A parametric analysis was performed on Minitab, applying the Poisson process model to calculate the MTBF and failure rate (see Table 4). Knowing these parameters is extremely important to optimize and improve maintenance operations, since it is an important indicator of the expected performance of the equipment.

Table 4 – Estimated parameters (A2)

Parameter	Estimate	Lower (95%CI)	Upper (95%CI)
MTBF (days)	25.29	19.94	32.08
λ (failures/day)	0.03953	0.03117	0.05014

Conclusions

Although the data was collected from two gas chromatographs with the same brand and model, they analyze distinct materials, which incur different factors of aggression to the equipment, requiring different maintenance planning in order to improve the performance of the analyzers. Thus two reliability analyses were carried out as a guide to maintenance planning and indeed reflected different failure process behaviors, A1 as a NHPP and A2 as a HPP. It is of upmost importance make these analyses a part of the planning management routine in order to try to control the deterioration process that leads to failures, as well as to identify future changes in the behavior patterns of the systems and uphold the consonance of the reliability analysis with maintenance management.

Abstract

In this work, a new multistage batch plant lot-sizing and scheduling formulation considering mixing and splitting operations at shared intermediate storage vessels is presented. The model relies on a batch-oriented general precedence representation that handles not only sequencing decisions at processing units but also intermediate storage time and capacity constraints. The proposed representation requires a predefined set of proposed batches for each product and processing stage. From these sets, selected batches are determined by the model through binary decisions. Batch integrity is not preserved but, instead, batches can be mixed/split between consecutive stages. The model includes allocation, timing, and sequencing variables and constraints similar to previous general precedence formulations. New binary variables are only added to handle material storage and transfer decisions, where both direct transfer and transfer through multiple storage vessels is supported. Besides, the general precedence sequencing binary variables are reutilized to also handle sequencing constraints at intermediate tanks. Time and capacity constraints for intermediate vessels are defined using the sequencing and material transfer binary decisions. Small/medium size examples are presented to illustrate the application of the model.

Keywords: Batch scheduling, Lot-sizing, Intermediate storage, Mixing and splitting, MILP optimization.

1. Introduction

Scheduling plays a fundamental role in most manufacturing industries. Scheduling problems can be broadly classified in 1) sequential and 2) network processes, the latter more complex and with arbitrary topologies which allow mixing and splitting operations and even material recycle (Méndez et al., 2006). In sequential processes, with multiple consecutive stages, batches are usually preserved throughout the processing sequence. Thus, sequential methods decomposing the general problem into the lot-sizing (or batching) subproblem and the batch scheduling subproblem itself have been applied. However, when operating multistage facilities where equipment units differ in capacity or processing rate, it may be convenient to mix or split the batches to attain a better use of the resources. While monolithic methodologies (integrating batching and scheduling subproblems) have been applied to sequential processes using continuous times representations (Sundaramoorthy and Maravelias, 2008; Marchetti and Cerdá, 2012), they always assume the same batch size at every stage. In this work, the general scenario of allowing multiple batches of the same intermediate product to be

mixed at a given vessel and split among different batches to be processed in the next stage is considered. The appropriate representation of intermediate storage vessels, including storage capacity and time constraints, is critical to handle mixing and splitting operations. Shared vessels requiring sequence dependent cleaning times are considered. Additional problem characteristics include: (a) multiple orders per product with different due dates, (b) variable processing times, (c) waiting times at units, (d) direct transfer of material between consecutive stages, (e) plant topology constraints.

2. Problem Statement

In this work, the unified batching and scheduling problem for multistage facilities considering limited shared intermediate storage and mixing/splitting operations is tackled. Given are: (a) the processing stages $s \in S$ of the plant, equipped with parallel units $j \in J_s$ and storage vessels $k \in K_s$, (b) the capacity of equipment/tanks and topology limitations, (c) the required products $i \in I$, together with their due date $d \in D_i$ and demands r_{id}, (d) the set $J_{is} \subseteq J_s$ of units available for processing product $i \in I$, together with the minimum batch size, the processing time parameters, and the maximum waiting time ($wt_{ij}^{\max}$) of a batch of product i in unit j, (e) the set $K_{is} \subseteq K_s$ of tanks available to store product i between stages s and s+1, together with the minimum and maximum storage times ($rt_{ik}^{\min}$, $rt_{ik}^{\max}$), (f) the sequence-dependent changeover/cleaning times $\tau_{ii'j}/\sigma_{ii'k}$, and (g) the length of the time horizon H. The problem goal is to determine: (i) the number and size of batches to be processed, (ii) the unit and storage allocation decisions, (iii) the processing sequence at each unit and tank, and (iv) the starting and completion times of each processing task, such that production orders and operational/storage constraints are all satisfied at minimum total tardiness or makespan.

We assume that a batch can be transferred to one or more tanks, but just a single transfer operation for each batch-tank pair is allowed. Also, transfer times are negligible, and loading and unloading operations do not overlap. The storage time available when batches are mixed is limited to the lowest remaining storage time of the parts. Moreover, there is unlimited storage capacity at the last stage and enough capacity of additional resources at every stage.

3. Mathematical Model

The detailed lot-sizing and scheduling mixed-integer linear programming (MILP) model of Marchetti et al. (2012) is used as a basis for the proposed approach. Please refer to this work for details of the model and the precedence based representation used.

3.1. Proposed batches for each processing stage

A set of tentative batches B_{is} is proposed for each product i and processing stage s. The set size, $n_{is} = |B_{is}|$, is chosen large enough to guarantee the optimality of the best solution found. We first consider the last processing stage (s^{ℓ}), where the approach of Marchetti et al. (2012) is used. At this stage, a set of batches B_{id}^{ℓ} is proposed for each production order (i, d). Batches $b \in B_{id}^{\ell}$ can be used not only to fulfil order (i, d) but also, if they are large enough, to meet future ones. In contrast, a different set of batches is used for each intermediate stage $s \in S' = S - \{s^{\ell}\}$. In this case, the parameter n_{is} is defined by Eq. (1) based on the overall demand of product i, $R_i = \sum_{d \in D_i} r_{id}$.

$$n_{is} = \lceil R_i / bs_{is} \rceil \qquad \forall i \in I, s \in S' \tag{1}$$

3.2. Storage allocation

The binary variable Y_{bk}^{S} is introduced to denote the allocation of batch b to storage tank $k \in K_{is}$. Using this variable, Eq. (2) is required in the general case where each batch can be stored in multiple tanks. The binary variable SEL_b represents the selection of batch b.

$$Y_{bk}^{S} \le SEL_b \qquad \forall k \in K_{is}, b \in B_{is}, i \in I, s \in S' \tag{2}$$

3.3. Material transfer representation

Transfer operations are determined using binary variables $V_{bb'}$ and $W_{bb'k}$. These variables represent the direct transfer between units (when $V_{bb'} = 1$) and the transfer through storage vessel k (when $W_{bb'k} = 1$) of intermediate product from batch b to batch b'. Non-negative continuous variables $\beta_{bb'}$ and $\eta_{bb'k}$ account for the volumes being transferred in each case. Appropriate upper-bound constraints are also included to guarantee that $\beta_{bb'}$ and $\eta_{bb'k}$ are zero whenever $V_{bb'}$ and $W_{bb'k}$, respectively, are not selected. Provided that BS_b is the batch size, using these variables the required material balance equations are:

$$BS_b = \sum_{b' \in B_{i(s+1)}} \left(\beta_{bb'} + \sum_{k \in K_{is}} \eta_{bb'k} \right) \qquad \forall b \in B_{is}, i \in I, s \in S' \tag{3}$$

$$BS_{b'} = \sum_{b \in B_{is}} \left(\beta_{bb'} + \sum_{k \in K_{is}} \eta_{bb'k} \right) \qquad \forall b' \in B_{i(s+1)}, i \in I, s \in S' \tag{4}$$

Also, specific constraints are included to guarantee that $V_{bb'}$ and $W_{bb'k}$ are zero whenever batches b, b' are not selected. The same to ensure that $W_{bb'k}$ is zero when $Y_{bk}^{S} = 0$. Since either direct transfer or transfer through a storage tank can be selected, the following constraint is needed:

$$V_{bb'} + W_{bb'k} \le SEL_{b'} \qquad \forall b \in B_{is}, b' \in B_{i(s+1)}, k \in K_{is}, i \in I, s \in S' \tag{5}$$

3.4. Intermediate storage time constraints

Timing constraints for transfer operations are considered next. On the one hand, if some portion of batch b at stage s is directly transferred to batch b' at stage s+1 ($V_{bb'} = 1$), then b' should start anytime between CT_{bs} and $CT_{bs} + WT_{bs}$, where WT_{bs} is the associated waiting time at the unit.

$$\left.\begin{aligned} CT_{bs} - H\left(1 - V_{bb'}\right) &\le ST_{b'(s+1)} \\ ST_{b'(s+1)} &\le CT_{bs} + WT_{bs} + H\left(1 - V_{bb'}\right) \end{aligned}\right\} \quad \forall b \in B_{is}, b' \in B_{i(s+1)}, i \in I, s \in S' \tag{6}$$

On the other hand, in order to receive intermediate product from batch b stored at vessel k, each selected batch $b' \in B_{i(s+1)}$ should start anytime between $CT_{bs} + T_{bk}^{W}$ and $CT_{bs} + T_{bk}^{W} + T_{bk}^{S}$. The continuous variables T_{bk}^{W} and T_{bk}^{S} are the waiting time before and the storage time after, respectively, batch b is transferred to vessel k. A combined maximum storage time including both waiting and residence times is accounted for by Eq. (8). Besides, the condition $T_{bk}^{W} \le WT_{bs}$ is required to guarantee that WT_{bs} is large enough so that every transfer takes place.

$$\left.\begin{aligned} CT_{bs} + T_{bk}^{W} - H\left(1 - W_{bb'k}\right) &\le ST_{b'(s+1)} \\ ST_{b'(s+1)} &\le CT_{bs} + T_{bk}^{W} + T_{bk}^{S} + H\left(1 - W_{bb'k}\right) \end{aligned}\right\} \quad \forall b \in B_{is}, b' \in B_{i(s+1)}, k \in K_{is}, i \in I, s \in S' \tag{7}$$

$$T^W_{bk} + T^S_{bk} \le rt^{\max}_{is}\, Y^S_{bk} \qquad \forall b \in B_{is}, k \in K_{is}, i \in I, s \in S' \tag{8}$$

In order to calculate the storage time of mixed batches, a conservative approach is taken in this contribution. As stated in Section 2, if two or more batches are mixed at a given vessel, the maximum storage time of the mixture is the minimum time still available for any of the batches. This condition is expressed by ensuring that, for any pair of batches b and b' that are mixed in vessel k, the storage interval of both finishes at the same time (i.e., $CT_{bs} + T^W_{bk} + T^S_{bk} = CT_{b's} + T^W_{b'k} + T^S_{b'k}$). To detect if batches b and b' get mixed at tank k, it is enough to check if there is any batch b'' at stage s+1 to which both b and b' transfer intermediate product. To this end, big-M constraints activated by the condition $W_{bb''k} + W_{b'b''k} = 2$ are used, for all $b'' \in B_{i(s+1)}$. Additional constraints based on sequencing and transfer decisions are included to ensure that the condition represented by Eq. (7) does not hold when material transfer is not selected.

3.5. Sequencing constraints for storage vessels

Let the binary variable $Y^U_{b'k}$ represent that product from vessel k is transferred to batch b' at the next stage (when $Y^U_{b'k} = 1$). Besides, let the continuous variable $T^U_{b'k}$ be the residence time of the material in k before it is transferred to b'. Eq. (9) guarantees that the appropriate values for $Y^U_{b'k}$ and $T^U_{b'k}$ are chosen. When both b and b' are loaded from the same vessel k (i.e., $Y^U_{bk} = 1$ and $Y^U_{b'k} = 1$) the sequencing variable $X_{bb'(s+1)}$ determines the relative ordering of the storage tasks at stage s.

$$\left.\begin{aligned} W_{bb'k} &\le Y^U_{b'k} \\ ST_{b'(s+1)} - CT_{bs} - T^W_{bk} - H\left(1 - W_{bb'k}\right) &\le T^U_{b'k} \end{aligned}\right\} \quad \forall b \in B_{is}, b' \in B_{i(s+1)}, k \in K_{is}, i \in I, s \in S' \tag{9}$$

$$\left.\begin{aligned} ST_{b(s+1)} + \sigma_{ii'k} &\le ST_{b'(s+1)} - T^U_{b'k} + H\left(3 - X_{bb'(s+1)} - Y^U_{bk} - Y^U_{b'k}\right) \\ ST_{b'(s+1)} + \sigma_{i'ik} &\le ST_{b(s+1)} - T^U_{bk} + H\left(2 + X_{bb'(s+1)} - Y^U_{bk} - Y^U_{b'k}\right) \end{aligned}\right\} \quad \begin{array}{l} \forall b \in B_{i(s+1)}, b' \in B_{i'(s+1)}, \\ k \in K_{ii's}, (i,i') \in I, s \in S' : i < i' \end{array} \tag{10}$$

3.6. Storage capacity

In order to define the storage capacity constraints, we introduce the continuous variable $L_{bb'k}$ representing the volume of batch b that remains in tank k immediately after batch b' starts at stage s+1. Different constraints are used to set the value of $L_{bb'k}$. On the one hand, constraint (11) ensures that both $\eta_{bb'k}$ and $L_{bb'k}$ are driven to zero when $W_{bb'k} = 0$. On the other hand, if $W_{bb'k} = 1$, appropriate bounds are set for the storage level variables $L_{bb'k}$ using Eqs. (12). Because of Eqs. (12), the volume of batch b that remains at tank k will decrease while it is transferred to consecutive batches, according to the order determined by the sequencing decisions at stage s+1. Moreover, the batches of $B_{i(s+1)}$ are sequenced avoiding redundant solutions (using an approach similar to constraints 11 and 12 of Marchetti and Cerdá, 2009).

$$L_{bb'k} + \eta_{bb'k} \le q^{\max}_{ik}\, W_{bb'k} \qquad \forall b \in B_{is}, b' \in B_{i(s+1)}, k \in K_{is}, i \in I, s \in S' \tag{11}$$

$$\left.\begin{aligned} L_{bb''k} + \eta_{bb''k} &\le L_{bb'k} + q^{\max}_{k}\left(2 - W_{bb'k} - X_{b'b''(s+1)}\right) \\ L_{bb'k} + \eta_{bb'k} &\le L_{bb''k} + q^{\max}_{k}\left(1 - W_{bb''k} + X_{b'b''(s+1)}\right) \end{aligned}\right\} \tag{12}$$

$$\forall b \in B_{is}, (b', b'') \in B_{i(s+1)}, k \in K_{is}, i \in I, s \in S' : \left(b' < b''\right)$$

Finally, storage capacity constraints for stage s are verified at the starting times of batches $b \in B_{i(s+1)}$ (at the next stage). Since any batch $b' \in B_{is}$ can both transfer product to b through k ($\eta_{b'bk} > 0$), or remain at tank k after batch b starts at stage s+1 ($L_{b'bk} > 0$), then the total volume stored at k before time $ST_{b(s+1)}$ is given by the LHS of Eq. (13), which is bounded by the capacity of the tank, $q_k^{\max}$.

$$\sum_{b' \in B_{is}} \left(L_{b'bk} + \eta_{b'bk} \right) \le q_k^{\max} \qquad \forall b \in B_{i(s+1)}, k \in K_{is}, i \in I, s \in S' \tag{13}$$

The application of Eqs. (11)-(13) taking into account the bounds on variables $\eta_{b',b,k}$ and $L_{b',b,k}$ is depicted in Figure 1(a). In this schedule, three batches b_1-b_3 at stage s_1 are mixed at vessel k_1 and later split among batches b_4 to b_6 of stage s_2. A more detailed inventory balance for tank k_1 is shown in Figure 1(b). It is important to remark that the solution shown in Figs. 1(a-b) is one of many alternatives to distribute the mixed volume of batches b_1-b_3 among batches b_4-b_6.

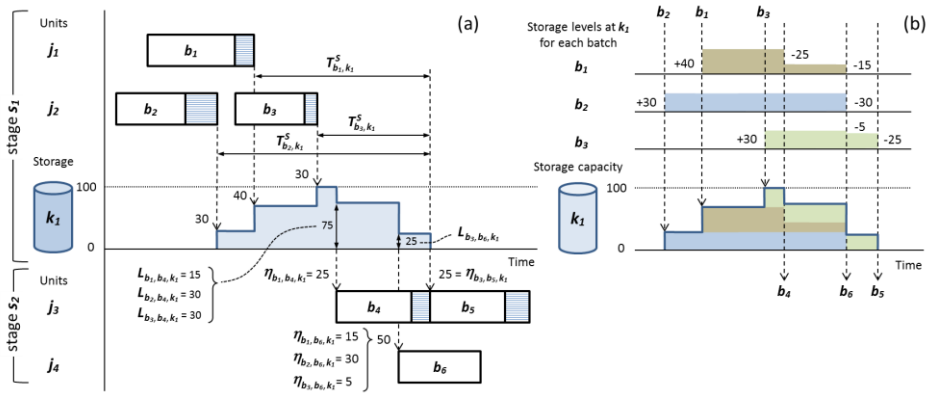

Figure 1: (a) Illustrative schedule considering multiple intermediate storage mixing and splitting operations; (b) Individual storage levels for each batch at k_1.

4. Case Studies

Both a small and a medium size example are presented to illustrate the application of the proposed model. A batch plant including two stages (S_1: mixing, S_2: reaction) with a total of 5 processing units and 2 intermediate vessels is considered. The problem goal is to minimize the overall tardiness. In example 1, two products (P_1 and P_2) are produced and a schedule for 3 orders is required. Different material handling alternatives for the intermediate products at stage S_1 are compared. Instance 1a assumes that batches are preserved between the consecutive stages and UIS is available. Instance 1b considers finite storage instead. In contrast, instance 1c includes both mixing and splitting and limited storage capacity (i.e., the proposed formulation). Finally, a medium size test case considering 3 products and 7 orders at different due dates (example 2) is solved with the proposed approach. Model size and computational results are reported in Table 1. The solution of instance 1c features the best overall tardiness of example 1. Since a more complex problem is addressed, 1c requires more computational effort than 1a and 1b. The medium size example 2 is considerably more complex than problem 1c. However, the required CPU time is still reasonable. The optimal solutions found for instance 1c and example 2 are shown in Figs. 2 and 3, respectively. Here, the relations between selected/proposed batches are 14/19 and 27/39, for each case.

Table 1. Test case statistics and computational results*

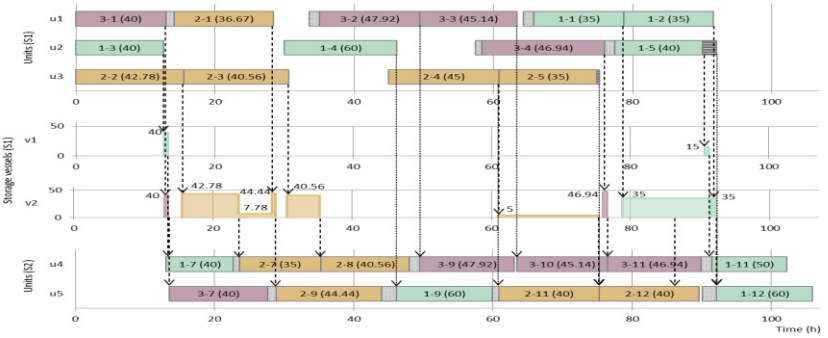

Figure 3. Optimal solution found for Example 2.

5. Conclusions

While the utilization of global-precedence sequencing decisions to set the relative ordering of processing tasks at equipment units is well known, this sequencing scheme has not been used at intermediate storage vessels to handle mixing and splitting operations before. Problems with increasing number of production orders, units or vessels are still difficult to solve. The proposed methodology bridges the gap to allow future applications of precedence-based sequencing schemes to general network-based multipurpose batch scheduling problems.

Strategic Planning of SAGD Reservoir Development under Exogenous and Endogenous Uncertainty

Farough Motamed Nasab, Hossein Shahandeh, Zukui Li*

Department of Chemical and Materials Engineering, University of Alberta, Edmonton, Alberta, T6G 1H9, Canada
zukui@ualberta.ca

Abstract

In this paper, a stochastic optimization framework for planning the development of SAGD drainage areas under uncertainty is presented. A multistage stochastic programming based optimization model is developed to arrange the multiperiod development plan of the drainage areas with consideration of reservoir production capacity and bitumen product price uncertainty. A linear decision rule based method is presented to handle the two different type of uncertainties. Results demonstrate that the method can effectively generate an economically optimal development plan that maximizes the profit under uncertainty.

Keywords: SAGD reservoir; strategic planning; endogenous and exogenous uncertainty; multistage stochastic programming; decision rule approximation

1. Introduction

Addressing uncertainty in reservoir development planning is critical since it significantly affects the economic performance of a project. Among the various sources of uncertainties, oil price and reservoir production capacity represent the major uncertain factors to be considered. In the past, stochastic programming has received lots of attention in the context of oil and gas investment and production planning under uncertainty. There are few number of publications addressing oil and gas planning problems including endogenous uncertainty. Jonsbraten (1998) discusses reservoir optimization and production uncertainty under reservoir size uncertainty and price uncertainty. Goel and Grossmann (2004) used a scenario-based and decomposing-based approximation approach for operational planning of gas field under uncertainty in gas reserves. Goel et al. (2006) discusses the problem of optimal investment and operational planning for development of gas fields under uncertainty in gas reserves and Lagrangean duality based branch and bound algorithm is used to solve the problem. Gupta and Grossmann (2014) proposed a new decomposition algorithm based on relaxation of non-anticipatively constraints that results in reduced computational expense while preserving the same optimality gap. All of the above mentioned methods required the discretization of uncertainty space which is computationally inefficient for large-scale problems. Recently Vayanos et al. (2011) proposed an algorithm for stochastic problems with endogenous uncertainty inspired by robust optimization methods that do not require discretization of uncertainty or relaxation of non-anticipativity constraints.

In this work, long term development planning of the oil sands steam assisted gravity drainage (SAGD) is addressed. The goal of this study is to maximize the net present value from the SAGD project during a long term time horizon while considering price and oil production uncertainties, capital restriction, processing capacity and steam generation limitation. We present a solution method that effectively incorporates the effect of price and oil production uncertainties. The problem is solved using linear decision rule technique.

2. Problem statement

In SAGD operations, usually several pairs of horizontal injector and producer well pairs are installed into a drainage area (DA) from a surface pad. Hot steam is injected into the upper injector well, as a result steam chamber grows and propagates into the reservoir which liquidizes the bitumen and subsequently bitumen is pumped out. The produced bitumen is processed in the central processing facility, where oil-water emulsion is separated and produced water is recycled and used for steam generation. In strategic planning of SAGD development, the development sequence and timing is optimized. In addition, the production rate plan is determined. To plan the development of the multiple drainage areas, we consider two important uncertainties: reservoir production capacity and oil price.

For reservoir production capacity uncertainty, it is assumed that for each DA, production capacity follows a uniform distribution around a nominal value. This reflects uncertainty in different reservoir geologic parameters such as porosity, permeability, saturation, etc. The uncertainty is modeled as $\tilde{q}_{i,k}^{maxoil} = q_{i,k}^{maxoil}(1+\zeta_i), \forall i \in \mathcal{I}, \forall k \in \mathcal{T}$, where $q_{i,k}^{maxoil}$ is the nominal value for oil production and $\tilde{q}_{i,k}^{maxoil}$ is the uncertain oil production capacity of i-th DA at year k. It is worth pointing out that the production capacity uncertainty is an endogenous uncertainty since it is revealed once the well is developed.

To model the oil price uncertainty, Auto Regressive Moving Average ARMA(p, q) is used: $OP_t = \{\phi_1 OP_{t-1} + \cdots + \phi_p OP_{t-p}\} + \{\epsilon_t + \theta_1 \epsilon_{t-1} + \cdots + \theta_q \epsilon_{t-q}\}$, where $\phi_1, \cdots, \phi_p, \theta_1, \cdots, \theta_q$ are model parameters that can be estimated from history data, ε_t represents uncorrelated white noise (with zero mean and constant variance). To predict the future oil price from time t+1 to t+T, we define $\epsilon = [\epsilon_{t+1}, \cdots, \epsilon_{t+T}]^T$. Then the future oil price can be compactly written as: $OP_{t+i} = A_{t+i}\epsilon + b_{t+i}, i \in \{1, \cdots, T\}$, where A_t is a vector, b_t is a scalar, both calculated using the model parameters. Oil price uncertainty is exogenous uncertainty since it is not depending on the decisions to be made.

For the stochastic planning problem, the following uncertainty set is constructed:

$$\Xi = \{\xi = [1, \zeta_1, \cdots, \zeta_N, \epsilon_1, \cdots, \epsilon_T]^T : \zeta_i \in [\underline{\zeta}_i, \overline{\zeta}_i], \forall i, \ |\epsilon_t| \le z_{1-\alpha}, \ \sum_t |\epsilon_t| \le \Gamma z_{1-\alpha}, A_t\epsilon + b_t \ge 10, \forall t\}$$

The constraints applied in the uncertainty set are explained as following: 1) For each drainage area i, $\zeta_i \in [\underline{\zeta}_i, \overline{\zeta}_i]$; 2) For oil price, the variation range of white noise is controlled by applying conditions on each ϵ_t such that $|\epsilon_t| \le z_{1-\alpha}$, with $[-z_{1-\alpha}, z_{1-\alpha}]$ being the $1-\alpha$ confidence level (CI) of ϵ_t, which follows zero mean normal distribution; 3) The total change of budget is controlled by: $\sum_t |\epsilon_t| \le \Gamma z_{1-\alpha}$, where Γ is

a scalar to control range of white noise change, t is time in project horizon; 4) Considering minimum oil price \$10/bbl: $OP_t(\xi) = A_t P\xi + b_t \geq 10, \forall t$. The above uncertainty set is a convex polyhedral, which can be compactly written as: $\Xi = \{\xi : W\xi \geq \nu\}$.

3. Multistage stochastic programming model

The proposed model aims to determine an optimal development sequence and production plan that maximizes the net present value (NPV) over a given time horizon.

$$\max \quad \sum_{t\in\mathcal{T}} \frac{1}{(1+DR)^t} \mathbb{E}\left[(1-RY)OP_t(\xi)\sum_{i\in\mathcal{I}} q_{i,t}^{oil}(\xi) - DA_{cost}\sum_{i\in\mathcal{I}} z_{i,t}(\xi) - FC\sum_{i\in\mathcal{I}}\sum_{k\in\mathcal{K}_i} z_{i,t-k+1}(\xi) q_{i,k}^{steam} N_w\right] \tag{1a}$$

$$s.t. \quad DA_{cost}\sum_{i\in\mathcal{I}} z_{i,t}(\xi) \leq CC_{DA} \qquad \forall t\in\mathcal{T}, \xi\in\Xi \tag{1b}$$

$$\sum_{t\in\mathcal{T}} z_{i,t}(\xi) \leq 1 \qquad \forall i\in\mathcal{I}, \xi\in\Xi \tag{1c}$$

$$q_{i,t}^{oil}(\xi) \leq \sum_{k\in\mathcal{K}_i} z_{i,t-k+1}(\xi)\, \tilde{q}_{i,k}^{maxoil}(\xi) N_w \qquad \forall i\in\mathcal{I}, t\in\mathcal{T}, \xi\in\Xi \tag{1d}$$

$$\sum_{i\in\mathcal{I}} q_{i,t}^{oil}(\xi) \leq Cap_{CPF} \qquad \forall i\in\mathcal{I}, \xi\in\Xi \tag{1e}$$

$$\sum_{i\in\mathcal{I}}\sum_{k\in\mathcal{K}_i} z_{i,t-k+1}(\xi)\, q_{i,k}^{steam} N_w \leq Cap_{steam} \qquad \forall t\in\mathcal{T}, \xi\in\Xi \tag{1f}$$

$$q_{i,t}^{oil}(\xi) \geq 0 \qquad \forall i\in\mathcal{I}, t\in\mathcal{T}, \xi\in\Xi \tag{1g}$$

$$x_{1,t}(\xi) = 1 \qquad \forall t\in\mathcal{T} \tag{1h}$$

$$x_{i+1,t}(\xi) = \sum_{t'\leq t} z_{i,t'}(\xi) \qquad \forall i\in\mathcal{I}, t\in\mathcal{T}, \xi\in\Xi \tag{1i}$$

$$x_{l,t}(\xi) = 0 \qquad \forall l \geq N_{DA}+3, t < l-(1+N_{DA}), \xi\in\Xi \tag{1j}$$

$$x_{l,t}(\xi) = 1 \qquad \forall l \geq N_{DA}+2, t \geq l-(1+N_{DA}), \xi\in\Xi \tag{1k}$$

$$q_{i,t}^{oil}(\xi) = q_{i,t}^{oil}(x_{t-1}(\xi)\bullet\xi) \qquad \forall i\in\mathcal{I}, t\in\mathcal{T}, \xi\in\Xi \tag{1l}$$

$$z_{i,t}(\xi)\in\{0,1\}, x_{l,t}(\xi)\in\{0,1\} \qquad \forall i\in\mathcal{I}, t\in\mathcal{T}, \xi\in\Xi \tag{1m}$$

In the above model, index *i*, *t*, *k* refer to DA number, the year within the lifetime of the project, and the year within life time of a specific DA, respectively. Furthermore, $z_{i,t}$ is a binary variable indicating whether *i*-th drainage area is developed at year *t* or not, binary variable $x_{i,t}$ denotes the information revealing status, and $q_{i,t}^{oil}(\xi)$ represents the oil production plan. Objective function (1a) is the Net Present Value (NPV) calculated based on the total annual revenue, the capital cost on DA investment, and the operating cost from steam generation which requires fuel consumption. *DR* is the discount rate and *RY* is royalty parameter. Constraints (1b) enforce capital cost of the project in each year. Constraints (1c) enforce that each DA starts only once. Constraints (1d) enforce that the oil production rate is less than the upper bound computed based on the reservoir model parameters. Constraints (1e) enforces that the total oil production at each year must be less than the central processing facility capacity. Constraints (1f) compute the

total steam requirements and enforces it is less than the steam generation capacity. Constraints (1g) enforce nonnegativity on oil production rate. Non-anticipativity is modeled through equation (1h) to (1l). Constraint (1h) is used for the trivial element 1 in the uncertain vector ξ. The logic relation between information revealing status variable x and development decision z is modeled by constraint (1i). For price uncertainty, the information revealing status variable is only dependent on the time, this is modeled by constraint (1j) and (1k). Constraint (1l) represents non-anticipativity constraints for production decision variables (it is only decided based on information revealed based on Hadamard product. In this study, linear decision rule (LDR) based counterpart model derivation is applied to the constraints. For continuous variables, the following decision rule is applied: $q_{i,t}^{oil}(\xi) = Q_{i,t}\xi,\ \forall \xi \in \Xi, \forall i \in \mathcal{I}, t \in \mathcal{T}$. The LDR based counterpart of the stochastic model is summarized below:

$$\max \sum_{t\in\mathcal{T}} \frac{1-RY}{(1+DR)^t}\{tr(P^T A_t^T \sum_{i\in\mathcal{I}} Q_{i,t}\,\mathbb{E}(\xi\xi^T)) + b_t \sum_{i\in\mathcal{I}} Q_{i,t}\mathbb{E}(\xi)\}$$

$$- \sum_{t\in\mathcal{T}} \frac{DA_{cost}}{(1+DR)^t} \sum_i z_{i,t} - \sum_{t\in\mathcal{T}} \frac{N_w FC}{(1+DR)^t} \sum_i \sum_{k\in\mathcal{K}_i} z_{i,t-k+1} q_{i,k}^{steam} \quad (2a)$$

$$s.t.\ DA_{cost} \sum_{i\in\mathcal{I}} z_{i,t} \le CC_{DA} \qquad \forall t \in \mathcal{T} \quad (2b)$$

$$\sum_{t\in\mathcal{T}} z_{i,t} \le 1 \qquad \forall i \in \mathcal{I} \quad (2c)$$

$$-\nu\Lambda_{i,t} - \sum_{k\in\mathcal{K}_i} z_{i,t-k+1}\, q_{i,k}^{maxoil} N_w \le 0 \qquad \forall i \in \mathcal{I}, t \in \mathcal{T} \quad (2d)$$

$$-W\Lambda_{i,t} = Q_{i,t} - \sum_{k\in\mathcal{K}_i} z_{i,t-k+1}\, q_{i,k}^{maxoil} N_w e_i \quad \forall i \in \mathcal{I}, t \in \mathcal{T}$$

$$\Lambda_{i,t} \ge 0 \qquad \forall i \in \mathcal{I}, t \in \mathcal{T}$$

$$-\nu\lambda_t \le Cap_{CPF} \qquad \forall t \in \mathcal{T} \quad (2e)$$

$$-W\lambda_t = \sum_{i\in\mathcal{I}} Q_{i,t} \qquad \forall t \in \mathcal{T}$$

$$\lambda_t \ge 0 \qquad \forall t \in \mathcal{T}$$

$$\sum_{i\in\mathcal{I}} \sum_{k\in\mathcal{K}_i} z_{i,t-k+1}\, q_{i,k}^{steam} N_w \le Cap_{steam} \qquad \forall t \in \mathcal{T} \quad (2f)$$

$$\nu\mu_{i,t} \ge 0 \qquad \forall i \in \mathcal{I}, t \in \mathcal{T} \quad (2g)$$

$$W\mu_{i,t} = Q_{i,t} \qquad \forall i \in \mathcal{I}, t \in \mathcal{T}$$

$$\mu_{i,t} \ge 0 \qquad \forall i \in \mathcal{I}, t \in \mathcal{T}$$

$$x_{1,t} = 1 \qquad \forall t \in \mathcal{T} \quad (2h)$$

$$x_{i+1,t} = \sum_{t'\le t} z_{i,t'} \qquad \forall i \in \mathcal{I}, t \in \mathcal{T} \quad (2i)$$

$$x_{l,t} = 0 \qquad \forall l \ge N_{DA}+3, t < l-(1+N_{DA}) \quad (2j)$$

$$x_{l,t} = 1 \qquad \forall l \ge N_{DA}+2, t \ge l-(1+N_{DA}) \quad (2k)$$

$$|Q_{i,t,l}| \le M x_{l,t-1} \qquad \forall i \in \mathcal{I}, l \in \mathcal{L}, t \in \mathcal{T} \quad (2l)$$

$$z_{i,t} \in \{0,1\}, x_{l,t} \in \{0,1\} \qquad \forall i \in \mathcal{I}, l \in \mathcal{L}, t \in \mathcal{T} \quad (2m)$$

The above LDR based stochastic planning model are both mixed integer linear optimization (MILP) problem, which can be solved using stand MILP solver.

4. Case study

In this section, an example problem is solved to investigate the proposed planning method. There are 43 DAs to be planned and each DA includes 6 pairs of wells. The project horizon is considered to be 25 years. The life time of the DAs varies from 6 to 10 years. All the optimization problems are modeled and solved in GAMS using the CPLEX solver. Relative optimality gap of 0.1% was considered as the stopping criteria. In this case, central processing facility capacity = 5.25×10^6 m^3/year and steam capacity = 16×10^6 m^3/year. For stochastic planning model, in order to investigate the effect of price uncertainty on NPV, 15 experiments were conducted using different Γ and confidence interval (CI) values. Reservoir production capacity perturbation are fixed at ±10% of the nominal value. Figure 1 illustrates the stochastic planning solution with Γ=10 and CI=95%. The plan shows the development sequence, lifetime of each DA, the overall operating well number, the NPV and the total production rate from all the wells.

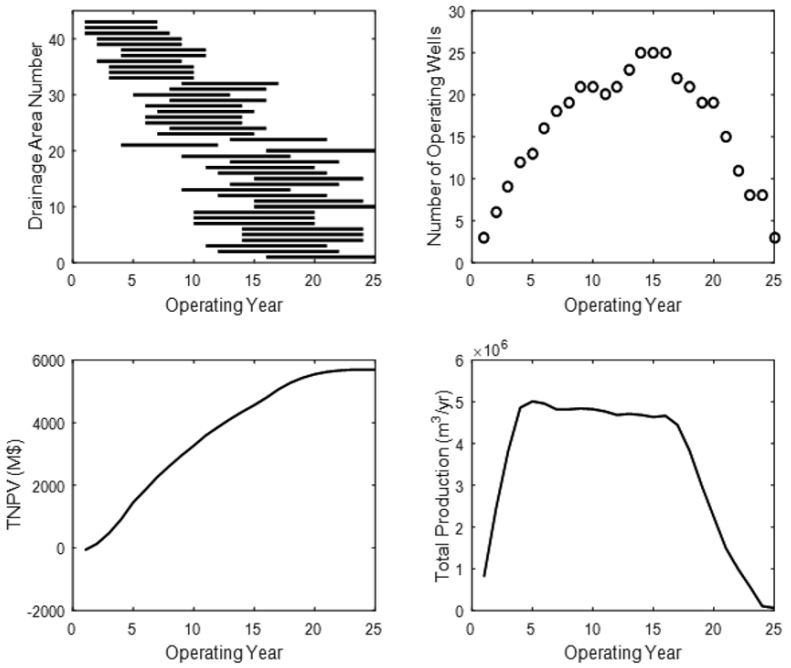

Figure 1. Stochastic planning solution

Table 1. Effect of price uncertainty set size on NPV

	CI=99%	CI=95%	CI=90%
Γ=25	6111.14	5692.72	5359.98
Γ=15	6096.67	5695.19	5365.10
Γ=10	6060.36	5546.57	5007.61
Γ=7	5475.82	4678.88	4216.29
Γ=5	4528.86	3897.52	3665.57

Table 1 illustrates the obtained results. For greater values of Γ and CI, the price uncertainty space is wider and since a minimum price constraint (bitumen price >10$/bbl) is applied in the uncertainty set, wider price uncertainty set results in greater bitumen price values and the NPV increases accordingly.

The performance of the stochastic planning solution was compared with the deterministic planning solution through sampling evaluation. Oil price uncertainty parameter confidence interval factor is fixed at 95% and Γ varies in the range of 5 to 25. For each Γ value, 1000 samples from the corresponding uncertainty set are generated and sampling method is applied on the results of stochastic and deterministic solutions. The advantage of stochastic programming is the feasibility of the solution. In stochastic solution, for all the different uncertainty sets (different Γ values), mean constraint violation is always zero which means stochastic optimization provides feasible solutions. While deterministic solution in general results in 16% of oil flow constraint violations among the 1000 samples. As a trade-off, the stochastic programming model is computationally more demanding, it takes 8 minutes to 4 hours for the various cases solved. While for the deterministic model, it is solved in 2 seconds.

5. Conclusions

In this work, multistage stochastic optimization model for SAGD reservoir development planning was developed. The objective of the models was to maximize the revenue obtained from the SAGD operation during the project horizon considering restrictions on capital investment, steam generation and oil processing capacities. The stochastic model was developed to incorporate oil price and oil production uncertainty. The principle advantage of the stochastic model is the feasibility of the solution subject to price and production uncertainty while the deterministic solution always resulted in infeasible plans violating realistic restrictions. Finally, since in this study a linear decision rule was employed in order to solve the nonlinear stochastic problem, the obtained solution was suboptimal. Future work includes improving the solution quality through better decision rule.

Abstract

This work presents a rescheduling strategy based on a model predictive closed-loop algorithm with shrinking horizon based on uncertain models. This formulation can address most of the rescheduling needs of a chemical production operation. The strategy is based on a quantitative model to forecast the effects of process operation changes and disturbances in the production goal by using uncertain models. The studied problem is based on a model predictive control algorithm that uses a set of state-space models to describe all possible scenarios with uncertain properties. It also evaluates the properties and features of the closed-loop rescheduling algorithm based on closed-loop performance objectives. A comparison with standard scheduling strategies is performed showing the great potential of the closed-loop dynamic rescheduling algorithm.

Keywords: rescheduling, model predictive control, uncertain models.

1 Introduction

Scheduling has great importance due to the necessity of arranging, controlling and optimizing operations, machinery and human resources, product supply and material purchase for a chemical production. Furthermore, scheduling is responsible for ensuring that all plant limits, such as maximum volume of tanks and maximum feed flow rates are respected.

As scheduling problems are dynamic in nature, rescheduling is necessary when new information, such demands and process units availability change. A closed-loop approach is a great alternative to deal with the dynamic behavior, since scheduling becomes an iterative process. Subramanian et al. (2012) reported a new approach in which a general mixed-integer (MIP) scheduling model was represented in state-space form. Certain disturbances were also modeled in state-space form leading to rescheduling. Concepts of model predictive control (MPC) was used in a closed-loop approach in order to deal with disturbances over the scheduling horizon. The approach showed great potential, and it was capable of solving an addressed problem composed by a single reactor and two possible reactions.

Baldea and Harjunkoski (2014) brought forward a review about works addressing the integration of scheduling and control. Moreover, essential elements for the integration between control and scheduling were identified. Dias and Ierapetritou (2016) lead a study focused on analyzing uncertainties in scheduling and control problems.

The present work main goal is to introduce a model predictive closed-loop algorithm with shrinking horizon to deal with rescheduling The strategy uses uncertain models to predict and reject disturbances on the process and contemplate an interval for system preparation, for example with cleaning, which makes the use of receding horizon with shrinking not the option of choice. A comparison was carried out between standard and closed-loop approaches, indicating that the proposed technique is a promising rescheduling technique.

2 Problem Description

The scheduling model used herein is presented below:

- A set of tasks $i \in I$ that can be performed in a set $j \in J$ of units; $\bar{\tau}_i$ is the execution time of task I; B_{it} is the volume of each task batch i in time instant t. The subset I_j refers to tasks i that can be performed in unit j.
- A set of material $k \in K$; the subsets I_k^+ and I_k^- denote material k being produced/consumed by a task i; ρ_{ik} is the proportion of material k produced/consumed by task i.
- A set of time instants denoted by $t \in T$.

2.1 Scheduling model

A time-discrete model was considered, in which time horizon is divided in T periods with equal duration. It is important to highlight that in discrete models, task can only start or end at the beginning of each time instant t.

The objective function is represented by Eq(1), where γ_i is the production cost of task i, W_{ijt} is the binary variable responsible for indicating the start of task i in unit j at time instant t, ν_k is the inventory cost of material k, S_{kt} is the inventory level of material k at time period t, ϕ_k is the backlog cost and U_{kt} is the backlog of material k at time period t.. It is important to emphasize that backlog cost represents the most representative cost of the objective function, intending to avoid the backlog from occurring.

$$\min_{\Xi} \max_{\Pi \in \Lambda} Z = \sum_{i,t} \gamma_i \cdot W_{ijt} + \sum_{i,t} \nu_k \cdot S_{kt} + \sum_{i,t} \phi_k \cdot U_{kt} \quad i \in I, k \in K, t \in T \tag{1}$$

Where $\Xi \equiv \{W_{ijt}, S_{kt}, U_{kt}\}$ and $\{\Pi_I \dots \Pi_M\} \equiv \Pi \in \Lambda$ represents a set of scheduling models belonging to a compact set . The nature of the formulated problem is to perform a maximization over the set Λ and corresponds to choosing the model Π_i: $x(t+1) = A_i x(t) + B_i u(t) + B_{d_i} d(t); i = I, \dots, M$ for prediction that would lead to the largest or **worst-case** model among all plant models in Λ.

2.2 State-space model for scheduling problems

Scheduling model use binary variables to indicate the start of tasks, but during the operation of the unit j there is no variable responsible for indicating that a task is occurring in unit j. Therefore, it is necessary to create a state variable to designate that unit j is carrying a task i at time period t. The same idea can be used for variables B_{it}, U_{kt} and S_{kt}.

The state-space model can be written as Π_l: $x(t+1) = A_l x(t) + B_l u(t) + B_{d_l} d(t)$, in which $x(t) = [\bar{W}_{ijt}^n, S_{k,t}, U_{k,t}, \bar{B}_{it}^n]$ is the state vector, $u(t) = [W_{ijt}, B_{it}, V_{kt}]$ is the input

vector and $d(t) = [\xi_{kt}]$ and is represented by $[A_l\ B_l\ B_{d_l}] \equiv \Pi_l$, where A_l, B_l and B_{d_l} are the state-space matrices of Π_l and t is the time instant (number of time periods T). The state-space model derived from the scheduling model is used as the prediction model on the closed-loop scheduling strategy.

Model uncertainty is introduced as a finite set of models as $\Pi := \{\Pi_I \dots \Pi_M\} = \{[A_I\ B_I\ B_{d_I}] \dots [A_M\ B_M\ B_{d_M}]\}$. Task i yield ρ_{ik} varies in a certain viable range on the prediction models, and the worst case scenario will be chosen at each time instant in order to ensure that the problem is able to address the desired scheduling even in the worst case scenario for the prediction model. In addition, the actual yield of the plant is a random variable satisfying a normal distribution within the same range of the ρ_{ik} values chosen in the used uncertain model. Where Π is some prespecified set representing the multi-model paradigm.

A variety of disturbances can be modeled in the state-space model framework presented. Demand at each time instant t has been modeled as a disturbance, and it is part of the disturbance vector d, thus the nominal demand just changes over the time horizon.

2.2.1 Losses during reactors unloading

It is possible to foresee at the beginning of a task i in unit j the mass of the material k produced at the end of that task. However, unexpected events can happen during the unloading or transport of the product and some losses can be caused. Those losses can be modeled through the variable $\hat{\theta}^p_{ikt}$, which represent the mass product lost. This variable will be now part of the disturbance vector d. The inventory level can be calculated by Eq(3), with $t \in T, j \in J, k \in K, i \in I$

$$S_{k,t+1} = S_{k,t} + \sum_{i \epsilon I_k^+} \rho_{ik}(\bar{B}^{\tau_i}_{it+1} - \hat{\theta}^p_{ikt}) + \sum_{i \epsilon I_k^-} \rho_{ik} B_{it} + V_{kt} \tag{3}$$

3 Case study

The case study selected involves two tasks (reaction A and B) in a single reactor, and is a modification of the one proposed by Subramanian et al. (2012). Each task has a different duration, and only one task can be performed at each time instant in the reactor. Reaction A requires raw material (RM) and it produces A during three (3) period of time and has a conversion in the range of 90% to 100%. Reaction B requires raw material (RM), produces B in two (2) period of time and has a conversion in the range of 90% to 100%. Moreover, if there is a changeover between the tasks in reactor, it is necessary a setup time of two time periods for restarting the production. The initial inventory for RM, A and B are as follows 100, 15 and 20 units of volume, respectively. The time horizon is 48 hours divided equally in time periods of 1 hour, but two cycles with a duration of 24 hours each in a shrinking horizon was performed in order to schedule 48 hours of production. Shrinking horizon can be a good alternative for rescheduling, since it is easier to implement terminal constraints at the end of the shrinking horizon, such as a setup time before restarting the operation and a constraint to ensure that the equipment finishes their operation empty at the end of the shrinking horizon, as indicated in the case study with 2h for restarting the operation. Herein two different disturbances is addressed, first the change of the nominal demand and secondly events like losses during reactors unloading as follows:

- at t = 3, occurs a loss of 4 units of mass of product A;
- at t = 6, occurs a loss of 2 units of mass of product A;
- at t = 6 the nominal demand changes for both products (A and B), from 1.5 to 2 units of mass;
- at t = 15 occurs a loss of 3 units of mass of product B;
- at t = 30 occurs a change on the nominal demand for both products (A and B), from 2 to 3.5 units of mass remaining at that level until the end of the scheduling horizon

4 Results

All the simulations was performed on a i7/16GB computer. Furthermore, the software Python 3.4.0 integrated with GAMS 24.4.6 was used for all simulations. When not indicated otherwise the parameters used are as follows $\gamma = [2\ ,6]^T, \nu = [8,2\ ,10]^T,$ and $\phi = [100{,}100]^T$.

4.1 Case Study 1- Exact Model (no uncertainty)

In this case, the scheduling was performed considering a exact model (no model uncertainty). Yields of 100% for both reaction A and reaction B were used. Besides that, no plant-model mismatch was considered. In this case, it is possible to analyze the closed-loop disturbance rejection over the time horizon.

Fig(1) presents the Gantt Chart for classical scheduling and for rescheduling using the MPC closed-loop algorithm. When disturbances occur, rescheduling was necessary and the remaining previously calculated operation were not implemented. Instead, the remaining operations were replaced by the closed-loop MPC new scheduling. The inventory level for the problem without rescheduling and with rescheduling are presented in Fig(2) and Fig.(3), respectively.

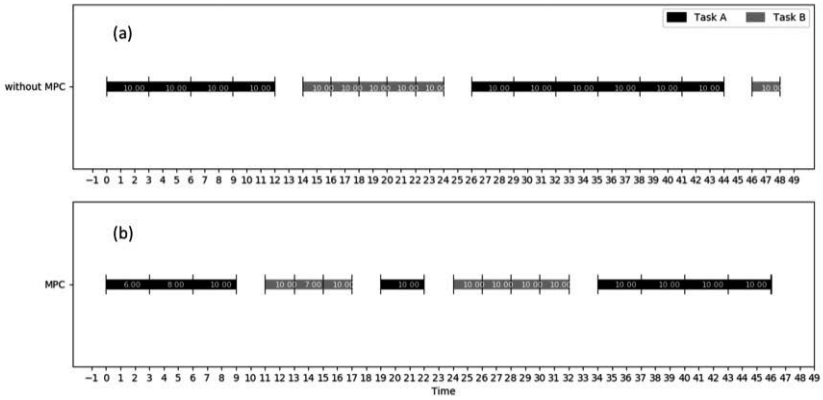

Figure 1- Case study 1 - Gantt chart: (a) Classical scheduling and (b) MPC rescheduling

The objective functions reached the values of \$178,898.00 and \$103,114.00, respectively. In this first case, at t = 6h the nominal demand changed, so the backlog started rising, since the scheduling did not take into account this change and did not plan shipments to meet the new demands.

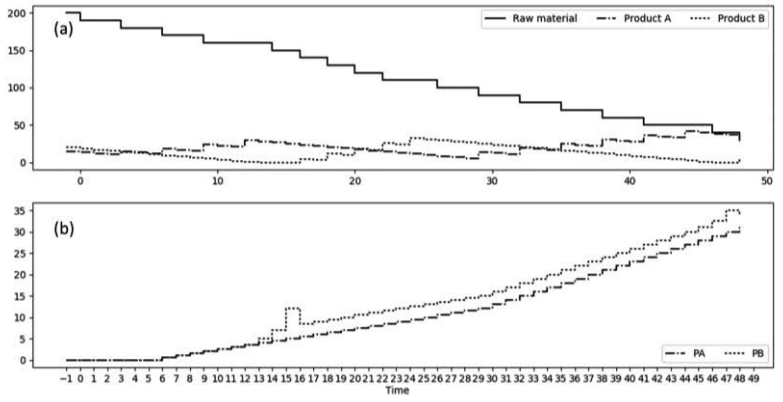

Figure 2 – Case study 1 without rescheduling: (a) Inventory level and (b) backlog

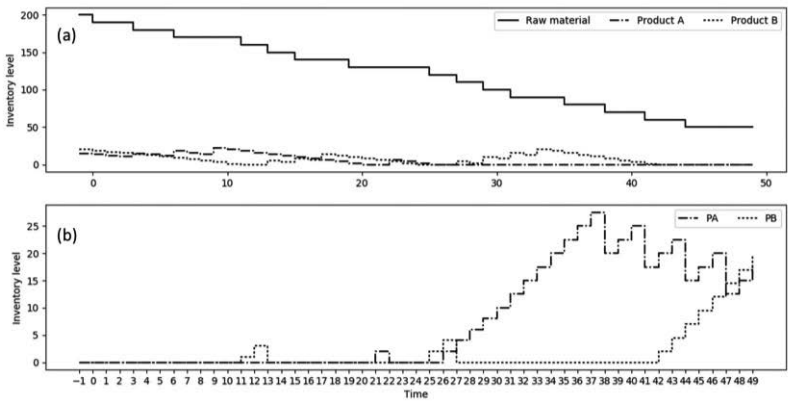

Figure 3 – Case of study 1 with rescheduling: (a) Inventory level and (b) backlog

The case with dynamic rescheduling performs new scheduling and shipments were changed so that the backlog occurred only when inventory was insufficient to meet nominal demand.

While backlog for the problem without rescheduling occurred at t = 6h, for the one using MPC rescheduling, it occurred at t = 9h. Moreover, reaction A was performed four times in a row because there were losses of product A over the time horizon. Even with losses, the backlog for product A occurred practically at the end of the time horizon ($t = 20$), showing how rescheduling can minimize the effect of disturbances.

4.2 Case Study 2 - Uncertain models

I this case study, a set of five models defined with reaction yields in the range of 0.9 to 1 were used at each iteration in the rescheduling multi-model problem. In addition, the actual yield of the plant was unknown and satisfied a normal distribution with value belonging to the range of specified yield for the plant. The set of yields used by the rescheduling in the case study was given by [0.9, 0.93, 0.95, 0.98, 1.0].

Fig(4) shows the inventory level for the problem with uncertainties. The objective function was $116,206.97. It is important to highlight that even when the decisions of

the worst case scenario was selected, the problem still presented satisfactory results. Moreover, in Fig(5) is pointed out that the solution is robust to uncertainties in the models, even when there exist plant-model mismatch, so it can be seen that the rescheduling based MPC algorithm is robust enough to reschedule the problem even under this range of uncertainties for this case study.

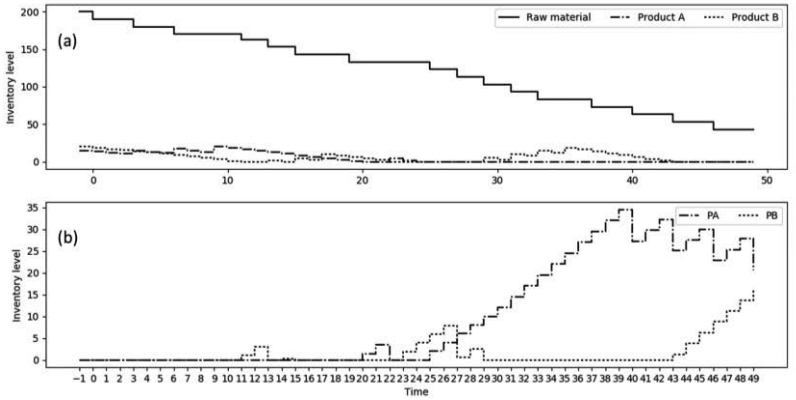

Figure 4 - Case study 2 - rescheduling with uncertainties: (a) inventory level and (b) backlog

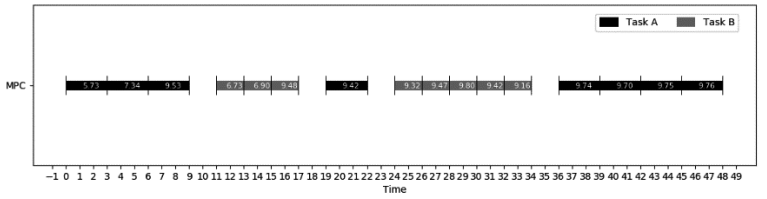

Figure 5 - Case study 2 - Gantt chart with rescheduling under uncertainties

5 Conclusions

A comparison of standard scheduling strategies and a closed-loop strategy for rescheduling showed that the later could reject disturbances and carry a lower backlog and objective function value. Shrinking horizon can be a good alternative for rescheduling allowing a realistic description of terminal constraints and objective function during setup times before restarting the process operation. The use of a set of uncertain models in a min-max framework applied to a plant with a normal distribution uncertainty on reaction conversion lead to satisfactory results. Finally, the closed-loop strategy showed great potential when applied to scheduling problems even when the used models are uncertain.

Abstract

By utilizing Picard's iteration and Laplace-Borel transform, a preliminary analytical solution is obtained for the Arneodo model of the B-Z reaction. For purposes of comparison, the numerical simulation of this model is also conducted. Then, the occurrence of chaos in this model is recognized and characterized by the Lyapunov exponent method, correlation dimension method and power spectrum method, respectively.

Keywords: Chaos, Laplace-Borel transform, B-Z reaction.

1. Introduction

The Belousov-Zhabotinsky (B-Z) reaction is the first studied oscillating chemical reaction, which is a typical self-organized nonlinear system with a chemical wave spreading over time and across space (Belousov, 1959). The oscillation behaviour in B-Z reaction is quite similar to that in bio-systems, hence the study of the B-Z system could facilitate further investigations of general bio-systems. The self-organized oscillatory behaviour can be explained by the Hopf bifurcation theory, i.e., once a system evolves beyond a Hopf point, it oscillates into a limit cycle period, then, chaos may follow, which can be described by certain mathematical models for the B-Z reaction, such as the Arneodo model (Arneodo et al., 1998).

A chaos behaviour of a process can be identified by its sensitivity to initial conditions, topological mixing, dense periodic orbits (Boris et al., 2003), which could be characterized by the Lyapunov exponent method, correlation dimension method (Strogatz, 2000) and power spectrum method (William, 1992). This behaviour is usually observed through numerical simulations, which makes these characterization methods limited to simulation data, as the system is considered as a black box during the analysis.

Theoretically, chaos only emerges in nonlinear systems with no less than 3 dimensions (Pedro, 2006), or, infinite dimensional linear systems (Bonet et al., 2001). With the Laplace-Borel transform, a nonlinear system can be expanded into an infinite dimensional linear system (Batigun et al., 1997), which provides a possibility for the study of chaos analytically and a feasible way to understand the mechanism of the onset of chaos.

In this paper, the Arneodo model for the B-Z reaction system is solved by the Laplace-Borel transform, and then characterization of the onset of chaos is studied. For comparison purposes, numerical simulation results are also provided.

2. Chemical kinetics and Arneodo model for B-Z reaction

The B-Z reaction can be considered as an open system with a constant negative entropy flow, which is characterized by non-linearity and away from the equilibrium state. The reaction mechanism can be easily explained by the Oregonator model (Field et al., 1974),

$$\begin{aligned} &A+Y\rightarrow X+P && r_1=k_1AY\\ &X+Y\rightarrow 2P && r_2=k_2XY\\ &A+X\rightarrow 2X+2Z && r_3=k_3AX\\ &2X\rightarrow A+P && r_4=k_4X^2\\ &B+Z\rightarrow 0.5fX && r_5=k_5BZ \end{aligned} \tag{1}$$

where X is $HBrO_2$, Y is Br^-, Z is Ce(IV), A is BrO_3^-, B is organic, and P is HOBr. Assuming that reactants A and B are of high concentration and do not change significantly during several oscillations, the intermediate products X, Y and Z are generated and consumed alternately, causing Z to change back and forth between Ce^{4+} and Ce^{3+}. After adding the ferroin indicator to the system, the medium will repeatedly change color between blue and red. Figure 1 shows an open system, the overall reaction of the system is $A + B \rightarrow P$, the entropy change of the reactants and product exhibits a continuous negative entropy flow into the system, a part of which is used to maintain the chemical wave, i.e., a typical dissipative structure.

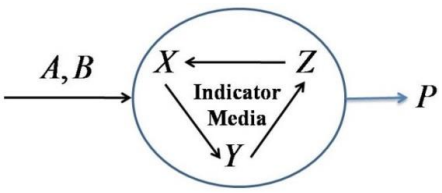

Fig. 1 The simplified structure of B-Z reaction.

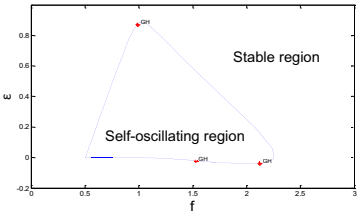

Fig. 2 The parameter space of Oregonator model. GH-generalized Hopf points.

From the dynamic system viewpoint (Fig. 1), the nonlinear term of the intermediate product leads to a supercritical Hopf bifurcation as shown in Eq. (1). According to the hypothesis, the dynamic model of the reaction intermediate of the dimensionless Oregonator model is displayed in Eq. (2) (Fig. 2), the blue line divides the parameter space of Eq. (2) into a self-oscillating region and a stable region,

$$\begin{aligned} &\varepsilon\frac{dx}{d\tau}=qy-xy+x(1-x)\\ &\delta\frac{dy}{d\tau}=-qy-xy+fz\\ &\frac{dz}{d\tau}=x-z \end{aligned} \tag{2}$$

where $x = X / X_0$, $y = Y / Y_0$, $z = Z / Z_0$, $\tau = t / T_0$, the steady-state value can be obtained by setting the right side of the system's dynamic equation to zero, thus X_0, Y_0, Z_0, $T_0 = F(k_1 \ldots k_5, A, B)$.

The B-Z reaction exhibits periodic oscillations, and sometimes chaos. The Oregonator model can only describe a limit cycle for this process, while more nonlinear behaviour is well illustrated by the Arneodo model. Thus the Arneodo model is studied here to identify the chaos in the B-Z reaction process,

$$\begin{aligned} &\partial x/\partial t = y \\ &\partial y/\partial t = z \\ &\partial z/\partial t = -\eta z - \upsilon y - \mu x + x^2 - 1.425y^2 + 0.2xz - 0.01x^2 z \end{aligned} \tag{3}$$

where $\mu = 1.38$, $\eta = 1.2$, $v = 1$.

2.1 Picard's iteration

The solution to ordinary differential equations can be expressed in terms of iterated integrals. Consider a differential equation given by

$$\frac{dX(t)}{dt} = f(X) \tag{4}$$

where *f(X)* is a continuous function. After expressing Eq. (3) in its integral form, successive approximations with the recurrence relations are given as,

$$X_k = X(0) + \int_0^t f(X_{k-1}, \tau)\, d\tau \tag{5}$$

If *f(X)* is a nonlinear function, the solution of this system can be expressed as

$$X(t) = X(0)\left[1 + \sum_{n=0}^{\infty} c(i_n \text{ K } i_0) \int_0^t d\xi_0 \text{ K } d\xi_n\right] \tag{6}$$

2.2 Integral algebra

It can be defined that

$$\int_0^\tau d\tau \Leftrightarrow x_0 \tag{7}$$

where x_0 is integral operator, and this operator satisfies the shuffle product operation which has two important properties. One is the distributive property described as,

$$\begin{aligned} &[F_1(x_0) + F_2(x_0)] \text{ C} [F_3(x_0) + F_4(x_0)] \\ &\quad = F_1(x_0) \text{ C } F_3(x_0) + F_1(x_0) \text{ C } F_4(x_0) + F_2(x_0) \text{ C } F_3(x_0) + F_2(x_0) \text{ C } F_4(x_0) \end{aligned} \tag{8}$$

The other is the multiplication of iterated integrals, which is expressed by the shuffle products as follows, where C is the shuffle product operation, on which the Laplace-Borel transform depends.

$$\begin{aligned} &(x_{\xi_j} \text{ L } x_{\xi_1}) \text{C} (x_{\xi_k} \text{ L } x_{\xi_1}) \\ &\quad = x_{\xi_j}[(x_{\xi_{j-1}} \text{ L } x_{\xi_1}) \text{C} (x_{\xi_k} \text{ L } x_{\xi_1})] + x_{\xi_k}[(x_{\xi_j} \text{ L } x_{\xi_1}) \text{C} (x_{\xi_{k-1}} \text{ L } x_{\xi_1})] \end{aligned} \tag{9}$$

2.3 Laplace-Borel transform

In Laplace-Borel transform, a domain change is employed to transform nonlinear differential equations to algebraic equations whose solution is represented by an infinite series. Consider a function *f(t)* that can be expanded in Taylor series,

$$f(t) = \sum_{n=0}^{\infty} a_n \frac{t^n}{n!} = \sum_{n=0}^{\infty} a_n \int_0^t d\xi_n \, \mathrm{K} \, d\xi_0 \tag{10}$$

Utilizing the relationship between iterated integrals and algebra, the Laplace-Borel transform is defined as

$$LB[f(t)] \equiv F(x_0) \equiv \sum_{n=0}^{\infty} a_n x_0^n \tag{11}$$

The explicit form of Laplace-Borel transform is derived as,

$$F(x_0) = \frac{1}{x_0} \int_{0^-}^{\infty} e^{-t/x_0} f(t) dt \tag{12}$$

The following is a relationship between Laplace transform and Laplace-Borel transform, which is the key to do inverse Laplace-Borel transform,

$$F(s) = x_0 F(x_0)_{x_0 = s^{-1}} \tag{13}$$

3. Results and discussion

In Eq. (3), variables y and z can be expressed by x, then the Laplace-Borel transform is:

$$x(t) \Leftrightarrow F(x_0) \tag{14}$$

Then an expanded solution is assumed in the form of

$$F(x_0) = F_0(x_0) + F_1(x_0) + F_2(x_0) + \mathrm{L} \tag{15}$$

where $F_i(x_0) = f(F_{i-1}(x_0), F_{i-2}(x_0), \mathrm{K}, F_0(x_0))$

By exploiting Eq. (13), performing an inverse Laplace transform, and setting *x(0)*, *x'(0)*, *x''(0)* to 0.1, the terms that define the time domain analytical solution can be obtained as,

$$\begin{aligned}
x_0(t) &= 0.07247e^{-1.269t} + (0.01376 + 0.09163i)e^{(0.03448-1.042i)t} \\
&\quad + (0.01376 - 0.09163i)e^{(0.03448+1.042i)t} \\
x_1(t) &= 1.524 \times 10^{-7} e^{-3.807t} + 0.0005225e^{-2.538t} + (7.722 \times 10^{-7} - 5.703 \times 10^{-10} i)e^{(-2.503-1.042i)t} \\
&\quad + (7.722 \times 10^{-7} + 5.703 \times 10^{-10} i)e^{(-2.503+1.042i)t} + 0.01331e^{-1.269t} \\
&\quad + (0.005697 + 0.007138i)e^{(-1.234-1.042i)t} + (0.005697 - 0.007138i)e^{(-1.234+1.042i)t} \\
&\quad + (0.00003872 - 4.118 \times 10^{-21} i)e^{-1.2t} - (2.919 \times 10^{-7} - 1.252 \times 10^{-7} i)e^{(-1.2-2.085i)t} \\
&\quad - (2.919 \times 10^{-7} + 1.252 \times 10^{-7} i)e^{(-1.2+2.085i)t} - (0.009917 - 0.005754i)e^{(0.03448-1.042i)t} \\
&\quad - (0.009917 + 0.005754i)e^{(0.03448+1.042i)t} + (0.001902 + 0.001588i)e^{(0.06896-2.085i)t} \\
&\quad - (0.009049 - 2.344 \times 10^{-19} i)e^{0.06896t} + (0.001902 - 0.001588i)e^{(0.06896+2.085i)t} \\
&\quad - (1.935 \times 10^{-7} - 2.178 \times 10^{-7} i)e^{(0.1034-3.127i)t} - (0.00009225 + 0.00004914i)e^{(0.1034-1.042i)t} \\
&\quad - (0.00009225 - 0.00004914i)e^{(0.1034+1.042i)t} - (1.935 \times 10^{-7} + 2.178 \times 10^{-7} i)e^{(0.1034+3.127i)t}
\end{aligned} \tag{16}$$

After evaluating the 2nd term in the frequency domain by 0th and 1st terms, it is found that the 2nd term cannot be computationally transformed back into time domain completely. The inverses in the time domain are omitted due to the page limitations. In time domain, the 0th term and most parts of the 1st term consist of conjugate pairs and convergent exponential terms, which exhibit an amplitude increasing oscillation over time, indicating that the oscillation of the state point starts with an amplitude increasing vibration, which can be regarded as the superposition of a series of periodic motions in 3D phase space

with gradually increasing linear velocities. Thus, the amplitude increasing oscillation can be assumed to be an instability process, which is accompanied by the onset of chaos. Fig. 3 exhibits that the 1st term contains a diverging exponential term, which leads to a symmetry breaking in the system, which is also an instability factor.

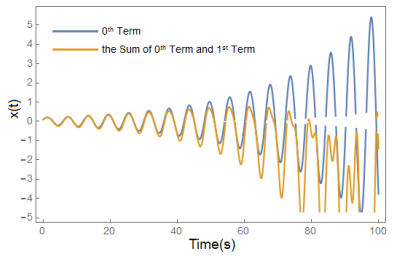

Fig. 3 0th term and sum of 0th and 1st terms.

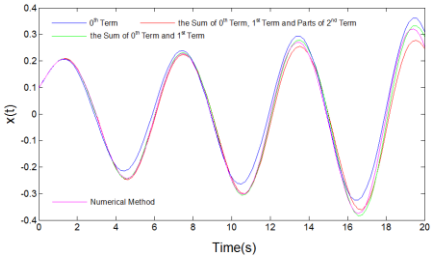

Fig. 4 Numerical and analytical methods.

It can be seen in Fig. 4 that the green line, representing the sum of 0th and the 1st terms, is closer to the purple line, representing the numerical method simulation, than the blue line, representing the 0th term. The red line represents the sum of 0th, 1st and part of 2nd term, so the green line still approximates the process better than the red line because of incomplete solution of the 2nd term in the time domain.

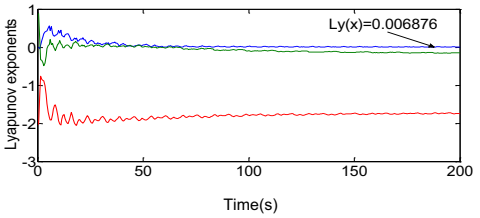

Fig. 5 Lyapunov exponents of Aronodo model.

Lyapunov exponents depict the degree that deterministic systems are affected by fluctuations in initial values. It can be seen from Fig. 5 that Lyapunov exponent of dimension x is positive, indicating that a slight fluctuation in initial value expands exponentially over time and the trajectory after a long time cannot be accurately predicted, which is a feature of chaos. To obtain the correlation dimension of this system, the phase space is first reconstructed based on the time sequence of a variable, which requires selecting the embedded dimension d and the delay time τ by seeking one point where curve is saturated in Fig. 6 and the other point at first valley of curve in Fig. 7, in this case, $d=6$ and $\tau=176$, then the slope of linear part of the double logarithmic curve of the correlation integral C and the radius parameter ε are calculated, whose fitting result in Fig. 8 shows that the system correlation dimension is 1.61, indicating that the system generates chaos for the dimension of this deterministic system being non-integer, which is also a feature of chaos.

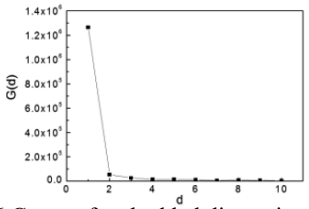

Fig. 6 Curve of embedded dimension.

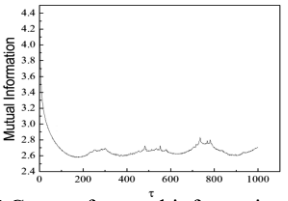

Fig. 7 Curve of mutual information.

In the power spectrum, the narrow peaks indicate the periodic behaviors, i.e., stable limit cycles (a kind of general attractor), and the broad peaks is the characteristic of the chaotic behaviors, i.e., or strange attractors. As shown in Fig. 9, there are five peaks in the power spectrum of the Arneodo model's attractor, which indicates that this attractor is not a stable limit cycle. The frequency interval of each of the two adjacent peaks is the same, which indicates that a regular pattern about frequency of sub-periodic behaviours exists. The first and second peaks are wider than others, which likely indicates a strange attractor, a feature of dissipative-system chaos.

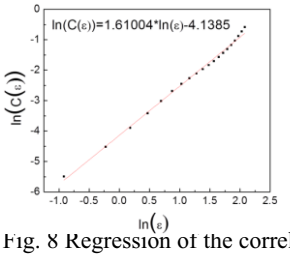

Fig. 8 Regression of the correlation dimension.

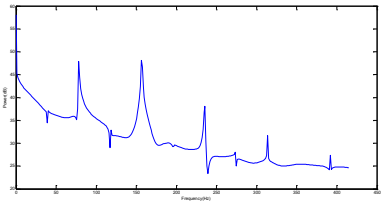

Fig. 9 The power spectrum of Arneodo model.

4. Conclusions

A preliminary analytical solution of Arneodo model of B-Z reaction was obtained for the Arneodo model of B-Z reaction by the Laplace-Borel transform. The numerical simulation for this model was also conducted. Then chaos occurring in this system was identified and characterized by Lyapunov exponent method, correlation dimension method and power spectrum method, respectively. We show that the nonlinear behaviour can be better studied and predicted if a complete analytical solution is available.

Design concept for coal-based polygeneration processes of chemicals and power with the lowest energy consumption for CO_2 capture

Hong Huang, Siyu Yang *

School of Chemical Engineering, South China University of Technology, Guangzhou, 510640, PR China
cesyyang@scut.edu.cn

Abstract

Single coal based chemicals production processes emit large amount of CO_2 during conversion of the syngas to the high H_2/CO ratio feed gas for chemicals synthesis. However, the feed gas is with a low CO_2 molar fraction, leading to high energy cost for CO_2 capture. In this work, we try to reduce energy consumption for CO_2 capture by improving its molar fraction. A new methanol and power polygeneration process is designed and analysed based on process modeling and simulation. The hierarchical conceptual design methodology is introduced to design the polygeneration more reasonably. In this process, the shifted syngas exiting from the water gas shift unit first goes into the CO_2 capture unit to remove CO_2. Then, the purified H_2-rich syngas is mixed with the unshifted syngas and fed into the methanol synthesis to produce methanol. Then, unreacted syngas out from the methanol synthesis unit is moderately recycled to use, while the rest is used to generate power. Energy consumption for CO_2 capture of the polygeneration process is 0.7 GJ/t-CO_2, which is a 40.6% reduction compared to that of the single coal-to-methanol process and a 22.2% reduction to that of coal-to-hydrogen for power generation process. Energy saving ratio of the polygeneration process is 16.5%.

Keywords: polygeneration, process design, CO_2 capture, energy consumption

1. Introduction

Coal is the dominant resource for chemicals production or power generation in China. This is as known due to lack of natural gas and oil. This energy structure brings severe greenhouse gas (GHG) emissions since the production processes transfer carbon rich resource to hydrogen rich product or to power (Xiang et al., 2014; Man et al., 2014). Carbon capture and storage (CCS) technology is broadly accepted as a feasible approach to reduce CO_2 emission (Xiang et al., 2014). However, a CCS process adds large amount of energy consumption and increases operational cost much. In the CCS process, energy for CO_2 capture takes the largest proportion, accounting for 70-80% of the total.

Increasing CO_2 molar fraction can effectively reduce energy for CO_2 separation. Zhang et al. (Zhang et al., 2013) studied energy consumption for CO_2 capture using membrane separation process. Results showed that the energy for CO_2 capture was reduced from about 1.8 GJ/t to 0.1 GJ/t CO_2 as the molar fraction increases from 0.025 to 0.5.

Some research attempts to increase the CO_2 molar fraction in coal based chemical process, Li et al. (Li et al., 2013) proposed a coal based natural gas (SNG) and power polygeneration process. Coal based syngas is sent directly to the methanation reactor to produce SNG without H_2/CO ratio adjustment. The active gas is reacted and the molar fraction of CO_2 is increased after the reaction. The unreacted gas is separated and the corresponding energy for the CO_2 separation is reduced. This theoretical process seems reasonable to reduce the energy for CO_2 capture. However, the syngas with an insufficient H_2/CO ratio is not suitable for SNG synthesis, leading to catalyst deactivation and a low reaction rate. In this case, the loss in product yield outweights the energy saving from CO_2 capture.

In this paper, we introduce a hierarchical polygeneration process design concept for chemicals and power production based on the "onion" model proposed by Smith (Smith, 2005). It can pursue energy cascade utilization and resource efficient utilization. In this model, a chemical process is decomposed into four layers, starting from reaction, followed by separation process, heat exchanger network and utility system, as shown in Fig. 1.

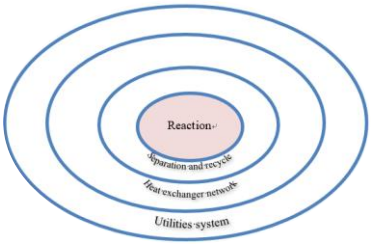

Figure 1. Onion diagram for process design.

For illustrative case study, a coal based methanol and power process is designed based on the concept, as shown in Fig. 2. Coal is converted into crude syngas in the gasifier. After heat recovery and scrubbring, the crude syngas is separated into two parts. One part is used for power generation and the other part is used for methanol synthesis. To maximize the CO_2 molar fraction, we place the CO_2 capture unit to the power generation side. In this branch, syngas is converted to hydrogen and the molar fraction is increased. The capture energy is lower than that in conventional chemical process. In the chemicals synthesis side, the H_2/CO ratio is increased by mixing with a part of H_2 from the power generation side. The key idea here is element /resource complementary. In addition, a part of unreacted syngas from the methanol synthesis reactor is recycled and the rest is used for power generation.

The key operating parameters and optimal process design are determined according to the simulation. Energy saving ratio of the polygeneration process is analysed to illustrate the advantage compared to single CTM and coal-to-hydrogen power generation processes.

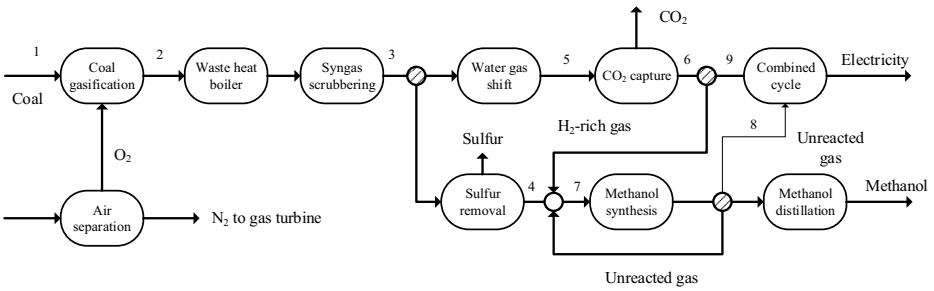

Figure 2. Schematic diagram of the methanol and power polygeneration process.

2. Process modeling and simulation

Different units are firstly modeled and simulated, including the ASU unit, the coal gasification unit, a WGS unit, a CO_2 capture unit, a methanol synthesis and distillation unit and a combined cycle power generation unit. In the following sections, we mainly describe the modeling and simulation of these units.

2.1. Coal gasification

For modeling the coal gasifier, coal is defined as unconventional solid using MIXCINC in Aspen Plus (He et al., 2013). RK-Soave is the property method. Coal gasification process is modeled as the combination of a pyrolysis, a gasification and a combustion stages. In the pyrolysis stage, coal is decomposed at 500 ℃. The pyrolysis reaction is modeled by the Rstoic block. In the gasification and the combustion stages，the main reactions include heterogeneous reactions. Due to the high temperature (>1000 ℃) of the gasification and the combustion stages, these reactions meet the equilibria and are modeled by RGibbs reactor according to Gibbs free energy minimization (Jarungthammachote et al., 2008).

2.2. Methanol synthesis

The crude syngas sent to the methanol synthesis and distillation firstly passes through a COS hydrolyzer where 100% of the COS is converted to H_2S via the hydrolysis reaction (Rhodes et al., 2000). After that, the syngas is cooled down to 40 ℃. H_2S is then absorbed by contacting with methanol solvent and subsequently released by heating the solvent. The CO-rich syngas ($H_2/CO \approx 0.7$) leaving the sulfur removal unit is mixed with the H_2-rich gas from CO_2 capture unit to adjust the H_2/CO molar ratio to 2.0-2.1. The mixed syngas is compressed to 8.0 MPa by a centrifugal compressor and then preheated to about 200 ℃ before going to the methanol synthesis reactor where an exothermic methanol synthesis reaction takes place. The methanol synthesis reaction converts CO and CO_2 into methanol over a $Cu/ZnO/Al_2O_3$ catalyst.

2.3. CO2 capture and power generation

In the power generation section, there are a WGS unit, a CO_2 capture unit and a combined cycle power generation unit. The syngas first goes into the WGS unit where CO and steam are converted to H_2 and CO_2. This unit has a two-stage configuration. The temperature of the crude syngas is increased to 250 ℃ before going into the first WGS reactor, according to the activation temperature of the CoMo catalyst (Carbo et al., 2009). In the reactor, axial temperature increases with the extension of the reaction.

Increase of temperature would limit the chemical equilibrium of the reaction and CO could not be further converted. The high temperature syngas leaving the first reactor is cooled down to 250 ℃ and goes into the second reactor for further conversion of CO.

The shifted syngas is sent to the CO_2 capture unit to remove acid gas such as H_2S and CO_2. The syngas from WGS unit is cooled down to 40 ℃ and fed into a Rectisol process. In this process, H_2S and CO_2 are sequentially absorbed in the H_2S absorber and CO_2 absorber by methanol solvent at a methanol/syngas molar ratio of about 0.85, and subsequently released by heating the solvent.

3. Energy consumption for CO_2 capture

Energy consumption for CO_2 separation and compression can be calculated by Eqs. (1) and (2) (Li et al., 2014).

$$E_{sep} = -RT_0 \frac{x_{CO_2} \cdot \ln x_{CO_2} + (1 - x_{CO_2}) \cdot \ln(1 - x_{CO_2})}{x_{CO_2} \eta_{cap}} F_{sep} \tag{1}$$

where R is the gas constant, 8.314 J/(mol K), T_0 is 298.15 K, x_{CO_2} is the CO_2 molar fraction in the gas before separation, η_{sep} is the separation efficiency and F_{sep} is the flow rate of the syngas.

$$E_{compr} = RT_0 \ln\left(\frac{P}{P_0}\right) \tag{2}$$

where P is the pressure after compression (MPa) and P_0 is the initial pressure (MPa) From the previous analysis, it is concluded that CO_2 molar fraction is a key factor affecting energy consumption. In this part, we calculate the energy consumption for CO_2 capture at different CO_2 molar fraction, as shown in Fig. 3. In the range of 0.3 to 0.46, energy consumption for CO_2 capture decreases from 1.2 GJ/t to 0.65 GJ/t. In this polygeneration process, CO_2 molar fraction is increased from 31% to 43.2%. Energy consumption for CO_2 capture stems from the compression refrigeration, and the steam consumption of the reboilers and CO_2 compression. Increasing CO_2 molar fraction brings reduction on the amount of methanol solvent. As a result, energy consumption for refrigeration and reboilers is reduced. On the other hand, the syngas flow rate in the polygeneration process is reduced compared to the single CTM process and coal-to-hydrogen for power generation process, and the amount of captured CO_2 is reduced. Thus, the energy consumption decreases to 0.7 GJ/t.

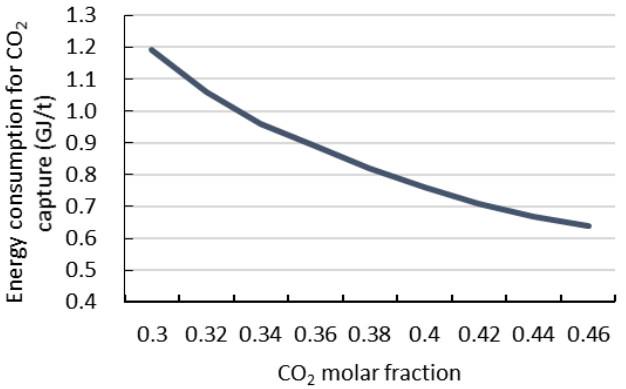

Figure 3. Energy consumption for CO_2 capture at different molar fractions.

4. Analysis of the polygeneration process

For analysing the polygeneration process, energy saving ratio ratio is the index for the analysis. This index is developed special for polygeneration process compared to pseudo single processes.

Energy saving ratio (ESR) is defined as the ratio of the differences between the single-product processes and polygeneation process to the single-product processes, as shown in Eq. (3) (He et al., 2012).

$$\mathrm{ESR} = \frac{E_{\mathrm{H,\,SG}} - E_{\mathrm{H,\,PG}}}{E_{\mathrm{H,\,SG}}} = \frac{\sum_{i=1}^{n}(E_{\mathrm{H,\,P}i} / \eta_i) - E_{\mathrm{H,\,PG}}}{\sum_{i=1}^{n}(E_{\mathrm{H,\,P}i} / \eta_i)} \tag{3}$$

where $E_{\mathrm{H,SG}}$ and $E_{\mathrm{H,PG}}$ represent the total fuel input based on higher heating value of the single-product processes and polygeneation process. $E_{\mathrm{H,Pi}}$ and η_i denote the higher heating value and energy efficiency.

The input-output material balance of the polygeneration process is listed in Table 1. Methanol output and power output are 75 t/h and 227 MW, consuming 200.7 t/h coal. Energy saving ratio is 16.5% according to Eq. (3). The power consumption of each unit is shown in Table 2. Compared to the CTM process, power is supplied by the combined cycle power generation unit in the polygeneration process instead of boiler, this contributes to higher energy efficiency. Due to less coal consumption, the production scale of the polygeneration process is reduced and therefore power consumption of each unit is reduced, especially the ASU. This leads to less energy consumption for methanol production. Moderate recycling of the unreacted syngas of methanol synthesis also contributes to the improvement of energy performance.

Table 1 Input-output of the polygeneration and the reference processes.

Item	CTME	CTM	IGCC
Input			
Coal (t/h)	200.7	147.1	93.4
Raw water (t/h)	570	375	309
Output			
methanol (t/h)	75	75	-
Power (MW)	227	-	227
Energy efficiency (%)	48.8	45	35.1
ESR (%)	16.5	-	-

Table 2 Energy consumption for the polygeneration process.

