicting a disturbance remains an open question. Literature provides many methods such as ARIMA models and Artificial Neural Networks (De Gooijer and Hyndman 2006). The methods are classified into first principle models, statistical methods and data-driven methods. Difficulties in choosing the method arise mainly when the disturbances are

caused by non-linear effects such as limit cycles, or when they arise because of random events. Cairano et al. (2014) improved the control of the battery management of a hybrid electric vehicle by predicting the disturbance, the driver driving style, with a data-driven Markov chain. Klenske et al. (2016) improved the control of an electrically actuated telescope proposing a model based on Gaussian processes that learns to fit nearly-periodic disturbances. However, these methods adapt their models based on the last measured samples and do not exploit the whole history of the measured disturbance. This paper presents two versions of a *k*-nearest neighbours method. Advantages of the *k*-nearest neighbours method include the ability to capture the repeating pattern typical of persistent disturbances, and its easy implementation. The result give an advance over previous uses of *k*-nearest neighbours for time series prediction which have typically predicted just one sample a few steps ahead. This paper shows it is possible to do the more challenging task of predicting the future evolution of the time series.
Section 2 describes the methods, and Section 3 presents the results of applying the method to real data coming from a refinery. The paper ends with a discussion and conclusions.

2. Method description

2.1. Introduction

The *k*-nearest neighbours method supposes that the current time series segment will evolve in future like a past time series segment (not necessarily a recent one) evolved previously (Kantz and Schreiber 2004). The task therefore is to identify past segments of the time series which are similar to the present one according to a certain norm.
The algorithm considers a measurement signal made of N samples $\boldsymbol{y}_M(N) = [y(1)\ y(2)\ \dots\ y(N)]$, termed 'memory'. The memory size increases as more samples $y(\cdot)$ are recorded. The segment made of the last m samples of $\boldsymbol{y}_M(N)$ is $\boldsymbol{y}_E(N) = [y(N-m+1)\ \ y(N-m+2)\ \dots y(N)]$. This segment represents the current evolving disturbance pattern and is called $\boldsymbol{y}_E(N)$ 'evolution', while m is known as the 'embedding dimension' (Kantz and Schreiber 2004). The algorithm searches within the memory $\boldsymbol{y}_M(N)$ for the k time series intervals of length m that are most similar to $\boldsymbol{y}_E(N)$. The similarity is measured in this paper with the Euclidean distance (Eq 1). These k time series intervals $\boldsymbol{y}_j,\ j = 1, \dots, k$ are the *k*-nearest neighbours and are those k time series intervals within $\boldsymbol{y}_M(N)$ with smallest Euclidean distances:

$$d\left(\boldsymbol{y}_E(N), \boldsymbol{y}_j\right) = \sqrt{\sum_{i=1}^{m}\left(y_E(i) - y_j(i)\right)^2} \tag{1}$$

As depicted in Figure 1, each nearest neighbour $\boldsymbol{y}_j$ is followed by a time series of length h, where h is the desired prediction horizon. These time series of length *h* are called the 'prediction contributions' $\boldsymbol{y}_{P\,j}, j = 1, \dots, k$. They show how their corresponding nearest neighbours evolved over an interval of length h. Therefore, they are the basis for building the prediction vector, as will be described in Section 2.2. Since all prediction contributions must stay within the memory $\boldsymbol{y}_M(N)$, there is a constraint for the starting points r_j of the nearest neighbours $\boldsymbol{y}_j$

$$\boldsymbol{y}_j = \left[y(r_j)\ \ y(r_j+1) \dots\ \ y(r_j+m)\right], \quad j = 1, \dots, k, \qquad r_j \in [1; N-h-m+1] \tag{2}$$

Consequently $\boldsymbol{y}_{P\,j}$

$$\boldsymbol{y}_{P\,j} = \left[y(r_j+m+1)\ \ \dots\ \ y(r_j+m+h)\right] \qquad\qquad j = 1, \dots, k \tag{3}$$

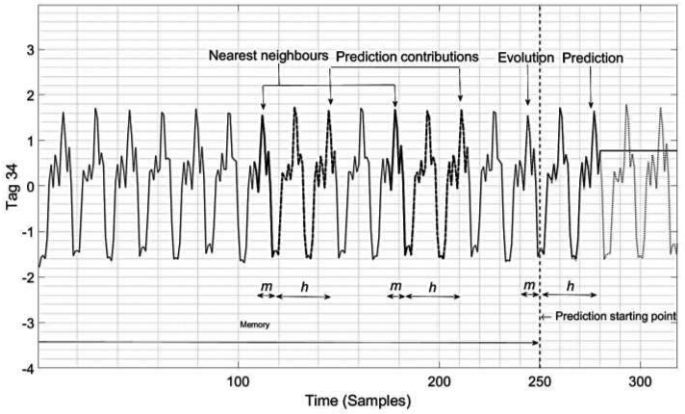

Figure 1 An example of a persistent disturbance and representation of terminology

2.2. The two versions of the algorithm

Unweighted and weighted versions of the algorithm differentiate themselves at this step. For the unweighted version, the prediction is an average of the prediction contributions. The prediction is a vector $\hat{\boldsymbol{y}}(N) = [\hat{y}(N+1) \dots \hat{y}(N+h)]$ where:

$$\hat{y}(N+i) = \frac{1}{k}\sum_{j=1}^{k} y_{P\,j}(i),\ i = 1, \dots, h \tag{4}$$

In the weighted version of the algorithm, the nearest neighbours contribute to the prediction proportionally to their distance from the evolution. First a weight w_j for each nearest neighbours is calculated. The weight $w_j = 1$ if the nearest neighbour $\boldsymbol{y}_j$ has the smallest distance with $\boldsymbol{y}_E(N)$. Conversely, $w_j = 0$ if the corresponding nearest neighbour $\boldsymbol{y}_j$ is the most distant from $\boldsymbol{y}_E(N)$.

$$w_j = \frac{\max_{\ell=1\dots k}(d(\boldsymbol{y}_E(N),\boldsymbol{y}_\ell)) - d(\boldsymbol{y}_E(N),\boldsymbol{y}_j)}{\max_{\ell=1\dots k}(d(\boldsymbol{y}_E(N),\boldsymbol{y}_\ell)) - \min_{\ell=1\dots k}(d(\boldsymbol{y}_E(N),\boldsymbol{y}_\ell))} \qquad k \geq 2 \qquad j = 1, \dots, k \tag{5}$$

$$w_1 = 1 \qquad k = 1$$

The prediction vector $\hat{\boldsymbol{y}}(N) = [\hat{y}(N+1) \dots \hat{y}(N+h)]$ is a weighted average of the prediction contributions, where:

$$\hat{y}(N+i) = \frac{1}{\sum_{j=1}^{k} w_j}\sum_{j=1}^{k} w_j\, y_{P\,j}(i) \qquad i = 1, \dots, h \tag{6}$$

2.3. Measuring the accuracy of the prediction for varying values of k and m

The tuning parameters of the methods are m and k. Varying them causes the average prediction distance to change. The prediction distance E_{av} is the Euclidean distance between the prediction and the corresponding segment of the actual future time series (not known in advance to the algorithm) divided by the chosen prediction horizon h so that the value does not depend on the length of the prediction horizon.

$$E_{av}(N) = \frac{1}{h}d(\hat{\boldsymbol{y}}(N), [y(N+1) \dots y(N+h)]) \tag{7}$$

The smaller $E_{av}(N)$ is, the more accurate the prediction is.

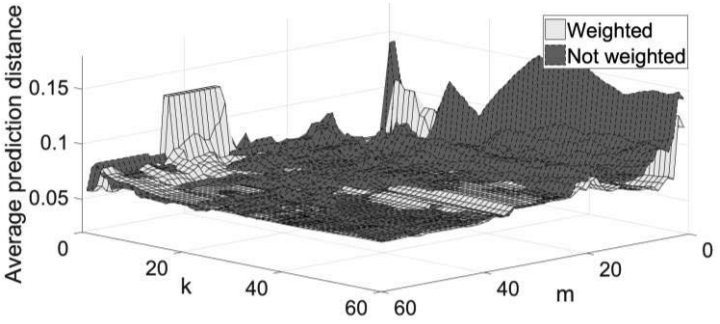

Figure 2 Effect of parameters *k* and *m* on prediction of Tag 33

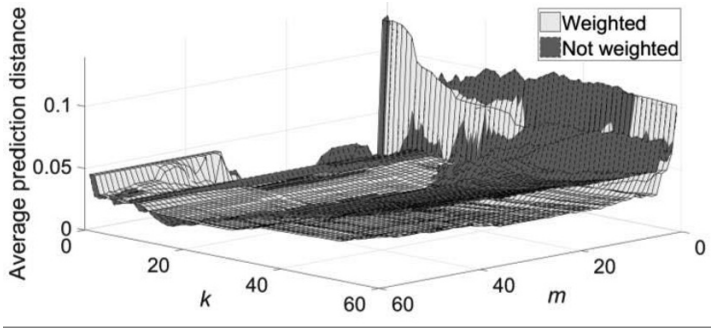

Figure 3 Effect of parameters *k* and *m* on prediction of Tag 34

3. Results

3.1. Description of the data

Figure 2 and Figure 3 show the performance of the prediction methods on two time trends called Tag 33 and Tag 34 which came from a SE Asian refinery (Thornhill 2005) and are composed of 512 samples. The signals have been mean-centred and scaled to unit standard deviation. The prediction starting point in these examples is $N = 450$ (the 450th over 512 samples) to give the algorithm enough samples to look for the nearest neighbours. The prediction horizon has been chosen to be 30 because this requires the algorithm to predict two cycles of the oscillation, constituting a stringent test.

3.2. Effect of k *and* m *on* E_{av}

Figure 2 and Figure 3 show the values of E_{av} as a function of $k \in [1,60]$ and $m \in [1,60]$ for the two methods. The figures show that for very small values of m, the prediction error can be high. This is because small embedding dimension might not identify the shape of the disturbance. For example, two points might have similar values in the ascending or descending phase of an oscillation but the prediction contributions $\boldsymbol{y}_P$ could be very different, thereby worsening the prediction. After a threshold, increasing m does not influence E_{av} for a periodic (or nearly periodic) signal like Tag 34. Instead m influences E_{av} for Tag 33, which is made of spikes different from each other. Each pattern lasts between 8 and 17 samples and indeed there is a decrease in values of E_{av} for $8 \leq m \leq 17$. A good choice is $m = \frac{1}{f_0}$, where f_0 is the main frequency of the disturbance. Therefore $m = 17$ in this case.

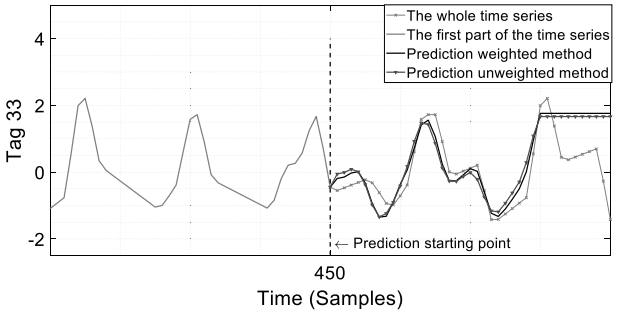

Figure 4 Prediction of Tag 33 with $N = 450, h = 30, k = 26, m = 27$ using the weighted ($E_{av} = 0.0679$) and unweighted ($E_{av} = 0.0855$) k-nearest neighbor methods.

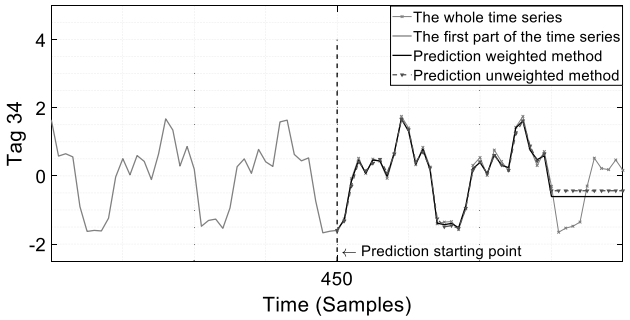

Figure 5 Prediction of Tag 34 with $N = 450, h = 30, k = 26, m = 27$ using the weighted ($E_{av} = 0.0178$) and unweighted ($E_{av} = 0.0202$) k-nearest neighbor methods.

The prediction error E_{av} rises for high values of k. Increasing k too much results in time series intervals being considered as nearest neighbours even though they are not very similar to $\boldsymbol{y}_E(N)$ and do not develop in the same way. Figures 2 and 3 show the weighted method reduces the impact of a large value of k compared to the unweighted nearest neighbour method and gives smaller values for E_{av}.

For small values of k, the surface of the plots is more irregular, showing E_{av} is sensitive to small changes of parameters k and m. The reason is that even persistent disturbances have some randomness. By averaging over more prediction contributions, the resulting prediction is closer to the true value. Therefore, the best value of k depends on the number of nearest neighbours sufficiently close to $\boldsymbol{y}_E$ available in the memory. A satisfactory choice is $k = \frac{N}{m}$ and therefore $k = 26$ in this case. A question for future work is to make the selection of k adaptable, because the memory vector $\boldsymbol{y}_M(N)$ grows as time goes by.

3.3. Quality of the prediction

Predictions for the Tag 33 and Tag 34 using the suggested parameters $m = 17, k = 26$ with both methods are shown in Figure 4 and Figure 5. The predictions are based on the history up to sample number 450. The figures also show what actually happened to the time trends. The accuracy is good for both methods, although slightly better for the weighted method. The figure captions give the E_{av} values. As mentioned earlier, Tag 34 is inherently more predictable than Tag 33 because Tag 33 is characterized by peaks with some variability from one to the next. The lower E_{av} values for Tag 34 reflect this qualitative observation.

4. Discussion

Figures 4 and 5 suggest the value of having a prediction of the disturbance. The ability to predict is of great value for a control system. It provides a mechanism for non-causal feedforward control, i.e. when the disturbance is predicted with good accuracy before it happens. Moreover, it is not necessary for a similar disturbance to have happened recently. Provided one or more similar deviations have been recorded within the history then the *k*-nearest neighbours method will give prediction based on those similar deviations. This is in contrast to time series modelling methods which use recent history with a forgetting mechanism to discard historical data. The next step in the work is to build predictions based on *k*-nearest neighbours into a control algorithm.

5. Conclusions

The *k*-nearest method has been proposed to predict the future values of process disturbances. The method has been able to provide good predictions of two signals coming from a refinery. The impacts of the parameters k and m have been described, and default values have been provided. The paper gave a comparison between the unweighted and weighted *k*-nearest method and concluded the weighted method is more robust and that it provides better performance.

Input Designs to Obtain Uncorrelated Outputs in MIMO System Identification

Kurt E. Häggblom

Faculty of Science and Engineering, Åbo Akademi University, Biskopsgatan 8, Åbo (Turku) FI-20500, Finland
khaggblo@abo.fi

Abstract

A problem in open-loop identification of multiple-input multiple-output (MIMO) systems is that standard designs using uncorrelated inputs tend to produce correlated outputs. If the system is ill-conditioned, this correlation may be very strong. Such a correlation reduces identifiability and may result in a model with different controllability properties than the true system. If the model is used for control system design, the result may be poor closed-loop performance and even instability.

The author has recently presented an experiment design method for MIMO system identification that solves the main problem by producing uncorrelated outputs for the model used in the design. The solution to the design problem is not unique, however. For a given type of input, the same output covariance can be obtained by different input designs. In this paper, various design options are studied. One of them is to minimize the input amplitudes. The considered signal types are pseudo random binary sequences (PRBS) and multi-sinusoidal signals with optimized phase shifts. Two systems having different directionality properties and number of inputs/outputs are used for illustration.

Keywords: System identification, Multivariable systems, Experiment design, Identification for control, Convex optimization.

1. Introduction

In the control of industrial MIMO systems, integral controllability (IC) is usually a required property. This means that the closed-loop system must be stable when controllers with integral action are used, and remain stable if the controllers are detuned (Garcia and Morari, 1985). Because IC is determined by the static gain matrix of the system, an experiment design procedure based on an estimate of the gain matrix was proposed by Koung and MacGregor (1992). In this design, the static gain directions of the system are explicitly excited. Although dynamics are not considered in this experiment design, it tends to work well also for identification of dynamics when the dynamics are aligned with the gain directions (Häggblom and Böling, 1998, 2013). Overviews of various developments of this procedure is given by Häggblom (2014).