Unit	Electricity (MW)
Air separation	82.7
Gasification	4.3
Acid gas removal	25.1
CO_2 compression	8.3
methanol synthesis and distillation	17.5

5. Conclusions

In this work, we proposed a new methanol and power polygeneration process, aiming to reduce energy consumption for CO_2 capture. In this process, CO_2 capture is transferred from methanol production process to coal-to-hydrogen process to improve its molar fraction. Based on process modeling and simulation, energy consumption for CO_2 is calculated and energy performance is analysed. Main conclusions are as follows:

(1) The hierarchical conceptual design methodology is introduced to design the polygeneration process.
(2) Energy consumption for CO_2 capture is reduced from 1.18 GJ/t CO_2 in CTM process and 0.9 GJ/t in coal-to-hydrogen for power generation process to 0.7 GJ/t, showing advantage for CO_2 capture.
(3) The proposed polygeneration process presents 16.5% energy saving ratio.

Abstract

The initialization of process models for chemical engineering systems is often a challenge. While dedicated strategies exist for state of the art column models, novel models need to be initialized manually. In this contribution, we present a first application of these decomposition methods for supporting the initialization and solution of equilibrium- and non-equilibrium-type column models for distillation and compare them to well-known sequential solution methods for each. We show that these methods can supply viable solution procedures for nonlinear systems and are especially helpful in deriving new initialization techniques for novel process equipment.

Keywords: nonlinear system, initialization scheme, distillation, absorption.

1. Status Quo - Initialization and Solution of Column Models

State of the art process simulation tools feature dedicated initialization and solution schemes for distillation and absorption columns, and many other unit operations. Famous examples are Amundson and Pontinen's (1958) equation tearing method for equilibrium stage models, the sum-rates method tailored for absorption problems (Friday and Smith, 1964), etc. Of course, these methods have seen many evolutions over time and by now the inside-out methods (Boston and Sullivan, 1974) and their descendants are dominating the field of equilibrium-based column models.

1.1. Inside-Out Method for Column Models

The main advantage of the inside-out method lies in the introduction of an intermediate layer between thermodynamic calculations and the column model itself. This additional layer contains simplifying surrogate models for the phase equilibrium coefficients K and enthalpies h, which are successively retrained with complex thermodynamic models based on updated state variables from the column (J.D. Seader et al., 2011). The inside-out method requires the user to guess a temperature profile for the entire column and to estimate a vapor/gas flow for each stage. Based thereon the column model is split into an outer and an inner iteration loop. For the inner loop the stripping factors are taken as iteration variables ($S_{c,tr} = K_{c,tr} \cdot V_{tr} / L_{tr}$). In the outer loop calculations, the K and h correlations are then retrained and returned to the inner loop. Further details can be found in (R.A. Russel, 1983) and (J. Jelinek, 1988). The inside-out methods have proven so successful that they are nowadays implemented in most modern flowsheet simulators and applied for equilibrium and rate-based calculations of distillation, absorption, and extraction. Nevertheless, there are still many cases, in which solution schemes inside process simulators fail to reliably solve them. One example are complex

absorptions with electrolytes, which are difficult to initialize given the wide range of concentrations of all ionic species (Esche et al., 2014).

1.2. Initialization of Novel Models

For new unit operation models, tailored initialization and solution schemes usually become necessary and need to be implemented by the designer of each unit operation. Naturally, these steady-state models are systems of nonlinear equations and the main reason for not solving all equations simultaneously upfront lies in the ill-conditioning or in how bad a user-supplied initial guess is. In this contribution, we will investigate techniques from linear algebra to derive initialization techniques for nonlinear models. To benchmark these, their performance is compared against the inside-out method for the initialization and solution of column models.

2. Review of Methods in Linear Algebra

In linear algebra, several techniques are known, which by preconditioning, sorting of equations and variables, definition of loops, etc. improve the convergence of linear solution methods. Two famous examples are the Dulmage-Mendelsohn Decomposition (Dulmage and Mendelsohn, 1958) and the Bordered Block Transformation (Erisman et al., 1985).

2.1. Dulmage Mendelsohn / Block Diagonal Decomposition

The Dulmage Mendelsohn decomposition (DM) is a block diagonal decomposition, i.e. the nonzero elements of the Jacobian matrix are aligned along the main diagonal, so far that individually solvable blocks are created, which can be computed in sequence. This is achieved by permuting the original order of both rows and columns of the Jacobian. To this extent the DM decomposition can also be used to identify over- and underdetermined subsystems of a nonlinear equation systems. Further details hereon can be found in (Bublitz et al., 2017). The DM decomposition has two modes. In its “fine decomposition” the number of blocks along the main diagonal is maximized, leading to as small as possible subblocks. The block at the bottom right of the reorganized matrix needs to be evaluated first and then step by step each further block along the diagonal. The upper triangular section of the matrix contains additional occurrences of variables in equations, which are not sorted into any of these blocks. The respective variables are computed in prior blocks and have fixed values for their later occurrence. Several implementations of the DM decomposition are available. For this contribution, the implementation contained in (HSL, 2017) is used.

2.2. Bordered Block Transformation

Whilst the DM decomposition has the goal of a mostly empty lower triangular section of the Jacobian matrix, the bordered block transformation (BBTF) leads to a sparse upper triangular section. The system is split into a dense and a sparse part. The BBTF is a maximum matching algorithm, which primarily identifies variables, which appear in numerous equations. These variables appear as spikes above the main diagonal in the resorted Jacobian matrix. These spikes are subsequently moved to the right side of the Jacobian. Variables with few appearances on the other hand are sorted below the main diagonal. Similarly, equations with few variables are moved to the top left of the matrix. As a result, the BBTF lists variables with a great influence on the whole equation system, albeit from a linear perspective. The variables corresponding to the spikes are possible candidates for tearing the nonlinear system for an outer iterative loop. Therefore, initialization of these variables is essential and needs to be carefully done to

allow for successful solution of the whole nonlinear system. All other variables could theoretically be left uninitialized seeing that they are calculated in sequence by iterative solution of the resorted and teared system starting from the tearing variables. In this contribution, the BBTF is also taken from the Harwell Subroutine Library (HSL, 2017). As outlined above, the DM decomposition and the BBTF can be used to ease the computational effort for the solution of a nonlinear system, solely based on the structure of the Jacobian matrix. Given that the conditioning of the individual subsystems identified by DM decomposition or the BBTF-teared system with its corresponding subsystems cannot be worse than the conditioning of the entire nonlinear system, it can be expected that the solution strategies outlined above will show a better numeric performance than the equation-oriented solution of the original system. However, the question remains, whether these decompositions lead to better solution strategies compared to dedicated column algorithms, e.g. the inside-out method outlined above.

2.3. Implementation in MOSAICmodeling and Export to MATLAB

To support the application of both decompositions (DM & BBTF), they have been implemented in our department's equation-based modeling and code generation environment MOSAICmodeling (Merchan et al., 2016). Hence, initialization and solution sequences can be automatically generated for all equation systems implemented in MOSAICmodeling, which are tailored to the specific numerical needs of an individual system. To benchmark the solution strategies provided by DM decomposition and BBTF, all four different options have been implemented in MATLAB. As the baseline, the entire NLE model implemented in MOSAICmodeling is exported to MATLAB and solved with a standard Newton-Raphson algorithm. This solution path will subsequently be referred to as NR. The DM and BBTF options are similarly exported to MATLAB and the same Newton method is employed for the solution of all nonlinear subsystems. Finally, for the comparison against the state of the art column algorithms, an inside-out method is manually implemented in MATLAB, which also uses the same Newton method for all implicit, nonlinear solution steps on the inside. This will subsequently be referred to as IO. The resulting calculation sequences for DM, BBTF, and IO are sketched in Fig. 1.

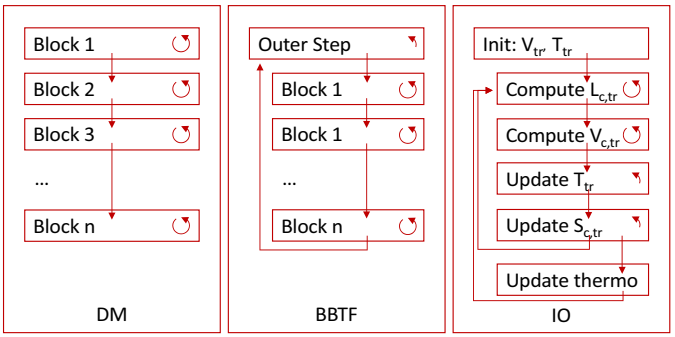

Figure 1: Graphical representation of calculation sequences based on DM and BBTF and for the implemented inside-out method. A full circular arrow implies a complete Newton-Raphson execution, a partial circular arrow depicts a single Newton step with dampening.

3. Case Studies

In this contribution two different applications of column models are investigated to benchmark the aforementioned implementations of DM and BBTF against an IO method and a basic NR algorithm.

3.1. Case Study 1 - Deisobutanizer

The first application is a distillation column for the separation of n- and i-butane. The column model consists of 20 trays using Raoult's law for the phase equilibrium and tray efficiencies based on DIPPR 102. Energy and molar component balances are formulated for each tray with enthalpies and densities based on further correlations from the DIPPR database (127 for enthalpy of vapor phase, 101 for the vapor pressure, 106 for the heat of evaporation, 105 for liquid phase densities). The model is further equipped with a total condenser and a common reboiler. The feed is positioned at stage 13 and consists of 40 % i-butane and 60 % n-butane. The pressure at the top of the column is set to 700 kPa and there is a constant pressure drop of 42 Pa per stage. Fig. 2 shows the incidence matrices of the distillation column model. As expected the DM decomposition (Fig. 2, left) shows a large block, which needs to be solved simultaneously. This block refers to the column itself and the interdependence of all trays given the countercurrent vapor and liquid flows. In any case, there is a sizeable reduction of the size of the largest sub-block compared to the overall system, by roughly 60 %. The BBTF (Fig. 2, right) generates a number of tear variables (spikes at the right above the main diagonal). Close inspection shows that these are temperatures on each tray and the vapor flows of i-butane leaving each tray. This is very similar to the guess values required by the IO methods, which demand temperature profiles and total vapor flow profiles entered by the user for the initialization of the IO procedure.

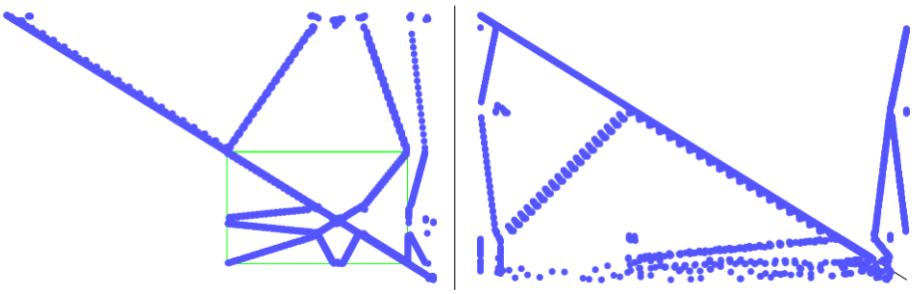

Figure 2: DM decomposition of the distillation column model (left) and BBTF (right).

For the subsequent case study the entire model is first of all manually initialized, i.e. all variables are given adequate guess values and then solved with the NR. The obtained solution is then used as a starting point for all further discussions. All state variables are then perturbed by ± 10, 20, and 30 % of their absolute values and the solution is then attempted with NR, DM, BBTF, and IO methods in turn. The results of this variation are summed up in Tab. 1. Apparently, the pure NR method has great issues with the variation of the initial points, which leads to large numbers of iterations and even failures to converge. The DM is coping better, despite the large block of equations it still has to solve simultaneously. Quite surprisingly the BBTF and the IO method show a highly similar behavior despite the fact that the IO performs a lot finer iterative computation compared to the BBTF with only two iterative layers. However, for both cases initializing temperature and vapor flows at reasonable values proved essential for

obtaining any solution at all, while the values of all other state variables can be left essentially uninitialized.

Table 1: Comparison of variation of initial point and its effect on the convergence of algorithmic solution methods of the deisobutanizer column in case study 1. For BBTF and IO the maximum number of iterations in inner (inn.) and outer (out.) iterations is given. For DM the maximum number of iterations in one subblock is given.

Variation	NR	DM	BBTF	IO
-30 %	failure	31 iterations	21 out. / 52 inn.	10 out. / 57 inn.
-20 %	failure	29 iterations	20 out. / 51 inn.	5 out. / 89 inn.
-10 %	4198 iterations	28 iterations	17 out. / 30 inn.	4 out. / 80 inn.
+10 %	4943 iterations	26 iterations	17 out. / 34 inn.	5 out. / 23 inn.
+20 %	failure	34 iterations	17 out. / 44 inn.	7 out. / 101 inn.
+30 %	failure	failure	19 out. / 68 inn.	7 out. / 75 inn.

3.2. Case Study 2 – Absorption Column

The second application is an absorption column for the removal of CO_2 from a flue gas stream using an aqueous solution of monoethanolamine (MEA) as scrubbing liquid. The column model has 35 theoretical equilibrium stages, which employ a tray efficiency correlation fitted to experimental data (Esche et al., 2014). Similarly, to the first example, molar component and energy balances are computed on each tray with correlations for enthalpies, heats of absorption, etc. The flue gas fed to the bottom of the column has a molar fraction of 18 % CO_2 and the liquid feed at the top a residual CO_2 load of 0.1 mol CO_2 per mol MEA. The column is operated at 2 MPa. The gas feed has a temperature of 20 and the liquid feed of 40 °C. Both models describe the same basic tray structure, the results regarding the decompositions are highly similar. For the individual absorption column, a large block will always remain based on DM. A slight change can be seen regarding the BBTF. Given that a ternary system is now in place, the tear variables change slightly: all stage temperatures and stage vapor flows for CO_2 an H_2O are recognized as important initials. Yet again, the model is initialized at a point close to the solution and then variations are carried out for the four different solution methods detailed above. The results are reported in Tab. 2.

Table 2: Comparison of variation of initial point and its effect on the convergence of algorithmic solution methods of the absorption column in case study 2 (same notation as in Tab. 1).

Variation	NR	DM	BBTF	IO
-30 %	107 iterations	21 iterations	15 out. / 60 inn.	3 out. / 77 inn.
-20 %	108 iterations	21 iterations	15 out. / 60 inn.	5 out. / 248 inn.
-10 %	86 iterations	20 iterations	14 out. / 60 inn.	5 out. / 82 inn.
+10 %	235 iterations	19 iterations	14 out. / 60 inn.	5 out. / 101 inn.
+20 %	727 iterations	21 iterations	15 out. / 60 inn.	5 out. / 52 inn.
+30 %	failure	529 iterations	15 out. / 60 inn.	4 out. / 56 inn.

The DM-based solution strategy outperforms the pure NR. Regarding the BBTF and the IO, variation of the initial temperatures for both by even 10% fails right away. Hence, the temperatures are initialized at reasonable values near the solution, while all other tear variables can be varied freely. For both latter techniques, the tear variables become absolutely essential for a successful solution. Of course, this is also a major advantage,

seeing that the set of variables to be initialized can be heavily reduced. It can be concluded that the maximum matching as implemented by the BBTF algorithm shows a reliable performance comparable to the IO method for complex column models. Seeing that the implementation of the solution strategy is quite straight forward based on the equation-oriented form of the nonlinear system, there is a clear advantage regarding novel, custom-made unit operations. The DM-based strategy appears robust and highly versatile for aiding in the solution, although more variables need to be initialized.

4. Conclusions and Outlook

The solution of nonlinear models remains an issue in chemical engineering. While dedicated solution strategies exist for common unit operations, these need to be designed for new models. Chemical engineering models can be reliably decomposed to improve their convergence compared to the monolithic solution with a single Newton-Raphson solver. In this contribution, we have presented an application of the DM decomposition and of the BBTF to find initialization strategies for custom unit operations. To evaluate their performance a comparison has been carried out against the inside-out method. The case studies of a deisobutanizer and of a CO_2 absorption column show the merit of the solution strategy in reducing the required effort on the initialization of all state variables. In future work, these decompositions are extended by new algorithms for maximum matching in nonlinear systems. In addition, the results of the decompositions will be made available inside MOSAICmodeling's user-defined language specification environment. Hence, the users will be able to design their own solution methods using the solution environment of their choice.

Numerical simulations on direct contact condensation of saturated vapor to subcooled liquid spray

Hengtao Ding, Yiqing Luo*, Yangmin Pan, Xigang Yuan

School of Chemical Engineering and Technology, Tianjin University, Tianjin 300072, China
luoyq@tju.edu.cn

Abstract

In the present study, computational fluid dynamics (CFD) simulations were carried out to investigate the direct contact condensation heat transfer of saturated steam to subcooled liquid spray, where the subcooled liquid was sprayed into the saturated steam through a pressure-swirl nozzle. The characteristics of spray hydromechanics with and without heat transfer were compared and analysed, including spray cone angle, sheet breakup length and sheet thickness. It was found that heat transfer had a great impact on spray cone angle and sheet breakup length but little effect on sheet thickness. And heat transfer coefficient in the sheet region was much higher than that in the droplet region, which indicated that the sheet region played the dominant role in the heat transfer process.

Keywords: CFD, direct contact condensation, heat transfer, pressure-swirl nozzle.

1. Introduction

Direct contact condensation heat transfer (DCCHT) of saturated steam to subcooled liquid spray has been of great interest to researchers for its application possibilities in modern industries. Pressure-swirl nozzles are usually used to spray the subcooled liquid into the saturated steam. The liquid emerges from the pressure-swirl nozzle, then forms an annular sheet (sheet region) and finally breaks up into fine droplets (droplet region).

Experimental researches had been carried out in the past to investigate the heat transfer mechanism in the sheet region and droplet region. Weinberg (1952) studied heat transfer process in the sheet and droplet regions experimentally. It was reported that the ratio of temperature rise in the sheet region was 73~93 % of the entire heat transfer region. Takahashi et al. (2001) studied the condensation heat transfer of saturated steam to a hollow-cone spray experimentally. They found from their experiments that the heat transfer coefficient in the sheet region was significantly higher compared to that in the droplet region. It had been commonly accepted that dominant heat transfer took place in the sheet region. However, in the experimental study of Mayinger and Chavez (1992) for the direct contact condensation of refrigerant R113 spray with saturated vapour at higher pressure, it was found that temperature rise of the spray in the sheet region was not more than 50%.

Previous studies showed differences on the heat transfer coefficient of the spray. The differences can be explained by that each study had used different nozzles and operating conditions affecting the sheet and droplet behaviours substantially. Besides, the real-time temperature field measurement can’t be achieved and the flow field was affected by measuring equipment. Therefore, the mechanism of DCCHT was still limited due to the

poor repeatability and complex characteristics of the fluid flow. However, it is obvious that CFD numerical simulation can avoid these problems. Ibrahim (2006) performed simulations on the hollow-cone sprays produced by pressure-swirl nozzles. The comparison between the predicted and measured breakup length showed a good agreement. Mandal et al. (2008) studied the effect of nozzle geometry parameters on the external flow characteristics. The simulation results were proved to predict the isothermal two-phase flow through a pressure-swirl nozzle with reasonable accuracy.

During the last few decades, the internal and external flow characteristics of the pressure-swirl nozzle had been studied experimentally and numerically. Considerable effort had been made to study the initial sheet breakup process and spray evolution without heat transfer and phase change. However, there has been a lack in the CFD models to simulate the condensation phenomena in the spray process, which more often than not occurs between the gas-liquid countercurrent flow in industrial processes. In order to clarify the heat transfer mechanism and develop the heat transfer theory with phase change. It is significant to do research on DCCHT numerically.

The primary intention of this work is to develop a CFD based model that allows the predictions of heat and mass transfer as well as gas-liquid interface in the DCCHT. The heat and mass transfer due to phase change were modelled by adding the suitable source terms in the energy and continuity equations. The temperature contours and spray characteristics were predicted using the established CFD models. The results were compared to the experimental data reported by Takahashi et al. (2001). The heat transfer mechanism in the sheet and droplet regions was discussed and interpreted through CFD predictions and experimental results.

2. Computational domain

Figure 1 shows the geometry of the pressure-swirl nozzle studied in the present work.

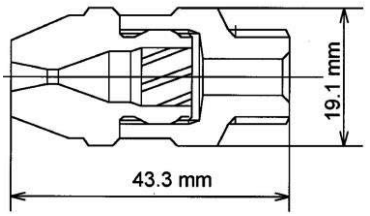

Figure 1: Hollow-cone spray nozzle

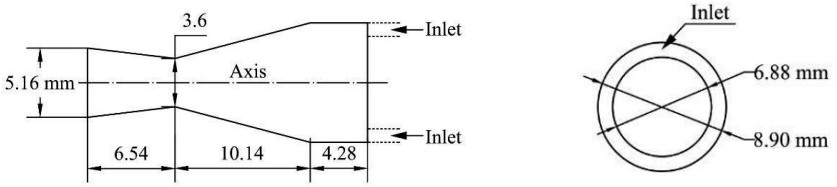
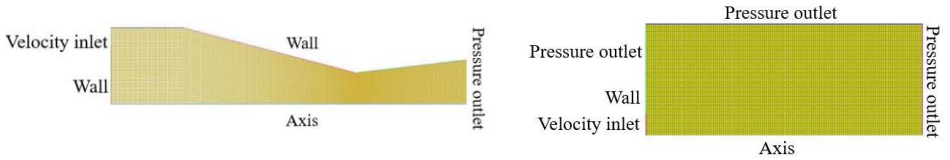
Because of the centrosymmetric structure of the pressure-swirl nozzle, the equivalent model was established as shown in Figure 2, which was used as the computational domain of the internal nozzle flow field. In addition, a cylindrical space with a height of 40mm and a radius of 16mm was determined to be the external flow field of the nozzle.



(a) Front view (b) Top view

Figure 2: Equivalent model of the nozzle

The software package ICEM 15.0 was used to generate rectangular mesh in the computational domain as shown in Figure 3. Based on the assumption that the internal and external flows of the nozzle were spatial symmetry, computational domains were set in 2-D axisymmetric models. In the velocity-inlet of the internal flow field, the volume fraction of the water was 1 and the velocity of the water stayed constant. The pressure was specified to atmospheric pressure and the temperature was 373.15 K in the pressure-outlet.



(a) Internal flow field (b) External flow field

Figure 3: Computational domain

3. CFD model

In the current study, the volume of fluid (VOF) model was used to model the multiphase flows in the DCCHT. The results of the momentum and energy equations were shared among phases. The tracking of the gas-liquid interface was accomplished by solving the volume fraction equation for the secondary phase (liquid phase):

$$\frac{\partial}{\partial t}\left(\alpha_l \rho_l\right)+\nabla\cdot\left(\alpha_l \rho_l \vec{v}_l\right)=\dot{m}_{vl}-\dot{m}_{lv} \tag{1}$$

Lee (1979) developed an evaporation-condensation model for the mass transfer between phases. Based on the assumption that the phase change occurs at a constant pressure and at a quasi thermo-equilibrium state, the mass transfer, as shown in the right side of Eq (1), can be described as follows:

Evaporation:

$$\dot{m}_{lv}=C_1\alpha_l\rho_l\frac{T_l-T_{sat}}{T_{sat}} \tag{2}$$

Condensation:

$$\dot{m}_{vl}=C_2\alpha_v\rho_v\frac{T_{sat}-T_v}{T_{sat}} \tag{3}$$

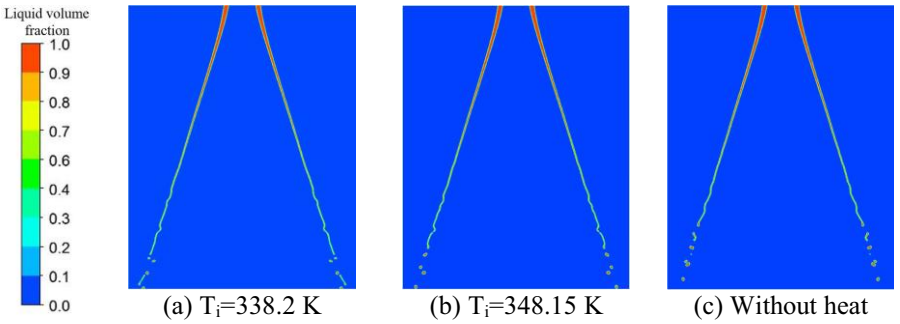
Where C is the so-called Lee model coefficient. Determination of the coefficient C requires the expressions for the interfacial temperature and the volumetric interfacial surface area of the liquid sheet. However, it is difficult to determine the volumetric interfacial surface area due to its dependence on the interfacial structure and phase change. The value of C must be fine tuned to numerically maintain the interface temperature within $T_{sat} \pm 1$ K. In the present study, C_1 was set to 0 and C_2 was set to 100. The source term in the energy equation can be obtained by multiplying the rate of mass transfer by the latent heat due to condensation.

The CFD analysis presented in this study was completed by ANSYS FLUENT version 15.0 using a pressure-based solver. In order to reach a low-resource-consumption

numerical calculation, the internal and external flow fields were calculated separately. The numerical results of the nozzle outlet boundary condition were used as the inlet boundary condition in the calculation of the external flow field.

4. Results and discussion

The external flow fields predicted by the CFD simulation with different water inlet temperatures T_i and without heat transfer are plotted in Figure. 4. It is measured that the spray cone angles are 34.6 °, 36.2 ° and 37.2 ° for water inlet temperature T_i of 338.2 K, 348.2 K and the case without heat transfer respectively. The corresponding measured spray cone angles from experiments (Takahashi et al., 2001) are 37.4 ° and 39.6 ° for water inlet temperature T_i of 338.2 K and 348.2 K. The relative errors between simulations and the experiments are 7.5 % and 8.6 %. It is found that spray cone angle increases with the increase of T_i.



(a) T_i=338.2 K (b) T_i=348.15 K (c) Without heat

Figure 4: Liquid volume fraction contour

The sheet breakup length is determined from the corresponding liquid volume fraction contour shown in Figure 4. The simulated sheet breakup length is 33.0 mm (without heat transfer), which is approximately the same as 33.2 mm predicted from the empirical correlation of Lee et al. (1984). In addition, sheet breakup length decreases from 35.4 mm to 34.3 mm when T_i increases from 338.2 K to 348.15 K.

As shown in Figure 5, the sheet thickness of T_i = 338.15 K is slightly higher than that without heat transfer. This is possibly because steam is condensed into liquid and then result in a small increase in the sheet thickness. However, both the two cases indicate that, as the sheet move downstream, it becomes thinner due to the steam shear exerted on the sheet.

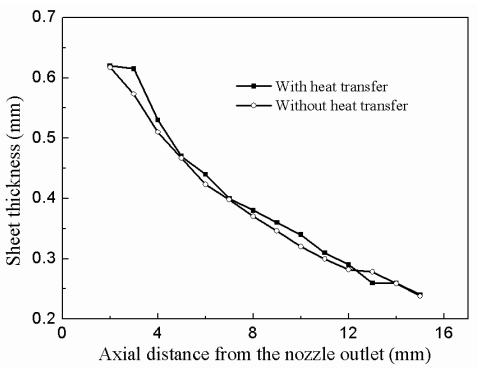


Figure 5: Profile of sheet thickness along the flow direction

Comparisons between the simulated and the measured radial temperature profiles from the thermocouples (Takahashi et al., 2001) have been performed in Figure 6. The mean deviation for temperatures at the center of the sheet is below 1.8 % with a maximum deviation of 2.8 % at x =20 mm. It can be found that with the increase in axial distance, the simulated and measured temperature profiles are broader. Overall, the temperature profiles obtained with the CFD model agree well with the experimental data. However, differences in the radial locations of the sheet can be found at the vicinity of the nozzle outlet. In the simulations, the resistances of the nozzle wall and steam on the liquid spray are not considered. As a result, the simulated radial locations of the sheet are larger than those in the experiments.

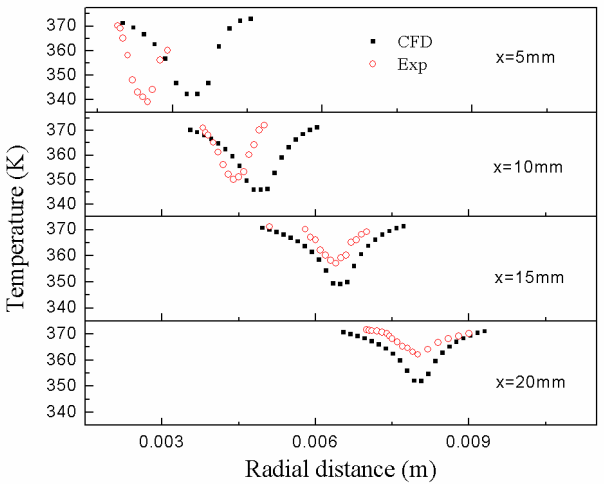

Figure 6: Comparison of the simulated temperature profiles with experimental data at various axial distance (x) from the nozzle outlet

The simulation results for the local heat transfer coefficient and the dimensionless temperature are shown in Figure 7. The local heat transfer coefficient decreases with the increase of the axial distance. It is obvious that the heat transfer coefficient in the sheet region is comparatively higher than that in the droplet region. The present data of sheet dimensionless temperature $(T-T_i)/(T_{sat}-T_i)$ where the sheet breakup is about 0.60, which means 60 % of heat transfer has been achieved in the sheet region. That is to say, dominant heat transfer takes place in the sheet region, even though the length of the sheet is small.

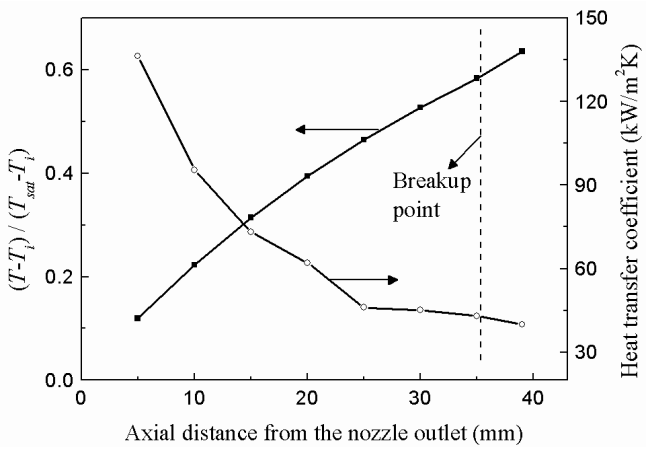

Figure 7: Variations of dimensionless temperature and heat transfer coefficient along the flow direction

5. Conclusion

A two-dimensional CFD model was developed to simulate the DCCHT. External flow characteristics of the pressure-swirl nozzle, as well as its performance parameters including spray cone angle, sheet breakup length, sheet thickness, temperature variations and heat transfer coefficient, were predicted. The computational model was verified by comparisons with experimental measurements and a good agreement was obtained. It was concluded that heat transfer in the sheet region was much more efficient than that in the droplet region. For the direct contact between the liquid spray and steam without heat transfer, results showed that sheet breakup length and sheet thickness were smaller while the spray cone angle was higher compared with DCCHT.

Abstract

Loop tearing is a conventional problem to solve in process simulation. Upadhye-Grens algorithm provided a solution to identify the family of all available tearing sets. However, the random starting point and unit-wise substitution may require more searching steps. In this work, information on both loop-stream and unit-stream are considered, and a logic matrix minus is defined and applied to replace the substitution based on individual unit in Upadhye-Grens algorithm. By utilizing the information on loop-stream in a loop matrix, the first non-redundant tearing set is easily identified. By defining a unit-stream matrix, the substitution in the improved algorithm is achieved by logic based matrix calculation, which could effectively speed up the identification of the family of all available tearing sets, as the substitution is simultaneously conducted at the process scale instead of simply unit-by-unit. In order to verify the proposed algorithm, an industrial process simulation is considered as an example. The searching process and result are compared with those obtained in Aspen plus.

Keywords: unit-stream matrix, logic minus for matrix, tearing algorithm

1. Introduction

Chemical process simulation technique is playing an important role in modern chemical process engineering design. Due to the inherent characteristics of chemical process, process model usually appears as a huge, sparse and nonlinear equation set, which is the key challenge for process simulation. Generally, all simulation problems can be converted into a series of sub-equation groups in certain order. It will get complicated when one or more recycle-loops (to be termed as "loop") exit in proposed process topology, where one or more starting points have to be identified first, called a tearing set. It has been proved that the convergence property depends on the selection of tearing sets (Gossner et al., 2003). Therefore, the efficiency of such a complex process simulation can be significantly influenced by the choice of the tearing sets.

Sargent and Westerberg (1964) proposed the computing time as a standard to evaluate the tear algorithm. An effective algorithm based on dynamic programming method was proposed by Upadhye and Grens (1972). In their later work (Upadhye and Grens, 1975), the non-redundant tearing set was defined to avoid repetitive tearing streams, and a

substitution rule was employed to identify all non-redundant sets. Subsequently, Westerberg (1979) proposed an algorithm to find an optimal tearing set based on the substitution rule. According to Yang and Ma (1988), the improved algorithm of Motard and Westerberg (1981) has been implemented in Aspen plus.

In general, the optimal tearing set should be at least a non-redundant tearing set and can be easily recognized if all the non-redundant tearing sets are identified, i.e. the non-redundant tearing family. Hence, after one of non-redundant tearing sets is found, it is easy to find all others, since all the non-redundant tearing sets are replaceable. Therefore, it is important to find the first non-redundant tearing set. However, for conventional Upadhye-Grens algorithm, it could be quite time consuming, when starting from a random valid tearing set, especially, when more units are included in one loop, where substitutions have to be conducted unit by unit, as the substitution rule is run in route, depending on the length of process system.

For a system with several loops, the information of loops and streams can be described by loop matrix, which consists of streams as columns and loops as rows. Topological information among streams are stored in a loop matrix and the redundant stream can then be easily identified via loop matrix. For the tearing of a loop, the concept of dependent stream was proposed by Lee (Lee et al., 1966), which is used to simplify calculations. However, in this approach, the logical relationship of unit-stream has not been considered, and the streams are simply removed.

In our work, a process topology information based algorithm is proposed. The tearing performance of the proposed algorithm is compared with that obtained from Aspen Plus for an industrial process.

2. Algorithm

2.1. Definition

A process system, as shown in Fig.1, is considered as a conceptual example, based on which definitions are given for the description of proposed algorithm.

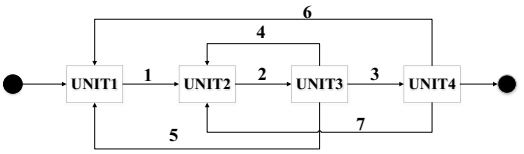

Figure 1 A simple process system

Loop matrix: It is a matrix with stream *j* as column and loop *i* as row, [a_{ij}]. If a loop *i* includes a stream *j*, the element in the loop matrix a_{ij}=1, otherwise a_{ij}=0. In the case of above, the loop matrix could be given as in Eqn.(1):

$$\begin{array}{c} \\ LOOP1 \\ LOOP2 \\ LOOP3 \\ LOOP4 \end{array} \begin{array}{c} \begin{array}{ccccccc} 1 & 2 & 3 & 4 & 5 & 6 & 7 \end{array} \\ \begin{bmatrix} 0 & 1 & 0 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 1 \end{bmatrix} \end{array} \tag{1}$$

Unit-stream matrix: It is defined as a matrix that shows streams information of output and input for every unit in a process, in which, column *j* is referred as stream and row *i*

corresponds to a loop. There should be n rows included in this incidence matrix for a process with n units [U_{ij}]. For a U_{ij}, the element for input stream is represented by 1, and that for output stream is represented by -1. In the case above, the unit-stream matrix could be given as in Eqn.(2):

$$\begin{array}{c} \\ UNIT1 \\ UNIT2 \\ UNIT3 \\ UNIT4 \end{array} \begin{array}{c} \begin{array}{ccccccc} 1 & 2 & 3 & 4 & 5 & 6 & 7 \end{array} \\ \begin{bmatrix} -1 & 0 & 0 & 0 & 1 & 1 & 0 \\ 1 & -1 & 0 & 1 & 0 & 0 & 1 \\ 0 & 1 & -1 & -1 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & -1 & -1 \end{bmatrix} \end{array} \tag{2}$$

Logical loop matrix minus: It is a logical operation, and can be implemented through the following three steps:

Step1. Give a valid stream-tearing set [X_k] for a process, in which the stream is torn if corresponding element is assigned to 1, otherwise to 0, i.e. it means that stream 2, 3, and 5 consist a valid tearing set if [X_k] is represented as [0 1 1 0 1 0 0].

Step2. Deduce every row of unit-stream matrix ([U_{ij}]) from the stream-tearing set [X_k] to obtain a new matrix with same size of [U_{ij}]. The element obtained in the new matrix [U_{ij}] can be -1, 0, 1, and 2. These elements have their specific physical meaning. If the element is -1, it means that the stream cannot be substituted via this unit, thus, the corresponding row shall be removed. If the element is 2, it means the stream is torn twice, the element shall be reset as 1. It can be seen that the element value is again either 0 or 1 in obtained matrix.

Step3. Put all obtained stream-tearing vectors together into matrix [Y_{ij}], keep all records of output [Y_{ij}].

The process of logical loop matrix minus is shown in Fig.2.

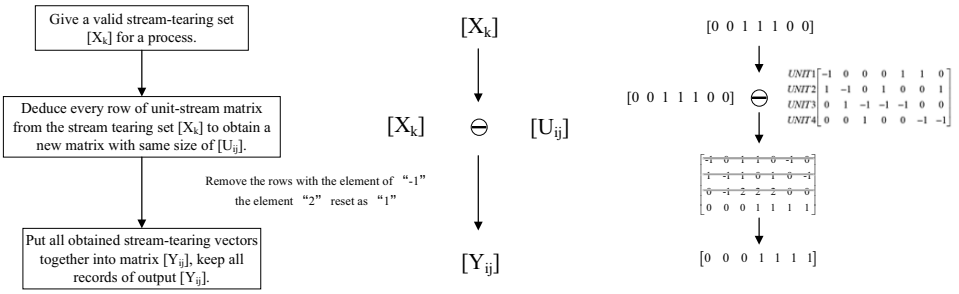

Figure 2 The schematic for logical loop matrix minus and an example

2.2. Method for identification of non-redundant stream tearing family

Given a process with a specified loop matrix and a unit-stream matrix, the non-redundant stream tearing family can be obtained through the following steps.

Step1. Randomly select a tearing stream in each row of loop matrix, to obtain a valid stream-tearing set, [X_k].

Step2. Check if there is a dependent stream among elements in the valid stream-tearing set, [X_k], obtained in Step 1, according to the loop-stream information described in loop

matrix, and set 0 to the element in $[X_k]$ corresponding to the dependent stream in the loop matrix, to obtain a new $[X_k]$.

Step3. Compare $[X_k]$ with each row in loop matrix $[a_{ij}]$, to see if there is a loop torn more than twice. If so, conduct a logical loop matrix minus between $[X_k]$ and unit-stream matrix, then perform Step 2 for each row; otherwise, go to Step 4, and in such case, the first non-redundant tearing stream set is obtained.

Step4. Conduct logical loop matrix minus, keep record of all rows in $[Y_{ij}]$ in the form of row vector.

Step5. Repeat Step 4 for each row vector in $[Y_{ij}]$ until the same non-redundant tearing stream set is obtained again. Collect all non-redundant tearing stream sets obtained from the row vector of $[Y_{ij}]$, i.e., the non-redundant tearing stream family. Stop searching if all row vectors in $[Y_{ij}]$ obtained in Step 4 have been considered. Put all non-redundant tearing stream sets together to form an overall non-redundant family for the process.

The corresponding block diagram is shown in Fig.3.

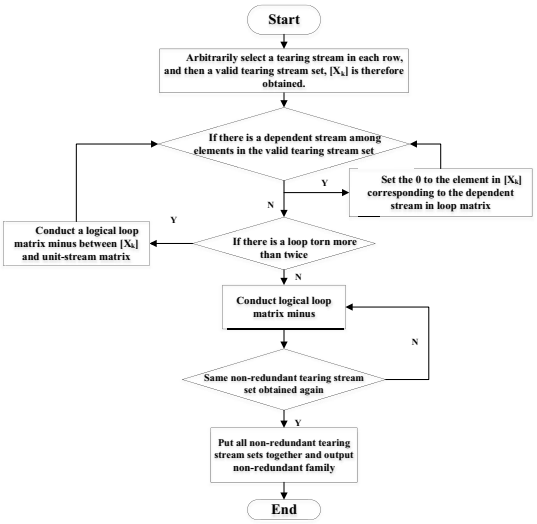

Figure 3 Algorithm block diagram

3. Application

3.1. A simple block diagram and discussion

The algorithm is applied to identify a tearing family for the process shown in Fig 1. The loop matrix and unit-stream matrix are given in section 2.1.

A valid tearing set can be obtained randomly for the system. For example, $[X_k]$ (3, 4, 5, 6) is a valid tearing set. It can be seen that stream 6 is a dependent stream relative to stream 3. Therefore, a new row $[X_k]$ (3, 4, 5) = [0 0 1 1 1 0 0] can be obtained.

In the Step 4, the stream tearing vector $[X_k]$ can be considered as non-redundant tearing set. Then, the process of logical loop matrix minus is calculated by proposed algorithm.

Finally, an overall non-redundant family can be obtained from the recorded row vectors. Non-redundant family: (3, 4, 5), (4, 5, 6, 7), (1, 4, 7) and (2).

For further discussion, an extreme starting point (1, 2, 3, 4, 5, 6, 7) is investigated. By the proposed algorithm, the non-redundant set (2) is obtained in one loop iteration. By contrast, at least three loop iterations are need to reach a non-redundant set by Upadhye-Grens algorithm for which the times of loop iterations are influenced by the choice of initial valid tearing sets. In the proposed algorithm, the introduction of stream-loop information allows the simultaneous consideration of both stream-unit and stream-loop, which makes the iteration is no longer completely conducted unit by unit along in the process. Consequently, the searching for the first non-redundant tearing set can be simplified significantly, and the initial value sensitivity can be reduced.

The algorithm is also applied on the well-known Cavett process (Cavett, 1963) to test the applicability of proposed algorithm. Details are not given because of the page limit. Compared to the conventional Upadhye-Grens algorithm, a non-redundant tearing set is obtained in less loop iterations, therefore, searching time is significantly reduced.

3.2. Application to an industrial process

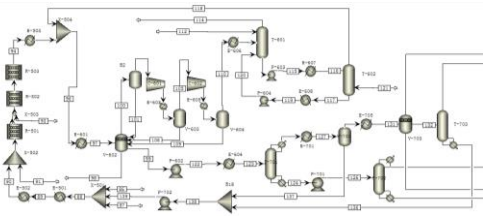

Figure 4 Flowsheet for an industrial process for the production of styrene through dehydrogenation of ethylbenzene dehydrogenation drawn in Aspen plus.

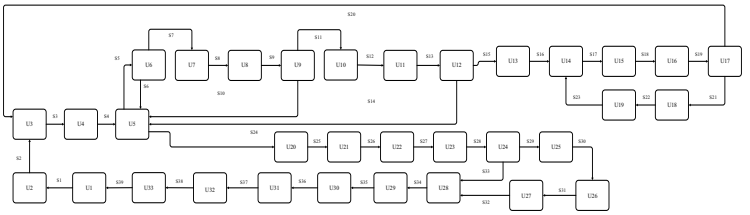

Figure 5 A simplified block diagram of the styrene production process

Figure 4 shows the flowsheet of an industrial chemical process where 250kt/y ethylbenzene is dehydrogenated to styrene. The proposed algorithm is tested on this process flowsheet. As shown in Figure 5, it is difficult to get the first non-redundant tearing set directly. The calculation results are obtained by proposed algorithm and compared with the result from Aspen plus.

A tearing set given by Aspen plus is (S5, S23, S34), which is similar to the first non-redundant tearing set (S5, S23, S27) we calculated by cutting all the streams in the process as the starting point. According to the process topology, they are equivalent in terms of the convergence in direct iteration in process simulation. Given the information available in the block diagram, it is hard to tell which one is better in simulation, therefore, another non-redundant tearing set (S5, S23, S39) is arbitrarily picked for comparison purpose. Process simulation is conducted with three tearing sets as the starting point respectively. The number of iterations needed to reach the convergence for each starting set is listed in Table 1. It can be seen that the least number of iterations is required when non-redundant

tearing set (S5, S23, S34) is adopted, which indicates that the one given by Aspen plus is not the best choice at least for the iteration algorithm employed by Aspen plus itself. With more stream information, the better or optimal tearing set can be easily identified based on the proposed algorithm.

Table. 1 No. of iterations required for three non-redundant tearing sets of Aspen plus

Non-redundant tearing set	No. of Iterations
S5, S23, S27	78
S5, S23, S34	112
S5, S23, S39	122

4. Conclusion

By introducing the topology information in a loop matrix and a unit-stream matrix, the non-redundant tearing sets can be identified more efficiently, compared to the Upadhye-Grens algorithm. Similar tearing sets are obtained with a default setting provided by Aspen plus, which shows the feasibility of proposed algorithm for the simulation of any chemical process. It has been noted that the optimal tearing set can be easily identified from the recognized non-redundant tearing sets by the proposed algorithm by providing more information on the units and streams of the flowsheet.

Abstract

Modelling residential water consumption is an important step towards knowledge about users' behaviour and later for the proposition of realistic goals that lead to the conscious consumption. The flows provided by smart meters facilitate the in-depth analysis of consumption and then it is possible to classify them into certain appliances using pattern recognition techniques. The research was conducted in low-income and "social interest" homes in Salvador, Brazil. The objective of this paper is to evaluate similarity measures using an adaptation of 1-nearest neighbour algorithm and to verify which stands out as a suitable option to classify disaggregated residential water flow. The measures chosen were dynamic time warping (DTW), longest common subsequence (LCSS), edit distance on real sequences (EDR) and edit distance with real penalty (ERP). It is also performed parameters optimization of each similarity measure to improve the classification accuracy.

Keywords: water flow, households, pattern recognition, similarity measures.

1. Introduction

Problems such as population growth, water pollution, urban disorderly development, intensive agricultural irrigation, climate change, degradation of spring areas and droughts contribute to disparities between the availability of quality water sources and consumption demand. In view of the above, a deeper understanding of residential water consumption is important tool for improvement of demand management strategies. Knowledge about how and when water is used can inspire viable solutions to decision makers facing water scarcity problems. In addition, the better management of water resources may indirectly influence the amount of energy needed for treatment of the sewage and reduction in the environmental impact caused by the discharge of the effluents in an inadequate manner.

The great availability of fresh water is a notable characteristic of Brazil, however, it is unevenly distributed (ANA, 2016). This study was carried out in the city of Salvador located in the northeast of Brazil, focusing on low-income households. In the socioeconomic aspect, they represent an expressive part of the population of Salvador and of the northeast of Brazil. The study of water consumption took place through the installation of smart meters and data loggers in some the residences.

The information coming from smart meters benefits the studies related to the characterization of indoor water consumption (NGUYEN et al., 2014; LIU et al., 2016). These are high-resolution electronic devices capable of measuring the consumption of water, energy or natural gas in short time intervals, jointly with equipment for almost instantaneous capture of emitted signal. The data collected provide detailed time series of consumption and it is possible to identify used appliances, through the application of a method for both consumption breakdown and pattern identification.

For low-income population, most of the appliances are taps (kitchen, bathrooms and outdoor area), showers and toilets. These devices depend exclusively on human handling and consequently it is associated to culture, water availability, plumbing and the level of awareness of proper water use. In addition, since the types of appliances is limited, they end up accumulating several functions, contributing to increase variation of duration and volume for the same type of equipment. Given the non-homogeneity of the data, it is necessary to develop a method that embraces this variability, without losing the quality of the classification. Among the techniques analysed, we propose a comparative study of similarity measures throughout an adaptation of 1-nearest neighbour (1NN) algorithm. The distances chosen were DTW, LCSS, ERP and EDR. According to Wang et al. (2013), the benefits in this type of approach using 1NN classifier are the ability of evaluate directly the efficacy of them since the performance of 1NN relies on the chosen distance and the simplicity of the algorithm that do not require parameter estimation.

The aim of this paper is to evaluate the selected similarity measures, using adapted 1NN algorithm, and to choose the one that presents the best potential to perform residential water flows classification. They will be tested in steps that includes use of prior restriction of equipment to be tested based on flow's volume and duration, parameter evaluation of each measure in order to find theirs optimal versions and establishment of a threshold to proper assign the water use into the chosen appliance.

2. Method

2.1. Similarity measures for time series

Berndt and Clifford introduced the DTW distance (KEOGH et al., 2005) in order to allow a time series to be "stretched" to provide a better combination with other time series. It is a widely employed and it makes use of distance L1 (also known as Manhattan) as the cost between elements. The EDR (CHEN et al., 2005), ERP (CHEN et al., 2004) and LCSS (VLACHOS et al., 2002) are adaptations for numerical series of the edit distance. It comes from string comparison field and computes the number of insertion, deletion and/or substitution operations that are required to make two series, of different possible lengths, identical to each other. The EDR looks for the minimum number of operations required to transform one series into another and removes noise effects by quantifying the distance between a pair of elements in two possible values: 0 and 1 (LCSS also performs the same quantization). The ERP uses a constant g to quantify the possible gaps in the time series and uses the distance L1 as the cost between the elements. The LCSS computes the distance between the series x and y, searching for the largest sequence in x that can also be found in y, that is, as the name itself says, seeks to find the longest common subsequence (not dealing with substitution operation). It has also a peculiarity, the biggest sequence does not depend on consecutive terms, they just need to occur in the same order (do not consider gaps). The

DTW and LCSS do not follow the triangular inequality and therefore are not metric distances.

The choice of the similarity measure demands that it can capture the dynamics between the time series and perform the classification in a coherent way. Wang et al (2013) presented an evaluation, among other techniques, of similarity measures (with those under evaluation here) by applying them in 38 real databases. One of the conclusions is that as the size of the database increases, the convergence between elastic measures and Euclidean's distance accuracies also increases. In addition, the LCSS, EDR and ERP presented accuracies very close to the DTW and they presented the best results in comparison with the elastic measures addressed.

2.2. Parameter optimizations

The best measure evaluation also depends on the choice of the best parameters through: limitation of the deformation window, minimum distance between two elements and gaps penalty (WANG et al., 2013, KURBALIJA et al., 2014). The limitation of the deformation window (local and/or global constraints) prevent misalignment, slightly accelerates the calculation and can be applied via methods suggested by Sakoe-Chiba, Itakura, among others. The minimum distance between two elements can be varied through the parameter ε for LCSS and EDR. For the ERP, the parameter g has the role to penalize the gaps and is adjustable however, the zero value is appropriate because it is a reference with the horizontal axis of the Cartesian coordinate system (CHEN et al. 2004).

3. Model construction

3.1. Collected data

The database used came from two projects CT-HIDRO (Sectorial Fund for Water Resources) and PROSAB (Basic Sanitation Research Program). The first had the period monitored from December 2010 to January 2012, and analyses intra-households water consumption of two residences in level of end-uses by flowmeter record and disaggregation of consumption using Trace Wizard® software. An important information is that one of the families move out from the house and another one started to reside, towards to end of the project. The new family agreed to continue the research and since they presented another behaviour of water consumption, three residences were considered instead of two. The second project occurred between December 2012 and April 2014, was monitored seven residences with the same methodology to obtain data. The flowmeter resolution was of 0.1L/pulse measured in 10s intervals. During recorded data period occurs a week period to investigate water consumption patterns, in first project these identifications were made with the residents help (by notes with time of consumption and appliance utilized) and in second project was utilized simplified flowmeters attached on each appliance of household. Trace Wizard® software processed these data, splitting simultaneous uses and classifying single uses. Thus, for the evaluation of this method, previously classified consumption data were used.

3.2. Initial tests

Initially, it was studied the application of prior restrictions to limit the number of equipment to be tested. In the model unrestricted (MUR), each unknown time series to be classified was compared with all references of each equipment. With the restriction (MR), duration and volume of time series were used to define which appliances should

be selected for the classification step. The volume and duration criteria were chosen because it is expected these information to be representative of each appliance and therefore to lead to the correct match. If at least one of these criteria fit, the equipment was chosen. Hence, this form of choice is very flexible, since the focus is the reduction of computational time. In general, the usages of taps in bathrooms and kitchen have very similar behaviours and they are therefore easily confused. Thus, they were simplified as taps.

After the initial tests, the most promising models went through parameter optimization step. The parameter ε (LCSS and EDR) suffered a variation with range from 0ml/s increasing in 10ml/s until 30ml/s. The parameter g (EDR) did not suffer modification. The local constraint used was established for Sakoe-Chiba and the chosen were trivial case of no constraint (NC), symmetric with slope constraint condition P=0 (SP0) and asymmetric with P=0 (ASP0). The global restrictions can be applied to all measures evaluated here. However, the size of the window is a function of the length of the time series and since there is a wide variety of lengths, the values must be large to avoid errors. Knowing that there is no limit to the size of the time series, the use of global restrictions becomes unfeasible. At the end of this phase, the final result will be calculated by choosing the most promising model and measures from the initial tests.

4. Preliminary results

4.1. Initial tests

The overall results are in figure 1. The columns indicate the accuracy for the tie results and in this case, it is the maximum value that can be reached, requiring one or more classifications steps to select a single class. The area graph show the accuracy for water flows classified to a single appliance. The line indicates the percentage of the tie results per model per distance. The first point of the analysis is the percentage of tie results and it is required that the value is near zero thus not requiring new classifications steps. Second, the accuracy of the single results is also an important factor and the results show that MR has present less tie results, but MUR is better in accuracy. The next analysis was performed by evaluating the classification in equipment level.

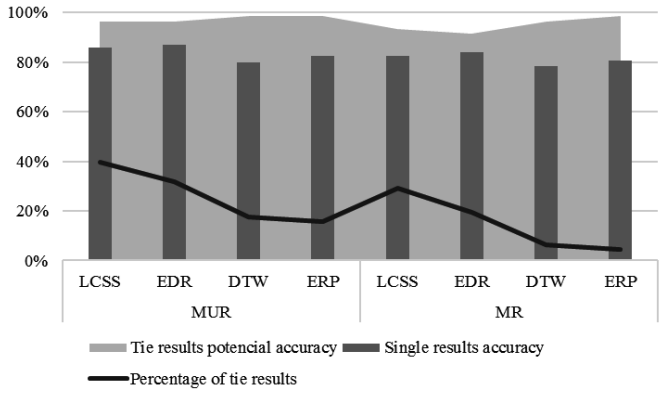

Figure 1 - Overall results of the suggested models.

The results (figure 2) relate the models with the similarity measures and the accuracy by equipment, disregarding the tie results. For both models, the EDR and ERP present in

general the best accuracies. The EDR and ERP have similar form to calculate the distances and because of this, the results are similar; the best outcomes happen mostly without restriction. The LCSS, in searching for the longest common subsequence without taking into account the gaps, has greater possibility of confusing appliances since there are large variability of user's behaviour. For the DTW, the restriction application seems to lead to the correct answer but the classification percentage is lower than the ERP and EDR.

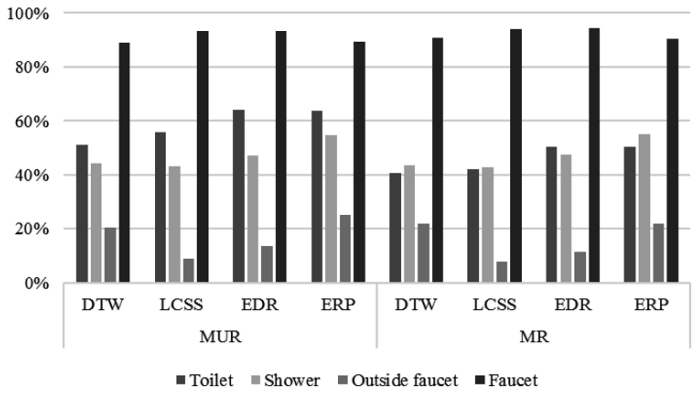

Figure 2 - Accuracy in equipment level.

According to the results, the contribution of the constraints is not clearly positive. Due to this problem, an evaluation of the pre-selection efficiency was carried out and the results indicate that 65% of the outside taps were pre-selected correctly; for the others, the correct pre-selection was higher than 74%. These values limit the accuracy and since the imposition of restriction criteria has the main function of optimizing the computational time, the next step was to perform parameter optimization using MUR.

4.2. Evaluation of measures parameters

The evaluation of the parameters measures variation occurs in the same way that initial tests. For the LCSS, as the threshold ε increased, an increasing of the percentage of tie results was also observed, with variations between 40% and 60%; in addition, there was a slight increasing in the accuracy of the single results. The EDR, which went through the same variation as the LCSS, initially had 31% of tie results and rose to 50%. For both, these variations barely affect the accuracy. With the DTW, the percentage of tie results was very low for SP0 and NC, about 17%, and their accuracy is inferior to the others. Based on all prior information, the final step was test data using EDR with ε = 10ml/s and ERP, in a MUR model.

The classification accuracy was also attributed to the diversity of flow references. Consistently, the faucet is the equipment that holds the highest percentage of flow references, followed respectively by the toilet, shower and outside faucet. This difference in quantities is associated with the frequency of equipment usage, suggesting that for those with low frequency it is necessary more time for data collection. Thus, it is suggested an increase in the flow references. However, this also causes an increasing in computational time.

5. Conclusions

The initial evaluation of the chosen similarity measures combined with adapted 1NN showed that there is an interesting potential of good results. The unrestricted model proved to be the ideal. The accuracy of each similarity measure pointed to interesting features of the modelled data. The LCSS demands homogeneity inside groups, and since the database has a heterogeneity characteristic, its tie results were high. The other measures presented acceptable performance, especially ERP and EDR. The variation of ε showed that, for LCSS and EDR, as it increased, higher was the percentage of tie results. As for the DTW, the best outcome was when the deformation window had no restriction; however, its results were less accurate. The next steps are testing with the major part of the database, determination of thresholds and an attempt to reclassify correctly the misclassified and tie results.

Acknowledgments

We would like to thank TECLIM Network for the data and Adelmo Aguiar for data organization.

Process design and simulation of a novel wet Claus desulfurization technology

Yang Yang, Xiao Feng and Qiao Zhang*

School of Chemical Engineering and Technology, Xi'an Jiaotong University, Xi'an, 710049, China
.zhang1986@stu.xjtu.edu.cn

Abstract

As the utilization of fossil fuels such as coal, oil and the waste discharged by chemical production process, the environment has been seriously polluted. A large amount of SO_2 emitted from flue gas in thermal power plants is an important cause of environmental pollution. In order to reduce such emission, this paper presents a new process design of liquid-phase Claus recovery process design based on traditional Claus technology. The process is composed of four parts: H_2S absorption and desorption, SO_2 absorption, Claus reaction and separation and recycling. Sodium citrate is employed to absorb sulfur dioxide in the flue gas and MDEA to absorb hydrogen sulfide in shale gas, hydrogen sulfide and sulfur dioxide reacts in the sodium citrate solution to form sulfur. Afterwards, sulfur separation is followed to achieve high efficient sulfur recovery. Meanwhile, absorbents of MDEA and sodium citrate are regenerated to reduce the cost. The simulation of the process is carried out by ASPEN PLUS 10.2 and the results show that hydrogen sulfide and sulfur dioxide can obtain high removal rate. After desulfurization, the sulfur content of purified gas is much lower than that of environmental tolerance level. Such sulfur recovery process is not only theoretical improvement but also useful to future application.

Keywords: Sulfur recovery; Shale gas; Flue gas; Liquid Claus reaction

1. Introduction

The exploitation, processing and utilization of fossil fuels have led to serious environmental pollution, which seriously threatens daily life and sustainable development of human society. Among traditional fossil fuels, because of the complex composition and the high ash, sulfur and nitrogen content, coal will cause dust, sulfur oxides and nitrogen oxides emissions in thermal power plants. Haze, acid rain caused by coal utilization has become urgent environmental issue. Generally, desulfurization processes are classified to wet and dry methodologies. The effect of toluene and carbon dioxide in the sulfur recovery process was investigated through experimental and simulation by Chardonneaua et al. (2015) and they revealed the importance of temperature and its excursion for enhanced sulfur recovery in a Claus process. A modified Claus process, enhanced by the use of High Temperature Air Combustion (HiTAC) technology in the Claus furnace was introduced by Mohamed and Ashwani (2008). Dowling et al. (1990) explored kinetics of the reaction between hydrogen and Sulfur under high-temperature Claus furnace conditions. S.Ibrahim et al. (2013) presented experimental investigations on the effect of different amounts of toluene addition to H_2S combustion in oxygen under Claus condition (pH = 3). In order to

increase the overall sulfur recovery as well as to decrease the costs, El-Bishtawi and Haimour (2004) developed a new modification on conventional Claus process and simulated and studied for various N_2/O_2 ratios with and without using double combustion technique. Chen et al.(2007) reviewed present status of Claus process based sulfur recovery units in domestic refineries. The super Claus sulfur recovery process and characteristics were introduced, and the parameters of device and process gas were calculated and analysed through simulation by Zhang et al.(2016). Cao et al. (2014) simulated the sulfur recovery project of Two oil refineries in China, and the results were in accordance with that of SULSIM software by and large, and the calculation error was within the allowable range. Chen (2003) reviewed the desulfurization and decarbonization by oxyamine process and the results indicates that the wet process has better application prospects. Li et al. (2006) compared several desulfurization process. Li (2008) used the traditional Claus process for desulfurization. Ghahraloud (2017) modeled and optimized the Claus process in thermal and catalytic section. These studies above show that the applications of Claus process in desulfurization are really common. However, traditional Claus process still have some disadvantages. i.e. The reaction temperature is 240 ℃ and the conversion rate is about 65 % in Cao et al. (2014) and the reaction temperature is 1061 ℃ in Zhang et al. (2016). Those process requires higher reaction temperatures and thus they are not conducive to the exothermic reaction. Moreover, since the reaction takes place in gas phase, the reaction rate and the conversion rate are limited. In order to deal with these problems in Claus process, this paper presents a new process design of liquid phase Claus reaction based on traditional Claus sulfur recovery technology. Compared with the traditional Claus process, this reaction is a gas-liquid phase reaction, which can fix gaseous pollutants in the liquid phase, easy to handle, mild reaction conditions, and can simultaneously treat two kinds of exhaust gases and has a high desulfurization rate.

2. Process design

According to existing Claus sulfur removal technology and absorption and desorption recycle, this paper puts forward a novel process design for recovery of sulfur from H_2S in shale gas and SO_2 in flue gas through wet Claus reaction. The novel process is mainly composed of four parts: H_2S absorption and desorption, absorbent recycling, SO_2 absorption and Claus reaction and separation. The flow diagram of the process is shown in Figure 1. This process contains a reactor(R_1), a centrifuge(CF_1), a pump(P_1), a compressor (C_1), 2 mixers (M_1 and M_2), 2 flashes (F_1 and F_2), 3 absorption columns (T_1,$T_2$and T_3) and 4 heat exchangers (H_1,H_2,H_3 and H_4). The model of the reactor we use is RCSTR and the model of the columns T_1-T_3 is RadFrac. Since the reaction system is an electrolyte-containing system, The property method we choose is ELECNRTL. In H_2S absorption and desorption part, shale gas is pressurized by C_1 and heated up by H_1 to arrive at required temperature and pressure of absorption column T_1. Meanwhile, makeup and recycled MDEA is mixed and pumped to T_1 for H_2S absorption. After H_2S absorption, the desorbed methane is sent out as natural gas and the H_2S concentrated MDEA absorption liquid from the bottom of T_1 is sent to desorption column T_2 for H_2S purification and MDEA regeneration. As for absorbent recycling part, the regenerated MDEA is recycled back to pump P_1 and H_2S is sent to flash 1 for further separation of entrained MDEA and H_2O. Afterwards, the separated MDEA is sent to T_2 for reuse and H_2S is purified and sent to reactor for sulfur generation.

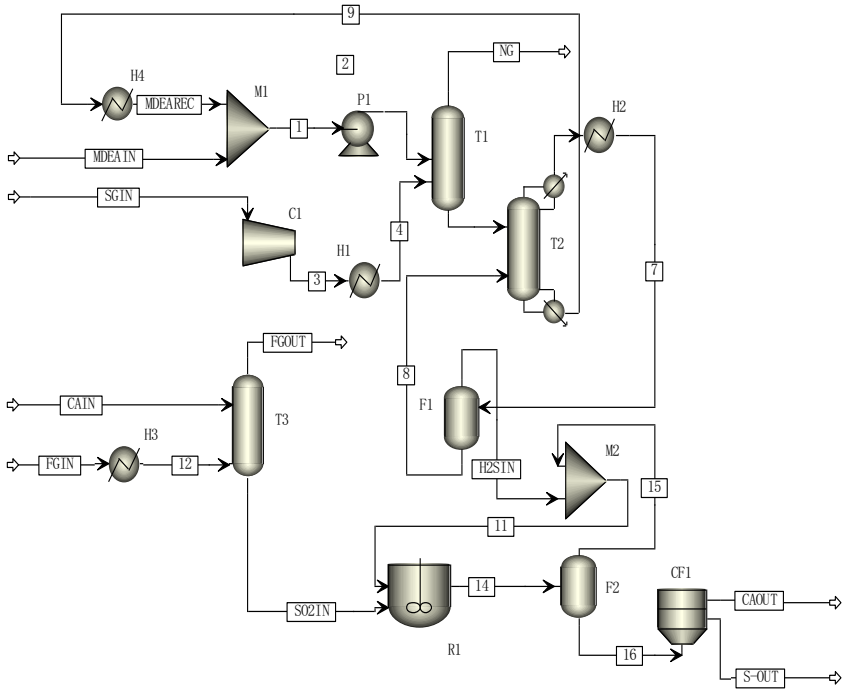

Figure 1 Novel wet Claus sulfur recovery process flowsheet

In SO_2 absorption section, flue gas and sodium citrate are sent to absorption column T_3 for SO_2 separation. After absorption, the residual gas is directly discharged to atmosphere and SO_2 concentrated sodium citrate solution is sent to R_1 for Claus reaction. In Claus reaction and separation section, H_2S and SO_2 react in CSTR reactor R_1 in the existence of acidic sodium citrate solution (pH=4.5) to generate sulfur content. The reactants and products, as well as sodium citrate solution are separated in flash F_1 and centrifuge CF_1 to reuse unreacted H_2S and collect the sulfur product.

3. Simulation and case study results

The shale gas and flue gas data is from practical petroleum enterprise and given by Table 1, where the flow rate and composition of main components are listed. The simulation in this article is carried out by ASPEN PLUS. All computational studies were performed on a HP 288 Pro G2MT desktop with Intel(R) Core(TM) i7,6700 CPU @3.40GHz and 8 GB RAM, using windows 7, 64 bit operating system.

Table 1 Shale gas and flue gas feed composition

	FGIN	SGIN	FGIN	SGIN
	Mole Flow (kmol/h)		Mole Frac	
H_2S	0	6.2	0	0.012
CH_4	0	493.8	0	0.988
N_2	1197	0	0.798	0
O_2	300	0	0.2	0
SO_2	3	0	0.002	0

The composition of shale gas is simplified as 1.24 % (mol) H_2S and 98.76 % (mol) CH_4 and the flue gas is 79.8 % (mol) N_2, 20 % (mol) O_2 and 0.2 % (mol) SO_2. This data comes from the actual data of a shale gas field in China. The 28% (wt) MDEA solution is used as the absorbent to absorb H_2S and the 0.5 mol/L sodium citrate is used as the absorbent to absorb SO_2. The reaction equation (Zhang et al., 2003) is given by Eq. (1).

$$H^+ + 2H_2S + HSO_3^- = 3S + 3H_2O \tag{1}$$

The reaction rate and kinetic equations(Zhang et al., 2003) are given by Eqs. (2) and (3):

$$r = kC_{H_2S}C_{HSO_3^-}^{0.5} \tag{2}$$

$$k = 1.531\times10^4 \exp(-\frac{1.778\times10^4}{RT}) \tag{3}$$

Where temperature and pH are key parameters to both conversion performance. Low temperature and proper acidity are in favor of the reaction. Besides, since the reaction is gas-liquid phase and the mass transfer is controlled by liquid film, high pressure is also an important driving force.

3.1. H_2S absorption and desorption

The mole flow rate of the shale gas is 500 kmol/h with 1.2% H_2S. The temperature and pressure of the absorption process are 25 ℃and 15 atm. Table 2 is the result of the H_2S absorption and desorption. The stream *SGIN* is the feed of the shale gas, the stream *SGOUT* is the gas phase after absorption and the H_2S feed is the H_2S after absorption and desorption. As shown in this table, the absorption rate of H_2S is about 100 %, and the desorption rate is about 99.97 % because MDEA is alkaline and thus has high efficient chemical absorption effect to H_2S. the absorption rate of H_2S is more than 98% at 0.004 MPa (Lin, 2013). The higher absorption pressure, 15 atm, which is more conducive to the absorption of H_2S, makes H_2S absorption rate can reach nearly 100 %. Absorbent MDEA can be recycled after desorption, and the recovery can be more than 98 %. Such high recovery rate of absorbent indicates the process can be economical.

Table 2 Shale gas data and stream compositions after H_2S separation

Streams	SGIN	SGOUT	H_2S feed	SGIN	SGOUT
		Mole Flow (kmol/h)			
H_2O	0	1.129	0.5	0	0.002
H_2S	6.2	0	6.198	0.012	0
CH_4	493.8	493.723	0.077	0.988	0.998

3.2. SO_2 absorption.

Table 3 is the result of the SO_2 absorption. Sodium citrate ($C_6H_5O_7Na_3$) is the absorbent. The stream *FGIN* is the feed of the flue gas and its flow rate is 1500 kmol/h with 0.2 % SO_2. The stream *FGOUT* is the gas phase after absorption and the SO_2 feed is the liquid phase after absorption. From the composition of SO_2 feed in sodium citrate solution, the absorption of SO_2 is about 100 % because of similar reason for H_2S absorption and such absorbent has been industrial applied.

Table 3 Flue gas data and stream compositions after SO_2 separation

Streams	FGIN	FGOUT	SO_2 feed	FGIN	FGOUT	SO_2 feed
	Mole Flow (kmol/h)			Mole Frac		
H_2O	0	23.365	57.236	0	0.015	0.761
N_2	1197	1197	0	0.798	0.787	0
O_2	300	300	0	0.2	0.197	0
SO_2	3	0	0.001	0.002	0	0
HSO_3^-	0	0	2.887	0	0	0.038
SO_3^{2-}	0	0	0.112	0	0	0.001
Na^+	0	0	10.56	0	0	0.14
$C_6H_8O_7$	0	0	0.02	0	0	0
CA-ION_1	0	0	1.429	0	0	0.019
CA-ION_2	0	0	2.834	0	0	0.038
CA-ION_3	0	0	0.118	0	0	0.002

3.3. Liquid Claus reaction

In this section, Claus reaction occurs in CSTR reactor and Table 4 shows the result of reactants and products composition. The stream *S-OUT* is the solid product of the react after separated and the stream *CAOUT* is the liquid phase after react and separated. Such composition shows that the total yield of sulfur reaches up to 91.16 %. The yield of sulfur in Li (2008) is about 90 %; the sulfur recovery after optimization is about 96.32% in Ghahraloud (2017); the conversion rate is about 65 % in Cao et al. (2014); and the total yield of sulfur is about 99.32 % in Zhang et al.(2016). Although those normal Claus processes can give superior yield such as 99.32 %, such result is obtained by multiple reactors in series and the reaction conditions are rigor. Compared with traditional Claus process, the yield can be raised from 65 % to 91.16 % after one reactor in this process. Thus, this process are superior to traditional ones both on performance and conversion condition aspects. From comparison in Tables 1-4, the H_2S and SO_2 components in shale gas and flue gas are concentrated and then converted to sulfur product. Furthermore, as all absorption, desorption and reaction occurs in liquid phase, the separation and conversion are high efficient. We can see that the whole process is simple, reaction and separation conditions are mild and the absorbents are recoverable. Thus, the process design and results are not only meaningful theoretically but also remarkable to industrial application.

Table 4 Reaction and separation products composition

Streams		FGIN	SGIN	S-OUT	CAOUT
Mole Flow (kmol/h)	H_2S	0	6.2	0	0.028
	HS^-	0	0	0.002	0.549
	S^{2-}	0	0	0	0
	SO_2	3	0	0	0
	HSO_3^-	0	0	0	0.003
	SO_3^{2-}	0	0	0.001	0.201
	S	0	0	8.387	0

4. Conclusions

This paper presents a novel wet Claus sulfur recovery process design and performs its simulation based on existing kinetic and reactive equations by ASPEN Plus. Compared with other processes of sulfur recovery, the new process has the advantages of simple process design, mild reaction condition, high safety and recyclable absorbents. Furthermore, it can not only deal with the sulfide in the flue gas and the shale gas to reduce environmental pollution but also obtain high value-added sulfur product. It can be expected good environmental and application prospects.

Abstract

Spinning Cone Column (SCC) showing higher removal efficiency under a mild operation condition can be an attractive option for the residual monomer removal process in polymer production. The effect of the rotation speed should be more carefully explored since the strong shear force and impingement on the wall, caused by a high rotational force, can induce operational stability issues. In this work, transport phenomena inside SCC are studied from a different angle. The Eulerian-Lagrangian approach is introduced in the CFD modeling to simulate the dynamics of the liquid droplets formation and movements as well as the complex motion of the fluid. Full 3D CFD transient simulations are conducted under various operation and design conditions. Key features for the enhancement in the residual monomer removal rate of SCC will be discussed based on the results.

Keywords: Spinning Cone Column, CFD modeling, Monomer stripping.

1. Introduction

Spinning Cone Column (SCC) is a stripping column that contains repeated units of a rotating cone attached to the rotating shaft at the central axis of the column and a stationary cone that is attached to the inner wall (Figure 1). It has been utilized as an equipment for stripping, especially in the food and cosmetics industries given its higher stripping efficiency with the shorter residence time that enable a mild operation as required by products like wine and perfume (Casimir, 1974).

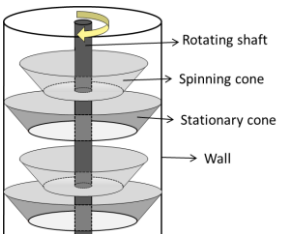

Figure 1. Simplified scheme of Spinning Cone Column

Due to its capability to operate in mild conditions with a satisfactory efficiency, our industrial partner has been exploring SCC (Joo et al., 2012) for the removal of residual monomers in polymer latex. A stripping process to remove residual monomers in polymer latex, which is a resultant mixture of emulsion polymerization, is essential as the residual monomers can negatively affect health and polymer quality.

Several studies have been performed to model and analyze the fluid dynamics inside SCC. Through a series of investigations into the flow regime followed by CFD simulations of SCC, a mass transfer analysis was performed (Makarytchev, et al., 2004).

Although comprehensive analyses have already been carried out on SCC, still there are necessities for additional investigations related to the phenomenon of monomer removal. First, to apply SCC for the different target mixture that is polymer latex in this study, separation should occur in milder condition with the adjusted design specification. Second, there are advantages of selecting different flow models in CFD modeling of SCC. Specifically, necessary data for analysis can be easily achieved through careful selection of flow model.

In this study, transient three-dimensional CFD modeling of a lab-scale SCC is performed. A novel approach, which is a combination of Discrete Phase Model (DPM) and Eulerian Wall Film (EWF) for liquid phase including droplets formation and movements, coupled with the Eulerian framework for vapor phase, is applied to express the complex flow fields in a more realistic way. Critical effects of the rotation on monomer removal in SCC will be discussed using several simulations at different conditions.

2. CFD modeling

CFD modeling is done in full three-dimension with ANSYS Fluent 18.0 to consider the effect of strong swirling motions and turbulences caused by rotation.

2.1. Geometry and mesh

The number of cones in SCC can be varied depending on the desired degree of separation and the properties of the mixture. In this work, not an entire, but a part of lab-scale SCC is modeled to reduce the computational cost of CFD. Total three stationary cones and two spinning cones are carefully selected so as to minimize the direct distortion of the by the adjacent inlet/outlet boundary conditions (Figure 2).

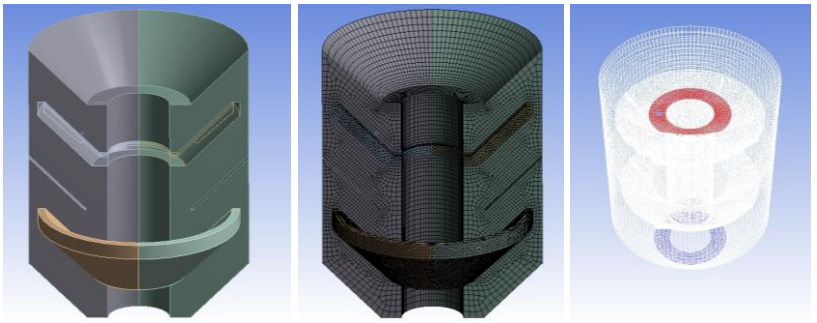

Figure 2. Details of CFD modeling: Geometry, meshes, and boundaries from the left

Geometry is drawn by referring to the design specification provided by the industrial partner. Meshes are finely set at the adjacent region of the cones where the complex flows of both liquid and vapor are expected. Mesh motion, which is a direct rotation of designated meshes, is utilized to express the rotation of the cone. Particularly fine meshes are used for the rotating meshes (The second plot in Figure 2). The total number of the mesh is 505,691. Hexagonal meshes are used in most regions except the rotating meshes. The rotating meshes are set as the tetrahedral type. Average skewness of the meshes is 0.21 and the maximum is 0.95, which sets the acceptable mesh quality.

2.2. Boundary conditions

For the inlet of a liquid phase, an arbitrary sized small surface is drawn near the end of the top stationary cone (a blue square in the red region shown in the third diagram of Figure 2). Liquid outlet is also designated at the bottom surface indicated in the blue donut shape, and it is also set as a vapor inlet so as to express counter-current flow inside SCC. With this configuration, injected liquid coming from the blue rectangle falls onto the spinning cone and is spread to the wall by the rotational force. Then, it flows down along the wall to the stationary cone by gravity. Vapor injected at the bottom goes upward and makes counter-current flow or crossflow.

With the above configuration of geometry and meshes, water is used as a pure component so as to focus on the fluid dynamics only without unduly increasing the computational cost. Water is injected in the form of uniformly distributed liquid droplets. Regardless of the setting of the diameter of the injected water, all droplets are converted to liquid film after touching the upper surface of the spinning cone, and the CFD results are unchanged. So, the diameter of injected water is set to an arbitrary value of 1mm.

2.3. Model description

This study involves novel selection of a model to reproduce the different flow types in SCC. The selected model is arranged in the following table.

Table 1. Summary of selected model

Phenomena		Selected model
Flow type	Vapor	Eulerian Equation
	Liquid film	Eulerian Wall Film
	Liquid droplet	Discrete Phase Model
Viscous model		Standard $k-\epsilon$ (scalable wall function)

The combination EWF and DPM enable the realistic tracking of liquid droplets movements as well as their generation and extinction. Information on the liquid film including film velocity and thickness can be obtained with a EWF model. At the edge of the cones, the film is torn off and droplets are generated according to the Foucart's criterion. Liquid droplets are affected by the vapor flow field until they impinge to the wall. When the droplets touch the cones and the wall, their fates are determined by Stanton-Rutland model which is the criteria deciding whether the droplets are attached, rebound, spread or splashed based on their kinetic energy (Stanton and Rutland, 1996).

Due to the spatial limitation, detail equations for each model are omitted. Related equations would be easily found from the references or through the Fluent theory guide.

3. Results

Effect of rotation on each flow and its relevance on the enhancement of residual monomer removal is the main focus of this study. Due to the space limit, some key results are written in flat sentences without figures.

3.1. Vapor

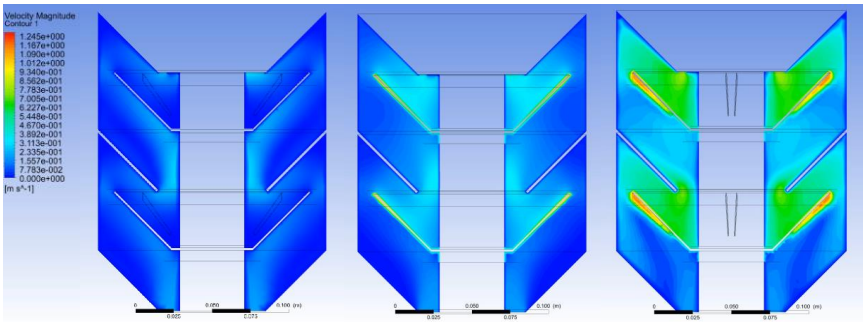

Figure 3. Vapor velocity (left: 0rpm, center: no fin/170rpm, right: fin/170rpm)

Figure 3 shows the overall characteristics of vapor flow inside SCC. All contour plots are expressed in the same range of velocity magnitude. These are the cases when the different operating and design conditions are applied, but the same amount of vapor injected. The first one is the case of no rotation (0rpm), the second is the case of no fin with the rotational speed of 170rpm, and the third one is the case of fins with 170rpm.

The effect of rotation is clearly observed by comparing the first with the second and third plots. Without rotation, vapor goes upward with the lower velocity along the shortest path. The maximum velocity occurs in the inner throat region that is a narrow space between the rotating shaft and the edge of the stationary cone.

When cones rotate, vapor flows faster, especially upon the spinning cone. An area-averaged velocity magnitude upon the spinning cone shows about 2.1 to 5.9 times higher value compared to other regions. This velocity is intensified with the existence of fin attached beneath the spinning cones. Main velocity component is the circumferential velocity, and this trend is also more distinctive on the spinning cone.

In addition, a remarkable observation is the decrease of axial velocity components heading upward at the inner throat region. When the cones rotate (170rpm), the average axial velocity at the inner throat region is reduced about 60% compared to the case of 0rpm. This indicates that advantages of rotation are the effective utilization of stripping agent as well as enhanced vapor velocity. The advantage also comes from its unique structure which causes bottleneck near the rotating shaft. In short, through the rotation, injected stripping agent sweeps the entire area inside SCC at a higher speed and a longer residence time by rotation. This advantage enhances the removal rate of monomer significantly since it is usually known that the contact of steam at the liquid interface enhances stripping in a polymer de-volatilization process.

3.2. Liquid film

Another continuous flow in SCC is the liquid film, which is modeled with a EWF model. Calculated data of liquid film velocity are extracted through the line drawn along the flow direction upon the spinning cone, the wall, and the stationary cone. Since the liquid film velocity shows significant fluctuations at each time step, time-averaged data are analyzed.

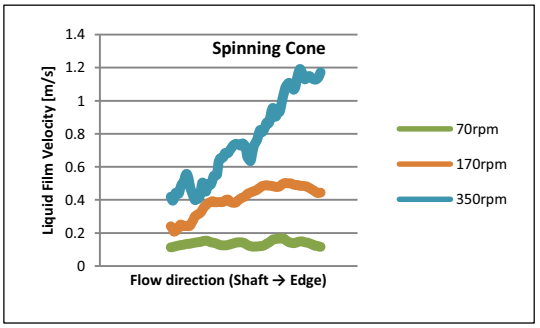

Figure 4. Liquid film velocity on the spinning cone with different rotation speed

CFD simulations are performed at different rotation speeds. Figure 4 shows the liquid film velocity enhancement on the spinning cone where the rotational force is directly applied to the liquid. Average values of above result are 1.36E-01, 4.01E-01, and 7.85E-01 [m/s] for 70, 170, and 350 [rpm], respectively.

To examine the effect of the liquid film velocity increase on the residual monomer removal, mass transfer coefficients are calculated based on the film theory using the CFD results. A mass transfer correlation of Eq.(1), developed by Vivian and Peaceman (1956), is applied.

$$Sh_L = \frac{k_L z}{D_{AB}} = 0.433(Sc_L)^{\frac{1}{2}}\left(\frac{\rho_L^2 g z^3}{\mu_L}\right)^{\frac{1}{6}}(Re_L)^{0.4} \quad (1)$$

D_{AB} indicates diffusivity of residual monomer in the liquid. z is computation domain. ρ_L and μ_L are density and viscosity of the liquid. g is gravitational acceleration. Re_L and Sc_L are Reynolds number and Schmidt number for the liquid phase.

Averaged values of liquid side mass transfer coefficient (k_L) for 70, 170, and 350 rpm are calculated as 4.05E-05, 7.03E-05, and 1.00E-4, respectively. It shows the clear increasing trend as rotating speed increased. By adjusting the rotation speed from 70 rpm to 350 rpm, stripping rate can be locally enhanced about 2.5 times. This implies that rotation of cone contributes to monomer removal by a direct increase of the liquid film velocity on the spinning cone.

3.3. Liquid droplets

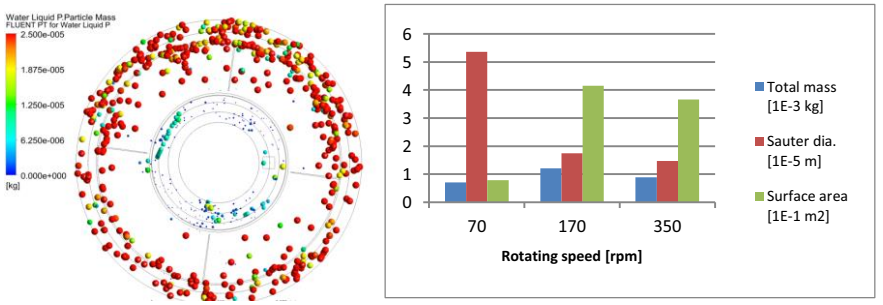

Figure 5. Simulation results on liquid droplets (left-overall configuration, right-summary)

Liquid droplets are generated usually at the edge of the cones by tearing of the liquid film. This phenomenon is reproduced by the combination of EWF and DPM. Film velocity at the edge is related to the flowrate of droplets, and their movements are affected changed by drag force from the vapor flows. Droplets are tracked in the Lagrangian frame of reference using DPM so that droplets information such as the location and the size of droplets can be easily effectively visualized. In addition, it is possible to obtain the quantitative information of overall liquid droplets with this approach.