Dynamics are explicitly taken into account in experiment design methods proposed by Rivera et al. (2007), Darby and Nikolaou (2014), and Kumar and Narasimhan (2016). These methods are rather complicated. Although not used as an optimization criterion, the designs yield almost uncorrelated outputs. A design procedure that directly addresses the output distribution has been proposed by Häggblom (2017). The aim is to produce uncorrelated outputs to maximize identifiability. The problem can be formulated as a convex optimization with linear matrix inequalities (LMIs) as constraints,

which is easy to solve. The user can select the type of input perturbation, e.g. random binary signal (RBS), pseudo random binary signal (PRBS), or multi-sinusoidal signal.

The solution to the optimization problem is not unique, however. For a given type of input, the same output covariance can be obtained by different input designs. In this paper, various design options are studied. One of them is to minimize the input amplitudes, which is equivalent to minimizing the crest factor. Two systems having different directionality properties and number of inputs/outputs are used for illustration.

2. Design to obtain uncorrelated outputs

It is assumed that an initial model is available for the dynamic system to be identified. The experiment design is based on a discrete-time state-space model,

$$\begin{aligned} x(k+1) &= Ax(k) + Bu(k) \\ y(k) &= Cx(k) + Du(k) \end{aligned}, \tag{1}$$

where k denotes sample number; $u(k)$, $x(k)$, and $y(k)$ are vectors of inputs, states, and outputs, respectively, at sample instant k; A, B, C, and D are matrices of appropriate dimensions in the state-space description. An initial model of any standard form can be converted to this form. Time delays can be modeled exactly by inclusion of additional states (Häggblom, 2017).

2.1. Covariance model

Equation (1) yields the covariance model (Häggblom, 2017)

$$\begin{aligned} P_x(k+1) &= AP_x(k)A^{\mathrm{T}} + AP_{xu}(k)B^{\mathrm{T}} + BP_{xu}^{\mathrm{T}}(k)A^{\mathrm{T}} + BP_u(k)B^{\mathrm{T}} \\ P_y(k) &= CP_x(k)C^{\mathrm{T}} + CP_{xu}(k)D^{\mathrm{T}} + DP_{xu}^{\mathrm{T}}(k)C^{\mathrm{T}} + DP_u(k)D^{\mathrm{T}} \end{aligned}, \tag{2}$$

where $P_u(k)$, $P_x(k)$ and $P_y(k)$ are (sample) covariance matrices and $P_{xu}(k)$ is the (sample) cross-covariance matrix between states and inputs, all at sample instant k.

Here, $P_{xu}(k)$ is problematic because it makes Eq. (2) underdetermined. In Häggblom (2017) it is shown that $P_{xu}(k)$ depends on the auto-covariance properties of the input. Including this dependency in the model would introduce undesired complications.

To overcome this problem, $P_{xu}(k) = 0$ is used in Eq. (2), and a scaled version of $P_y(k)$ is introduced to compensate for the exclusion of $P_{xu}(k)$. With the approximation $P_x(k+1) \approx P_x(k)$, and omission of the sample index k, Eq. (2) is thus replaced by

$$\begin{aligned} P_x &= AP_xA^{\mathrm{T}} + BP_uB^{\mathrm{T}} \\ S_yP_yS_y^{\mathrm{T}} &= CP_xC^{\mathrm{T}} + DP_uD^{\mathrm{T}} \end{aligned}, \tag{3}$$

where the scaling matrix S_y is determined as part of the optimization.

2.2. Optimization

The outputs are uncorrelated if P_y is diagonal. Thus, it is desired to have an input covariance P_u that produces a diagonal P_y. According to Hadamard's inequality (Horn and Johnson, 2013), $\det P_y \le \Pi P_{y,ii}$, where $P_{y,ii}$, $i = 1,\ldots,n$, are the diagonal elements

of P_y, with equality holding if and only if P_y is diagonal. This means that uncorrelated outputs can be obtained by maximizing $\det P_y$ subject to upper bounds on the diagonal elements of $P_{y,ii}$. The upper bounds $\text{var}\, y_i$ are the maximum desired output variances.

If there are no (active) constraints on input variances, the same solution is obtained by maximizing the minimum eigenvalue of P_y, i.e., $\max \underline{\lambda}(P_y)$ (Häggblom, 2017). The optimization can be formulated as $\max \lambda$ subject to $P_y - \lambda I \succcurlyeq 0$, which requires $P_y - \lambda I$ to be a positive semidefinite matrix.

The optimization is done subject to Eq. (3), which is linear with respect to the decision variables P_u, P_x and P_y. The scaling matrix S_y is updated iteratively as

$$S_y \leftarrow S_y P_y^{1/2} R_y^{-1/2}, \tag{4}$$

where R_y is the sample covariance matrix of the outputs resulting from a simulation of the system using the input determined from the current P_u in the iteration. The simulation can be done using Eq. (1), or a model from which Eq. (1) was determined. With $S_y = I$ as starting value, this makes R_y converge to P_y (if all matrices have full rank).

Thus, the input covariance matrix P_u is obtained as the solution to

$$\max_{P_u, P_x, P_y} \lambda \text{ s.t. } P_y - \lambda I \succcurlyeq 0, \ \text{var}\, y_i \geq P_{y,ii}, \text{ and Eq. (3)}, \tag{5}$$

with S_y updated iteratively by Eq. (4).

2.3. The input signal

The solution to Eq. (5) does not yield the type of input signal $u(k)$, only its covariance P_u. The user is free to choose any type of (persistently exciting) input signal normally used in system identification. It can, e.g., be a random binary signal (RBS), a pseudo random binary sequence (PRBS), or some version of multi-sinusoidal signals.

Let $\xi(k)$ denote the k^{th} sample of such a design signal. The sample covariance matrix of $\xi(k)$, P_ξ, should ideally be close to a diagonal matrix. This can usually be achieved by using time-shifted copies of a base sequence as components $\xi_i(k)$, $i = 1, \ldots, n$. The idea is to determine a constant matrix T such that the transformation

$$u(k) = T\xi(k) \tag{6}$$

yields an input $u(k)$ with the covariance P_u. From Eq. (6) it follows that

$$P_u = T P_\xi T^{\mathrm{T}}, \tag{7}$$

where P_u and P_ξ are known. Singular value decompositions (SVD) of these positive definite matrices yield

$$P_u = V_u \Lambda_u V_u^{\mathrm{T}}, \quad P_\xi = V_\xi \Lambda_\xi V_\xi^{\mathrm{T}}, \tag{8}$$

where V_u and V_ξ are orthogonal matrices and Λ_u and Λ_ξ are diagonal matrices of

singular values. From Eqs (7) and (8) it follows that

$$T = V_u \Lambda_u^{1/2} Q^{\mathrm{T}} \Lambda_\xi^{-1/2} V_\xi^{\mathrm{T}}, \tag{9}$$

where Q is an arbitrary orthogonal matrix of appropriate dimension. Different choices of Q yield different input and output distributions with the covariances P_u and P_y.

In the following examples, the effect of some choices of Q that follow naturally from the problem description are investigated. These choices are $Q = I$, $Q = V_\xi^{\mathrm{T}}$, $Q = V_u$, and $Q = V_\xi^{\mathrm{T}} V_u$. In addition, a solution minimizing $\| T \|_\infty$ is considered. Since $\| T \|_\infty$ is the largest row sum of absolute values $| T_{ij} |$, this minimizes the peak value of $u(k)$.

3. Examples

The optimizations in the following examples are done in the MATLAB environment using the YALMIP toolbox (Löfberg, 2004) and Mosek as SDP solver. For minimization of $\| T \|_\infty$, the MATLAB command fmincon is used with Eq. (7) as nonlinear constraint. The design signals are generated by the idinput command in the MATLAB System Identification Toolbox (Ljung, 2017).

3.1. A moderately ill-conditioned 2×2 system

The first example is a distillation column model presented by Wood and Berry (1973). It has been used as example in numerous studies, also in Häggblom (2017), where the model is given. The condition number of the gain matrix is 7.45. The transfer function model is sampled with sample time $T_s = 0.2$ and converted into the form of Eq. (1).

The design signal in the first study of the Wood and Berry column is a PRBS with minimum switching time $T_{\mathrm{sw}} = 1$ and sequence length $N = 127$, yielding the period length $P = T_{\mathrm{sw}} N = 127.$ The two signals are made uncorrelated by time-shifting one of them by half a period. Two periods of opposite signs are used. The PRBS is effective in the frequency range $2\pi / P \ldots 0.8\pi / T_{\mathrm{sw}}$.

In the second study of this model, a multi-sinusoidal design signal is applied. To cover the same frequency range as in the PRBS design, using the same period P, the frequencies $\omega_k = 2\pi k / P$, $k = 1, \ldots, n_{\mathrm{f}}$, with $n_{\mathrm{f}} \approx 0.4N \approx 51$, are used. To choose phase shifts, $100 n_{\mathrm{f}}$ randomly distributed phase shifts are generated, and a combination resulting in the smallest overall amplitude is selected by the idinput command. This is an alternative to the minimization of the crest factor by an intractable optimization (see Rivera et al., 2007). As in the PRBS design, the two signals are made uncorrelated by time-shifting one of them by half a period. Two periods of opposite signs are used.

In all design cases, the output specification $R_y = P_y = I$ was reached. The results of the designs are summarized in Table 1 and Table 2. Minimization of $\| T \|_\infty$, denoted $\min T_\infty$ in the tables, results in the smallest input peak values $| u_i |_{\max}$, as expected. The choice $Q = V_\xi^{\mathrm{T}}$, which is easy to apply, comes close to this result. The multi-sinusoidal designs result in considerably higher input peak values that the PRBS designs. Figures 1 and 2 show scatter plots of the output distributions for the choice $Q = V_\xi^{\mathrm{T}}$.

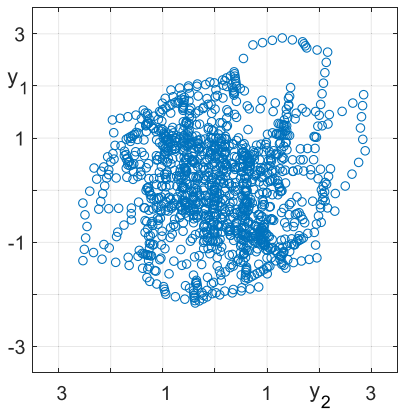

Figure 1. Output distribution of PRBS design for $Q = V_\xi^{\mathrm{T}}$.

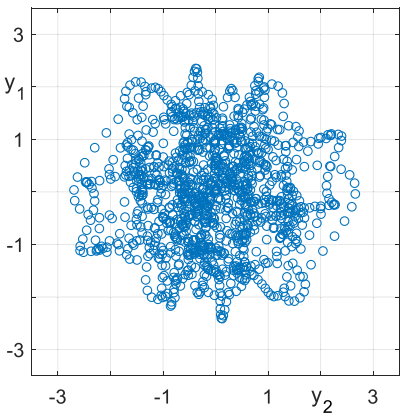

Figure 2. Output distribution of multi-sinusoidal design for $Q = V_\xi^{\mathrm{T}}$.

3.2. An ill-conditioned 3×3 system

The second example is a distillation column model presented by Vasnani (1994). In Häggblom (2016), a rescaled version of the model was introduced to make it slightly more ill-conditioned, resulting in the condition number 30. Here, this model is used. The transfer function model of size 3×3 is sampled with sample time $T_s = 1$ and converted into the form of Eq. (1).

A minimum switching time $T_{\mathrm{sw}} = 5$ and sequence length $N = 255$ are used in the PRBS design. The signals are made uncorrelated by time-shifting consecutive components by one third of the period. Two periods of opposite signs are used. The multi-sinusoidal design is done similarly as above with $n_{\mathrm{f}} = 102$.

The output specification $R_y = P_y = I$ was reached in all design cases. The results for $Q = V_\xi^{\mathrm{T}}$ and $\min \| T \|_\infty$ are summarized in Tables 3 and 4 with T omitted. The conclusions are similar to those for the 2×2 case.

Table 3. PRBS designs (3×3).

Q	$\operatorname{var} u$	$\lvert u\rvert_{\max}$	$\lvert y\rvert_{\max}$
V_ξ^{T}	$\begin{bmatrix}0.2957\\0.0032\\0.0016\end{bmatrix}$	$\begin{bmatrix}0.5500\\0.0799\\0.0584\end{bmatrix}$	$\begin{bmatrix}2.6655\\2.7126\\2.6002\end{bmatrix}$

$\min T_\infty$	$\begin{bmatrix}0.2267\\0.0025\\0.0013\end{bmatrix}$	$\begin{bmatrix}1.1910\\0.1391\\0.1122\end{bmatrix}$	$\begin{bmatrix}2.8931\\2.9325\\2.9903\end{bmatrix}$

4. Conclusions

Input designs to obtain uncorrelated outputs in MIMO system identification was studied. Inputs with peak values close to the optimized minimum can be obtained by the simple choice $Q = V_\xi^{\mathrm{T}}$ in the calculation of the transformation matrix T used for generating inputs from a design signal. The same output covariance is obtained with PRBS inputs having significantly smaller input peak values than multi-sinusoidal inputs.

Control Strategy Scheme for the Prehydrolysis Kraft Process

Antton Lahnalammi*, Herbert Sixta, Sirkka-Liisa Jämsä-Jounela

Aalto University, Kemistintie 1, Espoo 02150, Finland
antton.lahnalammi@aalto.fi

Abstract

This paper presents a control strategy scheme for the prehydrolysis stage in the prehydrolysis kraft process. The key element of the proposed control strategy is a soft-sensor, which estimates the rate of the unobservable reactions based on a physico-chemical dynamic model of the process. The rate of hydrolysis depends on the wood temperature and hydrogen ion concentration, which can be calculated by estimating the reaction heat due to deacetylation of wood and subsequent wood component degradation reactions. The estimated hydrogen ion concentration and reaction enthalpies are combined with dynamic temperature profile and kinetic reaction models for estimation of the main quality parameters for dissolving pulp, namely the lignin content and the content and degree of polymerization of the alpha-cellulose fraction. The developed model is tested based on parameters approximated from the literature and the feasibility of the model for testing the suggested control strategy scheme is discussed.

Keywords: prehydrolysis kraft process, dissolving pulp, dynamic model, soft-sensor, model-based control

1. Introduction

The prehydrolysis kraft (PHK) process is an extension of kraft cooking, where a separate prehydrolysis stage is conducted prior to the cooking stage, in order to selectively dissolve the major part of the wood hemicelluloses. The resulting almost pure (> 90 %) α-cellulose, denoted as dissolving pulp, can be used for the production of cellulose derivatives and regenerated cellulose fibers. The dissolving pulp demand is growing steadily, largely due to increased textile demand, which can no longer be met by increasing cotton production (Hämmerle, 2011).

The PHK-process is mainly conducted in batch digesters, where the prehydrolysis stage is accomplished by heating the wood chips with direct steam or pressurized water to 160 – 180 °C for up to two hours. The acetyl groups attached to the hemicelluloses are released as acetic acid, which gradually creates an acidic environment in the aqueous phase. The generated proton activity catalyzes the hydrolysis of the wood biopolymers into smaller, eventually water-soluble fractions. The addition of mineral acid is avoided due to adverse effects related to the formation of sulfate or chloride containing salts. The removal of wood hemicelluloses is accompanied by unavoidable partial hydrolysis of cellulose, which causes enhanced depolymerization and increased yield loss during the subsequent cooking stage due to alkaline hydrolysis and secondary peeling reactions, respectively. The degree of polymerization, determined as intrinsic viscosity, is the main dissolving pulp control parameter. Furthermore, the formation of delignification resistant condensed lignin from the released highly reactive acid soluble lignin hinders the following cooking stage and limits the recovery of sugars from the prehydrolyzate. On-line monitoring of

these aforementioned reactions is missing. Thus, the process has to be optimized off-line and only minor adjustments are made based on long run deviations.

Reaction kinetic models allow insight into the unobservable reactions. However, the extremely inhomogeneous and partially indeterminate morphology of hardwood on cell wall and macromolecular levels prevents comprehensive modelling of the reaction rates and the interlinked rate limiting mass transfer phenomena. Consequently, generalizations based on experimental results are unavoidable. Simmonds et al. (1955) showed early on that the removal of xylan during prehydrolysis consists of an initial fast phase, followed by a slower secondary phase. Based on this result, Conner (1984) developed a prehydrolysis model where xylan is divided into fast and slow reacting fractions, both of which are degraded following pseudo first order kinetics. Following the same logic, Borrega et al. (2011a, 2011b) developed kinetic models for the degradation of the main carbohydrates and the removal and condensation of lignin in hardwood. More recently Ahmad et al. (2016) developed an extensive physico-chemical model, which estimates the acid equilibrium and mass transfer based on the Nerst-Planck equation and the major wood component degradation pathways and molecular weight distribution of xylo-oligosaccharides by second order kinetics. Reaction kinetics of the following kraft cooking stage are outside the scope of this study, and have been reviewed elsewhere (Nieminen and Sixta, 2012).