The left picture in Figure 5 indicates the liquid droplets distribution in SCC viewed from z+ direction (looking down from the top). Heavy droplets are observed near the edge of the spinning cone while fine droplets exist around the rotating shaft.

The plot on the right side of Figure 5 summarizes the overall information on the liquid droplets existing in SCC at different rotating speed. A noticeable fact related to this summary is that the estimated values of the surface area of droplets are from 7.87E-02 to 4.15E-01 m^2. These correspond to 56 % or 298 % increases compared to the maximum area where the film can cover in SCC. In short, the residual monomer removal rate may be greatly enhanced by the significant increase in the mass transfer area due to the formation of droplets.

4. Conclusions

CFD modeling of SCC was performed with the combination of EWF and DPM. Several observations for each flow from the CFD simulation results conducted in different design and operating conditions were presented. Key features that can affect the monomer removal rate were analysed.

Vapor flows faster but with a longer residence time by rotation of the cones and the fluid dynamics of vapor is much intensified by the fins. Rotation also contributes to an increase in the liquid film velocity. The mass transfer coefficient for the monomer removal rate can be enhanced up to 2.5 times by changing the rotating speed from 70 to 350 rpm, according to the film theory. In addition, the surface area of liquid is significantly enlarged by the generation of liquid droplets. A 56 % to 298 % increase in the surface area is expected by the rotation.

Abstract

Solid oxide fuel cell (SOFC) based auxiliary power unit (APU) system using diesel fuel is expected to be an environmentally-friendly and highly-efficient alternative to supply non-propulsion power for long-haul trucks, replacing engine idling or diesel generator based APUs. The main components that govern the overall system performance are the auto-thermal reformer (ATR), which converts diesel fuel into hydrogen-rich gas, and the SOFC stack, which produces power by electrochemical reaction of the reformed fuel and oxygen. In this study, a dynamic ATR model including a reaction kinetic model with experimental validation and a dynamic SOFC stack model with induced theoretically derived electrochemical model, are constructed. Then, in order to investigate the effect of operating variables of the ATR on the SOFC stack, the two models are integrated by connecting the outlet of the ATR model to the anode inlet of the SOFC stack model. Finally, using the developed dynamic model, dynamic responses of the system to step changes in the oxygen-to-carbon ratio (OCR) and steam-to-carbon ratio (SCR), which are the main operating variables of the ATR, are examined.

Keywords: SOFC based APU system, dynamic modelling and system dynamics

1. Introduction

Recently, the solid oxide fuel cell (SOFC) based auxiliary power unit (APU) system has emerged as a new alternative to provide non-propulsion power to long-haul trucks or recreational vehicles, given its high efficiency, environment friendliness, and quiet operation, to replace engine idling or diesel generator based APU. It is important to understand the dynamics of the SOFC based APU system to develop control strategies during load changes and rapid start-ups, since the system is known to exhibit frequent load changes as well as "on- offs"s given the nature of its application. Despite this, most of the studies regarding this system have focused on steady-state behavior. A few dynamic studies on the system considered a system with CH_4 or natural gas as fuel, unlike in the actual heavy duty truck applications, which use the diesel as fuel (Andersson et al. (2011), Sorrentino and Pianese (2009)).

Therefore, in this study, we develop a dynamic model that can properly simulate the dynamics of the system using diesel as the fuel, in order to address the common practical situation. In addition, instead of steam reforming which requires a heat exchanger of considerable size, auto-thermal reforming (ATR), which is better suited to the application due to its thermally independent characteristic, is selected to reform diesel to hydrogen-rich gas.

The dynamic ATR model is constructed by including a reaction kinetic model of diesel reforming, which has been validated with experimental data. On the other hand, in the case of the SOFC model, the developed model could not be validated due to a lack of experimental data. Instead, the dynamic model is developed by introducing a rigorous electrochemical model obtained from the literature. The two models are integrated into a system model by connecting the outlet of the ATR model to the anode inlet of the SOFC stack model.

This paper focuses on the propagated effect of inlet variables of the ATR on the SOFC stack. As such, using the developed dynamic model, transient responses of the system to step changes in OCR and SCR, which are the main operating variables of the ATR, are analyzed and discussed.

2. Model development

2.1. Dynamic ATR model

Heavy-hydrocarbons such as diesel have difficulty in reaching the equilibrium of the reforming reaction unlike methane and natural gas. In addition, the reformed gas may contain light-hydrocarbons such as methane due to incomplete cracking. Thus, a reaction kinetic model for the catalyst used is required for dynamic simulation of ATR using diesel. In addition, since light-hydrocarbons such as methane can be reformed in the SOFC stack and affect the performance of the stack, the kinetic model that can account for light-hydrocarbons is needed to more accurately predict the system performance. Accordingly, a dynamic model of the ATR is built by introducing the reaction kinetic model of diesel reforming, which can account for methane. The model has been validated with experiments using a nickel-based catalyst. The reaction set considered in the kinetic model can be found in Table 1. A detailed description of the kinetic model can be found in Jeong et al. (2018).

In this study, a monolith type reactor coated with the nickel-based catalyst with high mechanical superiority is considered as the reactor type of ATR given its popularity in mobile applications. Also, the dynamic ATR model is constructed with the assumption that one single channel inside the monolith can represent the entire ATR reactor. The balance equations that make up the model are shown in Table 2 below. Assumptions applied to the dynamic ATR model construction as well as a more detailed description are given in Jeong et al. (2018).

Table 1. The reaction set considered in the reaction kinetic model of the ATR using diesel fuel (C_nH_m: diesel surrogate)

Total oxidation (TOX)	$C_nH_m + \left(n + \frac{m}{4}\right)O_2 \rightarrow nCO_2 + \frac{m}{2}H_2O$
Pre-reforming (PR)	$C_nH_m + \left(n - \frac{m}{4}\right)H_2O \rightarrow \left(\frac{n}{2} - \frac{m}{8}\right)CO_2 + \left(\frac{n}{2} + \frac{m}{8}\right)CH_4$
Steam reforming (SR)	$C_nH_m + nH_2O \rightarrow nCO + \left(n + \frac{m}{2}\right)H_2$
Water-gas shift (WGS)	$CO + H_2O \leftrightarrow CO_2 + H_2$

Table 2. The balance equations of the dynamic ATR model

Mass balance for gas phase $\frac{\partial(\rho_g x_i)}{\partial t} = -\frac{\partial(ux_i)}{\partial z} + MW_i \sum_j v_{i,j} r_j$
Energy balance for gas phase $\rho_g c_{p,g} \frac{\partial T_g}{\partial t} = -u_g c_{p,g} \frac{\partial T_g}{\partial z} - \hat{a}_s u_{overall} \left(T_g - T_s\right) + \sum_j \left(-\Delta H_j\right) r_j$
Energy balance for solid phase $\rho_s c_{p,s} \frac{\partial T_s}{\partial t} = \hat{a}_s u_{overall} \left(T_g - T_s\right) - \hat{a}_{amb} h_{amb} \left(T_s - T_{amb}\right)$

2.2. Dynamic SOFC stack model

The dynamic SOFC stack model is composed of two mass balances for the fuel and air channels, four energy balances for the fuel and air channels, PEN (Positive electrode / Electrolyte / Negative electrode) structure and interconnect, and the electrochemical model, which relates the composition and temperature to the electrochemical variables. In fact, in the case of SOFC, carbon monoxide or light-hydrocarbons, such as methane, can be used as fuel as well as hydrogen due to the characteristic of high operating temperature. In this paper, however, a theoretically derived electrochemical model is applied, which is based on the assumption that only hydrogen has electrochemical activity. Nevertheless, methane and carbon monoxide can be considered to be used as fuel because methane and carbon monoxide are converted into hydrogen through methane steam reforming and water gas-shift reactions, which are assumed to take place at the fuel channel as shown in Table 3. A detailed description of the electrochemical model can be referenced in Chan et al. (2001).

Similar to the monolith type of the dynamic ATR model, the dynamic SOFC stack model is built based on the assumption that one repeating unit inside the stack can be representative of the entire stack. In order to facilitate the analysis of the dynamic response of the stack to step changes in the main operating condition of the ATR, the model is established assuming a co-flow pattern, which minimizes the dimension of space, among several possible stack flow patterns. The balance equations that make up the model are summarized in Table 4. More detailed explanations of the dynamic SOFC stack model and further assumptions can be found in Aguiar et al. (2004).

2.3. Dynamic integrated system model

(a) of Figure 1 shows the layout of the system considered in this study. As can be seen from the layout, it is assumed that the fuel reformed from the ATR directly enters the anode inlet of the SOFC stack with no composition change or heat loss between them. The two heaters in the layout are respectively introduced to heat the water entering the ATR to 100 ℃ steam and to heat the room air to the cathode of the stack up to 650 ℃, and their dynamics were not considered.

Table 3. The reaction set considered in the dynamic SOFC stack model

Methane steam reforming (MSR)	$CH_4 + H_2O \rightarrow CO + 3H_2$
Water-gas shift (WGS)	$CO + H_2O \leftrightarrow CO_2 + H_2$
Electrochemical reaction (ER)	$H_2 + 1/2\,O_2 \rightarrow H_2O$

Table 4. The balance equations of the dynamic SOFC stack model

Mass balance for fuel channel

$$\frac{\partial C_{i,f}}{\partial t} = -u_f \frac{\partial C_{i,f}}{\partial z} + \sum_j \upsilon_{i,j} r_j \frac{1}{h_f}$$

Mass balance for air channel

$$\frac{\partial C_{i,a}}{\partial t} = -u_a \frac{\partial C_{i,a}}{\partial z} + \upsilon_{i,ER} r_{ER} \frac{1}{h_a}$$

Energy balance for fuel channel

$$\rho_f c_{p,f} \frac{\partial T_f}{\partial t} = -u_f \rho_f c_{p,f} \frac{\partial T_f}{\partial z} + k_{f,P}\left(T_P - T_f\right)\frac{1}{h_f} + k_{f,1}\left(T_I - T_f\right)\frac{1}{h_f} + \sum_{j \in MSR,WGS} \left(-\Delta H\right)_j r_j \frac{1}{h_f}$$

Energy balance for air channel

$$\rho_a c_{p,a} \frac{\partial T_a}{\partial t} = -u_a \rho_a c_{p,a} \frac{\partial T_a}{\partial z} + k_{a,P}\left(T_P - T_a\right)\frac{1}{h_a} + k_{a,I}\left(T_I - T_a\right)\frac{1}{h_a}$$

Energy balance for PEN structure

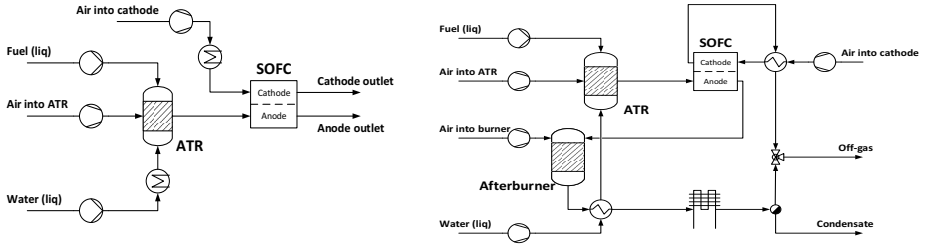
$$\rho_P c_{p,P} \frac{\partial T_P}{\partial t} = \lambda_P \frac{\partial^2 T_P}{\partial z^2} - k_{f,P}\left(T_P - T_f\right)\frac{1}{\tau_P} - k_{a,P}\left(T_P - T_a\right)\frac{1}{\tau_P} + \left[\left(-\Delta H\right)_{ER} r_{ER} - jU\right]\frac{1}{\tau_P}$$
$$+ \left[\frac{\sigma\left(T_I^{\,4} - T_P^{\,4}\right)}{1/\in_I + 1/\in_P - 1}\right]\frac{1}{\tau_P}$$

Energy balance for Interconnect

$$\rho_I c_{p,I} \frac{\partial T_I}{\partial t} = \lambda_I \frac{\partial^2 T_I}{\partial z^2} - k_{f,I}\left(T_I - T_f\right)\frac{1}{\tau_I} - k_{a,I}\left(T_I - T_a\right)\frac{1}{\tau_I} - \left[\frac{\sigma\left(T_I^{\,4} - T_P^{\,4}\right)}{1/\in_I + 1/\in_P - 1}\right]\frac{1}{\tau_I}$$

One of the important advantages of the SOFC system is that the outlet gas of the stack can be used as a high quality heat source due to its high temperature operating condition. Thus, in a practical system, such heat can be recovered by introducing an afterburner and heat exchangers, as shown in (b) of Figure 1.

However, in this study, the process simulation is carried out assuming the simplest layout shown in (a) of Figure 1, to place the priority on studying the effect of operating conditions of the ATR on the dynamic responses of the stack. This study can serve as a starting point, to investigate the dynamics of more complex and practical systems with interactions between the components of the system, including heat exchangers and recycling.



(a) The simplest system layout (b) exemplary practical system layout

Figure 1. System layouts

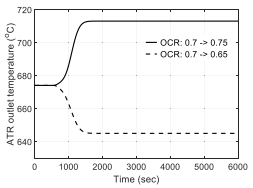
3. Simulation results and discussion

Using the developed dynamic model of the integrated system, step changes in the oxygen-to-carbon ratio (OCR) and steam-to-carbon ratio (SCR), which are the main operating variables of ATR, are introduced to see their eventual effect on the dynamic responses of the SOFC stack through the ATR. The simulation run of 6000 seconds interval starts from the steady state with OCR and SCR values of 0.7 and 2.5, respectively, and the step changes in the OCR (±0.05) and SCR (±0.3) are introduced to the system at 600 seconds into the run.

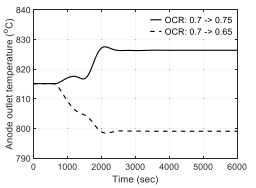
Although the dynamic responses of many variables such as compositions, flowrate, and electrochemical variables are investigated in this study, only the dynamic responses of the outlet temperatures of the ATR and the anode of the SOFC stack, which show the most remarkable behaviour, are discussed in here.

(a) and (c) of Figure 2 show the dynamics of the ATR outlet temperature in response to step changes in the OCR and SCR, respectively. A positive step change in the OCR means an increase of oxygen entering the ATR, which increases the reaction extent of the strongly exothermic total oxidation. Therefore, the ATR outlet temperature gradually increases with time as shown in the solid line of (a) and vice versa. In the case of SCR, although the response direction of the ATR's outlet temperature is reversed, it can be interpreted in similar frames. A positive step change in the SCR increases steam entering the ATR, increasing the reaction extent of the endothermic steam reforming. As a result, the ATR outlet temperature decreases as shown by the solid line of (c).

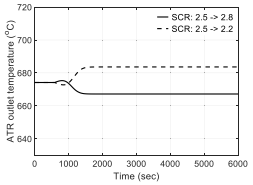
(b) of Figure 2 shows the dynamics of the anode outlet temperature, which is affected by the dynamics of the ATR due to the step change in the OCR. An oscillation is observed with time, and the influences of positive and negative step changes are asymmetric. The dynamics are results of complex interplay among various phenomena, but two factors that are most responsible for such response characteristics are the change in the anode inlet temperature and the change in the rate of methane steam reforming reaction near the anode inlet. In the case of the positive step change, which induces a more oscillatory behavior, the anode inlet temperature is exactly equal to the ATR outlet temperature, so the temperature gradually increases with time as shown by the solid line of (a). At the same time, however, this increase in the inlet temperature causes a cooling effect by



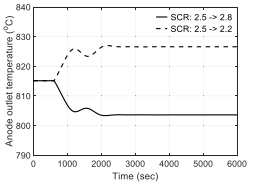
(a) ATR outlet temperature according to step change of OCR



(b) Anode outlet temperature according to step change of OCR



(c) ATR outlet temperature according to step change of SCR



(d) Anode outlet temperature according to step change of SCR

Figure 2. Dynamic responses of ATR outlet temperature and anode outlet temperature according to step changes of OCR and SCR

increasing the rate of the endothermic methane steam reforming reaction near the inlet of the anode. Eventually, the two conflicting behaviors work together to determine the temperature of the anode outlet. In the case of the negative step change, however, the above two factors do not conflict. Even though the rate of the methane steam reforming reaction is slowed down due to the decrease in the temperature of the inlet, this reaction is an endothermic reaction, so only the cooling effect is reduced. Thus, the asymmetric response characteristic shown in (b) is observed.
In (d) of Figure 2, which shows the dynamics of the anode outlet temperature to the step change of SCR, the responses to the positive and negative step changes are almost symmetric unlike the case of OCR. This result can be explained by the temperature change in the anode inlet and the corresponding voltage change. If the temperature of the anode inlet decreases due to the positive step change of SCR, the temperature inside the stack will gradually decrease and the voltage will also drop. However, such voltage drop increases the heat generation due to the loss of electrical energy, so the two effects are in conflict, and eventually, the response of the anode outlet temperature oscillates. On the other hand, in the case of the negative step change, the situation is completely reversed. Thus, the dynamic responses of the anode outlet temperature to the positive and negative step changes are symmetrical as shown in (d).

4. Conclusion

In this study, in order to investigate the dynamics of the SOFC based APU system, an integrated dynamic model of the system was developed, simply by connecting the outlet of the dynamic ATR model to the anode inlet of the dynamic SOFC stack model. The ATR model included an experimentally validated reaction kinetic model of diesel reforming, whereas the SOFC stack model was based on a theoretically derived electrochemical model. Then, by using the developed model, it was investigated how step changes in the OCR and SCR, which are the main operating variables of the ATR, affect dynamic responses of the SOFC stack through the system connection. This investigation was done using the simplest system layout. In the future, the developed dynamic model will be applied to more complex and practical system layouts like (b) of Figure 1 and control issues that can occur during such load changes or start-up will be identified and addressed.

Abstract

To overcome the short-coming in the previous tools on the simulation of composition of crystals during growth, we proposed a model based on multi-component mass transfer for modelling the growth behavior of crystals. The core of the model is a phase non-equilibrium model of a single crystal that treats the solute components equally and describes them by a set of mass transfer equations. The size, shape and composition of a crystal at a given time during the crystallization process, i.e. the size in each face direction and the area of each face, depend on the amount of each material deposited on each surface. This is unlike conventional facet growth kinetic model in which the growth rate is correlated directly to supersaturation.

Such models can be applied to describe co-crystallization processes, estimate the impurity content in product and enables the prediction of stability of crystalline pharmaceuticals. The modelling method is illustrated by reference to a detailed case study of $NaNO_3$ crystal growth in water in the presence of KNO_3. The dynamic evolution of crystal composition, shape, and size is predicted in simulation runs under different initial KNO_3 concentrations.

Keywords: Crystal growth; multi-component mass transfer; non-equilibrium; crystal shape; crystal composition; co-crystallization

1. Introduction

Considering that solution crystallization is regarded as a separation process for product purification in the chemicals, pharmaceuticals and food processing industries, its modeling and simulation should surely be able to estimate the composition of the multiple components in the crystal solids in the crystals at any time during the crystallization process. The modeling for crystallization, i.e. population balance (PB) modelling (Ramkrishna and Singh 2014) of crystallization however has focused on modeling crystal size and shape distributions, rather than the composition of multiple components in crystals. It seems illogical for the most important modeling tool for crystallization processes not to be able to estimate the composition of components in the crystals.

As a matter of fact, some attention was paid to the study of crystal growth behavior in an impure media via simulation, but the focus was still on the size and shape of crystals, or more accurately, on how an impurity, often in a much smaller concentration in comparison with the material to be purified, affects the size and shape change of the

crystal. There is limited simulation work on estimation of impurity content in the crystal solids which is often based on a partition coefficient which is obtained based on the assumption of solid-liquid phase equilibrium. Some researchers (Kubota and Mullin 1995, Kubota 2001, Kubota, Sasaki et al. 2004) considered adsorption models for impurities to improve the crystal growth rate estimation. To consider the incorporation rate of impurities, Borsos et al. assumed a concentration equilibrium between the incorporating impurities and the impurities in the solution (Borsos, Majumder et al. 2016). However, the model was based on the thermodynamic equilibrium while the kinetics of mass transfer was not taken into consideration. Another observation motivated the current work is the way crystal growth rate in population balance models is described. The kinetic equation of crystal face specific growth rate is often directly correlated to supersaturation. However, when the compositions are of similar order of magnitude (for example, co-crystallization), when talking about the solubility and supersaturation which material they refer to? In the work of (Holan, Ridvan et al. 2015) about co-crystallization, solubility and supersaturation was about the mixture at a fixed composition of the major materials in the co-crystal. But the composition of the major materials in the crystals clearly changes from batch to batch, so the solubility and supersaturation for one composition does not apply to crystals of a different composition.

In this work, a multi-component mass transfer rate based model for simulation of non-equilibrium growth of crystals is introduced. In the model, the multiple solute components are described by a set of diffusion, adsorption and integration equations to form a multi-component mass transfer system. Thus both the crystal growth in terms of size and shape and change of composition of all components in the crystal can be simulated simultaneously by solving the mass transfer equations.
The remaining part of this paper is organized as follows: Section 2 gives a detailed description of the proposed multi-component mass transfer models for modeling the non-equilibrium growth of crystals. Then in Section 3 a detailed case study on $NaNO_3$ crystallization in impure media is presented to illustrate the proposed modeling approach. Finally in Section 4 conclusions will be drawn and pointers to future research will be provided. .

2. Multi-component mass transfer rate based model for single crystal growth

2.1. Stage model

The multi-component mass transfer rate based model takes inspirations from the non-equilibrium stage model for the distillation column simulation (Krishnamurthy and Taylor 1985). In our model, each “stage” stands for a discretized moment during simulation of the crystal growth. At each stage, mass transfer occurs between the solution and the crystal and leads to the growth of the crystal. The left part of Figure 1 shows the details of a stage in the model for crystal growth. The simulation of the crystal growth is discretized in time, $j = 1 \ldots J$. In total there are C components, $i = 1 \ldots C$. Stage j refers to the status of the crystal and solution at time jth moment of the simulation. At stage j, the liquid phase and the solid phase were considered separately.

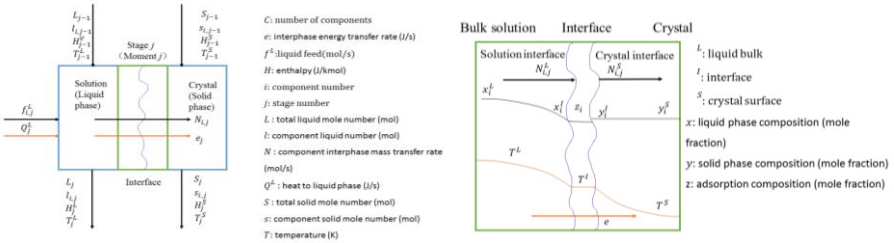

Figure 1 Schematic diagram of non-equilibrium stage model for solution crystallization: stage model (left) and interface model (right)

On stage *j,* the two phases are not at equilibrium because the process is moved to the next stage *j+1* before they reach equilibrium. There are mass transfers for each component between the liquid and solid phases in both directions. $N_{i,j}$ is the net mass transfer rate of component *i* from the liquid phase to the solid phase, for stage *j*, in mol/s. Q^L, Energy transfer between the two phases, and f^L, the liquid feed can also be modeled in the framework of our model but in the present work they are ignored. Then the stage model can be described with the following mass balance equations (*i* =1,2,…,*C; j= 2,3, ...,J; k=1,2,..F)*:

$$M_{i,j}^{L} \equiv l_{i,j-1} - l_{i,j} - \sum_{k=1}^{F} N_{i,j,k}^{L} \Delta t = 0 \tag{1}$$

$$M_{i,j,k}^{S} \equiv s_{i,j-1,k} - s_{i,j,k} + N_{i,j,k}^{S} \Delta t = 0 \tag{2}$$

$$M_{i,j,k}^{I} \equiv N_{i,j,k}^{L} \Delta t - N_{i,j,k}^{S} \Delta t = 0 \tag{3}$$

2.2. Interface model

The net mass transfer rate can be modeled with the interfacial model as the right part of Figure 1shows. In the solution, liquid mass transfer occurs due to the concentration difference between the bulk and the liquid interface. On the interface, adsorption equilibrium prevails between the liquid interfacial concentration and the surface layer concentration. In the crystal, solid mass transfer occurs in the form of molecule integration from the surface layer to the crystal surface.

It should be noted that Figure 1 only represent a "stage" on one crystal face. For different crystal faces, different model parameters should be considered. The total number of faces is *F*.

The mass transfer rate in the liquid phase and solid phase are described by equation (4) and (5) separately:

$$R_{i,j,k}^{L} \equiv N_{i,j,k}^{L} - k_{i,k}^{d} A_k (x_{i,j}^{L} - x_{i,j,k}^{I}) = 0 (i = 1,...,C-1) \tag{4}$$

$$R_{i,j,k}^{S} \equiv N_{i,j,k}^{S} - k_{i,k}^{r} A_k (z_{i,j,k} - K_{i,k}^{r} y_{i,j,k}^{I})^{r} = 0 (i = 1,...,C) \tag{5}$$

The composition in the adsorption phase is described with the Langmuir adsorption isotherms (*i* =1,2,…,*C*-1):

$$Q_{i,j,k}^{ads} \equiv z_{i,j,k} - \frac{K_{i,k} x_{i,j,k}^{I}}{1 + \sum_{m=1}^{C-1} K_{m,k} x_{m,j,k}^{I}} = 0 \tag{6}$$

The solid composition related to the mass transfer is equal to the composition of the crystal layer that formed in the last moment (i =1,2,…,C).

$$Q^{S}_{i,j,k} \equiv y^{I}_{i,j,k} - y^{S}_{i,j,k} = 0 \tag{7}$$

2.3. Summation relations

The summations components of the liquid phase, solid phase and adsorption phase should be 1. The solid phase summation equations can be obtained from the summation of $Q^{S}_{i,j,k}$ so they are not independent equations and won't be listed here (j=1,2,…,F).

$$S^{L}_{j,k} \equiv \sum_{i=1}^{C} x^{I}_{i,j,k} - 1 = 0 \tag{8}$$

$$S^{ads}_{j,k} \equiv \sum_{i=1}^{C} z_{i,j,k} - 1 = 0 \tag{9}$$

2.4. Numbers of equations and variables

There are $C+6FC$ unknown quantities for each stage j. These are the component liquid mole number ($l_{i,j}$: C in number), the solid mole number ($s_{i,j,k}$: CF), the liquid composition at the interface ($x^{I}_{i,j,k}$: CF), the solid composition at the interface ($y^{I}_{i,j,k}$: CF), the adsorption phase composition at the interface ($z_{i,j,k}$: CF), the mass transfer rate ($N^{L}_{i,j,k}$: CF and $N^{S}_{i,j,k}$: CF). It should be noted that $x^{L}_{i,j}$ and $y^{S}_{i,j,k}$ are not independent because they can be obtained from $l_{i,j}$ and $s_{i,j,k}$ separately. There are $C+6CF$ independent equations which are listed above (Equations (1) to (9)). Therefore, the equations can be solved.

2.5. Simulation of crystal shape and composition

Neither the face growth rate nor the normal distance straightforward appears in our model. However, based on the calculation of solid mole number of all components, the normal distance change can be obtained by summing up the solid mole number of each component divided by its density and molecular mass. On the other hand, based on the solid mass of each component, both the overall composition of the whole crystal or on a specific face normal direction, and the composition distribution along a specific face normal direction, can be obtained.

3. Case study

Sodium nitrate (NaNO3) crystallization is selected for the case study of our proposed model. Fig. 3 is the equilibrium morphology of a NaNO3 crystal which was predicted by Benages-Vilau (Benages-Vilau 2013) and also observed by Wu et al. (Wu, Ma et al. 2016) A NaNO3 crystal is rhombohedral with six faces. These faces can be classified into three groups of crystallographically equivalent faces, i.e. two {104}, two $\{1\bar{1}4\}$ and two $\{01\bar{4}\}$. Wu et al. also measured the crystal face specific growth kinetics of all the three faces.

In the case study, we will use our proposed model to simulate the shape and purity evolution of a single $NaNO_3$ with or without the presence of KNO_3 as the impurity. A pure $NaNO_3$ crystal is loaded in the crystallizer as a crystal seed and the crystallization temperature is kept constant. According to Benages-Vilau's work, KNO_3 is assumed to be adsorbed on {104} face only.

The mass transfer coefficients from the solution to the crystal surfaces can be predicted using a correlation given by Geankoplis(Geankoplis 1978). The adsorption constant $K_{i,k}$ and the equilibrium ratio $K^r_{i,k}$ are related with the solubility data of $NaNO_3$(Xu and Pruess 2001) and KNO_3(Rolfs, Lacmann et al. 1997). The other model parameters corresponding to $NaNO_3$ are regressed with the experimental data of Wu et al 19 while the other model parameters corresponding toKNO_3 are assumed.

Initially a pure $NaNO_3$ crystal is loaded in the crystallizer as a crystal seed and the crystallization temperature is kept constant. KNO_3 is assumed to be adsorbed on {104} face only. The crystallization temperature is kept 218.15K. The initial the molar fractions of NaNO3 is 0.1689. The initial face normal distances of {104}, $\{\bar{1}14\}$ and $\{0\bar{1}4\}$ are 100.06μm, 216.83μm and 253.28μm respectively. KNO_3 is added with $NaNO_3/KNO_3$ molar ratio of 10^{-3} and 10^{-5}. The normal distance evolution of face {104} and shape evolution during crystallization are shown in Figure 2. Because of the parameter setting of KNO_3 on $\{\bar{1}14\}$ and $\{0\bar{1}4\}$, the normal distance evolutions of faces $\{\bar{1}14\}$ and $\{0\bar{1}4\}$ show no differences from simulation in the absence of KNO_3.

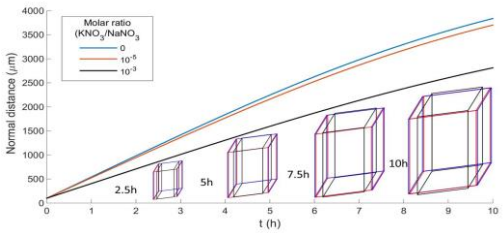

Figure 2 Evolution normal distance of face {104} and crystal shape during NaNO3 crystal growth with different KNO3/NaNO3 molar ratio

The overall molar fraction of KNO_3 of the growing $NaNO_3$ can also be predicted with the proposed model as is shown in Figure 3(a). On the other hand, due to the change of solution phenomenon, the composition of crystal in the normal direction of {104} is different at different locations and the distribution of KNO_3 molar fraction in the normal direction of {104} can also be simulated with the proposed model, as is shown in Figure 3(b). The left of the distribution curves is missing because it represents the initial KNO_3 molar fraction of 0 and cannot be shown in logarithmic coordinate.

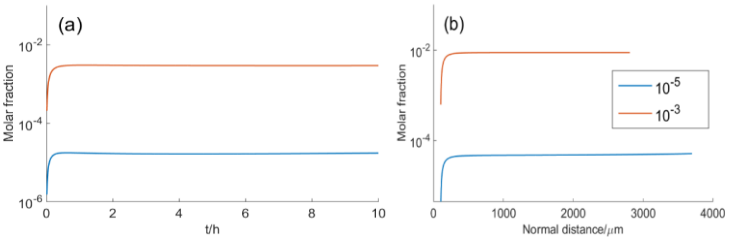

Figure 3 Crystal with different KNO3/NaNO3 molar ratio. (a) Evolution of KNO3 molar fraction in the whole crystal (b) KNO3 molar fraction distribution in the normal direction of face {104}

4. Conclusion

In this work, a multi-component mass transfer model is proposed for modelling the crystal growth of multi-component systems. In the model, all the solutes are equally

described by a set of diffusion, adsorption and integration equations. Through solving the equations, evolution of both the crystal shape and composition can be predicted.
A case study of NaNO3 crystal growth in the presence of KNO3 is conducted. The shape and composition evolutions of NaNO3 crystals of crystallization with different initial KNO3 concentrations are modelled.

The main contribution of this work is the proposal of a novel model for the prediction of composition evolution of multi-component crystallization processes. The model can be expected to work on other multi-component crystallization processes like co-crystallization. In future work, the proposed model will be validated with multi-component crystallization experiments.

Two-phase Dynamic Model for PEM Electrolyzer

Mariana Corengia[a], Ana I. Torres[a*]

[a]*Instituto de Ingeniería Química, Facultad de Ingeniería, Universidad de la República, Montevideo, Uruguay*
aitorres@fing.edu.uy

Abstract

This work develops a dynamic model for hydrogen production in Proton exchange membrane electrolyzer cells (PEMECs). The novelty of the model lies in considering gaseous and liquid phases for the species in both anode and cathode, and linking both phases using rigorous mass transfer equations. With these considerations the model properly accounts for the operating conditions usually encountered in PEMECs. The model thus derived defines an ODE system whose steady state solution is used as an input to compute the current-voltage operation curve of the cell. Validation of the model is performed comparing the steady state solution against experimental operation curves. Simulations show that for a constant current supply the anode reaches steady state faster and in a smother way, than the cathode.

Keywords: Energy storage, PEMEC dynamics, hydrogen production.

1. Introduction

Modern renewable energy sources such as wind or sunlight cannot be programmed to be available when needed, a feature that represents a barrier for their widespread usage. Conversion to chemicals is a promising alternative for storage of excess electrical energy. In particular, hydrogen production has been considered as an energy storage vector, either for reconversion to electricity (Gabrielli et al., 2017) or for conventional fuels substitution (Pereira and Samsatli, 2017).

Proton exchange membrane electrolyzer cells (PEMECs) are devices that produce hydrogen from water; hydrogen is produced in the cathode, and separated from the oxygen producer anode by a proton conductive polymeric membrane. PEMECs are regarded as the replacement of the current low temperature hydrogen production technology which is based on alkaline electrolyzers.

During operation, PEMECs will be integrated into the electrical grid, possibly as one of many technologies for renewable energy use and storage. Therefore, their operation will be inherently intermittent and mathematical models that capture their dynamics are required even at the design stage.

Dynamic models for PEMECs are already available in the literature. For instance, (Görgün, 2006) presented one in which the electrolyzer is divided in 4 subsystems: anode, cathode, membrane and an auxiliary component that models the relation between voltage and electric current. Although this model has been used by many later contributions, its development stems from models originally derived for proton exchange membrane fuel cells (PEMFCs), which received much more attention during the last decade (Carmo et al., 2013). Therefore, some of the assumptions included in current PEMEC models are inherited from the ones originally valid for PEMFCs, but do not represent the operational

conditions in PEMECs. In this direction, a recent review (Olivier et al., 2017) points out the need for alternative dynamic models.

In this work, we take the modular division proposed by (Görgün, 2006) as the basis to develop a dynamic two-phase (gas-liquid) model for both cathode and anode. This dynamic model allows for water to accumulate as a liquid in both cathode and anode. In each electrode, rigorous mass transfer equations are considered to link the concentration of the species among the two phases. A CSTR-like behaviour and incompressible biphasic flow is assumed to compute the outlet flow of the species for each electrode. The accuracy of the incompressibility simplification is checked by calculating the Mach number corresponding to each electrode outlet.

2. Model description

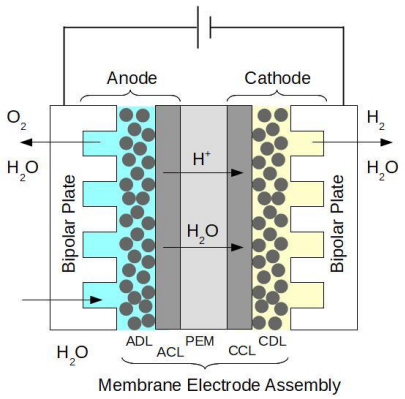

Figure 1. PEMEC diagram

Figure 1 shows a typical construction of a PEMEC cell. PEMECs consist of conductive solid bipolar plates that enclose the contents of the anode, the cathode and the membrane. The membrane is a polymer electrolyte that allows for selective diffusion of protons and water. The anode (in blue in the picture) is the section between the bipolar plate and the PEM itself and consists of a gas/liquid chamber, a diffusion layer (ADL) and a catalyst layer (ACL). The diffusion layer is a porous layer that allows both electrical conductivity and diffusion of the reactants. Electrochemical reactions take place in the catalytic layer, which has to be placed next to the polymeric membrane so that protons can migrate. The cathode (in beige in the picture) is the section enclosed by the bipolar plate and the other side of the PEM and as the anode is divided in three sub-sections: CCL, CDL and gas-liquid chamber, that have similar characteristics to the anode´s. An external power source connected to the circuit provides the required energy.

In the derivations that follow, the volume of each electrode (anode, cathode) is assumed to be constant. In contrast to previous dynamic models, we consider that two separate phases may be present in each electrode. The volume of the liquid phase (V_L) is calculated from the mass of water in the electrodes and assuming the electrolyzer temperature for calculation of density. The volume of the gas phase is calculated substracting (V_L) from the total volume of the electrode.

2.1. Mathematical model for the anode

Water is continuously fed into the anode (flowrate H_2O_{in}) and oxidizes to form gaseous oxygen and protons according to the electrochemical reaction: $2H_2O_{(l)} \rightarrow O_{2(g)} + 4H^+_{(ac)} + 4e^-$. Water consumed by this reaction is regarded as H_2O_{con}. Protons generate and immediately diffuse through the membrane, then do not accumulate in the anode. However, when diffusing they drag an amount of water H_2O_m through the membrane (electro-osmotic drag, see Section 2.3). O_2 generates at a rate $O_{2,gen}$ as dry bubbles within the aqueous phase, hence an amount of water vaporizes and transfers to these bubbles with rate $k_{MT}(p_{sat} - p_{H_2O,a})$.

Flow out of the anode occurs when the total pressure in the anode P_a exceeds the back-pressure (P_{a0}). This total pressure is computed as the sum of the partial pressure of each gas component (O_2, H_2O_{ag}): $P_a = p_{O_2} + p_{H_2O,a}$. When $P_a > P_{a0}$, a valve opens and both gas phase species as well as liquid water exit the anode. The exit flowrate of species X is represented as $X_{a,out}$. Considering the discussion above, the following three mass balances represent the operation of the anode:

$$\frac{dN_{O_2}}{dt} = O_{2,gen} - O_{2,a,out} \tag{1}$$

$$\frac{dN_{H_2O_{ag}}}{dt} = k_{MT}\left(p_{sat} - p_{H_2O,a}\right) - H_2O_{g,a,out} \tag{2}$$

$$\frac{dN_{H_2O_{al}}}{dt} = H_2O_{in} - H_2O_{con} - k_{MT}\left(p_{sat} - p_{H_2O,a}\right) - H_2O_{la,out} - H_2O_m \tag{3}$$

In here, partial pressure of each gas component (p_{O_2}, $p_{H_2O,a}$) is calculated by the ideal gas law; $O_{2,gen}$ and H_2O_{con}, are expressed as a function of the electric current in the electrolyzer (i_{el}) and the number of cells (n_{el}) by Faraday's law: $2O_{2\,gen} = H_2O_{con} = i_{el}n_{el}/2F$. Outlet flowrates for each species ($O_{2,a,out}$, $H_2O_{g,a,out}$ and $H_2O_{l,a,out}$) are calculated from the total exit flow (EF_a^*) assuming the outlet flowrates and the electrode have the same species distribution (CSTR-like behaviour). EF_a^* depends on the pressure difference between the pressure in the anode and the pressure outside and is computed with Bernoulli's equation:

$$EF_a^* = A_{a,out}\sqrt{2(P_a - P_{a0})/\rho_a} \tag{4}$$

In Eq. 4, $A_{a,out}$ is the area of the exit orifice and ρ_a is the average density in the anode. A discharge coefficient (C_D), is included to account for pressure losses and calculate a more realistic exit flow (EF_a): $EF_a = C_D EF_a^*$. It should be noted that Eq. 4 is valid only if there is not a significant variation of the density of the biphasic flow (i.e. incompressible flow). This assumption is valid if the Mach number is under 0.3, a limit that is checked in all simulations.

Finally, temperature of the electrolyser (T_{el}) is assumed to be constant, as it is common practice to feed an excess of water to the make this happen (Medina and Santarelli, 2010), hence energy balances are not considered.

2.2. Mathematical model for the cathode

There are three species present in the cathode: H_2, H_2O (both in liquid and vapor form) and N_2. Gaseous hydrogen is produced by the electrochemical reaction: $2H^+_{(ac)} + 2e^- \rightarrow H_{2(g)}$ at a rate given by Faraday´s law $H_{2gen} = i_{el}n_{el}/2F$; liquid water, is transported through the membrane at a rate H_2O_m as a result of the electro-osmotic drag; as in the anode part of the liquid water vaporizes at a rate given by $k_{MT}\left(p_{sat} - p_{H_2O,c}\right)$; N_2 is, for safety reasons, used to purge the cathode when the cell is not in operation, but it is not continuously fed. The four mass balances that represent the operation in the cathode are:

$$\frac{dN_{H_2}}{dt} = H_{2,gen} - H_{2c,out} \tag{5}$$

$$\frac{dN_{H_2O_{cg}}}{dt} = k_{MT}\left(p_{sat} - p_{H_2O,a}\right) - H_2O_{gc,out} \tag{6}$$

$$\frac{dN_{N_2}}{dt} = -N_{2c,out} \tag{7}$$

$$\frac{dN_{H_2O_{cl}}}{dt} = H_2O_m - k_{MT}\left(p_{sat} - p_{H_2O,a}\right) - H_2O_{lc,out} \tag{8}$$

As in the anode, partial pressure of every gas component is calculated by the ideal gas law, and total pressure in the cathode (P_c) as their sum: $P_c = p_{H_2} + p_{N_2} + p_{H_2O,cg}$. When P_c exceeds the back-pressure of the cathode, there is an exit flow (EF_c^*), calculated with an equation like Eq. 4. Same considerations are taken in both electrodes to calculate the exit rate of each component in each phase, and the validity of Eq. 4.

2.3. Mathematical model for the membrane

As in (Görgün, 2006) accumulation of water species in the membrane is neglected, then the flux of water from the anode to the membrane is identical to the flux of water from the membrane to the cathode and is referenced as H_2O_m. As we are considering that both electrodes operate at the same pressure, only two water-transport mechanisms are considered: electro-osmotic drag and diffusion. In short H_2O_m is computed as:

$$H_2O_m = \frac{n_d P M_{H_2O} i_{el}}{F} + \frac{D_W \rho_{m,d} P M_{H_2O} A(\lambda_a - \lambda_c)}{t_m M_{md}} \tag{9}$$

Electro-osmotic drag (first term) depends on the drag coefficient n_d (average number of water moles "dragged" through the membrane with every H^+ mole) and the current i_{el} applied to the electrolyzer. Diffusion (second term) is computed with Fick´s law and depends on the water content in the membrane (λ) which is estimated from the water activity at each side using the equations in (Görgün, 2006). Other parameters in this term include: water diffusion coefficient D_W, electrode area A, membrane water-free density $\rho_{m,d}$, membrane thickness t_m and the molar mass of the membrane compound M_{md}, all obtainable from vendor data or common correlations.

2.4. Current - Voltage Correlations

Once mass balances are solved, the operating voltage for each cell (V_{el}) is computed by summation of the open circuit potential (E) and the activation and ohmic overpotentials,

$$(\eta_{act}, \eta_{ohm}): V_{el} = (E + \eta_{act} + \eta_{ohm}) \tag{10}$$

Nernst equation is used to calculate the open circuit potential $E = E_0 + RT_{el}/(2F) * log\left(p_{H_2} {p_{O_2}}^{1/2}\right)$. Water activity in the anode is omitted from this equation as it can be assumed to be close to one. Net activation overpotential is the sum of the contribution of each electrode and calculated from Tafel's equation: $\eta_{act} = RT_{el}/(\alpha F) * log(j_{el}/j_0)$. The current density $j_{el} = i_{el}/A$ is the same for both electrodes; the charge transfer coefficient α is estimated as 0.5 for the cathodic reaction and 2 for the anodic one (Marangio et. al., 2009). j_0 , the exchange current density, is a characteristic of the catalyst employed in the catalyst layer, and also depends on the amount used. Ionic transport trough the membrane is the main contributor to ohmic overpotential: $\eta_{ohm} = t_m i_{el}/(A\sigma_m)$. In here σ_m is the membrane proton conductivity, which is obtained from correlations (Marangio et. al., 2009).

3. Numerical Results

The model in Eqs. 1-10 was simulated in Matlab© considering a single cell electrolyzer operating at a temperature of 80 °C and a backpressure of 101 kPa in each electrode.

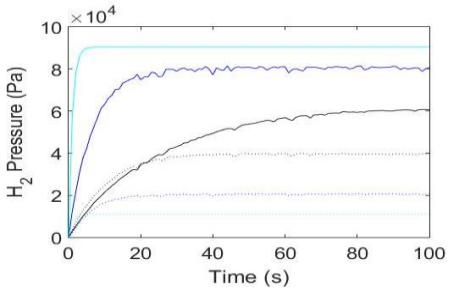

Figure 2. Partial pressures in the cathode. H_2 solid line. H_2O dotted line. $j_{el} = [0.02,0.1,1]$ Acm^{-2} (darker to lighter).

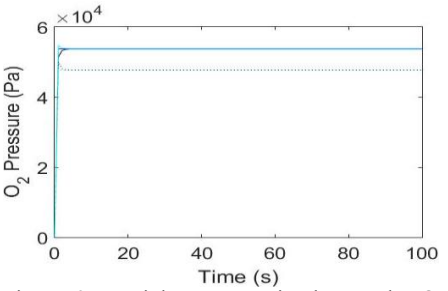

Figure 3. Partial pressures in the anode. O_2 solid line. H_2O dotted line. $j_{el} = [0.02,0.1,1]$ Acm^{-2} (darker to lighter).

According to available information for small commercial PEMECs, the area of the exit orifice was set to be 1% of the area of the electrodes. Physical and construction properties for the membrane were taken from Dupont© Nafion© 115 series. Mass transfer coefficients k_{MT}, were estimated from correlations in (Cussler, 2008). For contact areas, bubbles with a mean size diameter of 50μm were assumed in the anode, whereas in the cathode we assumed an area equal to the area of the membrane, representative of a water film covering the cathode diffusion layer. The assumed incompressibility of the flow was checked in all simulations; confirming a maximum Mach number below 0.01.

Figures 2 and 3 show the partial pressures in the cathode and anode respectively for three operation current densities: 0.02, 0.1 and 1 Acm^{-2}; which were selected following the usual ranges reported in the literature (Yigit and Salomet, 2016). It can be seen that while in the anode partial pressures build up fast and reach a current-independent steady state, the cathode shows a slower response, whose steady state also depends on the current applied to the cell. As the current increases, H_2 production rate increases proportionally, hence, N_2 leaves the chamber sooner, and sooner the pressure inside the chamber is only due to the presence of just H_2 and $H_2O(g)$. In addition, when j_{el} increases, as the characteristic time for water transfer to the gas phase is independent of it, pressure builds up having a larger contribution of H_2 with respect to $H_2O(g)$. Therefore H_2 exiting the cathode contains a lower amount of water in it.

Figure 4 shows the fraction of each electrode occupied by the liquid phase. Notice that although the anode reaches a steady state pressure independent of the current density, the number of moles in the gas phase are not independent of it. This happens because the model accounts for the possibility of changes in the volume of each phase. In particular in the anode, as the current increases, the fraction of liquid largely decreases, from 40% at $j_{el} = 0.1$ Acm^{-2} to 6% at $j_{el} = 1$ Acm^{-2}.

Figure 5 shows the operation curve for the cell $(V_{el}\text{-}i_{el})$ and the overpotentials as described in Section 2.4, for a current density in the range [0.02:0.02:1]. Each point then represents a steady-state solution of the system such as the one shown in Figs. 2 and 3. For Fig. 5 an exchange current density j_0=1E-7 Acm^{-2} was selected for the anode and 1E-3 Acm^{-2} for the cathode. The plot shows that the steady state reached with the proposed model is in agreement with the operation curves and overpotential values reported in literature, and obtained from experimental measurements (Awasthi et al, 2011).

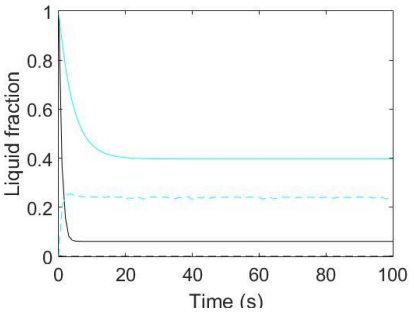

Figure 4. Liquid fraction of the electrodes: anode solid line; cathode (*10E4) dashed line. j_{el} =0.1 Acm^{-2} (lighter) j_{el} =1 Acm^{-2} (dark)

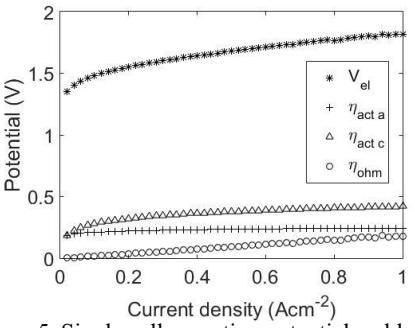

Figure 5. Single cell operating potential and losses. *: Operation voltage, +: anodic activation overpotential, Δ: cathodic activation overpotential, o: ohmic overpotential.

4. Conclusions

In here, a two-phase dynamic model for PEMEC was developed. The model results in steady states whose operational curves are in good agreement with previously reported experimental data and simulations. The dynamics of the individual electrodes show that steady state is not instantaneous but can be reached in the order of minutes, with the cathode being the slower electrode. Water mass transfer limitations in the cathode play a key role in this. In any case, these minutes-scale dynamics reasonably allow for matching with intermittent renewable energy sources.

Abstract

Distillation is one of the primary separation technique widely adopted in process industry. For separating a multicomponent mixture by distillation, a sequence of columns will be required. In this work, distillation sequences with both simple column and dividing wall column (DWC) are contained under the sharp split assumption for five-component separations. A two-level optimization is conducted with the objective of minimum total annual cost. The optimal distillation sequence with DWC can be efficiently identified based on dynamic programming method. In this work, alcohol system is studied to compare with a hydrocarbon system. Based on the optimal distillation sequence obtained, the impact of intermolecular forces is discussed, which could be instructive to reduce optimization computation load of distillation sequence and narrow the searching scope of the optimal position for multicomponent separation DWC. The optimal sequences with DWC included at the last step in five-component hydrocarbon system with various mixture contents are also investigated.

Keywords: DWC, distillation sequence, position

1. Introduction

Distillation is a well-known separation technique. For separating multicomponent mixtures, distillation operations are conducted sequentially. The energy-saving has always been the focus of researchers. Dividing wall column (DWC) proposed by Wright (1949) is an atypical distillation column with an internal partition wall for separating multicomponent mixture into three output streams. It is reported that about 30 % cost can be saved by the application of DWC (Triantafyllou and Smith, 1992). When including DWC, the number of columns in each sequence can be reduced, while the number of feasible distillation sequences will increase rapidly (Zhang et al., 2017), which makes it computationally challenging for finding the optimal sequence. The number of all possible sequences is obtained by simple enumeration of any possible subproblems, or columns for adjacent components, without considering the inherent characteristics of separation problem itself. The aim of this work is to find the possibility to remove some enumerated sequences by considering related physical-chemical property of materials in the separation system.

In this work, five-component separations in alcohol system and hydrocarbon system have been studied as examples. Based on the simulation and optimization results of all

subproblems achieved by Aspen Plus software, the correspondingly optimal distillation sequences are found by dynamic programming method. Then intermolecular forces are discussed in terms of their impact on energy consumption, as well as on the optimal separation sequence.

2. Methodology

2.1. Column level optimization

The column models are based on the equilibrium stage concept (Mueller and Kenig, 2007). Short-cut method implemented in Aspen Plus is used to get design parameters first. The parameters obtained were used to initialize the stage-to-stage rigorous method RadFrac for simple column. The simulation of DWC is achieved by functionally equivalent configuration Petlyuk (Petlyuk et al., 1965). Total annual cost is estimated based on optimization results obtained. To evaluate the operating cost, which contains recycling water cost and low pressure steam cost, 8000 hour operation per year is assumed. According to the diameter, height, temperature, pressure and other data of column, equipment costs can be indirectly calculated based on engineering calculation software SW6. The investment payback period is assumed as 6 years. The cost difference of dynamic control between simple column and DWC has not been considered in this work.

2.2. Distillation sequence level optimization

Separation sequences are different combinations of subproblems realized by specific columns, which have been optimized in previous section. The optimal sequence of separation system in this research is obtained through multi-stage decision-making by the dynamic programming method proposed by American mathematician Bellman in 1957, i.e., in such a problem, a sequence for a subproblem has to be optimized if it exists in the optimal sequence for the whole problem.

The objective function of multi-stage decision defined by Howard (1966) can be written as follow:

$$\Phi = min \sum_{i=0}^{N-1} C(X_k, U_k) \tag{1}$$

where X_k refers to the end state of k stage decision or the start state of k+1 stage decision; U_k represents the control or decision of k+1 stage; C represents the cost function of k+1 stage, which is the function of X_k and U_k.

Let the $V_j(X_i)$ refers to the minimum value of the objective function since the X_i state decision transfer to the end state. Recursive formula based on dynamic programming method can be shown as follow ($V_0(X_N) = 0$):

$$V_{N-k}(X_k) = \min_{U_k \in U} \{C(X_k, U_k) + V_{N-(k+1)}(X_{k+1})\} \quad (\mathrm{k} = 0,1,\ldots,\mathrm{N}-1) \tag{2}$$

2.3. Intermolecular force calculation

Considering the process of distillation, Wayner mentioned in 1999 that part of the energy consumption comes from overcoming intermolecular forces in micro perspective. Intermolecular force mainly includes: the interactions between ions, charged groups, dipoles and induced dipoles; hydrogen bonds; the interactions of hydrophobic groups and non-bond electronic repulsion (Duan and Zhou, 1989). By using Materials Studio

software, the intermolecular forces can be calculated and analyzed to show its impact on the final distillation sequence.

3. Case study

3.1. Cases

Hydrocarbon and alcohol are common separation systems in chemical industry and also typical systems for the DWC relevant studies. Feed fractions for all three cases considered in this work are given in Table.1. Product specifications are 0.990 (mol frac).

In most industrial process, pure product is more preferred. If a DWC is used to separate

Table.1 Feed Conditions

Cases	**Feed Fraction (mol frac)**				
Case 1	isobutane	pentane	hexane	heptane	octane
	0.200	0.200	0.200	0.200	0.200
	0.177	0.235	0.177	0.235	0.177
Case 2	hexane	heptane	octane	2-methyloctane	n-nonane
	0.200	0.200	0.200	0.200	0.200
Case 3	methanol	n-propanol	n-butanol	n-pentanol	n-hexanol
	0.200	0.200	0.200	0.200	0.200

three components into three pure products, it will appear at the last separation step in a sequence. In Case 1, light hydrocarbon separation system is studied with two sets of mixture contents. The number of distillation subproblems U and distillation sequences S_R can be calculated by Eq.(3) and Eq.(4), which are 23 and 20 respectively according to our previous work (Zhang et al., 2017).

$$U = \frac{R(R-1)(R+1)}{6} + (R-2) \tag{3}$$

$$S_R = \sum_{m=0}^{\frac{R}{2}} \frac{binomial(R-2m+1,m)\cdot binomial(2R-4m,R-2m)}{R+1-2m} \tag{4}$$

where R is the number of components. (R=1,2,3,…,n)

Table.2 Boiling points (BP) of five components in Case 2 and Case 3

	Component1	**Component2**	**Component3**	**Component 4**	**Component5**
Case 2	hexane	heptane	octane	2-methyloctane	n-nonane
BP (℃)	68.7	98.3	125.7	143.4	150.8
Case 3	methanol	n-propanol	n-butanol	n-pentanol	n-hexanol
BP (℃)	64.7	97.2	117.7	137.8	157

In practical separation process, the use of a dividing wall column in multicomponent separation is also a choice. In case 2 and case 3, DWC is not limited to the last step in the distillation sequence. It can be seen in Table.2 that boiling points of corresponding components are quite close in both case 2 and case 3.

The number of distillation subproblems U and distillation sequences S_R in case 2 and case 3 can be calculated by Eq.(5) and Eq.(6), which are 35 and 38 respectively according to our previous work (Zhang et al., 2017).

$$U = \frac{(R-1)R(R+1)(R+2)}{24} \tag{5}$$

$$S_{Q+1} = \sum_{k=0}^{\lfloor \frac{Q}{2} \rfloor} \frac{C_{2Q-k}^{Q+k} C_{Q+k}^{k}}{Q+1} \ (R = Q+1) \tag{6}$$

Peng-Robinson thermo model is used to calculate the vapor-liquid equilibrium for all cases. The optimization of single column and the distillation sequence is achieved as described in section 2.1 and 2.2. Number in optimal sequence represents carbon number.

3.2. The optimal sequence of Case 1

Through four-stage decision-making, each node in the dynamic programming tree has an optimal choice. Then the optimal sequence (4,5,6,7,8)→4/5678→5/678→6/7/8 is achieved from 20 possible sequences with two kinds of mixture contents. The optimal sequence with simple column only is (4,5,6,7,8)→4/5678→567/8→56/7 →5/6. The specific steps are shown in Figure 1. "*C*" refers to the cost function *C* in formula (1).

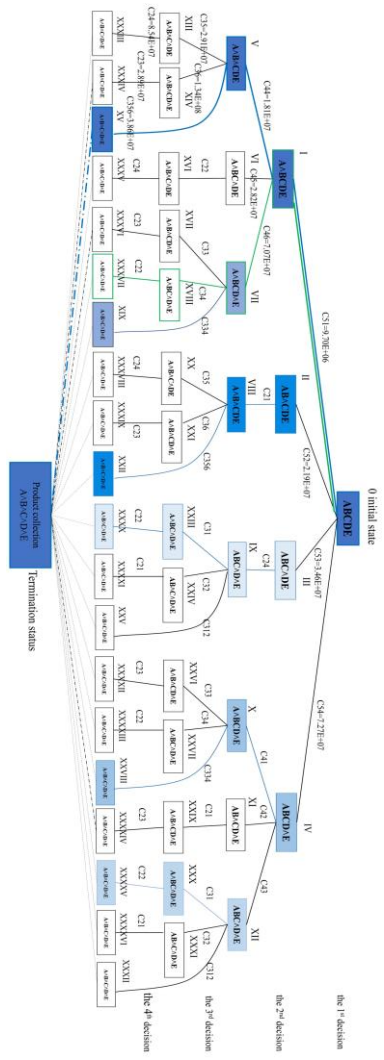

Fig. 1 Dynamic programming sequence tree for Case 1

3.3. The optimal sequence for Case 2

The optimal distillation sequence with DWC in new hydrocarbon system is (6,7,8,9a,9b) → 67/8/9a9b → 6/7+9a/9b. Besides, the best sequences with simple column only is (6,7,8,9a,9b) → 67/89a9b → 6/7+89a/9b → 8/9a, in which 9a and 9b represent 2-methyloctane and n-nonane.

3.4. The optimal sequence for Case 3

(1,3,4,5,6)→1/3/456→4/5/6 as the optimal distillation sequence with DWC in alcohol system, achieved from 38 possible sequences. The best sequences with simple column only is (1,3,4,5,6)→13/456→1/3+4/56→5/6.

Table.3 Cost comparisons

Optimal sequence	Hydrocarbon system(Case 2)		Alcohol system(Case 3)	
	Operating cost	Total cost	Operating cost	Total cost
DWC+Simple column	9.75E+07	9.91E+07	4.69E+07	4.74E+07
Simple column	1.14E+08	1.15E+08	6.89E+07	6.92E+07
Cost saving	14.3%	13.8%	31.9%	31.5%

The operating cost and total annual cost comparison between the two optimal distillation sequences are given in Table.3. The energy consumption of the sequence with dividing wall column is less that without it in both cases.

4. Results and discussion

4.1. The impact of intermolecular force on the optimal separation sequence.

It can be seen that DWC is adopted at the first step of optimal sequence in both case 2 and case 3, but the output components of DWC in the optimized sequences are different which should be determined by the inherent characteristic of each system. As mentioned above, the difference of boiling points between adjacent components are quite similar in case 2, case 3. Among all the factors, intermolecular forces cannot be neglected, which is considered as one of energy barrier for the separation of different components. By using Materials Studio software, the intermolecular forces can be simulated for single component, two to four adjacent components.

Table.4 The sum of intermolecular forces

Alcohol system	The sum of intermolecular forces /eV	Hydrocarbon system	The sum of intermolecular forces /eV
1/3/456	1.4114	6/7/89a9b	2.2267
1/34/56	3.2808	6/78/9a9b	4.1930
1/345/6	3.6290	6/789a/9b	4.1572
13/4/56	1.7300	67/8/9a9b	2.7604
13/45/6	3.8118	67/89a/9b	4.0601
134/5/6	1.6437	678/9a/9b	1.8159

*The numbers in the first and third columns in the table refer to the carbon numbers, and 9a and 9b represent 2-Methyloctane and n-nonane respectively.

The sum of intermolecular forces through the complete sequence is assumed positively related to the total energy for separating each adjacent components. As shown in Table.4, the sum of intermolecular forces can be clustered into two groups, and that of the optimal distillation sequence is found in the lower cluster, as marking with shadows in the table,

i.e. first step cutting form like A/B/CDE, AB/C/DE and ABC/D/E, are possibly candidates for optimal sequence. It can be concluded that those within the higher group shouldn't be considered during the searching for the optimal sequence, which could significantly reduce the computation load, especially at the stage of the optimization of single column. Besides, it is also found that the cutting point of the first step in optimal distillation sequence with simple columns only is one of the two cutting points of DWC in the optimal distillation sequence with both simple column and DWC.

Based on the discussion above, it can be seen that the intermolecular force does affect the total energy consumption of a distillation sequence. With the knowledge of it, the computation load can be significantly reduced in the optimization of distillation sequence.

4.2. The subproblem separated by DWC in the optimal sequence

It can be observed from the result of case 1 that the optimal sequences obtained are totally different when DWC is included, however, the DWC is always applied for separating the three most heaviest components once it is included. Same result can also be found in case 3. It can be explained that the benefit on energy saving of DWC is more significant when heavier mixture is processed.

5. Conclusions

The optimal distillation sequences with DWC for five-component separation in alcohol system and hydrocarbon system have been identified by dynamic programming method based on the results of simulation and optimization of single columns. Intermolecular forces are calculated, their impact on the optimal sequence has been discussed based on existing results, which could be a reference for reducing the computation load in the optimization of distillation sequence in other separation system by eliminate sequences with significant higher total intermolecular forces.

Abstract

Low-density polyethylene (LDPE) is a branched polymer whose processing and end-use properties are mainly determined by the molecular weight distribution (MWD), the long chain branching distribution (LCBD) and short chain branching distribution (SCBD). In general, a suitable characterization of LDPE needs a simultaneous knowledge of these three distributions. This work presents a rigorous model of the high-pressure ethylene polymerization in tubular reactors, capable of predicting the joint bivariate distributions MWD-LCBD and MWD-SCBD, as well as monomer conversion and average molecular properties. The bivariate distributions are modeled using the 2D probability-generating function (2D pgf) technique. This deterministic technique allows a simple and efficient calculation of the distributions, in spite of the complex mathematical description of the process. The reactor model is used to analyze the effect of different process and design variables on the above mentioned joint distributions and on other properties of the product.

Keywords: Low-density polyethylene, High-pressure, Tubular reactors, Mathematical model, Branching distributions.

1. Introduction

LDPE is one of the most widely used commodity polymers, with a production rounding 19 Mt per year. It is used in a broad variety of applications, such as food packaging, general-purpose containers, bags, toys, films, etc. It is suitable for different processing techniques, such as extrusion, blowing or injection. The molecular properties of the polymer, and therefore its processing and end-use properties, are strongly determined by the reactor operating conditions. For this reason, a predictive tool able to simulate the reactor output for a given operating point is very useful to gain insight into the process. The processing and end-use properties of LDPE are mainly determined by the MWD, the LCBD, and the SCBD. It is well established that in highly branched polymers, long chain branches have a great impact on the rheological behaviour, affecting the flow properties of the material. Additionally, they affect some of its solid state properties (Pladis and

Kiparissides, 1998). On the other hand, short chain branches have an important influence on the polymer density. In general, a complete characterization of LDPE requires knowing simultaneously all three distributions. A high-fidelity reactor model capable of calculating these three distributions is very desirable.

Several mathematical models have been reported for the production of LDPE in tubular reactors, but few of them deal with the joint distributions of molecular weight and branches. Meimaroglou and Kiparissides (2010) presented a stochastic algorithm that provides information about topological characteristics of LDPE, including both MWD-LCBD and MWD-SCBD. This model was later extended to include the prediction of the viscoelastic behaviour of the polymer (Kiparissides et al., 2010; Meimaroglou et al., 2011; Pladis et al., 2015).

Although stochastic methods provide very detailed information on the molecular structure, they may have high computational demands. Furthermore, they may have difficulties with the quantification of the high molecular weight tail of MWDs, where chain concentrations are very low (Meimaroglou and Kiparissides, 2010). In the present work, a novel deterministic model of the high-pressure ethylene polymerization in tubular reactors is developed. The model can predict joint bivariate distributions MWD-LCBD and MWD-SCBD, as well as average molecular properties and conversion.

2. Reactor model

The mathematical model is an extension of a previous work by the authors (Asteasuain and Brandolin, 2008). The former model was rigorous, considered a realistic reactor configuration and included detailed correlations for the physical and transport properties. It could predict average molecular properties, conversion, and the univariate MWD. The updates to that model presented here consist of the prediction of the bivariate MWD-LCBD and MWD-SCBD. The bivariate distributions are calculated applying the 2D pgf method (Asteasuain and Brandolin, 2010; Brandolin and Asteasuain, 2013; Brandolin et al., 2016).

Deterministic models of polymer processes are built based on population balance equations (PBEs) derived from a kinetic mechanism of the process. These equations describe the evolution of the population of polymer molecules characterized by a set of internal coordinates, the distributed properties of interest (i.e. molecular weight, number of short or long branches). Usually, direct solution of the PBEs is not feasible because they form a very large (infinite in theory) system of coupled equations. The 2D pgf method works by transforming the infinite system of bivariate PBEs (i.e. PBEs characterized by two internal coordinates) into the pgf domain, obtaining a finite system of equations in which the dependent variable is the pgf transform of the distribution. Pgf values obtained from the solution of the pgf equations are fed to an inversion formula to recover the desired bivariate distributions. Then, the final mathematical model is composed of the finite set of pgf equations and the algebraic pgf inversion equations. This method is a general modelling tool that does not assume any shape of the distribution and can be applied to different systems even those with complex kinetic mechanisms. In addition to the bivariate distributions, the extended model computes conversion, the number- and weight-average molecular weights ($\overline{M_n}$,$\overline{M_w}$), long-chain branches (LCB/1000 C) and short chain branches (SCB/1000 C).

The mathematical model is built upon two parallel set of equations for the prediction of the MWD-LCBD and the MWD-SCBD, respectively. Table 1 shows the corresponding

kinetic mechanisms. Here $R_{n,m}$ and $P_{n,m}$ represent living radical and dead polymer chains with chain length m and n-1 long chain branches (i.e subscript n computes the main chain+branches). Similarly, $R_{h,\,m}$ and $P_{h,\,m}$ are living radicals and dead polymer chains with chain length m and h short chain branches. Long chain branches are considered to be formed by chain transfer to a dead polymer chain (Eq. 17). In its turn, an intramolecular transfer reaction (Eq. 22) is considered to be responsible for the formation of short chain branches.

Table 1. Kinetic mechanism for chain branching prediction.

Step	Long chain branching prediction		Short chain branching prediction	
Peroxide initiation	$I_k \xrightarrow{f_k\, k_k} 2R_{1,0}$	(1)	$I_k \xrightarrow{f_k\, k_k} 2R_{0,0}$	(2)
Monomer thermal initiation	$3M \xrightarrow{k_m} R_{1,1} + R_{1,2}$	(3)	$3M \xrightarrow{k_m} R_{0,1} + R_{0,2}$	(4)
Oxygen initiation	$O_2 + M \xrightarrow{k_o} 2R_{1,1}$	(5)	$O_2 + M \xrightarrow{k_o} 2R_{0,1}$	(6)
Generation of inert	$O_2 + R_{\mathrm{n,m}} \xrightarrow{f_o k_o} X$	(7)	$O_2 + R_{\mathrm{h,m}} \xrightarrow{f_o k_o} X$	(8)
Propagation	$R_{\mathrm{n,m}} + \mathrm{M} \xrightarrow{k_p} R_{\mathrm{n,m+1}}$	(9)	$R_{\mathrm{h,m}} + \mathrm{M} \xrightarrow{k_p} R_{\mathrm{h,m+1}}$	(10)
Termination by combination	$R_{\mathrm{n,m}} + \mathrm{R}_{\mathrm{y,j}} \xrightarrow{k_{tc}} P_{\mathrm{n+y-1,m+j}}$	(11)	$R_{\mathrm{h,m}} + \mathrm{R}_{\mathrm{y,j}} \xrightarrow{k_{tc}} P_{h+\mathrm{y,m+j}}$	(12)
Thermal degradation	$R_{\mathrm{n,m+1}} \xrightarrow{k_{tdt}} P_{\mathrm{n,m}} + R_{1,1}$	(13)	$R_{\mathrm{h,m+1}} \xrightarrow{k_{tdt}} P_{\mathrm{h,m}} + R_{0,1}$	(14)
Chain transfer to monomer	$R_{\mathrm{n,m}} + \mathrm{M} \xrightarrow{k_{trm}} P_{\mathrm{n,m}} + \mathrm{R}_{1,1}$	(15)	$R_{\mathrm{h,m}} + \mathrm{M} \xrightarrow{k_{trm}} P_{\mathrm{h,m}} + \mathrm{R}_{0,1}$	(16)
Chain transfer to polymer	$R_{\mathrm{n,m}} + \mathrm{P}_{\mathrm{j,y}} \xrightarrow{k_{trp}} P_{\mathrm{n,m}} + R_{\mathrm{j+1,y}}$	(17)	$R_{\mathrm{h,m}} + \mathrm{P}_{\mathrm{j,y}} \xrightarrow{k_{trp}} P_{\mathrm{h,m}} + R_{\mathrm{j,y}}$	(18)
Chain transfer to transfer agent	$R_{\mathrm{n,m}} + \mathrm{S} \xrightarrow{k_{trs}} P_{\mathrm{n,m}} + R_{\mathrm{1,0}}$	(19)	$R_{\mathrm{h,m}} + \mathrm{S} \xrightarrow{k_{trs}} P_{\mathrm{h,m}} + R_{0,0}$	(20)
Backbiting	$R_{\mathrm{n,m}} \xrightarrow{k_{bb}} R_{\mathrm{n,m}}$	(21)	$R_{\mathrm{h,m}} \xrightarrow{k_{bb}} R_{\mathrm{h+1,m}}$	(22)
β-Scission of secondary radical	$R_{\mathrm{n,m+1}} \xrightarrow{k_{\beta 1}} P_{\mathrm{n,m}} + R_{\mathrm{1,1}}$	(23)	$R_{\mathrm{h,m+1}} \xrightarrow{k_{\beta 1}} P_{\mathrm{h,m}} + R_{0,1}$	(24)
β-Scission of tertiary radical	$R_{\mathrm{n,m+1}} \xrightarrow{k_{\beta}} P_{\mathrm{n,m}} + R_{\mathrm{1,1}}$	(25)	$R_{\mathrm{h,m+1}} \xrightarrow{k_{\beta}} P_{\mathrm{h,m}} + R_{0,1}$	(26)

3. Results and discussion

The reactor model was used to study the influence of the operating conditions on the bivariate molecular weight-branching distributions. As an example, Table 2 summarizes the operating conditions of two of the cases analysed. Operating the reactor under Case I conditions produces a polymer with a unimodal MWD, while operation under Case II conditions gives rise to a bimodal MWD with a low molecular weight tail. In Case II, average molecular weights and dispersity index are larger than in Case I, while average branching content is lower. More detailed information about the MWDs obtained and the reactor configuration can be found in Asteasuain and Brandolin (2008).

Figure 1 shows contour plots of the MWD-LCBD at the reactor exit for the two cases. For both of them, a high fraction of the polymer contains between 0 and 2 LCBs per molecule (excluding the main chain). Furthermore, as the number of LCBs increases the molecular weight distributions at a given branching content become narrower and the weight fractions of the polymer chains decrease. At the same time, distributions shift towards higher molecular weights. That is expected because branching formation implies reactivating a dead polymer chain that starts growing again. Note that the MWD-LCBD of Case II is shifted towards higher molecular weights compared to Case I, which means that the same branching content is present in chains that are longer than those in Case I.

Table 2. Case I and II operating conditions (Asteasuain and Brandolin, 2008).

Operating Conditions	Case I	Case II
Inlet temperature (° C)	77	85
Inlet pressure (bar)	2300	2173
Oxygen main feed (kg/s)	6.9×10^{-5}	8.9×10^{-5}
Transfer agent main feed (kg/s)	0.00762	0.064
Transfer agent first lateral injection (kg/s)	0	0
Transfer agent second lateral injection (kg/s)	0	0.61
Peroxide first lateral injection (kg/s)	0.00102	8.5×10^{-5}
Peroxide second lateral injection (kg/s)	1.57×10^{-4}	6.9×10^{-5}
Monomer main feed (kg/s)	11	10.2
Monomer first lateral injection (kg/s)	0	0
Monomer second lateral injection (kg/s)	0	0.8
Location of first lateral injection (z/L)	0.12	0.03
Location of second lateral injection (z/L)	0.63	0.62
Jacket temperature zones 1-8 (° C)	170-225-170-170-170-170-170-170	270-150-270-266-150-150-159-270
Conversion (%)	25.8	20.5
$\overline{M_n}$	21602	25670
$\overline{M_w}$	162958	224149
SCB/1000C	24.73	14.79
LCB/1000C	2.14	1.37

Similarly, Figure 2 shows the contour plots of the MWD-SCBD. It can be seen that most chains have between 0 and 40 short chain branches. At low SCB content, the molecular weight distributions at a given branching content shift towards higher molecular weights as the number of branches increases. This occurs until a certain value of SCB (about 40), from which the peaks of the distributions do not change significantly. Similarly to the MWD-LCBD, there is also a shift towards higher molecular weights of the MWD-SCBD, but more subtle in this case.

Figure 3 depicts the branching density, expressed as average number of branches/1000 C, as a function of molecular weight. It may be noted that for Case I the short and long branching density are higher in almost all ranges of molecular weight. This is consistent

with the data in Figures 1 and 2, which show that at constant branching content the chains are longer in Case II than in Case I. The effect is much more noticeable for the LCB. Figure 3 also shows that the change in the operating conditions has a stronger effect on the LCB density distribution than in the SCB density distribution, in the form of an important shift towards high molecular weights.

4. Conclusions

In the present work, a deterministic model is presented that can predict the bivariate molecular weight-long and short chain branching distributions of LDPE produced in high-pressure tubular reactors. To the best of our knowledge, this is the first deterministic model for this process that includes these features. To demonstrate the predictive capabilities of the proposed approach, two operating conditions were simulated, obtaining, as a result, detailed information on the LCBD-MWD, SCBD-MWD and average number of short and long chain branches.

Abstract

Agent-based modeling (ABM) is a novel modeling approach to address the complexity of systems that comprise heterogeneous interacting individuals. ABM is naturally hybrid for its ability to integrate quantitative and qualitative knowledge, deals with multiple levels of actions, and performs best when combined with conventional modeling approaches. In this study, a hybrid agent-based platform is developed using high performance computing to simulate a mammalian cell culture bioreactor. This platform enables communication of the agent-based model with the first principle models to account for quantitative changes in nutrient and metabolite concentrations and their distribution in the bioreactor. The model can predict viable cell density, and the cell cycle distributions along with the important nutrients and metabolites such as glucose and lactate. Integrating this cell culture agent-based model with high-performance computing leverages parallel processing to allow the ABM program to run faster, more efficiently, and with a higher capacity for the number of cells that can be modeled. The model is validated using bench-scale bioreactor experiments and showed good agreement with experimental data.

Keywords: Agent-Based Modeling, Mammalian Cell Culture, Cell Cycle, High-Performance Computing

1. Introduction

In the production of therapeutic proteins, cell cycle distribution, viable cell density and viability provide critical information on the health of the cell culture within the bioreactor. It is also useful to know the metabolic flux rates of glucose consumption and lactate production/consumption. This information can give insights into optimal feeding strategies and harvest decisions as well as the optimal process conditions for higher productivity.

Cell culture bioreactors have relied heavily upon experimental data for the purposes of scale-up, optimization, monitoring, and process control. Various types of computational models, including population balances, have been developed to predict cell physiology and behaviour (Mantzaris et al. 2001). Knowledge of cell cycle phase behaviour in response to environmental conditions and inputs can be used to optimize the production of therapeutic proteins because different proteins are optimally expressed in different

phases of the cell cycle. Studies showed it may be beneficial to arrest the cells in either the G1 or S phase through a temperature shift (Al-Rubeai and Emery, 1990; Leelavatcharamas et al. 1999).

Agent-based modeling is a powerful programming paradigm where autonomous computational entities, the agents, act in accordance with stochastic and deterministic rules. These rules describe the behaviour of agents within an environment or context. An environment can be a continuous or discrete space such as the substrate of a bioreactor or any type of network, such as a social or opinion network. The individual behaviour of heterogeneous agents on a microscopic level will combine to give the macroscopic behaviour of the entire system being modeled. The ABM approach easily integrates first principles models, heuristics, and probabilistic variation. These powerful capabilities make ABM a great candidate to model and understand complex cell behaviour in mammalian cell bioreactors. There are numerous software packages that can be used to construct ABMs including Repast (Recursive Porous Agent Simulation Toolkit) Simphony and Repast HPC (High Performance Computing) (Collier and North, 2013; North *et al.*, 2013). As the number of cells grows exponentially high performance computing becomes necessary to parallelize the code and speed up simulations. An ABM of CHO cell culture was developed in Repast Simphony (Bayrak *et al.*, 2016). Due to inherent computational limitations of desktop computer simulation the number of cells simulated using this model could not reach to realistic scales. In this work, it has been upgraded to Repast HPC to speed up the simulation time and increase the capacity of agents that can be handled through Message Passing Interface (MPI) used for parallel processing (Collier and North, 2013).

The overall goal of this work is to improve upon a model of CHO cell behaviour that was published in Bayrak et al. (2016), and develop this model using Repast HPC. The model can serve as an in-silico monitor to aid in process control and optimization of cell culture processes. This model intends to reduce the level of experimentation involved in cell culture process monitoring and optimization. It can potentially provide better insight into CHO cell behavior in response to their environment within bioreactors in order to reduce the need for black box parameter optimization and suggest promising regions for experimental validation and eliminate regions not worthy of testing.

2. Methods

The ABM rule-base used in this paper, based on Bayrak et al. (2016), is shown in Figure 1 below. Any set of conditions with high sodium or lactate is considered severe to cells. High oxygen is considered at least favourable or highly favourable depending on whether the glucose level is low or high, respectively. Based on these sets of environmental conditions, probabilities have been assigned to give the autonomously acting CHO cell agents actions to stochastically take as they progress through the cell cycle while sensing their environment. In the favourable conditions, CHO cells progress through the cell cycle and proliferate the most efficiently. Metabolic shift to lactate metabolism is also considered when glucose concentration is low and lactate production is high. Under mild and mild to severe conditions, cells have the option of shifting to G0 or a slight probability of entering apoptosis if they have not shifted to consuming lactate, however, G0 is experimentally indistinguishable from G1, and if they have shifted to consuming lactate then they will progress through the cell cycle inefficiently. As observed in the literature (Hwang *et al.*, 2011), pH outside a cell-line dependent

specified range within pH 7 and/or a shift to a temperature lower than 37 °C results in G1 or G2M arrest, but cells in S phase continue to replicate their DNA and progress through the cell cycle. Under severe conditions, cells have a high probability of progressing through the stages of apoptosis until cell death. A CHO cell metabolic flux model for glucose consumption and lactate production/consumption was also introduced into this ABM to predict glucose and lactate levels in the cell culture process.

The variables such as shear stress (τ), energy dissipation rate (ϵ), and the Kolmogorov micro-scale of turbulence (λ) are also considered in the rule base. According to Motobu et al. (1998), at a shear stress of 0.082 N/m^2, the percentage of confluent cells in S phase is much lower at 20% compared to 30% for 0 shear and a slight majority, close to 50%, of cells are in G2M compared to 40% for 0 shear. This observation supports the rule that shear stress contributes to G1 and G2M arrest. According to Vickroy et al. (2007), when the local Kolmogorov micro-scale of turbulence in a bioreactor is between 50% and 100% of the size of the cell's diameter, then the observed growth rate is reduced to 66% of its maximum rate. This observation supports the new rule that when a cell is exposed to an appropriately sized Kolmogorov eddy, its doubling time will increase by 50% and it will have a 33% probability of entering early apoptosis. According to Sieck et al. (2013), the energy dissipation rate seems to only have an impact on monoclonal antibody productivity, reducing it to 75% of its normal rate, and most of today's suspension CHO cell lines can thrive at energy dissipation rates several orders of magnitude higher than typically needed for plant-scale production, up to 1e5 W/kg compared to 1e0 W/kg. Since hydrodynamic conditions affect the viability of cells, it was decided in the rule base to check the Kolmogorov micro-scale of turbulence and shear stress first before checking the concentrations of the soluble media components.

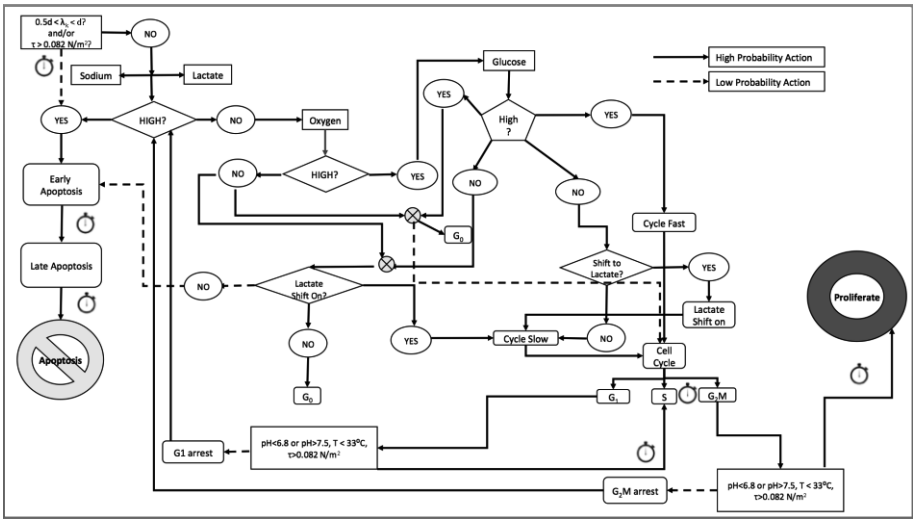

Figure 1. ABM rule-base.

Additionally, in order to represent heterogeneity of the culture, the ages of the initially inserted CHO cell agents were randomized. In other words, the amount of time they have previously spent in their initially assigned phase at the start of the simulation was randomized and could be non-zero.

The ABM was initialized with the first experimental data point and the CHO cell agents are subjected to the same pH, temperature, glucose, lactate, and sodium as the CHO cells in the corresponding experiment. However, the CHO Cell agents take actions autonomously based on the ABM rule-base.

A Red Hat (Maipo release 7.1) Linux server with an Intel(R) Xeon(R) 3.10GHz CPU and 62.5 GB RAM was used to build and run this model. The Agent-Based Modelling software used was Repast HPC version 2.2.0. Repast HPC consists of software libraries for a C++ compiler.

3. Results

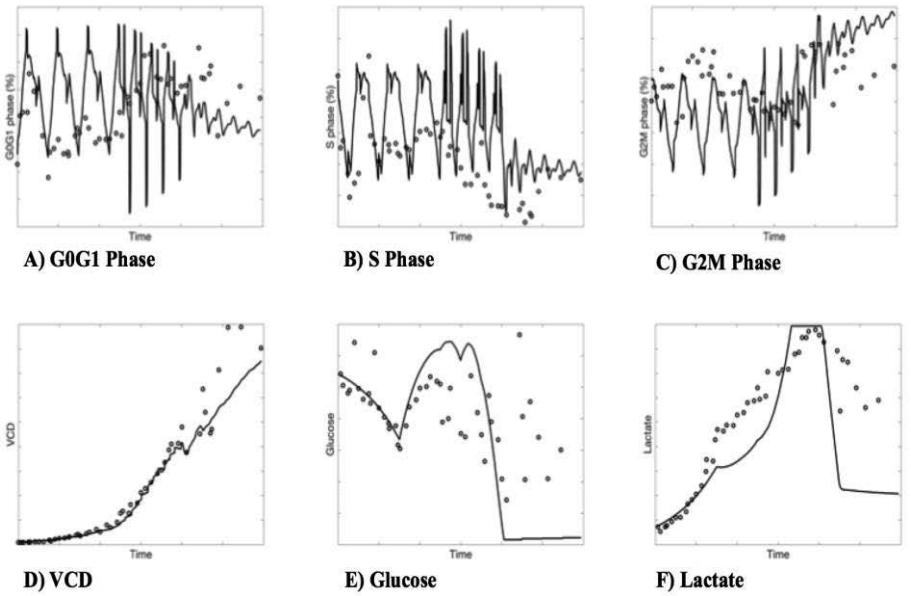

Figure 2. HP-ABM Experimental Validation for a cell culture process

The ABM predictions are compared with cell culture experiments without taking into account the hydrodynamic variables in the rule base, so the bioreactor was assumed to be homogeneous. Figure 2 shows that the ABM predictions for cell cycle distribution, viable cell density (VCD), glucose concentration, and lactate concentration for an Amgen proprietary cell culture process agree well with the experimental data. The simulation started initially with 9,600 agents to proportionally represent the proprietary initial VCD, and ended with 1,024,041 agents and took on the order of 10 minutes on the hardware mentioned in the methods section. The model prediction showed higher cyclic behavior compared to experimental data for the cell cycle predictions. The oscillations near the end of the experiment dampen because of cell cycle arrest. As expected, lactate production increases for the initial duration of the experiment, and then decreases as the cells shift to consuming lactate due to decreasing glucose and high availability of lactate to use as an energy and carbon source. The glucose agreement is good the duration of the experiment before a process change made that was not

accounted for in the model. The agreement for viable cell density to experimental data is higher. Different phases observed in the data correspond to Amgen proprietary cell culture process changes.

We have also conducted high performance bench-marking tests to measure the computational efficiency. The results of weak and strong scaling tests are shown in Figure 3 below. In the weak-scaling test where all processes have the same number of agents (10,000), the trend is near linear growth with slight increase for up to 32 processes. This might be due to less efficient parts in the algorithm. In the strong-scaling test where the same number of agents is divided among an increasing number of processes, significant decrease in computational time is observed as expected.

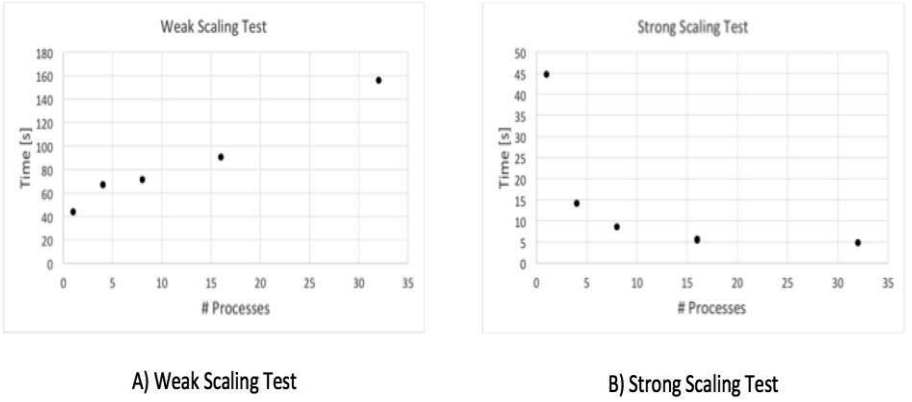

Figure 3. Weak and Strong Scaling Tests

4. Conclusions

The HP-ABM has been demonstrated to reasonably predict cell cycle phase distribution and more accurately predict viable cell density, glucose, and lactate. The computational time was reduced 100-fold using Repast HPC when compared to the desktop version of the model published in Bayrak et al. (2016). Repast HPC uses C++, which naturally compiles and runs faster than ABM code written in JAVA for, the language of the previous model done with Repast Simphony. Furthermore, the Repast HPC code has the capability of running on multiple CPU cores simultaneously. The model developed can be potentially used to monitor and control cell culture processes towards optimal productivity.

Abstract

A multiscale model combines the computational efficiency of a macro-scale model and the accuracy of a micro-scale model. With the current cyberinfrastructure resources available, using more computationally intensive and concurrent multiscale models are more feasible. This study proposes to use Discrete Element Method (DEM) and a Population Balance Model (PBM) in a simultaneous manner to model the granulation process of a pharmaceutical product inside a high shear granulator. The DEM provides the collision data while the PBM helps in predicting the macroscale phenomena like aggregation and breakage. The execution of each of the components is governed by a multilevel job scheduler which allocates resources. This method of using shorter bursts of each simulation led to faster simulation times as well as a more accurate model of the high shear granulator. The Quality by Design (QbD) approach is addressed using such a modelling framework and it also helps us understand the granulation process in a quantitative as well as in a mechanistic manner.

Keywords: Multi-scale Model, Population Balance Model, Discrete Element Method, High-performance computing, MPI.

1. Introduction

Particulate materials are products or intermediates of around 60% of the chemical industry (Ingram and Cameron, 2004). The modelling of these particulate processes pose a challenge when compared to modelling if uniform liquid systems. These solid systems usually comprise of solids which co-exist with various sizes and shape configuration, which have a large effect on the final composition and the performance of the product (Ingram and Cameron, 2005). This variation in the configuration of the product is unacceptable by the pharmaceutical industry. It could lead to differences in the dissolution rates and bioavailability of the product thus, affecting the quality of the product. The unit process that helps control the size of a granule of the powder in the pharmaceutical product is granulation. During this unit operation, fine powders are converted to the larger particles by the process of aggregation. This occurs due to addition of a liquid binder, making the particles agglomerate into larger granules. This process is also referred to as wet granulation as a liquid binder is added. Due to high restrictions set by the Food and Drug Administration (FDA) these products undergo

various batch rejections or have high recycle ratios (Sen *et al.*, 2014). One of the major aims of the industry currently is to reduce this waste, thus creating a need for better modelling of this process.

The most popular way to model the granulation process is to use a population balance model (PBM). This model tracks the number of particles with certain set of characteristics such as size, porosity and liquid content. It also takes into account the changes that may occur in these properties due to growth, breakage, consolidation, and other phenomena. This model is discussed in more detail in section 2.1. PBM fails to account for the particle level data, thus being inaccurate at times. This particle level data needed to improve the PBM can be obtained from discrete element methods (DEM). DEM helps obtain the velocity of each particle and the number of times it collides with other particles by solving the Newton's laws of motion. This information is vital to the PBM as it helps develop a more accurate model with a higher physical significance. As these methods are complementary to each other, they are usually coupled while building a model for the granulation process. These processes can be coupled serially like in Sampat *et al.*, 2017 or in parallel as discussed in this work. DEM is always executed at initiation and the particle level data is then transferred to the PBM. The DEM simulation is computationally very high as it needs to solve large amounts of simultaneous equations at every time step. The parallel execution of this type of coupling requires various instances of simulation of each of these models to be initiated, requiring high computational power. The most efficient way to make these simulations run faster is to take advantage of large number of CPU cores present on modern day high-performance computing systems (HPCs / supercomputers).

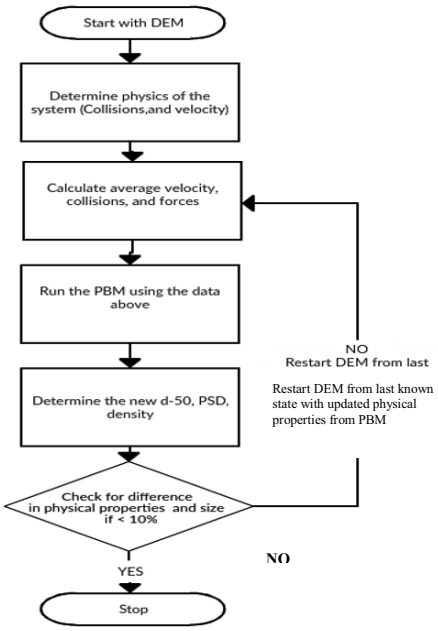

Figure 1: Schematic of the bi-directional approach used to model the high shear granulator.

This work focuses on the development of physically accurate model for a high shear granulator. Section 1 discusses the model equation used and the method of parallelization implemented on the PBM and DEM to enable them to run on various cores of HPCs. The resulting particle properties from the coupling and the speed improvements achieved when the number of cores used for the simulation are changed, is discussed in section 3.

2. Methods

Figure 1 represents the workflow that was used to model the high shear granulator. A two-dimensional PBM was developed for the solids present while a lumped model was used for the liquid and gas content. The PBM tracked particle flow, aggregation, breakage, consolidation and liquid addition. This PBM used the particle velocities and

collision data from the DEM simulations making it mechanistic in nature. The DEM simulation was used to obtain the particle residence time, velocities, inter-particle as well as particle-geometry collisions. These simulations were monitored using python scripts to switch in between the two simulations. The details of each of these components are discussed in this section.

2.1. Population Balance Model (PBM)

A detailed, mechanistic two-dimensional PBM was developed in C++, which tracked the particles as they undergo the aggregation, breakage, consolidation and liquid addition. The governing population balance model is shown in Equation 1.

$$\frac{\delta}{\delta t}F(s_1, s_2, x, t) = \Re_{agg}(s_1, s_2, x, t) + \Re_{br}(s_1, s_2, x, t) + \dot{F}_{in}(s_1, s_2, x, t) - \dot{F}_{out}(s_1, s_2, x, t) \quad (1)$$

Where, $\dot{F}(s_1, s_2, x)$ is the number of particles with an active pharmaceutical ingredients (API) volume of s_1 and an excipient volume of s_2 in the spatial compartment x. The rate of change of number of particles with time in different size classes depend on the rate of aggregation, $\Re_{agg}(s_1, s_2, x)$ and the rate of breakage, $\Re_{br}(s_1, s_2, x)$. Also, the rate of particles coming into, $\dot{F}_{in}(s_1, s_2, x)$ and going out, $\dot{F}_{out}(s_1, s_2, x)$ of the spatial compartment due to particle transfer affect the number of particles in different size classes.

The aggregation and breakage kernel as defined in Equations 2 and 3 respectively. These mechanistic kernels used the DEM inter-collision data as well as the impacts with the geometry to determine the collision and impact rate. The velocity of these particles were used to create a velocity distribution which decided whether the particle agglomerated with other particles or had to undergo breakage due to the impact on the geometry. The further details about the aggregation and breakage kernels can be found in Barrasso and Ramachandran, 2015. Details about the lumped model for the gas and liquid present in the system can be found in Sampat *et al.*, 2017.

$$\Re_{agg}(s_1, s_2, x) = \int_0^{s_1}\int_0^{s_2}\beta(s_1', s_2', s_1 - s_1', s_2 - s_2', x)F(s_1', s_2', x)F(s_1 - s_1', s_2 - s_2', x)ds_1'ds_2 - F(s_1', s_2', x)\int_0^{s_{max_1}-s_1}\int_0^{s_{max_2}-s_2}\beta(s_1, s_2, s_1', s_2', x)F(s_1', s_2', x)ds_1'ds_2' \quad (2)$$

Where, the aggregation kernel, $\beta(s_1, s_2, s_1', s_2', x)$ is expressed as a function of collision rate coefficient and probability that collision results in agglomeration.

$$\Re_{br}(s_1, s_2, x) = \int_0^{s_{max_1}}\int_0^{s_{max_2}} K_{br}(s_1', s_2', x)F(s_1', s_2', x)ds_1'ds_2' - K_{br}(s_1, s_2, x)F(s_1, s_2, x) \quad (3)$$

Where, the breakage kernel $K_{br}(s_1, s_2, x)$.

The number of solid bins selected for this simulation were 16 for each type of solid. The granulator was divided in 4 axial compartments to help with the parallelization of the *C++* code. Since each compartment needed to perform identical calculations which were independent each other, they could be sent different CPU cores without any decrease in the speed as there will be minimum communications between these

processes for a given time step. Thus, each of compartment was sent to a single process (core) using message parsing interface (MPI). The PBM code was made to dump the d50 and number of particles at an interval of *0.2s* such that the controller could monitor the execution.

2.2. Discrete Element Method (DEM) setup

The DEM simulation was performed on an open-source DEM software known as LIGGGHTS (Kloss *et al.*, 2012). The DEM simulation has to be initiated using a input file which was generated using a python script which was developed. The python script also helped generate the multiple restart files which would be required to restart the DEM simulation during the parallel multi-scale simulation. LIGGGHTS natively supports parallelization using MPI, which helps divide the geometry into various smaller simulation boxes thus, making them run faster compared to a serial code.

The particles used in the DEM simulation were of diameter 2mm and were considered to be granular in nature. A non-cohesive elastic contact model was used to model the collisions between the particles. The particles were introduced at the entry of the geometry with a constant mass flow rate of 15 kg/hr. The impeller of the granulator was set to rotate at 2000 rotations per minute. This was kept so high since this would lead higher number of particles colliding with the walls of granulator leading to breakage of the particles. Physical properties of the particles required for the simulation were taken from Sampat *et al.*, 2017. The collision and velocity data of the particles from the DEM simulation was printed at pre-decided intervals such that it could be monitored.

2.3. Controller Development

The controller scripts to monitor the DEM and PBM simulations were written in python. Each of these scripts were executed along with its respective simulation. The DEM controller script monitored the collision and velocity data being dumped by the DEM simulation. The data was first stored and the average of the velocities for each type of particles and the total number of collisions and impacts were determined. If there was a change in either of these properties of more than 15%, an exit status was sent which led to killing the execution of the DEM and indicated to start the PBM simulation. The DEM controller script also printed out various data files required for the PBM execution as well as for the restart of the DEM simulation if needed. In the case, the properties did not show a variation of more than 15% over the span of 5s of DEM simulation time, it was considered to be in steady state and that all the simulations were halted. The PBM controller read the d50 and number of particle files which were printed by the PBM after a constant time interval. The change in each of these properties in each compartment was monitored and an exit signal was sent if they varied by more than 15%. The halting of the PBM was accompanied by the printing of files required to restart DEM with new diameters and data for restarting the PBM if needed after the DEM simulation.

2.4. RADICAL – Pilot (RP)

Running several simulations that are dependent on High Performance Computing (HPC) resources can be extremely time consuming, since each simulation must be submitted in the resource independently, which can lead to varying queuing times. RADICAL-Pilot (RP) is a framework that implements the Pilot abstraction (Luckow *et al.*, 2012), where a container job is submitted to the HPC resource, the Pilot, and once

the necessary computing resources are being acquired they can be used to execute multiple simulations by reusing the same resources. By utilizing RADICAL-Pilot, we implemented an execution framework that allows to utilize the components described above. In addition, RP provides the necessary instructions to terminate or restart the execution of DEM or PBM simulations based on decisions made from the various controlling components.

3. Results and Discussions

This coupled DEM-PBM simulation were tested on the Stampede2 supercomputer with the Knights Landing configuration. Each of the compute node of the cluster consists of Intel Xeon Phi 7250 "Knights Landing" which has 68 cores on a single socket clocked at 1.4 GHz, with 96 GB of DDR4 RAM. Each of the cores consists of 4 hardware threads. Simulations were run on various configuration of the cores used for each of the component of the system. The number of cores used for the DEM simulation were 64, while the PBM used 4 MPI processes. The DEM and PBM controller scripts used 1 process each for their respective executions.

The coupled system took 10 DEM and 9 PBM simulations to reach steady state. Total simulation time of DEM execution was 3.575 seconds and PBM was 60 seconds.

3.1. Improved System Dynamics

The advantage of using a multiscale model in parallel is that the physical properties of the particles can be updated to the new values while moving among the simulations. This not only helps achieve better results but also reduces the time required for simulating the system. Granulation is used to control the size of the granules of a powder mixture. The median diameter of this powder mixture is usually used to characterise the behaviour of the system. For better control, median diameter of this system should increase gradually such that the time of granulation can be capped.

Figure 2 shows the evolution of median diameter of the simulated wet granulation process inside a high shear granulator with time. A slow but steady increase initially in the diameter is observed which is followed by breakage of granules into smaller ones due to the high amounts of shear present as the impeller rotates at high RPMs. This observation shows us that the model is better at predicting the characteristics of the process. The observed trend is better than previous works which only took into account only a serial coupling i.e. using the DEM collision information into the PBM for a single iteration.

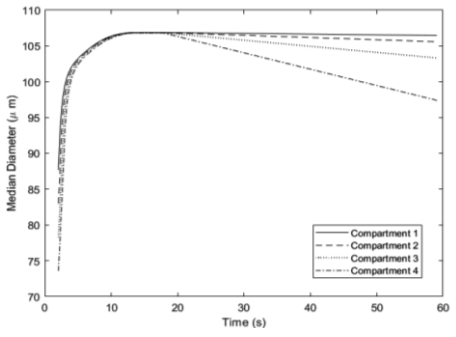

Figure 2: Median diameter of the system as a function of time. The value decreases in all compartments with time predicting high amounts of breakage as observed in a high

3.2. Simulation Speedup

When DEM and PBM are coupled for a single iteration, the steady state DEM data is passed to the PBM. DEM studies performed for this system showed that the system took

about 6 simulation seconds to reach steady state, which resulted in a wall time of 13 hours using 128 cores. The PBM was run on 4 MPI process which tool about 15 minutes to simulate. In this study, DEM studies ran for a total of 3.575 simulation seconds which took 9.76 hours. The PBM was simulated for a total of 60 simulation seconds consisting of 10 seconds of mixing and 50 seconds of liquid addition which took 49.27 minutes. Thus, it can be seen that the coupled simulation which has more components compared to a serial simulation finishes faster with better results. Since the data is updated after every iteration of each simulation and passed into the other it leads to the system reaching steady state quicker than a standalone simulation.

4. Conclusions

Multiscale models have recently been gaining popularity in pharmaceutical process modelling and some of its advantages are conveyed using this study. The coupled model is physically more accurate and has speed advantages over a serial model. The study also presents a model that utilizes HPCs for a quicker solution compared to traditional desktop computers and can also help design a control strategy for the granulation process. Currently, the challenge in implementation a control strategy lies in the online measurement of the particle size distribution (PSD) inside the equipment. The latest measurement techniques are not able to measure PSDs on the fly yet. Once the live data is available, a model can be initiated from the current state of the equipment and help reduce the computation required for the prediction. This work is a continued effort in the implementing a process control model to the granulator to help reduce pharmaceutical product waste.

edenmar@auburn.edu

Abstract

For petroleum exploration and engineering, the classification of underground formation lithology from well log data is a task of considerable import. This is because, lithology classification is the basis of reservoir parameter calculations and geological research studies. With the rising prowess of cheap computational devices, large amounts of data can now be analyzed with much higher accuracy and efficiency. Hence, there have recently been increased efforts to automate lithology classification. In one such effort, Xie et al. (2018) recently evaluated five machine learning methods to classify formation lithology by using data from the Daniudui gas field (DGF) and Hangjinqi gas field (HGF). Although their tree-based ensemble models performed well, there is still scope for improvement in the predictive ability. Motivated by the encouraging results obtained from the boosting approach to machine learning in their work, we applied this approach in our work with the aim of improving upon the predictive ability of their ensemble models. Specifically, we applied the AdaBoost and LogitBoost meta-algorithms using decision stumps and random trees as base learners. We evaluated the boosted trees by calculating metrics such as precision, recall, F1-score and PRC area after implementing 5-fold and 10-fold stratified cross-validation. In our analysis, amongst the applied meta-algorithms, we found that the implementation of the LogitBoost meta-algorithm, with random tree as a base learner, possessed the highest performance metrics.

Keywords: Lithology classification, ensemble machine learning, boosting, AdaBoost, LogitBoost

1. Introduction

Lithology identification involves the classification of rock formations based on their physical characteristics. In petroleum exploration and engineering, lithology identification forms one of the core tasks. It underlies the calculation of reservoir parameters. It also is the basis of geological research studies. Traditionally, the formation lithology has been identified in two ways (Salehi and Honarvar, 2014). First is through inference from cut pieces obtained during drilling. The second method of inference has been through analysis of core samples gathered from underground formations. In practice, however, both methods of inference can be unreliable. This may occur because geologists may introduce their bias while assessing rock samples. Consequently, different geologists may interpret rock samples differently (Akinyokun et al., 2009). Due to this concern, attention has shifted towards utilizing various computational techniques for assessing well log data for formation lithology classification. Well log data has proved useful not only for calculation of petrophysical parameters but also for sedimentologists and reservoir engineers. If computational models to identify different grain sizes of clastic rock with better accuracy are made

available, geologists can build better quantitative reservoir evaluation models (Xie et al., 2018). Recently, a variety of approaches have been introduced for lithology identification including those employing kernels (Sebtosheikh et al., 2015) and ensemble machine learning techniques like random forests. However, as Xie et al. (2018) note in their work, less work has been conducted to compare the performance of various machine learning methods for assessment of well log data. In their work, to address this paucity, they compared five machine learning methods. These were artificial neural networks, random forests, naïve bayes, support vector machines and gradient boosted trees. They analyzed data obtained from DGF and HGF located in China and found that ensemble methods, gradient boosted trees and random forests, overall, provided a good level of performance. Although the gradient boosted tree performs well on their dataset, there is still scope for improvement with regards to the classification accuracy metrics used by them. For example, for the dataset pertaining to DGF, they reported the average precision, recall and F1-scores to be 0.827, 0.824 and 0.822 respectively. Motivated by the encouraging performance of the gradient boosted tree on their datasets, we investigated the use of other boosting based machine learning approaches for classification in our work. Specifically, we implemented the AdaBoost and LogitBoost meta-algorithms in our work. To the best of our knowledge a comparative analysis of the AdaBoost and LogitBoost meta-algorithms has not been conducted on the dataset of Xie et al. (2018).

2. Methodology

Two diverse and labelled datasets consisting of well log data from DGF and HGF respectively were obtained from the work of Xie et al. (2018). The DGF dataset consists of 915 well log readings from five wells while the HGF dataset consists of 1238 log readings from seven wells. In both datasets, carbonate rock, coal, pebbly sandstone, coarse sandstone, medium sandstone, fine sandstone, siltstone and mudstone are the eight target lithology classes that need to be identified by the classification methods. Additionally, seven log parameters are used to identify the lithology. The seven log parameters consist of gamma ray log, acoustic log, density log, compensated neutron log, deep latero log, shallow latero log and caliper log. More details on the dataset and the features used can be found in the work of Xie et al. (2018). It is worth noting that the DGF and HGF datasets are imbalanced. Imbalanced datasets are those in which instances corresponding to certain classes are significantly lower than others. The imbalance is especially sharp in the HGF dataset where only 14 instances of the coal class exist. By comparison, 370 instances of pebbly sandstone exist in the HGF dataset. Also, unlike the DGF dataset, the HGF dataset has no instances of the carbonate rock class. In our work, like Xie et al. (2018), we use the reported seven features to identify the lithology classes. Also, we rely solely on the boosting approach to ensemble machine learning in our work. In our work, all ensemble boosting approaches were evaluated using the WEKA software (Hall et al., 2009).

2.1. Ensemble Machine Learning

As the name suggests, ensemble machine learning is performed by generating an ensemble of models, which can involve training constituent models on resampled datasets. These models are then concatenated in some form (for example, by averaging) to then provide predictions of response variables of interest (Dev et al., 2017). Ensemble methods have been applied successfully for tasks as disparate as image classification and compound classification. Contrary to expectations, ensemble learning methods may

generate constituent models that can predict barely better than what can be achieved by chance. The reason for employing such models for ensemble construction is that they are computationally inexpensive to generate. Such constituent models are termed 'weak learners' or 'base learners'. Two of the most common approaches to ensemble construction are randomization and boosting.

2.1.1. Randomization-Based Approaches

Randomization-based approaches (RBAs) produce distinct models from a single initial training set by introducing random perturbations into the learning procedure (Dev et al., 2017). Thus, ensemble construction in these approaches can be parallelized. A commonly utilized approach is bagging or bootstrap aggregation. Randomization-based approaches at the very least achieve a reduction in the error due to variance. Additional details and resources for consultation on RBAs can be found in Rokach (2016).

2.1.2. Boosting

Boosting involves choosing training sets for base learners such that they are forced to infer something new about the data each time they are called. Unlike RBAs, boosting constructs ensembles sequentially. Boosting works by assigning a large weight to training samples incorrectly classified by the current classifier. Next, another classifier is trained after accounting for the weights. This process is repeated until a certain stopping criterion is achieved. Essentially, at each iteration, a new base-learner is trained with respect to the error of the whole ensemble learnt so far. Unlike RBAs, the construction of each base learner is strongly dependent on the previously generated base learners. The Boosting approach to develop a model *f(x)* is visualized in Fig. 1, which has been adapted from Sugiyama (2016).

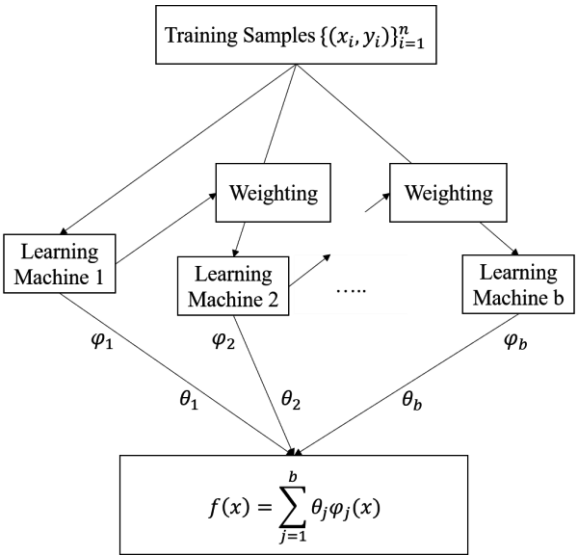

Figure 1: Boosting

In Fig. 1, φ_j is the j^{th} base learner and θ_j is the j^{th} weight associated with the j^{th} learner. Probably the most popular boosting approach is AdaBoost (Rokach, 2016). AdaBoost is short for adaptive boosting, and the algorithm is characterized by the adaptive manner in which it produces and concatenates weak learners. Friedman et al. (2000) observed that Adaboost is in effect approximating a stagewise additive logistic regression model by

optimizing an exponential criterion. Consequently, new variants of AdaBoost were developed that fit additive models directly. One such variant is LogitBoost (Friedman et al., 2000), which employs Newton-like steps to optimize the loss criterion. In our work, we have focused our attention on the AdaBoost and LogitBoost meta-learners. In our work, the meta-learners employed decision stumps (DSs) and random trees (RTs). A DS is a decision tree containing only the root node and the leaves, i.e., a stump contains no internal nodes. RTs are trees grown on a random subset of descriptors (Baskin et al., 2017). Thus, in total four methods were evaluated for classification in our work.

3. Results and Discussion

The average and weighted average performance metrics for classification, i.e., precision (Pr), recall (Re), F1-scores (F1) and the precision recall curve (PRC) area are reported in Tables 1-4. Table 1 and Table 2 contain metrics corresponding to 10-fold stratified cross-validation (SCV) and 5-fold SCV respectively, based on the DGF dataset. Similarly, Table 3 and Table 4 contain metrics corresponding to 10-fold and 5-fold SCV respectively, based on the HGF dataset. SCV is more appropriate for our datasets than cross validation (CV), which was implemented by Xie et al. (2018) in their work. This is because in the case of imbalanced datasets, it accounts for the distribution of the classes of the instances while creating the folds and offers additional variance reduction. Also, it should be noted that Xie et al. (2018) have not reported the weighted average values of the performance metrics despite class imbalance. Unlike Xie et al. (2018), we have also chosen to report PRC area values. They can especially be informative for imbalanced datasets (Saito and Rehmsmeier, 2015). Xie et al. (2018) have also restricted their analysis to 5-fold CV. However, it should be noted that, unlike our work, they have tuned their hyperparameters. In contrast, we chose the defaults offered by the WEKA software (Hall et al., 2009) for model evaluation. As can be noticed from the results, when AdaBoost employs DS the metrics are very low. LogitBoost with DS, however, improves the performance metrics. In general, LogitBoost with RT provides the best performance metrics, both for the DGF and the HGF datasets.

Table 1: Metrics for 10-fold SCV on DGF dataset

Method	Pr	Re	F1	PRC area	
AdaBoost w/DS	0.086	0.222	0.124	0.197	Average
	0.129	0.341	0.186	0.228	Weighted Average
AdaBoost w/RT	0.777	0.769	0.772	0.830	Average
	0.762	0.764	0.762	0.829	Weighted Average
LogitBoost w/DS	0.692	0.659	0.669	0.732	Average
	0.676	0.677	0.673	0.729	Weighted Average
LogitBoost w/RT	0.821	0.818	0.820	0.845	Average
	0.809	0.807	0.807	0.840	Weighted Average

Table 2: Metrics for 5-fold SCV on DGF dataset

Method	Pr	Re	F1	PRC area	
AdaBoost w/DS	0.124	0.223	0.148	0.200	Average
	0.163	0.336	0.207	0.232	Weighted Average
AdaBoost w/RT	0.774	0.755	0.765	0.820	Average
	0.764	0.764	0.763	0.818	Weighted Average

LogitBoost w/RT	0.845	0.797	0.819	0.879	Average
	0.829	0.829	0.828	0.899	Weighted Average

4. Conclusions

With the aim of developing classifiers with high accuracy and to improve upon the models trained in the work of Xie et al. (2018), in our work we investigated boosting based approaches to machine learning for lithology classification. Specifically, we applied AdaBoost and LogitBoost meta-learners to decision stumps and random trees. In our work, amongst the applied meta-algorithms, we found that AdaBoost when combined with decision stumps, performed poorly as compared to other combinations. We found that by using random trees as base learners instead of decision stumps much better accuracy was achieved. LogitBoost in combination with random trees performed best in our study of both the DGF and HGF datasets. This evaluation was based on 5-fold and 10-fold SCV. Despite not tuning the hyperparameters, we found our results to be comparable to those reported by Xie et al. (2018). We also made sure that the dataset imbalance was taken into consideration while reporting the performance metrics. This will help reservoir engineers and/or geologists in making a more informed decision. Our future efforts would likely be devoted to expanding the scope of our study to simultaneously analyse well log data from different countries. We would also like to overcome class imbalance by studying the impact of sampling techniques such as under-sampling, over-sampling and their hybrid variants. Additionally, we would like to optimize the hyperparameters and evaluate if it leads to better results.

Abstract

China is rich of oil shale as one of alternative fossil energy resources. The oil shale processing in China is mainly based on Fushun type technology. However, low utilization rate of raw material, low oil yield, and high content of heavy components in the oil are the main problems. An indirectly heated moving bed is developed by the Institute of Process Engineering of Chinese Academy of Sciences to de-bottleneck Fushun type technology. The new technology has shown good potential in its pilot operation. The oil shale refinery process with the indirectly heated moving bed is modeled and simulated in this work. Based on the simulation, a techno-economic analysis is performed and compared with the conventional Fushun oil shale refinery process. Results show that: for a shale refinery of 3.0 Mt/y scale, (1) 375 t/h oil shale retorting requires 149.6 MW of heat, in which 60% of the heat is produced by combustion of the oil shale pyrolysis gas, while remaining 40% from the coal gasified gas. (2) In consideration of investment and operation, the cost of product shale oil of the new process is 2636 CNY/t, which is 12% lower than that of the conventional Fushun refinery process. This benefit comes from higher utilization of raw material and oil yield of the new process. (3) The competitive crude oil price of the indirectly heated moving bed refinery process is about 51 $/bbl, while that of the Fushun refinery process is 58 $/bbl. During 2017 year, the crude oil price fluctuates at around 50 $/bbl, thus the new indirectly heated moving bed refinery process shows better economic competitiveness.
Keywords: indirectly heated moving bed, shale refinery, modeling, analysis

1. Introduction

The shale oil-equivalent reserves in the world is 6902×10^8 tons, three times the world's crude oil reserves, as shown in Figure 1 (Zuckerman, 2014). In 2014, the shale oil production reached 2.1×10^8 tons, one-third of conventional petroleum production in the U.S. This has completely changed the pattem of international oil and gas supply, known as the shale revolution (Zuckerman, 2014). In China, the amount of oil shale reserves is 476×10^8 tons oil-equivalent, twice China's crude oil reserves (Mulchandani and Brandt, 2011). Chinese oil shale mining is mainly concerned with surface mining of shallow shale seams stored 100-400 below the ground. By 2014, China produced 1 million tons of shale oil through oil shale refinery (Qian et al., 2014). The capacity of shale oil is expected to exceed 3 million tons by 2020 (Li et al., 2015). The exploitation and utilization of oil shale are strategically important in alleviating the shortage of oil and gas resources in China.

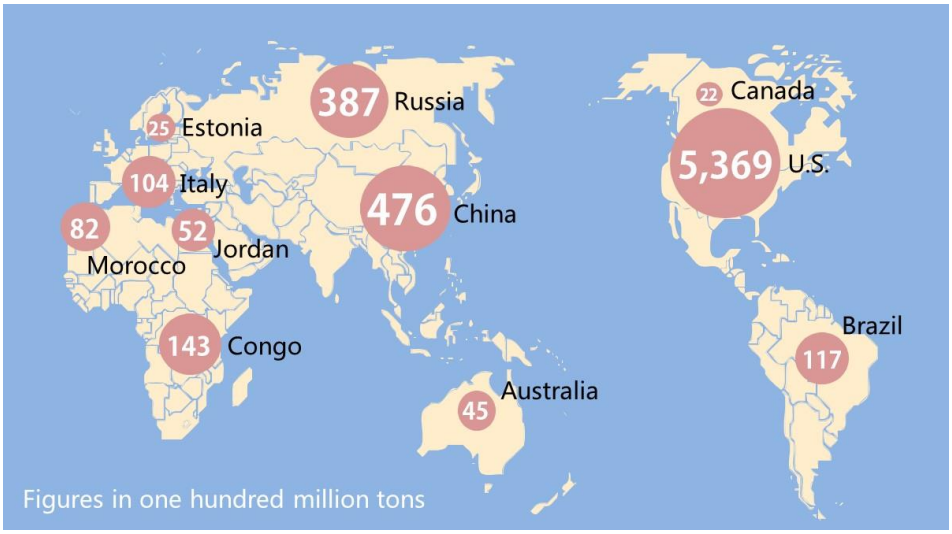

Figure 1. Shale oil-equivalent reserves in the world

There are two types of oil shale refinery technologies: in-situ and ex-situ (Wang et al., 2014). In China, only ex-situ represented by Fushun (FS) type technology has been applied (Qian et al., 2014). However, the Fushun technology suffers from low utilization of raw material (80%), low oil yield (65%), and low content of light components in the shale oil (20%) (Qian et al., 2014). The Chinese Academy of Science has developed an indirectly heated moving bed (IHMB) with the scale of 1000 tons/y oil shale (Lin et al., 2016). Compared with the Fushun technology, the utilization of raw material of this new technology is increased by 20%, the oil yield by 25%, and the content of light components in the oil by 46% (Lin et al., 2016).

The IHMB oil shale refinery process is shown in Figure 2. The process includes an oil shale pyrolysis unit, a coal gasification unit, an oil-gas separation unit, and a semi-coke for power generation unit. The oil shale is first milled and screened, and the shale particles below 10 mm in diameter enter the retort to pyrolysis. Part of the heat required for shale pyrolysis comes from the whole cycle of pyrolysis gas, while the remaining heat is provided by additional fuel gas. The syngas from associated coal gasification during the oil shale mining is used as fuel gas to complement the additional heat. The oil-gas mixture produced by pyrolysis is released from the top of the retort, and then fed into the cyclone separator to remove dust. After that, the oil-gas mixture enters the oil-gas separator to obtain retorting gas and shale oil. The retorting gas and coal gasification syngas are mixed and cycled to combust to supply heat for shale pyrolysis. In addition, the semi-coke produced by pyrolysis is discharged from the bottom of the retort. After drying, the semi-coke enters the circulating fluidized bed to burn to produce high-pressure steam, which is used to generate electricity through the steam turbine.

Figure 2. Flow diagram of the IHMB refinery process

Followed in this paper, the key units of the IHMB refinery process are modeled and simulated in Section 2. Techno-economic analysis of the new process will be conducted in Section 3, and the results are compared with the conventional Fushun refinery process to point out the advantages and disadvantages of the new process.

2. Modelling and simulation of oil shale refinery process

In this work, the Aspen Plus (Version 7.2) process modeling software is used to simulate the IHMB refinery process, in which the oil shale pyrolysis unit is modeled and simulated in details. The processing scale of the new process is 375 t/h oil shale. The raw materials adopt Huadian oil shale and associated coal, corresponding proximate and elemental analyses are shown in Table 1 (Qian et al., 2014; Lin et al., 2016).

Table 1 Proximate and elemental analyses of oil shale and coal

	Proximate (wt. %, ar)				Elemental (wt. %, ar)				
	M	FC	V	A	C	H	O	N	S
Oil shale	3.43	1.77	22.83	71.97	50.16	6.37	38.12	1.99	3.35
Coal	18.42	15.64	32.21	33.73	61.42	4.93	15.30	0.86	0.29

Figure 3 shows the Aspen Plus simulation calculation procedure of the IHMB. According to the actual process, the retort is divided into a drying stage and a retorting stage. A RYield block is utilized to model the drying stage. Its temperature is 200 °C and pressure is 0.1 MPa. In addition, a RCSTR block is used for modeling of the

retorting stage. The temperature and pressure of the RCSTR reactor are set to 550 °C and 0.1 MPa.

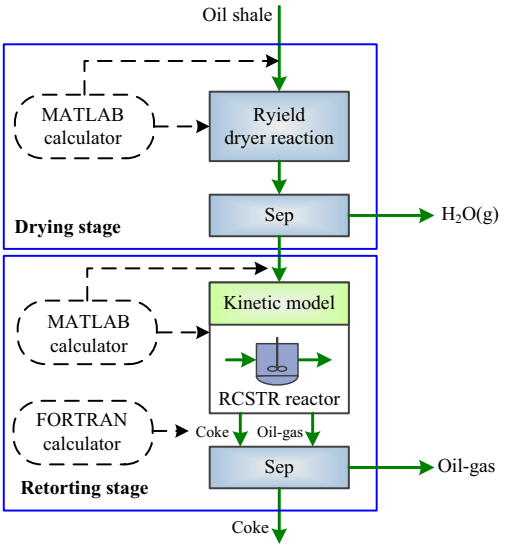

Figure 3. Aspen Plus simulation calculation procedure

The reaction in the drying stage is the removal of surface and internal moisture of the shale particles, while that in the retorting stage is kerogen pyrolysis, as follows:

$$\text{Kerogen} \rightarrow H_2 + H_2O + H_2S + NH_3 + CO + CO_2 + CH_4 + C_2H_4 + C_2H_6 + C_3H_8 + C_4H_{10}O + \text{Semi-coke} \quad (1)$$

The kinetic equation of the pyrolysis reaction is as follows (Syed et al., 2011):

$$\frac{\mathrm{d}x}{\mathrm{d}t} = k(1-x)^n \quad (2)$$

where x is the extent of conversion, t is the time, k is the specific rate constant, and n is the order of reaction. According to the Arrhenius equation, the reaction constant k is formulated as (Goldfarb et al., 2013):

$$k = A\mathrm{e}^{-Ea/RT} \quad (3)$$

where A is the apparent frequency factor, Ea is the apparent activation energy, and R is the gas constant. According to Qian et al. (2014), Ea is set to 158 KJ/mol, A to 2.03×10^9, and n to 1.0. The kinetic equation of the retorting reaction is as follows:

$$\frac{\mathrm{d}x}{\mathrm{d}t} = k(1-x)^n = A\exp\left(-\frac{E_a}{RT}\right)(1-x)^n = 2.03\times10^9\,\mathrm{e}^{-19004/T}(1-x) \quad (4)$$

Based on the kinetic equation Eq. (4), a piece of external FORTRAN subroutines are programmed and utilized in Aspen Plus to calculate the pyrolysis yields of oil shale. The simulation data of yields of the oil shale pyrolysis products are shown in Table 2. The results are validated by comparing with industrial data (Lin et al., 2016).

Table 2 Comparison between simulation and industrial data of oil shale pyrolysis

Component	Mass fraction (%)	
	Simulation data	Industrial data
Semi-coke	81.44	81.46
CO	1.16	1.14
CO_2	3.82	3.78
CH_4	0.93	0.91
C_2H_4	0.07	0.06
C_2H_6	0.16	0.18
C_3H_6	0.11	0.13
C_3H_8	0.29	0.25
H_2	0.28	0.27
NH_3	0.08	0.07
H_2S	0.18	0.17
H_2O	3.36	3.40
$C_{14}H_{10}O$	8.12	8.18

3. Techno-economic analysis

3.1. Thermodynamic performance

In this paper, we take the retort as a benchmark to conduct thermal balance calculation. The heat carried by oil shale, Q_{shale} and the heat required for pyrolysis, Q_{ret} are equal to the sum of the shale pyrolysis reaction heat, Q_{pyr} and the heat carried by pyrolysis products. The heat balance equation is shown in equation (5):

$$Q_{\text{shale}} + Q_{\text{ret}} = Q_{\text{pyr}} + \sum\left(Q_{\text{oil}} + Q_{\text{gas}} + Q_{\text{semi-coke}} + Q_{\text{vap}}\right) \tag{5}$$

where Q_{oil}, Q_{gas}, $Q_{\text{semi-coke}}$, and Q_{vap} represent the heat carried by shale oil, retorting gas, semi-coke, and evaporated moisture, respectively. According to equation (5), the heat required for pyrolysis is 149.6 MW. The heat required for oil shale pyrolysis is provided by pyrolysis retorting gas and coal gasification syngas. The amount of coal gasification syngas is calculated by equation (6):

$$V_{\text{syn}} = Q_{\text{supl}} / \sum\left(\Delta h_{\text{L},k} \cdot vol_k\right) \tag{6}$$

where V_{syn} represents the volume flow rate of syngas, and vol_k represents the volume fraction of each component in syngas. After calculation, $V_{\text{syn}} = 5.3\times10^4$ Nm^3/h, and the amount of coal consumption is 16.9 t/h.

3.2. Economic analysis

The economic analysis is performed in terms of production cost (PC). PC mainly consists of raw material cost C_{r}, utilities cost C_{u}, operating and maintenance cost C_{om}, depreciation cost C_{d}, plant overhead cost C_{poc}, administrative cost C_{ac}, distribution and selling cost C_{dsc}, as shown in equation (7):

$$\text{PC} = C_{\text{r}} + C_{\text{u}} + C_{\text{om}} + C_{\text{d}} + C_{\text{poc}} + C_{\text{ac}} + C_{\text{dsc}} \tag{7}$$

The raw materials and utilities cost are calculated based on simulation results. The labor cost is referred to our previous work, which occupies 10% of the total PC. A straight-line method is adopted to perform the depreciation cost under a consumption of 20 years lifetime and 4% salvage value. Based on equation (7), production costs the IHMB and

Fushun (FS) refinery processes calculated and results show that: (1) their production cost of unit product shale oil are 2636 CNY/t and 3024 CNY/t. As high utilization of raw material and oil yield, the production cost of the IHMB refinery process is 12% lower comparing to the Fushun refinery process with the same processing scale. (2) The competitive crude oil price of the IHMB refinery process is 51 $/bbl, while that of the Fushun refinery process is 58 $/bbl. The IHMB refinery process shows better competitiveness, while the Fushun refinery process has no economic competitiveness in 2017 year with the crude oil price of 50 $/bbl. However, when the crude oil price reaches to a high level of 100 $/bbl, both the IHMB and Fushun refinery processes show more competitiveness.

4. Conclusions

In order to de-bottleneck the Fushun type technology, the Chinese Academy of Sciences developed an indirect heating moving bed (IHMB). The heat required for shale pyrolysis of the IHMB is partly provided by the whole cycled pyrolysis gas, while the remaining comes from gasification syngas from associated coal during oil shale mining. In this paper, the IHMB refinery process is modeled and analyzed, and the following conclusions are obtained. (1) Thermodynamic analysis shows that the heat required for 375 t/h shale pyrolysis is 149.6 MW, in which 89.6 MW is provided by pyrolysis gas and the rest 60 MW is supplied by coal gasification syngas. (2) Economic analysis shows that the production cost for product shale oil of the IHMB refinery process is 2636 CNY/t, which is 12% lower than that of the conventional Fushun refinery process. (3) The IHMB refinery process's competitive crude oil price is 51 $/bbl, which shows better economic advantages comparing with the Fushun refinery process's competitive oil price, 58 $/bbl.

Abstract

We propose a systematic methodology to exploit partial least-squares (PLS) regression modeling to reduce the dimensionality of a feasibility analysis problem. PLS is used to project the original multidimensional space of input factors onto a lower dimensional latent space. We then apply a radial basis function (RBF) adaptive sampling feasibility analysis on this lower dimensional space to identify the feasible region of the process. A simple low-dimensional representation of the feasible region is thus obtained with this combined PLS-RBF approach. The performance of the methodology is tested on a mathematical example involving six inputs. We show the ability of this PLS-RBF approach to reduce the computational burden of the feasibility analysis while maintaining an accurate and robust identification of the feasible region.

Keywords: feasibility analysis, partial least-squares regression, radial basis function, adaptive sampling, model reduction

1. Introduction

The aim of feasibility analysis (Halemane and Grossman, 1983) is to determine the multivariate region of the input domain within which a process is considered to be feasible. When the original model is computationally expensive or the computation of model derivatives is difficult, surrogate-based approaches can be used (Boukovala *et al*., 2010). These methods build a surrogate as a computationally cheap and reliable approximation of the original model, and use this surrogate to identify the feasible region. Recently, Wang and Ierapetritou (2017) proposed a radial basis function (RBF) adaptive sampling approach that outperforms other surrogate-based approaches for low-dimensional test problems. Adaptive sampling is used to simultaneously explore regions of the original input domain that are close to the boundary of the feasible region and/or less explored regions, taking full advantage of the sampling budget.

The main drawback of feasibility analysis is that it suffers from the curse of dimensionality. The computational cost can increase very significantly when a large number of input factors is considered. Moreover, having a simple and compact graphical representation of the feasible region is impossible when more than three inputs are involved. In most common situations, not all the combinations of the original input factors have a strong effect on the model responses. A class of statistical models that can identify the dominant input combinations that mostly affect the model outputs are latent variable models (LVMs). In particular, partial least-squares (PLS) regression (Geladi and

Kowalski, 1986) is a multivariate latent variable (LV) technique that can be used to capture the variability of the input and output spaces by means of few meaningful variables, called LVs, that are usually much smaller in number than the original input factors. Therefore, PLS can be used to obtain a compact representation of the original multidimensional input space without losing significant information on the original input and output correlation structure.

The aim of this study is to overcome the curse of dimensionality problem of feasibility analysis by exploiting the ability of PLS to reduce the input space dimensionality. We use a PLS model to perform a linear transformation from the original multidimensional input space to a lower dimensional latent space. We then perform a RBF-based adaptive sampling feasibility analysis on this latent space and we assess the accuracy and robustness of the results with three appropriate metrics. We test the performance of the methodology on a 6-dimensional mathematical test problem, and we prove the ability of the methodology to give accurate and robust results by simultaneously reducing the computational burden for the feasibility analysis problem.

2. Methods

Let $\mathbf{y} = \mathbf{g}(\mathbf{d}, \mathbf{x})$ be the model of the process under consideration, where $\mathbf{y}$ is the vector collecting all the model outputs, $\mathbf{d}$ is the vector collecting the design variables (which are fixed since the process has already been designed) and $\mathbf{x}$ is the vector collecting all the input variables. Let $f_j(\mathbf{d}, \mathbf{x}),\ j = 1, \dots, J$ be a set of J inequality constraints for the process outputs $\mathbf{y}$. Two mathematical techniques are joint together in the proposed framework: PLS and RBF-based adaptive sampling feasibility analysis.
PLS (Geladi and Kowalski, 1986) is a data-driven technique that projects a historical dataset of inputs $\mathbf{X}$ $[I \times Q]$ and responses $\mathbf{Y}$ $[I \times M]$ onto a common latent space of A LVs, according to the following model structure:

$$\mathbf{X} = \mathbf{T}\mathbf{P}^{\mathrm{T}} + \mathbf{E}_{\mathbf{X}} \tag{1}$$

$$\mathbf{Y} = \mathbf{T}\mathbf{Q}^{\mathrm{T}} + \mathbf{E}_{\mathbf{Y}} \tag{2}$$

$$\mathbf{T} = \mathbf{X}\mathbf{W} \tag{3}$$

where $\mathbf{T}$ $[I \times A]$ is the score matrix, $\mathbf{P}$ $[Q \times A]$ and $\mathbf{Q}$ $[M \times A]$ are the $\mathbf{X}$ and $\mathbf{Y}$ loading matrices, $\mathbf{E}_{\mathbf{X}}$ and $\mathbf{E}_{\mathbf{Y}}$ the residuals, $\mathbf{W}[Q \times A]$ is the weight matrix.

The number A of LVs can be chosen in such a way as to explain a significant fraction of the variability of both the input and the output data. If the input collinearity is strong and/or the model outputs are only affected by a reduced set of input combinations, a significant reduction of the problem dimensionality can be obtained (i.e. $A \ll Q$). Eqs. (1)-(3) can be interpreted as a linear transformation L_{PLS} between the original set of input factors $(x_1, x_2, \dots, x_Q)$ and the new set of A LVs, identified by the model scores $(t_1, t_2, \dots, t_A)$, according to Eq. (1).

Feasibility analysis (Halemane and Grossman, 1983) is a mathematical technique that can be used to find the set of input combinations within which the process under investigation is considered to be feasible. This is obtained by determining the set of input combinations

for which the maximum value of all the process constraints is less or equal to zero. The maximum value of the process constraints is defined as the feasibility function $\psi(\mathbf{d}, \mathbf{x})$:

$$\psi(\mathbf{d}, \mathbf{x}) = \max_{j \in J} f_j(\mathbf{d}, \mathbf{x}) \tag{4}$$

The set of input combinations that satisfy $\psi(\mathbf{d}, \mathbf{x}) \leq 0$ represent the feasible region of the process under consideration. These combinations can be found using a RBF-based adaptive sampling approach. Mathematical details on this approach can be found in Wang and Ierapetritou (2017).

2.1. Proposed methodology

The proposed methodology can be described as a 7-step procedure.

1. Step #1: collection of simulated data from the model. A dataset that collects the original input factors and the corresponding values of the feasibility function is obtained using the original process model. The input space is spanned using the Kennard-Stones's sampling algorithm (KSA; Kennard and Stone, 1969). This algorithm ensures a uniform mapping of the input data, with the advantage that samples can be sequentially increased until a satisfactory coverage is obtained (Daszykowski et al., 2002). For each selected sample $\mathbf{x}^*$, the corresponding value of the feasibility function (4) is computed using the process model. Repeating this procedure for all the selected samples gives a dataset $[\mathbf{X}; \boldsymbol{\psi}]$, where $\mathbf{X}$ is the matrix that collects the selected input combinations, and $\boldsymbol{\psi}$ is the vector that collects the corresponding values of the feasibility function.
2. Step #2: PLS model calibration. A PLS model (Eqs.(1)-(3)) is calibrated with the dataset generated in step #1. The PLS model is used to obtain a linear transformation L_{PLS} between the original set of input factors $(x_1, x_2, \dots, x_Q)$ and the new set of A LVs, identified by the PLS model scores $(t_1, t_2, \dots, t_A)$, according to Eq. (1). In most situations, 2 or 3 LV are used to describe the original multidimensional input space.
3. Step #3: PLS model diagnostics. The values of the cumulative **X**- and **y**-variability ($R^2_{X,cum}$ and $R^2_{y,cum}$) explained by the PLS model for the given number of LVs are computed. If the value of $R^2_{y,cum}$ is high (e.g., > 90%), the PLS model can be directly used to determine the feasible region of the process, avoiding the feasibility analysis step. If the value of $R^2_{y,cum}$ is low (< 70%) and $R^2_{X,cum}$ is sufficiently high (> 90%), the PLS-RBF approach can be used to identify the feasible region with the chosen number of LVs. If $R^2_{X,cum}$ is smaller than 90%, the user should consider the possibility to increase the number of LVs of the PLS model to increase the projection accuracy. Intermediate situations can be handled according to user's risk adversity.
4. Step #4: feasibility analysis. The RBF-based adaptive sampling feasibility analysis is performed using the reduced set of latent variables $[t_1, t_2, \dots, t_A]$, while maintaining the original structure of the process model.
5. Step #5: results validation on the latent space. The accuracy and the robustness of the results obtained in the feasibility step are assessed on the latent space using three metrics (Wang and Ierapetritou, 2017):
   $CF(\%)$: percentage of the projection of the feasible region on the latent space that has been correctly identified by the PLS-RBF feasibility analysis;

$CIF(\%)$: percentage of the projection of the infeasible region on the latent space that has been correctly discovered by the PLS-RBF feasibility analysis;
$NC(\%)$: percentage of the projection of the feasible region on the latent space that has been overestimated by the PLS-RBF feasibility analysis.
The closer the values of $CF(\%)$ and $CIF(\%)$ to 100, the higher the accuracy of the results on the latent space. The closer the value of $NC(\%)$ to 0, the greater the conservativeness of the PLS-RBF predictions.

6. Step #6: PLS model inversion. If the values of the above metrics on the latent space is satisfactory, the results on the latent space are expressed in terms of the original input factors $[x_1, x_2, \dots, x_Q]$ using the inverse of the linear transformation L_{PLS}, according to the model structure (1). Every feasible and infeasible point on the latent space, identified in terms of the PLS model scores $[t_1, t_2, \dots, t_A]$, is projected back onto its original representation $[x_1, x_2, \dots, x_Q]$.
7. Step #7: results validation on the original input space. The three metrics are computed with respect to the original input space. They represent the accuracy and conservativeness of the results with respect to the true multidimensional feasible region of the process, and should thus be considered as the final quantitative assessment of the quality of the results obtained. The closer the values of the first two metrics to 100, the greater the accuracy of the estimation of the true feasible region of the process. The closer the value of the third metric to 0, the greater the robustness of the results obtained.

The methodology presented above was implemented in MATLAB® 2015, and the simulations were performed on an InteL® Core™ I7-5600U CPU@2.60GHz processor with 16.0 GB RAM.

3. Results and discussion

We considered a case study of a process composed by two units in series and a total number of 6 input factors $[x_1, x_2, x_3, x_4, x_5, u_1]$, as schematically shown in Figure 1.

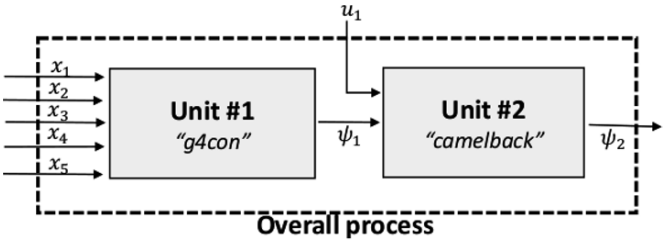

Figure 1. Block flow diagram of the two-unit case study considered.

The constraints for the first unit ("g4con") are described by the set of equations (Koziel and Michalewicz, 1999):

$$0 \leq 85.334407 + 0.0056858x_2x_5 + 0.0006262x_1x_4 - 0.0022053x_3x_5 \leq 92 \quad (5)$$

$$90 \leq 80.51249 + 0.0071317x_2x_5 + 0.0029955x_1x_2 + 0.0021813x_3^2 \leq 110 \quad (6)$$

$$20 \leq 9.300961 + 0.0047026x_3x_5 + 0.0012547x_1x_3 + 0.0019085x_3 \leq 25 \quad (7)$$

The maximum value of the constraints for the first unit is the feasibility function ψ_1. The constraint for second unit ("camelback") is described by:

$$\left(4 - 2.1\psi_1^2 + \frac{\psi_1^4}{3}\right)\psi_1^2 + \psi_1 u_1 + (-4 + 4u_1^2)u_1^2 \leq 0 \tag{8}$$

$$-3 \leq \psi_1 \leq 3;\ -2 \leq u_1 \leq 2 \tag{9}$$

The feasibility function for the second unit is ψ_2. Application of the RBF-based feasibility analysis on the original 6-dimensional problem was not computationally viable, due both to the high total computational time (within 24 h, with 64 initial points and 253 adaptive samples, the values of the three metrics were $CF = 54.1\ \%, CIF(\%) = 63.8\ \%, NC(\%)$=10.2%) and to the low accuracy of the results that could be obtained with a fixed sampling budget (accuracy less than 45% with a sampling budget of 198 (64 initial points +134 adaptive samples)). Therefore, we decided to apply the PLS-RBF methodology to overcome the curse of dimensionality. Following the step-by-step procedure, we first generated a dataset of 49 samples using the process model (5)-(10) and we calibrated a PLS model using this dataset (step #1 and step #2). The PLS diagnostics (step #3) is reported in Table 1. As can be noticed, 88.3% of the input variability is captured using two LVs only. We then used a PLS model with 2 LVs to obtain a linear transformation of the original 6-dimensional input space to a 2-dimensional latent space. The projection of the true feasible region of the process onto the latent space is represented by the grey-shaded area of Figure 2a. We applied the RBF-based adaptive sampling feasibility analysis to this latent space (step #4). We used 49 initial samples chosen according to a rectangular-grid sampling strategy to build the initial RBF surrogate, and a maximum number of 100 iterations for the adaptive sampling strategy. The results obtained are shown in Figure 2b. As can be noticed, after 100 iterations, most of the adaptive sampling points (circles in Figure 2b) are closely located near the boundary of the feasible region. The values of the three metrics $CF(\%), CIF(\%), NC(\%)$ were 95.47, 97.15 and 2.37 respectively, meaning that more than 95% and 97% of the feasible and infeasible regions (respectively) were correctly identified on the latent space (step #5). Since these values were satisfactory, we moved forward with the methodology by expressing the results in terms of the original 6-dimensional combinations of the input factors (step #6). The values of the three metrics $CF(\%), CIF(\%), NC(\%)$ on the original 6-dimensional space were 93.19, 96.85 and 2.89 respectively, meaning than more of 93% of the true 6-dimensional region was correctly identified, and more than 96% of the true 6-dimensional infeasible region. The total computational time for the simulation was 32 min. The results proved to be extremely satisfactory with respect to the original RBF approach.

Table 1. Diagnostics of the PLS model.

LV #	$R_X^2(\%)$	$R_{X,cum}^2(\%)$	R_y^2 (%)	$R_{y,cum}^2$ (%)
1	49.20	49.20	21.95	21.95
2	39.12	88.32	16.02	37.97
3	4.18	92.50	9.87	47.84
4	3.25	95.75	4.11	51.95
5	2.11	97.86	3.12	55.07
6	2.14	100.00	4.87	59.94

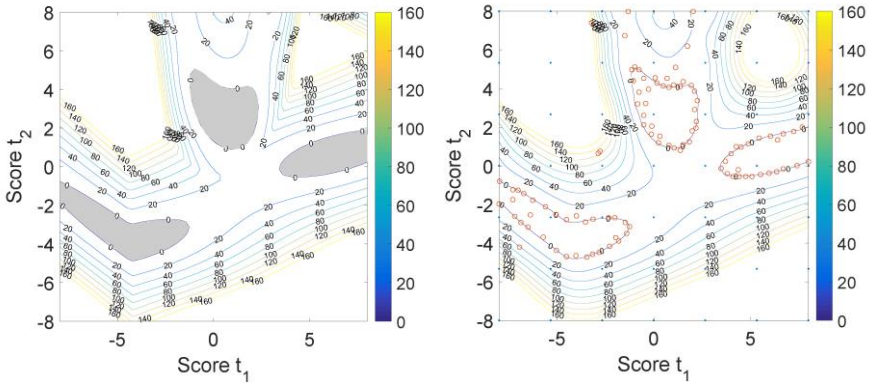

Figure 2. (a) Projection of the original function onto the 2-dimensional latent space. The grey-shaded area is the feasible region. (b) RBF model after 100 iterations. Dots represent the initial samples. Circles represent the adaptive sampling points after 100 iterations.

4. Conclusions

We proposed a methodology to identify the feasible region of a multiple-unit process by applying a combined PLS-RBF adaptive sampling feasibility analysis. We first used a PLS model to obtain a linear transformation between the original set of input variables and a reduced set of latent variables. We then applied RBF-based adaptive sampling feasibility analysis on the lower-dimensional latent space and we assessed the quality and robustness of the results with three metrics, that describe how well the feasible and infeasible regions are identified by the RBF model, and how large is the portion of overestimated feasible region. We tested the methodology on a mathematical test example involving two units and a total of 6 input factors. We proved the ability of the proposed approach to reduce the overall computational burden while maintaining a good accuracy and robustness of the results, with a correct estimation of the feasible region greater than 93%. In our future work, we will focus on the assessment of the performance of the methodology with real experimental data coupled with the original process model.

Abstract

The need for optimization tools for reliability design considering operational factors is motivated by the significance of availability of process systems and the lack of systematic and rigorous tools. In response to this need, this paper introduces a systematic approach to model the stochastic process of system failures and repairs as a continuous-time Markov chain, in which the impact of maintenance is incorporated in order to find the optimal selection of parallel units. An illustrative example is shown.

Keywords: Reliability, Availability, Maintenance, MINLP, Markov Chain

1. Introduction

Plant availability has been a critical consideration for chemical processes, as it represents the fraction of normal operating time, which directly impacts profitability. In practice, discrete-event simulation tools are used to examine the availability of a few selected designs of different redundancy levels under various maintenance policies (Sharda and Bury, 2008). However, the best plan selected through simulation is usually suboptimal because the list of candidates is not exhaustive. Thus, there is a strong motivation for systematic optimization tools for redundancy design considering operational factors.

Literature review of research in reliability engineering can be found in Ye et al. (2017) where a general mixed-integer framework is proposed to select standby units to maximize availability and minimize cost. However, for a more comprehensive optimization, it is also important to consider the impacts of operational factors such as maintenance. In particular, preventive maintenance (PM) is a major strategy to improve the availability of units (Ding and Kamaruddin, 2015). Pistikopoulos et al. (2001) and Goel et al. (2003) formulate an MILP model for the selection of units and production and maintenance planning for a fixed system configuration. Markov chain is a powerful mathematical tool being extensively used to capture the stochastic process of systems transitioning among different states. Bloch-Mercier (2002) models the deterioration process of a system as continuous-time Markov chain to optimize inspection intervals. Lin et al. (2012) model a simple utility system using Markov chain and carry out RAM (reliability, availability & maintainability) analysis iteratively to decide the optimal reliability design.

Given the aforementioned research gaps and knowledge basis, this work extends our recent mixed-integer framework Ye et al. (2017) by introducing a systematic approach to model the stochastic process of system failures and repairs as a continuous-time Markov chain, for which the impact of maintenance is incorporated in order to find the optimal selection of parallel units.

2. Problem statement

We define a general modelling framework for production systems with underlying serial structures for availability evaluation as shown in Figure 1. For each stage k, a set of potential parallel units J_k are available for selection at the design phase. The goal is to determine which one or several potential parallel units to install, as well as the length of inspection intervals t_k^i, in order to maximize the system availability (i.e. probability that the system performs without failures), while minimizing the total cost of the system.

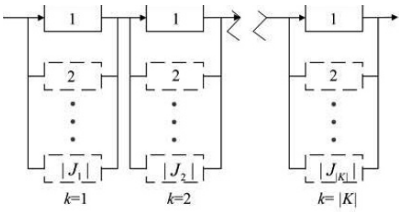

Figure 1 - A serial system

Each stage k has a set of potential units $j \in J_k$, for which the following is given:

- Availability parameters, i.e. Failure rate $\lambda_{k,j}$ and repair rate $\mu_{k,j}$.
- Operating priority within stage k (indicated by the order of j). A unit becomes active if and only if all the selected units with higher priorities have failed.
- Cost rates, including installation, inspection, maintenance and repair.

For each stage k, inspections are scheduled for active equipment at a certain time period to be determined, t_k^i, called inspection interval. If the inspection indicates that the equipment has a deterioration, a predictive maintenance task will be carried out in time. In that case, there will be enough time to order the spare parts and hence reduce the shipping costs, with which a maintenance task is cheaper than the repair upon failure. A deterioration can be detected by scheduled inspections in a certain period before it happens, called delay time (Christer, 1999), or PF-interval (Moubray, 1997) of length T_k^d.

Based on the parameters provided above, the availability of stage k will depend on the selection of parallel units $y_{k,j}$ and the inspection intervals of each processing stage t_k^i.

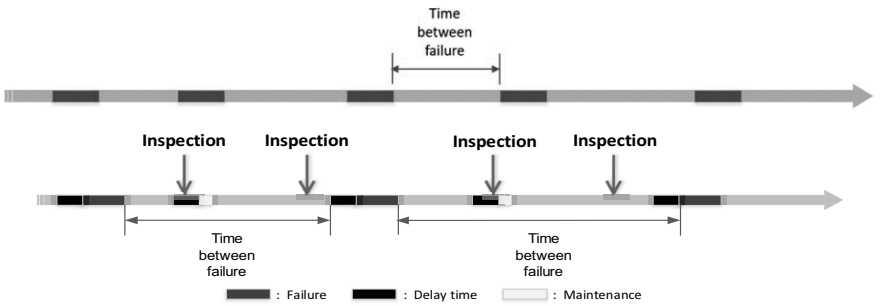

Figure 2 – Timeline of inspection/maintenance/repair

3. Modeling

3.1. Availability calculation

A continuous-time Markov chain is characterized by its transition rate matrix, the "**Q** Matrix", which can be used to solve for the stationary probability vector $\boldsymbol{\pi}$ through the linear equations, $\boldsymbol{\pi}^{\mathrm{T}}\mathbf{Q} = \mathbf{0}$ and $\boldsymbol{\pi}^{\mathrm{T}}\mathbf{1} = 1$. For the failure-repair system that we are considering, the availability can be obtained by adding up the probabilities of the non-failure states. Next, we show how to construct the "**Q** Matrix" of the system, and model the impact of the selection of units and inspection intervals on the "**Q** Matrix", and therefore on $\boldsymbol{\pi}$ and system availability.

First, for single stages, as we are making selections among the potential parallel units within stage *k*, there are several exclusive designs indexed by *h*, and each of them has a corresponding "**Q** Matrix" constructed as follows:

- A state space $T_{k,h}$ is enumerated where the transition from state *i* to state *j* ($i, j \in T_{k,h}$) is due to the happening of a failure or a repair. For example, the design decision of installing two units has the following 4 states:

Table 1 - State space example

Unit 1	Active	Active	Being repaired	Being repaired
Unit 2	Standby	Being repaired	Active	Being repaired

- Then the **Q** Matrix of design h is a 4×4 matrix where the element in row *i* and column *j* is equal to the failure rate or repair rate of the transition from state *i* to state *j*.
- And the element on the diagonal is equal to the opposite number of the sum of the other elements in the same row.

After the **Q** Matrices for the designs in stage *k* are formulated, they are put together to form a block-diagonal matrix $\mathbf{QM}_k$ called the "pseudo **Q** matrix" of stage *k,* which include all possible states for stage *k*. Following from that, the "pseudo **Q** matrix" of the system, $\mathbf{WM}_k$ is calculated using the following formula, where $\otimes$ is the Kronecker product and satisfies the associative law of addition.

$$WM = I_{n_{|K|}n_{|K|-1}\cdots n_2} \otimes QM_1 + I_{n_{|K|}n_{|K|-1}\cdots n_3} \otimes QM_2 \otimes I_{n_1} + I_{n_{|K|}n_{|K|-1}\ldots n_4} \otimes QM_3 \otimes I_{n_2 n_1} + \cdots$$
$$+ I_{n_{|K|}} \otimes QM_{|K|-1} \otimes I_{n_{|K|-2}n_{|K|-3}\cdots n_1} + QM_{|K|} \otimes I_{n_{|K|-1}n_{|K|-2}\cdots n_1}$$

The following constraints are used to manipulate the elements in $\mathbf{WM}_k$. The values of binary variables $y_{k,j}$ decide which columns and rows are eliminated from $\mathbf{WM}_k$ to find the actual $\mathbf{Q}$ matrix through equations (1)-(11). The variables t_k^i will affect the failure rates of single units, and therefore the values of the elements in $\mathbf{WM}_k$ ((12)-(18)).

$$instCost = \sum_{k\in K}\sum_{j\in J_k} y_{k,j} c\_inst_{k,j} \tag{1}$$

$$\sum_{j\in J_k} y_{k,j} \geq MIN_K, \qquad \forall k \in K \tag{2}$$

$$Z_{k,h} \Leftrightarrow \bigwedge_{\alpha_{j,k,h}=1} Y_{k,j} \bigwedge_{\alpha_{j,k,h}=0} \neg Y_{k,j}, \qquad \forall k \in K, h \in H_k \tag{3}$$

$$\bigvee_{h\in H_k} Z_{k,h}, \qquad \forall k \in K \tag{4}$$

$$ZZ_{k,s} \Leftrightarrow Z_{k,h}, \qquad \forall k \in K \tag{5}$$

$$\bar{Z}_{\bar{h}} \Leftrightarrow \bigwedge_{k\in K, h\in H_k, |h|=hc_{k,\bar{h}}} Z_{k,h}, \qquad \forall \bar{h} \in \bar{H} \tag{6}$$

$$\overline{ZZ}_{\bar{s}} \Leftrightarrow \bar{Z}_{\bar{h}}, \qquad \forall \bar{h} \in \bar{H}, \bar{s} \in \bar{T}_{\bar{h}} \tag{7}$$

$$\begin{bmatrix} \overline{ZZ}_{\bar{s}} \\ 0 \leq \pi_{\bar{s}} \leq 1 \end{bmatrix} \vee \begin{bmatrix} \neg\overline{ZZ}_{\bar{s}} \\ \pi_{\bar{s}} = 0 \end{bmatrix}, \qquad \forall \bar{s} \in \bar{S} \tag{8}$$

$$\left[\sum_{\bar{s}} \pi_{\bar{s}} WM(\bar{s},\bar{r}) = 0\right] \vee \left[\sum_{\bar{s}} \pi_{\bar{s}} WM(\bar{s},\bar{r}) < \infty\right], \qquad \forall \bar{r} \in \bar{R} \tag{9}$$

$$\sum_{\bar{s}} \pi_{\bar{s}} = 1 \tag{10}$$

$$A = 1 - \sum_{\bar{s}\in\bar{S}^f} \pi_{\bar{s}} \tag{11}$$

$$\lambda_{k,j}^0 - \lambda_{k,j} = \frac{e^{-\lambda_{k,j}^0 t_k^i} - e^{-\lambda_{k,j}^0 \left(t_k^i + T_k^d\right)}}{t_k^i}, \qquad \forall k \in K, j \in J_k \tag{12}$$

$$\sum_{l\in L} x_{k,l} = 1, \qquad \forall k \in K \tag{13}$$

$$\sum_{l\in L} x_{k,l} T_l^i = t_k^i, \qquad \forall k \in K \tag{14}$$

$$inspCost \geq \sum_{k\in K} \frac{T}{t_k^i} c\_insp_k \tag{15}$$

$$repaCost \geq T \sum_{\bar{s}\in\bar{S}^f} -WM(\bar{s},\bar{s})\pi_{\bar{s}} \sum_{k\in K_{\bar{s}}^f} c\_repa_k \tag{15}$$

$$prevTimes_k \geq \frac{y_{k,j}\left(\lambda_{k,j}^0 - \lambda_{k,j}\right)}{\lambda_{k,j}}, \qquad \forall j \in J_k \tag{16}$$

$$prevCost \geq T \sum_{\bar{s}\in\bar{S}^f} -WM(\bar{s},\bar{s})\pi_{\bar{s}} \sum_{k\in K_{\bar{s}}^f} prevTimes_k c\_prev_k \tag{17}$$

$$prevTime \geq T \sum_{\bar{s}\in\bar{S}^f} -WM(\bar{s},\bar{s})\pi_{\bar{s}} \sum_{k\in K_{\bar{s}}^f} prevTimes_k T\_prev_k \tag{18}$$

$$A^{net} = A - \frac{prevTime}{T} \tag{19}$$

3.2. Economic dependence

The net profit is the sum of the revenue, penalty and bonus minus the sum of costs. The total revenue is considered proportional to the availability of the system. Generally, in the contract between the plant and the customer, two reference bounds are set for the availability of the plant. If the actual availability of the plant does not meet the lower bound, the plant will be charged proportional to the difference. Conversely, if the actual availability exceeds the upper bound, the customer reward the plant with a bonus that is also proportional to the difference.

$$\max NP = RV - PN + BN - instCost - repaCost - inspCost - prevCost \quad (20)$$

$$RV = rvA^{net} \quad (21)$$

$$W_1 \veebar W_2 \veebar W_3 \quad (22)$$

$$\begin{bmatrix} W_1 \\ A^{net} \le A\_lo \\ PN = (A\_lo - A^{net})pn \\ BN = 0 \end{bmatrix} \vee \begin{bmatrix} W_2 \\ A\_lo \le A^{net} \le A\_up \\ PN = 0 \\ BN = 0 \end{bmatrix} \vee \begin{bmatrix} W_1 \\ A^{net} \ge A\_up \\ PN = 0 \\ BN = (A^{net} - A\_up)bn \end{bmatrix} \quad (23)$$

4. Example

In this section, a small example is shown featuring the system in Figure 3 with 2 serial stages, where stage 1 has 3 potential units and stage 2 has 2 potential units. Both of the two stages require at least 1 unit to function properly. Table 2 displays the parameters for the case study. A 10-year time horizon is considered.

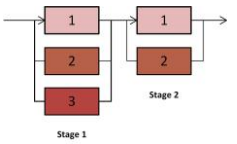

Figure 3 - Two stage-two unit system

Table 2 - Parameters

Stage	Unit	MTBF (day)	MTTR (day)	Fixed cost (k$)	Repair cost rate (k$ per time)	Inspection cost rate (k$ per time)	Maintenance cost rate (k$ per time)	Maintenance time (day)	Delay time (day)
1	1	50	7	200	12	0.1	0.6	1	10
	2	45.5	7.7	160					
	3	41.7	8.3	120					
2	1	66.7	2.6	240	10	0.1	0.5	1	12
	2	50	2.8	200					

Revenue rate (k$)	Penalty rate (k$)	Bonus rate (k$)	Availability lower bound	Availability upper bound
700	1000	10000	0.988	0.998

The MINLP model without maintenance is solved with BARON in 91.26 CPUs ((1)-(9) and (17) -(19)). There are 44921 equations and 44737 variables with 40 binary variables. The optimal design is to have all potential units installed. The expected system availability is 0.999, and the net profit is $6039.6 k, with a revenue of $6990.1 k and a bonus of $5.83 k. $920 k is spent on unit investment, and $36.3 k is spent on repair. The entire MINLP model with maintenance ((1)-(19)) is solved with BARON in 14924.15 CPUs, which has 44938 equations, 44458 variables with 49 binary variables. The optimal design is to install the last two units for stage 1 and both two units for stage 2. The expected system availability is 0.994. The expected net profit is $6131.6 k, with a revenue of $6959.9 k

and no bonus or penalty. \$720 k is spent on unit investment, \$52.1 k on inspections, \$2.7 k on maintenance, and \$53.4 k on repair. Other results are shown in Table 3.

Table 3 - Optimization results

Stage	Inspection interval (day)	Equivalent MTBF (day)
1	14	Unit2: 98.0, Unit 3: 86.2
2	14	Unit1: 181.8, Unit 2: 117.6

From the above results we can see that when maintenance is considered, the model suggest additional costs on inspection and maintenance, while less is to spend on the unit investment, which leads to an overall higher net profit.

5. Conclusion

In this paper, we have proposed a general modeling framework to represent the failure-repair process of a multi-unit system as a continuous-time Markov Chain, and to incorporate the design decision of selecting one or more standby units, as well as the operation decision of determining inspection intervals. The resulting MINLP model was implemented and solved for an illustrative example.

Abstract

This study presents a methodology to apply Monte Carlo methods for property uncertainty propagation in the process simulation software *SimSci PRO/II*. The aim of this work is to integrate advanced uncertainty and sensitivity analysis tools into commercial process simulators. The property uncertainty and sensitivity analysis tools were applied to a heat pump system with cyclopentane as a working fluid. Monte Carlo sampling technique was used to generate property samples of the SRK equation of state parameters critical temperature, critical pressure and acentric factor. The samples were subsequently evaluated in the heat pump flowsheet built in *SimSci PRO/II*. This allowed describing the process model output uncertainty in a distribution and with the 95% confidence interval. Furthermore, Monte Carlo based standard regression could be used to analyse the sensitivity of the respective fluid properties. The results showed that property uncertainty propagation strongly depends on the correlation between the property parameters. The sensitivity analysis showed that the acentric factor is the most sensitive SRK parameter. This works demonstrates that Monte Carlo methods are a simple and useful tool, which can be used in commercial process simulators by industrial users.

Keywords: Monte Carlo method, process simulator, uncertainty

1. Introduction

Process design and simulation heavily rely on property data. Property data is subject to varying uncertainties depending on the experimental data or property models used. The propagation of property uncertainties through the process simulation on to the process model output gives important information on the reliability and sensitivity of the property model and influences the design decisions to be taken (Sin et al., 2009).

There have been significant efforts on the quantification of uncertainties in experimental (Dong et al., 2005) and predicted property data (Frutiger et al., 2016). Furthermore, a variety of studies have analysed and emphasized the importance of property uncertainties of the uncertainties in physical-property models on process design over the past decades (Macchietto et al., 1986; Whiting, 1996; Hajipour and Satyro, 2011; Frutiger et al., 2017). However, property uncertainty analysis is still not applied in chemical engineering industrial practice. One possible reason is that methods suggested by researchers are currently not available in commercial process simulators, such as

SimSci PRO\II or Aspen Plus. This paper aims at showing a methodology that integrates property uncertainty analysis and commercial process simulators.

Recently Mathias et al. (2014; 2017) performed several studies performing property uncertainty analysis in Aspen Plus software. The authors quantified the property uncertainty propagation of mixtures through different unit operations using Margules-based perturbation scheme for the activity coefficients. They propagated the uncertainties through process flowsheets in Aspen Plus. However, Mathias and co-workers did not take into account correlations between the input property parameters. Considering large property databases such as NIST TDE (Diky et al., 2013; Frenkel et al., 2005) or AIChE DIPPR database (Rowley et al., 2014), the property parameters of one compound are not completely independent. If correlation is neglected the uncertainty propagation can lead to an overestimation of the output uncertainty (Helton and Davis, 2003). Furthermore, Mathias et al. did not analyse the global sensitivity of the properties with respect to the model output.

Monte Carlo methods have been used in a variety of studies (Sin et al., 2009). Recently it has also been used for property uncertainty analysis (Hajipour et al., 2014; Frutiger et al., 2017). However, none of the authors implemented Monte Carlo method in a commercial process simulator.

In the current study we will present a simple methodology based on Monte Carlo sampling and evaluation techniques in order to propagate and analyse property uncertainties through the commercial process simulation software SimSci PRO\II (PRO/II, 2017). The methodology is applied to a case study of a heat pump system for the recovery of heat in food industries. Monte Carlo uncertainty propagation is used to analyse the output uncertainty and Monte Carlo standard regression is applied to study the global sensitivity of the properties.

2. Monte Carlo based strategy to address property uncertainties in SimSci PRO/II process simulator

The strategy to apply Monte Carlo method in *SimSci PRO/II* is based on the methodology of Frutiger et al. (2017) for property uncertainty propagation in process models:

1) A process model is built in the commercial process simulations software *SimSci PRO/II*. Process constants and variables are specified. The property models and parameters for the uncertainty analysis need to be selected.

2) The property uncertainty data is collected from databases (e.g. NIST TDE (Frenkel et al., 2005), AIChE DIPPR (Rowley et al., 2014)) or literature studies.

3) Monte Carlo sampling technique is used to sample property values within its corresponding uncertainty range i.e. 95%-confidence interval using the software MATLAB (2015b). Latin Hypercube Sampling method can be utilized for probabilistic sampling of the fluid property input space of a compound. The probability of uncertainty is assumed to follow normal distribution A total of 100-250 samples is obtained, each sample containing one value for each input parameter. The rank-based method for correlation control of Iman and Conover (1982) allows taking into account correlations between the property parameters. This is necessary, when parameters are not completely independent, as often the case for property models.

4) The Monte Carlo samples are evaluated in the process model in SimSci PRO/II. To this extend the PRO/II COM Server can be used, which allows to read and write access to property information in PRO/II through Python software (Python, 2017).

5) Uncertainty analysis: The process model output uncertainty is quantified and analyzed (Frutiger et al., 2017). The Monte Carlo results provide a distribution function for desired process model output of PRO/II. This can be analysed using mean and percentile calculations. Hence, the 95%-confidence interval of the PRO/II output with respect to the corresponding input property values can be obtained.

6) Sensitivity analysis: By constructing linear regression models on the outputs obtained from the Monte Carlo procedure (Sin et al., 2009), it is possible to obtain the standardized regression coefficient (SRC) β_j of parameter set θ_j given by

$$\frac{W_{NET} - \mu_{WNET}}{\sigma_{WNET}} = \sum_{j=1}^{M} \beta_j \cdot \frac{\theta_j - \mu_{\theta j}}{\sigma_{\theta j}} + \varepsilon_j \tag{1}$$

W_{NET} is the simulator output, ε_j is the error of the regression model, $\mu_{\theta j}/\sigma_{\theta j}$ and μ_{NET}/σ_{NET} are the corresponding mean and standard deviations of the parameters and the model output. The SRC is a measure of how strongly the parameter contributes to the model output (Frutiger, 2016).

3. Case study

The methodology for Monte Carlo methods for property uncertainty analysis is demonstrated through a case study for a heat pump waste heat recovery. The heat pump system is used to recover heat from exhaust gas from spray drying in food industries (heat source) to preheat the air before the spray dryer (heat sink), utilizing secondary cycles with pressurized water (Zühlsdorf et al., 2017). Cyclopentane is selected as a working fluid. The process model output is the coefficient of performance (COP), which is the enthalpy provided by the heat source divided by the compressor work: $COP=\Delta H_{Source}/W_{Compressor}$ The system has been implemented in PRO/II (see Figure 1). The mass flows and specifications can be found in the work of Zühlsdorf et al. (2017).

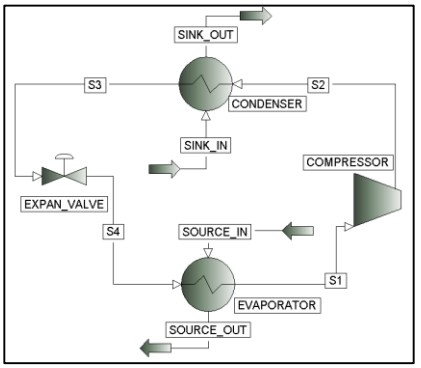

Figure 1: Pro/II flowsheet of a heat pump.

Table 1: Property parameter correlation

Correlation matrix			
	T_c	P_c	ω
T_c	1.00		
P_c	-0.89	1.00	
ω	0.80	-0.48	1.00

As a property model for the system Soave-Redlich-Kwong equation of state (SRK) is selected. The SRK parameters are the critical temperature T_c, the critical pressure P_c and the acentric factor ω. The goal of the case study is to propagate the uncertainty of T_c, P_c and ω through the SRK property model and process model in PRO/II following the methodology described in section 2. The uncertainty range and the correlation matrix of the SRK parameters are collected from the work of Frutiger et al. (2017), who obtained the correlation matrix using bootstrap method (Efron, 1979) (Table 1).

Furthermore, two different sampling strategies are applied. 1) Monte Carlo sampling without correlation, and 2) Monte Carlo sampling with correlation control according to Iman and Conover (1982). This allows comparing the influence of property parameter correlation on the process model output uncertainty. Figure 2 visualizes the two sampling procedures. Here, only the fluid properties of the working fluid cyclopentane are sampled and propagated. Property data of water stay constant.

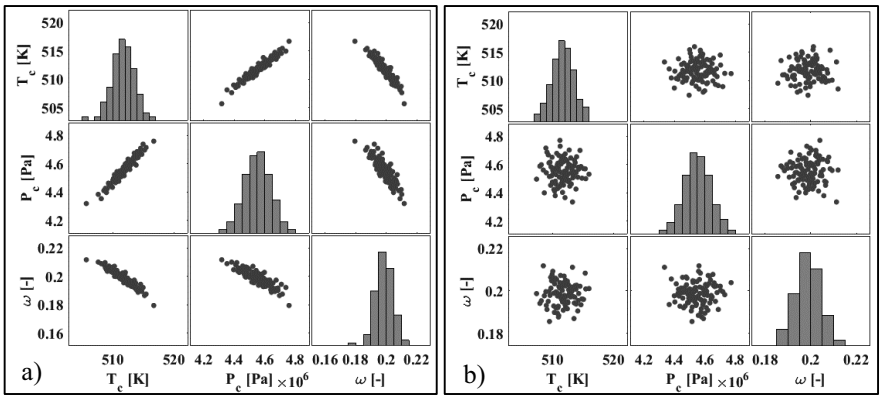

Figure 2: Illustration of samples generated by Latin Hypercube Sampling method with Iman and Conover correlation control (subplot a) and without correlation control (b).

4. Results and discussion

4.1. Uncertainty analysis

The Monte Carlo simulation results can be illustrated by distribution plots of the COP for both sample sets (see Figure 3). The larger the width of the COP output, the higher the output uncertainty. From the output distributions the 2.5% and 97.5% percentile defining the lower and upper bound of the uncertainty range (95%-confidence interval) for the process simulator output (here the COP) can be obtained (Table 2).

Table 2: Lower and upper bound of 95% confidence interval for COP for the correlated property samples (a) and the uncorrelated property samples

	COP mean values [-]	COP 95% confidence itnerval values [-]	
		Lower bound	Upper bound
Correlated samples	2.87	2.41	2.94
Uncorrelated samples	2.83	2.10	2.94

As it can be seen in Figure 3 and Table 2, the uncertainty range of the COP is larger for the results based on uncorrelated Monte Carlo sampling. In particular the lower bound of the uncertainty range is different. The uncorrelated samples also give COP values below 2.4 compared to the results of the correlated samples. This shows that, correlation between the property parameter samples can have a strong influence on the Monte Carlo uncertainty propagation procedures. If no or a wrong correlation is imposed on the property parameter samples, the process output uncertainty can be overestimated. This implies that parameter correlation should be considered carefully in the context of property uncertainty propagation through process simulators.