Control of the PHK-process is limited by shared resources and recirculation of residual heat and chemicals, which impose scheduling limits to displacement batch cooking facilities. As a result, the temperature profile is the only available control variable during the prehydrolysis stage. In industrial settings, the extent of hemicellulose removal is traditionally estimated by the P-factor (Brasch and Free, 1965; Lin, 1979) which is analogously to Vroom's (1957) H-factor used in kraft cooking: time integral computed over Arrhenius type equation using experimentally determined average activation energy and frequency factor for overall delignification. The plant control system's optimization tool solves optimal temperature profile leading to the predetermined P-factor, subject to limitations imposed by available time and resources.

The earliest applications of model based control strategies for batch digesters were single corrections to target H-factor based on effective alkali conduction measurements after initial fast reactions, which were correlated with simplified kinetic models (Kerr, 1976; Noreus et al., 1974). Later, Paulonis and Krishnagopalan (1991) introduced an adaptive inferential control system, which utilized additional UV and refraction index liquor analysis methods for real time estimation of kappa number based on material balances. Lee and Datta (1994) further developed the approach into a state observer based model predictive controller for batch kraft cooking. More recently, de Vaal and Sandrock (2007) introduced a model based control strategy for acid sulphite pulping in a batch digester, which utilizes a fundamental model (Kilian and De Vaal, 2000) for estimating the degree of polymerization. However, no model based control strategy for the PHK-process has been published to date.

The temperature profile remains the only available signal from the digester during the prehydrolysis stage, which suggests the utilization of energy balance for real time estimation of the reaction rates. Courchene et al., (2005) successfully determined heat of reaction of kraft cooking from overall energy balance of a batch laboratory digester. This paper presents a fundamental dynamic model for the prehydrolysis kraft process, for the estimation of the energy and component balances. Subsequently a control strategy design based on the model is outlined and the validity of the model is tested with approximated parameters.

2. Process description

Batch pulp digester consists of a steel reactor vessel and external heat exchanger. According to academic inclination, the model system described here utilizes water phase prehydrolysis, where liquid fraction is continuously circulated through the heat exchanger, while the solid wood fraction remains immobilized inside the reactor. The simplest case is assumed here, where the circulation liquid flows in from the top and out from the bottom of the reactor (Figure 1 Right). Sieves are installed into the top and bottom of the reactor vessel: the flow is spread evenly on vertical dimensions, allowing simplification to plug flow. The heat exchanger is simulated as a multi-tube system.

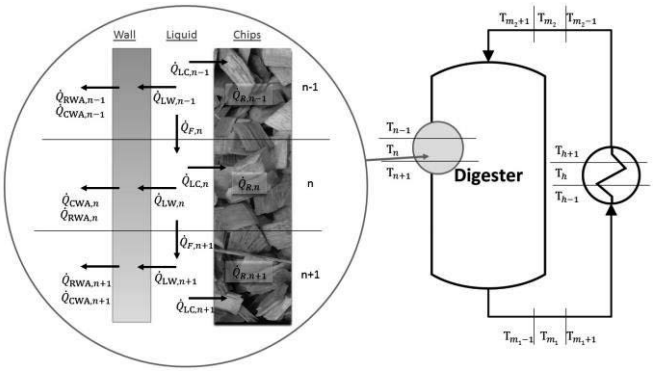

Figure 1. Right: Digester system liquid circulation. Left: Direction of the simulated thermal energy fluxes inside the reactor vessel. The wood chip fraction is absent in the pipes and the heat exchanger.

3. Dynamic model

The dynamic model of the digester is formulated through energy and material balances. The former are defined for the circulating liquid ($\dot{Q}_L$), the wood chips including entrapped liquid ($\dot{Q}_C$) and the digester system walls ($\dot{Q}_W$) and the latter for α-cellulose [C], xylan [X], lignin [L], glucomannan [G], acetyl groups [OAc] and acetic acid [AcOH]. The reactor, the outflow pipe, the heat exchanger and the inflow pipe are divided into N, M_1, H and M_2 sections respectively. Inside each section uniform temperature and component concentration is assumed.

3.1. Energy balance

Heat is carried from one section on to the other with the flow of the liquid fraction ($\dot{Q}_F$) and convected form the liquid into the chips ($\dot{Q}_{LC}$) and the walls ($\dot{Q}_{LW}$). Inside the heat exchanger, the flux from the walls is positive. Heat is lost from the wall sections to ambient by convective ($\dot{Q}_{CWA}$) and radiative heat transfer ($\dot{Q}_{RWA}$). Conduction between separate sections is assumed to be insignificant. The general energy equations for the chip, liquid and wall sections are described below (Eq. 1-3, Figure 1).

$$\dot{Q}_{L,n} = \dot{Q}_{F,n} - \dot{Q}_{LC,n} - \dot{Q}_{LW,n} \tag{1}$$

$$\dot{Q}_{C,n} = \dot{Q}_{LC,n} + \dot{Q}_{R,n} \tag{2}$$

$$\dot{Q}_{W,n} = \dot{Q}_{LW,n} - \dot{Q}_{CWA,n} - \dot{Q}_{RWA,n} \tag{3}$$

3.2. Component balances

Wood degradation reactions take place inside the wood chips. Main wood components [X], [C], [L] and [G] are divided into fast and slow reacting fractions. Additionally, the solubilized and condensed lignin are included. Degradation and condensation reactions and the acetyl group cleavage are modelled using second order kinetics as described in Eq. 4, where $[R_i]$, $[H^+]$ and k stand for the reactant concentration, hydrogen ion concentration and reaction rate coefficient respectively. The water autoionization and acetic acid dissociation are modelled as equilibrium reactions. The diffusion of acetic acid, acetate anions and hydrogen cations form the entrapped water to the free liquid fraction is modelled according to Fick's law of diffusion. The development of cellulose degree of polymerization (DP)—which relates to the pulp viscosity—can be approximated by the concept of degradation increase (DI) and degree of degradation (DD) described in (Kilian and De Vaal, 2000).

$$\left[\dot{R}_{i,n}\right] = -k_{R_i}\left[R_{i,n}\right][H_n^+] \tag{4}$$

4. The control strategy scheme

The aim of the proposed control strategy is to improve pulp quality control by estimating the unobservable reactions during the prehydrolysis stage. The hypothesis is that variations in raw material quality lead to variable hydrolysis rate, which can be explained by the variation in the development of the temperature and hydrogen ion profiles inside the wood chips. By estimating these profiles from the measured data, the developed model can adapt to the variations in raw material quality and calculate the optimal T-profile for achieving the target pulp quality. Consequently, measured liquid temperature ($T_{L,n,m}$) and measured rate of change in liquid energy balance ($\dot{Q}_{L,n,m}$) are combined with the model energy balance for development of soft sensor ($[]_{ss}$) for estimation of the wood chip fraction temperature (Eq. 5) which can in turn be used for estimation of hydrogen ion concentrations (Eq. 6). The Equations 5 and 6 are derived by rearranging Equations 1 and 2 respectively and by observing that the $\dot{Q}_{LC}$ term consists of average heat transfer coefficient between liquid and chip ($\bar{h}_{LC,n}$) and the temperature gradient, while the reaction enthalpy term ($\dot{Q}_R$) is summation over all N_R reaction rates (Eq. 4) multiplied by the corresponding heat of reaction (λ_i). The measurements from the soft sensor are combined with the estimates from the dynamic model component balance using state-estimator, the model states are updated, and finally the optimal temperature set point trajectory is computed using nonlinear model predictive controller (Figure 2).

$$T_{C,n,ss} = \left(\left(\dot{Q}_{L,n,m} + \dot{Q}_{LW,n} - \dot{Q}_{F,n}\right)\bar{h}_{LC,n}^{-1} + T_{L,n,m}\right) \tag{5}$$

$$[H_n^+]_{ss} = \left(\dot{Q}_{C,n} - \dot{Q}_{LC,n}\right)\left(\sum_{i=1}^{N_R} k_i\left[R_{i,n}\right]\lambda_i\right)^{-1}\Big|_{T_{C,n,ss},T_{L,n,m}} \tag{6}$$

For model validation and parameter estimation with industrial data, a correlation between fully cooked and prehydrolysis treated PHK-pulp needs to be established, as the dissolving pulp quality parameters can be measured only after the entire PHK-cycle. This can be accomplished by a simple regression model or a full cooking model and will

furthermore allow the periodic model parameter estimation for adaption to long term deviations (Figure 2). In case a full cooking model is used, the degradation increase computed in estimation of DP allows also the computation of the increase in reducing end groups, which has major effect on the rate of the yield and viscosity reducing peeling reactions.

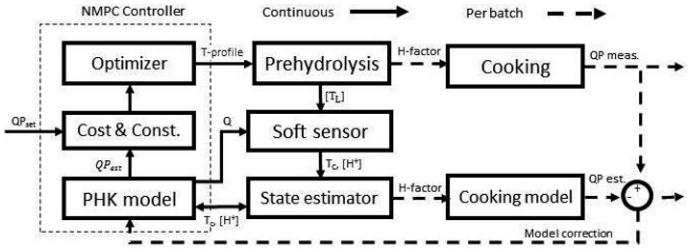

Figure 2. Overall scheme of the proposed control strategy.

5. Preliminary testing and discussion

All the kinetic parameters and initial concentrations, with the exception of xylan, were obtained from Ahmad et al. (2016), where the cellulose degradation is modelled as one fraction and the proportion of fast reacting lignin was 50.06%. The xylan degradation was modelled using the parameters from (Borrega et al., 2011b), scaled to second order kinetics by dividing with the average hydrogen ion concentration. The diffusion rate constants for acetic acid and lignin were obtained from (Haynes et al., 2017), where the solubilized lignin was approximated as ethylbenzene. Temperature relation was modelled by Stokes-Einstein relationship, and multiplied by effective capillary cross sectional area of 0.1 (Inalbon et al., 2017). The heat transfer coefficients used for liquid-wood, liquid-wall and wall-ambient interfaces were 200, 500 and 37 W/(m^{2}K) respectively.

With the used parameters, the temperature of the solid fraction lags behind the liquid fraction by 10 – 15 ºC during the heating period, resulting in a smoother curve and attenuation of the overshoot in temperature control. The hydrogen ion and solubilized lignin diffusion and the mixing through the circulation flow results in almost homogenous pH and solubilized lignin concentration. Lignin and xylan concentrations deviate only slightly between the reactor sections, regardless of the temperature gradient of almost 0.5 ºC. The trends are similar in shape to those presented in the original kinetic model and the model seems to offer a realistic framework for development and testing of the suggested control scheme. Furthermore, the model has potential to provide information about the in batch variance of pulp quality parameters.

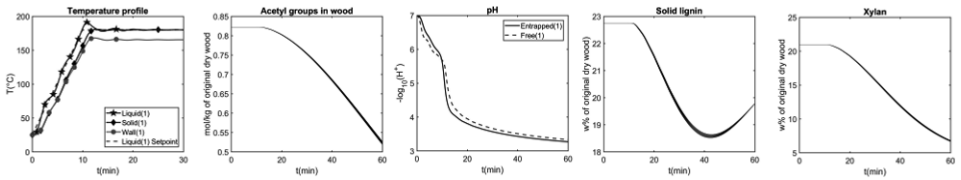

Figure 3. Model output for temperature profile and component balances for acetyl groups, hydrogen ions, lignin and cellulose during autohydrolysis

6. Conclusions

A dynamic mechanistic model for the prehydrolysis stage was presented and a model based control strategy was outlined. The validity of the control strategy relies on the exactness of the computed enthalpy signal ($\dot{Q}_R$), which in turn requires a precise modelling of the energy balance, mass transfer phenomena, reaction enthalpies and reaction rates. However, as the pulping processes are highly non-ideal, the convective heat transfer coefficients and the reaction rate constants are system dependent. In addition, no model for loss of viscosity or heats of reaction during prehydrolysis have been published. The implementation of the model for a real system consequently calls for additional experimental research for determining of these key parameters. Furthermore, the prehydrolysis model needs to be combined with a full cooking model for control of the final PHK-pulp quality. However, initially a simple regression model can be used for model testing and validation.

bequette@rpi.edu

Abstract

Chemical manufacturing processes are often complex and large-scale, with many variables to monitor and control. The startup and shutdown of process units can be particularly challenging, with specific and coordinated sequences of events to assure safety while completing operation goals in a reasonable amount of time. Recent advances in cognitive computing, "big data" and process data analytics have great potential to improving the transient operation of chemical processes. A framework to study process startups, shutdowns and abnormal events using graph theory, cognitive computing and machine learning is presented. Preliminary results based on a simple two-tank problem show the usefulness of graph-based analyses. The procedure detects a sensor fault and startup protocol deviations. Ongoing research tests the proposed strategy on more realistic larger scale chemical processes.

Keywords: Startup/shutdown, cognitive computing, process operators, smart manufacturing

1. Introduction

Startups and shutdowns (SU/SD) are the most hazardous times during process operations, yet most process systems engineering research has been focused on continuous, steady-state operation. Startups and shutdowns have an incident rate 10 times that of steady-state operation (CSB, 2007). While chemical processes are highly automated, it is during these times that the human-in-the-loop plays a critical role, and several disasters have occurred because proper protocols were not followed.

SU/SD involves a combination of manual and automatic operations. Sometimes loops are put into manual because the response is faster than a closed-loop controller Li et al. (2016) use a fuzzy logic based approach to analyze the interactions between operators in a nuclear power plant. Sand and Terwiesch (2013) note that process plant operators have the tasks of SU/SD, supervising the automated operation, and diagnosing and managing disturbances. They stress the need to increase the performance of human-machine interfaces.

Our research effort uses several mathematical and computational tools to analyse the complex non-linearities during SU/SD and provides a framework for the "control room of the future,". This paper focuses on the use of graph theory to detect process deviations or faults. Network and Graph theory has been applied to a range of problems, with important results by Fiedler (1973). Spectral graph theory, especially using the normalized Kirchoff (or Laplacian matrix in graph theory) matrix was discussed in Chung (1994). In process dynamics and control, Jogwar and Daoutidis (2017) use the concept of

communities to design controllers, while Heo and Daoutidis (2015) use graph representations to simplify the analysis of a complex plant.

Much of the focus on fault detection has been steady-state or small dynamic perturbations from steady-state. Isermann (2005) provide reviews of fault detection, with selected applications, of quantitative model-based fault detection and diagnosis techniques. Data-driven approaches for detecting multiple faults are detailed by He et al. (2014). Severson et al. (2016) provide an overview of recent work in process monitoring. Most notable for our application, Wang et al. (2012) develop a hybrid fault diagnosis strategy for chemical process start-up. In the following sections, a novel method is proposed that involves human-machine interactions during a dynamic process

2. Methodology

The goal of this paper is to define a framework to analyse complex dynamic processes and include the human elements in the analysis to understand the temporal patterns over which such a process operates. Fig 1 outlines our complete research goal and vision. The work highlighted in blue in Fig 1 is presented by using a simple proof-of-concept example.

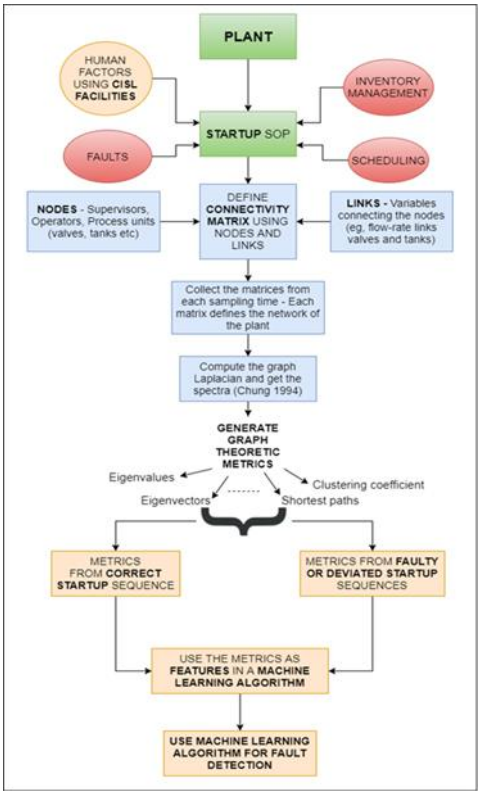

Figure 1. Flowchart of proposed fault detection methodology using process dynamics, graph theory, machine learning and CISL facilities. Color code – Green (available information for any process), Red (external disturbances affecting the startup sequence), Blue (Ongoing work in the lab), Yellow (Future work)

Consider a system of two tanks in series along with the individuals responsible for managing the process (Fig 2) Process model equations are shown in Table 1. The inlet flow to T_1 is controlled by control valve 1 (CV_1). CV_2 controls the flow between T_1 and T_2, and CV_3 controls the flow out of T_2. There are two shifts of operators with their respective supervisors. Shift 1 has Supervisor 1 (S_1) with Operators 1 and 2 (O_1 and O_2). Shift 2 has Supervisor 2 (S_2) with Operators 3 and 4 (O_3 and O_4). Here we assume only shift 1 is active. O_1 controls CV_1 and O_2 controls CV_2 and CV_3. Finally, Sensor 1 and 2 (Sen_1 and Sen_2) give the tank height readings to the shift operators.