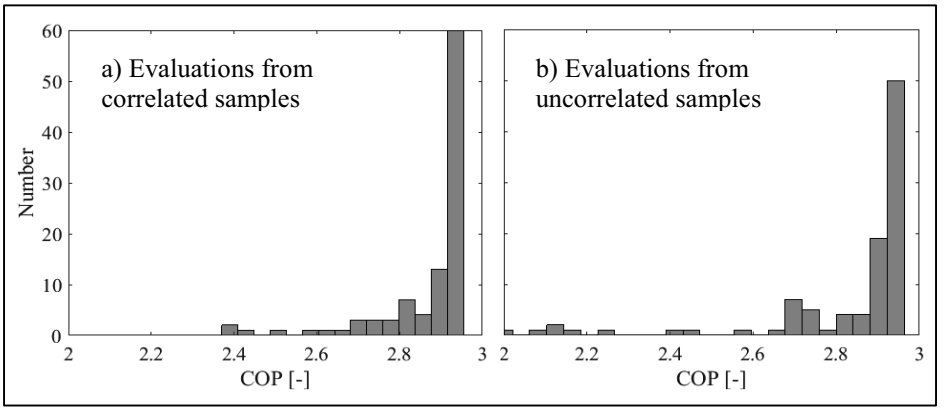

Figure 3: COP output distribution from the evaluation of the correlated property samples (a) and the uncorrelated property samples (b).

4.2. Sensitivity analysis

The regression coefficients – SRCs – of the fluid parameters were obtained from linear least square regression using Eq. 1 (see Figure 4). Correlated samples were used.

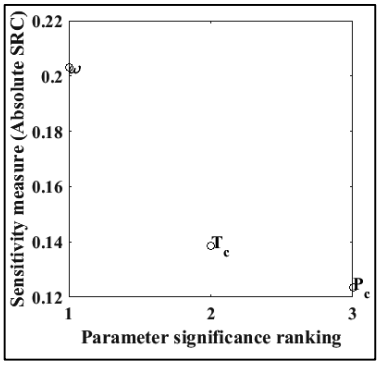

Figure 4: Standardized Regression Coefficients (SRCs) and ranking of SRK equations of state property parameters (using correlated samples).

The SRCs were ranked according to their absolute value. According to the analysis the acentric factor ω has by far the highest influence compared to the other parameters. This is in agreement with previous studies (Frutiger et al., 2016). Using a linear model between the inputs and outputs may mask some of the important properties. However, this can be analyzed through the Pearson correlation coefficient R^2 (>0.7), which shows to what

extend the model is linearizable. In case that it is not linearizable other statistical methods (such as polynomial chaos expansion need to be applied (Sin et al., 2009).

5. Conclusions

The study presented a Monte Carlo based methodology for property uncertainty and sensitivity analysis in a commercial process simulator. A heat pump system with cyclopentane as a working fluid was analyzed. The uncertainties of critical temperature, critical pressure and acentric factor were propagated through the SRK equations of state and the process model implemented in Pro\II. The results showed that considering correlation control in the sampling procedure provides influences the model output uncertainty. The most sensitive property parameter was the acentric factor. The study also showed that it is possible to use Monte Carlo techniques with commercial process simulators, which is currently not state-of-the-art in industrial practice.

Strategic design and analysis of large-scale shale gas monetizing projects under mixed uncertainty

Hua Liu, Qingsong Xie, Ming Pan, Chang He*

School of Chemical Engineering and Technology, Guangdong Engineering Center for Petrochemical Energy Conservation, Sun Yat-sen University, Guangzhou 510275, China. hechang6@mail.sysu.edu.cn

Abstract

This article developed a systematic monetization framework that incorporates stochastic modeling and probabilistic analysis of a large-scale shale gas monetization process under mixed uncertainties including feedstock composition, estimated ultimate recovery, and economic parameters. The major products investigated were polymers including HDPE and PP. To accommodate the reality of uncertainty, a new stochastic data processing strategy integrating the SAA, KSM, and DSAC methods was proposed to generate appropriate scenarios and to determine the corresponding values of each uncertain variable. These output variabilities were passed to the process simulator to implement the detailed process design and techno-economic analysis. A distributed-centralized conversion network employing two monetization pathways of shale gas to polymers, namely NGLs pathway and hybrid pathway, was presented. Uncertain economic parameters were nested in this stochastic model to identify the probabilistic distributions and to analyze the MLE of techno-economic objectives. The proposed strategy and models are illustrated in four case studies with different plant locations and pathway designs.

Keywords: stochastic modeling, probabilistic analysis, shale gas, mixed uncertainty

1. Introduction

Uncertainty is an inherent characteristic in process industries, which leads to significant challenges in handling variability in parameter values. Especially, increasing scientific evidence is showing that the shale gas monetizing process is inevitably subject to mixed and multi-dimensional uncertainties from gas acquisition to end-use production, significantly affecting the profitability and environmental impacts of the whole project. First, raw shale gas acquisition (the initial step of shale gas projects) is most influenced by the endogenous uncertainties of gas compositions. (Gao and You, 2017; Li et al., 2011) In fact, most of the shale gas regions produce raw shale gases with high compositional variabilities due to the differences in geological and petrophysical characteristics in these regions and wells. (Gong and You, 2017) Another challenge involves the supply of shale gas including special production decline and well-refracturing operation. Meanwhile, the variability associated with shale gas acquisition refers to the estimated ultimate recovery (EUR), which is affected by the special decline in production rate and well-refracturing operation. (Tavassoli et al., 2013; Cafaro et al., 2016) In addition, exogenous uncertainties normally occur throughout the entire project caused by market variabilities such as product prices, drilling costs, utility prices, and significantly increases the complexity of uncertainty in practice. (Grossmann et al., 2016) The resulting mixed uncertainties must be explicitly figured out at the design and development stage. Given the complex

uncertain variability, a comprehensive systems design and analysis framework is required to decipher the true economic risk of the shale gas monetization to the end-use products process under changing feedstock conditions and market fluctuations. To date, a number of research challenges in this field remain unsolved. These challenges are summarized as follows (a) how to simultaneously account for the mixed uncertainties, (b) how to incorporate field data into the stochastic modeling, (c) how to develop efficient shale gas monetization pathways, (d) how to apply statistical techniques to interpret the risks.

This article focuses on addressing these research challenges and develops a systematic monetization framework that incorporates stochastic modeling and likelihood analysis of a large-scale shale gas to polymers process with consideration of endogenous and exogenous uncertainties. To capture the feedstock variabilities, for the first step it proposes a new data processing strategy to generate appropriate scenarios from real-world data related to shale gas compositions and EUR. Next, this work employs the detailed process design and techno-economic modeling, by which the raw shale gas in each scenario is processed in multi-site distributed processing facilities, and then either NGLs, or the mixture of NGLs and methane, can be pipelined to a centralized plant for polymer production. These generated scenarios are considered together with a set of uncertain economic parameters to identify their probabilistic distributions and techno-economic objectives based on likelihood analysis. Finally, the applicability of the proposed framework is illustrated through four case studies under different plant locations and monetization pathways.

2. Methodology

As shown in Figure 1, the proposed methodology involves a three-step statistical analysis including (II) feedstock variability quantification, (II) process modeling and synthesis, and (III) probabilistic analysis. Herein, due to page limitations we only summary the bullet points of this methodology. More details are reported by He et al. (2018).

Step I: it proposes a stochastic data processing strategy to characterize and quantify the endogenous uncertainties including raw gas composition and EUR associated with the feedstock acquisition. A finite size of scenarios is generated to accommodate the diverse nature of feedstock variability. Three rigorous statistical methods included in the data processing strategy are sample average approximation (SAA), Kriging-based surrogate model (KSM), and integrated decline-stimulate analysis curve (DSAC). First, we used an SAA method to generate a scenario set of initial C_1 production rate of well i ($P^{r_0}_{i,C_1}$) to approximate the original expected objective value by calculating the sample average. The number of scenarios is determined by the desired level of accuracy of the solution, which can be measured by the confidence interval of the optimal solution of a stochastic programming (SP) problem. Next, KSM method implemented by DACE (Design and Analysis of Computer Experiments) toolbox in MATLAB includes multiple sub-steps in series to determine the corresponding initial production rate of other components that corresponds to C_2($P^{r_0}_{i,C_2}$), C_3($P^{r_0}_{i,C_3}$), C_{4+}($P^{r_0}_{i,C_4}$), N_2($P^{r_0}_{i,C_5}$), CO_2($P^{r_0}_{i,C_6}$), and H_2S($P^{r_0}_{i,C_7}$). (He et al., 2018) In each sub-step, we fit a single response surface with respect to the original component distribution using field data reported by Zavala-Araiza et al. (2018) Finally, an integrated DSAC method integrating Arps decline formula and refracturing formula is developed to quantitatively estimate the EUR under uncertainty. In addition, this step classifies the shale wells into wet and dry ones by checking the high heating value of raw

gas quality (S_{hhv}) in each scenario. Only raw shale gas extracted from wet wells is considered in this work since it is suitable for the downstream monetizing technologies.

Step II: the feedstock variability is propagated through performing a detailed process modeling method on distributed-centralized conversion network systems. Herein, detailed distributed-centralized network systems of shale gas-to-polymers considering different monetization pathways are developed through rigorous process design, modeling and synthesis. Specially, either the hybrid methane and NGLs or solely the NGLs are converted to polymers in a centralized production plant, resulting in two monetization pathways termed hybrid pathway (H) and NGLs pathway (O). The first pathway includes five process units (mixture fractionation, H_2/olefins recovery, C_2-C_3 pyrolysis, C_1 pyrolysis, and CO_2 capture and storage) and a utility facility. While the last two process units, namely C_1 pyrolysis unit and CO_2 capture and storage unit, as well as the syngas separator in C_2-C_3 pyrolysis unit, need to be eliminated in the second pathway due to the absence of C_1 conversion.

Once all the scenario runs are completed, a set of model output variables of interest is mapped and collected. We obtain a stochastic model with a finite number of independent scenarios. For per-scenario, the model outputs including plant-level yields, consumptions, equipment sizes, and emissions are known perfectly for the next step.

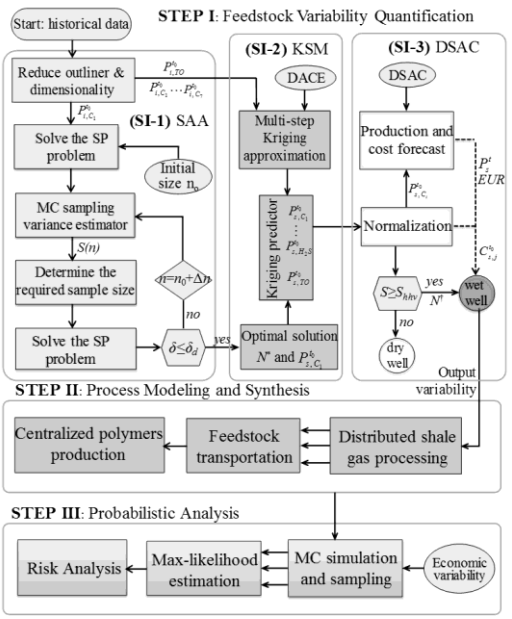

Figure 1. Flowchart of the proposed methodology

Step III: uncertain economic parameters extracted from the entire process are nested in the stochastic model to identify the probabilistic distributions and to perform a likelihood analysis of techno-economic objectives. In particular, each economic parameter can be assigned a certain type of probability distribution. As shown in Figure 1, Monte Carlo simulation method is used to perform the uncertainty analysis of economic parameters. The values of varying economic parameters are sampled randomly from the user-specified probabilistic distribution. In this way, for each scenario, a set of resulting outputs (sub-scenarios), with respect to the process performances, is recorded by

conducting a sufficient number of sets of samples. In this way, we can identify the probability distributions and then estimate the max-likelihood estimation (MLE) of levelized production cost of HDPE (LCOP, $/t):

$$\mathrm{LCOP}=\frac{TPC+\sum_{t\in T_{ls}}\left[\frac{AF+AO}{(1+DR)^t}-\frac{RV}{(1+DR)^t}-\frac{\sum_{bp}R_{bp}}{(1+DR)^t}\right]}{T_{ls}\times AP_{\mathrm{HDPE}}} \tag{1}$$

where AF, AO, and AP_{PE} are annualized parameters including the feedstock cost, operati ng cost, and production amount of PE, respectively; TPC, DR, RV, and R_{bp} are the total p roject cost, discount rate, residual value, and the revenue by selling by-product bp. Note that, in the calculation of LCOP, we consider that the raw shale gas is directly purchased from the raw shale gas producer at its real extraction cost instead of the market price.

3. Case Studies

The proposed shale gas monetization framework is applied to four distinct case studies including two sets of influencing factors as follows. (1) Plant location: feedstock is collected from two shale regions, namely the Appalachians (AP) and the Gulf Coast (GC); (2) monetization pathway: end-use products can be manufactured via either only a NGLs pathway design or a combination of C_1 pathway design and NGLs pathway design. Thus, these examples will be denoted by AP-O, AP-H, GC-O, and GC-H where AP and GC denote the plant located in the AP and GC regions. The distributed processing facility and centralized production plant are considered at 50 mmscfd of raw gas input and 300 kt per year of polymers production. Besides, allowable by-products consist of PG, butanes+, sulphur, and electricity.

4. Result and Discussion

Figure 2 shows the financial variability in terms of the LCOPs. In a vertical comparison, the histograms of LCOP distribution of the shale gas monetizing projects located in the same region but employing different production routes are presented. It is interesting that the case studies employing the NGLs pathway design has a much broader cost distribution. For example, as the monetization projects located in the AP region, the LCOP associated with the hybrid pathway ranges from $200/t to $2,250/t, while for the NGLs pathway design this value ranges from $-1,000/t to $4,350/t. This difference suggests that hybrid pathway design can effectively reduce the variability of production costs. It should be noted that a negative value of LCOP indicates that the monetizing project of interest is economically competitive even only considering the sale of by-products in some extreme scenarios. In a horizontal comparison, the LCOP distributions of the monetizing project located at different shale regions but considering the same production route are investigated. As an example, when the hybrid pathway design is taken into account, the projects located in the AP region had a slightly narrower distribution of LCOP compared with the GC region case. In the case of the NGLs pathway design, the difference in the distribution width of LCOPs becomes wider and more apparent for the two shale regions investigated.

To present the financial risk analysis, we consider that the LCOP cannot exceed a certain threshold, which is assumed to be $1,400/t of HDPE according to the high level of market

prices in the last three years. Once the LCOP exceeds this value, the distributing range is marked by a translucent dashed-box and the resulting cumulative probability distributions (Ω_R) are provided in Figure 2. As shown in this figure, the monetizing projects considering the hybrid pathway design have a much lower financial risk in relation to the Ω_R. For example, the financial risk can be remarkably mitigated from 29.6% for the AP-O case study to 17.2% for the AP-H case study.

Figure 3 compares the max-likelihood of LCOP results for different case studies with consideration of multi-refracturing treatments. Compared with the mean value shown in Figure 2, the MLE of LCOPs has a greater value by 8~12% for all case studies investigated. This increment clearly indicates that the true production cost is underestimated using the conventional statistical method under uncertainty which, in turn, results in an over-optimistic forecast of financial risk. For each case study, first the refracturing treatment leads to a decrease in the MLE of LCOP, but when the number of well-refracturing continues to grow, the LCOP's MLE remarkably increases. The single refracturing treatment case (M=1) has the minimum MLE of LCOP, which is \$975/t for the AP-H case study, \$1,038/t for the AP-O case study, \$994/t for the GC-H case study, and \$1,153/t for the GC-O case study. This result suggests that a single refracturing treatment should be performed over the lifespan of the wells, which is sufficient to guarantee a minimum LCOP. Note that the optimal number of well-refractures comes from the EUR growth and nominal operation expense for an additional treatment.

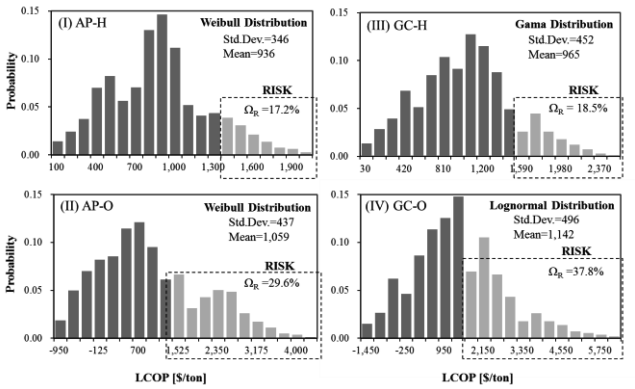

Figure 2. Comparison of the LCOP distributions for the HDPE production.

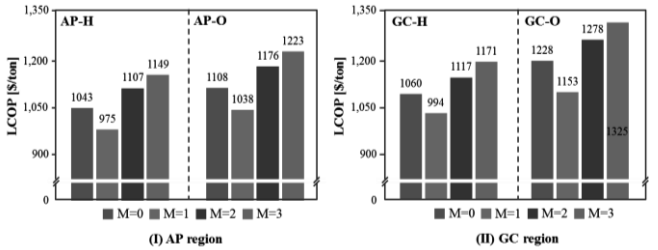

Figure 3. Comparison of the MLE of LCOPs.

As has been concluded above, the hybrid pathway design provided an effective solution to reduce the financial risk of shale gas monetizing projects. The advantage is not limited to this aspect. For the GC region case shown in Figure 3, the hybrid pathway design can

reduce the MLE of LCOPs by 10~15%, although this reduction significantly declines to about 5% for the AP region. This reflects that the hybrid pathway design is more amenable to reducing the risk of projects fed by raw shale gas that have high NGLs content. In other words, wet shale gas used as feedstock provides an opportunity to perform the process integration and equipment sharing considered in the hybrid pathway design, as NGLs are comparable to the methane in terms of the feed amount; otherwise, the improvement on the real production cost is not as much as anticipated.

5. Conclusions

This work proposed a systematic framework for monetizing raw shale gas to polymers and other by-products with consideration of complex mixed uncertainties. The mixed uncertainty considered in the monetization framework not only included endogenous variabilities of gas composition and EUR, but also the exogenous ones of the entire project, often corresponding to market variabilities. To accommodate the reality of uncertainty, a new stochastic data processing strategy integrating the SAA, KSM, and DSAC methods was proposed to generate appropriate scenarios and to determine the corresponding values of each uncertain variable. These output variabilities were passed to the process simulator to implement the detailed process design and techno-economic analysis. Uncertain economic parameters were nested in this stochastic model to identify the probabilistic distributions and to analyze the MLE of techno-economic objectives. The proposed framework was applied to four case studies based on different plant locations and the above-mentioned pathways. The results highlighted the benefits of the hybrid pathway as it reduced the MLE of LCOPs. In particular, the hybrid pathway design was more amenable to reducing the economic risk of the projects located in the GC shale region where the raw shale gas has appropriate NGLs content but suffers from expensive extraction expenses.

Abstract

We propose an improved L-shaped method to solve large-scale two-stage convex 0-1 mixed integer nonlinear stochastic programs with mixed-integer variables in both first and second stage decisions. Solving the deterministic equivalent of the two-stage stochastic programs with a large number of scenarios directly with commercial solvers is computationally expensive. To address the difficulties in solving large problems, we propose a Benders-like decomposition algorithm that includes both Benders cuts and Lagrangean cuts in the Benders master problem. The proposed algorithm is applied to solve a batch plant design problem under demand uncertainty. It is shown that the proposed algorithm outperforms the commercial solver DICOPT for the problems with a large number of scenarios. Also it is proved that the proposed algorithm can always yield a lower bound that is at least as tight as the one from Lagrangean decomposition algorithm.

Keywords: Stochastic programming, L-shaped method, Convex MINLP, Integer recourse

1. Introduction

Stochastic programming is an optimization framework that deals with decision-making under uncertainty. A special case is two-stage stochastic programming. Decomposition algorithms like Benders decomposition (Geoffrion, 1972) and Lagrangean decomposition (Guignard, 2003) have been used to solve stochastic programs with linear constraints and continuous recourse. However, for two-stage nonlinear 0-1 mixed-integer stochastic programs, relatively little work has been done. Li et al. (2011) propose a nonconvex generalized Benders decomposition (NGBD) algorithm for mixed-integer nonlinear stochastic programs with pure binary first stage variables. Ogbe (2016) proposes a joint decomposition method for mixed-integer nonlinear nonconvex programs.

To the best of our knowledge, there is no effective decomposition algorithm that can solve two-stage 0-1 mixed-integer convex nonlinear stochastic programs with mixed-integer variables in both first and second stage decisions. In this paper, we propose an improved L-shaped algorithm that has different types of valid inequalities in the Benders master problem.

2. An improved L-shaped method

In this paper, we consider two-stage stochastic programs with convex nonlinear constraints and 0-1 mixed-integer variables in both first and second stage. The deterministic equivalent of the two-stage stochastic program that we address in this paper is defined as (*P*) and shown in Eq.(1)-Eq.(5).

$$(P): \quad min \quad z = c^T x + \sum_{\omega \in \Omega} \tau_\omega d_\omega^T y_\omega \tag{1}$$

$$s.t. \quad A_0 x \geq b_0, \quad g_0(x) \leq 0 \tag{2}$$

$$A_{1,\omega} x + g_{1,\omega}(y_\omega) \leq b_{1,\omega} \quad \forall \omega \in \Omega \tag{3}$$

$$x \in X, \quad X = \left\{x : x_i \in \{0,1\}, \forall i \in I_1, \;\; 0 \leq x \leq x^{ub}\right\} \tag{4}$$

$$y_\omega \in Y \quad \forall \omega \in \Omega, \quad Y = \left\{y : y_j \in \{0,1\}, \forall j \in J_1, \;\; 0 \leq y \leq y^{ub}\right\} \tag{5}$$

Here, x represents the first stage decisions. y_ω represents the second stage decisions in scenario ω. $g_0, g_{1,\omega}, g_{2,\omega,}$ are convex functions. Both the first and the second stage decisions are 0-1 mixed-integer. Let *I* be the index set of all the first stage variables. $I_1 \subseteq I$ is the subset for indices of the binary first stage variables. Let *J* be the index set of all the second stage variables. $J_1 \subseteq J$ is the subset for the indices of the binary second stage variables. x^{ub} is a vector that represents the upper bound of all the first stage variables. y^{ub} is a vector that represents the upper bound of all the second stage variables. In this paper, we assume problem (*P*) has relatively complete recourse, i.e., any solution *x* that satisfies the first stage constraints has feasible recourse decisions in the second stage. Solving (*P*) with a large number of scenarios directly using MINLP solvers is prohibitive since the computational time grows exponentially with the number of scenarios. In order to solve problem (*P*) more efficiently, we propose an improved L-shaped method that is based on generalized Benders decomposition (Geoffrion, 1972). The basic idea of generalized Benders decomposition is to decompose (*P*) into a Benders master problem which only contains first stage decisions and Benders subproblems each of which only contains second stage decisions for a given scenario. In this paper, we add both Benders cuts and Lagrangean cuts to the Benders master problem to tighten the relaxation.

We first define the Benders master problem (MB^k), with both Lagrangean cuts Eq.(8), and Benders cuts Eq.(9) for a given set of iterations $k \in K$. z_{MB}^k is the objective of the Benders master problem at iteration k. $z_{SL,\omega}^{*k}$ and $z_{SB,\omega}^{*k}$ are the optimal values of the Lagrangean subproblem (SL_ω^k) and the Benders subproblem (SB_ω^k), which are defined next.

$$(MB^k): \quad min \quad z_{MB}^k = \sum_{\omega} \eta_\omega \tag{6}$$

$$s.t. \quad A_0 x \geq b_0, \quad g_0(x) \leq 0, \quad x \in X \tag{7}$$

$$\eta_\omega \geq z_{SL,\omega}^{*k} - \mu_\omega^k x \quad \forall \omega \in \Omega, k \in K \tag{8}$$

$$\eta_\omega \geq z_{SB,\omega}^{*k} + (\lambda_\omega^k)^T (x - \tilde{x}^k) + \tau_\omega c^T x \quad \forall \omega \in \Omega, k \in K \tag{9}$$

Next, we show how the valid inequalities Eq.(8) and Eq.(9) can be derived. The deterministic equivalent problem (P) can be reformulated by duplicating the first stage decisions x for each scenario ω and adding nonanticipativity constraints (*NACs*), $x_{\omega 1} = x_{\omega 2}, x_{\omega 1} = x_{\omega 3}, \cdots x_{\omega 1} = x_{\omega|\Omega|}$, to guarantee that all the first stage decisions made for all the scenarios are the same. The *NACs* can be dualized by multiplying π_ω to the constraints, $x_{\omega 1} = x_{\omega 2}$, $x_{\omega 1} = x_{\omega 3}, \cdots x_{\omega 1} = x_{\omega|\Omega|}, \omega = \omega_1, \omega_2, \cdots, \omega_{|\Omega|-1}$. Then the deterministic equivalent problem can be decomposed into $|\Omega|$ scenarios. Each subproblem is defined as a Lagrangean subproblem (SL_ω^k) for iteration k:

$$(SL_\omega^k): \quad min \quad z_{SL,\omega}^k = \tau_\omega (c^T x_\omega + d_\omega^T y_\omega) + \mu_\omega^k x_\omega \tag{10}$$

$$s.t. \quad A_0 x_\omega \geq b_0, \quad g_0(x_\omega) \leq 0 \tag{11}$$

$$A_{1,\omega} x_\omega + g_{1,\omega}(y_\omega) \leq b_{1,\omega} \tag{12}$$

$$x_\omega \in X, \quad y_\omega \in Y \tag{13}$$

where $\mu_{\omega 1}^k = \sum_{\omega=\omega_1}^{\omega_{|\Omega|-1}} \pi_\omega^k$, $\mu_{\omega+1}^k = -\pi_\omega^k$, $\omega = \omega_1, \omega_2, \cdots, \omega_{|\Omega|-1}$. Each Lagrangean subproblem (SL_ω^k) is solved to optimality. The optimal value of the subproblem ω at iteration k is defined as $z_{SL,\omega}^{*k}$. $\eta_\omega \geq z_{SL,\omega}^{*k} - \mu_\omega^k x$ is a valid inequality for the Benders master problem defined as a Lagrangean cut. The proof of the validity of the Lagrangean cuts is shown by Li and Grossmann (2017). After solving the Lagrangean subproblems at each iteration k, the multipliers of the Lagrangean subproblems can be updated using the subgradient method (Oliveira et al., 2013). After adding the Lagrangean cuts to the Benders master problem, the lower bound obtained by solving the Benders master problem is at least as tight as the lower bound that can be obtained by using Lagrangean decomposition (Li and Grossmann, 2017).

Assume the solution to the Benders master problem at iteration k is $\tilde{x}^k$, x is fixed at $\tilde{x}^k$ for the relaxation of deterministic equivalent problem (*RP*). (*RP*) can be decomposed into $|\Omega|$ subproblems. Each subproblem is defined as the Benders subproblem (SB_ω^k):

$$(SB_\omega^k): \quad min \quad z_{SB,\omega}^k = \tau_\omega d_\omega^T y_\omega \tag{14}$$

$$s.t. \quad x = \tilde{x}^k \tag{15}$$

$$A_{1,\omega} x + g_{1,\omega}(y_\omega) \leq 0 \tag{16}$$

$$0 \leq y_\omega \leq y^{ub} \tag{17}$$

According to Geoffrion (1972), a Benders cut can be generated at iteration k:

$$\eta_\omega \geq z_{SB,\omega}^{*k} + (\lambda_\omega^k)^T (x - \tilde{x}^k) + \tau_\omega c^T x \tag{18}$$

where λ_ω^k is the optimal dual multiplier for Eq.(15) at iteration k. $z_{SB,\omega}^{*k}$ is the optimal value of (SB_ω^k).

After the Benders master problem is solved at iteration k, x in problem (P) is fixed at $\tilde{x}^k$. The rest of the problem can be decomposed into $|\Omega|$ scenarios. A feasible solution to the deterministic equivalent problem can be obtained by solving the upper bound subproblems (UB_ω^k) defined as Eq.(19)-(20). Let $z_{UB,\omega}^{*k}$ be the optimal value of (UB_ω^k). An upper bound of (P) can be obtained by calculating $c^T \tilde{x}^k + \sum_{\omega\in\Omega} z_{UB,\omega}^{*k}$.

$$(UB_{\omega}^{k}): \quad min \quad z_{UB,\omega}^{k} = \tau_{\omega} d_{\omega}^{T} y_{\omega} \tag{19}$$

$$s.t. \quad g_{1,\omega}(y_{\omega}) \leq b_{1,\omega} - A_{1,\omega}\tilde{x}^{k} \tag{20}$$

The steps of the improved L-shaped method are outlined in Figure 1. The lower bound is initialized with $-\infty$. The upper bound is initialized with the optimal value obtained by solving the stochastic program with the first stage decisions fixed at the optimal solution of the expected value problem. The Lagrangean multipliers are initialized to 0. At each iteration, the Lagrangean subproblems, the Benders master problem, the Benders subproblems, and the upper bound subproblems are solved sequentially. The optimal solution of the Benders master problem is used to initialize the Benders subproblems and the upper bound subproblems. Valid inequalities for the Benders master problem can be derived by solving the Lagrangean subproblems and the Benders subproblems. The algorithm iterates until the relative optimality gap is within a given value ϵ.

3. Optimal design of multi-product batch plant under demand uncertainty

We study a multi-product multi-stage batch plant (Figure 2) under demand uncertainty. Every product has to be processed through all the stages. It is assumed that in each stage there can be multiple processing units with equal volume. The number and the volume of the processing units purchased have to be decided before the demand for each product is known. After the demand of each product is realized, operating decisions including the number of processing units actually used and the batch size of each product have to be made. We assume the batch sizes for any given product are the same. Not all the processing units purchased have to be used, i.e., processing units can be idle when the demand is low. There will be a fixed cost for using one processing unit, so one should try to use as few processing units as possible. One should also try to complete all the processing tasks within a given time horizon and there is a penalty cost for exceeding the time horizon. This problem can be formulated as a two-stage stochastic program where the first stage decisions are the number and volume of the processing units. The second stage decisions are the batch size of each product, the number of processing units used in each stage, and the cycle time of each product. The problem can be formulated as a convex MINLP which is shown by Li and Grossmann (2017).

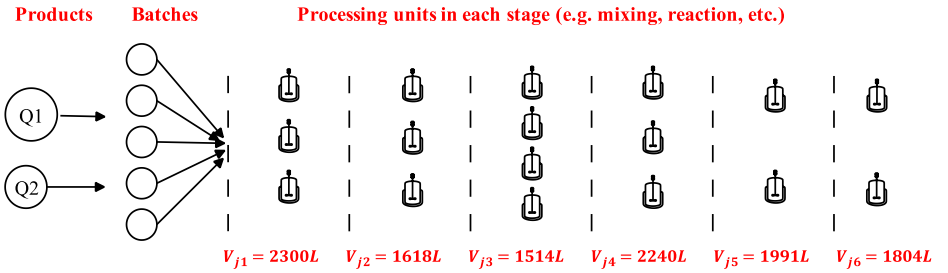

Figure 2. A multi-product multi-stage batch plant for two products with corresponding demands Q_1 and Q_2.

In the case study, we study a batch plant with 6 stages, 5 products. Each stage can have at most 4 processing units. We assume that there are 3 scenarios, where the demand of each product can be high, medium, or low with probability of 25%, 50%, 25%, respectively. The high and low demand are +10% and -10% away from the medium. The problem is first solved in deterministic equivalent form in GAMS using DICOPT on the 12 processors of an Intel Xeon (2.67GHz) machine with 64 GB RAM. The model has 96 binary variables, 64 continuous variables, 316 constraints. The optimal solution yields a minimum cost of 423.5(10^3\$). The NLP relaxation of this problem is 408.4(10^3\$). The wall time of solving the deterministic equivalent problem is 0.8 sec. The number and the volume of each processing units purchased in each stage is shown in Figure 2. The number of processing units that are operating in each stage in each scenario ($N_{j\omega}^S$) is shown in Table 1, where $\omega_1, \omega_2, \omega_3$, correspond to high, medium, and low demand, respectively. It is easy to see that the recourse decisions of different scenarios are different. When the demand is low, not all the processing units purchased are used. However, if we solve the expected value problem with the demand of all products fixed at their mean values, the number of units purchased at each stage is 3, 2, 4, 3, 2, 2, respectively. Compared to the stochastic solution, the number of units at stage *j2* decreases from 3 to 2. Therefore, with the expected value solution, the high demand cannot be satisfied without an extension of the time horizon. The expected value solution has an expected cost of 433.4(10^3\$). The value of stochastic solution (*VSS*) of this problem is 9.9(10^3\$).

Table 1: Optimal number of processing units in each stage in each scenario

Stage	*j1*	*j2*	*j3*	*j4*	*j5*	*j6*
$N_{j\omega_1}^S$	3	3	4	3	2	2
$N_{j\omega_2}^S$	3	2	4	3	2	2
$N_{j\omega_3}^S$	3	2	4	2	2	2

If the demands for the 5 products are independent and the demand for each of the products can be high, medium, or low as in the 3-scenario problem, the total number of scenarios is 243. The deterministic equivalent model has 5,856 binary variables, 4,144 continuous variables, 23,596 constraints. In this case, DICOPT fails to obtain a feasible solution for the deterministic equivalent problem within 50,000 seconds. The proposed decomposition algorithm is implemented to solve both the 3-scenario and the 243-scenario problem. The decomposition algorithm is allowed to run for 30 iterations

adding both Lagrangean cuts and Benders cuts to the Benders master problem in each iteration, or the relative optimality gap is less than 1%, whichever comes first. If the relative optimality gap after 30 iterations is greater than 1%, the algorithm is allowed to run for another 30 iterations only adding Benders cuts to the Benders master problem because it is observed that for most cases the Lagrangean multipliers are close to convergence after the first 30 iterations. As before, all the problems are solved using the 12 processors of an Intel Xeon (2.67GHz) machine with 64 GB RAM. All the MINLP problems are solved using DICOPT and all the NLP problems are solved using CONOPT. All the subproblems are solved in parallel using Grid GAMS. The wall time of solving the 3-scenario problem and the 243-scenario problem are 26 seconds and 604 seconds, respectively. The relative optimality gaps for the two cases are 0.4% and 0.7%, respectively. The upper bound of the 243-scenario problem is 413.3(10^3\$), while the lower bound is 410.5(10^3\$). The *VSS* of the 243-scenario problem is 4.9(10^3\$) based on the upper bound obtained by the proposed decomposition algorithm.

From the case study, we can see that although DICOPT can solve the small-scale deterministic equivalent problem quite fast, it fails to obtain a feasible solution for the large-scale deterministic equivalent problem. In comparison, the proposed decomposition algorithm scales better with the number of scenarios.

4. Conclusion

In this paper, we have proposed an improved L-shaped method that can effectively solve two-stage convex 0-1 mixed-integer nonlinear stochastic programs with mixed-integer variables in both first and second stage decisions. The decomposition algorithm is tested using the batch plant design problem under demand uncertainty. The algorithm can achieve a relative optimality gap of less than 1% for the problems tested. The proposed decomposition algorithm is faster than using DICOPT to solve the deterministic equivalent problem directly when applied to the problem with a large number of scenarios. However, the proposed algorithm is not guaranteed to close the optimality gap of the problems. A more rigorous algorithm that has finite convergence is currently being developed.

Abstract

This work presents a two-stage stochastic programming model to optimize the expected net present value (ENPV) of CO_2-EOR projects under uncertainty. The mathematical formulation relies on a multi-period planning approach aimed to find the optimal exploitation strategy for a mature oil reservoir. Given uncertain prices and productivity scenarios, the model sets the most convenient time to launch the CO_2-EOR project, and establishes efficient operating conditions over the planning horizon. It determines the number of production and injection wells to operate at every period, the CO_2 injection rate in every well, and the timing for maintenance and conversion tasks. The problem complexity grows rapidly with the number of wells and scenarios considered, resulting in a large-scale decision-making problem. Well productivity forecast functions are nonlinear (typically hyperbolic), yielding a mixed integer nonlinear (MINLP), nonconvex formulation. A moving horizon framework is adopted to take recourse actions when uncertain production parameters are revealed. The proposed approach helps operators to increase CO_2-EOR profitability by minimizing losses in low-price and productivity scenarios and maximizing the gain under more promising conditions.

Keywords: Carbon Dioxide Enhanced Oil Recovery, Stochastic Programming, Optimization, MINLP

1. Introduction

Carbon dioxide enhanced oil recovery (CO_2-EOR) and CO_2 sequestration in oil reservoirs is a relatively new technique with great potential to increase hydrocarbons production from mature reservoirs[1]. CO_2-EOR can increase the oil production from mature fields that have been primary and secondary exploited. While primary and secondary production stages typically yield between 30% and 50% of the original oil in place (OOIP, Melzer, 2012), CO_2-EOR techniques can increase the oil production by 15% or more (Advanced Resources International, 2011). Carbon dioxide injection in all its variants, specially the miscible option (combined with water), proves to be an effective option in different types of reservoirs. The main purpose is both to extend the reservoir productive lifespan and to increase the field productivity. Moreover, CO_2-EOR can reduce greenhouse gas emissions since large amounts of anthropogenic and/or natural CO_2 remain stored into the oilfield after performing the EOR, thus mitigating the environmental impacts of the oil and gas industry. Although many EOR projects take advantage of existing wells, data and facilities of the secondary recovery phase, several investments have to be made to achieve a reliable operation. The most relevant

investments are due to: (a) workover of existing wells (for production or injection); (b) CO_2 supply, compression and recycling facilities; (c) drill and completion of new wells; (d) field analysis to predict the reservoir response to CO_2 injection; and (d) new monitoring and operating equipment.

This work presents a two-stage stochastic programming model to determine the optimal investment and operation strategy for a CO_2-EOR project under uncertainty. To assess the performance of the EOR process, a nonlinear model is adopted, thus yielding a Mixed-Integer Nonlinear (MINLP) formulation. The oil production is forecasted by the Capacitance-Resistance-Model (CRM, Tao and Bryant, 2015, Eshraghi et al., 2016) combined with the Fractional Flow Method (FFM, Albertoni, 2002), based on hyperbolic decline functions of the oil composition. The main advantage of these approaches is their proven effectiveness to predict the oil production based on simple evaluations of historical data, regardless of geological simulations (Gentil, 2015). We embed the model on a moving horizon framework to account for changes in the problem conditions (Drouven et al., 2017).

2. General Problem Statement

We consider an oil reservoir that has completed its secondary recovery phase. We assume that: (a) Reservoir characterization data is available, given that the field has produced oil during a considerable amount of time. However, the well productivity after CO_2 injection is uncertain. We use a set of discrete scenarios $\{p \in P\}$ to account for the oil production rate variability. Once the EOR project is launched and the field starts to produce, production uncertainty is assumed to vanish. (c) CO_2 purchase and delivery cost, as well as future oil prices are uncertain parameters of the mathematical formulation. We consider a finite set of price forecast scenarios $\{f \in F\}$ to address this exogenous uncertainty. (d) Injection and production wells can be operated at different capacity levels. Higher operation rates imply larger facilities, but unit fluids handling costs reduce due to economies-of-scale.

Given the above assumptions, the proposed approach is aimed to: (1) decide whether or not to invest in the EOR-CO_2 project; (2) select new and/or existing wells to use for the EOR; (3) determine the most suitable operating mode (injection or production) for every well at every period; (4) set the most profitable well operation capacity level; and (5) find the right amount of carbon dioxide to inject at every period in every injection well; so as to maximize the expected net present value (ENPV) of the project. Furthermore, the model should find proper timings for maintenance and/or switching interventions, according to given prices and performance scenarios. In fact, the well's selection strategy should account for every future scenario (first stage, here-and-now decisions), while the CO_2 injection rates and the operation mode of each well over future periods will depend on the oil production response after the first interventions (second stage, wait-and-see decisions).

3. Mathematical Formulation

Besides production and price forecast scenarios, the optimization model is based on the following sets: time periods $t \in T$ (commonly quarters), new and existing available wells $i \in I$, production and injection capacities $cp \in CP$, $ci \in CI$. Furthermore, the MINLP model comprises the following 0-1 variables: V (= 1 if the project is launched), $Y_{i,t,ci}$ (= 1 if the well i is used as an injector during period t, at capacity level ci), $X_{i,t,cp}$ (=

1 if well *i* is set as producer during *t* at capacity level *cp*), $NW_{i,t}$ (indicating that the well *i* is inactive during period *t*), $MI_{i,t,ci}$ / $MP_{i,t,cp}$ (denoting that production/injection well *i* is under maintenance during *t*), $WPI_{i,t,ci}$ / $WPP_{i,t,cp}$ (denoting that the well *i* begins to inject/ produce at capacity *ci* / *cp* during period *t*), and $WRI_{i,t,ci}$ / $WRP_{i,t,cp}$ (= 1 if the production/injection well *i* turns to be an injector/producer at period *t*). Except for the variable *V* and the time period $t = 1$ (here-and-now decisions), all of the above 0-1 variables can take a different value for every production scenario *p* and price forecast *f* (wait-and-see decisions). The two-stage stochastic programming formulation seeks to:

$$Max\ ENPV = \sum_p \varphi_p \{ \sum_f \varphi_f [\sum_t CF_t^{(f,p)}/(1+r)^t] - Inv^{(f,p)} \} \quad (1)$$

where φ are the probabilities of every single scenario, *CF* are the cash flows, *r* is the discount rate and *Inv* is the initial investment. The main model constraints are presented below. For the sake of simplicity, indexes *p* and *f* (scenarios) are omitted.

$$\sum_{ci} Y_{i,t,ci} + \sum_{cp} X_{i,t,cp} + NW_{i,t} = V \qquad \forall i \in I, t \in T \quad (2)$$

$$WPP_{i,t,cp} \geq X_{i,t,cp} + NW_{i,(t-1)} - 1 \qquad \forall\, i \in I, t \in T, cp \in CP \quad (3)$$

$$WPI_{i,t,ci} \geq Y_{i,t,ci} + NW_{i,(t-1)} - 1 \qquad \forall\, i \in I, t \in T, ci \in CI \quad (4)$$

$$WRI_{i,t,ci} \geq X_{i,t,cp} + \sum_{ci} Y_{i,(t-1),ci} - 1 \quad \forall\, i \in I,\ t > 1,\ cp \in CP \quad (5)$$

$$WRP_{i,t,cp} \geq Y_{i,t,ci} + \sum_{cp} X_{i,(t-1),cp} - 1 \quad \forall\, i \in I,\ t > 1,\ ci \in CI \quad (6)$$

Eq.(2) to Eq.(6) determine the condition of every single well at every period. The injection/production rate is limited by Eq.(7) and Eq.(8). Parameters η and μ account for losses in the well productivity due to switching and maintenance interventions.

$$Q_{i,t,ci} \leq capi_{ci}\ (Y_{i,t,ci} - \eta i\ \ WRI_{i,t,ci} - \mu i\ \ MI_{i,t,ci}) \quad \forall i \in I, t \in T, ci \in CI \quad (7)$$

$$Q_{i,t,cp} \leq cap_{cp}\ (X_{i,t,cp} - \eta p\ \ WRP_{i,t,cp} - \mu p\ \ MP_{i,t,cp}) \quad \forall i \in I, t \in T, cp \in CP \quad (8)$$

Maintenance tasks are enforced to be performed periodically, depending on the operating conditions of the well (for the sake of shortness, the equations are omitted).

One of the most challenging issues is the relationship between inflows and outflows to/from injection and production wells. We adopt the Capacitance-Resistance-Model [3,4], omitting the transient term (initial phase) given that this period usually lasts few hours (negligible when compared to quarters). The CRM is given by Eq.(9) to Eq.(11).

$$QP_{i,j,t} \leq \psi_{i,j}\ \ QI_{i,t}\ (1 - \rho_t) \qquad \forall i \neq j, t \in T \quad (9)$$

$$\sum_{cp} Q_{i,t,cp} = \sum_{j \neq i} QP_{j,i,t} \quad ; \quad \sum_{ci} Q_{i,t,ci} = QI_{i,t} \qquad \forall i \in I, t \in T \quad (10)$$

$$\sum_j \sum_{cp} Q_{j,t,cp} = \sum_i \sum_{ci} Q_{i,t,ci}\ (1 - \rho_t) \qquad \forall\, t \in T \quad (11)$$

Every pair of wells is characterized by an inter-well connectivity factor (ψ_{ij}) where *i* and *j* are injection and production wells, respectively. Larger values of ψ_{ij} imply higher transmissibility. Parameter ρ is the retention factor of CO_2 into the reservoir, which usually decreases with time.

Another modelling challenge is to predict the oil composition in the flows produced by every well over the time horizon. In this case, we use the basis of the Fractional Flow Method[4,5] that estimates the oil yield of a single production well in a CO_2-EOR project. In our model, the oil fraction for every pair *i-j* declines hyperbolically with the cumulative amount of CO_2 already pumped through that link (*CGII*), in any direction, as expressed by Eq.(12) and Eq.(13). More specifically, the oil composition in the outflow of a production well can be forecasted through parameters a_j and b_j (specified for every single well, under every production scenario). In our model, similar to Drouven et al.[7], endogenous uncertainty is related to the production yield (a_j and b_j), which is assumed to be revealed as soon as the EOR project is started.

$$CGII_{i,j,t} \geq \sum_{t' \leq t} \psi_{i,j}\, QI_{i,t'} + \sum_{t' \leq t} \psi_{j,i}\, QI_{j,t'} \qquad \forall (i \neq j) \in I, t \in T \tag{12}$$

$$Qoil_{i,j,t} \left(1 + a_j \left(CGII_{i,j,t} \right)^{b_j} \right) \leq QP_{i,j,t} \qquad \forall (i \neq j), t \in T \tag{13}$$

Finally, the overall production from the reservoir during the whole time horizon should not exceed the fraction of the original oil in place expected to be recovered in each scenario, as imposed by constraint (14).

$$\sum_t \sum_{i \neq j} Qoil_{i,j,t} \leq u\ OOIP \tag{14}$$

To calculate revenues, investment and operating costs during every time period we account for: oil selling, CO_2 acquisition, CO_2 capture and storage (CCS), drill and completion of new wells, set up and maintenance of existing wells, operation mode switching, CO_2 / oil handling equipment, CO_2 recycling plant, production/injection equipment, among others (Wei et al., 2015). We consider exogenous uncertainty in the CO_2 purchase cost and the oil selling price. This uncertainty realizes regardless of what the decision-maker does. To react against this, a moving horizon framework is implemented, periodically updating production strategy.

4. Case Study Results

The MINLP formulation is applied to a representative case study comprising 15 existing wells that can be adapted to operate in a miscible CO_2-EOR project. The time horizon length is ten years, divided into quarters. The production strategy is revised every year, following a moving horizon framework. It is assumed that three price forecast scenarios are likely to occur (low, average and high) at every planning instance. As shown in Figure 1, EOR projects are the largest CO_2 consumers. As a result, we assume a direct correlation between oil prices and CO_2 purchasing cost. Figure 2 shows the oil price forecast scenarios. Each scenario is assumed to have the same occurrence probability.

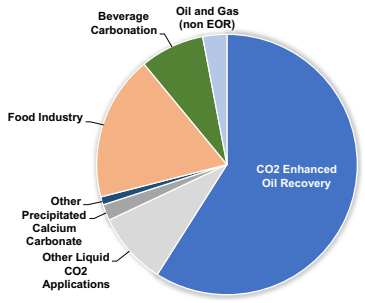

Figure 1: Global CO_2 market demand share (Source: CCS Institute, 2017)

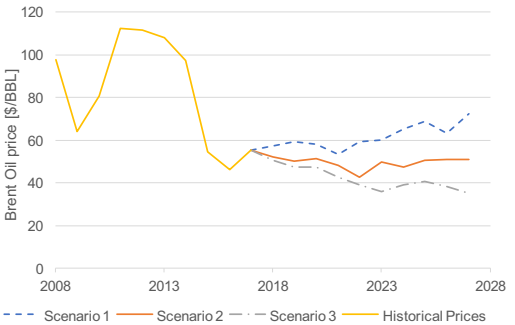

Figure 2: Oil price forecast scenarios

Similarly, two productivity scenarios (optimistic and pessimistic) are generated by introducing different sets of parameters a_j and b_j for every well. The optimistic scenario implies moderate declines of the well productivity (Scenario A), while pessimistic values mean a more rapid reduction of the oil fraction with the cumulative amount of CO_2 injected (Scenario B), as shown in Fig. 3 for a single production well.

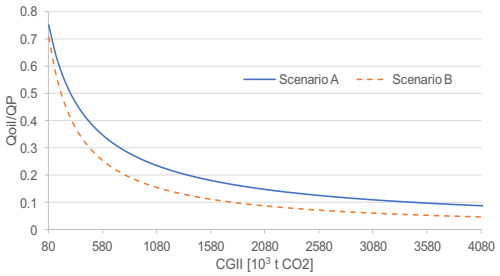

Figure 3: Oil fraction vs. Cumulative CO_2 reaching the well

Predictive maintenance tasks need to be performed at least every 2 and 3 years for production/injection wells, respectively. It is assumed a 10% reduction in the production/injection capacity of the well during the corresponding quarter. Analogously, the well capacity is reduced by half during the quarter in which the operation mode is switched.

From the hyperbolic decline function (13) the MINLP model is clearly nonconvex, thus requiring global solvers to guarantee optimality. However, the model dimensions largely exceed the maximum number of variables and equations to be solvable by commercial global solvers. For the case study, for instance, the model has more than 48 thousand variables (more than 10 thousand discrete) and 50 thousand constraints. As a result, an outer approximation solver (DICOPT) is adopted in this case.

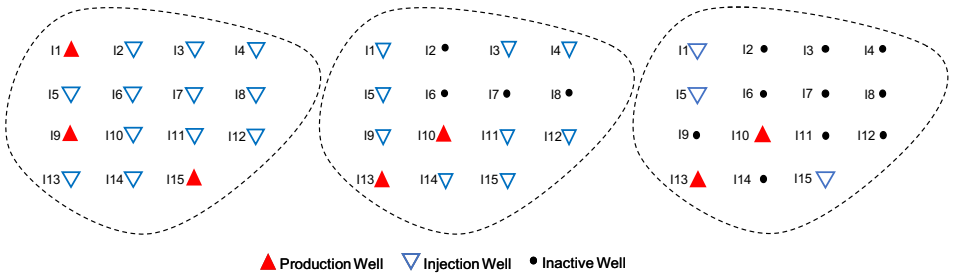

Figure 4: Well selection and operation modes for quarters T1, T25 and T40, respectively

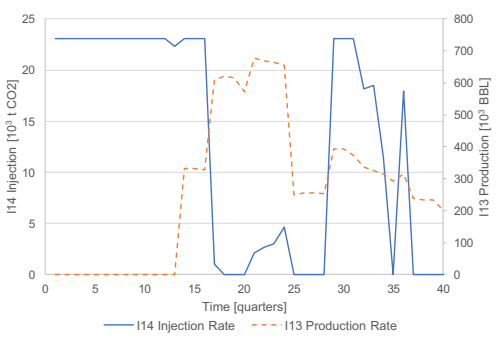

Figure 5: Production/Injection rates planned for wells I14 and I13, respectively

Using GAMS software on an Intel Xeon CPU, 8 GB RAM, (NLP solver: CONOPT4, MILP solver: CPLEX) it takes more than 4 hours and 5 major iterations to reach a local optimal solution. Some details on the solution found for the optimistic scenario are illustrated in Figs. 4 and 5. The most productive wells are I1, I5, I9, I10, I13, and I15. However, the model suggests a progressive development of the field and some changes in the wells operation strategy over time. As shown in Fig. 4, the recovery is more intense

in the first years, while several injection wells are gradually shut-in as oil production declines below threshold values. Under the optimistic scenario, the NPV amounts to 957.77 M$, 211 M$ better than the NPV of aggressive production strategies commonly applied in practice under promising scenarios. Maintenance tasks in production wells are planned at periods T8-T29 (I1); T14-T18-T26 (I5); T13-T26-T38 (I9); T13-T24-T37 (I10); T17-T26-T33 (I13); and T9-T13-T26-T38 (I15). Moreover, I1 is converted to an injection well at period T17; I5 switches to injection at period T25; I9 starts operating as an injection well at period T6; and I15 is converted to injection in quarter T13. Injection rates are properly managed, seeking to keep a quite stable oil production rate over time, maximizing the revenues when oil prices are high. To illustrate this, Fig. 5 represents injection and production rates of wells I14 and I13, respectively.

5. Conclusions

The two-stage stochastic approach presented in this work proves to be a valuable tool to aid EOR-CO_2 planning under uncertainty. The proposed MINLP model finds profitable solutions to a very complex combinatorial problem in reasonable CPU times. Although global optimality cannot be warranted since the model is nonconvex, the EOR development strategy is very efficient. By properly selecting the wells, managing injection rates and planning switching and maintenance tasks, project margins increase significantly (more than 28% with regards to EOR strategies typically implemented in practice). Future work will focus on reducing the computational burden by adding linear approximations of the decline functions and decomposition strategies. Reservoir representation can also improve by using more detailed well connectivity models.

Abstract

In this work, we address the scheduling problem under uncertainties in electricity price and product demand in an air separation plant. The operation of the plant is represented by an efficient discrete-time MILP model as a process state transition network in order to deal with short-term production scheduling. On the one hand, uncertainties in electricity are addressed with stochastic programming techniques to find a schedule that minimizes expected cost over a proposed set of scenarios. On the other hand, uncertainties in product demand are tackled as flexibility constraints in order to ensure flexible operation over the entire range of variation of this uncertain parameter.

Keywords: Optimal schedule under uncertainty, power-intensive processes, two-stage stochastic programming, flexibility analysis.

1. Introduction

Demand side management is critical for maintaining profitability, especially in industrial power intensive processes where operating cost can be reduced by adjusting the production schedule to time-dependent electricity pricing schemes. However, uncertainty in these systems not only arises from electricity price but also from product demand.

Stochastic programming is the framework that models mathematical programs with uncertainty by optimizing the expected value over the possible realizations (Birge and Louveaux, 2011). The expected value is computed by integrating over the set of uncertain parameters. A simplification of this calculation involves a discretization of the uncertainty sets, where the realizations can be characterized with a finite number of scenarios. The most common stochastic programs that consider recourse is the Mixed-Integer Linear Programming (MILP) with continuous recourse in a second stage. The two-stage stochastic programming formulation considers two types of decisions: first stage, made before uncertainty reveals, and second stage, independent for each scenario.

Stochastic programming has found applications in process synthesis. For example, Halemane and Grossmann (1983) presented a two-stage approach for the design of flexible processes under uncertainty. The design problem is formulated to minimize a cost function and to guarantee feasible operation over a polyhedral uncertainty set.

The design of robust or flexible chemical processes under uncertainty has been dominated by the concept of flexibility analysis, which was first proposed and then further developed by Grossmann and co-workers, a description of its historical development can be found

in Grossmann *et al*. (2016). Recently, Zhang *et al*. (2016) presented insights on the strong connection between flexibility analysis and robust optimization.

The basic idea of flexibility analysis is to consider explicitly uncertainties in chemical processes. In general, the study of the flexibility can be performed at different stages. First at the design stage, where the optimization models for process design explicitly include flexibility constraints. Then with fixed design variables, to evaluate if certain design can tolerate the uncertainties in a specified range, known as the flexibility test problem. Finally, to quantify the range of uncertainties that the design can tolerate, called the flexibility index problem.

In this work, we propose a novel approach for the optimal production schedule with flexibility constraints, an analogous approach for the design of flexible processes under uncertainty proposed by Halemane and Grossmann (1983). We deal with uncertainties in electricity price and product demand in a production scheduling model of an air separation plant (Basán *et al*., 2018). Operation is represented by a discrete-time MILP model as a process state transition network, a scheme of the states can be seen in Fig. 1. We propose to explore the use of stochastic programming to account for uncertainties in electricity price in order to find the optimal production schedule that minimizes expected cost over a given set of scenarios. A two-stage stochastic programming problem is formulated considering the plant state binary variables as first-stage and the operation variables, such as power consumption, production and inventory levels, as second-stage.

Moreover, we address uncertainty in product demand to achieve robustness. We consider flexibility constraints to ensure flexible operation over the entire range of this parameter values. To obtain a flexible schedule with respect to product demand, the two-stage stochastic model evaluated at discrete electricity price scenarios with flexibility constraints need to satisfy the flexibility test. The test is evaluated with two different methodologies: affinely adjustable robust optimization and an iterative framework based on a dual-based flexibility analysis (Zhang *et al*., 2016). Once a flexible schedule is obtained, we calculate the flexibility index with both approaches to obtain a measure of the flexibility that can actually be achieved. We illustrate the application of the proposed models with a number of examples that show the effectiveness of the proposed approach for handling the uncertainties.

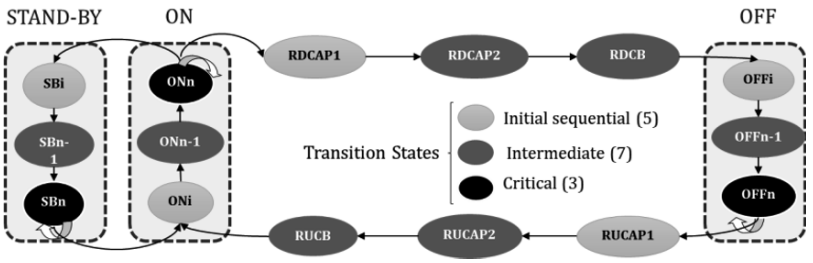

Figure 1. Process Transition Network (Basán *et al.,* 2018). Operation modes with minimum stay time: on (ON_i, ON_{n-1}, ON_n), stand-by (SB_i, SB_{n-1}, SB_n), and off (OFF_i, OFF_{n-1}, OFF_n). Start-up operation modes: ramp-up compressor A phase I (RUCAP1) and II (RUCAP2), and ramp up compressor B (RUCB). Shutdown modes: ramp down compressor A phase I (RDCAP1) and II (RDCAP2), and ramp down compressor B (RDCB).

2. Problem Statement and Methodology

The main objective is to minimize the expected value of the optimal cost function by selecting schedule variable *s* over the entire region *T*, which is the uncertainty set. First, the scheduling model corresponds to a MILP of the general form (see Basán *et al*., 2018):

$$\min c^T x + d^T y \tag{1}$$

$$s.t. \qquad Ax + By \leq d\,, x \leq 0, y \in \{0,1\} \tag{2}$$

In order to represent the feasible region of operation, the model is expressed as: $f(\mathrm{s}, z, \theta) \leq 0$, where *s* correspond to the 0-1 scheduling variables, z are the control variables and θ the uncertain parameters. The problem of optimal schedule under uncertainty corresponds to a two-stage programming problem, leading to an infinite programming problem because the feasibility constraint must be satisfied for the whole range of variation of θ.

$$\min_{S} \mathrm{E}_{\theta \in T} \left\{ \left(\min_{z} c(\mathrm{s}, z, \theta) \,\middle|\, f(\mathrm{s}, z, \theta \leq 0) \right) \right\} \tag{3}$$

$$s.t. \qquad \forall\, \theta \in T \{ \exists\, z \left(\forall\, j \in J \left[f_j(s, z, \theta) \leq 0 \right] \right) \} \tag{4}$$

The flexibility test problem states that for every point $\theta \in T$ there must exist at least one value of the vector control variable z that gives rise to non-positive values for all the individual constraint functions *j*. This means that irrespective of the actual values taken by the bounded parameters θ, the plant schedule *s* has the flexibility of operating to satisfy the specifications. A first simplification involves the discretization over the parameter space in order to approximate the expected cost by a weighted cost function. By using global maximum and minimum operators and inductive reasoning Halemane and Grossmann (1983), derived an equivalent multilevel optimization for the logical condition (4): $\max_{\theta \in T} \min_{z} \max_{j \in J} f_j(s, z, \theta)$

The general formulation of optimal schedule with flexibility analysis is then:

$$\min_{S, z_1, z_2, \ldots, z_n} \sum_{i=1}^{n} \varphi_i \cdot c(s, z_i, \theta_i) \tag{5}$$

$$s.t. \qquad f(s, z_i, \theta_i) \leq 0, i = 1, 2, \ldots, n \tag{6}$$

$$\max_{\theta \in T} \min_{z} \max_{j \in J} f_j(s, z, \theta) \leq 0 \tag{7}$$

where φ_i are discrete probabilities or weights for the selected finite number of parameter points θ_i. To solve the optimal schedule for the air separation plant with flexibility demand constraints we address two approaches: dual-based flexibility analysis (DFA) and adjustable robust optimization (AARO) following Zhang *et al*. (2016).

2.1. Schedule with Flexibility Constraints

Consider a set of *m* inequality constraints

$$f_j(s, z, \theta) = a_j s + b_j z + c_j \theta \leq 0 \;\; \forall\, j \in J \tag{8}$$

where $s \in \mathbb{R}^{n_s}$ are schedule variables, $z \in \mathbb{R}^{n_z}$ are control variables and $\theta \in \mathbb{R}^{n_\theta}$ are uncertain parameters, a_j, b_j and c_j are row vectors, and J is the set of constraints.

Table 1. DFA and AARO formulations for the scheduling problem under uncertainty and for flexibility index.

Schedule problem with Dual-based Formulation	Schedule problem with AARO Formulation

$\bar{\lambda}_{pj} \le 0, \lambda_j \le 0, x_p \in \{0,1\}$	

DFA is derived using LP duality theory, considering that solution must lie in the vertices, and then applying exact linearization to bilinear terms, leading to an MILP problem. Whereas, in the AARO approach the control actions are considered affine functions of θ, i.e. $z(\theta) = p + Q\theta$, which allow some degree of recourse, but leading to a restricted problem. In this reformulation, it is also assumed that the solution lies in the vertices, which is true when the constraints are jointly convex. To obtain the affinely adjustable robust counterpart, a constraint-wise worst-case approach and LP duality theory are applied. An advantage of this approach is that it does not add any binary variable. The final formulation of both approaches is described in Table 1. Details of the reformulation steps for both approaches can be found in Zhang *et al*. (2016).

The flexibility function $\chi(s)$ of schedule *s* with respect to the uncertainty set *T* represents the projection of the feasible region. If *T* is inscribed in the projection, then $\chi(s) \le 0$ meaning that a feasible schedule is obtained. When *T* is not completely constrained in the projection, then $\chi(s) > 0$.

The algorithm for the DFA is based on an iterative column-and-constraint generation approach, which relies on the fact that a schedule is feasible for all $\theta \in T$ if it is feasible for the worst-case realization of the uncertainty, which lies at one of the vertices of *T*. Vector θ is partitioned into two subsets, θ_{EP} for electricity prices and θ_D for demand uncertainty. It includes the following steps:

1) Set k=0. Choose an initial set $\widehat{T_0}$ of N_0 critical points
2) Solve:

$$\eta = \min_{S,\bar{z},\hat{z}} \hat{c}^T s \sum_{i=1}^{n} \varphi_i \cdot c^T \bar{z}_i \tag{9}$$

$$s.t: \quad As + B\bar{z}_i + C\bar{\theta}_{EP,i} \le 0, \forall\, i \in I \qquad \text{Electricity Price Scenarios} \tag{10}$$

$$As + B\hat{z}_t + C\hat{\theta}_{D,t} \leq 0, \forall\, t \in \hat{T}_k \qquad \text{Product Demand Vertices} \qquad (11)$$

where $\bar{z}_i$ and $\hat{z}_t$are the control variables that compensate electricity prices uncertainty, $\bar{\theta}_{EP,i}$, of the *i* scenarios, and demand uncertainty, $\hat{\theta}_{D,t}$, of the *t* vertices, respectively . To obtain s_k:

3) Solve Problem: Dual-based Flexibility Analysis with $s = s_k$, Obtain critical point θ_k^c
   If $\chi(s) \leq 0$, Stop. Else go to step 4.
4) Set $\hat{\theta}_{k+1} = \theta_k^c,\ N_{k+1} = N_k + 1,\ \hat{T}_{k+1} = \{1,2,\dots,N_{k+1}\},\ k = k+1$. Go to Step 2.

The algorithm converges in a finite number of iterations, since there is a finite number of vertices. Another difference between both approaches is that AARO does not require an iterative framework.

2.2. Flexibility Index

Consider the uncertainty set as $T(\delta) = \{\theta: \theta^N - \delta\Delta\theta^- \leq \theta \leq \theta^N + \delta\Delta\theta^+\}$, where δ is a positive scalar, $\Delta\theta^-$ and $\Delta\theta^+$ are negative and positive deviations from the nominal value. The flexibility index is a measure of how much flexibility can actually be achieved in the given schedule. The objective is to find the largest δ such that by proper adjustment of control variables *z*, the inequalities $f_j(s,z,\theta) \leq 0\ j \in J$ hold for all $\theta \in T(\delta)$. Following a similar reasoning as in the flexibility test, the flexibility index problem can be reformulated into the problems described in Table 1. If the value of *FI*>1, then schedule exceeds the flexibility target, whereas when *FI* < 1, it does not meet the target.

3. Numerical Results

The presented methodology is applied to scheduling model of an air separation plant with a time horizon of 168 hours, proposed by Basán *et al*. (2018). First, two-stage stochastic programming is applied considering the plant state (binary variables) as the first stage decision. Second stage decisions are production level, inventory and power consumption. The different electricity price scenarios profiles proposed are shown in Fig. 2, together with the nominal demand profile, whose range of variation is ±10%.

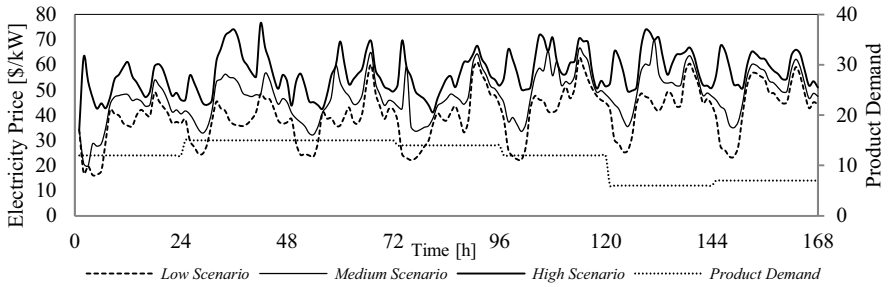

Figure 2. Proposed electricity price scenarios and nominal product demand profile.

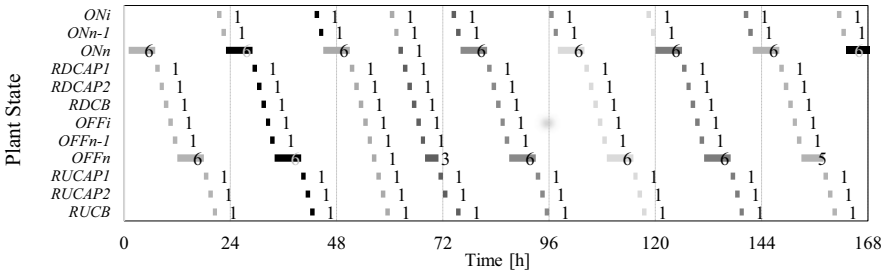

Figure 3. Optimal and flexible production schedule

Table 2. Scheduling under uncertainty with flexibility constraints and flexibility index results.

Problem	Approach	# of bin. variables	# of cont. variables	# of constraints	Result	Gap (%)	Solution Time (s)
Schedule under uncertainty	Dual-based	168	116,948	348,355	Cost 40814*	0	46
	AARO		247,218	116,779	40814		10.6
Flexibility Index	Dual-based	168	116,948	348,355	FI=1.083	0	10,739
	AARO		131,131	116,780	FI=1.083		135.6

(*) The DFA problem converges in the first iteration.

DFA and AARO formulations lead to the same production schedule, shown in Fig. 3. Additionally, both approaches provide the same flexibility index value for the uncertain demand. This implies that the same level of flexibility can be achieved even when considering a restricted control variable as in the case of AARO. The solution time required by the AARO LP models is less, as compared to the DFA, especially in the case of the flexibility index with two orders of magnitude of difference, as detailed in Table 2.

4. Conclusion

In this paper, we have addressed the scheduling problem under uncertainty. We proposed to deal with uncertainty in electricity price stochastically and in product demand in a robust way by considering it as the uncertain parameter set of the flexibility constraint. We solved the problem with the dual-based flexibility analysis and affinely adjustable robust optimization formulations.

The proposed approach has allowed the efficient calculation of the optimal schedule for the expected value of electricity price profiles and feasible operation for the range of variation of product demand over a time horizon of 168 hours. In addition, flexibility indices were computed successfully with both formulations, providing a measure of feasibility of the obtained schedule. Both formulations led to the same results for the different problems, with shorter solution times for the AARO approach, in line with the results obtained by Zhang *et al*. (2016).

Raw material supply strategy for petrochemical process under market uncertainty

Byeonggil Lyu, Seokyoung Hong, Seunghyeon Oh, Il Moon*

Department of Chemical and Biomolecular Engineering, Yonsei University, 50 yonsei-ro, Seodaemun-gu, Seoul 03722, Korea
Ilmoon@yonsei.ac.kr

Abstract

In the petrochemical industry, raw material supply is a very important consideration that directly affects the operating condition and profit of the process. In particular, due to fluctuation in raw material price, there can be a huge difference in profit with the same amount of raw material procurement. However, due to various uncertainties regarding price fluctuation, it is very difficult for decision makers to arrive at an optimum supply strategy. In this study, we tried to establish an optimal supply strategy for petrochemical process considering the price uncertainty of naphtha and crude oil. To consider price uncertainty, we construct a system dynamics model to predict fluctuation of "crack," which is the price gap of naphtha and crude oil. Based on the system dynamics model, comparative analysis and optimization of naphtha purchase and production from crude oil were performed. Since the forecasting model focused on the rising and falling of the price gap rather than absolute numbers, it was more helpful in establishing short-term supply strategies. The developed supply strategy shows improved cost saving compared with the conventional supply model.

Keywords: supply strategy, system dynamics, forecasting, market uncertainty, decision making

1. Introduction

Raw material supply is a key issue directly affecting a plant's profit. However, it is very difficult to formulate material supply strategy because of market price uncertainty. Therefore, in response to this market uncertainty, supply decision makers developed several strategies. The raw material procurement problem is a topic of ongoing research. Deterministic and stochastic optimization models considering various cases of crude oil and refinery and petrochemical products are suggested (Al-Othman et al., 2008). Suggested model considered uncertainty in market prices and demand as a case study of each price, and market demand varied in the 20% range. With fluctuating raw material prices, the net present value framework of the raw material procurement model is suggested (Arnold et al., 2009). The crude oil procurement problem is also solved by considering sales, purchase, and the manufacturing cost (Chen et al., 2015). In this study, a stochastic multi-period price model is used for optimal refinery operation. The price uncertainty follows a Brownian motion price model. The problem of selecting procurement contracts is also solved (Calfa & Grossmann, 2015). In this study, contract selection is based on selling price optimization under supply and demand uncertainty.

Previous studies used various methods to solve the supply and procurement problems under uncertainty. However, several case studies of price fluctuation were used to find

solutions to price uncertainty. This is because of "the difficulty of forecasting." Accurate forecasting models that reduce market uncertainty would help in supply decision making. Figure 1 illustrates the novel decision-making framework suggested in this study.

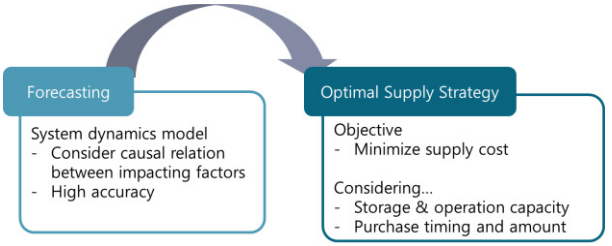

Figure 1. Framework for supply decision making

First, an accurate forecasting model that predicts raw material price at least three months in advance is developed using the system dynamics (SD) theory. Based on the forecasting result, a raw material supply strategy that minimizes the supply cost is suggested.

2. Problem Statement

The problem considered in this study is the supply of naphtha for naphtha cracker. Figure 2 shows that a cracker has two sources of naphtha: one is produced from condensate oil and the other is naphtha procured from the market. When condensate oil price falls, the naphtha produced is more competitively priced. On the contrary, naphtha procured at a decreased market price adds more competitiveness than naphtha produced from condensate oil. Because of the high price fluctuations of naphtha and condensate oil, the decision of whether to procure naphtha from the market or to produce it from oil is an issue. Therefore, our focus is to decide which, when, and how much to buy.

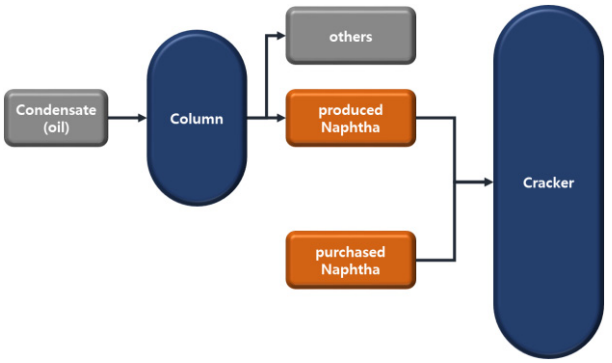

Figure 2. Process diagram for naphtha supply

Price forecasting of condensate oil and naphtha is necessary to solve the problem. However, to forecast the price of each material is very difficult and not very accurate. Therefore, we suggest a new forecasting term "crack," which is the price gap of naphtha and condensate oil. Since our objective is minimizing the supply cost, forecasting changes in "crack" can help lower the cost compared with forecasting price value.

3. Forecasting of Naphtha Crack

3.1. Forecasting methodology

System dynamics (SD) is a theory of problem solving based on the feedback control theory. SD uses relevant variables for the presented problem, defines the system, and models relationships among variables. It is based on the synthesis of many themes such as operating theory and system theory, control theory, information feedback theory, decision-making theory, mechanical system, and computer science. SD uses various control elements, such as feedback loops and delay times, to observe how the system reacts and responds to trends. The prediction procedure using the SD model is described in Figure 3. The naphtha crack forecasting model is suggested based on a causal loop diagram, a quantitative model, and an old data set.

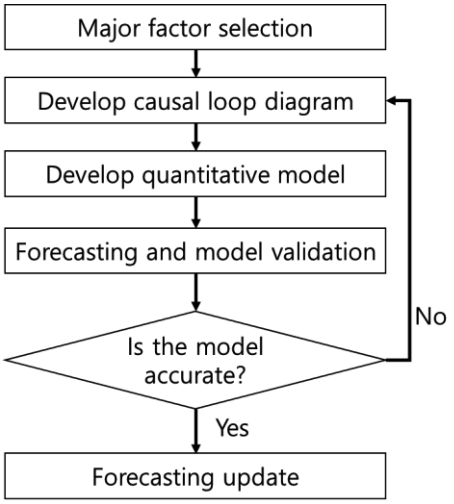

Figure 3. SD model development procedure

3.2. Forecasting model description

The forecasting model described in this section follows the model developed by our group (Lyu et al., 2017). A brief description as well as figures are introduced in this section. Following the model development procedure described in Figure 1, the forecasting model of naphtha crack is developed. First, major factors are selected by the heuristic of field engineers and the Pearson product-moment correlation coefficient (PPMCC) analysis.

$$p_{X,Y} = \frac{cov(X,Y)}{\sigma_X \sigma_Y} \tag{1}$$

PPMCC, as expressed in Eq.(1), is a measure of linear correlation between two variables, which give values between −1 and 1. When the PPMCC value is 1, it means that the two variables have a positive correlation, −1 means a negative correlation, and 0 means no correlation. Following the factor selection procedure, the causal loop diagram between the selected factors is developed. Vensim, a widely used SD software, is used for modeling the naphtha crack forecasting SD model. Vensim supports drawing of the causal loop diagram and editing of interaction formula and equations. Our model and forecasting result are described in Figures 4 and 5 and Table 1.

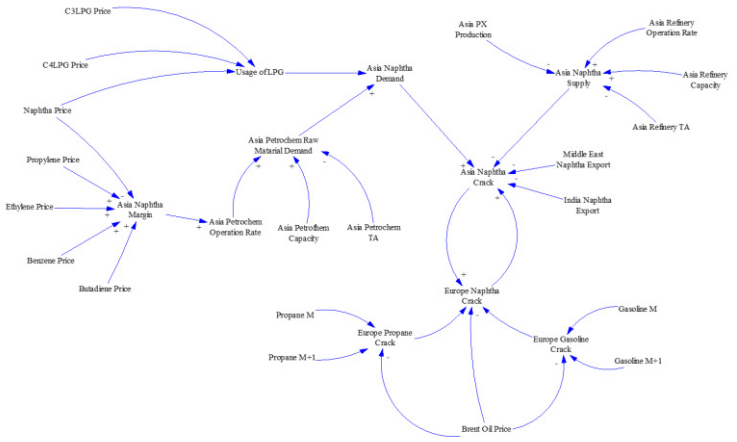

Figure 4. SD model of the naphtha crack (Lyu et al., 2017)

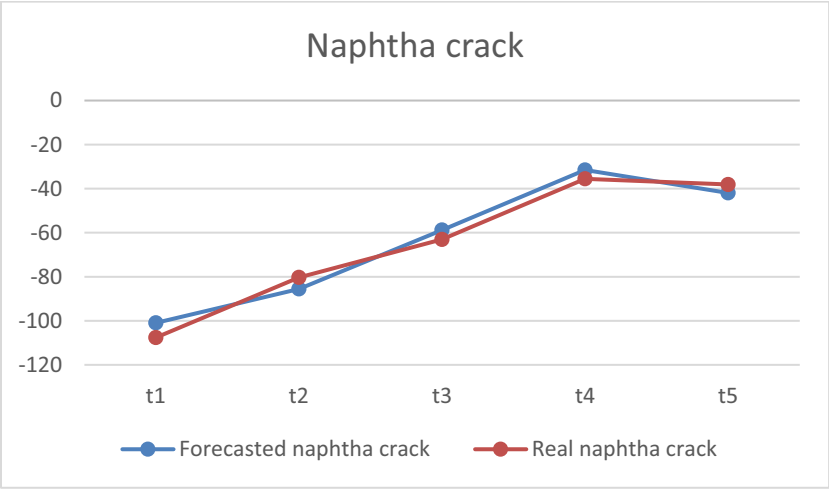

Figure 5. Naphtha crack forecasting result

4. Raw Material Supply Optimization

In the problem presented in section 2, a naphtha cracker has two naphtha sources: one is naphtha produced from condensate oil and the other is naphtha procured from the market. Because of high price uncertainty of naphtha and condensate oil, decision making regarding supply strategy is difficult. With the developed forecasting model, which helps to reduce uncertainty, an optimal raw material supply model under market uncertainty is suggested in this section.

4.1. Optimization model description

The objective is to minimize the total supply cost in Eq.(2). The cost which expressed in Eq.(3) and (4) is calculated as the product of the average price *Pa* and the feed amount *F* of each material.

$$total\_cost = \sum cost_m \ (m = naphtha\ and\ condensate) \tag{2}$$

$$cost_m = \sum F_{m,t} * Pa_{m,t} \tag{3}$$

Average price *Pa* is defined based on the amount of existing inventory, previous average price, newly added amount, and its trading price. The defined model has three storage tanks of condensate, naphtha from condensate, and naphtha from the market. The equations for average price and inventory are described as follows.

$$Pa_{m,t_{i+3}} = \frac{T_{m,t_0} * Pt_{m,t_0} + I_{m,t_{i+2}} * Pa_{m,t_{i+2}}}{T_{m,t_0} + I_{m,t_{i+2}}} \ (i = 0,1,2,\dots) \tag{4}$$

Eq.(4) shows the average price of each material. As the transportation time is three months, three-month-before trading amount and the price are used to define the average price.

$$I_{m,t_{i+3}} = T_{m,t_0} - F_{m,t_{i+3}} + I_{m,t_{i+2}} \tag{5}$$

Eq.(5) shows the inventory of each material. Material procured three months ago is added to the existing inventory and the feed amount is subtracted.

Trading price of each material changes in every time domain, but the future trading price information is unknown. Therefore, the forecasted naphtha crack is used to define the trading price of each material.

$$Pt_{m,t_{i+1}} = Pt_{n,t_i} \pm 0.5 * crack_{t_{i+1}} \tag{6}$$

We applied the forecasted crack equally to each material. The forecasted crack value is divided into two, added to the previous trading price of naphtha, and subtracted from the previous trading price of condensate.

The optimization model assumes a storage capacity of 800,000 tons and a maximum operating capacity of 300,000 tons per month.

4.2. Optimization result

The conventional supply cost and optimized supply costs for five months are expressed in Table 1 and 2.

Table 1. Conventional supply cost

(million USD)

	Conventional		
	Naphtha	Condensate	Total
t1	186.540	213.437	399.978
t2	208.487	228.560	437.047
t3	234.950	250.709	485.660
t4	242.614	251.500	494.114
t5	238.600	248.132	486.732
Ave.	222.238	238.467	460.706

Table 2. Optimized supply cost

(million USD)

	Optimized		
	Naphtha	Condensate	Total
t1	198.792	213.437	412.230
t2	242.162	228.560	470.722
t3	276.029	61.997	338.027
t4	285.566	37.501	323.068
t5	280.947	31.980	312.927
Ave.	256.699	114.695	371.395

The conventional supply strategy does not adjust the purchase amount in each time period because of high market uncertainty. However, the optimized model with reduced uncertainty changes the purchase amount in each time period. The forecasted price helps to decide when to buy large amounts. In the optimization model based on the forecasting result, the average cost of naphtha increased but the condensate cost decreased considerably. Finally, the optimized supply strategy saves US$89 million in the five-month period.

5. Conclusions

Because of dynamic market conditions, market uncertainty is vital yet challenging for the development of a raw material supply strategy. To deal with this problem, a novel framework is suggested in this study. First, a price forecasting model is suggested using the SD theory. The forecasting model forecasts the price gap between two raw materials, not the price value. This model helps build a strategy for when, what, and how much to buy. Subsequently, an optimization model that minimizes supply cost is developed with the forecasting result information. The optimization model considers the average price of raw materials, trading amount, and inventory capacity. With the forecasted crack (price gap between naphtha and condensate oil), the trading prices of naphtha and condensate are defined. This price information helps make a decision regarding the purchase amount of each raw material. As a result, the suggested supply model shows a cost saving of US$ 89 million compared with the conventional supply strategy.

Inventory Pinch Based Algorithm for Gasoline Blend Planning with Uncertainty in Components Qualities

Mahir Jalanko, Vladimir Mahalec*

Dept. of Chemical Engineering, McMaster University, 1280 Main Street West, Hamilton L8S 4L7, Canada
mahalec@mcmaster.ca

Abstract

In order to meet gasoline specifications, qualities of the blend components are analysed either in a lab or via on-line analysers. Deterministic gasoline blend planning assumes a quality of each blend component, even though there is an uncertainty associated with these qualities. In this work we present a chance constrained based methodology which enables a blend planner to decide what percent of the blends will meet specifications even if it means that some blends will give away qualities. This enables the planner to trade-off the cost of reblending the off-spec blends vs. the increase in the blend costs which guarantees that the quality specifications will be met. We employ a chance constrained formulation in (i) a two-level inventory-pinch based algorithm to optimize gasoline blend planning with uncertainty in components qualities; (ii) full space model for both linear and nonlinear blending rules. Inventory pinch based algorithm performs much better than the full-space formulation in terms of time required to reach the optimal solution, time to close the optimality gap to the required level, and robustness in achieving the optimal solution. Proposed algorithm enables construction of a trade-off curve of probability that the constraints will be satisfied vs. blend cost, which is not practical via full space formulation since the latter typically does not close the optimality gap or often it does not converge.

Keywords: Stochastic programming; Gasoline blending planning with uncertainty; Inventory pinch concept; Uncertainty in components qualities

1. Introduction

Refining plant section is a key element in the supply chain of the petroleum industry. About 60 % - 70 % of refinery revenue comes from selling gasoline products, therefore minimizing the cost of blending can greatly impact the profitability of the refinery. Blending components qualities fluctuate and are uncertain. Gasoline blend plan needs to compute blend recipes which are likely to be feasible and also minimize the overall costs. Fine adjustments to the blend recipes are via closed-loop blending where analyzers are used to correct the blend recipe based on the actual measured qualities. However, analysers have inherent measurement errors. Therefore, the blend plan and the closed loop blending need to consider uncertainties in the component qualities in order to guarantee on-spec products. Nonlinear nature of gasoline blending, and the multiperiod planning model make gasoline blend planning a mixed integer nonlinear problem.

One approach to solve the gasoline blend planning problem (MINLP) is to compute the blend recipes and the blended volume of gasoline products at each period simultaneously. Such approach is computationally expensive and might lead to suboptimal solution for

large scale problem. Therefore, this approach has been limited to use approximate linear formulation to simplify the model. (Li et al., 2009) developed a slot-based MILP formulation using blending indices and linear blending correlation to address nonlinear blending properties and solve the gasoline blend planning problem. Another approach which utilizes inventory pinch was introduced by (Castillo and Mahalec, 2014a) which decomposes the problem into two levels solve in sequence. At the top-level, number of periods are delimited by inventory pinch points and amount to blend at each of these periods are fixed. In this level, the solver computes the optimal blend recipes during each first level period. The lower-level typically has higher number of periods, and it computes amounts of volume blended for each product during each second level periods using the blend recipes computed at the top-level.

Stochastic optimization is mainly used when full knowledge about probability distribution of the uncertain parameters exist; this information is used to obtain a less conservative solution (Yang and Barton, 2016). (Monder, 2001) incorporated uncertainty in gasoline blend optimization problem using probabilistic programming. Single probability constraint was used to deal with uncertain parameters in multiple constraints. Monder designed a real-time optimization layer that deals with the disturbance (uncertainty) in the components qualities for linear and nonlinear blending rules. (Zhang et al., 2002) extended the previous results by dealing with uncertain parameters in multiple constraints as a joint probability constraint.