2.1 Spectral analysis

Using the above description, the following steps are executed:

1. The total number of physical units = 13 (6 personnel, 3 CVs, 2 tanks, 2 sensors).
2. Define a symmetric matrix called the adjacency matrix ***Ad*** of size 13X13 where each node is a physical unit. This is described in Table 2.
3. Define the links (connection between each node) as follows:

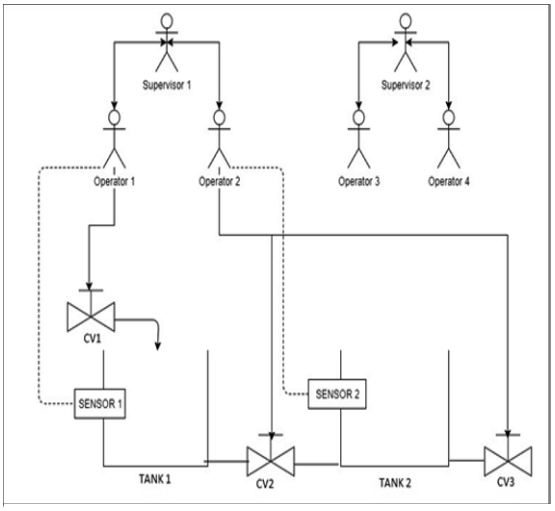

Figure 2. Two tank interacting system hierarchy

S_1 with O_1, O_2 (and S_2 with O_3, O_4) – weights vary from 0 to 1 depending on the level of interaction between the supervisor and the operators. A higher weight indicates more interaction during a process. In the present example, the weights are assigned based on assumptions. In future studies these will be determined from human-interaction based models (Riley et al, 2016) and cognitive computing. O_1 with CV_1 - fraction of the valve opened (K_1, ranges from 0-1). O_2 with CV_2 and CV_3 - fraction of the valve opened (K_2, K_3 ranges from 0-1). CV_1 with T_1 – Flow in (F_1). CV_2 with T_1, T_2 – Flow out of T_1 or flow in to T_2 (F_2). CV_3 with T_2 – Flow out of T_3 (F_3). Sen_1 with T_1 and Sen_2 with T_2 – 1 in case of no fault and 1.3 (i.e a sensor bias) in the faulty scenario. Sen_1 with O_1 and Sen_2 with O_2 – Tank height readings. 4. From these definitions, at each time step, the matrix ***Ad*** can be created using data from the plant. ***Ad*** thus forms a connectivity matrix (or adjacency matrix) for the entire plant. The connectivity changes with respect to the SU sequences with time. As a result, analysing changes in the matrix ***Ad*** connectivity gives us consolidated information about the entire plant.

Table 1: Two-tank interacting system model

Equations	Definitions
$dh_1/dt = (F_1 – F_2)/A_1$	h_1, h_2 fluid heights of T_1 and T_2 (m). A_1, A_2 are cross-sectional area
$dh_2/dt = (F_2 – F_3)/A_2$	F_{in} is $1m^3$ F_1 is flow in to tank 1 in m^3/min
$F_1 = K_1*F_{in}$	, F_2 is flow in to tank 2 in m^3/min, F_3 is flow out of tank 2 in m^3/min
$F_2 = K_2*\beta_1\sqrt{(h_1-h_2)}$	β_1 (=1) and β_2 (=1) are flow coefficients in $m^3/min/m^{0.5}$
$F_3 = K_3* \beta_2\sqrt{h_2}$	K_1-K_3 are fraction open of CV_1-CV_3

An example of the ***Ad*** matrix is given below

$$Ad = \begin{bmatrix} 0 & 0 & [0,1] & [0,1] & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & [0,1] & [0,1] & 0 & 0 & 0 & 0 & 0 & h1 & 0 \\ [0,1] & 0 & 0 & 0 & 0 & 0 & K1 & 0 & 0 & 0 & 0 & 0 & h2 \\ [0,1] & 0 & 0 & 0 & 0 & 0 & 0 & K3 & K3 & 0 & 0 & 0 & 0 \\ 0 & [0,1] & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & [0,1] & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & K1 & 0 & 0 & 0 & 0 & 0 & 0 & F1 & 0 & 0 & 0 \\ 0 & 0 & 0 & K3 & 0 & 0 & 0 & 0 & 0 & F2 & F2 & 0 & 0 \\ 0 & 0 & 0 & K3 & 0 & 0 & 0 & 0 & 0 & 0 & F3 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & F1 & F2 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & F2 & F3 & 0 & 0 & 0 & 1 \\ 0 & h1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & h2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \end{bmatrix}$$

Table 2: Defined nodes for the process

Nodes	Description
1	Supervisor 1 (S_1)
2	Supervisor 2 (S_2)
3	Operator 1 (O_1)
4	Operator 2 (O_2)
5	Operator 3 (O_3)
6	Operator 4 (O_4)
7	Control valve 1 (CV_1)
8	Control valve 2 (CV_2)
9	Control valve 3 (CV_3)
10	Tank 1 (T_1)
11	Tank 2 (T_2)
12	Sensor 1 (Sen_1)
13	Sensor 2 (Sen_2)

5. We now borrow concepts from network/graph theory to analyse ***Ad***. Let $\mathbf{L} = \mathbf{D}-\boldsymbol{Ad}$ where ***Ad*** is the adjacency matrix, **D** is the degree matrix and **L** is the Kirchoff (also called Laplacian in graph theory) matrix. The degree matrix is defined as a diagonal matrix whose elements are the sum of all edges for a particular node in ***Ad***.
6. Define $\mathbf{L^*} = \mathbf{D^{-1/2}LD^{-1/2}}$ where **L*** gives us the normalized Kirchoff matrix and the eigen-decomposition of $\mathbf{L^*} = \boldsymbol{\Theta\Lambda\Theta^T}$ where $\boldsymbol{\Theta}$ are the eigenvectors and $\boldsymbol{\Lambda}$ the eigenvalues. For a nXn matrix, there will be n eigenvalues and n eigenvectors (Chung, 1994). Some key features from this decomposition are as follows:

• The set of eigenvectors $\boldsymbol{\Theta}$ form an orthonormal basis of the network and eigenvalues of **L*** are scaled from 0-2 for any symmetric matrix
• The multiplicity of zero eigenvalues give the number of connected components in the graph/network and number of eigenvalues equal to 1 gives information about similar nodes (especially isolated nodes)
• The eigenvector corresponding to the first non-zero (and thus second smallest) eigenvalue is called the Fiedler vector - gives information about the clustering or grouping of nodes in a network and is often used to compare networks. In this example, the Fiedler vector will be used to show the differences in the SU sequences.

2.2 Shortest paths
Shortest path analyses are very useful to understand the information flow in a complex network. In this work, we use MATLAB's shortest path module on the ***Ad*** matrices and Dijktra's algorithm (Dijktra, 1959) to find the information flow between the components. An analysis of three different SU procedures is presented below.

3. Results

The SU/SD of a plant is defined by a Standard Operating Procedure (SOP) containing a series of sequential steps. As a result, SU/SDs are temporal in nature and any deviations in it should be studied in a simple manner to detect process deviations. Since SU/SD disasters occur due to deviations from the SOPs, it is pertinent to have a method to detect these deviations. In this study, the use of network parameters like Fiedler vectors (FVs) and shortest paths are used to show how different kinds of information can be extracted from a dynamic process as defined before.

For the process in Fig 2, an SOP is defined as given in Table 3.

Table 3: SOP of the two-tank system

Startup sequence	Fraction of valve opened in the startup protocol
Correct	0-50mins – K_1=0.5, K_2=1, K_3=0
	51-100mins – K_1 = 0.1, K_2=0, K_3=0
	101-150mins – K_1=1, K_2=1, K_3=1
Deviated	0-30mins – K_1=1, K_2=1, K_3=0
(to fill the tank faster compared to the Correct startup sequences)	31-150mins – K_1=1, K_2=1, K_3=1
Deviated+Faulty	0-30mins – K_1=1, K_2=1, K_3=0
(Starts with the same protocol as Deviated but changes to a more ad-hoc scenario due to the faulty sensor reading)	31-60mins – K_1=1, K_2=1, K_3=1
	61-90mins – K_1=0.8, K_2=1, K_3=1
	91-120mins – K_1=0.92, K_2=1, K_3=1
	121-150mins – K_1=0.92, K_2=0.9, K_3=1

Simulating the process for the three different SU sequences, the ***Ad*** matrices for the three SU: Correct, Deviated and Deviated+Faulty are found at each time step using steps 3-4

in Methodology. Using the three sets of ***Ad*** matrices, the spectral decomposition is computed and the FV are obtained using steps 5-6 in Methodology. Fig 3 plots the FV for the three SU at 3 different time steps. At t=15 and 60 mins, both the Deviated and Deviated+Faulty SU show differences with the Correct SU as this is the transient region. However, at t=135 mins, the Correct and Deviated cases have the exact same plant state (all weights are same) as they reach steady state. As a result, their FV match exactly, indicating that the two processes are the same at all hierarchy. In Fig 4, it is shown that when we change S_1-O_1 and S_1-O_2 to 0.5 (indicating occasional interaction of operators with supervisors) only for the Deviated scenario, even at t=135 when all the process variables are having the same values (steady state), due to a change in S_1-O_1 and S_1-O_2 weights from the Correct scenario (=0.1), the FV do not match.

The shortest path can provide insights about the flow of information in the network. Using the graphshortestpath() command in MATLAB the following paths were found:

1. S_1-O_2-Sen_2-T_2, S_1-O_2-CV_2-T_2, S_1-O_2-CV_2-T_1, S_1-O_2-CV_3-T_2
2. S_1-O_1-Sen_1-T_1, S_1-O_1-CV_1-T_1
3. S_2-O_3, S_2-O_4

It is easy to see that if Shift 2 was in charge, then the paths would have been different and hence we end up with a technique to see changes in shift with time. Interestingly, this change is also captured in the eigenvalues reported in Table 4. The multiplicities of eigenvalues (=1) equals the number of human personnel not connected to the process due to a different shift. This can be generalized to any process equipment as well.

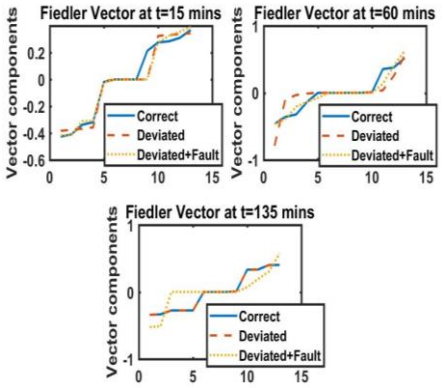

Figure 3. Fiedler vector comparison of the three SU sequences at three time snapshots.

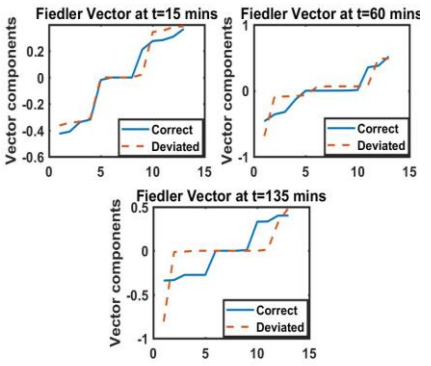

Figure 4. Fiedler Vector of Correct and Deviated. S1-O1 and S1-O2 are 0.1 and 0.5 for Correct and Deviated respectively.

Table 4: Eigenvalues of the normalized Laplacian at t=135 minutes.

Correct	0	0	0.009	0.813	0.921	1	1	1	1.078	1.186	1.99	2	2
Deviated	0	0	0.009	0.812	0.921	1	1	1	1.078	1.186	1.99	2	2
Deviated+Faulty	0	0	0.068	0.617	0.991	1	1	1	1.080	1.382	1.931	2	2

4. Conclusion and Future work

Graph theory was used to analyse SU of a simple process. The results from the FV show that sets of sequential processes will show differences if the links in the individual networks change. It is also useful to analyse the sequences with time; a user-defined time window can be defined to get average ***Ad*** matrices and FV. Similarly, deviations in shortest paths of SU sequences and eigenvalues of a process indicate a change in information flow paths between the physical units and the connectivity of a node in a network. It is evident from these results that for a complex process, such an information transformation helps to identify the changes that are taking place dynamically. These are preliminary results and that we have a vision of the control room of the future that includes the use of IBM Watson based facilities at RPI and machine learning approaches to improve operations.

Abstract

Incorporating a high fidelity model that accurately describes a dynamical system in an optimization and control study may often lead to an intractable formulation, hence the use of model approximation is required. This computational study closely examines various approximation techniques in the context of multiparametric optimization and control with the use of key error metrics including: (i) open loop comparison of the high fidelity and approximate model, (ii) verification of step response profiles, and (iii) comparison of key features of the feasible space and objective function in the optimization formulation. Two systems are used as a basis for this study: a tank system utilized to highlight the main principles of this approach, and a Continuously Stirred Tank Reactor (CSTR) where the reaction mechanisms are manipulated to increase the model complexity.

Keywords: multiparametric programming, model reduction, model predictive control.

1. Introduction

Model based optimization for control, such as Model Predictive Control (MPC), has been gaining traction in the academic and industrial communities for more than 3 decades now (Camacho and Bordons, 2007). In recent years, more advanced models are being incorporated into these model predictive control frameworks (Santos et al, 2001). These direct formulations may typically result in an intractable, large scale, complex, non-convex optimization problem. Problems of this nature can be reduced to tractable forms via model approximation techniques (Diangelakis et al. 2017) that can then be solved offline explicitly using multiparametric programming (Bemporad et al., 2002).

Many techniques have been used for model approximation in Multiparametric Model Predictive Control (mpMPC), two common techniques include (piece-wise) linearization and system identification. Such model approximations are also at the heart of the PARameteric Optimization and Control (PAROC) framework for the derivation of these explicit/multiparametric controllers (Pistikopoulos et al., 2015). A key question that remains open within the PAROC framework is "*what constitutes a suitable approximate model for the derivation of explicit control strategies with multiparametric programming*?".

In this work, we present a computational study towards addressing this question. In particular, we study system identification (Ljung, 1998), and linearization. These model

approximation techniques are widely used to develop linear discrete time state space models that can be incorporated into an MPC formulation. An additional approximation technique based on forward Euler discretization is also studied to compare against the aforementioned techniques. Key error criteria will be used to ascertain the effectiveness of each of the approximation techniques. These error criteria include: (i) open loop error analysis comparing the approximate model against the high fidelity model, (ii) step response profile analysis for each of the approximate models, (iii) comparison of the closed loop trajectory against the optimal trajectory determined from dynamic optimization in the gPROMS® environment, (iv) comparison of the objective values from the different mpMPC formulations and the optimal value determined in gPROMS®, and (v) comparison of the feasible space and objective function for the mpMPC formulations.

2. Methodology

The three approximation techniques used in the work are linearization, system identification, and a technique based on forward Euler discretization. Linearization is performed using first order Taylor Series approximation, where the linearization point is chosen to be at the defined set point of interest. In addition, system identification was performed using the MATLAB routine N4SID which is a subspace based approach to determine the state space matrices that best represent a set of outputs based on a given set of inputs.