This work deals with gasoline planning (off-line blend recipe optimization over extended time horizon) under uncertainty in components blending qualities utilizing chance constrained formulation. It uses a two-level algorithm that utilizes inventory pinch concept to solve the blend planning problem with uncertainties. We compare this solution method to solving the problem as a single level full space model to evaluate the effectiveness of using inventory pinch algorithm versus the full space algorithm.

2. Problem Statement

The system studied has nine feedstocks components produced by the upstream processes and stored in individual component tanks. Components are sent to blenders where mixing occurs to produce four different products with different qualities specifications. Products are sent from blenders to eleven storage tanks before being shipped to satisfy the required demands. For the linear case, aromatic content (ARO), benzene content (BI), olefin content (OLF), research octane number (RON), rapid vapor pressure (RVP), Specific gravity (SGI), flammability limit (FI) are blended linearly on a volume basis, while oxygenates limit (OXI) and sulfur content (SI) are blended linearly on a weight basis. For the nonlinear case, research octane number (RON) is assumed to blend as described by a nonlinear model and the rest of the qualities are the same as the linear case. The objective of the model is to compute optimal blend recipes and volume blended for all products along the planning horizon when component qualities are uncertain. Optimal blend recipes correspond to the recipes that minimize the blending cost while meeting required probability of meeting products specifications. The model has tanks capacity constraints, products quality specifications constraints, and blending capacity constraints.

3. Solution Approach

Gasoline blend planning problem can be formulated as a full space MINLP model with uncertainty in components qualities for fixed discretized periods along the planning horizon. Such model faces difficulties in computing an optimal solution for large scale

cases due to the nonlinearities in the blend recipe calculation, some of them stemming from the nonlinear qualities blending while the others are due to the chance constraint formulation. The proposed approach to solve the gasoline blend planning problem with uncertainty utilizes inventory pinch concept, aggregation and disaggregation techniques to compute optimal blend recipes in shorter executions times by decomposing the problem into two smaller subproblems. The inventory pinch points (the boundaries of the first level periods) can be identified by constructing a cumulative total demand (CTD) curve. Then a cumulative total average production (CATP) curve is constructed as a straight line with a starting point representing initial inventories at the beginning of the planning horizon and extending to the point where the line is tangent to the CTD curve. The point where both curves intersect is called the inventory pinch point. At inventory pinch point, the slope of the CATP curve changes as shown in Figure 1. Hypothesis is that the optimal blend recipe for a time period between the inventory pinch points is constant. At the top-level chance constrained programming formulation is implemented to account for uncertainties in the component qualities. The deterministic quality constraints are presented by Eq. (1), where k, p, i, s, and S refers to the period, product, component, quality and uncertain quality sets respectively. The deterministic constraint is transformed to account for uncertainty in components qualities ($\widehat{Q_{i,s}^{comp}}$) for linear blending case is presented in Eq. (2) and its equivalent under normal distribution assumption is presented in Eq. (3). Where α is the probability of meeting the constraint and $\Phi(\alpha)$ is the α-quantile of the standard normal distribution.

$$\sum_i \left(V_{i,p,k}^{comp} \, Q_{i,s}^{comp} \right) \geq V_{p,k}^{blend} \, Q_{p,s}^{prod,min}, \ \forall p, s \epsilon US, k \tag{1}$$

$$\mathrm{P}\left\{ \sum_i \left(V_{i,p,k}^{comp} \, \widehat{Q_{i,s}^{comp}} \right) \geq V_{p,k}^{blend} \, Q_{p,s}^{prod,min} \right\} \geq \alpha \ \ \forall p, s \epsilon US, k \tag{2}$$

$$\sum_i \left(V_{i,p,k}^{comp} \widehat{Q_{i,s}^{comp}} \right) + \Phi(\alpha) \sqrt{\sum_i (V_{i,p,k}^{comp\,2} \sigma_{i,s}^{comp\,2})} \geq V_{p,k}^{blend} Q_{p,s}^{prod,min}, \forall p, s \epsilon US, k \tag{3}$$

The solution of this level gives optimal blend recipes for each grade of the gasoline products while minimizing the total cost of blending. At the bottom-level, an integer linear programming problem (MILP) is solved to using blending recipes calculated at top-level to determine amount produced of each product in each unit in each period. At this level the planner defined fixed length for the periods. If the blend recipes calculated at the top-level result in inventory infeasibilities at the bottom level, then the top-level period corresponding to the point of infeasibility is subdivided and the blend recipe at top level is re-optimized.

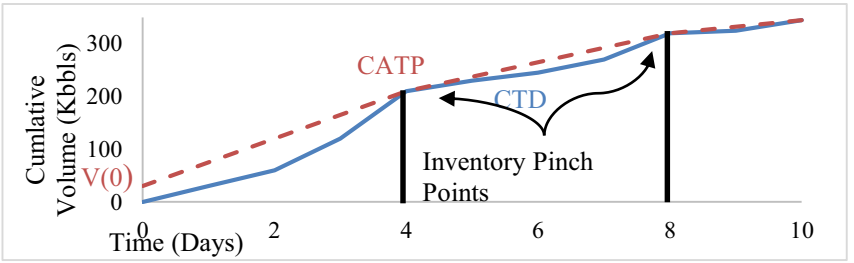

Figure 1: Example of inventory pinch points obtained from constructing CTD and CATP curves

In this paper, chance constrained programming is used to take uncertainty in qualities of the blending components into account. The chance constraints formulation in this paper assumes all uncertain parameters to follow normal distribution and the user knows the mean and standard deviation of all these parameters. The chance constrained formulation

seeks to satisfy the product qualities constraints at a predefined confidence interval chosen by the operator. Chance constrained can be introduced directly for the linear blending rules model. While, introducing chance constrained formulation into the nonlinear blending rule model for RON quality requires linearization of the constraints with respect to the uncertain parameters around their mean values.

4. Results & Discussion

In this work, test problems from (Li and Karimi, 2011) are used. The test problems were solved based on two models. The first model used assumed linear blending rules for all qualities utilizing blending index method. While, the second model assumed nonlinear blending rules for RON quality based on ethyl RT-70 equations. The two different models were solved using both full space MINLP and inventory pinch algorithm to compare the effectiveness of using the inventory pinch algorithm versus the traditional full space algorithm. (Li and Karimi, 2011) examples do not specify MON values for the components which are required to calculate products RON quality when ethyl RT-70 equations are used. Therefore, MON values for the blending components were assumed but MON quality was not included in the product quality specification constraints. Uncertainty in RON quality is assumed for linear blending rule case and uncertainty in both RON and MON are assumed for nonlinear blending rule case, while all other qualities are assumed to have fixed and known values. The standard deviation of all RON and MON are assumed to equal 1 % from their mean values.

All case studies were implemented in GAMS 24.4.1 software. CPLEX 12.6 and ANTIGONE 1.1 solvers were used to solve linear and nonlinear models. All problems were solved on HP Notebook 1703 (Intel ® Core™ i7-6500U CPU, 2.50 GHz, and 8.0 GB RAM) running Windows 10 Home. For linear blending rules cases, a 0.01 % optimality gap or maximum computational time of 3600 seconds is the stopping criteria, while 0.1 % optimality gap or maximum computational time of 10800 seconds is used as stopping criteria for nonlinear blending rule cases.

Table 1 shows the model size of linear and nonlinear blending rule cases for the full-space model and the inventory pinch top and bottom levels model. Figure 2 shows the relationship between blending cost and probability of meeting products specifications for linear and nonlinear blending rules. Higher probability of meeting products specifications results in higher blending cost. Nonlinear blending rules model gives a higher blending cost compared to linear blending rules model and the extra blending cost of incorporating uncertainty is higher for nonlinear blending because the nonlinear blending model is affected by uncertainty in RON and MON qualities, while the linear blending model is affected by RON uncertainty only.

Table 1: Full space and inventory pinch models size for linear and nonlinear blending rules

Example ID	Linear blending rules	Nonlinear blending rules
Full space (MINLP for uncertainty cases)		
# periods	4	4
# equations	3467	4175
# continuous variables	941	2041
# discrete variables	371	371
# nonlinear terms	576	1408
Top-level Pinch Point (NLP for uncertainty cases)		
# periods	2	2
# equations	488	574
# continuous variables	238	272
# discrete variables	0	0
# nonlinear terms	144	208

Bottom-level Pinch Point (MILP)		
# periods	4	4
# equations	2323	2323
# continuous variables	1399	1399
# discrete variables	371	371
# nonlinear terms	0	0

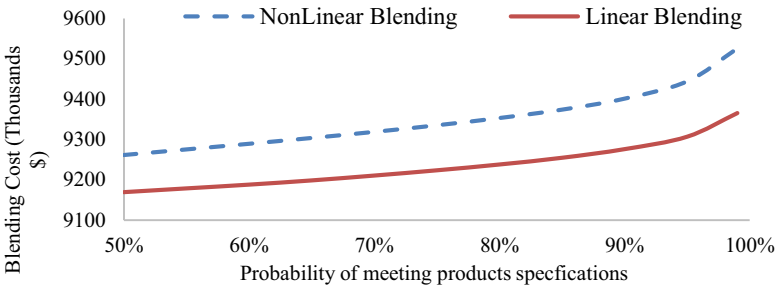

Figure 2: Blending cost versus probability of meeting products specs.

Table 2 shows the results obtained from solving linear and nonlinear blending rules models using both full space and inventory pinch algorithms.

Table 2: Inventory pinch and full space models results for linear and nonlinear blending rules

Nonlinear Blending Rules				Linear Blending Rules						
99	95	90	50	99	95	90	50	Probability of meeting products specifications		
9525.72	9444.28	9401.34	9261.63	9365.56	9307.23	9276.38	9169.91	Objective function (thousands$)		
2.85	1.97	1.51	-	2.13	1.50	1.16	-	Increase in blending cost (%)		
0.1	0.1	0.1	0.1	0.1	0.1	0.1	0.1	GAP (%)		Pinch Point
21.8	16.7	16.5	1.28	0.17	0.24	0.25	0.37	Optimal solution	CPU time to reach (s)	Pinch Point
1	5	4	1	0.17	0.24	0.25	0.37	Final upper bound	CPU time to reach (s)	Pinch Point
0.1	0.1	10.3	0.93	1.66	1.10	0.92	0.01	GAP (%)		Full Space
8202	1864	10800	10800	3600	3600	3600	0.262	Optimal solution	CPU time to reach (s)	Full Space
257	227	268	1	5	5	5	0.26	Final upper bound	CPU time to reach (s)	Full Space

The nonlinear blending rules model are harder to solve due to the nonlinearity added for the RON quality computation. The results show that computation of optimal solution and closing the optimality gap can be done for all cases when inventory pinch is used, while full-space took longer time to compute the optimal solution and failed to close the optimality gap for some of the cases.

5. Conclusion

Gasoline blend planning (off-line optimization) problem under uncertainty in component qualities is solved using chance constrained formulation. Chance constrained formulation deals with uncertainty in components qualities by giving some qualities away to ensure products blended are on-specs products. By giving quality away, the planner is willing to operate at higher blending cost at the benefit of minimizing the risk of reblending off-specs products which can result in high additional cost. Incorporating chance constrained formulation into the gasoline blend planning model increase the nonlinearity terms making it more complex and harder to optimize. For the linear blending rule model, inventory pinch algorithm could compute the optimal solution in less than a second, while Full space model required at least twenty-fold that time to reach the optimal solution and failed to close the optimality gap after one hour. For the nonlinear blending rules, inventory pinch algorithm could compute the best solution and closed the optimality gap within seconds, while full space algorithm needed forty-fold the times to reach the optimal solution and failed to close the gap for some cases after three hours. Although results for large scale case are not included in the report, the results showed that full space algorithm might fail in computing a feasible solution after hours of running, while the inventory pinch algorithm can achieve the optimal solution and close the optimality gap within an hour. Results of this work indicate that the inventory pinch based approach is likely to be effective in solving the refinery planning problems with uncertainties in the crude qualities and the components qualities. Therefore, future work will investigate implementing similar approach to the refinery model.

Abstract

Coefficients and constraint values for many optimization problems are best modeled as uncertain. Examples include reaction rates for chemical processes, demand for products in a supply chain, and the availability of renewable energy in a power grid. General purpose software is available for solving the resulting stochastic optimization problems given probabilistic scenarios as input [Hart et al., 2011, Hart et al., 2017, Watson et al., 2012]. In this research, we describe software that starts with data and produces these inputs. One of the motivating applications for the software is creating the stochastic inputs for the Institute for the Design of Advanced Energy Systems (IDAES). Other recent applications come from incorporation of renewables in the energy grid.

Here are the design goals and features of the software:

1. Allow for separation of the work of optimization modeling from the work of stochastic process and uncertainty modeling.
2. Support multi-stage optimization fully from the start.
3. Support "raw" scenario data that could be read by non-Python programs.
4. Provide a lot of flexibility.
5. Allow for easy use of data directly by deterministic models.

Keywords: Stochastic optimization; scenario creation; Uncertainty quantification.

1. Scenario Sets for Optimization

We present information and examples for the use of a software package called *daps*, which stands for 'Data to PySP.' This software is designed to use real, available data to create scenarios for use in stochastic optimization problems.

1.1. Optimization Under Uncertainty

We use x to represent the vector of variables whose values are set by the optimization process and use x^t to represent the part of the decision vector that corresponds to stage t. Only the first stage decisions can be implemented immediately, but of course additional stages must often be considered in order to make a good first-stage decision. We use $\vec{x}^t$ for $1 \leq t \leq T$ to represent the decisions for all stages up to, and including, stage t. We decompose the objective function by stages and for the first stage we write $f_1(x^1)$ and for subsequent stages $f_t\left(x^t; \vec{x}^{t-1}, \vec{\xi}^t\right)$, where ξ is the problem data and $\vec{\xi}^t$ is gives the values that will become known by time t.

This notation allows us to write the optimization problem as

$$\min_x f_1\left(x^1\right) + \mathbb{E}\sum_{t=2}^{T} f_t\left(x^t; \vec{x}^{t-1}, \vec{\xi}^t\right) \tag{1}$$

We use the notation $\mathbb{E}$ to indicate that an expectation will be taken over possible realization of ξ.

Some risk measures are easy to add directly. For example, the expected value of the $1-\alpha$ tail is known as CVaR (conditional value at risk) or sometimes TCE (tail conditional expectation). This can be implemented by augmenting this problem following the implementation given by Schultz and Tiedemann [Schultz and Tiedemann, 2005].

1.2. Scenarios

For practical reasons, we typically work with discrete scenarios. Define $\xi \equiv \{\xi(t)\}_{t=1}^{T}$ on a discrete probability space and use Ξ to represent the full set of scenarios. Each scenario, ξ, has probability π_ξ We organize ξ into a tree with the property that scenarios with the same realization up to stage t share a node at that stage. So, we note that $\vec{\xi}^t$ refers also to a node in the scenario tree. Let $\mathcal{G}_t$ be the set of all scenario tree nodes for stage t and let $\mathcal{G}_t(\xi)$ be the node at time t for a particular scenario, ξ. For a particular node $\mathcal{D}$ let $\mathcal{D}^{-1}$ be the set of scenarios that define the node.

This allows us to re-write the optimization problem in terms of the scenario tree as follows:

$$\min_{x,\hat{x}} \sum_{\xi\in\Xi} \pi_\xi \left[f_1(x^1(\xi)) + \sum_{t=2}^{T} f_t\left(x^t(\xi); \vec{x}^{t-1}, \vec{\xi}^t\right)\right] \tag{2}$$

$$\pi_\xi x^t(\xi) - \pi_\xi \hat{x}^t(\mathcal{D}) = 0, \quad t = 1,\ldots,T-1,\ \mathcal{D}\in\mathcal{G}_t,\ \xi\in\mathcal{D}^{-1} \tag{3}$$

Non-anticipativity must be enforced at each non-leaf node, which is done using $\hat{x}$ (with the same dimension as x) in this formulation.

Methods for obtaining scenarios include statistical models, perhaps obtained by data mining. Once a model has been fit, scenarios can be obtained by Monte Carlo sampling (see, e.g., [Löhndorf, 2016]) or moment matching (see, e.g.,[Høyland and Wallace, 2001]) Other ways include simulations (see, e.g.,[Watson et al., 2010]) and forecast error distributions when a forecast and a history of forecasts is available (see, e.g.,[Rios et al., 2015, Staid et al., 2017].)

1.3. Small Example

To illustrate some of the inputs, we will make use of the well-known "farmer" example from Birge and Louveaux [Birge and Louveaux, 1997]. The details of the model are not important to us here, but in order to understand the examples, one needs to know the following. Variables are vectors indexed by the three crops: Corn, Wheat and Sugar Beets. The variables are named DevotedAcreage, QuantitySubQuotaSold, QuantitySuperQuotaSold, and QuantityPurchased. Note that in Pyomo, an optimization model variable is called a `Var` in part to make a distinction with Python variables and random variables. The reserved word `Param` is used for some optimization model parameters. The uncertain optimization model parameter vector is a `Param` called Yield and it is also indexed by the three crops.

2. Using the Software

The software works with PySP, which is part of Pyomo [Hart et al., 2017]. Here, we present a list of items required to use the daps software.

- The Model: As one would expect, the modeler must provide a model file that is often called `ReferenceModel.py` and it must contain a cost `Expression` for each of the stages.
- Tree Template: The template provides the model-specific information about the scenario tree (as distinct from the scenario-specific data). Although there are other ways to specify a scenario tree template, this software presently makes use of two methods: 1) json and 2) AMPL [Fourer et al., 2003] format. The modeler must supply the stage names, the assignment of each `Var` to a stage and the names of the cost expressions for each stage. This can be done using a json file that contains a dictionary with outer keys that are PySP reserved words Stages, StageVariables, and StageCost. Wildcards are supported within the StageVariables declaration of each `Var` for each stage. Here is a sample json tree template file for farmer:

```
{
   "Stages": ["FirstStage", "SecondStage"],
   "StageVariables":
   {"FirstStage": ["DevotedAcreage[*]"],
     "SecondStage": [
 "QuantitySubQuotaSold[*]",
          "QuantitySuperQuotaSold[*]",
          "QuantityPurchased[*]"
     ]
   },
   "StageCost": {
"FirstStage": "FirstStageCost",
          "SecondStage": "SecondStageCost"
   }
}
```

- Scenario template data: This provides data needed by the model that does depend on the individual scenario. This is a flexible concept that might be a full scenario, might be root node data only, or might be empty. It is the starting point for every scenario and when the scenario is created, data for the scenario will be added to the template and/or replace template data. The template could be in a variety of formats, such as an AMPL format data file, a JSON file or a csv file, etc. The details of how it gets used depends on the format.
- Raw Scenario Tree Node Data: This stores the data for each scenario, and we use a tree structure to support multi-stage problems. For two-stage problems, nodes other than the root node are one-to-one with scenarios. These data need to find their way into a dictionary whose elements are either data or dictionaries. For abstract models using AMPL format input files, the dictionary names are intended to be `Param` names. For concrete models (and for use by abstract model build actions) they are intended to be whatever is needed by the modeler. If the elements are a dictionary, the indexes in the inner dictionary are intended to be the entire index string for a `Param` or else whatever they should be. When these data are supplied in a file, the goal is to have a lot of flexibility in the format and to be sure that packages written in other languages would have a shot

at using them if they wanted to. Furthermore, we want to be sure that for two-stage concrete models the files can be used directly as deterministic input if that is desired. Hence, we are coding the scenario tree in the file names:

NODE-name-PARENT-name-PROB-prob.ext

where the upper case tokens are literals and must be present and ext signals the type of data in the file (e.g., json). The special node name ROOT is assumed to exist unless a file is present with the special parent name NONE, which then defines the root node (it will be unusual for a raw root node data file to be created, but that is an option). Note that the numeric value `prob` is the conditional probability.

There is nothing stopping such a file from having a full scenario, but it is only responsible for being correct up to its node. When a scenario is assembled it is done in stage order.

3. Creating Node Data

Statistics and stochastic process modeling are needed in order to create node data. Exact details must always depend on the particular application, but the software presently provides some examples.

3.1. Sampling

We describe two examples now, both assume the Python program contains the following line:

```
import distr2pysp as dp
```

A sensible way to create scenarios in some settings is to fit a continuous probability distribution to data observations and then sample from that distribution. The first example shows how to use *daps* to read data given in a json file (datafiledict.json) to populate a scenario tree given in TreeTemplateFile.dat. It creates four scenarios and puts the resulting input files in dptest.

```
dp.indep_norms_from_data_2stage('concrete_farmer/dptest/datafiled
ict.json',
          'concrete_farmer/TreeTemplateFile.dat',
          4,
          'concrete_farmer/dptest',
          Seed = 7734)
```

But one might also fit the data using other software (e.g. R) and then provide the distribution information to *daps*, which uses *scipy* distributions described in distrdict.json. This time, only three scenarios are created, and unlike the previous example, the pseudo random number seed is not controlled.

```
dp.json_scipy_2stage('concrete_farmer/dptest/distrdict.json',
          'concrete_farmer/TreeTemplateFile.dat',
          3, 'concrete_farmer/dptest')
```

Here is `distrdict.json`

```
{"Yield":
  {"CORN": ["norm", {"loc" : 3, "scale" : 0.5}],
   "WHEAT": ["norm", {"loc" : 2.9, "scale" : 0.6}],
   "SUGAR_BEETS": ["norm", {"loc" : 24, "scale" : 4.5}]
  }
}
```

3.2. Importance Sampling

The expectation shown in Expression 1 is implemented by summing probabilities over a discrete probability space in Expression 2, which brings to mind ideas from numeric

integration such as importance sampling [Barrera et al., 2016, Infanger, 1992, Parpas et al., 2015]. The idea is that instead of drawing samples from the distribution of ξ as suggested in the previous subsection, one draws samples from a distribution where the objective function is likely to take extreme values. For the applications of interest to us, one can often anticipate which sorts of values those might be (e.g., large or small values, or both) based on engineering judgment. This enables a very simple form of importance sampling based on cutting points of a distribution that is sampled to obtain discrete values ξ. Previous sections used $f_t(\cdot)$ to refer to the objective function. In this subsection, $f(\cdot)$ refers to the probability density function (pdf) when ξ values could be directly sampled. $F(\cdot)$ is the corresponding cumulative distribution function (CDF). The symbol f is commonly used in these two contexts, although the functions $f_t(\cdot)$ and the function $f(\cdot)$ have nothing to do with each other.

We now describe the univariate version. We are given a list of C cutting points c_i. We assume here that $c_0 = 0$ and $c_C = 1$ and have in mind a cutting point list like (0, 0.1, 0.9, 1) or (0, 0.1, 0.9, 0.99, 1) or some other list that tends to emphasize the tails. We then obtain a list of region boundaries $v_i = F^{-1}(c_i)$. For long tailed distributions of ξ, the values of v_0 and v_C might need to be approximated to avoid excessively wide intervals (e.g. they might be placed five or six standard deviations from the mean instead of at zero and one respectively).

We select from among the regions with probability $1/C$ regardless of the width of the region; this is what enables emphasis of tails. Within the region we select a sample point uniformly; we refer to the pdf for this sampling distribution as $g(\cdot)$. For one of N samples, ξ, drawn from g, the corresponding probability with respect to expectations of f is

$$\frac{1}{N}\frac{f(\hat{\xi})}{g(\hat{\xi})}.$$

In practice, we rescale the probabilities so that they sum to exactly one. Once a region, i, is selected and a point is generated within the region according to a uniform distribution, the pdf for the point is

$$(C(v_i - v_{i-1}))^{-1}$$

4. Conclusions and Future Directions

We have described software that starts with data and produces inputs for optimization in the presence of uncertain data. We have described some of the downstream support to get the scenarios to PySP and some of the upstream support to create scenario data. Much of our present research centers on adding upstream support to create scenario data for a range of applications including parameter estimation and chemical process optimization.

An important area of further research involves using *daps* to facilitate scenario creation based on data from parameter estimation experiments, which explicitly recognizes that there is uncertainty around parameter values. This research has the potential to be interesting, since stochastic programming formulations can be used to obtain the parameter estimates [Word et al 2012] which are then intended for use in subsequent stochastic programs.

Abstract

This paper proposes a stochastic optimization framework for scheduling of a large-scale parallel-unit seawater reverse osmosis (SWRO) desalination plant. Two kinds of uncertainties, water consumption fluctuation and RO units malfunction, are considered. A combination scheduling frame including two routes, a robust pre-scheduling and a reactive rescheduling, is built to handle these two uncertainties. Both optimal scheduling problems are built as change constrained models, and the Monte Carlo method is used to solve the uncertainty problems. An improved genetic algorithm is constructed to compute the efficient solutions. The simulation results show that pre-scheduling can greatly overcome the effect of water consumption fluctuations, and the reactive rescheduling can improve the behaviours of dynamic operation.

Keywords: optimal scheduling, rescheduling, change constraint, Monte Carlo method

1. Introduction

The seawater reverse osmosis (SWRO) desalination is one of the most useful technology to alleviate the shortage of fresh water in coastal areas (Gao, 2016). A large-scale SWRO desalination plant is usually structured with a number of independent RO units in parallel (Figure 1, Wang, 2015). The optimal scheduling is necessary for a large-scale SWRO plant to reduce the operating cost (Jiang, 2015). However, there are many uncertainties in the desalination process. It is a challenge to make an excellent scheduling to deal with the uncertainties.

2. Pre-scheduling

Changing of freshwater demand and the stoppages of RO units are two typical uncertainties in the SWRO process. In order to cope with the uncertainty of freshwater demand, an optimal pre-scheduling is built.

2.1. Objective function

The objective function of pre-scheduling problem is the total cost of production, which includes energy consumption C_{en} and maintenance C_{mn}. The purpose of pre-scheduling is to minimize the objective function f.

$$\min\ f = C_{en} + C_{mn} \tag{1}$$

Where, the energy consumption C_{en} mainly considers power consumption (Eq.(2)), and the maintenance cost C_{mn} includes the maintaining expense when the machine runs and the cleaning and repairing expense when the machine stops (Eq.(3)).

$$C_{en} = \sum_{k=1}^{K} \left\{ Pe(k) \sum_{i=1}^{n} \left(\alpha_i(k) \times c_3 \times Q_i(k) \right) \right\} \tag{2}$$

$$C_{mn} = \sum_{k=1}^{K} \sum_{i=1}^{n} \left(c_1 \cdot \alpha_i(k) \cdot Q_i(k) + c_2 \cdot (1 - \alpha_i(k)) \right) \tag{3}$$

Where, K is the time period of scheduling, n is the number of RO units. $Pe(k)$ is electricity price at time k, and $\alpha_i(k)$ is the on/off status of unit i at time k, $\alpha_i(k)$=1 when the unit i is running; $\alpha_i(k)$=0 when it stops. $Q_i(k)$ is the amount of freshwater generated by unit i at time k. c_1 is the coefficient of maintaining expense which is proportional to $Q_i(k)$; and a constant c_2 during cleaning and repairing period, c_3 is the coefficient used to calculate the energy cost.

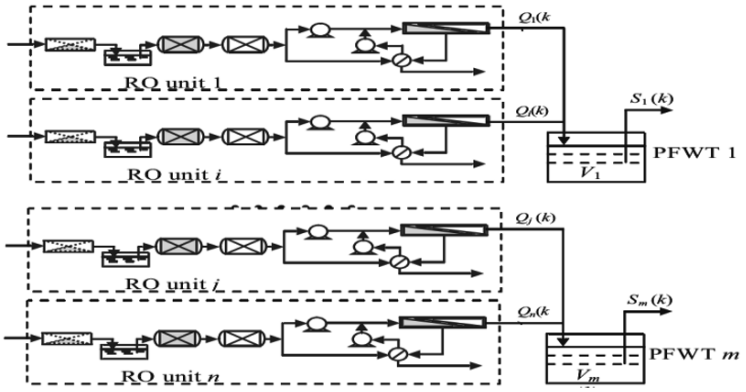

Fig. 1. Schematic diagram of a large-scale SWRO desalination plant

2.2. Constraints

The change constraint programing model is used to solve the uncertainty problem, and a confidence level is given to indicate the credibility of solution.

2.2.1 Freshwater supplement constraint

$$\Pr\left[\sum_{j=1}^{m} w_j(k) \geq D(k) \right] \geq \beta_1, \text{ where } D(k) = \xi_k, \quad \forall k \tag{4}$$

Where, $w_j(k)$ is the maximum water supply of produced freshwater tank (PFWT) j at time k; $D(k)$ is the consumption of freshwater at time k, which is a random variable ξ_k, m is the number of the PFWTs, β_1 is the confidence level of the constraint.

2.2.2 Capacity constraint of each PFWT

$$\Pr[V_j(k) \le V_j^U] \ge \beta_2 \quad j = 1, 2, \ldots, m; \forall k \tag{5}$$

$$V_j(k) = w_j(k) - S_j(k) + V_j^L \quad j = 1, 2, \ldots, m; \forall k \tag{6}$$

$$w_j(k) = V_j(k-1) + \sum_{i=1}^{n_j} \alpha_i(k) \cdot Q_i(k) - V_j^L \qquad j = 1, 2, \ldots, m; i = 1, 2, \ldots, n_i \tag{7}$$

$$S_j(k) = \frac{w_j(k)}{\sum_{i=1}^{m} w_i(k)} D(k) \quad j = 1, 2, \ldots, m; \forall k \tag{8}$$

Where, $V_j(k)$ is the capacity of PFWT j at the end of time k; V_j^U, V_j^L are the upper capacity limit and the lower capacity limit of PFWT j; $S_j(k)$ is the real amount of supplied freshwater by PFWT j at time k; n_j is the number of ROs at time k.

2.2.3 Constraints of produced freshwater

$$Q_i^L \le Q_i(k) \le Q_i^U, i = 1, 2, \ldots, n; \forall k \tag{9}$$

Where, Q_i^U and Q_i^L are the upper and the lower limit of the amount of RO unit i.

2.2.4 Robustness evaluation index

According to the change constraint programming, we define a robustness evaluation index γ_r to indicate the uncertainty of process, it is shown as Eq.(10).

$$\begin{aligned} &\Pr\{g_1(x^*, \xi, k) \wedge \ldots \wedge g_n(x^*, \xi, k) \le 0\} = \gamma_k \\ &\gamma_r = \min_k \gamma_k \ \forall k \end{aligned} \tag{10}$$

Where, γ_r is the robustness index of the scheme when the uncertain variable is ξ under the decision variable x^*.

3. Reactive scheduling

All the units will work according to the pre-scheduling plan. However, when unit malfunction happen, the pre-plan will not work well. A new reactive scheduling must be made to meet the changed situation.

3.1. Objective function

We use a bi-objective function in the reactive scheduling, shown by Eq.(11).

$$\min \quad F = \omega_1 \times F_{obj} + \omega_2 \times M \tag{11}$$

Where, F_{obj} is the economy goal of SWRO plant (shown by Eq.(12)) and M is the deviation between the pre-scheduling and the reactive one, given by Eq.(14), and ω_1 and ω_2 are the weights of F_{obj} and M respectively.

$$F_{obj} = C_{en} + C_{mn} + DF \tag{12}$$

Besides the energy cost C_{en} and the maintenance cost C_{mn}, a penalty value DF is added into the objective function of the reactive scheduling. That means that we do not hope to fail to meet the requirement of water consumption.

$$DF = p_w \cdot \sum_{k=1}^{K} \omega_{DF}(k) \max\left\{0, D(k) - \sum_{j=1}^{m} U(k)\right\} \tag{13}$$

Where, $\omega_{DF}(k)$ is the penalty factor, p_w is the average cost of pre ton production water.

$$M = \left|S_r - S_p\right| = p_w \cdot \sum_{k=k'}^{K}\left[\sum_{i=1}^{n}\left|\alpha_i'(k) \times Q_i'(k) - \alpha_i(k) \times Q_i(k)\right|\right] \tag{14}$$

Where, S_r is the rescheduling scheme which contains the new scheduling decision variables $\alpha'_i(k)$, $Q'_i(k)$; S_p is the pre-scheduling scheme which contains the pre-plan decision variables $\alpha_i(k)$, $Q_i(k)$; k' is the moment when the unit malfunction.

The constraints of reactive scheduling problem is similar to the pre-scheduling, to avoid repetition, it's not described here again.

4. Experimentation and discussion

The Monte Carlo simulation method is used to deal with the change constraints problem (Fan, 2015). An improved genetic algorithm (GA) is presented to calculate the results of change constraint. Two improvements are put forward to the GA: one is to keep the best 1/4 solutions into the next generation so that to keep the population on the optimal direction and maintain the diversity of species; another is to adjust the crossover rate and mutation rate from the adaptive function, which is calculated according to the individual fitness, the population fitness mean and the extreme value.

4.1. Simulation parameters

The actual water consumption at each hour is given by Eq.(15).

$$D_r(k) = D_p(k) + \Delta d,\ \Delta d \sim N(0, \sigma^2) \tag{15}$$

Where, $D_p(k)$ is the predictive value of water supply, Δd is the deviation between predicted and actual of water consumption, it is a random variables subject to normal distribution $N(0, \sigma^2)$.

The probability of unit malfunction is very small, so it is assumed that only one RO unit fails at the same time. The faulty unit is randomly selected from set [1, n]. The fault randomly occurs at the time m_1 and goes back to work at time m_2. The fault duration is uniformly distributed.

$$X = m_1 - m_2,\ X \sim U(a,b), a < b \tag{16}$$

Here, we take an example from "Wang, 2013" for numerical experimentation, which is a large-scale parallel-unit SWRO desalination plant with 8 RO units, 4 PFWTs and a

capacity of 100,000 m^3 freshwater a day. Different from "Wang, 2013", the maintaining plan of RO units is not considered in this paper.

4.2. Comparison of robust pre-scheduling and static scheduling

The parameters of the improved GA are set to: population size $N_{A,p}$=100, the maximum number of iterations $G_{A,m}$=100, mutation factor F_A =0.4, Crossover rate CR_A =0.8, the number of Monte Carlo simulation N_T = 1000, change constraint probability β_1=β_2=0.9, the standard deviation of fluctuations σ = 100.

Figure 2 shows the relation between production freshwater, freshwater demand and electricity price (underneath the Figure) under the robust pre-scheduling plan S_0. Figure 3 shows the total freshwater dynamic between the pre-scheduling plan S_0 and the static scheduling S_a (without considering the fluctuation of water consumption).

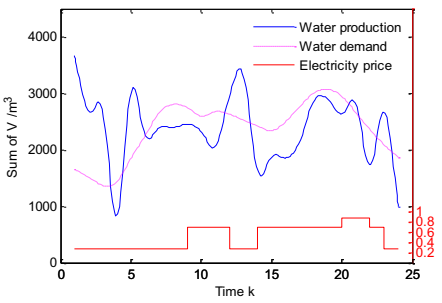

Figure 2: The relation between production water, water demand and electricity price under S_0 scheme

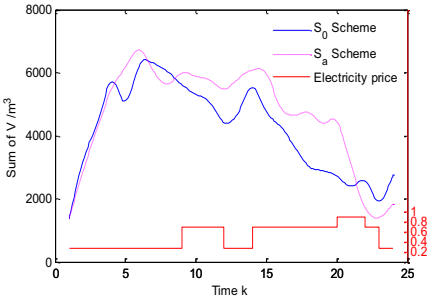

Figure 3: Comparison of total water volume with electricity price between S_0 and S_a

Figure 2 shows that the robust pre-scheduling has some predict ability to the electricity price. That is, when the price is low, the RO units work hard to produce much freshwater than the demand, and when the price is high, the production will go less than the demand, by supplying the pre storage of freshwater to meet the needs of freshwater. By this way, the electricity consumption reduces.

Figure 3 shows that the robust pre-scheduling has more sensitive to the electricity price and the fluctuation of water consumption than the static scheduling. That makes the former has less energy consumption than the latter.

4.3. simulation of reactive scheduling

Three cases of fault information are produced according to the probability of malfunction of the RO unit.

Table 1: Three sets of fault information

Case	Fault unit number	Failure time m_1	Recovery time m_2
1	4	18	20
2	6	7	12
3	5	13	17

Set $\omega_1=\omega_2=1$ are the parameters of multi-objective function, and reactive scheduling will be triggered when the malfunction happen and the maximum deviation of production freshwater demand is large than 10 % than pre-plan; penalty factor $\omega_{DF}(k)$ = 3.65; *Sp* means that the original scheduling scheme is still implemented after the failure happening; S_r means the reactive scheduling is triggered. The scheme comparison in each fault case is shown in Table 2.

Table 2: Comparison of S_p and S_r in 3 cases

Case	Cost of S_p	Cost of S_r	deviation degree M	Robust index γ_r
1	94552	93185	1088.4	0.80
2	99493	95279	1551.9	0.98
3	94066	92675	1386.2	0.98

Table 2 shows that reactive rescheduling reduces the total cost when the RO unit stoppage happens than the pre-scheduling plan, even considering the insufficient of water supply. The objective function of deviation degree *M* ensure the rescheduling plan changing in a small range from the pre-scheduling plan.

5. Conclusions

In this paper, a robust pre-schedule model with change constraint is proposed, which improves the stability of the system by sacrificing a certain amount of economy. A reactive rescheduling, taking into account both the deviations and the economy goal, is built to deal with the RO unit malfunction. An improved GA is used to compute the solution by using the Monte Carlo method. The simulation results show that the stochastic optimization framework proposed in this paper has high practicability.

Abstract

This contribution employs a simulation-based approach to assessing the accuracy and computational efficiency of different strategies for estimation of probability distributions, applied to ODE/DAE systems. Specifically, two Bayesian Markov-chain Monte Carlo approaches are compared to a fast, new PDF estimation strategy, based on projection techniques. The two case studies analyzed confirm that this new PDF estimation strategy offers a very good trade-off between accuracy and computational efficiency, thus being excellent for time-critical PDF estimation tasks.

Keywords: Bayesian inference, PDF estimation, Reverse propagation of uncertainty.

1. Introduction

The application of statistical techniques to the quantification of model uncertainty is a new paradigm, which has recently emerged due to the growing interest of industry and of the PSE community in stochastic optimization frameworks, robust design strategies and quantitative risk assessment. Specifically, strategies for uncertainty quantification are commonly applied in areas such as robust process/product design (especially within the pharmaceutical sector) (Mockus et al., 2011), drug delivery (Laínez et al., 2011) and robust optimization/control of industrial processes (Rossi et al., 2016).

Typically, model uncertainty quantification comes down to the estimation of the joint probability distribution (PDF) of some key uncertain parameters of the model, which often is a system of differential equations (ODE) or differential-algebraic equations (DAE). Currently, there exist two principal types of strategies, applicable to the estimation of the PDF of the uncertain parameters of an ODE/DAE system: rigorous Bayesian inference coupled with random sampling approaches, e.g. Markov-chain Monte Carlo (Green and Worden, 2015), and approximate Bayesian inference exploiting optimization techniques, e.g. Variational Bayes (Beal, 2003) and frameworks based on the Laplace approximation (Dass et al., 2017). Although all of these techniques are well-established and commonly applied, they are usually very computationally demanding. Moreover, no systematic analyses have been conducted to assess their accuracy and computational efficiency, especially when ODE/DAE models must be dealt with.

Therefore, this contribution proposes a simulation-based comparison of two different PDF estimation strategies applied to ODE/DAE systems, namely, Bayesian Markov-chain Monte Carlo (BMCMC) and a new approach, named PDFE&U, which relies on a combination of fitting, back-projection techniques and maximum likelihood estimation. The level of accuracy and computational efficiency, attainable by these two methodologies, are evaluated by analyzing their outputs, especially their PDFs, and by comparing their computational times. The analysis of the PDFs is performed using both contour plots and well-known statistical indicators, i.e. expectation, variance, covariance, and quantiles. The specific ODE/DAE models used as benchmark systems for this analysis include a batch adaptation of the Tennessee Eastman Challenge problem and a pharmacokinetic/ pharmacodynamic model (PB/PK model).

The rest of the paper is organized as follows: first, we introduce the principal ideas, on which PDFE&U relies; then, we report the most interesting results of our analysis on the accuracy and computational performance insured by PDFE&U and BMCMC; finally, we discuss the most relevant consequences of such analyses.

2. Principal features of PDFE&U

PDFE&U is a strategy for estimating/updating the probability distribution of the uncertain parameters of a dynamic model using experimental data and, optionally, an existing PDF of the parameters (a prior). The rationale of this algorithm is summarized in Figure 1, where four distinct phases executed in series, namely, the initialization, Phase I, Phase II and Phase III, are indicated.

The initialization phase is the first task to be executed and serves to acquire user-supplied inputs and to set essential configuration options. The principal input data required by PDFE&U include one or more raw data sets containing measurement of the states, of the manipulated variables and of the disturbances of the target system, the system model formulated as a set of ODEs/DAEs, a parametric family of probability distributions used to approximate the joint PDF of the model parameters (a basis set), and, optionally, a prior (i.e. an existing PDF of the uncertain parameters).

After the initialization, the three steps included in Phase I are executed sequentially. First, we solve a conventional fitting problem and compute an initial estimate of the values of the uncertain parameters of the system model (Step A). Second, we scan the raw data sets for gross errors in the state measurements and eliminate them (Step B). The rationale used to identify gross errors is rather unconventional and relies on the sensitivity of the SSE (sum of squared errors) to this type of measurements. Finally, we project every state measurement, which has not been eliminated in Step B, onto the uncertainty space (Step C). This procedure is the core of Phase I, and is conceptually the inverse of the problem of propagation of a probability distribution through a system of ODEs/DAEs. It allows conversion of every state measurement into a corresponding set of parameters of the system model, i.e. a point belonging to the uncertainty space. Note that this back-projection procedure is the most computationally demanding task of PDFE&U, as it requires solution of a dynamic optimization problem for every state measurement, which must be projected. However, all these complex optimization problems are completely independent of each other, so parallel computing can be employed to drastically reduce the overall computational cost of their numerical solution.

The set of “pseudo-measurements” of the uncertain parameters, estimated in Step C of Phase I, can be easily converted into a probability distribution via maximum likelihood

estimation. This operation is performed in Phase II. Then, if no prior distribution has been supplied to PDFE&U in the initialization, Phase III is not executed (the algorithm is terminated at the end of Phase II). Conversely, if a prior distribution is available, we perform Phase III, which involves combination of the PDF, estimated in Phase II, with the prior, supplied by the user, to yield the posterior probability distribution of the parameters of the ODE/DAE model. In this last phase, we first discretize the two PDFs using an optimization-driven, incremental mapping approach, which relies on key level surfaces of the two distributions (Step A). Subsequently, we apply a modified maximum likelihood estimation strategy to combine the two discrete mappings and convert them into the posterior PDF of the parameters of the model (Step B). The relative weight, with which these two mappings are combined, is controlled by a bounded combination coefficient, which can alter the number of points in each mapping. This coefficient is treated as an additional optimization variable within the aforementioned, modified maximum likelihood estimation strategy.

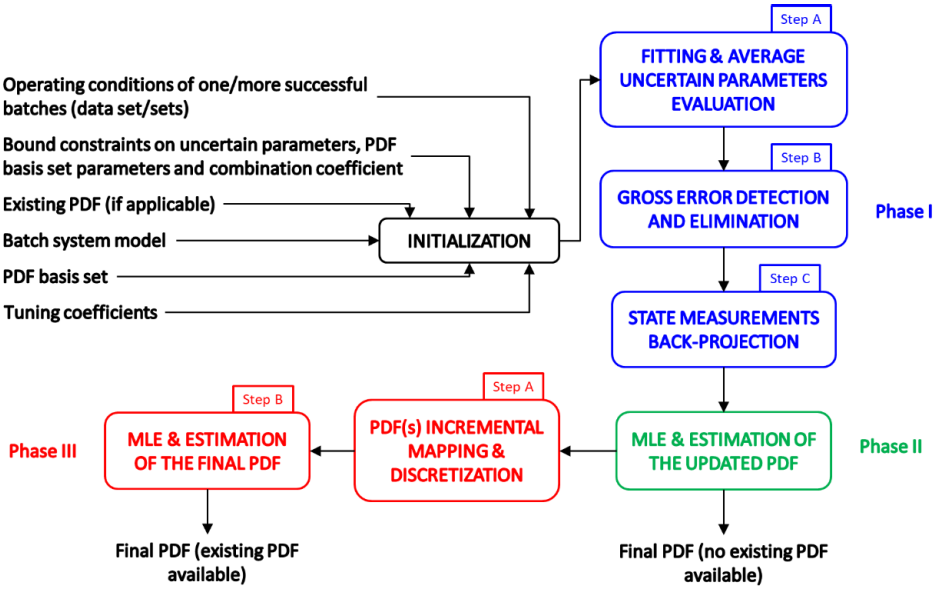

Figure 1: Architecture of the PDFE&U framework.

PDFE&U has been coded in C++ using a sequential, parallel implementation scheme, in which we make use of the BzzMath library (Buzzi-Ferraris and Manenti, 2012) to integrate the ODE/DAE model and solve the required optimization problems, and we exploit well-known multi-threading libraries to manage all the concurrent tasks.

Before moving on, note that, although brief, this outline of the rationale and implementation of PDFE&U should make it apparent that the proposed algorithm has little in common with conventional Bayesian inference strategies. In fact, it does not rely on Bayes theorem, thus does not require definition of a likelihood function. Moreover, it decomposes the estimation of the posterior PDF of the parameters of the system model into two stages, performed in series. We will see that it is this innovative decomposition strategy that yields a significant computational advantage over more conventional Bayesian inference approaches.

3. Performance and computational efficiency of PDFE&U and BMCMC

The computational performance and accuracy provided by PDFE&U and by two different tools for Bayesian Markov-chain Monte Carlo, i.e. BAT (Caldwell et al., 2009) and Stan (Carpenter et al., 2017), have been analyzed using two different case studies. The features of these two test problems forced the use of the two different BMCMC approaches.

The first test case involves estimation of the PDF of the uncertain parameters of the model of a fed-batch reaction process, which is a batch adaptation of the well-known Tennessee Eastman Challenge. The reactor model is comprised of 12 highly nonlinear ODEs, which include two uncertain parameters: the overall heat transfer coefficient (ν_U) and the activation energy of one of the main reactions (ν_{E1*}). The sets of measurements, used to estimate the joint PDF of ν_U and ν_{E1*} in several different scenarios, range from 170 to over 1000 data points.

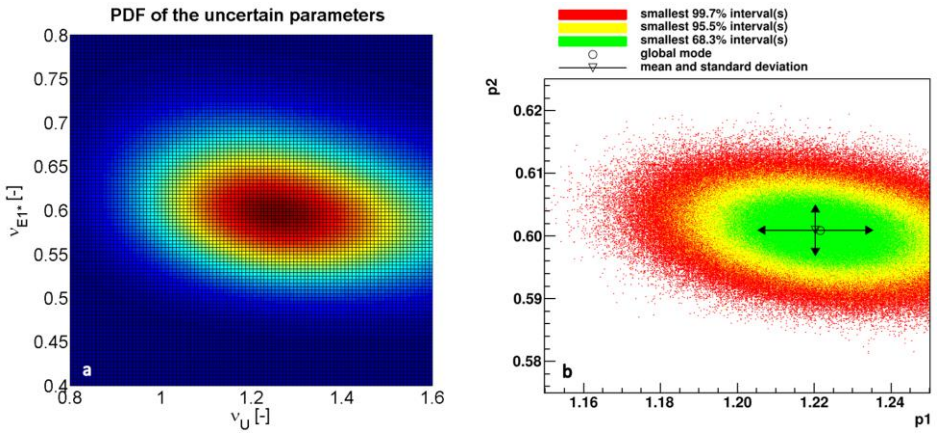

Figure 2: Contour plots of the PDFs yielded by PDFE&U (a) and by BAT (b) (the basis set used in PDFE&U is a bivariate lognormal distribution).

The results of one of these PDF estimation problems are reported in Figure 2, where we show the contour plots of the PDFs estimated by PDFE&U and BAT. Notice that PDFE&U tends to provide good estimates of central tendency measures (mode and expectation) and of the Pearson's correlation coefficient, but tends to overestimate variances. However, PDFE&U usually preserves variance ratios, thus can properly capture the qualitative shape of the probability distribution. Finally, note that a single PDFE&U run is approximately two orders of magnitude faster than a single run of BAT (Table 1). Both PDFE&U and BAT are C++ tools, so this is a fair comparison.

Table 1: Computational performance of PDFE&U, BAT and Stan.

Case study	Model size	Number of uncertain parameters	Time elapsed for solving a single PDF estimation problem [h]		
			PDFE&U	BAT	Stan
Batch reactor model	12 ODEs	2	0.05 – 0.4	6 – 24	-
PB/PK patient model	34 ODEs	8 – 10	0.3 – 0.6	-	≈ 120

The second case study involves the estimation of the joint probability distribution of the uncertain parameters of a PB/PK model, which simulates the response of a patient to the

administration of Gabapentin. The model is comprised of 34 nonlinear ODEs and includes either 8 or 10 uncertain parameters, depending on the characteristics of the patient. The data sets, used in these PDF estimation problems, range from 15 to 170 data points, and consist of measurements of plasma drug concentration.

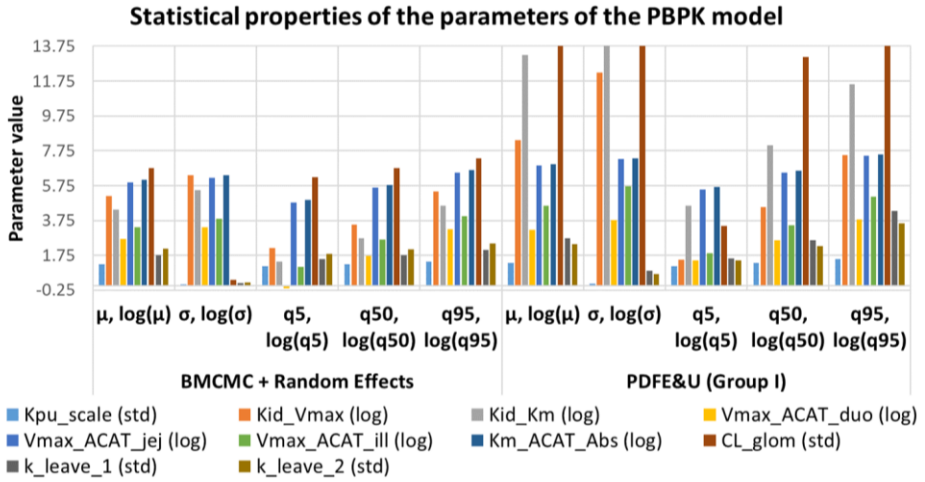

Figure 3: Statistical properties of the PDF of the parameters of the PB/PK model generated by PDFE&U and Stan (some quantities are reported in log-scale to improve the chart readability; μ, σ and qX stand for expectations, standard deviations and X % quantiles).

The results of one of the aforementioned PDF estimation problems are summarized in Figure 3 and Figure 4. In this scenario, the PB/PK model has 10 parameters, thus Figure 3 shows their most important statistical properties, computed by PDFE&U and Stan (BMCMC + Random Effects). In addition, Figure 4 shows the predicted enclosure of the temporal trajectories of drug concentration in a patient's blood stream, associated with the 95 % confidence region of the PDF of the model parameters.

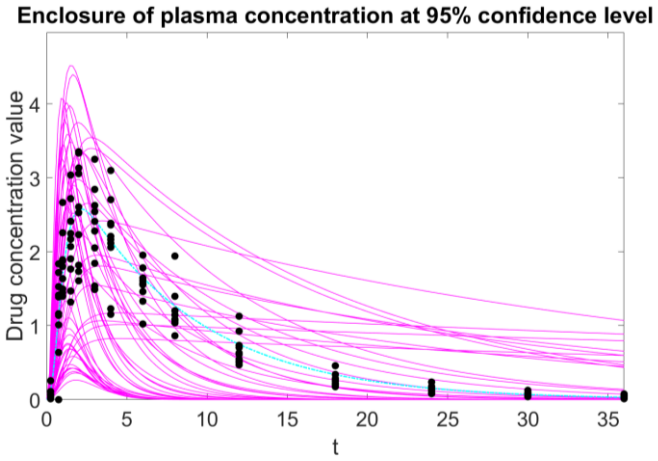

Figure 4: Predicted enclosure of the temporal trajectories of drug concentration in a patient's blood stream at 95% confidence level (the black dots are the experimental data; the light blue curve represents the profile of drug concentration in the blood stream of the average patient).

Both Figure 3 and Figure 4 confirm that PDFE&U tends to overestimate variances, but provides decent estimates of the central tendency measures and of the qualitative properties of the probability distribution, at a very attractive computational cost (Table 1). Finally, note that some of the largest deviations between the predictions of PDFE&U and those of Stan may be partially due to the small ratio of the number of data points to the number of uncertain parameters, which increases the probability of non-uniqueness of some of the projections of the state measurements (see the description of Step C of Phase I of PDFE&U).

4. Conclusions

The results of these analyses suggest that PDFE&U provides a favorable trade-off between accuracy and computational efficiency, by comparison to Bayesian Markov-chain Monte Carlo methods. This allows us to conclude that PDFE&U is more suitable for time-critical applications, where the PDF estimation task must be completed as soon as possible (e.g., in stochastic dynamic optimization and robust data reconciliation). Conversely, Bayesian Markov-chain Monte Carlo is more accurate and reliable, and is more suitable for offline, detailed PDF estimation studies.

In the near future, we are planning to extend these comparative studies by also analyzing the trade-off between computational performance and accuracy offered by Variational Bayes and Bayesian inference frameworks based on the Laplace approximation.

Quantitative and Probabilistic approach for Underground Pipeline management Optimization

Keonhee Park*, Gunhak Lee, Chongyoung Nam, Wonbo Lee

Department of Chemical Engineering, Seoul National University, 615-8510 Seoul, KOREA
wblee@snu.ac.kr

Abstract

The risk of old underground pipelines installed in industrial complexes is increasing globally, Several methodologies for managing these equipment safely are being developed. Underground buried piping is damaged due to various causes such as corrosion and other construction, and it loses its function originally, which increases the risk of human life and environmental damage around facilities. QRA (Quantitative Risk Assessment) methods help to prioritize pipeline management with relative risk comparisons, but decisions on specific management strategies and methods are still in the hands of skilled experts. And it has limitation that relies heavily on experience. Also, it is difficult to fully consider the uncertain factors of piping in this deterministic approach.

In this study, a new piping management decision framework is proposed by combining risk assessment methodology for determining optimal piping life management strategy. The limit state function for each failure cause is defined and the accident probability is calculated by Monte Carlo simulation. The result is verified with the accident frequency using accident database of European Gas Incident Group (EGIG) and Department of Transportation USDOT.

In addition, pipeline accident consequence is defined by the Potential Impact Radius calculation method reflecting the characteristics of the Flammable and Toxic material. Finally, we can define objective function for management optimization using costing indexes for piping management. This optimal solution of this objective function helps us determining a cost-effective method for managing uncertain pipeline system. Based on the piping data embedded in the Ulsan National Industrial Complex in Korea, several case studies are performed and the expected results are presented in the proposed framework.

Keywords: Reliability, Quantitative Risk Assessment, Management Costing, Limit State Function, Probabilistic Approach, Optimization

1. Introduction

Pipeline systems, which is a typical fluid transport method, is managed by industrial companies. However, there have been fatalities in the world due to the explosion of gas pipeline in Kaohsiung, San Bruno and Ghislenghien pipeline leakage and pipe breakage accidents. Many accidents have been caused by defects in the welds, pipe breakage due to construction work, and the lack of proper piping management in accident reports. Most of the buried pipelines are not appropriately managed due to difficulties in management and investment of safety expenses. Various methods for efficiently

managing buried pipelines have been attempted. In order to detect and respond to faults causing major accidents, high-resolution devices such as ILI (Inline-inspection), Hydrostatic Testing, and External Corrosion Direct Assessment (ECDA) can be used. However, it is difficult for management companies to determine which methodology is cost-effective. In the world, aged pipelines are running in the industrial complex for more than 30-40 years, but there is no precise management system. Appropriate monitoring, inspection, and maintenance of piping can last for longer than the design life, which can be an optimization problem for the management company as there is a tradeoff between the uncertain damage caused by the accident and the costs involved in maintenance and management.

The Cost-Benefit Analysis problem has been a subject of continuous research and various methods have been tried. Several frameworks for diagnosing piping management by using a fuzzy logic model or introducing a risk based inspection concept has been proposed. However, these methodologies are only semi-quantitative and can only be used to prioritize the application of risk measures in piping, and it is difficult to quantitatively determine actual cost effects. In order to compensate for this, a methodology for evaluating pipeline integrity using a quantitative methodology based on the Structural Reliability Method can be used.Canadian Standards Association(CSA) summarizes the application of reliability based methods to the design and assessment of natural gas transmission pipelines. This method demonstrates the structural stability of a pipeline by making an explicit estimate of its reliability and comparing it to a specified reliability target. Structural reliability analysis are obtaining wider acceptance as a basis for evaluating pipeline integrity and these methods are ideally suited to managing metal corrosion damage as identified risk reduction strategies. These maintenance strategies considered included higher inspection frequencies and more higher accuracy test equipment usages. These results can explain whether the risk level of the current pipe is acceptable. This approach is to combine deterministic failure models with maintenance data and the pipeline attributes, experimental corrosion growth rate database, and the uncertainties inherent in this information. The calculated failure probability suggests the basis for informed decisions on which defects to repair, when to repair them and when to re-inspect or replace them.

This study provides an overview of pipeline management optimization solution using structural reliability method. Reliability based approach can be used to determine cost-effective safety measures. Consequence and probability calculation model was formulated to calculate the reliability using the limit state function model and the potential impact radius model referenced by Canadian standard association and British standards Some parameters of the literature model were adjusted based on piping information and management data in Ulsan and Yeosu, representative national industrial complexes located in Korea. The proposed decision making framework can help pipe management decision makers to establish an optimal maintenance strategy to time the investment decision; this strategy balances cost efficiency against stability in an uncertain future pipeline management system.

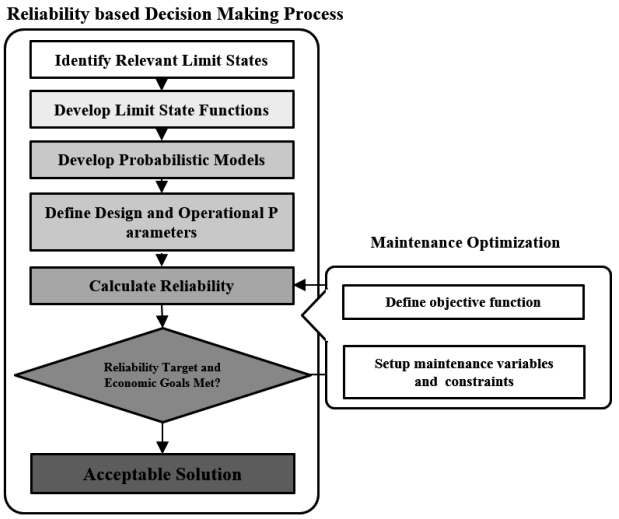

Figure 1. Proposed Decision making framework for underground pipeline management

2. Model Formulation

This paper is based on the probabilistic model and consequence model considering possible uncertainties of pipeline parameters. Failure mode can be defined to calculate the accident probability of the pipe.Failure modes are defined for small leaks, large leaks, and ruptures, and define a limit state function for each failure mode that is appropriate for the cause of the accident, such as corrosion or other construction. The model for calculating the failure probability of seven functions was established by citing the limit state function defined in CSA.The probabilistic distribution model of the piping variables included in each function was also referenced in the literature, and parameter tuning was performed based on the piping data in the Korean industrial complex and the experimental data from Korea Gas Safety Corporation. The calculation for this is based on the calculation setting of 100,000 times using Monte Carlo simulation. The results of the calculation of the accident probability are confirmed by the results of the PHMSA accident statistical data of the European Gas Incident Group EGIG (1970-2013), US Department of Transportation, and Pipeline & Hazardous Materials Safety Administration.

The Consequence model plays a role in predicting the magnitude of accidents occurring in each scenario and converting them into costs. The prediction model is classified into the Flammable gas consequence model and the Toxic gas consequence model depending on the type of pipeline transport material.Generally, the worst-case model is set as calculated in the risk assessment.The damage model assumes full rupture of the pipe and the type of accident to be modeled is defined as Jet fire and Toxic gas dispersion. In the Ulsan and Yeosu industrial complexes, fire and toxic hazardous materials are all included.

The distance of the accident influence in the Jet Fire accident type was calculated from the relation between the heat generation intensity and the distance to the maximum effect distance from death. The parameters used here were obtained by using Phast (DNV-GL) as a risk assessment program.

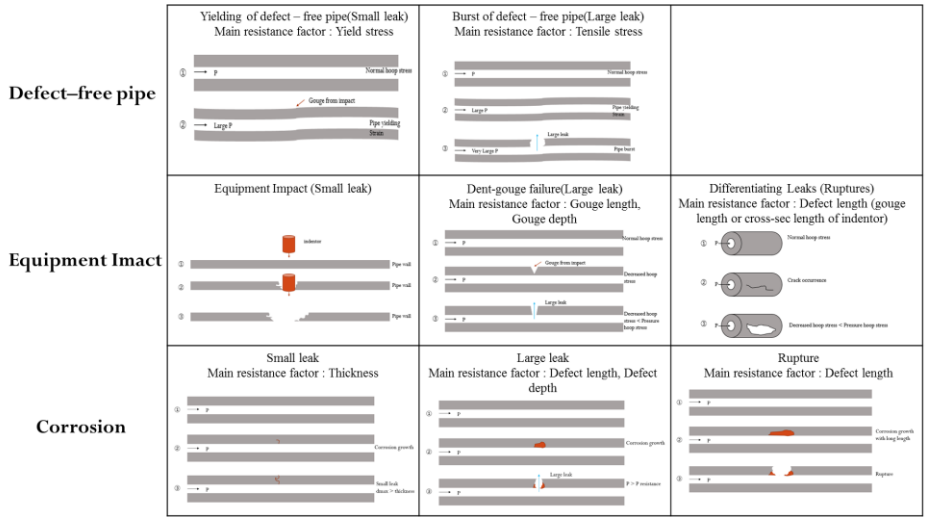

Figure 2. Description about main underground pipeline failure causes for limit state design

On the other hand, Probit probabilities of toxic substances were calculated by using Phast in the purple book, and the values of a, b, and n for each substance were substituted. The C-FER Technical Report shows that the distance that toxic gases are diffused and the harmful effects on the human body are related to the leakage amount and the exponential logarithm.The distance of influence was defined as the diffusion distance which corresponds to the concentration of 100% of the lethality.The amount of leakage was proportional to the square of the pressure and the diameter, and the influence distance (r) value was used.

Cost information was defined and applied to three risk reduction strategies: Inline Inspection, Hydrostatic Testing, and Direct Assessment. We define the objective function to approach the optimization problem of piping maintenance to derive the appropriate diagnosis time, cycle, and method for the pipe satisfying the acceptable risk level.The subsequent Constraint has the maximum allowable limit pipe wall thickness, reliability target, and so on.The allowable reliability target is set at 10-4 / km / yr, and the maximum allowable pipe wall thickness is calculated differently depending on the type of pipe, diameter, design pressure, etc.

Table 1. 8 Limit State functions and descriptions

Failure Mode	Failure Cause	Limit State function	Description
Small Leak	Yielding and burst of defect free pipe	$2\sigma_y t - PD$	σ_y : yield stress P : Operating pressure D : Diameter
Small Leak	Equipment Impact (1)Puncture	$r_a - q$	ra:estimated resistance q: normal impact force
Small Leak	Corrosion (1)Small leaks	$t - d_{max}$	t : wall Thickness dmax : maximum corrosion depth
Large Leak	Yielding and burst of defect free pipe	$1.906c\sigma_f t - PD$	c : model error σ_f : flow stress
Large Leak	Equipment Impact (2)Dent-gouge failure	$\sigma_c - \sigma_h$	σ_c : critical hoop stress σ_h : hoop stress

Large Leak	Corrosion (2) Large leak and ruptures	$r_a - P$	ra : estimated resistance (corrosion)
Rupture	Equipment Impact (3) Differentiating leaks and rupture	$S_{cr} - \sigma_h$	S_{cr} : critical resistance with unstable axial defect growth
Rupture	Corrosion (3) differentiating large leaks and ruptures	$\frac{1.8t\sigma_u}{m \times D} - P(SMYS \geq 241MPa)$ $\frac{2.3t\sigma_y}{m \times D} - P(SMYS \leq 241MPa)$	m : folias factor σ_u : tensile strength

3. Result

We will integrate the proposed methodology and data to define piping management optimization problem and interpret it using CPLEX 9.0 (GAMS). It is possible to analyze what is a single or multiple methodology with a lower cumulative management cost when viewed at 10, 20, and 30 years, while satisfying the Constraint.

Currently, it is possible to confirm the change in the probability of corrosion accident by the year when the pipe inspection cycle is different. In addition, the yearly changes in how the pipe design thickness affects the probability of an accident can be confirmed.
We will confirm the effectiveness of this reliability-based method by supplementing the optimized results.

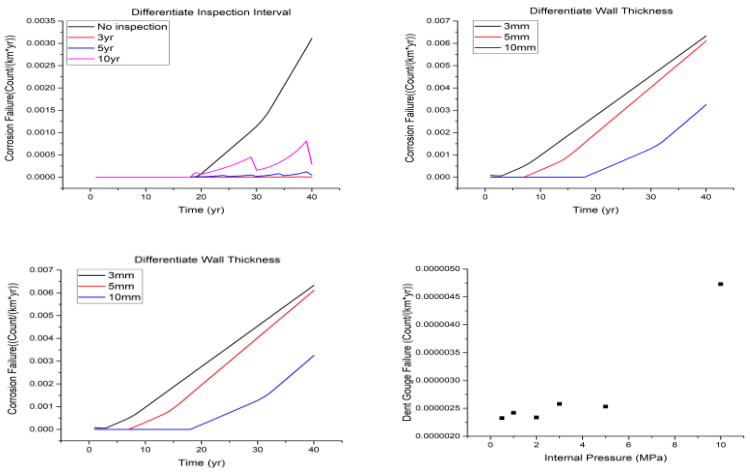

Figure 3. Case studies about propylene pipeline failure rate changes (Differentiate Inspection Interval and pieline parameters)

4. Conclusion

In order to solve the problem of setting the optimal piping management method, the framework was established by applying the reliability-based analysis method which is better than the existing semi-quantitative method. It is possible to approach the optimization problem by quantitatively reflecting the risk reduction effect of each risk reduction strategy by supplementing the uncertainty of the piping variables and forecasting the accident probability. In this study, only three risk reduction strategies have been considered, but if more diverse methodologies can be considered in the future,

optimal mathematical models and parameters can be supplemented to make optimal strategy analysis for more diverse methodologies. The proposed methodology can be used as a strategic tool for piping management decision makers who are concerned about cost and risk.

Abstract

The solution of the Optimal Power Flow (OPF) and Unit Commitment (UC) problems (i.e., determining generator schedules and set points that satisfy demands) is critical for efficient and reliable operation of the electricity grid. For computational efficiency, the alternating current OPF (ACOPF) problem is usually formulated with a linearized transmission model, often referred to as the DCOPF problem. However, these linear approximations do not guarantee global optimality or even feasibility for the true nonlinear alternating current (AC) system. Nonlinear AC power flow models can and should be used to improve model fidelity, but successful global solution of problems with these models requires the availability of strong relaxations of the AC optimal power flow constraints. In this paper, we use McCormick envelopes to strengthen the well-known second-order cone (SOC) relaxation of the ACOPF problem. With this improved relaxation, we can further include tight bounds on the voltages at the reference bus, and this paper demonstrates the effectiveness of this for improved bounds tightening. We present results on the optimality gap of both the base SOC relaxation and our Strengthened SOC (SSOC) relaxation for the National Information and Communications Technology Australia (NICTA) Energy System Test Case Archive (NESTA). For the cases where the SOC relaxation yields an optimality gap more than 0.1 %, the SSOC relaxation with bounds tightening further reduces the optimality gap by an average of 67 % and ultimately reduces the optimality gap to less than 0.1 % for 58 % of all the NESTA cases considered. Stronger relaxations enable more efficient global solution of the ACOPF problem and can improve computational efficiency of MINLP problems with AC power flow constraints, e.g., unit commitment.

Keywords: ACOPF, Second-order cone programming, McCormick, Bounds tightening.

1. Introduction

Reliable and economic operation of the electricity grid is vital for the economy, public safety, and health. Key practical problems relating to the operation of the grid include the Optimal Power Flow (OPF) and the Unit-Commitment (UC) problems. The OPF, also referred to as the ACOPF problem, seeks to find generator operating conditions for a single time period that minimize the total operating cost while satisfying physical power flow laws and other operational constraints, such as generator and transmission limits. The UC problem solves for a generator on/off schedule across multiple time periods, introducing discrete variables for these scheduling decisions. Both problems require a model for the AC power flow (ACPF), giving rise to a large number of

nonlinear, non-convex constraints. To remove these nonlinearities, the ACOPF problem is typically simplified to a linear approximation known as the DCOPF problem. This approximation is more computationally efficient; however, it does not guarantee global optimality or even feasibility for the system under consideration. For this reason, there has recently been extensive research in convex relaxations for the ACOPF model to support global optimization of ACOPF and UC with ACOPF constraints.

Lavaei and Low (2012) present a semidefinite programming (SDP) formulation for the dual of the ACOPF problem and provide a rank-one sufficient condition under which the duality gap is guaranteed to be zero. Coffrin et al. (2017) propose a quadratic relaxation on the polar form of the ACOPF problem. Jabr (2006) introduced a convex second-order Cone (SOC) programming relaxation of the ACOPF problem. Kocuk et al. (2016) proposed extensions to the SOC relaxation including (1) relaxations on the arctangent constraints relating the SOC variables to voltage angles differences and (2) linear cutting planes to incorporate information from the SDP relaxation. Liu et al. (2017) propose a piecewise outer approximation based global optimization algorithm for solving the ACOPF problem.

In this paper, we propose a strengthened SOC (SSOC) relaxation that relates the auxiliary variables in the SOC relaxation to the real and imaginary components of the voltages in the rectangular form through McCormick envelopes. The ACOPF problem has an infinite number of solutions unless the voltage angle is specified at an arbitrary bus, typically referred to as the reference bus. By relating the SOC auxiliary variables to the rectangular voltages, this reference bus specification may now be included in the proposed relaxation, providing tighter bounds on the voltage variables at the reference bus. Results for several widely studied ACOPF test cases demonstrate that this approach improves the effectiveness of optimality-based bounds tightening (OBBT) and strengthens the SOC relaxation significantly. In the next section, we present a review of the SOC relaxation; our SSOC relaxation is described in Section 3. Computational results comparing the optimality gap of the SOC and SSOC relaxations are presented along with results showing the impact of the reference bus on bounds tightening.

2. ACOPF Second-Order Cone Relaxation

A power system is modeled with a set of buses connected by transmission lines and/or transformers. Each bus may have one or more generators and loads. The rectangular form of the ACOPF includes real and imaginary components of the voltage, v^r and v^j respectively, at each bus. With the following definitions,

$$c_{b,b} \equiv (v_b^r)^2 + (v_b^j)^2 = v_b^2, \;\; c_{b,k} \equiv v_b^r v_k^r + v_b^j v_k^j, \;\; s_{b,k} \equiv v_b^r v_k^j - v_k^r v_b^j \tag{1}$$

the SOC relaxation of the ACOPF problem can be written as follows:

$$\min \sum_{g \in \mathcal{G}} [A_g^2 (p_g^G)^2 + A_g^1 p_g^G + A_g^0]$$

s.t.

$$\sum_{(b,k) \in \mathcal{L}_b^{in}} p_{b,k}^t + \sum_{(b,k) \in \mathcal{L}_b^{out}} p_{b,k}^f + G_b^{sh} c_{b,b} + P_b^D - \sum_{g \in \mathcal{G}_b} p_g^G = 0 \qquad \forall\, b \in \mathcal{B}$$

$$
\begin{aligned}
&\sum_{(b,k)\in\mathcal{L}_b^{in}} q_{b,k}^t + \sum_{(b,k)\in\mathcal{L}_b^{out}} q_{b,k}^f - B_b^{sh} c_{b,b} + Q_b^D - \sum_{g\in\mathcal{G}_b} q_g^G = 0 && \forall\, b \in \mathcal{B} \\
&p_{b,k}^f = G_{b,k}^{ff} c_{b,b} + G_{b,k}^{ft} c_{b,k} - B_{b,k}^{ft} s_{b,k} && \forall\, (b,k) \in \mathcal{L} \\
&q_{b,k}^f = -B_{b,k}^{ff} c_{b,b} - B_{b,k}^{ft} c_{b,k} - G_{b,k}^{ft} s_{b,k} && \forall\, (b,k) \in \mathcal{L} \\
&p_{b,k}^t = G_{b,k}^{tt} c_{k,k} + G_{b,k}^{tf} c_{k,b} - B_{b,k}^{tf} s_{k,b} && \forall\, (b,k) \in \mathcal{L} \\
&q_{b,k}^t = -B_{b,k}^{tt} c_{k,k} - B_{b,k}^{tf} c_{k,b} - G_{b,k}^{tf} s_{k,b} && \forall\, (b,k) \in \mathcal{L} \\
&(p_{b,k}^f)^2 + (q_{b,k}^f)^2 \le (S_{b,k}^{max})^2,\ (p_{b,k}^t)^2 + (q_{b,k}^t)^2 \le (S_{b,k}^{max})^2 && \forall\, (b,k) \in \mathcal{L} \\
&(V_b^{min})^2 \le c_{b,b} \le (V_b^{max})^2 && \forall\, b \in \mathcal{B} \\
&P_g^{G,min} \le p_g^G \le P_g^{G,max},\ Q_g^{G,min} \le q_g^G \le Q_g^{G,max} && \forall\, g \in \mathcal{G} \\
&c_{b,k} = c_{k,b},\ s_{b,k} = -s_{k,b} && \forall\, (b,k) \in \mathcal{L} \\
&c_{b,k}^2 + s_{b,k}^2 \le c_{b,b} c_{k,k} && \forall\, (b,k) \in \mathcal{L}
\end{aligned}
\tag{2}
$$

Here, capitalized symbols represent parameters and lower-case symbols represent variables. Real power is denoted by $\boldsymbol{p}$, reactive power by $\boldsymbol{q}$, and the relaxation variables by $\boldsymbol{s}$ and $\boldsymbol{c}$. The superscripts *G* and *D* denote generation and demand, and *f* and *t* denote the "from" and "to" ends of transmission lines. Subscripts denote indices of the sets of buses $\boldsymbol{\mathcal{B}}$, generators $\boldsymbol{\mathcal{G}}$, and transmission lines $\boldsymbol{\mathcal{L}}$. The optimization objective is to minimize the aggregate operating cost of all the generators. The constraints enforce real power balances at all the buses and reactive power balances at all of the buses, model real and reactive power flow on transmission lines at the "from" and "to" ends of the transmission lines, and enforce thermal limits on the transmission lines, voltage limits at the buses, and generator limits on real and reactive power. The last two constraints are derived from the definitions of *s* and *c*, while the final constraint is relaxed to be an inequality, forming the SOC relaxation. Eq.(2) is a convex optimization problem that may be solved efficiently with off-the-shelf solvers, e.g., Ipopt.

Note that bounds tightening does not improve the relaxation as written since none of the relaxations depend on variable bounds, as is the case when using McCormick envelopes. Further, the voltage variables have been removed from the model, so there is no direct way to incorporate a specification of the voltage angle at the reference bus. In the following section, we present our SSOC relaxation that incorporates McCormick envelopes for Eq.(1) into the SOC relaxation, allowing specification of the reference bus angle and providing a mechanism to effectively tighten the relaxation with OBBT.

3. McCormick Envelopes for Strengthening the SOC Relaxation

First, let $\widehat{xy}$ be an auxiliary variable for the bilinear term xy. We represent the set of McCormick envelopes for the bilinear term as $\widehat{xy} \in MCC(x,y)$. With this notation, Eq.(1) may be relaxed with McCormick Envelopes, as follows:

$$
\begin{aligned}
&c_{b,b} = \widehat{v_b^r} + \widehat{v_b^j}, \;\; c_{b,k} = \widehat{v_b^r v_k^r} + \widehat{v_b^j v_k^j}, \;\; s_{b,k} = \widehat{v_b^r v_k^j} - \widehat{v_b^j v_k^r} \\
&(v_b^r)^2 \leq \widehat{v_b^r} \leq (V_b^{r,\max} + V_b^{r,\min}) v_b^r - V_b^{r,\max} V_b^{r,\min} \\
&(v_b^j)^2 \leq \widehat{v_b^j} \leq (V_b^{j,\max} + V_b^{j,\min}) v_b^j - V_b^{j,\max} V_b^{j,\min} \\
&\widehat{v_b^r v_k^r} \in MCC(v_b^r, v_k^r), \;\; \widehat{v_b^j v_k^j} \in MCC(v_b^j, v_k^j) \\
&\widehat{v_b^r v_k^j} \in MCC(v_b^r, v_k^j), \;\; \widehat{v_b^j v_k^r} \in MCC(v_b^j, v_k^r)
\end{aligned}
\tag{3}
$$

The initial bounds on the real and imaginary voltage components are determined by the voltage magnitude limits provided in the problem specification. However, at the reference bus, the imaginary component is fixed to zero (i.e., the voltage angle is fixed to zero), and the bounds on the real component of the voltage at the reference bus can be tightened as with Eq.(4). The SSOC relaxation is then given by Eqs.(2-4).

$$
\begin{aligned}
&-V_b^{\max} \leq v_b^r, v_b^j \leq V_b^{\max} \\
&V_{ref}^{\min} \leq v_{ref}^r \leq V_{ref}^{\max}, \;\; v_{ref}^j = 0
\end{aligned}
\tag{4}
$$

To Further tighten the SSOC relaxation, OBBT is performed on the voltage variables at each bus. The relaxations in Eq.(3) are then updated, the SSOC relaxation is solved, and the process is repeated until either the optimality gap is less than 0.1 % or 20 iterations are performed with a cumulative reduction in the optimality gap of less than 0.1 %.

4. Results

4.1. Performance of the SSOC Relaxation

Table 1 compares the optimality gap for the SOC and SSOC relaxations for several of the NESTA test cases (Coffrin et al., 2014). The relaxations were modelled in Python 3.5.2 with Pyomo (Hart, 2011) and solved with Ipopt 3.12.5 (Wächter, 2006). The results show that the SSOC relaxation tightens the SOC relaxation significantly. Of the cases for which the optimality gap with the SOC relaxation is greater than 0.1 %, the SSOC relaxation with bounds tightening further reduces the optimality gap by an average of 67 % and overall reduces the optimality gap to less than 0.1 % for 58 % of the NESTA cases.

4.2. The Impact of the Reference Bus on Bounds Tightening

Figure 1 shows the importance of the reference bus and the corresponding bounds in Eq.(4). The figure shows the variable bound ranges for the real and imaginary components of the voltages averaged over all buses of the same shortest path in terms of the number of transmission lines from the reference bus. The iteration count for OBBT is shown on the x-axis. The figure shows the first four iterations of bounds tightening for nesta_case24_ieee_rts__api. As shown in the figure, before any bounds tightening is performed, the reference bus is the only bus with good bounds on the voltage. After one iteration of bounds tightening, the bounds on the voltages at buses connected directly to the reference bus are tightened dramatically. On the second iteration of bounds tightening, the bounds on the voltages at buses a distance of 2 from the reference bus

Table 1: Comparison of optimality gap of SOC and SSOC with OBBT.

are tightened more than the bounds on variables at other buses. The trend continues through all four iterations of bounds tightening shown. In this figure, it is clear that the effectiveness of bounds tightening at a given iteration is directly related to the distance of the corresponding bus from the reference bus. Additionally, although not shown in Table 1, the SSOC relaxation was solved with the bounds tightening procedure described in Section 3 but without the tight bounds on the reference bus voltages. The optimality gap did not improve at all beyond the gap obtained with the SOC relaxation for any of the test cases. This further indicates the necessity of the tight voltage bounds at the reference bus for effective bounds tightening.

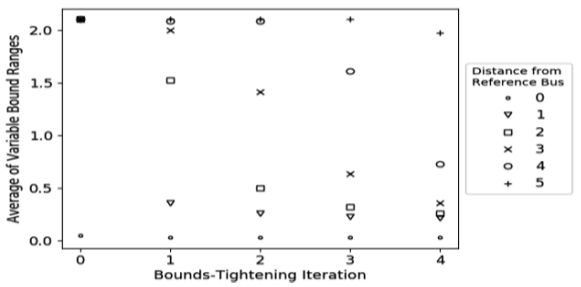

Figure 1:Impact of the reference bus on bounds tightening for nesta_case24_ieee_rts__api. The abscissa shows the iteration count, and the ordinate shows the average range between the upper and lower variable.

5. Conclusions

We describe the use of McCormick envelopes and OBBT to strengthen the well-known second-order cone (SOC) relaxation of the ACOPF problem. With the proposed relaxation, tight bounds on the voltages at the reference bus can be specified, and we demonstrate the necessity of this specification for bounds tightening to be effective. In Section 4.1, we showed that, of the NESTA test cases for which the optimality gap with the SOC relaxation is greater than 0.1 %, the SSOC relaxation with bounds tightening further reduces the optimality gap by an average of 67 % and ultimately reduces the optimality gap to less than 0.1 % for 58 % of all the cases considered. In Section 4.2, we demonstrated that the effectiveness of OBBT at a given iteration is directly related to the distance of the corresponding bus from the reference bus. In future work, this relationship may be exploited to develop more efficient strategies for bounds tightening.

Dual adaptation strategy for model-based operation

Cheng Yang, Kexin Wang, Zhijiang Shao*

College of Control Science and Engineering, Zhejiang University, 38 Zheda Road, Hangzhou 310027, China
szj@zju.edu.cn

Abstract

Model-based operations are frequently challenged by unsatisfactory model accuracy, which hampers finding the true plant optimum. Integrated parameter estimation and optimization methods were proposed to handle the problem. However, they did not focus on improving model accuracy or confining optimization to a valid operating range. Dual adaptation strategy is thus presented in this paper to integrate local parameter model and real-time optimization through trust-region framework. On one hand, application range of the local model is decided adaptively so as to avoid invalid operations. On the other hand, the local model is updated adaptively for purpose of reducing plant-model mismatch in moderate cost. The above two aspects contribute to dual adaptation concept. It is guaranteed that the optimal operations derived from this dual adaptation strategy converge to the plant optimum. Case study of significant load change for HTR-PM demonstrates effectiveness of the proposed method.

Keywords: plant-model mismatch, dual adaptation strategy, trust-region method, iterative method.

1. Introduction

Model-based applications are required to calculate valid operations for complex systems. The main difficulty lies in that plant-model mismatch is unavoidable, as it can arise from simplifications in modelling, characteristics variation during the operation course, and limited as well as contaminated data for deriving the model. Due to the mismatch, model-based operation is prevented from converging towards the plant optimum. Therefore, the desirable model applicable to the full operating range and strategy which guarantees convergence to the plant optimum in the presence of plant-model mismatch are indispensable in model-based applications.

Plant-model mismatch should be handled properly. This problem was considered in the framework of classical iterative two-step (ITS) method (Marlin and Hrymak, 1997), where parameter estimation (PE) and real-time optimization (RTO) are performed iteratively. However, the consistence of the model-based solution and the plant optimum cannot be guaranteed. Methods which modified the ITS framework were therefore developed to force convergence of model-based operations towards the true plant optimum (Brdys and Tatjewski, 2005; Marchetti, Chachuat, and Bonvin, 2009), where the formulation of the optimization problem was improved by taking advantage of KKT systems of the plant. Although convergence to the plant optimum was proved, these methods have nonanalytic input correction in each iteration.

Following the ITS concept, we propose a trust-region based strategy with dual adaptation. A sequence of local models is applied in the sought of optimal operations, at the same time, proper amount of input correction in each iteration is determined by

precise optimization. Moreover, the local model is updated only if necessary to reduce computational effort.

2. ITS method for model-based operation

ITS method intends to decrease the plant-model mismatch and provide model-based operations through performing PE and RTO iteratively, which can be expressed as follows.

Step 1: Apply the current operations to the plant and solve a PE problem to determine the model parameters using the resulting measurements.

Step 2: Calculate the operations for optimizing some performance index by solving a RTO problem based on the model with the updated parameters.

Step 3: If no further improvement is implemented, stop. Otherwise, go to Step 1.

However, model-based operations by ITS method rarely converge to the true plant optimum due to structural mismatch (Yip and Marlin, 2004). Moreover, sufficient data are usually unavailable and the local model derived from limited data sets fails to characterize the process over the full operating range.

3. Dual adaptation strategy to address plant-model mismatch

Dual adaptation strategy is designed in the framework of trust-region method that confines each optimization problem to a valid local model. As the local model derived from limited measurements may not be applicable to a wide range, we meant to extend its application range by constructing a more predictive model. At the kth iteration, parameters p can be approximated around the current conditions u_k by

$$m_k^p(u) = \hat{p}_k + \left(\frac{\partial p}{\partial u_k}\right)^T \cdot (u - u_k) \tag{1}$$

where $\hat{p}_k$ are the estimates from measurements at current conditions, the linearization term $\partial p/\partial u_k$ represent the sensitivities of parameters p with respect to the inputs u at the kth iteration and are obtained from perturbations to the system inputs.

The model parameters in Eq.(1) should be restricted to a proper region, which gives rise to an extended model, compared to the model at a single operation point, with restricted operating range. Based on such a model, the RTO problem for dual adaptation strategy is formulated in

$$\begin{aligned} \min_{u} \quad & \varphi(u) \\ s.t \quad & f(u, m_k^p(u)) = 0 \\ & c(u) \le 0 \\ & \|u - u_k\|_\infty \le \Delta_k \end{aligned} \tag{2}$$

where $\varphi(u)$ denotes the RTO objective function, f represents the system model, and c are constraints on the inputs. As the states and outputs are determined by inputs, they are omitted for simplicity. Δ_k is iteration related and limits operation u to a region around the current conditions u_k. This added constraint defines the application range of

the approximated model and allows us to integrate PE and RTO through trust-region framework.