The last approximation technique is based on Forward Euler discretization, which approximates the derivative information by taking a finite difference, instead of letting the limit approach zero, as seen in Eq.(1).

$$\frac{\boldsymbol{dx}}{\boldsymbol{dt}} = \boldsymbol{f(x)} \Longrightarrow \frac{\boldsymbol{\Delta x}}{\boldsymbol{\Delta t}} \approx \boldsymbol{f(x_t)} \tag{1}$$

The benefit of this technique is that the derivate information is preserved through approximate discretization. As seen in Eq.(2), nonlinear state terms are treated as uncertain parameters, θ_t and ψ_t, to be used in an mpMPC formulation. In Eq.(2), the term $\psi_t u_t$ results in left hand-side uncertainty when formulated as an mpMPC problem. To avoid the challenges in solving a parametric programming problem with left hand-side uncertainty, this term can be grouped to form a new manipulated variable, as seen in Eq.(3). The new manipulated variables, $\tilde{u}$, will have varying bounds, which can be handled via multiparametric programming. However, grouping an uncertain parameter with a manipulated variable can only occur once for each manipulated variable.

$$\boldsymbol{x_{t+1} = f(x_t) + g(x_t)u_t = \theta_t + \psi_t u_t} \tag{2}$$

$$\boldsymbol{x_{t+1} = \theta_t + \tilde{u}_t} \tag{3}$$

The error criteria used in this work includes (i) root mean squared error deviation between the open loop profile for the high fidelity and approximate model, (ii) qualitative verification of the step response profiles of the approximate models, and (iii) comparison of the feasible space and objective function for the optimization formulations. Open loop analysis is performed using a random input profile on the high fidelity model and the approximate models developed. Step response profiles are verified based on how the real system is expected to perform. To compare feasible spaces of the optimization formulations, the volume of each feasible space is determined using Monte Carlo techniques, and to compare objective functions, the L^2 norm is used as seen in Eq.(4).

$$\|\boldsymbol{f}(\boldsymbol{x})\|_2 = \left(\int_{\boldsymbol{X}} |\boldsymbol{f}(\boldsymbol{x})|^2 \, \boldsymbol{dx}\right)^{\mathbf{0.5}} \tag{4}$$

3. Tank and Continuously Stirred Tank Reactor Examples

To demonstrate the criteria and approximation techniques used, a simplified tank system is examined. The tank has a fixed inlet flow and the flow out of the tank is manipulated via a valve on the exit of the tank. The control objective of the system is to maintain the level of the tank at a specified target. The system maintains a nonlinearity in the form of a square root, as seen in Eq.(5).

$$\frac{\boldsymbol{dh}}{\boldsymbol{dt}} = \frac{\boldsymbol{F}}{\boldsymbol{A}} - \boldsymbol{u}\sqrt{\boldsymbol{2gh}}\frac{\boldsymbol{A_{out}}}{\boldsymbol{A}} \tag{5}$$

The manipulated variable, u, maintains bounds between 0 and 1. The state of the system, h (m), must remain nonnegative. The parameters g (m/s^2), A (m^2), and A_{out} (m^2) are gravity, the area of the tank, and the outlet area of the tank respectively. The MPC formulation can be seen in Eq.(6).

$$\begin{aligned} &\min_{\boldsymbol{u}} \int_0^{\boldsymbol{\tau}} \left(\left(\boldsymbol{x} - \boldsymbol{x_{ref}}\right)^{\boldsymbol{T}} \boldsymbol{Q}\left(\boldsymbol{x} - \boldsymbol{x_{ref}}\right)\right) \boldsymbol{dt} \\ &\boldsymbol{s.t.}\ \ \dot{\boldsymbol{x}} = \boldsymbol{Ax} + \boldsymbol{Bu}, \quad \boldsymbol{x} \in \boldsymbol{X}, \boldsymbol{u} \in \boldsymbol{U} \end{aligned} \tag{6}$$

where Q is a cost matrix, x_{ref} is the set point of the system, x is the state of the system, and u is the input to the system. The MPC formulation can be discretized and converted to a multiparametric MPC where it is solved explicitly offline to determine the optimal control action as an affine function of the uncertain parameters, namely the initial state of the system and the set point.

As a second example, a single reaction, isothermal, and constant volume Continuously Stirred Tank Reactor (CSTR) is considered where the reaction rate complexity is increased. The reaction rate is either first order, second order, or third order. The CSTR has an adjustable flow rate of reactant into the reactor. Constant volume in the reactor is assumed and the reactor is considered to be isothermal. The control objective for this example problem is to maintain a specified reactant concentration level in the reactor while minimizing the use of the reactant flow.

$$\frac{\boldsymbol{dC_A}}{\boldsymbol{dt}} = \frac{\boldsymbol{F}}{\boldsymbol{V}}\left(\boldsymbol{C_{A_i}} - \boldsymbol{C_A}\right) - \boldsymbol{kC_A^{\alpha}} \tag{7}$$

$$\frac{\boldsymbol{dC_B}}{\boldsymbol{dt}} = \frac{\boldsymbol{F}}{\boldsymbol{V}}\left(-\boldsymbol{C_B}\right) + \boldsymbol{kC_A^{\alpha}} \tag{8}$$

The mass balance for the system can be described by Eq.(7) and Eq.(8), where the amount of reactant and product vary based on the inlet flow and the reaction mechanism. The manipulated flow into the reactor, F (m^3/s), is bounded between 0 and 1, and the states of the system, the reactant (C_A) and product (C_B) concentration (mol/m^3), are also bounded between 0 and 1. V (m^3) is the volume of the system, k is the rate constant of the system, C_{Ai} is the inlet reactant concentration, and the system order is α. The MPC formulation for this example problem, similar to Eq.(6), includes set point tracking on the reactant concentration, since there is a 1:1 correspondence between the reactant concentration and

the product concentration, and a penalty on the usage of the reactant material, or a penalty on the input to the system.

4. Results and Discussion

Both examples were simulated and dynamically optimized using the gPROMS® software. The dynamic optimization was performed using Control Vector Parameterization which discretizes the manipulated variable over a control interval, and over each interval the manipulated variable is assumed to follow a simple function. The optimal trajectory determined from gPROMS® is considered as the optimal trajectory and is compared against the mpMPC closed loop trajectories. The objective function used in the mpMPC formulation is the same in all formulations. For the mpMPC formulations, the output and control horizon is 3 and 2 respectively for the tank example and 5 and 2 respectively for the CSTR example.

Figure 1a shows the open loop response of the approximate models and the high fidelity model for the tank example, where the legend shows the root mean squared error. The open loop performance of system identification performs the worst out of the approximation techniques, and linearization performs the best. Figure 1b is a comparison of the step response profiles. All of the step response profiles show a decrease in the output for an increase in the input, which is consistent with how the system would react. The approximate model resulting from forward Euler discretization is a straight line because the state space representation is critically stable. Figure 2 shows trajectories from using different approximate models and control strategies, and the corresponding output of the system. The optimal trajectories are determined from the mpMPC formulation, a dynamically optimized PI controller, and open loop dynamic optimization on the full process model in gPROMS®. Table 1 shows a comparison of the objective function costs, volume of the feasible space, and distance between objective functions. From Table 1, based on the objective function costs, linearization has the most comparable performance to the open loop dynamic optimization results. This can be attributed to linearization performing well around the linearization point, which was chosen as the set point. Forward Euler has a similar cost and an objective function that more closely matches the 'real' objective function. System identification performs the worst, except it has a feasible space volume that is closer to the actual the feasible space volume.

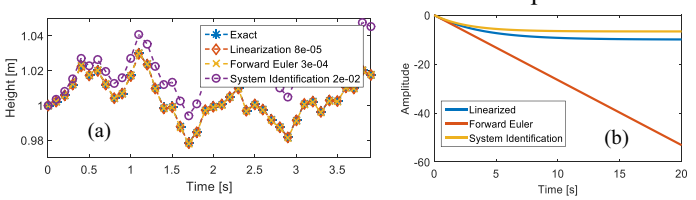

Figure 1. (a) Open loop comparison of output via root mean squared error (b) Step response profiles of the approximate models for the tank example

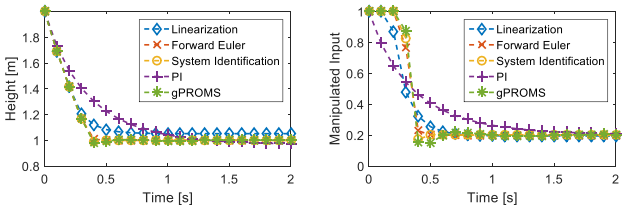

Figure 2. Closed loop performance comparison for the various controllers and open loop dynamic optimization for the tank example

Table 1. Quantitative results of different error criteria

	Linearization	System Ident	Forward Euler	Exact
Optimal Trajectory Cost (Tank)	1.1264	1.12738	1.12723	1.1261
Feasible Space Volume (Tank)	98	98.3	94.9	100
Objective Function L^2 (Tank)	5.19	13.42	0.1497	0
Optimal Trajectory Cost (CSTR),α=1	0.139	0.140	0.140	0.135
Feasible Space Volume (CSTR), α=1	0.47	0.44	0.26	1
Objective Function L^2 (CSTR), α=1	0.54	0.42	3.1604	0
Optimal Trajectory Cost (CSTR),α=2	0.112	0.113	0.112	0.110
Feasible Space Volume (CSTR), α=2	0.41	0.38	0.19	1
Objective Function L^2 (CSTR), α=2	0.67	1.54	4.22	0
Optimal Trajectory Cost (CSTR),α=3	0.174	0.181	0.174	0.173
Feasible Space Volume (CSTR), α=3	0.36	0.43	.22	1
Objective Function L^2 (CSTR), α=3	0.84	1.25	4.22	0

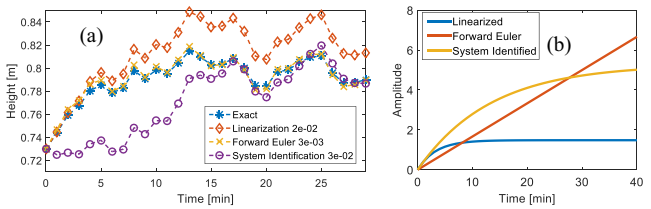

Figure 3. (a) Open loop comparison of output via root mean squared error (b) Step response profiles of the approximate models for the CSTR example

The open loop performance and step responses for the CSTR are only compared for an α value of 3. As seen in Figure 3a, the open loop performance of system identification performs the worst out of the approximation techniques. Figure 3b is a comparison of the step response profiles. All of the step responses show an increase in the output concentration for an increase in the input, as expected for this system. Forward Euler approximation has a straight line due because its state space model is critically stable. Figure 4 shows optimal trajectories from using different approximate models and techniques, and the corresponding output of the system. The optimal trajectories are determined from the mpMPC formulation, a dynamically optimized PI controller, and open loop dynamic optimization on the full process model. Comparison of the objective function costs, volume of the feasible space, and distance between objective functions can be seen in Table 1. For all of the different values of α, linearization performs the best, while maintaining a feasible space and objective function most similar to the real system. Because the system has a set point that matches the linearization point the linearized state space model can accurately represent the system in this region. Forward Euler performs well for all α even though it has a feasible space that is smaller than both the system identification and linearization feasible spaces. Its objective function distance is also farther away than the objective functions for both linearization and system identification. The feasible space being small is not enough on its own to categorize poor performance

and the distance in objective functions is not large enough to cause performance issues either.

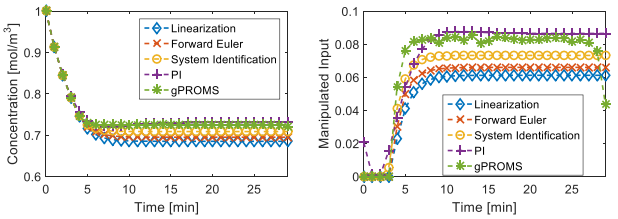

Figure 4. Closed loop performance comparison for the various controllers and open loop dynamic optimization for the CSTR example

5. Conclusions

Various model approximation techniques have been utilized to develop multiparametric model predictive controllers. These approximate models and resulting optimization formulations were assessed using various error criteria. For the example problems presented, and criteria used, the linearization technique provided an optimal trajectory that was closest to the 'desired' trajectory using dynamic optimization in gPROMS®. Future work is to apply these concepts on a system of significantly increased complexity and further development on the concepts of feasible space volume and distance between objective functions.

Abstract

The product composition control in a multicomponent distillation column presents several challenges in the industry. The development of a soft sensor enables the monitoring of the product quality using an inferential model and on-line measured process variables. To be useful in an industrial application, the inferential model needs to provide fast sampling rates and with high accuracy. A new inferential model to estimate the gas composition product from a multicomponent distillation column is proposed. It is based on a model that combines a first-principles model at the equilibrium stage with heuristic rules based on the process knowledge. Moreover, strategies for key components selection and a model for the systematic correction of input variables are used to ensure the robustness on a real-time application. A rigorous simulation of a debutanizer distillation is implemented to compare with the proposed inferential model. The results of the soft sensor show a good capability of prediction and accuracy compared to the rigorous model, even using less input process variables.

Keywords: Multicomponent distillation columns, Key components selection, Soft sensor.

1. Introduction

Modern chemical processes have challenging profitability targets and require tight control on their product quality in real time. For that, accurate measurements of critical variables at fast sampling rates are of utmost importance. Usually, the disadvantage of using hardware sensors is either technical (e.g., with the time delay from gas chromatographs) or economic (a large number of online variables leads to high cost device sensors). Soft sensors enable the monitoring of important variables such as product compositions (dependent variables) from other easily measured variables (independent variables) such as temperature and pressure, provided by a mathematical model (Fortuna et al, 2005, Grbić et al. 2013, Jian et al. 2017). Evidently, the quality of this model is critical to the soft sensor performance.

To overcome online measurements difficulties, many soft sensor development techniques have been investigated. Model-driven soft sensors are based on first principle models (FPMs) and require a deep knowledge of the process. Its main advantage is its accurate extrapolation to different operating points (Luyben, 2012). However, building a rigorous model of a complex process can be time consuming. For this reason, industry has explored data-driven soft sensors more often in recent years.

Many authors have developed soft sensors using multivariate statistical methods, such as Principal Components Analysis (PCA), Partial Least Squares (PLS), Artificial Neural Networks (ANN) and Neuro-fuzzy systems (NFS) (Kadlec et al., 2011). However, these methods usually need a large set of past measurements, selection of appropriate inputs and quality assessment techniques to account for outliers, co-linearity and missing data (Rani et al., 2013; Grbić et al. 2013).

In this work, we present a new soft sensor for a gas multicomponent distillation column. This soft sensor is built by simplifying the rigorous model of a distillation column by two equilibrium stages and a strategy for the selection of the light key and the heavy key components. Based on the process knowledge, this method also combines an FPM with heuristic rules. To ensure robustness, we propose a methodology for correcting input temperatures. The model is tested with a debutanizer column and its results are compared with the analysers' outputs.

2. Description of the Problem

In natural gas processing plants (NGPPs), the recovery of sales gas and Liquefied Petroleum Gas (LPG) from natural gas uses several stages of separation units. The composition of natural gas from oil wells is usually majorly composed of methane and heavier hydrocarbons. The sales gas is obtained in the top product of the demethanizer column (primarily with methane and ethane) and the bottom product is a mixture of liquid hydrocarbons. This mixture is then processed in the debutanizer, where the LPG (primarily with propane and butanes) is separated from the natural gasoline (C_5^+).

The LPG composition requirements vary according to local regulations. In this work, we focus on monitoring the concentration of C_5^+ in the LPG product, whose maximum value is 2 % mol of total pentanes, and the Reid Vapor Pressure (RVP) of the gasoline product, with a maximum value of 15 psi (103.421 kPa). Therefore, the soft sensor needs to provide frequent estimations of these variables.

Figure 1 shows a schematic representation of the gas processing plant, highlighting the five regulatory control loops that mostly affect the variables of interest.

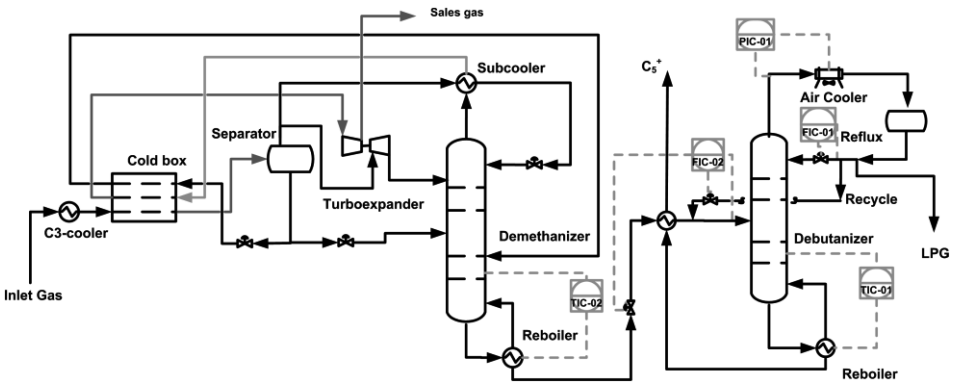

Figure 1. Simplified flow sheet representing the NGPP considered in this work.

In order to evaluate the estimation performance of the product composition, we developed and simulated a full FPM for the process represented in Figure 1 using Aspen Plus Dynamics®. The soft sensor then used data from such simulation as input.