In trust-region methods, both the model and trust-region radius are updated in each iteration based on model evaluation (Biegler, Lang and Lin, 2014). As it is expensive in this paper to calculate the plant derivatives to approximate the parameters, model update should be called only when necessary. This gives rise to dual adaptation strategy, where both the approximated model and its application range are updated adaptively based on model evaluation. The algorithm is stated below, where the merit function ϕ is exploited to balance between reducing the objective function and improving feasibility.

Algorithm: Dual adaptation strategy based on trust-region framework

Step 0 (Initialization): Give the current operation conditions u_0 and the initial trust-region radius Δ_0. Choose constants $0 \le \eta_0 \le \eta_1 < 1$ (with $\eta_1 \neq 0$), $\eta_0' = 2\eta_0$, $\eta_1' = 2\eta_1$, $0 < \gamma_0 \le \gamma_1 < 1$, and termination tolerance ε_t. Set $k \leftarrow 0$, and $\mathcal{E}x = \phi$.

Step 1: Estimate the parameters to obtain $\hat{p}_k$.

Step 2: If $k-1 \in \mathcal{E}x$, then go to Step 3. Calculate sensitivities $\partial p/\partial u_k$. Set $l = k$ and denote $V_l = \partial p/\partial u_k$. Build the local property model with $m_l^p(u) = \hat{p}_k + V_l^T \cdot (u - u_k)$.

Step 3: If $\|\nabla\phi(u_k, \hat{p}_k\| \le \varepsilon_t$, stop. Otherwise, solve problem (2), substituting m_l^p for the property model. Obtain solution u_{k+1}.

Step 4: Apply u_{k+1} to the plant and compute

$$\rho_k = \frac{\phi\big(u_k, p(u_k)\big) - \phi(u_{k+1}, p(u_{k+1}))}{\phi(u_k, \hat{p}_k) - \phi(u_{k+1}, m_l^p(u_{k+1}))} \tag{3}$$

Step 5: Consider the following conditions.

- If $\rho_k < \eta_0$ and $k = l$, then $u_{k+1} \leftarrow u_k$, $\Delta_{k+1} \leftarrow \gamma_0 \Delta_k$.
- If $\rho_k < \eta_0'$ and $k \neq l$, then $u_{k+1} \leftarrow u_k$.
- If $\eta_0 \le \rho_k < \eta_1$ and $k = l$, then accept u_{k+1} as the new iterate, $\Delta_{k+1} \leftarrow \gamma_1 \Delta_k$.
- If $\eta_0' \le \rho_k < \eta_1'$, $k \neq l$ and Eq.(4) holds, then accept u_{k+1} as the new iterate.
- If $\rho_k \ge \eta_1$ and $k = l$, or $\rho_k \ge \eta_1'$, $k \neq l$ and Eq.(4) holds, then accept u_{k+1} as the new iterate, add k to $\mathcal{E}x$, $\Delta_{k+1} \leftarrow \Delta_k$.

Step 6: $k \leftarrow k+1$. If u_{k+1} is accepted, go to Step 1; else if the sensitivities of the current iterate has been calculated, go to Step 3; otherwise go to Step 2.

For convergence of this algorithm, we focus on the iterates where derivatives are not updated. Consider the sequence $\{u_k, u_{k+1}, u_{k+2}\}$, where derivatives are calculated at u_k, which lead to the new iterate u_{k+1}; from this point, u_{k+2} is generated and accepted without updating the derivatives. We have the following results for iterations corresponding to this sequence, which can be easily extended to sequences where more iterates are involved before derivative update.

Remark 1 $\langle \nabla\phi(u_k, p(u_k)), u_{k+2} - u_{k+1} \rangle \le 0$. This is required to ascertain $d' = u_{k+2} - u_k$ is a descant direction.

Remark 2 Based on the above result, the gradient relatedness of d' can be established, i.e. $|\langle \nabla\phi(u_k, p(u_k)), u_{k+2} - u_k\rangle|/\|u_{k+2} - u_k\| = 0$ only if $\|\nabla\phi(u_k, p(u_k))\| = 0$. This is essential for convergence as we do not always calculate and search along the plant derivatives.

Remark 3 The descent along d' is sufficient. Specifically, suppose $\rho_{k+1} \geq \eta_0'$. If for some constant $b \geq 0$,

$$\frac{\phi\left(u_{k+1}, m_k^p(u_{k+2})\right) - \phi\left(u_k, m_k^p(u_{k+2})\right)}{\phi(u_k, p(u_k)) - \phi(u_{k+2}, p(u_{k+2}))} \leq b \tag{4}$$

then

$$\frac{\phi(u_k, p(u_k)) - \phi(u_{k+2}, p(u_{k+2}))}{\phi(u_k, \hat{p}_k) - \phi\left(u_k, m_k^p(u_{k+2})\right)} \geq \eta_0 \tag{5}$$

Setting $b = 1/\eta_0'$ reveals $\eta_0' = 2\eta_0$. Moreover, the same result holds for η_1' and η_1. According to this result, if a new iterate is generated without updating the derivatives and then is accepted, it will be accepted by standard trust-region methods, as well.

With these results, the first order convergence theory of standard trust-region methods is applicable to the dual adaptation algorithm.

4. Numerical results

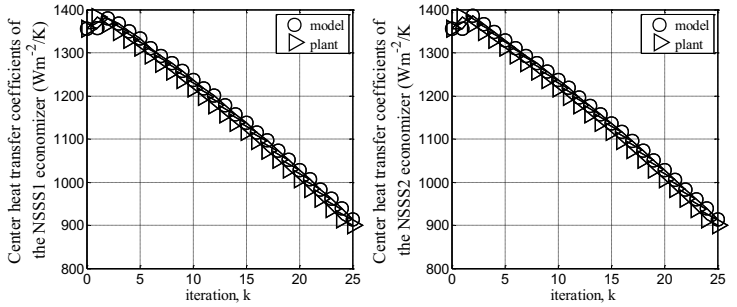
Dual adaptation strategy is applied to implement significant load change of high-temperature gas-cooled reactor pebble-bed module (HTR-PM) (Li, Huang and Zhang, 2008), where both reactors in two nuclear steam supply systems (NSSS1 and NSSS2) are expected to change from 100%RFP (reactor full power) to 50%RFP synchronously. Heat transfer coefficients in HTR-PM model vary with load so that the local model with estimated parameters may not be applicable to the full operating range. Meanwhile, key outputs of HTR-PM are required to stay close to the design values. Consequently, the task should be completed step by step due to safety and operation limits.

The RTO objective function for load change of HTR-PM is defined as the deviations between the model predicted and design values of the key outputs at the target load level. The key outputs include relative nuclear power, outlet helium temperature of the core, outlet steam temperature and pressure of the steam generator, steam temperature and pressure just before the turbine. The freedom for operation leaves to external reactivity, helium inlet flow rate, and feedwater flow rate, and opening of the valve prior to the turbine. At the *k*th iteration, heat transfer coefficients are approximated by Eq.(1) where their estimates $\hat{p}_k$ are calculated from measurements at u_k. The approximated parameters contain process information and affect RTO as expressed in Eq.(2). For comparison, ITS method is also used to realize the same task. Different from dual adaptation strategy, ITS method obtains the model through parameter estimation, based on which it defines the application range of the local model by directly restricting the maximal load change in each RTO step instead of limiting the operation region. Larger step of 8%RFP and smaller of 2%RFP for ITS method are implemented, respectively.

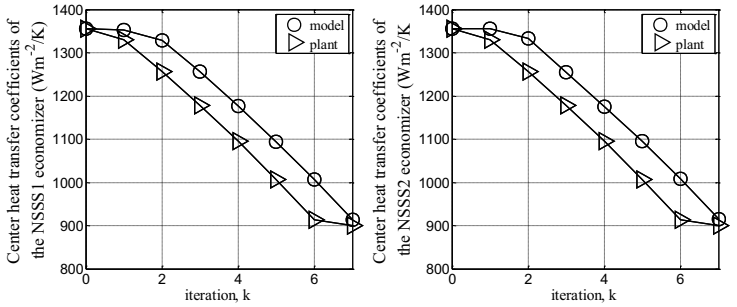
The resulting parameters are presented in Figure 1. As can be seen, ITS method with stepsize of 8%RFP and 2%RFP suffer the largest and smallest parameter mismatch,

respectively. Parameter mismatch from dual adaptation strategy is moderate. Model update is called twice in dual adaptation strategy, which is marked by '*'. One is at the beginning of load change, and the other is after the 3rd iteration when parameter mismatch becomes large.

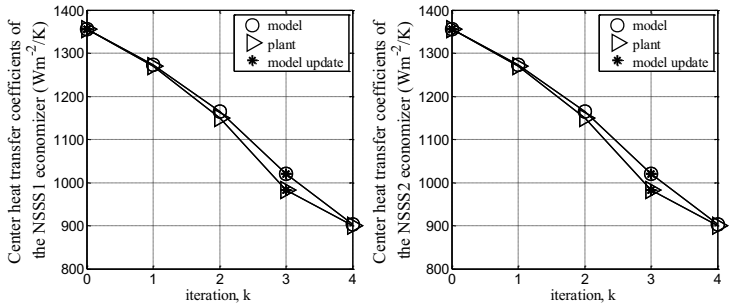
Numerical results by the three strategies are listed in Table 1. In particular, #iter denotes the number of iterations to realize the load change task, and stepsize denotes the sequence of load change in each iteration. Only the maximal parameter mismatch each strategy suffers is listed. The ITS method with stepsize of 8%RFP violates the safety requirements on steam temperature just before the turbine, under the maximal mismatch 10.2%. This indicates the local model in that step is not applicable to the maximal load change of 8%RFP in the next step. Although it is fast with least CPU time and moderate number of iterations, this strategy is not safe for load change of HTR-PM. On the other hand, the other two strategies satisfy the safety requirements during the whole process, where the ITS method with stepsize of 2%RFP suffers the smallest mismatch (i.e. 2.2%), while takes the most CPU time and iterations, which is conservative and inefficient. Dual adaptation strategy takes 4 iterations, which is the least among the three strategies, to realize the significant load change. This can be attributed to its ability in control and maintaining of model accuracy. Note that it costs more CPU time than the ITS methods per iteration, duo to calculation of plant derivatives and possible solution of the RTO problem with more restricted operation regions.



(1a) ITS method with stepsize of 2%RFP



(1b) ITS method with stepsize of 8%RFP



(1c) Dual adaptation strategy

Figure 1. Comparison of model accuracy - heat transfer coefficients

Table 1. Numerical results comparison

Strategy	#iter	Stepsize (%RFP)	Maximal mismatch	Output violation	CPU time (sec)
ITS-2%RFP	25	2	2.2%	-	1019
ITS-8%RFP	7	8 (first 6 steps) →2	10.2%	steam temperature	324
Dual adaptation	4	11→14→17→8	3.8%	-	620

5. Conclusions

We propose dual adaptation strategy to enforce correct convergence of model-based operations when plant-model mismatch is present. Different from ITS method, dual adaptation strategy is engaged in improving model accuracy and determining proper application range of the local model, so as to offer valid operations. In particular, the RTO step is adjusted adaptively to confine optimization to an appropriate operating range, and the local model is updated adaptively as well to avoid big mismatch at reasonable cost. The numerical results of implementing significant load change of HTR-PM shows that dual adaptation strategy is efficient in handling plant-model mismatch, and thus deriving operations with better performance in practice.

Abstract

Integrated design strategy for optimization of utility supply and CO_2 mitigation (USCM) is an important task for companies dispersed spatially in an industrial complex. The integrated strategy considers utility supply sub-strategy such as fossil fuel-based Rankine cycle, and CO_2 mitigation sub-strategy such as CO_2 capture, storage, and utilization systems. This work presents a multi-period deterministic model of the integrated design strategy for optimization of USCM. The proposed model determines where and how much (1) utilities are supplied one company to the others, (2) amount of CO_2 to be captured and transported, and (3) amount of CO_2 to be stored or utilized about the excess value over emissions permits allocated to each company over a multi-period planning horizon. The real scenario of Yeosu Industrial Complex in the Republic of Korea is applied to validate the integrated model. The optimization results will help to determine investment strategies for USCM.

Keywords: deterministic model; multi-period; utility supply; optimization; CO_2 storage; CO_2 utilization.

1. Introduction

In an industrial complex (IC), significant amounts of carbon dioxide (CO_2) have been emitted by the production of many chemicals or fuels, simultaneously consuming large amounts of utility such as steam, electricity, and water (Jung et al., 2012). Utility consumption has to be minimized to reduce the CO_2 emission. Many studies have been carried out to reduce utility consumption by designing the optimized supply chain network for exchanging utilities among companies in the IC (Han and Lee, 2014; Kim et al., 2010). To reduce CO_2 emission directly with indirect reduction of CO_2 caused by utility optimization of supply chain network, carbon capture and storage (CCS) system (Li et al., 2013) have to be considered to meet the CO_2 mitigation target of the IC. Many studies for the carbon mitigation were presented considering the mitigation demand and economics for the systems (Lima et al., 2016; Karimi and Sibudjing, 2016). Among CO_2 migration methods, CCS system, especially CO_2 capture using monoethanolamine (MEA) absorption, consumes large amounts of utility (Sethi, 2017). Moreover, the CCS poses a significant cost burden with the geological limitation on storage of CO_2. As an alternative, carbon capture and utilization (CCU) system is aimed to use CO_2 as a feedstock for production of commodity chemicals or fuels (Gollodi et al., 2017). Microalgae-based biodiesel production via hydrocracking has considered as the primary

one of CCU system, and it also produces by-products, such as naphtha and electricity (R Davis, 2009; Ryan Davis et al., 2011). Biodiesel is a conventional fuel to use in the IC, and by-products from biodiesel production can improve the economics of the IC by sending them as raw material and utility to companies in the IC. Therefore, an integrated network between utility supply (US) and CO_2 mitigation (CM) is needed to reduce CO_2 emission in the IC, and CO_2 utilization as the CM needs to consider for the optimization of the integrated network.

This study presents the development of a deterministic model for the optimal design of an integrated network between US sub-strategy such as fossil fuel-based Rankine cycle and CM sub-strategy such as CO_2 capture (CC), storage (CS), and utilization (CU) systems. The objective of the proposed model is to minimize the expected total cost of the integrated network for meeting USCM demands considering US and CM sub-strategies.

2. Problem definition and formulation

2.1. Problem statement

In this study, a decision-making framework defined as the optimal way is found between the different decision levels, such as USCM strategies over the multi-period planning horizon. A source company with sub-nodes such as chemical plant, US system, and CM strategies, and a sink company with the same sub-nodes excluding the US system are considered in this study. CM strategies can be classified into three types: CC system captures CO_2 directly from the off-gas in each company (MEA-based absorption); CS system transports and stores CO_2 captured from CC system (storage in depleted oil and gas reservoirs); CU system transports and utilizes CO_2 captured from CC system to produce CO_2-based products (biodiesel).

2.2. Model formulation

2.2.1. Objective function

$$\text{Minimize } \text{Cost}^{\text{total}} = \text{Cost}^{\text{utility supply}} + \text{Cost}^{\text{CO}_2\text{ mitigation}}. \quad (1)$$

The objective function consisted of utility supply and CO_2 mitigation network cost and all of the model notations are shown in Table 1.

2.2.1.1 Utility supply network

$$\text{Cost}^{\text{utility supply}} = \text{Cost}^{\text{utility onsite}} + \text{Cost}^{\text{utility offsite}}. \quad (2)$$

$$\text{Cost}^{\text{utility onsite}} = \text{FICU} + \text{FOCU} + \text{VICU} + \text{VOCU} + \text{RMCU}. \quad (3)$$

$$\text{Cost}^{\text{utility offsite}} = \text{ESC}. \quad (4)$$

Utility supply network cost consisted of onsite and offsite utility supply network cost including fixed capital and operating, variable capital and operating, raw material, and external steam cost.

2.2.1.2 CO_2 mitigation network

$$\text{Cost}^{\text{CO}_2\text{ mitigation}} = \text{Cost}^{\text{CC}} + \text{Cost}^{\text{CS}} + \text{Cost}^{\text{CU}}. \quad (5)$$

$$\text{Cost}^{\text{CC}} = \text{ICC} + \text{OCC} + \text{RMCU}. \quad (6)$$

$$\text{Cost}^{\text{CS}} = \text{TCC} + \text{SCC}. \quad (7)$$

Table 1. Model notation

b	utilization site	i	company	r	green emission
d	boiler	l	stage	t	time
h	company	p	steam	u	carbon capture

gamma	Emission allocated rate (%)
$N_{t,i,a,m}^{initial_{inventory}}$	Initial inventory of fuel (t)
$x_{t,i,r}^{ir}$	Flue gas amount at company (t/y)
$Cost^{total}$	Total cost of proposed model ($/y)
$Cost^{utility\ supply}$	Total cost of utility supply network ($/y)
$Cost^{CO_2\ mitigation}$	Total cost of CO_2 mitigation ($/y)
$Cost^{utility\ onsite}$	Total cost of utility onsite supply network ($/y)
$Cost^{utility\ offsite}$	Total cost of utility offsite supply network ($/y)
FICU, FICCU	Fixed investment cost of US and CU system ($/y)
FOCU, FOCCU	Fixed operating cost of US and CU system ($/y)
VICU, VOCU	Variable investment, operating cost of US system ($/y)
RMCU, RMCC, RMCCU	Raw material cost of US, CC, and CU system ($/y)
$Cost^{CC}$, $Cost^{CS}$, $Cost^{CU}$	Total cost of CC, CS, and CU system ($/y)
ICC, OCC	Investment and operating cost of CC system ($/y)
TCC, TCCU	Transportation cost of CC and CU system ($/y)
SCC	Storage cost of CO_2 in CS system ($/y)
BCU, ESC	Benefit and external steam cost of CU system ($/y)
$RI_{t,i,a,m}$	Required amount of fuel (t/y)
$x_{m_{t,i,a,m,"OUT"}}^{a}$	Requirement of fuel at the fuel tank (t/y)
$x_{t,i,d,r,l}^{dr}$	GHG amount at boiler (t/y)
$x_{p_{t,i,e,p,l}}^{e}$, $x_{n_{t,i,e,wt,l}}^{e}$	Steam and water amount at turbine (t/y)
$z_{t,i,u,r,l}^{ur\ cc}$	Captured gas amount at CC system (t/y)
$z_{t,i,h,r,l}^{ur\ cs}$, $z_{t,i,b,r,l}^{ur\ cu}$	Captured gas amount entering CS and CU system (t/y)

$$Cost^{CU} = FICCU + FOCCU + RMCCU + TCCU - BCU. \quad (8)$$

CO_2 mitigation network cost consisted of CC, CS and CU system cost including invest, operating, raw material, transportation, storage cost and benefit.

2.2.2. Constraint

2.2.2.1 Boiler and turbine

$$RI_{t,i,a,m} = x_{m_{t,i,a,m,"OUT"}}^{a} - N_{t,i,a,m}^{initial_{inventory}}. \quad (9)$$

$$x_{p_{t,i,e,"HS","IN"}}^{e} = x_{p_{t,i,e,"MS","OUT"}}^{e} + x_{p_{t,i,e,"LS,"OUT"}}^{e} + x_{n_{t,i,e,"wt","OUT"}}^{e}. \quad (10)$$

The required amount of fuel is calculated between the requirement of fuel and initial inventory at each company. And the amount of high-pressure steam entering turbine is equal to the summation of medium and low-pressure steam and water leaving turbine.

2.2.2.2 CO_2 emission

$$\left(1 - \frac{gamma}{100}\right)\left(\sum_d x_{t,i,d,r,l}^{dr} + x_{t,i,r}^{ir}\right) = \sum_u x_{t,i,u,r,l}^{ur\ cc}. \quad (11)$$

The amount of CO_2 emission from production process of target product and utility system to the atmosphere can be emitted by emission permits allocated to each company.

2.2.2.3 CO_2 mitigation

$$\sum_u z^{ur\ cc}_{t,i,u,r,"OUT"} = \sum_{pt} z^{ur\ cs}_{t,i,pt,"CO2","IN"} + \sum_{brr} z^{ur\ cu}_{t,i,b,"CO2","IN"}. \quad (12)$$

The amount of CO_2 from CC system can be mitigated by CS and CU systems.

3. Results and discussion

3.1. Case study

To demonstrate the validity of the deterministic model considering USCM strategies, the case study of the Yeosu Industrial Complex (YIC), which is adopted as a benchmark to apply the real scenario in the Republic of Korea from the previous studies (Han and Lee, 2014; Kim et al., 2010), conducted to satisfying the USCM demands over multi-period in a year. This study considers (1) multi-site both demands, (2) company types with different utility systems, (3) CO_2 mitigation methods, and (4) single site for storage and multi-site for utilization. The companies located in YIC are composed five types (A, B, C, D, and E) with different specifications of the utility system. From A to D types of companies have various kinds of boilers and turbines, and they can produce utilities and meet their US demand by themselves. However, E type of the company does not have boiler and turbine and must meet its US demand by an external source. CM strategies jointly use the CC system and decide whether to use CS or CU system to mitigate CO_2. The simulation results were evaluated by applying the model using GAMS (CPLEX 12.6) on a computer with Intel® Core ™ i7-7700 CPU@3.60 GHz and 16 GB RAM. The optimization results for the deterministic model of CSCU sub-strategy were compared with the CS-only sub-strategy regarding (1) optimal cost (Table 2), (2) amounts of CO_2 mitigation (Table 3), and network flows for steam and CO_2 (Fig. 1).

3.2. Optimal cost

Table 2 showed USCM costs within total cost for CS-only and CSCU sub-strategies. Total cost for CSCU sub-strategy (US$ 181.19 x 10^6/y) was 8.5 % lower than the CS-only sub-strategy (US$ 197.96 x 10^6/y).

Table 2. Comparison of optimal costs between only-CS and CSCU strategies.

		Strategy (million US$/y)	
System	Cost	Only-CS	CSCU
Utility supply	Raw material	127.40	126.77
	Investment	0.52	0.57
	Operating	7.17	7.23
CC	Raw material	41.87	42.78
	Investment	19.24	21.23
	Operating	0.09	0.10
CS	Operating	1.67	1.55
CU	Raw material	-	31.10
	Investment	-	45.01
	Operating	-	19.33
	Benefit	-	-114.47
Total		197.96	181.19

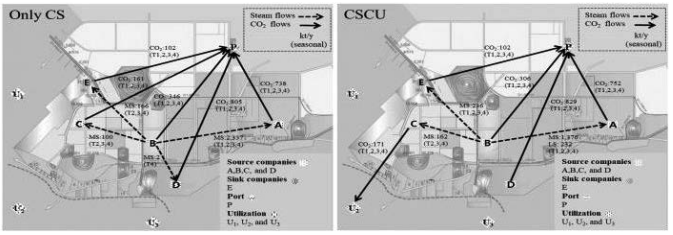

Figure 1. Comparison of network flows between five companies for only-CS and CSCU strategies.

The cost of US for CSCU sub-strategy (US$ 134.58 x 10^6/y) was 0.37 % lower than the CS-only sub-strategy (US$ 135.08 x 10^6/y). Notably, there was a distinct cost difference for the cost of CC system between CS-only and CSCU sub-strategies. The cost of CC system for CSCU sub-strategy (US$ 64.11 x 10^6/y) is 4.74 % (US$ 2.9 x 10^6/y) higher than the CS-only sub-strategy (US$ 61.21 x 10^6/y).This results showed that the amount of utilities used by the particular company (C type) is determined to provide the amounts of CO_2 demand in CU system and the larger capacity of CC system deployed in the other company (D type) than the previous capacity in order to satisfy the USCM demands of all companies through the network.

3.3. Network structure

In Table 3, the results showed that the CM amounts for CSCU strategy decreased compared to the result for only-CS strategy. The amount of CO_2 used in the CU system is 0.17 million t/y for only one of biodiesel production systems. Currently, the proposed model in the study was developed to select one system between CS and CU systems. If CU system was selected in a certain company, a utility system included in the company is implemented to emit the amount of CO_2 needed in one number of biodiesel production system. The details in steam and CO_2 flows among five companies, one port, and three utilization sites for only-CS and CSCU strategies were shown in Fig. 1. It shows that the USCM strategy has changed for satisfying the USCM demands in the IC. When comparing the only-CS and CSCU strategies, the specific portion is that the number of steam and CO_2 flows in CSCU strategy was different from only-CS strategy.

The number of steam flows decreased (only-CS: 4; CSCU: 3), and CO_2 flow to storage site decreased (only-CS: 5; CSCU: 4) and increased for utilization site (only-CS: 0, CSCU: 1) (Fig. 1). To provide the CO_2 required by the CU system, the CO_2 captured by the company C was provided to U_2 utilization site, and changes for the amount of utility exchanged and CO_2 captured can be confirmed to meet all USCM demands in the IC.

3.4. Sensitivity analysis for variation of biodiesel price

The most important parameter in this study is biodiesel price because it has the high influence to the benefit from the selling of biodiesel produced from the CU system. The CU system could be constructed in three sites, where the number of systems that could be constructed was limited to one. According to the limitation of construction for CU system, this system can produce the limited amount of the biodiesel.

Table 3. Comparison of the amounts of CO_2 mitigation between only-CS and CSCU strategies.

	Strategy (million t/y)	
	Only CS	CSCU
Storage	2.15	1.99
Utilization	-	0.17

Table 4. Sensitivity analysis of biodiesel prices for CSCU strategy.

Price ($/gallon)	Total cost (M$/ton)	CU system
11.73	181.19	O
11	187.93	O
10	197.19	O
9.9	197.96	X

Therefore, the construction of the CU system to produce biodiesel is determined by the price of biodiesel (Table 4). When the price of biodiesel is less than US$ 10/gallon, CS system is more economical than CU system in order to mitigate CO_2 because the cost of CU system is higher than that of CS system.

4. Conclusion

To find an optimal solution for the integrated network for USCM strategies, the deterministic model was developed. The goal of the proposed model is to minimize the expected total cost of the integrated network to meet the USCM demands. Comparison of the results between CS-only and CSCU sub-strategies was presented. To utilize captured CO_2, changes in the amount of utility transport and CO_2 capture occurred in the IC, and the biodiesel price has a significant influence on the use of CSCU strategy for CO_2 mitigation. As a further study, it will be possible to expand the model considering the alternatives in US system (renewable energy-based fuels) and CM system (biomass-based chemicals).

Abstract

In this study, we aim to design and analyze a comprehensive biomass-derived hydrogen energy system considering all processes from biomass collection to hydrogen storage or transport, and different biomass types. In addition, we compare the economics of this system with that of other non-renewable/renewable hydrogen energy systems to evaluate the feasibility of the proposed energy system. To achieve this goal, we first develop an optimization model using a mixed-integer linear programming (MILP) technique, then apply this model to the future hydrogen economy of Korea. We confirmed that biomass availability for hydrogen production is one of the critical factors in determining the configuration of the proposed energy system, contrary to a typical hydrogen energy system controlled mainly by hydrogen demand. Hydrogen supply cost is $23.1/GJ, and the main cost driver is the annualized capital cost of technology (35 %). While the hydrogen supply cost of the proposed energy system is higher than that of conventional routes ($10.3–14.7/GJ), it is more efficient than other renewable options (wind power: $25.5/GJ, Photovoltaic (PV): $34.0/GJ).

Keywords: Biomass, Hydrogen, Optimization model, Economic analysis, Korea

1. Introduction

Hydrogen is one of the most promising energy carriers in that it can provide both chemical and environmental advances: high specific energy (~142 MJ/kg) and zero carbon dioxide (CO_2) emission during combustion (Kim and Kim, 2016). Harnessing renewable energy sources (RES) for hydrogen production can maximize the strengths of a hydrogen energy system by integrating the merits of hydrogen and RES. Among different RES, biomass can be a main resource since it has the capability of being sustainably mass produced due to its regional abundance (Cho and Kim, 2015). Because of such an advantage, there are several studies on biomass-based hydrogen energy systems. Some researchers have analyzed the efficiency of technologies that convert biomass to hydrogen (Duman et al., 2014) and others have conducted techno-economic analysis of conversion technologies (Abuadala and Dincer, 2012). The previous studies focused mainly on improving the conversion efficiency or assessing the economics of hydrogen production technologies. However, to design the biomass-based hydrogen energy system as an alternative energy

system, researchers should perform an all-inclusive study taking other processes into consideration (e.g. cultivation of biomass crops and collection or hydrogen storage and transport) as well as the conversion process. Furthermore, they should include several biomass types such as residue or energy crop to ensure a stable biomass supply and to assess the feasibility of the biomass-based hydrogen energy system. Hence, in this study, we design a comprehensive biomass-derived hydrogen energy system using an optimization model and estimate the competitiveness by comparing the economics of the proposed energy system with that of other systems.

2. A biomass derived hydrogen energy system

A biomass-derived hydrogen energy system (Fig. 1) comprises different materials (i.e. biomass and hydrogen) and technologies (i.e. biomass storage, hydrogen production, hydrogen storage).

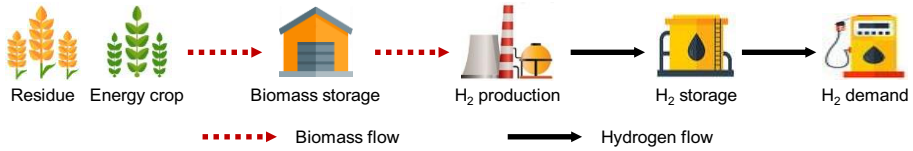

Fig. 1 The structure of the biomass derived hydrogen energy system

In this study, we consider two types of biomass: residue and energy crop. Residues are wastes obtained from other activities: e.g., a stump from a lumber field or woodchip from the paper industry. Although such resources are easily obtained, the amounts available for hydrogen production are limited by the fact that residues are widely used for different purposes (e.g. as a feed or a fertilizer). Energy crops mean additional resources which are not currently utilized but could be used for the sole purpose of hydrogen production. Even though, unlike residues, these types of biomass are freely utilized without limitation, several activities such as cultivation or crop harvesting are needed to make them fit for use as resources. Note that we do not consider food crops which can create a conflict between food and energy. There are three types of technologies. The properties of biomass (e.g., humidity or size) are maintained in biomass storage, and the handled biomass is transported to production technology. In this study, we choose a gasification process including gas cleaning, reforming, water gas shift reaction, and pressure swing adsorption as the conversion technology due to its easy operation and high economics. The hydrogen that is produced is stored in a hydrogen storage and used to satisfy the final hydrogen demand. As a hydrogen storage technology, we choose a liquid hydrogen storage because it has both high energy density and cheap transportation cost (Almaraz et al., 2014).

3. Optimization model

In this study, we develop an optimization model based on a typical hydrogen supply chain model. The objective function is to minimize the total annual cost required for establishing the proposed energy system.

$$TAC = BSC + ACC + TOC + TRC \tag{1}$$

where TAC is the total annual cost, BSC is the biomass supply cost required for collecting residue or utilizing energy crops, ACC is the annualized capital cost of technology, TOC

is the total operating cost of a technology, and *TRC* is the transportation cost. In this study, we develop a snapshot model that does not consider the time changes. There are four main constraints: 1) mass balance, 2) demand satisfaction, 3) resource availability, and 4) technology capacity.

3.1. Mass balance & demand satisfaction

$$B_{il} = \sum_{j \in J^B} \sum_{l' \in L} Q_{iljl'} \quad \forall i \in I, l \in L \tag{2}$$

where B_{il} is the amount of biomass I from all regions L, $Q_{iljl'}$ is the transported amount.

$$P_{jl'} = \sum_{i \in \left\{I, J^B, J^H\right\}} \sum_{l \in L} \alpha_j Q_{iljl'} \quad \forall j \in \left\{J^B, J^H, J^S\right\}, l' \in L \tag{3}$$

where the amount ($P_{jl'}$) produced in each technology (biomass storage J^B, hydrogen production J^H, and hydrogen storage J^S) is calculated by the transported amount from the previous process; for example, the amount of hydrogen produced in J^H is calculated by the amount transported from biomass storage J^B to hydrogen production. α_j is the process efficiency.

$$\sum_{j \in J^S} P_{jl'} \geq \rho_{l'} \quad \forall l' \in L \tag{4}$$

where the amount of hydrogen stored at J^S in all regions must be greater than or equal to the hydrogen demand ρ in all regions.

3.2. Resource availability

$$B_{il} = R_{il} + E_{il} \leq \upsilon_{il} \quad \forall i \in I, l \in L \tag{5}$$

where R_{il} is the amount of residues, E_{il} is the amount of energy crops, and υ_{il} is the available amount of both residue and energy crops in all regions.

3.3. Technology capacity

$$C_j^{min} N_{jl'} \leq P_{jl'} \leq C_j^{max} N_{jl'} \quad \forall j \in J, l' \in L \tag{6}$$

where the produced amount of biomass or hydrogen is subject to the minimum (C_j^{min}) and maximum capacities (C_j^{max}) of the corresponding technologies, and $N_{jl'}$ is the installed number of technologies in all regions.

4. Case study: Korean hydrogen economy from biomass

4.1. Hydrogen demand and biomass availability

In this study, we selected 15 Korean provinces as a case study and modified the demand used in our previous work (Kim and Moon, 2008)**.** The value is presented in Table 1. Here, residues can be divided into two types: woody residue and non-woody residue. While woody residue consists of lignocellulosic biomass like stumps or wood chips, non-woody residue, as an herbaceous biomass, includes straws, husks and reeds. The unit supply cost of residues is assumed to be $30/dry ton, and the total amounts available for hydrogen production can be found in Table 1. We also consider five types of energy crops:

corn stover, sugarcane bagasse, switchgrass, *Miscanthus*, and poplar. The information on energy crops can be found in Table 2.

Table 1. Hydrogen demand and biomass availability in different regions

Region	L1	L2	L3	L4	L5	L6	L7	L8
Hydrogen (ton/yr.)	130	42	30	41	20	23	16	200
Biomass (kton/yr.)	0.4	0.3	0.3	0.2	0.2	0.1	0.2	2.2
Region	L9	L10	L11	L12	L13	L14	L15	
Hydrogen (ton/yr.)	18	19	29	19	19	32	44	
Biomass (kton/yr.)	5.6	1.4	1.5	1.7	2.2	4.5	2.2	

Table 2. Technical and economic data of energy crops (Cheng and Timilsina, 2011)

	E1	E2	E3	E4	E5
Unit supply cost ($/ton)	74.5	192.7	58.3	41.3	130.2
Cultivation yield (ton/km^2)	667	934	1,357	1,334	1,112
By-product credit ($/ton)*	0.2	0.3	-	-	-

E1: corn stover, E2: sugarcane bagasse, E3: switchgrass, E4: Miscanthus, E5: popular
*: by-product credit means an additional benefit gained by selling the food crops.

4.2. Technology data

The economics of hydrogen production technology is largely contingent dependent on the type, capacity, and location. Hence, in this study, we adapted the technical values by taking into account the scale of the case study. The relevant data on the technologies is shown below in Table 3.

Table 3. Technical and economic data of all technologies (Won et al., 2017)

	B1	B2	H1	H2	S1	S2
Capacity (1,000 ton/yr.)	52	189	175	350	7	14
Capital cost (million $)	5	10	69	105	8	12
Operating cost ($/ton)	15	15	140	140	15	15
Lifetime (yr.)	20	20	15	15	20	20

B: biomass storage, H: hydrogen production, S: hydrogen storage

5. Results

We designed the biomass derived hydrogen energy system using a mathematic model. Table 4 shows the cost contributions of the proposed energy system. The total annual cost is 2.2 billion $/year, and the unit hydrogen supply cost is $23.1/GJ. Among all cost drivers, annualized capital cost of technology (ACC) accounts for 35 % of total annual cost. From this result, we identified that the economics of the proposed energy system largely depend on the capital cost of technologies.

Table 4. Cost distribution of the proposed energy system (million $/year)

	Biomass supply cost (BSC)	Annualized capital cost (ACC)	Technology operating cost (TOC)	Transport cost (TRC)	Total annual cost (TAC)
Value	449	778	304	372	2,233

As shown in Fig. 2, all technologies were installed in 14 regions, but not in L1. In particular, hydrogen production technology (H1 or H2) is primarily installed in L9 and

L14, where biomass availability is high. In addition, biomass or hydrogen storage facilities are installed close to production technology. From these results, we confirmed that installing technology in each region is more economical than transporting all materials between regions.

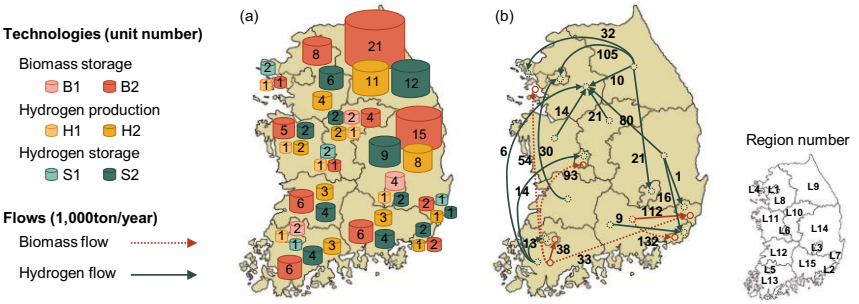

Fig. 2 (a) System configuration and (b) biomass or hydrogen flows

In this study, we suggest a strategy regarding energy crop supply detailing which type of energy crops should be cultivated in order to secure a stable supply. We increased the hydrogen demand up to 24 % from the baseline to identify the change in selected types. As shown in Fig. 3, residues are used as much as possible regardless of hydrogen demand, and the unmet demand is fulfilled by energy crops. To elaborate, when the demand of energy crop is relatively small, energy crops with by-product credit (E2) and low supply cost (E4) are selected. On the other hand, when the demand is high, the energy crop with a high cultivation yield (E3) is selected to produce as much hydrogen as possible.

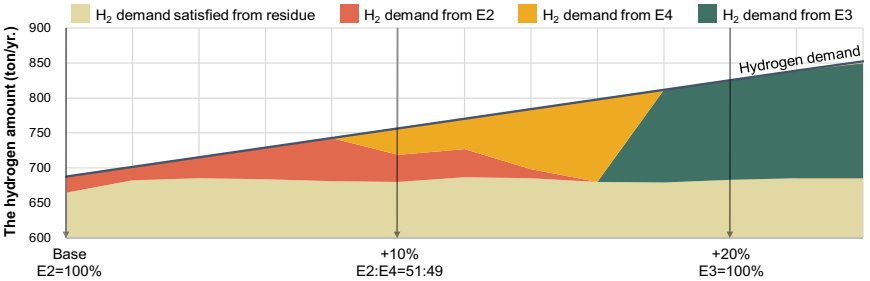

Fig. 3 Supply strategies of energy crops with demand change

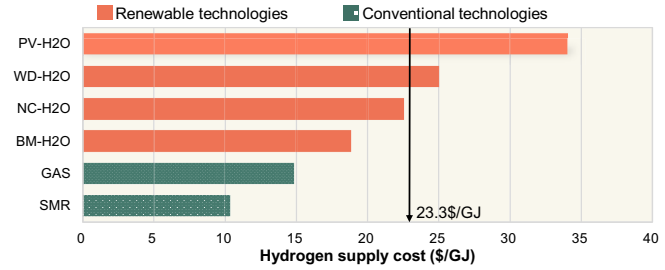
Even though basic design and analysis are critical in establishing the biomass derived hydrogen energy system, it is also crucial to evaluate the feasibility of the proposed energy system by comparing the economics with those other systems.



PV-H2O: H_2 via PV electrolysis, WD-H2O: H_2 via wind electrolysis, NC-H2O: H_2 via nuclear electrolysis, BM-H2O: H_2 via biopower electrolysis, GAS: coal gasification, SMR: steam methane reforming

Fig. 4 Comparison of hydrogen supply cost in different technologies

According to Fig. 4, while using steam methane reforming (SMR) process is the cheapest pathway, using Photovoltaic-power (PV) for water electrolysis is required but has the highest supply cost. The hydrogen supply cost in this study is $23.1/GJ, and the value is cheaper than wind and PV based routes, but is more expensive than others. From this, we concluded that the biomass derived hydrogen energy system can be a viable alternatives based on the assumption that the conversion efficiency will be improved.

6. Conclusions

In this study, we designed and analyzed the comprehensive biomass-derived hydrogen energy system, considering all processes from biomass collection to hydrogen storage or transport and different biomass types. The major findings and contributions of this study are as follows:

- Most technologies are located in the regions where biomass availability is high rather than in the regions with high hydrogen demand, and the main cost driver of the proposed energy system is the technology capital cost.
- When the required amount of energy crop is small, the crops with subsidiary benefits and low supply cost are preferred. However, in cases of high hydrogen demand, the crops with high cultivation yield are selected to obtain as much hydrogen as possible.
- Compared to other renewable hydrogen options, the biomass-derived hydrogen energy system may be a promising technology.

This study provides a baseline model for the biomass-based hydrogen energy system. Although such fundamental design and analysis are useful, further rigorous study should be conducted to evaluate practical obstacles to the proposed energy system. In future, we will revise the optimization model in terms of several critical variables like demand uncertainty, change of biomass productivity, and improvement in conversion efficiency.

Abstract

In this paper, a resource utilization and supply chain optimization framework is presented. The reported MILP framework incorporates novel formulation techniques to address several complexities, such as, container utilization, vehicle capacity utilization, transit time, warehouse capacity & license limitation etc., which are part of any industrial supply chain. The results demonstrates the efficacy of the proposed framework in addressing several limitations & complexities that can arise in liquefied gaseous product supply chain. However, the presented approach requires more computationally efficient formulation techniques and that paves the way for future research in this domain.

Keywords: Stock Keeping Unit, Inventory Management, Distribution Scheduling.

1. Introduction

The liquefied gaseous products are transported in different type of cylinders or equivalent containers (such as, tonner, drums etc.).These containers vary in size, capacity, storing mechanisms etc. These containers are used for a specific products and have their own unique tracking IDs (contains the information regarding the product, manufacturer, etc.) attached to improve the efficiency and transparency of the inventory system. A specific container attached with uniquely identifiable bar code are called as, stock keeping units (SKU) (Sawaya and Giauque 1986). These SKUs are bottled in a plant, then transported to various warehouses using trucks or ships. The filled SKUs are sent to customers and empty SKUs are picked up from the customer and returned to the warehouse. Warehouse stores both filled & empty SKUs. As the SKUs are reusable, these empty SKUs are sent back to the plant for refilling purpose. The entire upstream and downstream network can become very large and complex, and often it has been noted that total transportation and distribution costs become quite higher compared to the actual production cost of the product (Samuelsson 2016). So, to attain an overall minimum transportation and distribution cost while maintaining a sustainable supply chain that ensures an efficient utilization of the assets, an optimum logistics & distribution schedule is necessary.

In recent past a few attempts has been made, to optimize the supply chain network for packaged gas. Singh et al. (2015) proposed a decomposition based framework to calculate optimum plant locations, production capacities, inventories & number of packages to be routed in distribution network. However, their algorithm does not focus on optimum logistics or distribution schedule. In a similar tone, Samuelsson (2016) presents a framework to optimally design the logistics network of a leading air separation industry, using an MILP framework. However, the approach does not provide any delivery

schedules. It also directly considers the product & does not provide any insight regarding SKU capacity or vehicle capacity utilization.

There are various bottlenecks in the above-mentioned supply chain which can be improved considerably using optimization techniques. The main characteristics and limitations of this supply chain are: 1) the delivery period can range from days to months, 2) limited storage space at warehouse as well as at customer location, 3) inventory for both filled and empty SKUs at warehouse needs to be maintained as the SKUs are reusable, 4) filled SKUs are sent to customer locations according to their demand & consumption profiles and demands need to fulfilled at any cost, 5) filled SKUs are sent to the customers using trucks or other vehicles in supply trip and empty SKUs needs to be carried back on the return trip, 6) SKU transport capacity for every vehicles according to the types and configurations needs to be respected, 7) Some liquefied gaseous products can be inflammable or hazardous and need special licenses to stock at warehouse.

The main objective of the optimization of this supply chain is to reduce the logistics (plant to warehouse transportation by ship or trucks) and distribution (warehouse to customers by truck or smaller vehicles) costs by proper utilization of available resources (SKUs) in the supply chain while respecting above mentioned constraints and limitations.

A mathematical formulation, to represent the above mentioned characteristics, is presented in the following. Though the formulation below is posed as an MILP, the framework is integer variable dominant, as the variables, to represent the number of trips to be executed or number of SKUs needed to be transported, have to be integer variables.

2. Formulation

A set of SKUs $k \in K$ carrying a set of products/items $i \in I$ are stocked in a set of warehouses $m \in M$. The SKUs are product specific, i.e. an SKU k can only be used for an item i. So, in the following formulation k will denote both the SKUs and the associated products. The empty SKUs in the warehouses are sent to the packaging centres $s \in S$ using ships. In the plant location the empty SKUs are filled and sent back to the warehouses by the same ships. So, the total travel time includes the onward & return journey time between the warehouses and the plants and the time required for filling the SKUs. The filled SKUs from the warehouses are then sent to the customer locations $c \in C$ using the delivery trucks. Both trucks & ships are part of a set of delivery vehicles denoted as $v \in V$. The trucks deliver the filled SKUs at customer locations and bring the used and empty SKUs back on its return journey. The waiting time required for delivering filled and collecting empty SKUs from customer locations are assumed negligible.

2.1. Stock Balance - Warehouse

Both filled & empty SKUs stocks are stored at warehouse. To maintain a steady supply chain, the more SKUs the warehouse can stock is the better. However, the trade-off is with the storage area expansion cost. Moreover, as the products are generally hazardous, special licenses, specifying maximum SKUs that can be stored, needs to be acquired.

$$FMQ_{m,k,d} = FMQ_{m,k,d-1} + \sum_{\substack{s=1 \\ (:MS_{m,s}=1)}}^{S} \sum_{\substack{v=1 \\ (:VT_v=0)}}^{V} SMSup_{s,m,v,k,(d-\sum_{a=1}^{A} TT_{m,s,v,a})} + \sum_{s=1(:MS_{m,s}=1)}^{S} SMPastSup_{m,s,k,d} - \sum_{r=1(:MR_{m,r}=1)} \sum_{v=1(:VT_v=1)}^{V} FMRDis_{m,r,v,k,d} + Add_{m,k,d} \quad \forall m,k(:MK_{m,k}=1), d(:d=1..ND) \tag{1}$$

Equation 1 describes the filled SKU inventory balance at warehouse. The variable, $FMQ_{m,k,d}$ indicates the inventory of SKU type k at a given day d at warehouse m. Similarly, the inventory balance for empty SKUs are expressed in Equation 2,

$$EMQ_{m,k,d} = EMQ_{m,k,d-1} - \sum_{\substack{s=1 \\ (:MS_{m,s}=1)}}^{S} \sum_{\substack{v=1 \\ (:VT_v=0)}}^{V} SMSup_{s,m,v,k,d} + \sum_{c=1(:MC_{m,c}=1)}^{C} RMPastDis_{m,r,k,d} + \sum_{r=1(:MR_{m,r}=1)} \sum_{v=1(:VT_v=1)}^{V} EMRDis_{m,r,v,k,d} \quad \forall m,k(:MK_{m,k}=1), d(:d=1..ND) \tag{2}$$

The empty SKUs collected from the customers are added in the empty SKU storage. These SKUs are then sent to the suppliers for refilling. The framework presented here can also include an option to facilitate the sale of extra empty SKUs in the supply chain. The maximum number of SKUs (both filled & empty) that can be stored in a warehouse at any day is limited by two factors: 1) storage capacity, 2) license for maximum storage. The former one is generally a hard constraint, while the second one is a soft constraint, i.e. the maximum stock limitation dictated by the license that can be increased by incurring suitable costs. The following equation calculates the maximum license violation in the entire horizon, which will then be minimized as a part of the objective function with suitable costs.

$$XML_{m,l} \geq \sum_{\substack{k=1 \\ (:KL_{k,l}=1)}} (FMQ_{m,k,d} + EMQ_{m,k,d}) - MLMax_{m,l} \qquad \forall m,l,d(d=1..ND) \tag{3}$$

The variable $XML_{m,l}$ denotes the extra licenses that need to be bought for a specific type of SKU $l \in L$. In this algorithm SKUs are considered as product specific, so similar type of SKUs, used for different products, are considered as different entities. The warehouses also required to maintain a minimum stock of filled SKUs to avoid disruption in the supply chain. The safety stock limitation constraints are represented using Equation 4.

$$FMQ_{m,k,d} \geq MinMK_{m,k} \qquad \forall m,k(:MK_{m,k}=1), d(:d=1..ND) \tag{4}$$

2.2. Vehicle Capacity Utilization

The entire distribution area associated with certain warehouse are divided into multiple regions based on the customer locations. This segregation of the distribution area reduces the rigorous vehicle routing effort which is needed to account single and multi drop scenarios. The assumption here is, once the vehicle reaches a particular region, all the customer in that region will be catered within a day. In this framework regions act as a virtual secondary distribution centres from where the customers can be catered without any delay. So, instead of a direct customer to warehouse suitability, connections between warehouse & region and region & customers are established. Each vehicle can carry a certain amount of SKUs in a trip. The minimum & maximum number of SKUs that can carried by a vehicle for a certain trip is dictated by the configurations. We introduce an

integer variable $y_{m,r,v,x,d}$ which indicates the number of trips that has been made from plant m to region r in vehicle type v with configuration x day d .The SKU quantity that can be carried on that trip is limited by the following equations,

$$\sum_{k=1(:KG_{k,g}=1)}^{K} FMRDis_{m,r,k,v,d} \geq \sum_{x=1(:VCap_{v,x,g}^{min}>0)} y_{m,r,v,x,d} * VCap_{v,x,g}^{min} \quad (5)$$
$$\forall m, r(:MR_{m,r}=1), v(:VT_v=1 \text{and} MRV_{m,r,v}=1), g(:VG_{v,g}=1), d(:d=1..ND)$$

$$\sum_{k=1(:KG_{k,g}=1)}^{K} FMRDis_{m,r,k,v,d} \leq \sum_{x=1(:VCap_{v,x,g}^{max}>0)} y_{m,r,v,x,d} * VCap_{v,x,g}^{max} \quad (6)$$
$$\forall m, r(:MR_{m,r}=1), v(:VT_v=1 \text{and} MRV_{m,r,v}=1), g(:VG_{v,g}=1), d(:d=1..ND)$$

Similar equations can be written for empty SKUs. As, the same vehicle picks up the empty SKUs from the customer locations, vehicle configurations at the return trips (customer to warehouse) are same as the onward trips (warehouse to customer). However, the number of SKUs carried in each vehicle can be different in return trips from the onward trips. The limitations in the logistics part can also be described using equation similar to Equation 5 & 6. The SKUs supplied from the warehouse reach the customer regions after a stipulated time indicated by the parameter $RTT_{m,r,v,a}$.

$$\sum_{m=1(:MR_{m,r}=1)}^{M} \sum_{v=1(:VT_v=1)}^{V} FMRDis_{m,r,v,k,(d-\sum_{a=1(:ATT_{ta}=1)}^{A} RTT_{m,r,v,a})} = \sum_{c=1(:CR_{c,r}=1)}^{C} FRCDis_{c,k,d} \quad (7)$$
$$\forall r, k, d(:d=1..ND)$$

Similarly, the empty SKUs from all the customers in that region are collected and sent to the warehouses associated with that region.

$$\sum_{m=1(:MR_{m,r}=1)}^{M} \sum_{v=1(:VT_v=1)}^{V} EMRDis_{m,r,v,k,(d+\sum_{a=1(:ATT_{ta}=0)}^{A} RTT_{m,r,v,a})} = \sum_{c=1(:CR_{c,r}=1)}^{C} ERCDis_{c,k,d} \quad (8)$$
$$\forall r, k, d(:d=1..ND)$$

2.3. Stock Balance – Customer Location

The inventory balance for filled and empty SKUs are also formulated for each customer locations. The continuous variables $FCQ_{c,k,d}$ and $ECQ_{c,k,d}$ indicate the filled & empty SKU inventory, at each customer location at every day, respectively in Equation 9 & 10.

$$FCQ_{c,k,d} = FCQ_{c,k,d-1} + FRCDis_{c,k,d} - DD_{c,k,d} + \sum_{m=1}^{M} MCPastDis_{m,c,k,d} \quad (9)$$
$$\forall c, k(:CK_{c,k}=1), d(:d=1..ND)$$

$$ECQ_{c,k,d} = ECQ_{c,k,d-1} - ERCDis_{c,k,d} + DD_{c,k,d} \quad (10)$$
$$\forall c, k(:CK_{c,k}=1), d(:d=1..ND)$$

The parameter $DD_{c,k,d}$ indicates the daily consumption of the product at every customer location in terms of SKU. The following constraint addresses the safety stock limitations at customer locations.

$$FCQ_{c,k,d} \geq UP_{c,k} - 1 \quad (11)$$

The parameter $UP_{c,k}$ indicates the number of use points available to connect a specific SKU type k at customer location c .

2.4. Objective Function

The main objective of the abovementioned framework is to attain 1) minimum logistics cost, 2) minimum distribution cost while ensuring optimum usage of the transportation vehicle capacity. The objective function for the abovementioned framework can be written as,

$$\min f = \sum_{m=1}^{M}\sum_{s=1}^{S}\sum_{v=1(:LC_{m,s,v}>0)}^{V} LC_{m,s,v} * \sum_{d=1}^{ND}\sum_{x=1(:YX_{v,x}=1)}^{X} y_{m,s,v,x,d} + \sum_{m=1}^{M}\sum_{r=1}^{R}\sum_{v=1(:SC_{m,s,v}>0)}^{V} DC_{m,r,v} * \sum_{d=1}^{ND}\sum_{x=1(:YX_{v,x}=1)}^{X} y_{m,r,v,x,d} +$$
$$\sum_{m=1}^{M}\sum_{l=1(:LC_{m,l}>0)}^{L} LC_{m,l} * XML_{m,l} + PC * \sum_{d=1}^{D}\sum_{v=1}^{V}\sum_{g=1}^{G}\left(\sum_{x=1(:VCap_{v,x,g}^{min}\neq VCap_{v,x,g}^{max})} VCap_{v,x,g}^{max} - \sum_{r=1}^{R}\sum_{m=1}^{M}\sum_{k=1(:KG_{k,g}=1)}^{K} FMRDis_{m,r,v,k,d} \right)$$

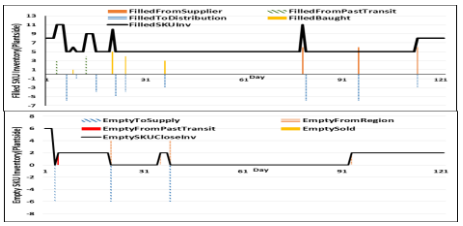
A detailed model incorporating more operational limitations, such as, 1) increasing or decreasing demands, 2) new and departing customers etc. are excluded from this paper due to brevity and will be a subject matter of a future publication (Misra *et al.* (2017)).

3. Result & Discussion

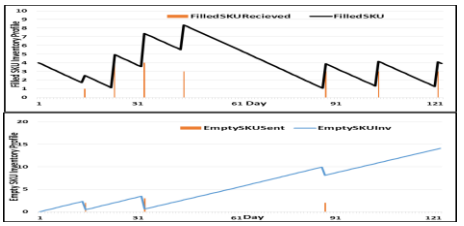
The abovementioned MILP formulation is tested upon a simple case study. Two liquefied gaseous products say A and B are stored in a warehouse in `tonner' type SKUs. Two suppliers are connected with the warehouse. Empty SKUs are sent to suppliers using ship for refilling purpose. 4 customer (say C1 to C4) are associated with the warehouse in which two customers has quoted demand for product A & the rest wants product B. The customer quotes demand for each month & the demands are converted to an average daily consumption pattern. Two regions are created based on customer locations & vehicle availability. C1 & C2 are located in region R1 whereas, C3 & C4 are in region R2. Two types of trucks are available & according to the vehicle customer SKU suitability, those are used for distribution purpose. The horizon is taken as 4 months starting from April to July. The entire horizon is discretized on a day basis.

The MILP formulation is solved for two different scenarios using Fico© Xpress Optimization suite using 'mmxprs' module version 2.8.1 on a Intel® Core™ i7(3.6 GHz) machine with 16GB RAM. Each of the scenarios contains 7885 constraints, 7323 variables in which 2440 are integer type, and is optimized for 15 minutes, and the optimality gap reached are 11.34% and 15.36 % respectively. After the abovementioned simulation time, there are no significant improvement in the solutions. As, the results presented in the following suggests, in both the scenarios, the framework aptly addresses the constraints regarding storage at warehouse or customer locations while meeting demands. The delivery time constraints are also respected at both logistics and distribution part as shown in Figure 1 & 2. Figure 1a and 2a also indicates that the framework exercises buying filled SKUs from other sources option to sustain the supply chain at the starting of the horizon. So, according to the result the framework aptly handles the limitations and provide optimum delivery schedules. However, the two scenarios presented here are also designed to focus on another important aspect of this supply chain: the circulation of SKUs. In the first scenario, there are no maximum limits on the customer storage. So, as the horizon progresses the empty SKUs are getting stored in the customer location as there are no incentives to bring those back to the warehouse. Moreover, there is a license limitation for the storage of SKUs at warehouse location. These two factors influence the decision behind stacking empty SKUs at customer location at the end of the horizon. The resultant warehouse and customer inventory profiles for both filled & empty SKUs are shown in Figure 1. The plots shown here only consider one customer and one SKU for brevity. The case in scenario 1 is not an ideal

one as, the SKUs need to be recirculated in the supply chain. This idea can be achieved by adding a storage capacity limitation at the customer locations. In scenario 2, the vehicles carry the empty SKUs back to the warehouse on their return trip opposed to scenario 1, where most of the return trips are empty i.e. vehicles are not carrying any empty SKUs specially near the end of the horizon. The results also indicates that the transit times among warehouse & customers and also among supplier and warehouses are respected, which can be seen from Figure 1 & 2.

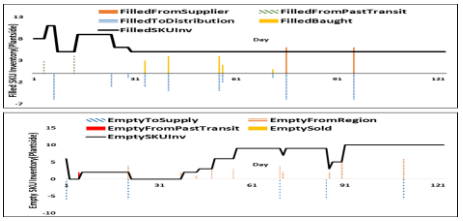


(a) Filled & Empty SKU Inventory at Warehouse

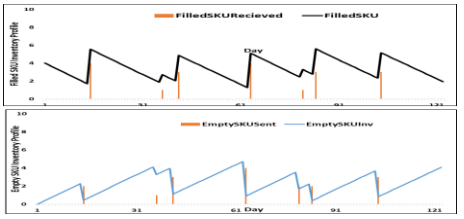


(b) Filled & Empty SKU Inventory at Customer Location

Figure 1: Filled & empty SKU inventory at customer location for scenario 1



(a) Filled & Empty SKU Inventory at Warehouse



(b) Filled & Empty SKU Inventory at Customer Location

Figure 2: SKU inventory profile at warehouse & customer location for scenario 2

4. Conclusions

In this paper, a novel MILP formulation is introduced to represent a resource utilization and supply chain optimization framework for liquefied gaseous products. The results show that the framework is formulation is rigorous and using the same a near optimal delivery and logistics schedule can be reached while respecting the limitations regarding warehouse and customer inventory, transit time and cost of the vehicles. The main bottle neck however is that even if the framework is optimized for longer time, the optimality gaps remains quite high, and requires more computationally efficient approach. As, the formulation is integer variable dominant, constraint programming approach might prove useful. A more systematic approach to improve the efficacy of the proposed framework is currently under investigation.

Abstract

This study proposes a decision-making tool for stochastic planning of a carbon capture utilization and sequestration (CCUS) network by optimizing conflicting objectives under uncertainties. A scenario-based two-stage stochastic model is formulated to handle various sources of uncertainty, such as fluctuation of CO_2 emission level, variability of construction and operation cost, and unpredictable events. In the model, a concept of downside risk is introduced to evaluate the risk caused by uncertainties. This model holds its strength in that it provides an intuitive decision-making algorithm for financial impact, environmental impact, and risk on a CCUS network within a single framework. To evaluate environmental impact, Life Cycle Assessment method, specifically Eco-indicator 99, considering all contributions caused by installation and operations over a whole chain of CCUS is applied. By formulating as a stochastic multi-objective optimization model, it can evaluate the trade-off between total annual benefit with financial risk considering an environmental impact. This problem is formulated as a mixed integer linear program model with linear constraints. A case study for the industrial complex on the east coast of Korea in 2030 is presented to illustrate the applicability of the proposed model.

Keywords: CCUS, multi-objective optimization, Life Cycle Assessment, stochastic model, downside risk

1. Introduction

Carbon capture and sequestration (CCS) is seen world-wide and considered as the most promising technology to mitigate CO_2 released from industrial point source or power plant (Karim and Kawi, 2016 and Lima et al., 2016). However, the past years have shown that significant potential techno-economic bottlenecks are associated with CCS options mainly because of its expensive capture cost and geological sequestration limitation. For this reason, this paper gives an insight of alternative CO_2 mitigation solution: carbon capture utilization and sequestration (CCUS).

One of the key success factors for CCS projects is economics of scale which operated as a large-scale (1 Megaton CO_2 per year) based on Han et al. (2012). While potential capture plants are located near big cities where industrial complex is developed, geological sequestration site can be located in a limited area due to expensive onshore

storage cost and problems with public acceptance for possibility of leakage by uncertainties. To find ways to adapt to these problems, a nation-wide CCUS network should be introduced.

To tackle environmental uncertainties such as leakage from storage site and erosion of pipes, the model is formulated as a multi-objective problem based on a stochastic method (Ozturk and Turkay, 2016). To minimize the total cost and the associated environmental impact, there are recent studies conducted based on multi-criterion optimization (Guillen-Gosalbez et al., 2014). The model aims to maximize CCUS profit and minimize environmental impact by using Life Cycle Assessment (LCA), specifically Eco-Indicator 99 method (EI 99).

Moreover, to take into account the preference of risk caused by uncertainties, the model enables decision makers to choose their own tolerance of risk of a CCUS network by applying 2-phase-2-stage stochastic multi-objective problem (2P2SSMOOP) algorithm developed by Lee et al. (2017). Here is the main difference with previous studies that can derive a fixed risk-neutral optimal solution (M. Hasan et al., 2014).

This study addresses the following novel challenge, which differs from previous research: (a) introducing the concept of risk to a CCUS network, (b) incorporating financial risk problems with environmental concerns using LCA, and (c) enabling decision-makers to choose their own tolerance for risk by uncertainties.

2. Problem Statement

The goal is to find the optimum plan of CCUS infrastructure by developing a supply chain network model considering the preference of a decision maker. This paper presents a mathematical model for optimal design of a CCUS network to maximize profit while minimizing environmental impact and uncertainty risk as a solution to mitigate CO_2. The network superstructure for CCUS infrastructure is based on Han et al. (2011).

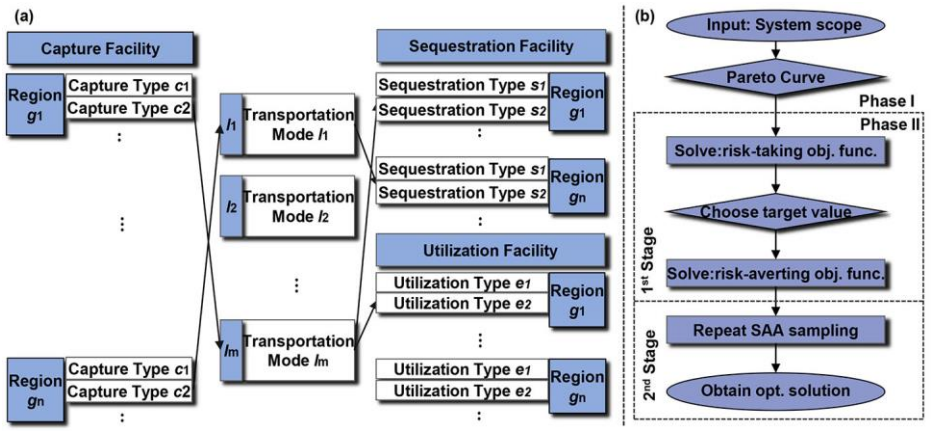

Figure 1: (a) CCUS network superstructure. (Components are described in the text)

(b) Solving algorithm for a 2P2SSMOOP

Given are the following data: A) the target amount of CO_2 reduction at each scenario, B) cost data for each type of facility construction and operation, C) capital charge rate and learning rate of facilities, D) capacity data of each facility, E) transportation availability

between regions. The model determines: (1) location and type of capture facilities, (2) location, type, and number of sequestration facilities, (3) type, capacity, and number of pipe lines, (4) location, type, and number of utilization facilities, and (5) flows of CO_2 between capture, utilization, and sequestration regions.

3. Mathematical Model

The mathematical formulation is presented as a mixed inter linear programming (MILP). The first stage variables of a two stage stochastic problem of Phase II (see Fig. 1) are implemented as either binary variables or integer variables; other variables are continuous variables for the second stage of Phase II. The mathematical model and notation of variables and parameters are based on the CCS network model developed by Lee et al. (2017) which optimizes the cost and environmental impact using a risk-considering approach. Several constraints used in the previous model are also applied in this model; these include constraints on facility capacity, transportation capacity, reduction target, cost, IE 99, and environmental impact management. The following additional equations are included in the CCUS network optimization model developed here.

Eq.(1) states overall mass balance of a certain region *g,* in a physical from CO_2 *i,* and for a scenario *sc*. $U_{sc,i,p,g}$ is a continuous variable for consumed amount of CO_2 by utilization in a physical form CO_2 *i,* by a utilization facility type *p*, in region *g*, for a scenario *sc*.

$$\sum_{c}\sum_{si}\sum_{sp} C_{sc,i,c,si,sp,g} = \sum_{l}\sum_{g'} (Q_{sc,i,l,g,g'} - Q_{sc,i,l,g',g}) + \sum_{s} S_{sc,i,s,g} + \sum_{p} U_{sc,i,p,g} \quad \forall sc, i, g \qquad (1)$$

Eq.(2) is a capacity constraint for CO_2 utilization facility. $BP_{e,p,g}$ is a binary variable which holds a value 1 if investment of utilization facility in a product form *e*, by a product facility type *p*, in region *g* is installed. $PCap_{e,p,g}$ is minimum and maximum availability of utilization facility form *e* by product facility type *p* in region *g*.

$$PCap^{\min}_{e,p,g} BP_{e,p,g} \le P_{ep,p,g,sc} \le PCap^{\max}_{e,p,g} BP_{e,p,g} \qquad \forall\, sc,\ e,\ p,\ g \qquad (2)$$

Eq.(3) and Eq.(4) are reduction target constraints. $CUF_{e,p}$ is a vale of CO_2 use factor in product form *e* by product facility type *p*. Eq.(3) states that the sum of CO_2 consumed amount by sequestration and utilization should be larger than the target reduction amount.

$$\sum_{i}\sum_{g}\sum_{s} S_{sc,i,s,g} + \sum_{i}\sum_{g}\sum_{p} U_{sc,i,p,g} \ge T_{sc} \qquad \forall sc \qquad (3)$$

$$U_{sc,i,p,g} = \sum_{e} CUF_{e,p} P_{sc,e,p,g} \qquad \forall sc, i, p, g \qquad (4)$$

Eq.(5) and Eq.(6) state cost of a CCUS network. $PCC_{e,p,g}$ is a capital cost parameter of establishing utilization facility of product form *e* by product facility type *p* in region *g*. $UPC_{sc,e,,p,g}$ is a unit operating cost parameter of utilization facility of product form *e* by product facility type *p* in region *g* for a scenario *sc.*

$$FCC = \sum_{g}\left[\frac{CCRf}{LR}\left\{\sum_{i}\left(\sum_{c}\sum_{si}\sum_{sp} CCC_{i,c,si,sp,g} BC_{i,c,si,sp,g} + \sum_{s} SCC_{i,s} NS_{i,s,g}\right) + \sum_{e}\sum_{p} PCC_{e,p,g} BP_{e,p,g}\right\}\right] \qquad (5)$$

$$FOC_{sc} = \sum_{g}\sum_{i}\sum_{c}\sum_{si}\sum_{sp} UCC_{sc,i,c,si} C_{sc,i,c,si,sp,g} + \sum_{g}\sum_{i}\sum_{s} USC_{sc,i,s} S_{sc,i,s,g} + \sum_{e}\sum_{p} UPC_{sc,e,p,g} P_{sc,e,p,g} \quad \forall sc \tag{6}$$

Eq.(7) states total annual selling benefits (TAB_{sc}) of CCUS of a scenario *sc* and Eq.(8) states total annual profit (TAP_{sc}) of a scenario *sc* .

$$TAB_{sc} = \sum_{e}\sum_{p}\sum_{g} USB_{sc,e,p} P_{sc,e,p,g} \qquad \forall sc \tag{7}$$

$$TAP_{sc} = TAB_{sc} - TAC_{sc} \qquad \forall sc \tag{8}$$

Eq.(9) and Eq.(10) state operation and installation environmental impact for each.

$$\begin{aligned} IO_{sc,n,x,g} = & \sum_{i}\sum_{c}\sum_{si}\sum_{sp}\sum_{b1} wo^{Ca}_{sc,b_1,c} v_{sc,n,x,b_1} C_{sc,i,c,si,sp,g} + \sum_{e}\sum_{p}\sum_{b_1} wo^{Ut}_{sc,b_1,s} v_{sc,n,x,b_1} P_{sc,e,p,g} \\ & + \sum_{i}\sum_{s}\sum_{b_1} wo^{Sq}_{sc,b_1,s} v_{sc,n,x,b_1} S_{sc,i,s,g} + \sum_{i}\sum_{l}\sum_{b_1} wo^{Tr}_{sc,b_1,l} v_{sc,n,x,b_1} \sum_{g'} Q_{sc,i,l,g,g'} \quad \forall sc,n,x \end{aligned} \tag{9}$$

$$\begin{aligned} II_{n,x,g} = & \sum_{i}\sum_{c}\sum_{si}\sum_{sp}\sum_{b_2} wo^{Ca}_{b_2,c} v_{n,x,b_2} BC_{i,c,si,sp,g} + \sum_{i}\sum_{s}\sum_{b_2} wo^{Sq}_{b_2,s} v_{n,x,b_2} NS_{i,s,g} \\ & + \sum_{e}\sum_{p} wo^{Ut}_{b_2,c} v_{n,x,b_2} BP_{e,p,g} + \sum_{i}\sum_{l}\sum_{b_2} wo^{Tr}_{b_2,l} v_{n,x,b_2} \sum_{g'} NT_{i,l,g,g'} \quad \forall n,x,g \end{aligned} \tag{10}$$

The environmental objective function (EI 99) is based on Eq.(11).

$$EI99_{sc} = \sum_{g}\sum_{r}\sum_{n} \vartheta_{r,n}\eta_n \left(\sum_{x} IO_{sc,n,x,g} + \sum_{x} II_{n,x,g}\right) \qquad \forall sc \tag{11}$$

To derive a CCUS infrastructure network considering the risk tolerance, the objective function for risk-taking and risk-averting can be formulated as follows: Eq.(12) states objective function for risk-taking decision makers and Eq.(13) and Eq.(14) state risk-averting objective function introducing the concept downside risk.

$$\min E[TAP_{sc}] = \sum_{sc} prob_{sc} TAP_{sc} \tag{12}$$

$$FDRisk(x, \Omega^{Fin}) = \sum_{sc} prob_{sc} \delta^{Fin}_{sc}(x, \Omega^{Fin}) \tag{13}$$

$$\delta^{Fin}_{sc}(x, \Omega) = \begin{cases} \Omega^{Fin} - TAP_{sc} & if \ \ TAP_{sc} < \Omega^{Fin}, \\ 0 & otherwise. \end{cases} \qquad \forall sc \tag{14}$$

4. Case Study

The presented mathematical model is used to assess a CCUS deployment scenario for the industrial complex on the east coast of Korea in 2030 the same as the previous case study reported by Han et al. (2011). As the reduction target, we set 38% of the estimated CO_2 emission from industrial plants in Korea. The cost data and capacity parameters used in this case study are calculated based on the Chemical Engineering Plant Cost Index using six-tenths factor rules. Environmental impact by constructing a CCUS network is evaluated by LCA analysis suggest by Goodkoop et al. (2001).

Table 1: Summary of the capture, sequestration, transportation, and utilization technologies

Activity	Type
Industry type	Power generation / Steel / Oil refinery / Petrochemical
Capture technology	Absorption using Monoethanolamine (MEA)
Sequestration technology	Depleted Gas Reservoir (DGR) / Saline Aquifer Storage (SAS)
Transportation mode	Compressed gaseous CO2 via pipeline
Utilization	Green-polymer / Bio-butanol

5. Results

A case study (see Fig. 2) was solved using the proposed mathematical model to plan the CCUS infrastructure on the east coast of Korea. The proposed model was implemented on GAMS 24.5 and solved using the CPLEX 12.0 MILP solver on an Intel 4.20-GHz computer. All solutions were obtained with zero optimality gaps. The case study was conducted to compare the finance risk-taking choice and the financial risk-averting choice considering environmental impact by using ε-constraint method widely used for a multi-objective programming (M. Ehrgott 2006).

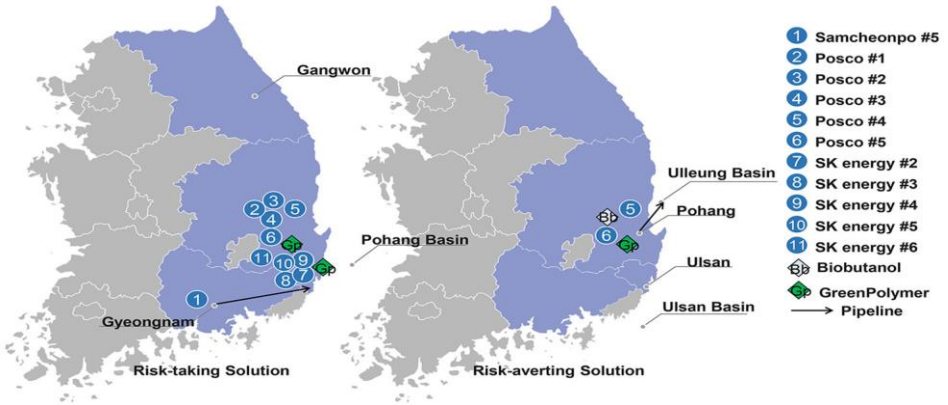

Figure 2: Case study results: financial risk minimization at target profit M$ 1,000 with ε: 0.1

Major difference between risk-taking decision and risk-averting decision is choice between utilization and sequestration. Since risk-averting decision makers avoid the worst case scenario which earns profit under a given target value, they tend to capture less amount of CO_2 and less utilize it. Moreover, to minimize transportation cost, they choose not utilization but sequestration. Since utilization is cost effective compared to sequestration, risk-taking decision makers try to capture and utilize CO_2 as much as they can in the boundary of the environmental burden they can afford of. However, this strategy is not effective for risk-averting decision makers because risk-taking decision leads to a wide range of profit results for each scenario. Thus, the downside risk of it is larger than that of risk-averting ones.

In both cases, green polymer is preferred as utilization technology and utilization facilities are established in Pohang city. This is due to the fact that the land price of Pohang is less expensive compare to Ulsan. Land price is the major key factor of capital cost for

utilization facility, thus capturing plant are determined in the same city where utilization facilities are located to reduce transportation cost.

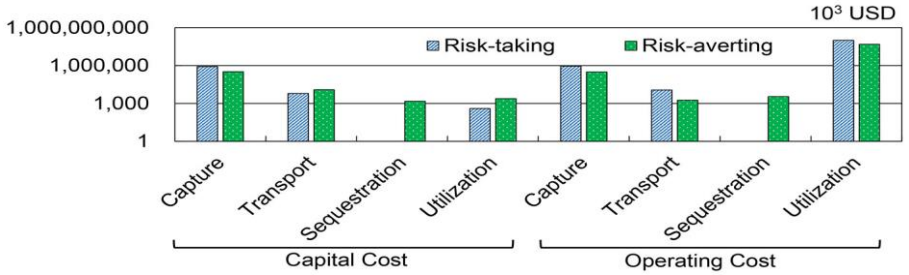

Figure 3: Case study results of capital, operating cost (10^3 USD) of CO_2 infrastructure planning

6. Conclusion

A mathematical modelling has been developed as a tool for planning a CCUS network by optimizing conflicting objectives under uncertainty. The goal is developing an intuitive decision-making algorithm for a stochastic programming problem with multiple objectives. The suggested model holds its novelty in that it provides the optimum CCUS network plan taking into account financial impact, environmental impact, and risk caused by uncertainty within a single framework. Conducted case study shows risk-taking decision makers invest more and earn more profit, while risk-averting decision makers capture less amount of CO_2 and prefer sequestration method lather than invest another utilization plant. Also, the location of capture plants is determined by the location of utilization plant which is highly dependent on land price. The overall model is addressed as MILP, which can be solved by a commercial linear optimization solver. The model is applied to the scenario of the east coast of Korea of 2030.

Abstract

A supply chain is a system consisting of different entities, which add value from the original resource sources to the final products while exchanging information on market, production, and so on. Although each entity is indispensable to obtain the final product, the degree of importance of each entity varies depending on the value of information each entity produces. In this paper, we apply the page ranking idea used in ranking Web pages to evaluate the value of information each entity produces in the supply chain. The developed method searches an information network of the supply chain according to the index, developed based on the value of information, for evaluating the entire supply chain. The accuracy of the information is also evaluated using a value map, then the method modifies the information network of the supply chain.

Keywords: eigenvector, matrix analysis, page rank, supply chain management.

1. Introduction

Because of the increasing severe competition in the global market, today's companies, including the process industry, have keen interests in making their supply chain (SC) more competitive than those of competitors. SC is a complex system consisting of entities, such as suppliers, manufacturers, warehouses, distributers, retailers, and so on. Thus, to design and operate SC effectively, Supply Chain Management (SCM) that focuses on the combination of strategies and tools to integrate all the entities of the SC (Bonfill et al., 2008) is expanded. Although a variety of solutions have been developed for SCM (Simchi-Levi, et al., 2007), almost all of them take advantage of information associated with SC in many ways.

In this paper, we develop a method of analysis and design of SC by focusing on the value and accuracy of information each entity produces. In the method, the value of information is calculated based on the same idea used for ranking Web pages. Then the method searches the information network of SC according to the ranking of each entity in order to control SC effectively based on the assumption that the higher ranked entity has a higher value of information, thus has stronger inference to the SC operation. In addition, the method modifies the information network of SC in consideration of the accuracy of the information each entity produces.

2. Evaluation of supply chain based on the value of information

Both researchers and practitioners, including the field of process systems engineering, have recognized that the information associated with SC, such as inventory, demand,

production plan, and so on, is key for effective management of the entire SC. In fact, literature on SCM has focused on this kind of information in many ways. For example, Lee et al. (2000) showed the value of information sharing in a two-level supply chain. Vegetti et al. (2005) proposed the design of an ontology that provides the foundations for the specification of information logistics processes in supply chains. Zamarripa, et al. (2014) showed a model that integrates third parties to optimize the planning decision in supply chains. Rasello and Manca (2014) focused on market information of oil prices, and presented a methodology to determine dynamic models of prices of different oils and the derived distillates in SC.

However, these types of literature have focused on tools and applications that use information associated with SC, and not on the analysis and design using the value and accuracy of information each entity produces in SC. In this paper, the method of analysis and design of SC in consideration of the value and accuracy of information is developed based on the principle shown below.

2.1. Principle of page rank calculation

The page rank is used for ranking Web pages, and it is considered that the page of a higher rank has a higher value of information. In the page rank calculation, $\boldsymbol{R}$ that holds the relationship of Eq.(1) is a vector representing the page rank of each web page (Page et al., 1999). That is, $\boldsymbol{R}$ is the eigenvector of the matrix $\boldsymbol{A}$ representing the structure of page links, and the element r_i (i =1 to n) of $\boldsymbol{R}$ is the page rank of page i. Where n is the total number of Web pages.

$$\boldsymbol{R} = c\,\boldsymbol{A}\,\boldsymbol{R} \tag{1}$$

In Eq.(1), $\boldsymbol{A}=(a_{v,u})$ is a square matrix in which row v and column u correspond to the links between Web pages, and its elements are determined as follows: where N_u is the total number of links from web page u to other web pages. From page u to page v, if there is a link: $a_{v,u} = 1 / N_u$, otherwise: $a_{v,u} = 0$.

2.2. Value of information of each entity in the supply chain

Since information is key to operate SC effectively, it is necessary to share and exchange information on production, inventory, transportation, etc. among entities constituting SC. Therefore various links of information among the entities are formed, and those links affect information each entity produces differently. Based on the idea of page ranking, it can be assumed that the entity ranked higher produces information that has a stronger affect than that of the lower ranked entity, thus we can say the entity has higher value.

In this paper, to calculate the value of information each entity produces by applying Eq.(1), SC is expressed in an $n \times n$ square matrix $\boldsymbol{A}$ from its entity number n, and the value of information each entity produces is calculated as its eigenvector $\boldsymbol{R}$. Where for element r_i of $\boldsymbol{R}$, $r_i \geqq 0.0$, $\Sigma_{i=1,n}\, r_i = 1.0$. The elements of $\boldsymbol{A}$ are obtained in Eq.(2) in consideration of the importance of information links from each entity.

$$a_{v,u} = W_{v,u}/N_u \tag{2}$$

where N_u is the total number of links from the entity u to other entities v. $W_{v,u}$ is a real number from 0 to N_u indicating relative importance of the links from entity u to v, and $\Sigma_{v=1,n} W_{v,u} = N_u$ (u=1 to n). If there is no link, $W_{v,u}$=0.0.

It is also clear that the different amount of values are added to the products incrementally at each entity via SC. Since we can say that the entity adding the higher value should have a higher value of information to manage the entire SC effectively, the difference between the value of information and the added value in each entity can be an index that measures the soundness of the entire SC from the view point of controllability. In other words, we can say that SC should be designed for the effective operation based on the index as Eq.(3) which determines the evaluation index of the entire SC, i.e., *SCV*, as the distance between $\boldsymbol{R}$ and $\boldsymbol{VA}$. Where $\boldsymbol{VA}$ is the vector of the relative value added by each entity i, and for element va_i of $\boldsymbol{VA}$, $va_i \geqq 0.0$, $\Sigma_{i=1,n}\, va_i = 1.0$.

$$SCV = |\boldsymbol{R} - \boldsymbol{VA}| \tag{3}$$

In addition, when the management level of the high ranked entity, where many pieces of critical information gather, is low, inaccurate production plans or inventory data etc. propagate to the entire SC. This will cause poor decision making in each entity. In other words, it can be said that the management level of the entity having high value of information among entities should be kept high.

However, all the entities within SC are not always within the framework that can manage SC effectively. It is difficult to manage adequately the entities outside the controllable framework, such as an external organization, and so on. In such a case, increasing the value of information of the manageable entity is required to reduce the influence to the entire SC by the inaccurate information of the uncontrollable entities.

3. Method of supply chain analysis and design based on the value of information

Based on the observations up to the previous section, we develop the analysis and design method of SC consisting of two stages. The method searches the information network of SC according to the *SCV* index in the first stage, then the information network is modified in consideration of the accuracy of information in each entity of SC.

3.1. First stage: Design of information network based on SCV index

Based on *SCV*, the developed method searches the information network of SC so that the *SCV* index is as small as possible based on the following steps:

Step 1.1: Calculate the *SCV* by Eq. (3) from the eigenvector $\boldsymbol{R}$ calculated by Eq.(1) and the vector $\boldsymbol{VA}$ showing the relative value added in each entity i in SC.

Step 1.2: Attempt to minimize the *SCV* by the following evolution rules R1 and/or R2.

(a) R1: For the element k with the largest difference between $\boldsymbol{R}$ and $\boldsymbol{VA}$, review the value of $a_{k,u}$ (u=1 to n) to reduce the difference between the value of information and relative value added to k.

(b) R2: For the element k with the largest difference between $\boldsymbol{R}$ and $\boldsymbol{VA}$, where $r_k < va_k$, makes new links from elements not currently connected to k.

3.2. Second stage: Modify the information network based on accuracy of information

The information network of SC designed in the first stage is modified by the accuracy of information according to the following steps:

Step 2.1: From the relative value of information in each entity and its relative accuracy, as shown in the value map of Figure 1, the position of each entity, i.e., Area I, Ⅱ, Ⅲ, and Ⅳ, is determined. The relative value of the information is obtained by Eq.(4). Where r_i is the rank of entity i, and n is the total number of entities in SC.

$$r_i \cdot n - 1 \tag{4}$$

Step 2.2: In the value map, the entity whose accuracy is relatively low, despite the high value of information, is located in Area Ⅳ, thus the following actions are taken based on the controllability of the entity to improve its accuracy.

(a) Information accuracy is controllable in the relevant entity: Improve management level of the relevant entity in order to move the entity in the direction of Area Ⅱ.
(b) Information accuracy is NOT controllable in the relevant entity: Establish a new entity that has equivalent function of the relevant entity, or construct a new information link in SC in order to move the entity in the direction of Area Ⅲ.

Step 2.3: If there is an entity in Area IV, repeat Steps 2.1 and 2.2. Otherwise, terminate all the Steps.

4. Numerical examples and discussion

To illustrate the developed method of analysis and design of SC, we show numerical examples using a simple SC consisting of five entities, i.e., A, B, C, D and E. Figures 2 and 3 show the flow of materials and the initial information links among entities in the example SC, respectively. In Figure 3, the real-valued numbers indicate the ranks of each entity, i.e., the value of each element of $\boldsymbol{R}$. The values of the fraction indicate the importance of information links from each entity, i.e., the value of each element of $\boldsymbol{A}$.