3. Soft Sensor

3.1. General concept

Soft sensors have been used in distillation columns to obtain accurate online measurements of products compositions. As the product composition is a function of the temperature, methods based on the relationship between the temperature stages and the products compositions have been used to correlate these variables (Rani et al., 2013).

In this study, a Simplified Robust Soft Sensor (SRSS) is proposed to estimate the gas product composition of a multicomponent distillation column during its regular continuous operation. The soft sensor was implemented in EMSO, an Equation-Oriented process simulator. The data used as input to the SRSS is composed by:

- Composition of the debutanizer's inlet gas (C1, C2, C3, i-C4, n-C4, i-C5, n-C5, n-C6, n-C7, n-C8, n-C9), or the bottom product from the demethanizer;
- Temperature and pressure from the top outlet vapour stream.
- Temperature and pressure from the bottom outlet liquid stream.

The SRSS is based on flash models, which combine the vapor/liquid-equilibrium (VLE) condition, $\phi_i^V y_i = \phi_i^L x_i$, with the mass and energy balances, where x_i, y_i are the liquid and vapor compositions of component i, respectively, and the fugacity coefficients ϕ_i^V and ϕ_i^L are determined from the equation of state (for example, SRK or PR equations). These equations and the mass and energy balances have been suppressed due to lack of space.

The Two-Flash Process Model (TFPM) depicted by Figure 2 is used as a surrogate of the distillation column. The top flash unit, representing the column's top stage, is set as in dew point and the bottom flash unit, representing the column's bottom stage, is set as in bubble point. Therefore, inputting the temperatures and pressures for each flash is enough to determine the remaining degrees of freedom: the Heavy Key (HK) and Light Key (LK) flow split ratios. To determine which of the several components should be set as light and heavy keys, we propose heuristic rules based on the process knowledge.

3.2. Selection of light and heavy keys

First, it is necessary to know the key components governing the separation design of the distillation process. The objective of the debutanizer is to output all components lighter than the butanes as the top product, while a small amount of pentanes is admissible. In a regular operating point, it is expected that only butanes and pentanes will be switched between the top and the bottom products. Components lighter than the Light Key (LK) are set to go straight to the top product and the components heavier than the Heavy Key (HK) are set to go directly to the bottom product.

Finally, within both LK and HK, the proportion of each component needs to be in accordance with the product composition. These proportions should reflect the ones typically found in the products. If those are not available, a good starting point is using the proportions from the feed. In our work, we used the LK proportion from the feed but

the HK proportion (nC5/iC5) was tuned to 0.3 to better match the full FPM results. For general applications, these adjustments need to be made on each column. Once they are done, the soft sensor performance is guaranteed. Due to the small number of parameters that need to be adjusted, this is a simple task.

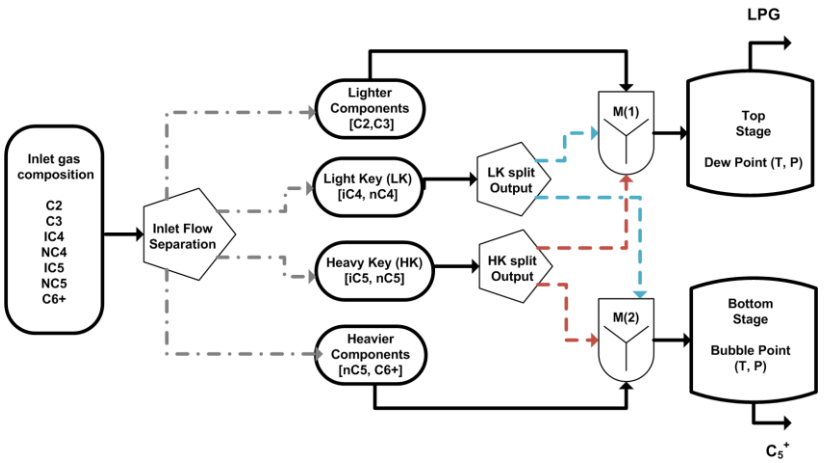

Figure 2. Scheme of the Two-Flash Process Model (TFPM) used for the SRSS.

4. Soft Sensor Robustness

4.1. Concept and implementation

The plant temperatures are subject to noises and transient behaviours that could fall out of the operating range of the TFPM. Hence, the soft sensor input variables need to be systematically corrected to avoid convergence issues in real time. Our concept involves using four copies of the TFPM to calculate temperature limits in parallel with the main TFPM. Each TPFM receives the plant pressure data as input, but assume different LK and HK splitting characteristics to calculate the temperature limit as follows:

1. Bottom Temperature Reference TFPM – Assumes perfect LK/HK split.
2. Top Stage High Temperature TFPM – Assumes that all HK goes to the top product. This is a maximum temperature under regular operation.
3. Top Stage Low Temperature TFPM – Assumes all LK flows to the top product. Only considered if the bottom temperature is above its reference.
4. Top Stage Very Low Temperature TFPM – Assumes all HK flows to the bottom product.

The TFPMs 2, 3 and 4 also receive the plant's bottom temperature as input.

The flowchart in Figure 3 explains how the variables output from each of the TFPMs above are used. Whenever necessary, the top stage temperature will be limited to one of the calculated temperature limits. In the flowchart, BS-Ref, TH-Lim, TL-Lim and TVL-Lim are the outputs of TFPMs 1, 2, 3 and 4, respectively.

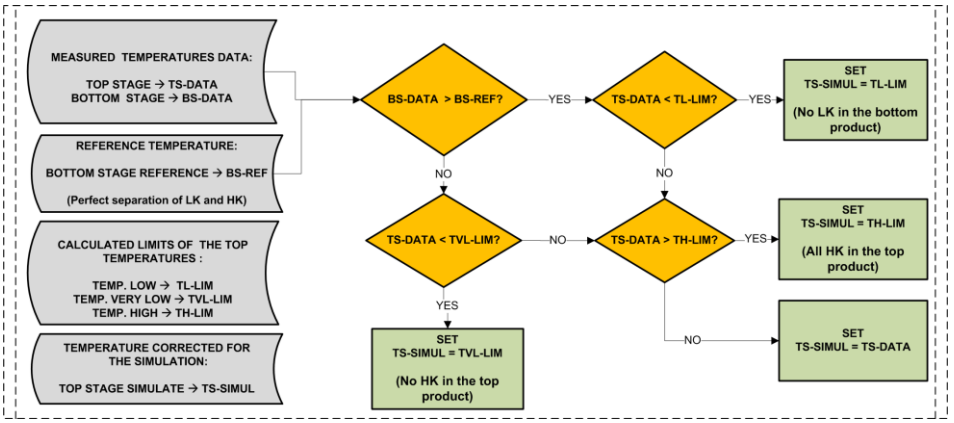

Figure 3. Temperature data correction scheme based on the top stage constraints.

4.2. Testing the soft sensor robustness

Figure 4 displays the results of a robustness test, with the top temperature (TS-Data) occasionally falling below the minimum limit (TVL-Lim). The bottom temperature (BS-Data) from the plant data can be higher or lower than its reference temperature (BS-Ref). In this test, the bottom temperature starts below the reference value. At minute 43, it raises above it, which switches the limit to TL-Lim. The online calculation of new limits ensures a robust estimation at different operations points.

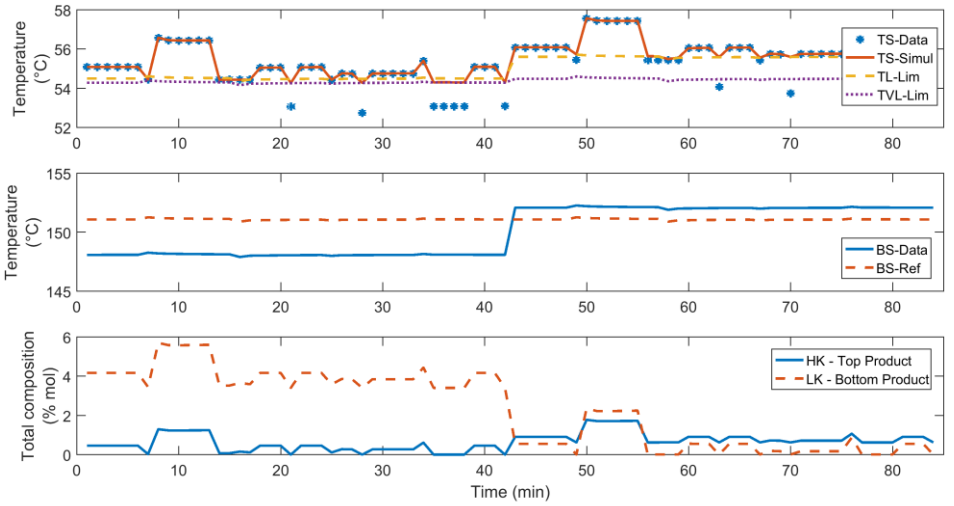

Figure 4. Tests to validate the top stage temperature correction

5. Soft sensor performance

Figure 5 compares the results from the SRSS with the full FPM throughout five step tests in the regulatory control loops. An offset correction was used in both variables inferred by the SRSS, using +0.24 % mol for the C5's composition in the top product and +0.64 psi for the RVP of the bottom product. The SRSS results have high correlation with the full FPM even subject to nonlinearities, as shown by the step test in

TIC-01 (temperature control of the debutanizer column's sensitive tray). The Root Mean Square Error (RMSE) was 0.072 % mol for C5's composition and 0.018 psi for the PVR.

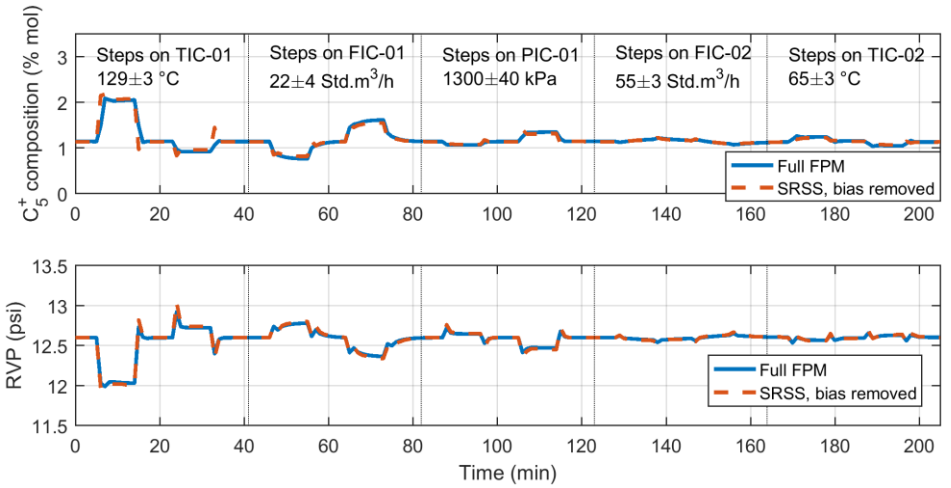

Figure 5. Prediction of total pentanes in the debutanizer overhead product and RVP from bottom product in different step tests in the regulatory controls of distillation units.

6. Conclusions

The proposed inference model accurately predicts critical variables of a multicomponent distillation column. The results indicate good accuracy during variations in the operating point when compared to a rigorous model, despite using fewer input variables. There were no convergence issues in any of the tested points, which is highly desirable for real-time applications. Tests with industrial data are being conducted. Future work includes generalizing the SRSS to other distillation columns.

Abstract

The present work proposes a new application of algorithms of signal processing and machine learning known from the literature to identify, characterize and locate gas leaks through pipelines. Leakages are often dangerous and unpredicted events confronted daily in distributions of fluids. The purpose of this paper is to establish a methodology for the diagnosis of gas leaks. Among the techniques found in the literature for study of leakage patterns, the investigation of the sound produced was chosen in the present paper. The sound signals were studied in the frequency domain calculated by Fast Fourier Transform. For the identification and classification of patterns contained in the frequency data, two classes of machine learning were used independently: a supervised and an unsupervised learning algorithm. Both algorithms were able to distinguish the diameter of the leak and provide a notion of its location. However, the supervised method demonstrated difficulty in identifying and recognizing events with no leakage. In conclusion, it was possible to identify, characterize and locate leak events, specially using the unsupervised algorithm, with the proposed methodology.
Keywords: leaks, signal processing, acoustics

1. Introduction

The transportation of gas, as well as that of liquids and oils, is conducted primarily through pipelines and a majority of the leakage incidents occur during transportation. These incidents can cause property damage, ecological imbalance and financial debts. In the field of chemical engineering, a common situation of undesirable leakage involves the loss of reagents before entering the reactor. This hinders the control of the chemical reaction and can cause the entire production to be interrupted by safety measures. Thus, the study of a methodology capable of identifying leakage becomes important to avoid damages whenever leakage is not desired.

There are several works in the literature investigating methodologies to identify leaks. These investigations include principles of mass balance, volume balance, transient pressure behavior analysis, vibration monitoring techniques along the pipeline and, among others, acoustic response analysis. In this work, the purpose of choosing the acoustic method is to have an easy to install and inexpensive method to be investigated.

The acoustic method demands a simple experimental setup. Thus, considering that each event, leakage or absence of leakage, has its own acoustic characteristics, it becomes possible to classify and identify them through the system's sound behavior.

In order to make the identification, two machine learning algorithms were proposed: the Multi-Layer Perceptron (MLP) and the Kohonen neural network. They were

independently analyzed for the ability to identify leaks in occurrence, characterize the leak size and whether they can locate it in the pipeline.

2. Material and Methods

The data acquisition apparatus consisted of two acoustic sensors coupled to the pipeline (microphone 1 and microphone 2), a preamplifier, an analog-to-digital converter (National Instruments, NI cDAQ-9178) and a computer for storing the data. A recommended book on data acquisition and signal processing is (Drongelen, 2007).

The acoustic data were studied in the frequency domain calculated by Fast Fourier Transform (FFT). However, to reduce computational efforts in the system identification process, data compression was performed by Principal Components Analysis (PCA). As reported by Fernandes et al. (2016), PCA can be used for dimensional data compression preserving more than 97% of the original information.

Thus, the two proposed algorithms are evaluated in relation to their ability to identify the system. Neural networks have the ability to learn and improve performance through training following their learning algorithm, which can be classified as supervised or unsupervised. The MLP algorithm belongs to the supervised class, which means that input and output data must be provided for network training. The result of this network is numeric. The fundamental theory of neural networks is found in the book (Haykin, 1994).

Meanwhile, the Kohonen algorithm belongs to the unsupervised learning algorithm class. It is a self organizing map with the ability to dimensionally organize complex data into clusters (Kohonen, 2001). During training, only input data is required. The result of this training is visualized in the form of u-matrix (unified distance matrix) normally in 2-D. The u-matrix is a map of the patterns found in the input data (Vesanto et al., 2000). In the u-matrix, Euclidian distances are represented by a color scale and patterns are mapped according to their similarities.

Finally, to test the result of both networks, a set of data not present in the training is used. The quality of the neural network is considered good if the test result coincides with the training result and corresponds to the experimental values.

2.1. Data Acquisition and Signal Processing

The parameters for data acquisition were virtually configured in the LabView software, such as the sampling frequency at 30,000 Hz. Signal processing was also performed in this software, such as the realization of the Fast Fourier Transform and the use of a digital filter (to disregard frequencies above 10,000 Hz). However, the data compression and the analysis of the machine learning algorithms were performed using Matlab software.

2.2. Experimental setup

The experimental setup used compressed air as the fluid for the leak simulations. The pipeline was made of copper ½ inch in diameter. In all, it was 53 meters long and comprised thirty 90˚ elbows. For the simulations of the leaks, seven holes were drilled in different positions along the pipeline, they measured from 0.5 to 4 millimeter of diameter, as seen in Table 1. Also in Table 1, it is observed that ten different simulations were performed in total: three without leak, and one leakage simulation in each drilled hole. Each data acquisition lasted fifty seconds.

Table 1. Experimental Simulations, hole positions and diameters

Experiment number	Simulation	Hole name	Distance to gas inlet (m)	Hole diameter (mm)
1	No leakage; “nl”	-	-	-
2	No leakage, beats in the gas cylinder; “sc”	-	-	-
3	No leakage, beats in the pipeline; “sp”	-	-	-
4	Leakage in orifice 1	F1	0.2	1.0
5	Leakage in orifice 2	F2	1.0	0.5
6	Leakage in orifice 3	F3	1.6	2.0
7	Leakage in orifice 4	F4	2.4	1.0
8	Leakage in orifice 5	F5	3.4	4.0
9	Leakage in orifice 6	F6	4.8	3.0
10	Leakage in orifice 7	F7	5.6	0.5

Experiments 2 and 3 in Table 1 added sounds to the system that were not generated by leaks, but by beats in a gas cylinder and by beats in the pipeline, respectively. Microphone 1 (m1) is coupled to the pipeline at 0.1 m from the gas inlet, while microphone 2 (m2) is located at 19.2 m. Then, with the values in Table 1, m1 is closer to the holes than m2. Microphone 1 captures the sound signals of leakage within a distance of 5.5 m in all simulations. Meanwhile, microphone 2 from a distance of 13.4 m to 19 m.

2.3. Neural Networks Configurations

Both networks were tested for their ability to estimate the leakage dimension and to locate it. For the supervised network, the identification response (output) must be numeric. To identify the size of the leak, the leakage diameter in millimeters was chosen as the network response and, in situations without leakage, the output of the network would be zero, “0”. And to identify the location of the leak, the network response was chosen as “1” if the patterns belong to m1 and “2” if the patterns correspond to m2.

For the unsupervised net, a quadratic map was created and visualized as u-matrix. No output value is required for training. In both networks, the compressed frequency data (Fernandes et al., 2016) were used as input for training and testing.

3. Results

Both microphones were in range of distance capable of capturing the acoustic changes in the system in all experimental simulations. The sound response was evaluated in the frequency domain and compressed in terms of principal components. From the experimental observations points, 1,000 points were used to train the networks and 46, to test.

The results of the supervised network training is shown in Figure 1. The identification of the leakage diameter is seen to the left (A) and the identification of the microphone to the right in (B).

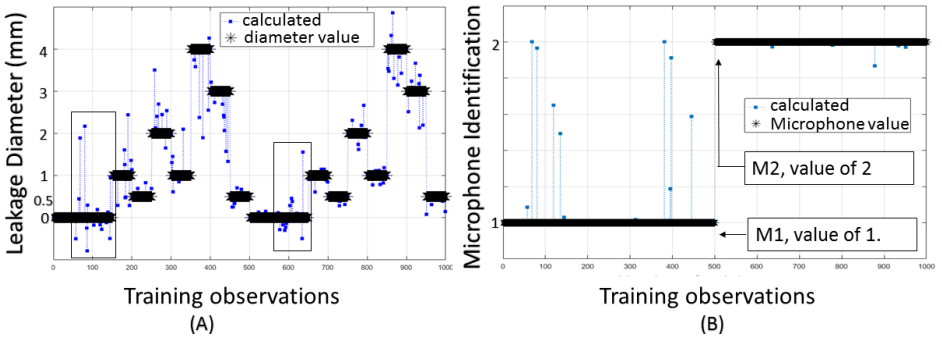

Figure 1. Values calculated by the supervised network and the observations used to train the network. (A) Leakage diameter value; (B) Microphone value

In Figure 1 (A), it is possible to notice that a large part of the calculated values are close to the diameter value. However, uncertainty specially around the value of zero does not facilitate the evaluation of events without leakage, situations in evidence by rectangles. Figure 1 (B) represents the identification of the microphone that is capturing the signal. If the distance of the captured signal to the leak hole is within a range of approximately 5.5 m, the network must recognize the first microphone, m1. If it is farther away- within 13.4 m to 19 m- it must recognize microphone 2. Figure 1 (B) showed good agreement for most of the calculated and expected values.

The results of the supervised network test are shown in Figure 2. In Figure 2 (A), two situations were used for test: observations with pipe strikes and leakage in F1, but different from those used in the network training. The expected results for these situations were zero "0" (no leakage) and one "1" (leakage diameter of 1 mm), respectively. However, in the situation without leakage, in evidence by rectangle, the calculated values are not consistent and vary from zero. Still in Figure 2 (A), for the test with the leak situation of 1 mm diameter, the network responses are approximately "1", as expected.

The represented test in Figure 2 (B) showed good results, the calculated values matched the expected values. For test observations captured by microphone 2, the value "2" was correctly calculated by the network. And, by microphone 1, the value "1", as expected.

Alternatively, Figure 3 represents the results of the unsupervised network. It represents the u-matrix resulting from the mapping of the patterns found in the frequency data.

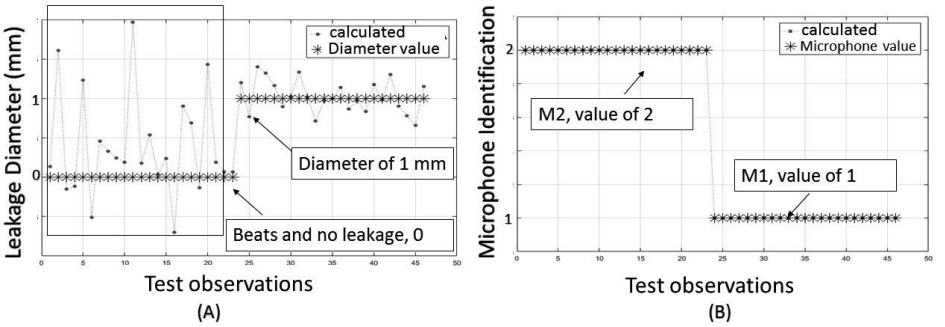

Figure 2. Values calculated by the supervised network and the observations used to test the network. (A) Leakage diameter value; (B) Microphone value

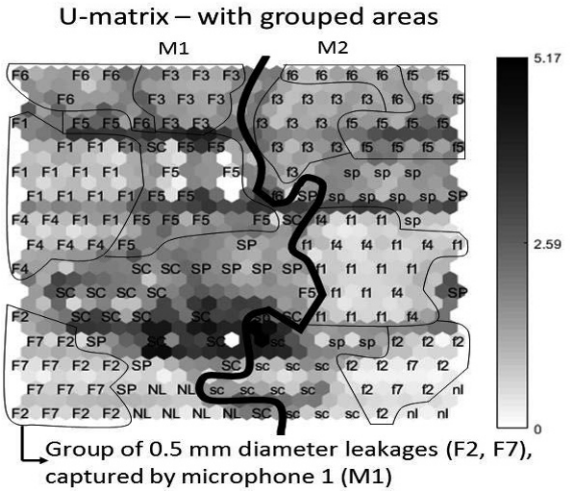

Figure 3. The self organizing map in u-matrix

In the resulting self-organized map in Figure 3, the areas corresponding to a given pattern are exposed and grouped according to their similarities. As in emphasis in Figure 3, in the same group there are "F2" and "F7" meaning areas activated by leakages of 0.5 mm. The same happens with "F1" and "F4", leaks of 1 mm. In addition, capital letters indicate that the signals come from microphone 1, they are seen mostly on the left side of the map. In contrast, lowercase letters indicate that they are from microphone 2 and are seen mostly on the right side of the map. The ticker line divides these two sides.

The simulations without leaks, with and without beating simulations, were not attributed to any explicit group, but are indicated in the map by "nl", "sc" and "sp", as in Table 1.

Then, examining Figure 3, the map created by the Kohonen algorithm can differentiate characteristics of different diameters and different distances between the source of leakage and the microphone.

The same test performed in the supervised network was repeated to the unsupervised one. In Figure 4, the self-organizing map is shown containing circles in the areas corresponding to the closest patterns found in test data. In Figure 4 (A), the test data used corresponds to observations with strikes in the pipeline. As a result, twelve areas were circled accused of having a pattern close to this tested data: six of strikes in pipeline ("sp"), three of absence of leakage ("nl"), one is not representing any feature, one with 1 mm ("f1") and one with 0.5 mm ("F2") leakage. The last two were mistakenly activated, but most of the activated areas are correctly informing that no leakage is occurring.

Figure 4 (B) depicts the second data test considering only 1 mm leakage acquired by microphone 2, m2. All the activated areas were circled. A total of 14 areas were activated: almost all are representing "f4" or "f1"- leakages of 1 mm. It is therefore correctly stating that the mapped pattern most similar to the test data is a 1 mm diameter leak. In addition, it is noted that these circled areas are on the right side of the map, also verifying that the test data have characteristics close to the data captured by m2.

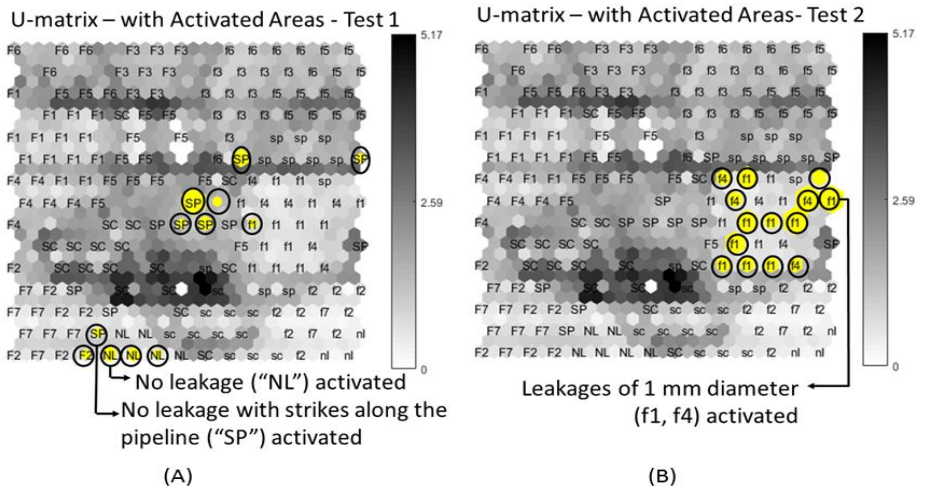

Figure 4. Self-organized map with test results in u-matrix, areas with patterns similar to test data are circled. Test data with (A) beats in the pipeline (B) 1 mm leakage

4. Conclusions

The proposed algorithms were able to identify leaks and characterize it. They also distinguished signals from one microphone to another, proving that the algorithms were able to differentiate characteristics in the signal caused by different distances from the leakage to the acoustic sensor. However, the unsupervised map was more accurate and has the advantage of not needing a numeric output to train. In the generated map, areas of similar events can be grouped and will be activated by test observations that contain characteristics similar to that group.

To identify situations without leakage but with beats in the simulation, the supervised net provided an uncertain response. On the contrary, the same test was performed on the unsupervised map, and the identification that it was an event without leakage was more accurate.

Then, it can be concluded that the signal processing performed in this work as well as the networks used to identify the system were successful in the identification. However, the unsupervised algorithm was found to be a more adequate choice.

Abstract

The paper deals with the optimal operation of processes that are composed by continuous and batch units tightly integrated by means of mass or energy flows. It uses as a reference process a benchmark developed in the EU project HYCON2: a simplified crystallization section of a sugar factory. The aim is to present a novel formulation that allows the coordination of the continuous and discrete processes generating feasible crystallizer schedules that can be easily integrated in a wider optimization scheme. The approach uses formal scheduling methods on continuous time to deal with the shared resources integrating the continuous dynamics.

Keywords: Real-time optimization, process scheduling, integration MPC-scheduling, distributed optimization, sugar crystallizers.

1. Introduction

Decisions about global production and plant–wide operation are increasingly being considered as highly relevant in the decision hierarchy of a factory. Nevertheless, the well-known control pyramid does not fit very well with the reality when the production process includes a combination of continuous and batch processes. In this case, the usual static models and non-linear programming tools of the RTO layer are useless due to the dynamic and discontinuous nature of the problems, which require coordination and scheduling of the operations over time in order to avoid creating bottlenecks, violating constraints or risking the safe operation of the plant.

The problems become much more complex due to their dynamic and discontinuous nature, which leads to large-scale mix-integer optimization problems that must be solved with sensible computing times in order to allow for real-time implementation. The subject is receiving increased attention, not only because of its importance, but also due to the opportunities opened by the integration of different decision layers and the use of improved optimization methods and tools, Harjunkoski, et al. (2014), Nie et al. (2015).

This paper intends to contribute to the advances in the field studying the special plant wide optimization problems that results when continuous plants must operate together with batch ones in series interchanging materials and energy and sharing resources, and presents a novel and efficient formulation of the scheduling problem combining continuous and discrete time domains. The approach is illustrated with an example taken from the sugar industry organized around the interface of the sections of evaporation and crystallization.

The paper is organized as follows: after the introduction, section 2 shows the case study that has been used to illustrate the approach. Then, section 3 describes the formulation of the scheduling problem and, finally, section 4 provides results corresponding to a test on the case study. The paper ends with some conclusions and references.

2. Sugar factory case study

In this section we consider a benchmark problem that was designed to experiment with plant-wide control and optimization strategies. It corresponds to a process of the sugar industry that combines units of continuous and semi-batch type, so that its operation and control requires taking into account continuous and discrete decisions. The model was proposed as a benchmark in the FP7, EU Network of Excellence "Highly-complex and Networked Control Systems" (HYCON2) and it is represented in the Figure 1.

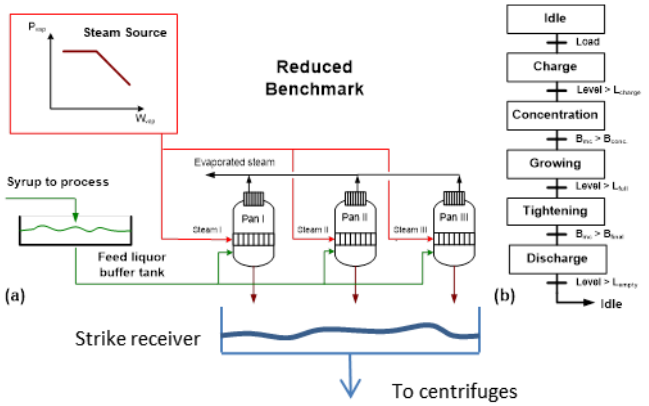

Figure 1. Schematic of the benchmark problem with two buffer tanks and three vacuum pans for sugar crystallization

It incorporates a buffer tank for supplying syrup to three semi-batch crystallizers that can operate in parallel following a certain recipe to produce sugar crystals. The operation in the crystallizers, also called "tachas" or vacuum pans, follows a cycle with several stages as in Figure 1(b), and uses steam from the evaporation section and syrup from the tank, which are shared resources. When the crystals reach the required size and the crystallizer is full, the strike ends and the resulting massecuite is discharged to the strike receiver tank. The target is to schedule the crystallizers optimally respecting the constraints in the shared resources: total amount of steam and level in the tanks, in spite of changes in the supply syrup.

3. Scheduling and coordination of the batch and continuous units

The joint operation of the crystallizers and the supply and strike receiver tanks can be formulated as a scheduling problem where one has to decide on the starting times of the crystallizers over time while maintaining the shared resources (syrup in the supply tank, massecuite in the strike receiver tank and total steam demand from the crystallizers) within admissible ranges at all times.

The approach we present in this paper to formulate the scheduling problem looks for computational efficiency in order to be applied in real-time, and enough flexibility as to

be adapted to the real process in a sensible way. This requires a linear mix-integer formulation in spite of the presence of clear non-linear profiles of many variables as well as large horizons that must cover at least a factory shift. With these aims in mind, the formulation of the problem combines three elements:

- An assignment problem, described in continuous time, to compute the scheduling of the crystallizers.
- A description of the non-linear profiles of the variables associated to the operation of the crystallizers in terms of a set of local linear approximations.
- A description of the dynamic constraints imposed by the shared resources using a discrete time grid synchronized with the continuous one.

The reason it uses two base times is linked to the fact that assignments in continuous time provide information only on the start and end times of each batch unit, but some shared continuous variables needs to check the fulfilment of its associated constraints at regular and more frequent time intervals.

Each crystallizer will process a certain number of batches of syrup from the supply tank. We will denote by I a set of indexes i, each one representing a batch or processed syrup lot. In the same way, we will denote by M the set of crystallizers m. The continuous inflow of syrup to the supply tank can be considered as composed of a series of syrup lots arriving to the tank to be processed later on. The size of each lot is equal to the amount of syrup consumed by a crystallizer for a whole batch. Depending of the characteristics of the syrup, we can associate to each lot a processing time or duration in the crystallizer that can be different in each crystallizer and that will be denoted as p(i,m). In parallel, we can assign a cost associated to the processing of a syrup lot i in a crystallizer m, denoted by c(i,m). In addition, the scheduling problem uses the following continuous time variables:
ts(i) denotes the start time of lot number i (continuous variable)
te(i) denotes the earliest time in which lot i can be processed
td(i) denotes the latest time in which lot number i should have been processed

Note that te and td are known parameters at time zero, when the scheduling problem has to be solved over the prediction horizon. For all lots present in the supply tank according to its capacity, te will be zero, as they can be processed in parallel, while the rest will have different values of te according to their expected arrival times. As well, two binary variables are defined following a general precedence approach:
y(i,m) will be equal to 1 if lot i is processed in crystallizer m and o otherwise
z(i, j) will be equal to 1 if lot i precedes lot j on the same crystallizer and zero otherwise

Then, the optimal allocation of lots and its sequencing within each crystallizer can be formulated easily if we select as optimality criterion to minimize the overall costs by means of equations (1). Here the first equation guarantees that only cost of each effective assignment is counted in the cost function. The first two sets of constraints assure that a lot I will not be assigned before the time te(i) and will be processed before the time td(i). The following equation guarantees that each lot will be processed in a crystallizer and only in one of them. Next equation serves to limit the number of lots that can be assigned to a single crystallizer. Finally, the first of the two final equations assures that if two lots, i and j, are assigned to the same crystallizer m, then either i precedes j or j precedes i. Then, the last equation stablish that if i precedes j on

crystallizer m, the start time ts of j cannot be earlier than the start time of I plus its processing time.

$$
\begin{aligned}
&\min_{y,tz} \sum_{i\in I}\sum_{m\in M} c(i,m)\,y(i.m) \\
&s.t. \quad ts(i) \geq te(i) \\
&\qquad ts(i) \leq td(i) - \sum_{m\in M} p(i,m)\,y(i,m) \quad \forall i \in I \\
&\qquad \sum_{m\in M} y(i,m) = 1 \quad \forall i \in I \\
&\qquad \sum_{i\in I} y(i,m)\,p(i,m) \leq max_i\{td(i)\} - min_i\{te(i)\} \quad \forall m \in M \\
&\qquad 1 \geq z(i,j) + z(j,i) \geq y(i,m) + y(j,m) - 1 \quad \forall i,j \in I,\ i > j,\ m \in M \\
&\qquad ts(j) \geq ts(i) + \sum_{m\in M} p(i,m)\,y(i,m) - M(1 - z(i.j)) \quad \forall i,j \in I,\ i \neq j
\end{aligned}
\tag{1}
$$

The above formulation can be used for assignment but it does not consider neither the constraints associated to the shared resources (syrup, steam and massecuite) nor the ones of the continuous elements (supply tank and strike receiver). Because of that, it needs to be expanded, first with a representation of the time evolution of flows associated to the shared resources and, then with the corresponding level or range constraints.

For the representation of the profile of the demand of syrup made from a crystallizer over time, as well as for the demand of steam and the discharge flow of a crystallizer, we define a set of time points tp(n) covering from $-t_N$ to t_N and approximate the continuous profile by a series of linear segments, each one with an associate binary variable w, as in Figure 2. Outside the range of the operation, the profile is fixed to zero.

This non-uniform discrete time base is linked to each batch and needs to be synchronized with the overall time scale. Also notice that the times ts(i) are only a relatively small number and likely not equally spaced over time, so that they are not adequate to check if a variable like the level in a tank is within the desired range. For these reasons, we need to define a third time base that consists of a larger set of time points t(k) equally distributed over the future horizon.

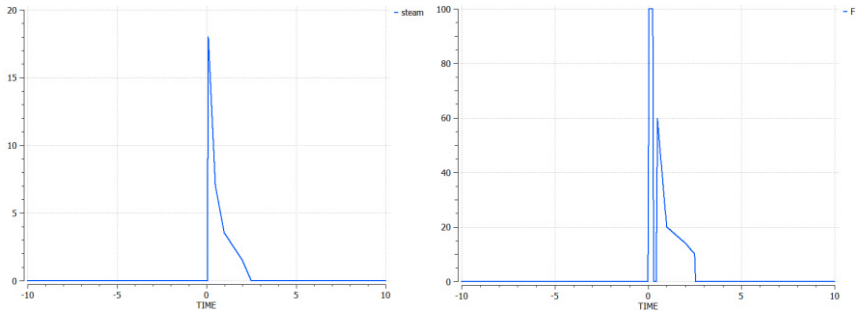

Figure 2. Profiles of the steam flow (left) and syrup demand (right) over the operation of a crystallizer approximated by piecewise linear segments at different time points tp(n)

For the synchronization of the different times, the following variables have been defined:
w(k,i,n) is a binary variable equal to 1 if the time instant t(k) – ts(i) belongs to the interval n of the corresponding profile and 0 otherwise.
α(k,i,n) is a coefficient between cero and one used for linear interpolation in the n piecewise profiles for each time instant t(k) and each crystallizer batch i

The following set of equations can be used then for computing the total flow of syrup Q(k), steam Qs(k) and discharge to the strike receiver Qd(k) at a given time instant t(k) by synchronizing the corresponding profiles and the start times and interpolating later on according to the particular value of the elapsed time.

$$\begin{aligned}
&\sum_n w(k,i,n) = 1 \qquad w(k,i,N) = 0 \\
&\sum_n \alpha(k,i,n) = 1 \qquad \alpha \geq 0 \\
&\alpha(k,i,n) \leq w(k,i,n-1) + w(k,i,n) \\
&t(k) - ts(i) = \sum_n \alpha(k,i,n) tp(n) \qquad \forall i \in I, \forall k \in K \\
&Q(k) = \sum_i \sum_n \alpha(k,i,n) F(i,n) \\
&Qd(k) = \sum_i \sum_n \alpha(k,i,n) Fd(n) \\
&Qs(k) = \sum_i \sum_n \alpha(k,i,n) Fs(i,n)
\end{aligned} \tag{2}$$

The first equation stablish that one and only one interval n of the profile can be active in a time instant k and a batch i. The following equations identify the interval n and the fraction of time α of the interval that corresponds to the time relative to the beginning of the batch i. The last set of equations computes the corresponding flows interpolating with that fraction α in the profiles. Notice that these can be particularized according to the characteristics of the syrup lot I being processed. Finally, once the global flows at the synchronization points k have been computed, mass balances in the tanks can be formulated and the constraints associated to levels or total steam demand are added to the model:

$$\begin{aligned}
&L(k) = L(k-1) + (q(k) - Q(k))\Delta t / A_t \\
&Lm(k) = Lm(k-1) + (Qd(k) - qc(k))\Delta t / A_m \\
&L_{max} \geq L(k) \geq L_{min} \qquad \forall k \in K \\
&Lm_{max} \geq Lm(k) \geq Lm_{min} \\
&Qs_{max} \geq Qs(k) \geq Qs_{min}
\end{aligned} \tag{3}$$

Here L(k) stands for the level of syrup in the supply tank, Lm for the corresponding level in the strike receiver, q(k) represents the incoming syrup flow to the tank and qc(k) the centrifuges demand to the strike receiver.

The resulting problem is a MILP one that can be solved with the appropriate algorithms, CPLEX in our case in 0.06 s. in the considered case study that involves 3252 equations 4439 variables, 2170 of them binaries.

4. Scheduling

The above approach has been tested in the case study using a variable syrup inflow to the supply tank as given in Figure 3 (left), which presents a strong increment after two hours and another decrement after five hours of operation. The capacity of the syrup tank is 77 m^3 and the one of the strike receiver 90 m^3. The level is constrained to operate in a range [10% , 90%] and the total maximum demand of steam is limited to 27 t/h. The problem considers six future lots and assumes that crystallizer 1 has started its operation one hour before the current time. Results of the corresponding scheduling can be seen also in Figure 3 (right) where the starting times of each batch of every crystallizer are also shown.

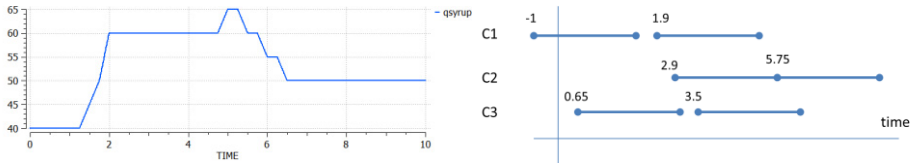

Figure 3. Time evolution of the incoming syrup to the supply tank in m^3/h

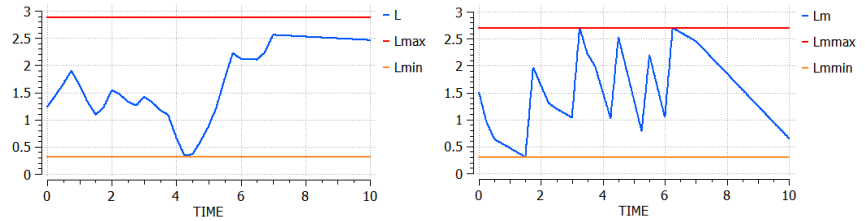

Figure 4. Time evolution of the levels in the supply tank (left) and strike receiver (right) with the corresponding upper and lower limits.

In the same way, Figure 4 shows the time evolution of the levels that are maintain within their allowed ranges in spite of the strong changes in the supply flow.

5. Conclusions

A formulation for a challenging problem involving the joint operation of continuous and batch processes have been presented. The approach uses MILP to obtain optimal schedules, providing solutions in 0.06 sec. using CPLEX and can be integrated in a predictive optimization environment.

Abstract

A continuous rotary tablet press is a multi-stage process with many punch stations running in parallel, in which each punch undergoes the following steps: die filling and metering, pre-compaction, main-compaction, tablet ejection, and tablet take-off from lower punch. Process uncertainties or disturbances within a punch station or among stations in the tablet press are a major source of variation in final product quality attributes, e.g., hardness, weight, etc., which in turn imposes challenges for the real-time release in pharmaceutical continuous manufacturing of solid dosage. In this study, the direct compression line at Purdue University was investigated and a Natoli BLP-16 tablet press was used to characterize powder compressibility, system dynamics and variation, as well as the interaction effects on process control development. The compressibility of tablets made from a blend of Acetaminophen (API), Avicel Microcrystalline Cellulose PH-200 (excipient), and SiO_2 (lubricant) was found to be largely independent of tableting speed. By contrast, filling depth or dosing level, turret speed, feed-frame speed, and compression force were interacting and significantly affected the die-filling process and the final product quality attributes. Thus, the design of the process control structure plays an important role in reducing process and product quality variations. A hierarchical three-level control design was proposed and evaluated, consisting of Level 0 Natoli built-in control, Level 1 decoupled Proportional Integral Derivative (PID) cascaded control loops for tablet weight and production rate control, and Level 2 advanced model predictive control. Process variations, e.g., in powder bulk density changes, during continuous steady-state operation were also investigated. Finally, a risk analysis of the effects of the process dynamics on variation on the product quality control was briefly discussed and summarized.

Keywords: continuous manufacturing; tablet press; process control; risk analysis.

1. Introduction

A real-time release strategy is essential to the pharmaceutical manufacturing industry as it shifts from batch to continuous processing. Such a strategy requires effective on-line process monitoring and control of pharmaceutical critical process parameters (CPPs) and critical quality attributes (CQAs) so as to achieve steady-state and consistent production of pharmaceutical ingredients, intermediates, or final products. Systematic frameworks for the development and implementation of process monitoring and control

strategies in pharmaceutical continuous manufacturing have been extensively discussed in the past decade (Singh et al., 2014); however, reports of practical and thorough studies of the implementation and evaluation of monitoring and control systems in a physical pilot plant or manufacturing facility are still limited in the open literature. Specifically, the dynamic performance and risk analysis of the continuous manufacturing process in a control closed-loop operation are rarely reported (Bhaskar et al., 2017). In this study, our particular interest was focused on the control performance of a continuous rotary tablet press in the Purdue University pharmaceutical continuous manufacturing pilot plant. The continuous rotary tablet press is a multi-stage process, in which each station undergoes the following major steps: die filling and metering, pre-compaction, main-compaction, tablet ejection, and tablet take-off from lower punch. Process uncertainties or disturbances within a punch station or among stations in the tablet press are a major source of variation in final product quality attributes, e.g., hardness, weight, etc., which in turn challenges the real-time release decisions in continuous manufacturing of solid dosage. The Natoli BLP-16 tablet press was investigated within the direct compression line to characterize powder compressibility, system dynamics and variation, as well as their effects on process control development.

2. Process variation and characterization

The challenges of maintaining consistent product quality in the output of a tablet press are to identify the appropriate CQA and CPP variables, and to understand the effect of their variations on the target product profiles (TPPs). These critical-to-quality variables for the given system were identified as tablet weight, relative density, strength (hardness) and compaction force. For example, the weight of the tablet ultimately determines the API potency within a dose. Further, it also determines the main compression force at the set punch displacement and thus the relative density and tensile strength of the tablet, which in turn affect the final product attributes such as dissolution rate. Inline process characterization of the output of the tablet press was conducted using the Sotax AT4 automatic tablet testing system for a powder formulation of 10% Acetaminophen (API), 89.8% Avicel Microcrystalline Cellulose PH-200 (excipient) and 0.2% of SiO_2 (lubricant) by mass.

Tablet weight is the desired outcome of the die filling station, whose variation could be due to the changes in powder flowability and die filling time. It was found that powder bulk density is responsive to the variations in blend composition, moisture content, and temperature, which also result in variation in its flowability. Hence, the tablet weight variation was characterized by the following equation,

$$W_t = \tilde{\rho}_b \frac{\pi D^2}{4} DP(1 - cTS) \tag{1}$$

where W_t is the tablet weight, $\tilde{\rho}_b$ is the powder bulk density, D is the diameter of the die, DP is the dosing position, TS is the turret speed, and c is an efficiency parameter of powder flowing into the dies from the feed-frame.

Tablet relative density is the ratio of tablet bulk density to the powder true density, which can be calculated from tablet weight, as shown below and verified in Figure 1(a),

$$\rho_r = \frac{4W_t}{\pi D^2 t \rho_t} = \frac{\tilde{\rho}_b DP(1 - cTS)}{t\rho_t} \tag{2}$$

where ρ_r is the tablet relative density and t is the in-die tablet thickness and ρ_t is the known powder true density.

Tensile strength is a measure of tablet hardness which is independent of tablet dimensions. It can either be measured using a destructive test which fractures the tablets in between two platens (e.g., Brazilian test) or it can be estimated using the Leunberger equation (Kuentz and Leunberger, 2000), as described below,

$$\sigma_{t,m} = \frac{2F}{\pi D \bar{t}} \tag{3}$$

$$\sigma_{t,p} = \sigma_{max}\left[1 - \left(\frac{1-\rho_r}{1-\rho_{c,\sigma}}\right)\mathrm{e}^{(\rho_r - \rho_{c,\sigma})}\right] \tag{4}$$

where $\sigma_{t,m}$ is the tensile strength measured from the Brazilian test, $\bar{t}$ is the out-of-die tablet thickness, and F is the breaking force. $\sigma_{t,p}$ is the predicted tensile strength from the tablet relative density as in Eq. (2), $\rho_{c,\sigma}$ is the critical density of strength, and σ_{max} is the tensile strength at full density, i.e., at $\rho_r = 1$.

Powder compressibility is characterized by the relationship between main compression force CF during compaction and the resulting tablet relative density ρ_r. It is one of the critical material attributes (CMAs) that affect consistent tablet manufacturing. There are many models characterizing the compressibility of a powder at various degrees of compression. In this study, the Heckel relationship was employed to characterize the main compression force at high tablet relative density, as given below and verified in Figure 1(b),

$$\frac{CF}{1-\frac{\rho_c}{\rho_r}} = \frac{CF}{a} + \pi\frac{\frac{D^2}{4}}{ab} \tag{5}$$

where ρ_c is the critical density during compaction, parameters a and b are interpreted as the maximum degree of compression and the reciprocal of the pressure applied to attain the maximum degree of compression, respectively.

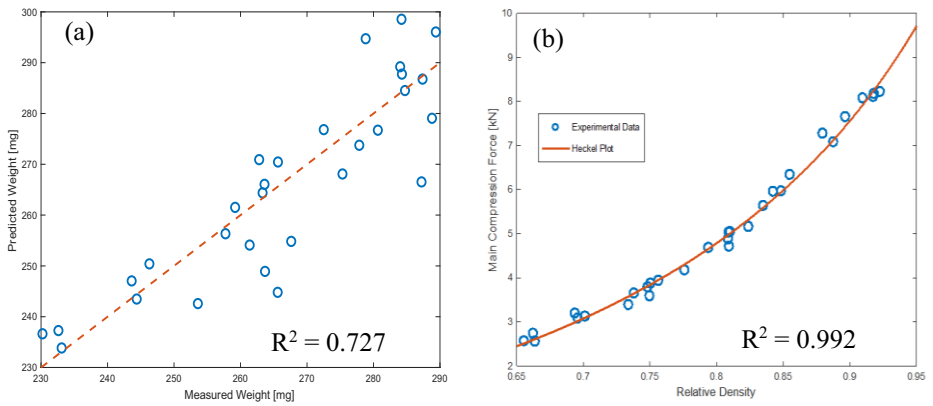

Figure 1. Comparisons between predicted and measured tablet weight (left) and main compression force (right).

3. A hierarchical control development