First, in Step 1.1, the importance of information links from each entity is expressed as each element of a 5×5 matrix $\boldsymbol{A}$ as Eq.(5), then $\boldsymbol{R}$ is calculated. We assume that the matrix $\boldsymbol{A}$ can be set by evaluating the information exchanged among entities in SC. In this example, as shown in Figure 3, $\boldsymbol{R}$ is calculated as (0.308, 0.189, 0.396, 0.0651, 0.0437). In addition, if the relative value added $\boldsymbol{VA}$ by each entity i is set to (0.25, 0.35, 0.2, 0.1, 0.1), the SCV is calculated as 0.264 by Eq.(3).

$$R = c \begin{pmatrix} 0 & 1/4 & 2/3 & 0 & 0 \\ 1/4 & 0 & 1/6 & 0 & 1 \\ 3/4 & 1/2 & 0 & 1 & 0 \\ 0 & 0 & 1/6 & 0 & 0 \\ 0 & 1/4 & 0 & 0 & 0 \end{pmatrix} R \tag{5}$$

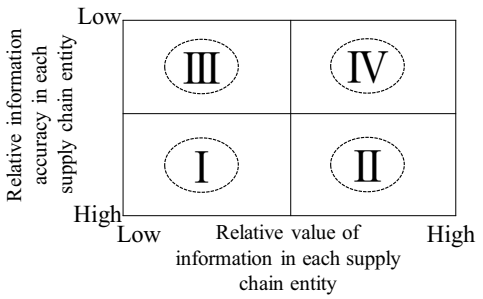

Figure 1. Value map of supply chain entity.

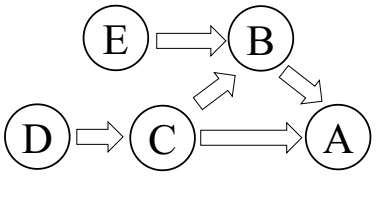

Figure 2. A materials flow of a supply chain.

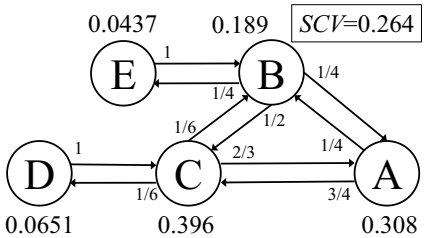

Figure 3. Information links and ranks (Case 0).

Next, in Step 1.2, *SCV* is reduced by rules R1 and/or R2. In Case 1, the importance of the information link from entity A to B is increased from 1/4 to 1/2 by rule R1. As a result, as shown in Figure 4, ***R*** and *SCV* are calculated as (0.286, 0.264, 0.330, 0.0549, 0.0659) and 0.169, respectively. Namely *SCV* is reduced by about 36% compared to Case 0. In addition, a new link of information from D to B is applied in Case 2 by rule R2. As shown in Figure 5, it reduced *SCV* to 0.140. In Step 2.2, the information network is modified according to the information accuracy of each entity so that the entity categorized in Area IV moves in the direction of Area II or III. For example, in Case 2 shown in Figure 5, the relative values of information of IV in the value map shown in Figure 1. Furthermore, if it is difficult to manage the information on entity C by SC, the method considers setting up entity F as an entity having the same function as entity C. Figure 6 shows the new information network of SC, its new ranking, and *SCV* when entity F is added. From Figure 6, it can be seen that the addition of a new entity F lowered the rank of entity C from 0.309 to 0.193. The relative value of information decreased from 0.546 to 0.156. However, *SCV* increases from 0.140 to 0.203. The results suggest the necessity of the process that repeats the first and the second stages of the developed method, or integrates the stages to design the information network that minimizes *SCV*.

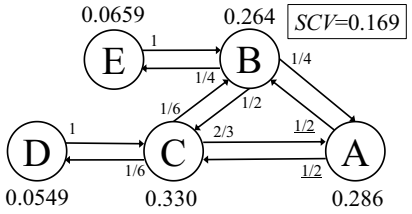

Figure 4. Information links and ranks (Case 1).

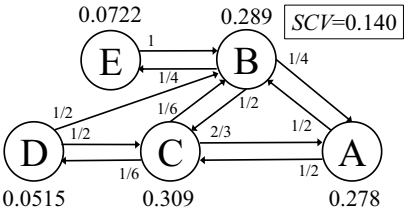

Figure 5. Information links and ranks (Case 2).

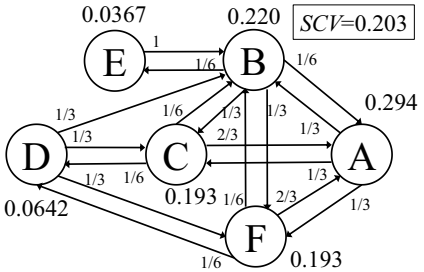

Figure 6. Information links and ranks (Case 3).

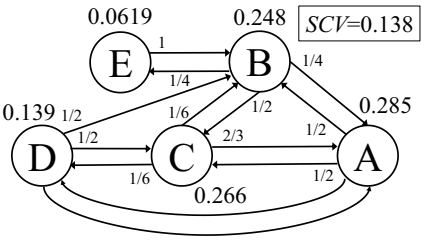

Figure 7. Information links and ranks (Case 4).

In addition, the rankings of Case 4 that makes new information links between entities D and A are shown in Figure 7. In this case, the ranking of entity C has decreased from 0.309 in Case 2 to 0.266, and the relative value of information has decreased from 0.546 to 0.327, thus the category of entity C moves from Area Ⅳ to the Area Ⅲ direction on the value map. The *SCV* also changed from 0.140 to 0.138.

5. Conclusions

In this paper, we have addressed a method of analysis and design of SC based on the value and accuracy of information each entity produces. In the method, we apply the page rank idea used in ranking Web pages to evaluate the value of information each entity produces. The effectiveness of the proposed method is demonstrated via numerical experiments using a simple SC model.

There are several issues that require further investigation. For example, the required data and process to determine the importance of each link within the information network of SC should be investigated. In addition to the importance of information, diverse factors must be considered, such as cost, risk, technical feasibility, and so on, to make a well-designed SC. The method that integrates these factors should be developed.

Abstract

Municipal solid waste management (MSWM) is associated with the control of generation, storage, collection, transportation, processing and disposal of solid waste in accordance with the principles of public health, economics, engineering, conservation, aesthetics and other environmental considerations. However, the management of municipal solid waste (MSW) involves multiple stakeholders such as government agencies, suppliers, consumers, providers of treatment/recycle services and transporters. Furthermore, the product prices constantly change due to offer and demand, and the composition of the generated MSW depends on many factors including the place where they are produced, the season and the economic development. An optimal management strategy should take into account the uncertainties in the supply chain of MSW as well as the multiple participants involved. This way, an optimum and more realistic waste management system that creates synergistic opportunities to benefit the multiple stakeholders can be obtained. This paper presents a multi-objective optimization approach for the strategic planning of a municipal solid waste management system under uncertainty. The formulation considers tasks such as recycle, reuse, transportation, separation and distribution. The proposed approach also takes into account the multiple stakeholders, with the objective of maximizing the benefit of all participants. A case study from Mexico is analyzed to probe the applicability of the proposed model. Furthermore, this model considers the financial risk by analyzing the optimistic, mean and pessimistic cases. This way, the obtained results provide additional information about the system to improve accuracy in decision-making.

Keywords: Multi-objective optimization; Multi-stakeholders, Municipal solid waste; Uncertainty; Waste management.

1. Introduction

Municipal solid waste management is an important environmental concern around the word. Solid wastes are constantly produced in mega-cities, small towns and large villages, and if residues do not receive the right management, they can cause several affections on the environment and human health. These affections include greenhouse gases emissions, soil contamination, bad odours, underwater contamination, and spread of diseases, among others. Commonly, the treatment of MSW is not carried out because this requires a substantial proportion of government budget without any economic remuneration. Due to

most of the projects for MSWM depend on the stakeholders interested in founding the project, and all stakeholders are interested in satisfying their expectation, it is needed to propose an optimization approach for the MSWM that takes into account the multi-stakeholders involved. Furthermore, as the production and the composition of the municipal solid waste (MSW) depend on many factors including the population growth, consumption patterns, season and climatic conditions, the uncertainties associated to the MSWM must be considered. In this way, several contributions have been published, Habibi et al. (2017) developed a multi-objective optimization model for the supply chain of MSW in Tehran, Entezaminia et al. (2016) presented a model for the production planning in a green supply chain considering the traditional production system with recycling hubs. Other publications have focused on predicting the generation of the MSW through linear and nonlinear models, considering certain variables that affect the amount of MSW generation (Sun and Chungpaibulpatana, 2017), or analysing the economic viability of a power generation project from MSW (Pin et al., 2017). The dependence on time in the supply chain of MSW is an important issue, which has been recently considered (Santibañez-Aguilar et al., 2017; Nguyen-Tron et al., 2017; Zhang and Huang, 2013; Dai et al., 2012). To determine the incentives for the government and recycling industries to invest in the MSWM, Zheng et al. (2014) analysed the application of the landfill gas-fired and MSW incineration to produce power, and presented a series of preferential policies and regulations to encourage the expansion of MSW to energy. Wang et al. (2018) introduced a multi-attribute decision analysis method for prioritizing the MSW treatment alternatives based on the interval-valued fuzzy set theory. Nevertheless, none of the papers mentioned above has taken into account the uncertainty in the availability of the MSW, the demand of the products obtained from them, or the multi-stakeholders involved at three different level of financial risk (optimistic, mean and pessimistic). Therefore, this paper proposes a model formulation to provide to the involved stakeholders a tool for decision making from a wider perspective.

2. Model Formulation

To develop the mathematical model, a superstructure of the analysed system was proposed (Figure 1). Figure 1 shows a set of neighbouring cities, where the MSW are collected to be distributed to different processing facilities. Each industry has a set of technologies to treat a certain type of residue. It is assumed that only one type of product is produced from each type of technology. Then, the products are sent to different hubs located in specific places to be sent to markets or an industry as feedstock. The proposed mathematical model is describe as follows.

To analyse the involved financial risk, and determine the probability to obtain the best results, the next relationships are used. The optimistic objective function must be the greatest of all the objective functions o in the different scenarios e.

$$OptFunction_{o} \geq Function_{o,e} \qquad \forall o \tag{1}$$

It is necessary to limit the value of the optimistic function through the next set of relationships.

Equation (2) stays that only one binary variable can be one.

$$\sum_{e} y_{o,e}^{op} = 1 \qquad \forall o \tag{2}$$

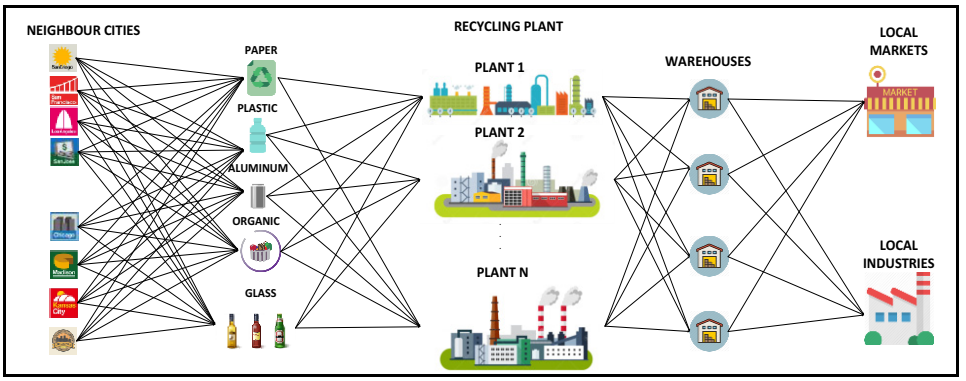

Figure 1. Superstructure for the municipal solid waste management system.

Furthermore, Equation (3) states that if the value of the binary variable is 0, then the optimistic function will be always lower than de right side of the equation. Thus, the parameter $OptF^{max}$ is an upper limit. Otherwise, if the binary variable takes a value of 1, the relationship in the disjunction is activated.

$$OptFunction_{o,e} \leq Function_{o,e} + OptF^{max}\left(1 - y_{o,e}^{op}\right) \qquad \forall o,e \tag{3}$$

The mean case is the average of the each objective function, in other words, it is equal to the sum of the objective functions for each scenario divided by the number of scenarios:

$$MeanFunction_o = {\sum_e Function_{o,e}} \Big/ {card(e)}, \quad \forall o \tag{4}$$

The pessimistic scenario corresponds to the lowest value for the objective function o between all the objective functions of a certain type o for all the scenarios.

$$PessimisticFunction_o \geq Function_{o,e} \qquad \forall o \tag{5}$$

Once the optimistic, mean and pessimistic cases are analysed, it is important to normalize the objective function for these three cases to formulate an equation that involves the multi-stakeholders. Equation (6) describes the normalized optimistic function, which is obtained by the difference between the greatest value obtained for the objective function when it was maximized individually (upper bound) and the optimistic function, divided by the difference between the upper bound for the optimistic function minus the lower bound for the optimistic function:

$$NOF_o = \frac{OF_o^{UB} - OptFunction_o}{OF_o^{UB} - OF_o^{LB}} \qquad \forall o \tag{6}$$

Similarly, the normalized mean function is equal to the relation between the upper bound for the mean function minus the mean function and the upper bound for the mean function minus the lower bound for the mean function:

$$MOF_o = \frac{MF_o^{UB} - MeanFunction_o}{MF_o^{UB} - MF_o^{LB}} \qquad \forall o \tag{7}$$

In the same way, for equation (8) the normalized pessimistic function is equal to the difference between the upper bound for the pessimistic function and the pessimistic function, divided by the difference between the upper bound for the pessimistic function minus the lower bound for the pessimistic function:

$$POF_o = \frac{PF_o^{UB} - PessimisticFunction_o}{PF_o^{UB} - PF_o^{LB}} \quad \forall o \tag{8}$$

The overall compromise function is the sum of all the normalized objective functions for the three cases (optimistic, mean and pessimistic).

$$OCS = \sum_o \left(NOF_o + NMF_o + NWF_o \right) \tag{9}$$

3. Results and discussions

Three different levels of financial risk for each objective function were analysed, then the upper and lower values for each objective function were calculated (see Table 1). These values were used to implement the multi-stakeholder approach. The results for the overall compromise solution (OCS) are shown in Figure 2.

Table1. Upper and lower bounds for the objective functions according to the financial risk.

OBJECTIVE FUNCTION	OPTIMISTIC		MEAN		PESSIMISTIC	
	UPPER BOUND	LOWER BOUND	UPPER BOUND	LOWER BOUND	UPPER BOUND	LOWER BOUND
%CONSUMED	99.96	0.46	99.96	4.10	99.95	4.039
ONP	-10.61	-14.75	-11.24	-14.70	-11.32	-14.72
NPP	96.67	-525.28	96.67	-517.55	67.85	-524.35
NPM	0.00	-11.94	0.00	-11.94	0.00	-11.95
NPG	2.15	-2.50	2.15	-2.50	2.15	-2.50
NPRP	7.94	-4.87	7.94	-4.87	7.24	-4.86
NPO	0.00	-14.26	0.00	-14.26	0.00	-16.20
GOVEXP	99.95	-483.75	99.95	-483.80	80.01	-483.75

The objective functions with the highest values are the percentage of consumed MSW (%CONSUMED), the overall net profit (ONP) and the net profit from organics (NPO): 97.66%, 73.69$MM/y and 81.22$MM/y, respectively. The curve for the %CONSUMED is constant at first, just two of the ten considered scenarios show a different value with consumptions of 65% and 45%. While the curves for ONP and NPO are similar, they tend to decrease almost constantly, except for one scenario that shows the lowest value for this function with zero for the NPO and a negative value for the ONP. The curves with the lowest values, but still with profits, are the net profit for paper (NPP) and the net profit for metals (NPM). These curves keep almost a constant linear trend, the highest values from them are 7.3 and 1.7$MM/y. For most of the scenarios, these curves take values very similar at the end. The curve for the net profit from recycled plastic (NPRP) takes a value of zero, since recycling plastic is not feasible for this problem; this also can be seen

in Table 1, where the upper bound for NPRP is zero. Now, analysing the results for the government expenditures (GOVEXP), the curves show a linear behaviour with a smooth slope. The range of values taken for this curve are between -10.9 and -13.48$MM/y.

Figure 3 shows the dissatisfaction percentage for each objective function when the OCS was minimized. The functions with less percentage of dissatisfaction, in most of the scenarios, were the NPRP, the NPM and the government expenditures; the best values for them were 0 %, 3.2 % and 3.7 %, respectively, and the worst 2.7 %, 17 and 17.1 %, respectively. For the % CONSUMED, the percentage is low in most of the scenarios, just in two of ten the percentage increase drastically from 2.4 % to 56.8 %. Similarly, the NPM and NPP have the lowest value of 7.8 % and 4.81 %, respectively; then, they tend to increase to 46.3 % and 61.9 %. The objective function with the greatest percentage was the NPG with a value between 13.6 -16.7 % for most of the scenarios.

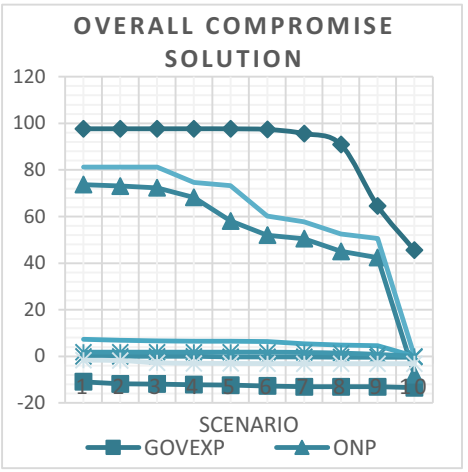

Figure 2. Results for each objective function.

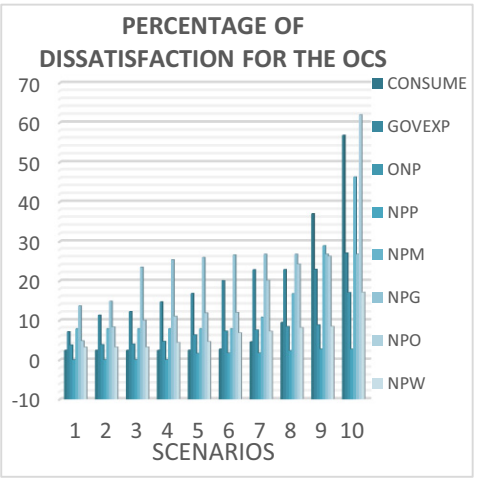

Figure 3. Percentage of dissatisfaction.

4. Conclusions

This paper proposed an optimization approach for the strategic planning of the municipal solid waste management system. The optimization accounts for the involved uncertainty, where three different financial risks (optimistic, mean and pessimistic) through a multi-stakeholder formulation were considered. This way, an optimum and more realistic waste management system that creates synergistic opportunities to benefit the multiple stakeholders can be obtained. It should be noticed that in this work the three financial risks were optimized simultaneously. The number of scenarios taken into account was used to reduce the computation time; additionally, the results for 100 scenarios showed a similar trend. The scenarios were generated from historical data (standard deviation) using the GAMS software through a deterministic algorithm (called a generator).

A case study from Mexico is presented to show the applicability of the proposed approach. The results show that it is possible to obtain attractive solutions for all the involved stakeholders with a low level of financial risk. In addition, the proposed approach allows determining the level of dissatisfaction of the involved stakeholders, and this way the proposed approach can be a useful framework for decision makers.

Finally, implementing the multi-stakeholder optimization approach to the proposed model allows obtaining solutions that look for satisfying all the involved parts. Therefore, the proposed approach promotes the economic and environmental incentives for the MSWM. The proposed approach can be applied to other problems and it represents a good alternative to consider simultaneously several objective functions.

A Game Theory Approach to Design and Optimization of Decentralized Supply Chains under Uncertainty

Jiyao Gao, Fengqi You*

Cornell University, Ithaca, New York, 14853, USA

Abstract

Supply chains are normally managed in a decentralized way by multiple stakeholders pursuing distinct objectives. However, most existing supply chain studies rely on centralized models and neglect the uncertain behaviors of stakeholders in the decision-making process. In this work, we propose a novel game theory based stochastic model that integrates two-stage stochastic programming with a single-leader-multiple-follower Stackelberg game scheme. The aim is to address the optimization problem of decentralized supply chains considering multiple stakeholders under uncertainty. The resulting model is formulated as a stochastic mixed-integer bilevel nonlinear program, which can be further reformulated into a tractable single-level stochastic mixed-integer linear program by applying KKT conditions and Glover's linearization method. To illustrate the applicability of proposed modeling framework, a case study of a large-scale shale gas supply chain is presented, which demonstrates the advantages of the proposed modeling framework and efficiency of the solution algorithm.

Keywords: Game theory, supply chain, uncertainty, stochastic, bilevel program.

1. Introduction

The management of supply chains normally involves multiple stakeholders. Each stakeholder may pursue different objectives, thus leading to compromised solutions (Cachon and Netessine, 2004). Nevertheless, most existing studies on the optimal design and operations of supply chains still rely on centralized models (Garcia and You, 2015). Consequently, the optimal solutions of centralized models can be suboptimal or even infeasible in a decentralized supply chain (Gao and You, 2017a). To address this research challenge, multiple game theoretic models are developed to explicitly account for the interest of each stakeholder. For instance, there are models for the optimization of cooperative multi-enterprise supply chains based on the generalized Nash bargaining solution approach (Gjerdrum et al., 2001; Yue and You, 2014a). On the other hand, optimization models integrating game theories of Stackelberg game and Nash-equilibrium are proposed for the design and operations of noncooperative supply chains (Yue and You, 2014b; Yue and You, 2017; Gao and You, 2017b; Gao and You, 2017c). However, these models assume that all the information among different players is deterministic, so that players can always make decisions that benefit them the most based on perfect knowledge. In practice, there are always time delays between the design and operational decisions for each player, and various types of uncertainties, such as price fluctuation, change of productivity, etc., can occur during the operation phase. These uncertainties in turn may significantly affect the rational behaviors of other players (Hjaila et al. 2016). Therefore, it is necessary to develop a holistic game

theoretic model that can systematically optimize the design and operational decisions of different stakeholders with uncertainty behaviors.

In this work, we propose a novel modeling framework that integrates the leader-follower Stackelberg game with two-stage stochastic programming approach into a holistic game theoretic model. Specifically, this modeling framework allows consideration of one leader and multiple followers. Following the sequence of time, decision variables for both the leader and the followers are classified into design decisions that must be made "here-and-now" and operational decisions that are postponed to a "wait-and-see" mode after the realization of uncertainties from both sides of players (Birge and Louveaux, 2011). As a result, both players will interact with each other to determine their optimal design strategies at the first stage. Uncertainties from both the leader and the followers are then realized, and both players go to the second stage to determine their best operational strategy based on their previous design decisions and given uncertainty information. Following the stochastic programming approach, uncertainties are depicted with discrete scenarios with given probabilities. The objectives of the leader and the followers are to maximize their own expected net present values. The resulting problem is formulated as a stochastic mixed-integer bilevel programming (MIBP) problem, where the upper-level problem corresponding to the leader's optimization problem is formulated as a mixed-integer nonlinear programming (MINLP) problem, and the lower-level problems corresponding to the optimization problems of the followers are formulated as linear programs. We further reformulate this MIBP problem into a single-level mixed-integer nonlinear programming (MINLP) problem by replacing the lower-level problems with their equivalent Karush-Kuhn-Tucker (KKT) conditions. To make this MINLP problem more tractable, we apply the Glover's linearization approach to reformulate it into an equivalent MILP problem (Glover, 1975). The applicability of the proposed modeling framework is illustrated by a large-scale case study of shale gas supply chains based on Marcellus Shale. According to the optimization results, both players tend to choose more conservative strategies when considering the uncertainties in the noncooperative supply chain optimization problem.

2. Problem Statement

As mentioned in the previous section, the proposed modeling framework integrates the leader-follower Stackelberg game with two-stage stochastic programming approach. We aim to simultaneously optimize the design and operations decisions of different stakeholders under uncertainty. The Stackelberg game is selected to depict the sequential decision-making process among different players. Specifically, the shale gas producer in the shale gas supply chain is identified as the leader that enjoys decision-making priority. The leader's decisions comprise "here-and-now" design decisions, including drilling schedule at each candidate shale site, instalment of gathering pipelines, and processing contract selection, and operational decisions that are made "wait-and-see", namely production profile of shale gas, amount of raw shale gas transported to each existing processing plant, and water management strategy. Meanwhile, the midstream shale gas processing companies are identified as followers in the supply chain. After the observation of leader's decisions, the follower will react rationally and make corresponding decisions, including design decisions regarding the unit process fee associated with the processing contracts, and operational decisions on the planning of processing and distribution activities.

Following the stochastic programming approach, uncertainties are depicted with discrete scenarios with given probabilities. Thus, both the leader and the followers strive to maximize their own expected net present value (NPV).

3. Model Formulation and Solution Algorithm

The general model formulation is presented as follows.

$$\max\ TEP^{leader} = \mathbb{E}_{\xi}\left[TP^{leader}\left(x^u, y^u, x^l, \xi\right)\right] \tag{1}$$

$$\text{s.t. } A_R(\xi)x^u + A_Z(\xi)y^u + B_R(\xi)x^l < r(\xi) \tag{2}$$

$$x^u \in \mathbb{R}_+^{m_R},\ y^u \in \mathbb{Z}_+^{m_Z}$$

where x^l solves:

$$\max\ TEP_p^{follower} = \mathbb{E}_{\xi}\left[TP_p^{follower}\left(x^l, \xi\right)\right], \quad \forall p \in P \tag{3}$$

$$\text{s.t. } Q_R(\xi)x^u + Q_Z(\xi)y^u + P_R(\xi)x^l < s(\xi) \tag{4}$$

$$x^l \in \mathbb{R}_+^{n_R}$$

where TEP^{leader} denotes the leader's total expected NPV. TP^{leader} denotes the leader's total NPV associated with realization of uncertainty ξ. $TEP_p^{follower}$ denotes the follower p's total expected NPV. $TP_p^{follower}$ denotes the follower p's total NPV associated with realization of uncertainty ξ. x^u and y^u indicate the continuous variables and discrete variables corresponding to the leader's decisions, respectively. x^u involves decisions including the shale gas production rate at each shale site in each time period, the amount of shale gas transported from shale sites to processing plants, capacity of gathering pipelines, amount of freshwater required for each shale site, and amount of wastewater treated by different technology options. y^u involves discrete decisions on the number of wells drilled at certain shale site in each time period, and whether a gathering pipeline should be installed or not. x^l indicates the continuous variables corresponding to follower's decisions, including the unit processing fee of processing contracts, processing schedule of shale gas, and amount of natural gas and NGLs extracted from raw shale gas. As can be observed, the leader's and the follower's decisions variables appear in both the upper level problem and the lower level problem. This indicates that the leader's optimization problem is partially dependent on the follower's decisions, and the follower's optimal strategy will be determined based on the leader's decisions. The final optimum of such a bilevel program follows the solution concept of Nash equilibrium.

As can be seen, the resulting problem is a stochastic MIBP that cannot be tackled directly by general-purpose MINLP solvers. Therefore, we first replace the lower-level optimization problems with their equivalent KKT conditions, so the original bilevel problem is reformulated into an equivalent single level MINLP problem with bilinear terms. To improve the computational efficiency, we further adopt the Glover's linearization approach to reformulate this single level MINLP problem into an equivalent MILP problem (Glover, 1975), which can be solved directly by MILP solver CPLEX 12.6.3.

4. Application to a Decentralized Shale Gas Supply Chain

To illustrate the applicability of the proposed modeling framework and solution approach, we consider a case study of a decentralized shale gas supply chain based on Marcellus Shale. A shale gas producer is considered as the leader, who oversees five potential shale sites. Each shale site allows for drilling of up to four to eight shale wells. The wastewater can be handled by three different water management options, including underground injection into Class-II disposal wells, centralized wastewater treatment (CWT), and onsite treatment and recycling with multi-stage flash, multi-effect distillation, or reverse osmosis technologies. The produced raw shale gas can be transported to three shale gas processing plants. Alternatively, the raw shale gas can be sold directly to the market. Each processing plant represents a follower, who will charge the producer for their processing service based on the processing contracts. Specifically, three types of fee-based processing contracts are considered, corresponding to 50%, 75%, and 100% of total processing capacity in a shale gas processing plant. A 10-year planning horizon is considered, which is divided into 10 time periods. Detailed input data are taken from Gao and You (2015). We consider two types of uncertainties in this shale gas supply chain, namely the uncertain productivity of a shale well at a certain time period and the uncertain processing capacity that can be provided by the processing plants. We assume normal distributions for both uncertainties following existing studies (You et al. 2009). By applying sampling approximation approach, the number of scenarios is finalized as 200 scenarios with 98% confidence interval (Shapiro and Homem-de-Mello, 1998). After the reformulation steps mentioned above, the resulting single level MILP problem has 341 integer variables, 115,016 continuous variables, and 65,557 constraints. All the models and solution procedures are coded in GAMS 24.7.3 on a PC with an Intel® Core™ i7-6700 CPU and 32GB RAM.

In Figure 1, we summarize the leader's total NPV and the followers' NPV in different scenarios to demonstrate the impacts of uncertainties. Each point in this figure indicates a specific solution point associated with a scenario. The straight line indicates the total expected NPV throughout the 200 scenarios considered in this case study. Meanwhile, by comparing with the traditional deterministic models, we note that the optimal solution of the proposed model is relatively conservative, but it can effectively hedge against extreme cases with worse economic performances.

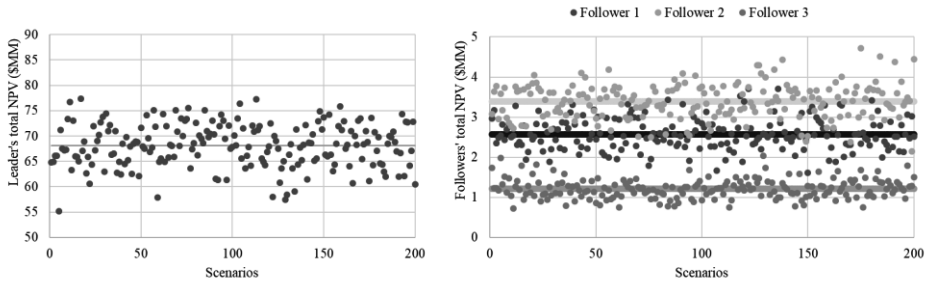

Figure 1. Stakeholders' total NPV in 200 scenarios.

In Figure 2, we present the optimal drilling schedule determined by the leader. The corresponding average shale gas production profile based on the 200 scenarios is included as well. As can be seen, a total of 27 shale wells are drilled within the 10-year planning horizon. Specifically, 10 shale wells are drilled in the beginning at shale sites

1, 2 and 3 to satisfy the initial natural gas demand. Later, based on the forecasted price of natural gas, there will be a price increase in the fourth year. As a result, the leader determines to drill 12 extra shale wells at shale sites 1, 3, and 4 to make more profit. Due to the decreasing feature of productivity of shale wells, 5 more shale wells are drilled in the sixth year to compensate for the production decrease. Despite the production uncertainty at each shale well, this optimal drilling schedule sets the basic tune of shale gas production profile as shown in the right figure.

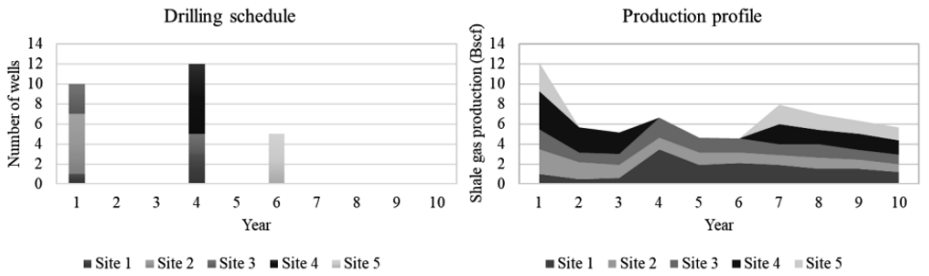

Figure 2. Optimal drilling schedule and shale gas production profiles at shale sites.

The optimal shale gas processing strategies of the leader and the followers are summarized in Figure 3, including the leader's selection of processing contracts and the followers' price setting decisions. As can be observed, in most years, the leader chooses to sign a processing contract with only one processing plant, and 50% of the total processing capacity is considered enough for the raw shale gas output. Since different processing plants have distinct processing capabilities, the leader may switch to other processing plants when production fluctuation is encountered. In the fourth year, with 12 extra shale wells being developed, additional processing capacity is required. Thus, the leader signs contracts with both processing plants 2 and 3 to purchase 75% and 100% of their processing capacities, respectively. Notably, the leader's strategy is also affected by the follower's price setting decisions. We can easily identify that: (a) processing plants tend to offer a lower unit processing price for smaller processing capacity contracts; (b) processing plants have higher chance to be selected by the producer when their unit processing fee is lower than other competitors.

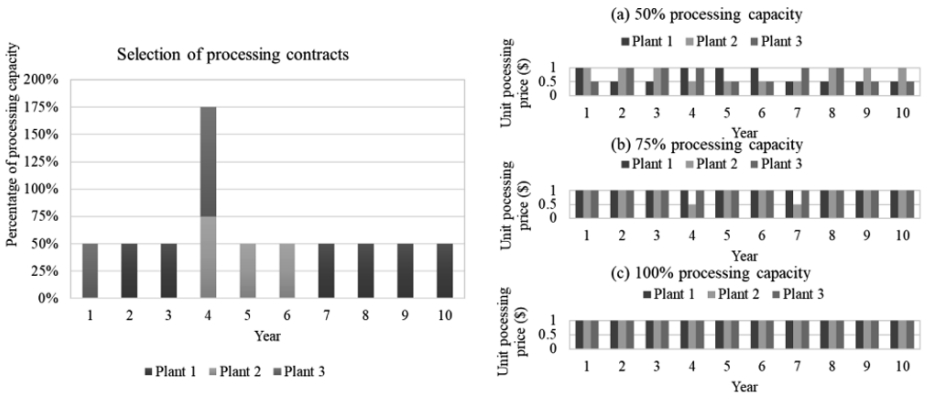

Figure 3. Optimal shale gas processing strategies of the leader and the follower.

5. Conclusions

An optimization framework is proposed that integrates the Stackelberg game with two-stage stochastic programming. This framework enables us to investigate the optimal design and operations of decentralized supply chains involving multiple stakeholders under uncertainty. To illustrate the application, we consider a case study of Marcellus shale gas supply chain. The optimization results show that stakeholders tend to choose more conservative strategies when considering uncertainties in decentralized supply chains.

Abstract

In this paper, a mixed integer linear programming (MILP) model for the optimization of a municipal solid waste (MSW) system in a supply chain (SC) network is presented with the aim of maximizing the total net profit over a specified time horizon. The proposed model covers waste collection at sites, separation at dumps, and processing for waste recycling and waste to energy (WtE) production at plants, as well as selling the end products. A case study is illustrated to demonstrate the feature and validity of the model. MSWs including biomass materials such as paper and food waste, non-biomass combustible materials such as plastic, and non-combustible materials such as glass and metal are managed by a combination of disposal in landfill sites, recycling to produce useful products, and incineration to produce power.

Keywords: municipal solid waste, supply chain, mixed integer linear programming.

1. Introduction

The generation of MSWs is increasing worldwide due to the rapid population and economic growth, and change in life style behaviors and consumption patterns, which leads to the need for proper waste management strategies. Inappropriate management of MSW systems results in serious environmental risks such as human health damage, harm to ecosystems and resource availability, and water, soil and air pollution, as well as negative economic and social effects. Waste management generally contains six hierarchical steps: waste prevention, reduction, reuse, recycle, energy recovery and disposal. Among all the available options, WtE is still one of the most viable option for many countries as an effective waste management solution. WtE technologies can solve the dilemma of energy demand and provide the valuable energy in forms of electricity and heat, reduce the waste volume and increase the landfill space, and diminish greenhouse gas emissions.

1.1. Municipal solid waste supply chain

The MSW management can be considered as a strategic SC problem as it generally consists of waste collection, separation, disposal, processing and transportation. Although much consideration has been devoted to developing the mathematical models for optimization of MSW systems, specifically in production and distribution sectors, most of these models have considered partial integration of the functions in an SC. Only a few studies focused on the optimization of the MSW systems in an integrated SC network. An integrated network involves all enterprises of the entire process of SC

including MSW collection stations, waste distribution centers, waste disposal/treatment facilities, and end product distribution centers, which will result in smooth and cost-effective allocation of waste flows, extracting the maximum value from the produced waste, efficient logistics, as well as providing a cost breakdown across different levels of the SC. More detailed information related to the optimization of the entire SC for MSW management can be found in Nwe et al. (2010), Santibañez-Aguilar et al. (2013) and Zhang et al. (2014). Based on the existing literature, little attention has been paid to the optimization of an MSW system in a multi-level SC considering multiple time periods and products. Thus, there is a need for developing an integrated mathematical model and solution approach to address these shortcomings. The target is to develop a generic MSW model that is granular enough to bring the SC planning closer to operations.

2. Mathematical model formulation

In this paper, an optimal planning of an MSW management system in a multi-period multi-product multi-level SC is presented. The resulting optimization problem is modeled as an MILP. The MSW model covers waste collection at sites, separation at dumps, processing for recycling and incineration at plants, as well as selling the end products. The modeled mass flows include waste transportation from sites to dumps, waste delivery from dumps to processing plants and product delivery from plants to the markets at sites. The proposed model can determine the quantity of waste types distributed from sites to dumps and from dumps to plants, amount of wastes in plants transferred to different technologies, and amount and types of generated products distributed from plants to sites.

2.1. Notation

Indices:

w	Waste type, $w \in \{1, 2, \dots, W\}$
s	Waste collection site, $s \in \{1, 2, \dots, S\}$
d	Dump, $d \in \{1, 2, \dots, D\}$
p	Waste processing plant, $p \in \{1, 2, \dots, P\}$
j	Waste treatment technology, $j \in \{1, 2, \dots, J\}$
i	Product, $i \in \{1, 2, \dots, I\}$
t	Time period, $t \in \{1, 2, \dots, T\}$

Parameters:

A_{wst}^{prod}	Amount of waste w produced in site s in period t
DL_{is}^{low}	Lower limit for demand of product i in site s
DL_{is}^{up}	Upper limit for demand of product i in site s
SL_{wd}^{d}	Storage limit for waste w in dump d
SL_{wp}^{p}	Storage limit for waste w in plant p
TL_{pj}^{low}	Lower capacity limit for technology j to be used in plant p
TL_{pj}^{up}	Upper capacity limit for technology j to be used in plant p
E_i	Price of product i
CD_d	Disposal cost in dump d
CS_w	Separation cost of waste w
CO_{wpj}	Operation cost of waste w sent to technology j to produce a product in plant p
CT_w^{sd}	Transportation cost of waste w from sites to dumps
CT_w^{dp}	Transportation cost of waste w from dumps to plants

CT_i^{ps} Transportation cost of product *i* from plants to sites
CF_{wpj} Fixed cost to purchase technology *j* for processing waste *w* in plant *p*
CV_{wpj} Variable cost associated with the capital of technology *j* to process waste *w* in plant *p*
dis_{sd}^1 Distance from site *s* to dump *d*
dis_{dp}^2 Distance from dump *d* to plant *p*
dis_{ps}^3 Distance from plant *p* to site *s*
α_{wd} Separation factor for waste *w* in dump *d*
β_{wij} Conversion factor of waste *w* to produce product *i* by technology *j*
ε Annualization factor for the fixed cost

Decision variables:
q_{wsdt}^{dist} Quantity of waste *w* distributed from site *s* to dump *d* in period *t*
q_{wdt}^{in} Quantity of waste *w* inlet to dump *d* in period *t*
q_{wdt}^{sep} Quantity of waste *w* separated in dump *d* in period *t*
q_{wdt}^{stor} Quantity of waste *w* stored in dump *d* in period *t*
q_{wdt}^{out} Quantity of waste *w* outlet from dump *d* in period *t*
q_{wdt}^{land} Quantity of waste *w* landfilled in dump *d* in period *t*
a_{wdpt}^{dist} Amount of waste *w* distributed from dump *d* to plant *p* in period *t*
a_{wpt}^{in} Amount of waste *w* inlet to plant *p* in period *t*
a_{wpt}^{stor} Amount of waste *w* stored in plant *p* in period *t*
a_{wpjt}^{tech} Amount of waste *w* in plant *p* transferred to technology *j* in period *t*
n_{ipt}^{p} Number of product *i* produced in plant *p* in period *t*
n_{ipst}^{dist} Number of product *i* distributed from plant *p* to site *s* in period *t*
n_{ist}^{s} Total number of product *i* transferred to site *s* in period *t*
y_{pj} Binary variable = 1 if plant *p* uses technology *j* (else = 0)

2.2. Objective function

The objective function of the proposed model is shown in Eq. (1), where the revenue from sales should be maximized from which the total cost of the entire SC including disposal, separation, operation, transportation from site to dumps, from dumps to plants and from plants to sites, and capital costs is deducted.

$$\begin{aligned} Max\ f = & \sum_i \sum_s \sum_t n_{ist}^s E_i - \left(\sum_w \sum_d \sum_t q_{wdt}^{land} CD_d + \sum_w \sum_d \sum_t q_{wdt}^{in} CS_w \right. \\ & + \sum_w \sum_p \sum_j \sum_t a_{wpjt}^{tech} CO_{wpj} + \sum_w \sum_s \sum_d \sum_t q_{wsdt}^{dist} CT_w^{sd} dis_{sd}^1 \\ & + \sum_w \sum_d \sum_p \sum_t a_{wdpt}^{dist} CT_w^{dp} dis_{dp}^2 + \sum_i \sum_p \sum_s \sum_t n_{ipst}^{dist} CT_i^{ps} dis_{ps}^3 \\ & \left. + \varepsilon \sum_w \sum_p \sum_j y_{pj} CF_{wpj} + \sum_w \sum_p \sum_j \sum_t a_{wpjt}^{tech} CV_{wpj} \right) \end{aligned} \tag{1}$$

2.3. Constraints

i. Waste collection

Equation (2) expresses that each site generates a given amount of waste, which is distributed to different dumps during each period. The amount of waste inlet to each dump per period is shown in Eq. (3).

$$A_{wst}^{prod} = \sum_{d} q_{wsdt}^{dist} \quad \forall w, s, t \tag{2}$$

$$q_{wdt}^{in} = \sum_{s} q_{wsdt}^{dist} \quad \forall w, d, t \tag{3}$$

ii. Waste processing at dumps

The amount of waste being separated from the inlet in each dump during each period is calculated in Eq. (4). Equation (5) shows the amount of waste stored at each dump per period and Eq. (6) indicates the amount of waste landfilled in dumps in each period. The storage limit for wastes in dumps is defined by Eq. (7).

$$q_{wdt}^{sep} \leq \alpha_{wd} q_{wdt}^{in} \quad \forall w, d, t \tag{4}$$

$$q_{wdt}^{stor} = q_{wdt-1}^{stor} + q_{wdt}^{sep} - q_{wdt}^{out} \quad \forall w, d, t \tag{5}$$

$$q_{wdt}^{land} = q_{wdt}^{in} - q_{wdt}^{sep} \quad \forall w, d, t \tag{6}$$

$$q_{wdt}^{stor} \leq SL_{wd}^{d} \quad \forall w, d, t \tag{7}$$

iii. Waste processing at plants

Equation (8) defines the amount of wastes distributed from dumps to plants. The amount of wastes inlet to plants during each period is indicated by Eq. (9) and Eq. (10) computes the amount of waste stored in each plant per period, which is limited by Eq. (11).

$$q_{wdt}^{out} = \sum_{p} a_{wdpt}^{dist} \quad \forall w, d, t \tag{8}$$

$$a_{wpt}^{in} = \sum_{d} a_{wdpt}^{dist} \quad \forall w, p, t \tag{9}$$

$$a_{wpt}^{stor} = a_{wpt-1}^{stor} + a_{wpt}^{in} - \sum_{j} a_{wpjt}^{tech} \quad \forall w, p, t \tag{10}$$

$$a_{wpt}^{stor} \leq SL_{wp}^{p} \quad \forall w, p, t \tag{11}$$

The amounts of waste distributed to processing technologies in each plant are limited by Eq. (12) and in Eq. (13) the amounts of products produced by different technologies at each plant per period are computed.

$$TL_{pj}^{low} y_{pj} \leq \sum_{w} a_{wpjt}^{tech} \leq TL_{pj}^{up} y_{pj} \quad \forall p, j, t \tag{12}$$

$$n_{ipt}^{p} = \sum_{w} \sum_{j} \beta_{wij} a_{wpjt}^{tech} \quad \forall i, p, t \tag{13}$$

iv. Products distribution

Equation (14) presents the number of end products obtained within each plant distributed to different sites in each period. Equation (15) shows the total amount of per product

shipped to each site per period, which is limited by the demand of product as shown in Eq. (16).

$$n_{ipt}^{p} = \sum_{s} n_{ipst}^{dist} \quad \forall i, p, t \tag{14}$$

$$n_{ist}^{s} = \sum_{p} n_{ipst}^{dist} \quad \forall i, s, t \tag{15}$$

$$DL_{is}^{low} \leq n_{ist}^{s} \leq DL_{is}^{up} \quad \forall i, s, t \tag{16}$$

3. Results and discussions

The problem features considered in this paper are taken from a real case study conducted in Mexico (Santibañez-Aguilar et al., 2015). However, their proposed model is modified by considering the intermediate storages and multiple time periods, and data is revised to fit the model requirements presented in this paper. In order to validate our model, the input data from the above study was used. For the variables which were missing in their study, the value of zero was assigned. After running the proposed model, the same result for the objective function was obtained as acquired by the previous model.

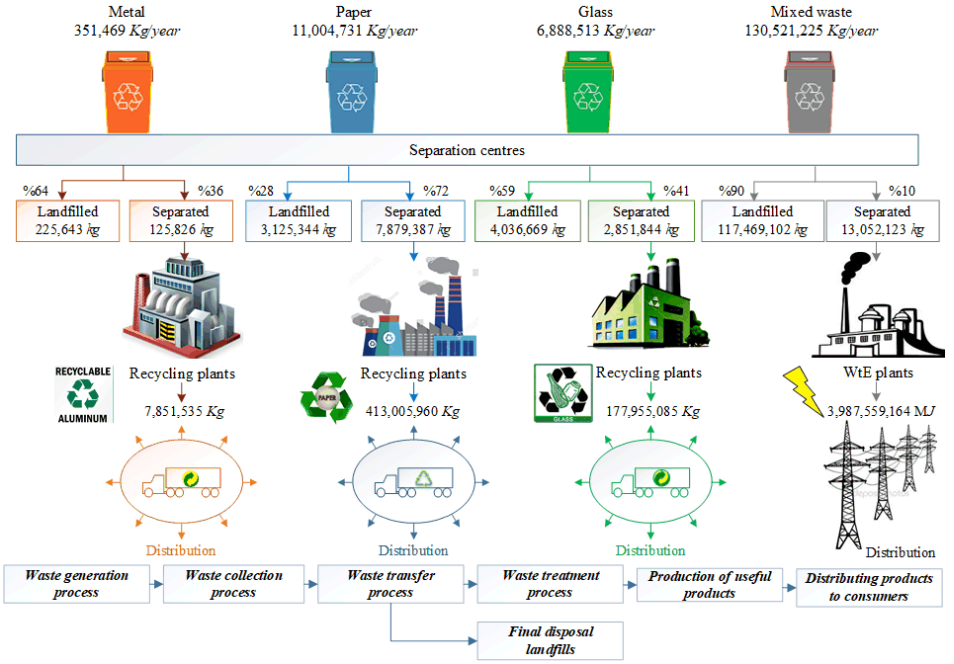

Figure 1. Schematic of considered municipal solid waste management supply chain network

Based on the collected data, it was observed that the MSW generation varies over time. During summer months, due to the change in consumption habits caused by the hot weather and higher consumption of drinks and fresh foods and vegetables, higher amount of glass wastes is produced, whereby less kitchen waste is generated. In winter, generally more solid wastes such as metal, paper and mixed waste are generated. The considered MSW system consists of three sites, two dumps and three plants. The problem is split into weekly planning periods with a total time horizon of one year. During one year, about

149 kt MSWs of metal (0.24 %), paper (7.40 %), glass (4.63 %) and mixed waste (87.73 %) are produced. The technologies used to process the waste include recycling technologies for metal, paper and glass, and pyrolysis arc gasification technology to generate electricity. The produced products are aluminum, paper, glass, and electricity.

The MILP model is formulated and solved using GAMS/CPLEX (v.24.9.1) on a laptop with an Intel Core i5/2.40 GHz and 8 GB of RAM. The model includes 9,784 constraints, 11,864 continuous variables and 12 binary variables. It was solved in 31.52 seconds. The results show that the model produces an annual net profit of -88.68 M€. The total cost is 402.81 M€, mainly consisting of capital cost (76.29 %), operation cost (14.63 %) and separation cost (8.68 %). Disposal and transportation costs construct only a small portion of the total cost. The total annual revenue obtained from selling the recyclable waste and produced energy is 314.13 M€. It is worth mentioning that consumption of the total available waste is not plausible since some wastes cannot be recycled and reused, and each waste has a certain percentage of separation. Figure 1 presents the separated and landfilled amounts of each type of waste and total amount of produced products during a year. It is indicated that mixed waste was the most valuable waste category in terms of production of useful product (electricity).

4. Conclusions

This paper presented an MILP model to analyze the profitability and SC network design of the MSW system. The structure of the proposed model is multi-level, multi-facility, multi-product and multi-period. A case study was selected to test the effectiveness and efficiency of the proposed model. The objective of the model is to find the optimal amount of waste distributed from waste production sites to dumps, from dumps to processing plants, as well as products transported from plants to consumers, so that the demand can be satisfied with the lowest cost over a given planning horizon. Furthermore, selling the recycled products and energy at sites was considered. The presented MILP model was solved efficiently in a reasonable computational time.

Abstract

Scheduling gasoline blending and order delivery operations is an important routine task in an oil refinery since gasoline can account for as much as 60-70% of total revenue. In this work we improve the mixed-integer nonlinear programming (MINLP) model of Li et al. (2016) to ensure optimality and incorporate nonlinear property correlations. To solve such nonconvex MINLP model to ε- global optimality, a global optimization method is proposed. It is shown that our improved model and proposed method can solve industrial examples to 1%- global optimality and generate the same or better solutions with less CPU time than those from Cerda et al. (2016). Using nonlinear property correlations could lead to more accurate prediction than linear correlations.

Keywords: Scheduling, gasoline, blending, global optimization, nonlinear prediction

1. Introduction

Scheduling gasoline blending and order delivery operations is an important routine task in an oil refinery since gasoline can account for as much as 60-70% of total revenue (Li and Karimi, 2011). Optimal scheduling can avoid ship demurrage, minimize quality give-aways, reduce transitions, etc. However, this scheduling problem is a nonconvex mixed-integer nonlinear programming (MINLP) problem. Li and Karimi (2011) and Castillo-Castillo and Mahalec (2016) developed MINLP models for this problem, incorporating many realistic features such as non-identical parallel blenders, minimum run length and amount, constant blending rates, multipurpose product tanks, piecewise constant profiles of blend component qualities and feed rates. Li et al., (2016) improved the MILP relaxation of Li and Karimi (2011) and proposed a global optimization method. However, their model may lead to suboptimality. Although Cerda et al. (2016) improved efficiency, their model results in infeasibility or suboptimality in some cases.

In this work we improve the nonconvex MINLP model of Li et al. (2016) to ensure optimality and incorporate nonlinear property correlations instead of property indices. The nonlinearities come from not only modelling constant blending rate in a run, but also the property correlations. To solve such model to ε- global optimality, a global optimization method is proposed, which first allows blending rates to vary and removes nonlinear property correlations, then uses adjustment procedure, solves a feasibility problem with nonlinear property correlations and an iterative MILP and NLP procedure, and finally employs deterministic global optimization solver ANTIGONE (Misener and

Floudas, 2014) to find ε- global solutions. It is shown that our improved model and proposed method solve all examples to 1%- global optimality and generate the same or better solutions with less efforts than those from Cerda et al. (2016). Using nonlinear property correlations could lead to more accurate prediction than linear correlations.

2. Problem statement

Figure 1 illustrates a general gasoline blending, storage and order delivery process in a typical oil refinery. It involves I blend components in exactly I dedicated component tanks (i = 1, 2, …, I) , B blenders (b = 1, 2, …, B), J multipurpose product tanks (j = 1, 2, …, J), and some lifting ports. P (p = 1, 2, …, P) grades of gasoline are produced and O orders (o = 1, 2, …, O) is to be fulfilled in the scheduling horizon H. Given the scheduling horizon and data on components, blenders, component and product tanks, orders and economics, the scheduling problem is to determine (i) blending schedule; (ii) charging schedule for blenders to product tanks; and (iii) order delivery schedule. The objective is to minimize total operating cost including component, transition, demurrage, and delivery costs. More details can be referred to Li and Karimi (2011).

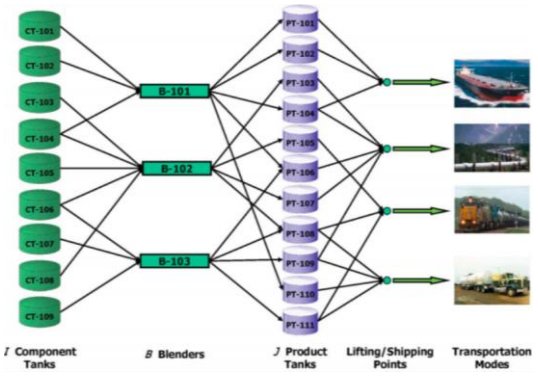

Figure 1 Schematic of a general gasoline blending, storage and order delivery in an oil refinery

3. Motivating Example

Consider an example from slight modifications of Example 1 in Li and Karimi (2016). The blending rate ranges are modified to 10-15 kbbl/h and the capacities of product tanks are reduced to 55 kbbl except for PT-101 whose capacity is reduced to 95 kbbl. The initial product in PT-104 changes to P1. It is found that no feasible solution is generated from the model of Cerda et al. (2016), whilst a feasible solution of 5470.422 K$ is obtained from the model of Li et al. (2016). In addition, a better solution of 5139.929 K$ for Example 1 is obtained from Cerda et al. (2016). All these motivate to improve the model of Li et al. (2016) to ensure optimality for any cases.

4. Improved MINLP formulation

In this section, only improvements for Li et al. (2016) is presented. We first remove eqs. 11a-b in Li et al. (2016) which do not allow a blender to process the same product in two consecutive blend runs. Then, 0-1 variables $xe(b,n)$ denoting the end of a blend run are imposed as binary. To account for transition cost correctly when empty event points exist in two consecutive blend runs, 0-1 auxiliary continuous variables $xx(b,p,n)$ and $xxe(b,n)$ are employed, which have the following relationship with $x(b,p,n)$.

$$xx(b,p,n) \geq x(b,p,n) \qquad \forall n, (b,p) \in \mathbf{BP} \qquad (1)$$

$$xx(b,p,n) \geq x(b,p,n-1) - \sum_{p':(b,p)\in\mathbf{BP}} x(b,p',n) \qquad \forall n, (b,p) \in \mathbf{BP} \qquad (2)$$

$$\sum_{p:(b,p)\in\mathbf{BP}} xx(b,p,n) = 1 \qquad \forall n, (b,p) \in \mathbf{BP} \qquad (3)$$

$$xxe(b,n-1) \geq xx(b,p,n-1) - xx(b,p,n) \qquad \forall (b,p) \in \mathbf{BP}, n \qquad (4)$$

$$xxe(b,n-1) \geq xx(b,p,n) - xx(b,p,n-1) \qquad \forall (b,p) \in \mathbf{BP}, n \qquad (5)$$

$$xxe(b,n-1) + xx(b,p,n-1) + xx(b,p,n) \leq 2 \qquad \forall (b,p) \in \mathbf{BP}, n \qquad (6)$$

$$\sum_{b=1}^{B}\sum_{n=1}^{N-1} xxe(b,n) \leq NP - NB \qquad (7)$$

The nonlinear prediction correlations for RON and RVP are given below,

$$\theta(b,p,s,n) = \overline{r}(b,p,n) + \overline{a}_1 \cdot [\overline{r}_s(b,p,n) - \overline{r}(b,p,n)\cdot\overline{s}(b,p,n)] + \overline{a}_2 \cdot [\overline{o}_{sq}(b,p,n) - \overline{o}(b,p,n)^2]$$
$$+\overline{a}_3[\overline{\mathrm{a}}_{\mathrm{sq}}(b,n,p)^2 - 2\overline{\mathrm{a}}_{\mathrm{sq}}(b,n,p)\cdot\overline{a}(b,p,n)^2 + \overline{a}(b,n,p)^4] \quad \forall (b,p) \in \mathbf{BP}, n, s = RON \qquad (8)$$

$$\theta(b,p,s,n)^{1.25} = \sum_i recipe(i,b,p,n)\cdot\theta(i,s)^{1.25} \qquad \forall (b,p) \in \mathbf{BP}, n, s = RVP \qquad (9)$$

$$\theta^L_{PS}(p,s)\cdot x(b,p,n) \leq \theta(b,p,s,n) \leq \theta^U_{PS}(p,s) \quad \forall (b,p) \in \mathbf{BP}, n, s \in \{RON, RVP\} \quad (10a,b)$$

More details about eqs. 8-9 can be referred to Parkash (2003). The variables *recipe*(*i*,*b*,*p*,*n*) in eqs. 8-9 denote the recipe of a product, which is calculated as follows,

$$q\mathrm{l}(i,b,p,n) = Q_P(b,p,n)\cdot recipe(i,b,p,n) \qquad \forall (b,p) \in \mathbf{BP}, n, i \qquad (11)$$

To model constant blending rate in a run, the following constraints are enforced.

$$Q(b,n) = BR(b,n)\cdot BL(b,n) \qquad \forall b, n \qquad (12)$$

$$BR(b,n) - F^U_B(b)\cdot xe(b,n) \leq BR(b,n+1) \leq BR(b,n) + F^U_B(b)\cdot xe(b,n) \quad \forall b, n < N \quad (13\text{-}14)$$

Note that eqs. 12-14 are the same as eqs. 22-24 in Li et al. (2016). All other constraints are also the same as those in Li et al. (2016). The objective function is given as follows,

$$TC = \sum_{i=1}^{I}\sum_{b=1}^{B}\sum_{n=1}^{N} c(i)\cdot q(i,b,n) + \sum_{b=1}^{B}\sum_{n=1}^{N-1} CB(b)\cdot xxe(b,n) + \sum_{b=1}^{B} CB(b)\cdot xxe(b,0) + \sum_{o=1}^{O} DM(o)\cdot d(o)$$
$$+\sum_{j=1}^{J}\sum_{n=1}^{N-1} CT(j)\cdot ue(j,n) + \sum_{j=1}^{J} CT(j)\cdot ue(j,0) + \sum_{j=1}^{J}\sum_{o:(j,o)\in\mathbf{JO}}^{O}\sum_{n=1}^{N} COT(o)\cdot z(j,o,n) \qquad (15)$$

5. Global optimization method

Figure 2 shows the proposed global optimization method including solving an MILP underestimator, adjustment procedure, a feasibility model, an iterative MIP and NLP procedure, and global optimisation solver ANTIGONE to ensure ε- global optimality.

MILP underestimator

Nonlinear constraints (i.e., eqs. 12-14 and 8-11) are dropped from the original MINLP

model to allow varying blending rates and eqs. 16a-b are added to ensure blending rates vary within limits, which provides a lower bound (LB) for the original MINLP model.

$$F_B^L(b)\cdot BL(b,n) \le Q(b,n) \le F_B^U(b)\cdot BL(b,n) \qquad \forall b,\, n \qquad (16a,b)$$

Schedule adjustment procedure

The constant blending rate in a run is computed using the optimal solution from the MILP underestimator. It is then fixed in the original MINLP model as parameters with other variables varying to build an MILP model without eqs. 8-11, ensuring constant blending rate in a run but without satisfying eqs. 8-10 for RON and RVP. The values of 0-1 discrete variables from this MILP model are extracted to fix 0-1 discrete variables in the original MINLP model and build a NLP model with eqs. 8-11. The optimal solution from this NLP provides an upper bound (UB) for the original MINLP model.

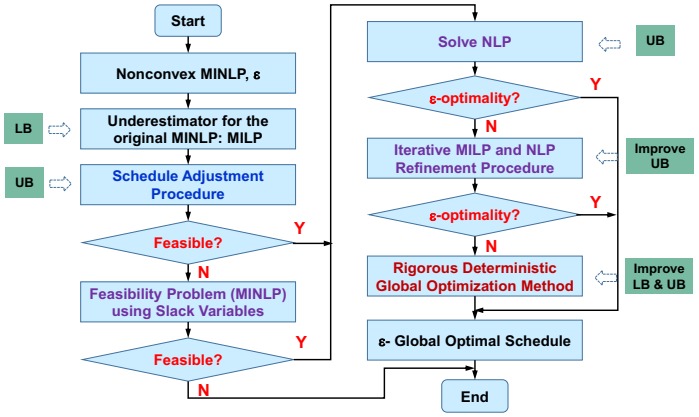

Figure 2 Schematic diagram of the proposed global optimization method

Feasibility problem

Two positive slack variables $s1(b,p,s,n)$ and $s2(b,p,s,n)$ are introduced to eqs. 8-9 in the original MINLP model.

$$\theta(b,p,s,n) = \overline{r}(b,p,n) + \overline{a}_1\cdot[\overline{r}_s(b,p,n) - \overline{r}(b,p,n)\cdot\overline{s}(b,p,n)] + \overline{a}_2\cdot[\overline{o}_{sq}(b,p,n) - \overline{o}(b,p,n)^2]$$
$$+\overline{a}_3[\overline{a}_{sq}(b,n,p)^2 - 2\overline{a}_{sq}(b,n,p)\cdot\overline{a}(b,p,n)^2 + \overline{a}(b,n,p)^4] + s1(b,p,s,n) - s2(b,p,s,n)$$
$$\forall (b,p) \in \mathbf{BP},\, n,\, s = RON \qquad (8')$$

$$\theta(b,p,s,n)^{1.25} = \sum_i recipe(i,b,p,n)\cdot\theta(i,s)^{1.25} + s1(b,p,s,n) - s2(b,p,s,n)$$
$$\forall (b,p) \in \mathbf{BP},\, n,\, s = RVP \qquad (9')$$

The objective is to minimize slack variables in eq. 15′. This feasibility model which is solved using ANTIGONE can ensure if the original MINLP model is feasible.

$$z = \sum_b \sum_{p:(b,p)\in\mathbf{BP}} \sum_{s\in\{RON,RVP\}} \sum_n s1(b,p,s,n) + s2(b,p,s,n) \qquad (15')$$

Note that UB is a feasible solution for the original MINLP model. An iterative MILP and NLP procedure is used to improve the quality of the UB, which is similar to that of Li et al (2016). The difference is that blending recipes as well as blending rates are fixed in the original MINLP model to construct an MILP model in the iterative procedure.

6. Computational studies

We revisit the motivating example with our improved model and global optimization method. The optimal solution of 5470.422 K$ is obtained, whilst it is infeasible from Cerda et al. (2016). We also solve 5 examples with single and multiple periods from Li and Karimi (2016) using CPLEX 12.6.3/GAMS 24.7.4 on a Desktop (Intel® XeonR CPU 3.2 GHz, 8 GB memory) running Windows 7. The results are given in Tables 1-2. From Table 1, we obtain the same optimal solution of 5139.929 K$ as Cerda et al. (2016) for Example 1. Although we obtain the same optimal solution as that from Cerda et al. (2016) for Example 10, the CPU time is reduced significantly. For others, we obtain better solutions. Similar conclusions can be made for multi-period from Table 2.

Table 1 Comparative results of ours with that of Cerda et al. (2016): single-period

Example	Model	Binary Variables	Constraints	Cost (K$)	CPU Time (s)	Gap (%)
1	Ours	175	2057	5139.929	0.748	0.0

	Cerda	4043	29056	Infeasible	-	-

We solve Example 14 to 1%-global optimality using nonlinear correlations for RON and RVP instead of property indices. The optimal solution of 18164.576 K$ is generated within 6178 s. The quality values from nonlinear and linear models are given in Table 3. The RON and RVP values from the linear model is off-specification in some cases, whilst they are on-specification from the nonlinear correlations.

7. Conclusions

In this work we improved the model of Li et al. (2016) for scheduling gasoline blending and order delivery operations. Nonlinear property correlations were included. A global optimization method is proposed to solve the nonconvex MINLP model to ε- global

optimality. It is shown that our improved model and proposed global optimization method solved these examples to 1%- global optimality and generated the same or better solution with less efforts than those from Cerda et al. (2016). Using nonlinear property correlations could lead to more accurate prediction than linear correlations.

Abstract

In this work, a holistic methodology was developed and implemented in a computer-aided framework with the purpose of establishing a pedagogical simulation tool for bioprocess applications. The methodology integrates the development of a process simulator with the use of gamification elements to improve the pedagogical experience. Moreover, model development and reuse was incorporated into the framework through creating a generic model template. The application of the methodology was demonstrated by the simulation of a batch fermentation process of *Saccharomyces cerevisiae* cultivated under aerobic conditions with glucose as substrate, thereby, demonstrating mixed metabolism dynamics and considering the inhibition of ethanol consumption due to the presence of glucose with an integrated learning design and gamification elements. The learning experience, done with beta users with different previous levels of knowledge about fermentation processes, confirmed an interest for using gamification for training chemical engineering, biochemical engineering, and biotechnology students.

1. Introduction

Institutions of higher education are facing the challenge of providing quality education to an increased number of students with a budget that has remained constant (Balamuralithara and Woods, 2009). A special area of concern is engineering education, in which students require extensive practical experience to acquire technical competences for their career. Acquiring this experience often comes with complications due to economic expenses and limitations of experimental teaching. One way to tackle these limitations is exploration through creating "what if" scenarios, or the possibility to simulate a variety of fictional environments, and consequently create "intuition" and provides a platform for learning by failure. Today, this is often partially achieved using process simulation tools. However, most of these tools do not target teaching and therefore, they come with educational limitations. For example, there is not a clear connection between visual/graphic features and underlying mathematical models, and this results in the majority of process simulators being experienced by the user as black-

box modules. Interestingly, research has shown that including game-elements into simulations of complex systems can provide an excellent framework for making the theoretical knowledge more approachable (Ebner and Holzinger, 2007).

In this work, the objective is to propose and implement a methodology for the development of pedagogical simulation tools. Furthermore, the application of the methodology is highlighted through a specific case of a fermentation process. The implemented software tool includes game-elements, and a user experience experiment is carried out amongst three beta groups with different educational backgrounds. This is done to measure the learning experience, to quantify the intrinsic motivation and to involve the future users in the design of the project.

2. Computer-aided Framework

The framework for the development of a pedagogical simulation tool including methods and tools and information flow is presented in Figure 1. The framework consists of five hierarchical steps. The framework is generic, and each step may be applied independently, provided the availability of input information, and it is described in the forthcoming sub-sections.

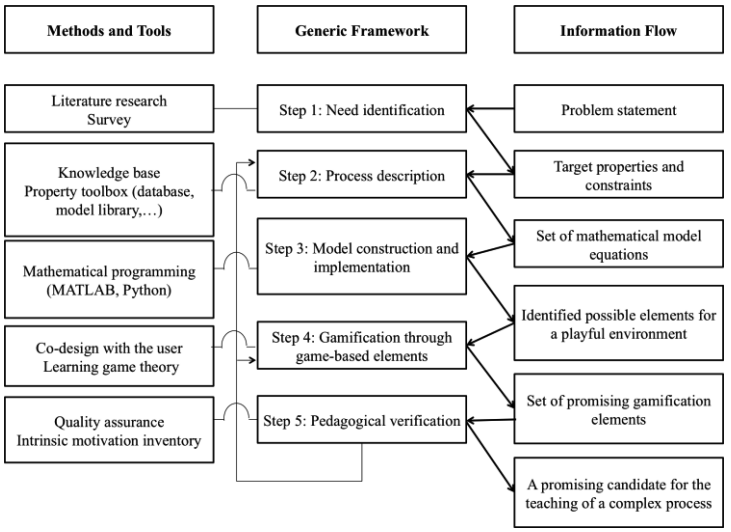

Figure 1. Framework for the development of a pedagogical simulation tool.

2.1. Step 1: Need identification

In this step, the problem statement is defined to identify the need that has to be fulfilled through a pedagogical approach. In a chemical engineering context, this need may be to provide sufficient training associated with any process or unit operation. Thereby, the problem statement is based on either user-need (often quantified through a survey) or a comprehensive literature survey. The objectives to be fulfilled as a result of satisfying the identified need may be qualitative in terms of learning experience or quantitative through a set of properties and constraints. The problem formulation and statement will then be used as an input to make structural decisions to describe a given process.

2.2. Step 2: Process description

In this step, the case study process is mathematically and pedagogically described based on the target properties and constraints that were included in the problem formulation in Step 1. In this step, there is a need for information about pure component properties, reaction rate constants, transfer coefficients and other relevant process parameters that are stored in a property toolbox, supported by information collected from literature or database. Meanwhile, the learning design is done using a didactic frame designed by Hiim and Hipee (1997), pursuing a learning based on experience, understanding, and action. Therefore, by completing this step all information that is needed to describe the process mathematically and pedagogically is obtained.

2.3. Step 3: Model construction and implementation

This step is intended to design, construct, solve and validate a process model. For this, a workflow is developed for the creation and use of a process template (Figure 2).

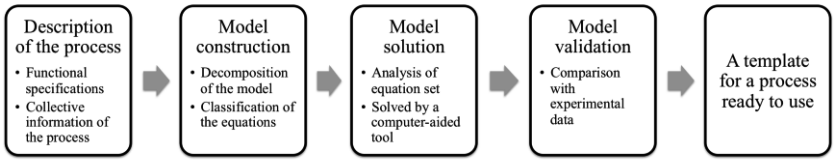

Figure 2. Workflow for the creation and use of a process template.

This workflow is based on the work of Fedorova (2015), for the module modelling due to template creation, and it is based on the idea of the combination of parts of previously developed models into a new set of equations for a specific case. Therefore, templates can be modified generating different versions of the base model, and all those options can be stored.

2.4. Step 4: Gamification through game-based elements

Game-based elements are introduced in this step to engage the users in the learning experience and in order to support their intrinsic motivation (Ebner, and Holzinger, 2007, Jayasinghe and Dharmaratne, 2013). Although gamification is usually developed in parallel with experimentation, it is initially based on the supportive framework of the Smiley Model (Weitze, 2016), which combines learning design and game design elements.

2.5. Step 5: Pedagogical verification

Finally, this module corresponds to model application and validation and is done by a learning experience, in which it is evaluated the learning design and the use of gamification elements.. To do so, a questionnaire for data collection can be distributed before and after the trial of the prototype amongst users, evaluating previous knowledge and the learning experience or by personal interview. This module should provide information that can help improve the simulation tool by modifying the process description (the theoretical content) or the gamification elements used.

3. Case Study: *Saccharomyces cerevisiae* cultivated under aerobic conditions with glucose as substrate in batch fermentation

For the application of the proposed methodology (see Figure 1), a prototype template of the cultivation of *Saccharomyces cerevisiae* under aerobic conditions and glucose as a carbon source in a batch system was used.

Step 1: Need identification: *S. cerevisiae* is one of the most common microorganisms in the biotechnological industry (Ostergaard *et al*., 2000) and therefore its understanding is a basic need in a bioprocess course.

Step 2: Process description: In its cultivation under aerobic conditions, and therefore considering liquid and gas phases actives, *S. cerevisiae* presents a mixed metabolism controlled by the availability of oxygen that involves the oxidation of glucose as substrate and formation of ethanol as a fermentation product (Sonnleitner and Käppeli, 1986). Ethanol consumption is inhibited by the presence of glucose, and by the reduction of glucose. On the other hand, the pedagogical design is based on a constructive learning, with an educational content for the complete description of a fermentation process.

Step 3: Model construction and implementation: – For the specific case of a fermentation, a sub-workflow for the construction of the model was developed and is shown in Figure 3.

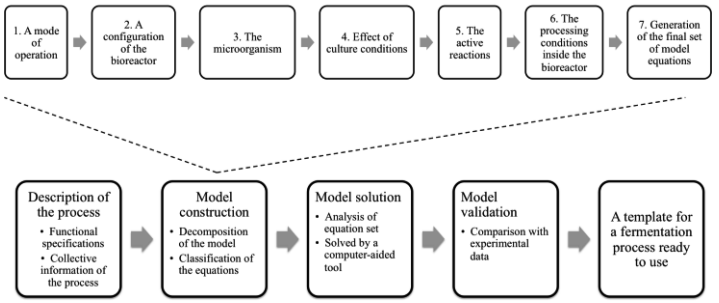

Figure 3. Workflow for the model construction of fermentation.

A set of model equations corresponding to the mathematical equations, shown in Table 1, are implemented as a computational problem and solved within Python while the user only interacts through a visual interface. The parameter values and the constants are based on the work by Fernandes *et al*. (2013).

Table 1. Set of mathematical equations used for the modelling of the fermentation process of *S. cerevisiae*

Definition	Equation
Mass balance for a batch bioreactor	$N_{A0}\frac{dx}{dt} = r_A V$
Volumetric flux of oxygen	$\dot{N_{O_2}} = k_L a\,(C^*_{O_2} - C_{O_2})$
Kinetic model	Sonnleitner and Käppeli (1986)

Step 4: Gamification through game-based elements: Although gamification is usually done in parallel with experimentation, the game elements used in the first step of the prototype were:

1. Goal and action space. The game is developed in the context of finding a job, and at the end of it, the user will be prepared to start working in a company.
2. Choice. Parameters and kinetic equations are easily modified, providing the opportunity of checking "what if" scenarios by the student.
3. Challenge. It is introduced in the way of questions that increase in level of difficulty with a correct answer, although there is also an answer option "No idea" that will teach the concept to the student.
4. Feedback.

Step 5: Pedagogical verification: This was done through evaluating the learning experience at three different pre-knowledge levels about fermentation processes in order to verify the pedagogical value of the prototype and involve the student in an what they want or what would be useful for them, using a paper prototype and personal interviews or questionnaires. The pre-knowledge levels were: novice, elemental knowledge of biotechnology at bachelor level and expert knowledge. In the learning experience with novices, done by personal interviews, an excessively high level of the unknown theory behind the game was perceived, and a higher number of gamification elements and hints were requested. However, in the case of previous elemental knowledge, the information obtained during the learning experience was non-uniform and, in some cases, conflictive as students had problems to answer some questions but considered the content as easy. Furthermore, students generally believed that the tool could be very helpful and considered gamification useful for teaching complex knowledge (see Figure 4). Meanwhile, the expert user-experience, to whom was provided the same questionnaire than the elemental knowledge users, showed initially some resistance to the use of gamification, but in the survey carried out after the learning experience, an interest was shown in its use. One key issue is the development of a more attractive interface and overcoming user reluctance in playing a gamified pedagogical simulation tool.

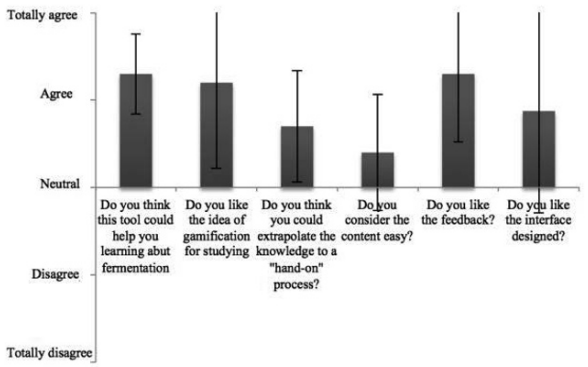

Figure 4. Survey about the usability and enjoyability of the prototype from a class of the second year of the bachelor in Sustainable biotechnology.

4. Conclusions

A computer-aided framework has been developed to support the creation of pedagogical simulation tools integrating the use of gamification elements to engage the learning process. The application of the proposed methodology has been highlighted through a case study of *Saccharomyces cerevisiae* cultivated under aerobic conditions with glucose as substrate in batch fermentation and is implemented in a computer-aided software tool. Furthermore, a learning experience survey, in which users were involved in the co-design, showed a general interest in the use of this tool for the study of fermentation, but also that the design should be adapted to the specific level of pre-knowledge of the user.

Abstract

This paper describes the progress of our efforts to lead the CACHE (Computer Aids for Chemical Engineering Education) Task Force in transforming from chemical process design toward chemical product design. Through CACHE, we are coordinating the development of a library of product-design case studies. Beginning with preliminary product designs created previously over several semesters, we are arranging for faculty experts, knowledgeable in the underlying technology platforms, to work with student groups to enrich the product designs. Over a 3-year period, a collection of approximately 25 case studies is being prepared. This article describes the research envisioned as innovative product designs are created, both regarding applications of new technologies, and product design evolution/evaluation; and in advancing strategies for teaching product design. The anticipated use of these case studies in departments worldwide for design courses taught by similar technology experts, just a few in each department, is discussed. These will align with the expertise of the faculty members, who will help undergraduate student design groups gain the technology skills to carry out specific design projects.

Keywords: product design, innovation, technology platforms, teaching assessment.

1. Introduction

1.1 Background

The creation of product and process designs are integral tasks in the commercialization of any chemical product. Traditional chemical engineering focuses on process design because commodity products tend to be well defined and product design is not required. For these mature products, the companies compete in the marketplace by reducing product cost. This is achieved by improving the production process or by switching to a cheaper feedstock. The latter often necessitates the development of a new process.

With the emergence of traditional chemical engineering in developing economies such as Saudi Arabia, China, South Korea, Vietnam, Thailand, and so on, companies in developed economies can no longer prosper by merely producing mature products. To attain a higher profit margin, the obvious way is to produce innovative consumer products that enhance human comfort, health, and convenience. For these consumer products, product design is crucial. The designer has to select the proper product ingredients and design the process to configure / process these ingredients in such a way that the final product provides the desired product attributes.

Since product design has not received much attention in the chemical engineering community until the late 90s (Stephanopoulos, 2003; Cussler and Wei, 2003; Gani, 2004; Wesselingh et al., 2007; Ng et al., 2007, Wei, 2007; Cussler and Moggridge, 2011; Seider and Widagdo, 2012; Bröckel et al., 2013), there are significantly less teaching materials and fewer case studies for teaching product design than for process design. At present, all chemical engineering curricula finish with a course (or two courses) on chemical process design – with a few curricula offering an elective on chemical product design. Process design (designing the manufacturing processes) builds upon process-oriented engineering-science courses (i.e., thermodynamics, fluid mechanics, heat and mass transfer, separations, and reactor design). Not surprisingly, most design projects, including the capstone design projects, in typical chemical engineering curricula are related to process design, simulation and optimization.

Over decades, process designers have built upon engineering-science fundamentals – with textbooks and process simulators widely available. Few handle both product and process design. Recently, Seider et al. (2017), in *Product and Process Design Principles* (4^{th} Ed., John Wiley), in addition to process design of traditional chemical plants, methods for designing and manufacturing new chemical products for consumers are also comprehensively covered. It offers a natural transition from process to product design and from commodity to consumer products.

Pedagogically, the product design strategies lead naturally to the process design strategies. However, product design often involves complex technology platforms that characterize pastes and creams, soft materials, tailor-made solvents, detergents, dehumidifiers, mosquito repellents, and so on. To carry out the product designs, faculty and students need examples of how to work with specific technology platforms. This leads to a key reason for carrying out this educational research – that is, it seems clear that a coupling is needed that links specific product-design problems with the expertise of specific faculty members. Our faculty collaborators are developing case studies closely aligned to their specific interests/expertise and to those of their departments in general. Also, we anticipate that just a few of the resulting case studies will be selected by faculty in each department worldwide, depending upon the interests/expertise of the faculty in each department.

This collaboration is timely because a gradual shift from traditional process design to new product and process design in academia has been taking place without fanfare for almost two decades. This can be seen in the recently hired chemical engineering faculty. Relatively few engage in traditional process engineering areas such as unit operations (distillation, crystallization, and so on), reaction engineering, or process design and control. The majority are bio- and materials-oriented projects. These teacher-researchers with their domain knowledge are well positioned to contribute to a product-process design curriculum suitable for the new generation of chemical engineers in advanced economies such as the U.S.

1.2 The Hong Kong Experience

Hong Kong is a global financial center engaging in the development and commercialization of non-commodity chemical products. Manufacturing is often carried out by OEM in Mainland China. For this reason, the curriculum at The Hong Kong University of Science and Technology (HKUST) has already significantly shifted from process design to product design. New product design courses have been developed for freshmen, seniors, and graduate students. We believe that, with the recent developments in fracking and the use of natural gas as feedstock for the chemical industry, the change from a primarily process design curriculum towards a more balanced product and process design curriculum will be delayed by several years in the U.S. But, it will happen.

Over the past four years, HKUST has tried different products in their product-design projects (Table 1). In each design project, a team of 3-5 students is given a project statement defining the scope of the project, relevant literature and consulting sources to help complete the product, guidelines for creating the written and oral reports, and an assessment rubric for evaluating student performance. Advice and comments are provided to the students throughout the project.

Table 1. Products Used for Design Projects in Hong Kong

• **Wine Aerator**	• Air Conditioner with Green Refrigerants
• **Faucet Water Filter**	• Building Air Conditioning System
• **Conductive Ink**	• Phase Transition Type Heating Pad
• **Vitamin C Tablets**	• Energy Recovery Ventilator
• **Hand Lotion**	• Conductive Paste for Printed Electronics
• **Laundry Detergent**	• Disposable Diaper
• **Shampoo**	• Desiccant Dehumidifier
• **Toothpaste**	• Refrigerant Dehumidifier
• **Mosquito Repellent Vaporizer**	• Respirator
	• Portable Seawater Desalination System
• **Mosquito Repellent Mat**	• Wearables
• **IR Blocking Smart Window**	• Powdered Milk
• **PM 2.5 Air Purifier**	• Controlled Release Granule
• **Wound Dressing**	• Membrane Bioreactor
• **Magnetocaloric Fridge**	• Biosensor
• **Refrigerator**	

At the end of the project, the team submits a written report and a video using a power point presentation to summarize all the main points. The items addressed in the final report are given in Table 2. In class, the video presentation is followed by a Q&A session of about 10 minutes. The student solutions to these design projects were the basis for our workshop on Process and Product Design Instruction at the ASEE Summer School for Chemical Engineering (Young) Faculty at North Carolina State University in the Summer 2017. Several solutions distributed to the attendees are available from the first author, Prof. Ng. Attendees of our workshop, and others, have been encouraged to help design groups develop improved product-design case studies, as discussed in Section 2.1.

Because of the open-ended nature of these design problems, they do not have unique and complete solutions. Indeed, different students often come up with very different products for the same problem statement. For example, the design of disposable diaper was one of the design projects. One group of students considered a product that focused on reusing part of the disposable diaper, while another group designed a product that comes with an RFID (Radio Frequency Identification) wetness sensor. Clearly, it is impossible for one single instructor to possess the necessary domain-specific knowledge to guide the students to explore deeply and broadly all the different products in Table 1. Without doubt, a team effort, involving many collaborators worldwide, is the best way to identify interesting and workable chemical products for student design projects.

Table 2. Items Addressed in the Student Written Report

- The product and its desired functions.
- The market size, major companies selling this and related products, competitive analysis, potential innovative products, and so on.
- The required product attributes to succeed in the marketplace.
- The product concept including product microstructure, macrostructure, types of ingredients, and so on.
- The product specifications
- The product manufacturing process; e.g., the flowsheet, equipment to be used, equipment operating conditions, material balances, and so on.
- A financial analysis accounting for the R&D cost, equipment cost, material cost, advertising cost, and so on.

2. Research

This section first describes the foci of the product-design case studies. Unfortunately, space is not available to present an example case study, showing examples of the research issues addressed. But, the research issues in teaching product design, which we are working to explore are included – emphasizing the research aspects of motivating and assessing the success of achieving our objectives with chemical engineering seniors and design instructors.

2.1 Product Design Case Studies

As described previously, up to 25 faculty members from different universities are being identified, many of whom have agreed to help design groups develop improved product-design case studies. Each technology expert will advise a student design team that expands on one of the case studies in Table 1, or creates a completely new product design project following the multidisciplinary, hierarchical approach described in Seider et al. (2017). Note that the products designed by student groups at HKUST were primarily formulated products, functional products, or devices, not including molecular products, which will be included going forward. For each of the 25 case studies, the faculty advisers will prepare the students and guide them toward designing more innovative products. After carrying out their product designs, several learning outcomes are anticipated, including the ability to:

- Perform a market study including competitive analysis using information in the public domain

- Generate new product ideas to enhance human comfort, health, and convenience in a sustainable manner and determine whether such a product is potentially profitable using methods such as business model canvas
- Identify product attributes and product specifications using methods such as house of quality
- select product ingredients using thermodynamic databases and computer-aided molecular design tools such as ICAS from Prof. Rafiqul Gani
- model product performance and adjust the design to meet product specifications
- design the manufacturing process
- perform prototyping
- set product price
- perform capital budgeting
- perform product sustainability analysis
- present a realistic product development plan both orally and in writing effectively

While this is not a requirement, ideally, the faculty adviser, responsible for teaching product/process design, will team up with another faculty member with expertise in the fundamental sciences and applications of the selected product.

2.2 Expected Advances in Teaching Product Design

Learning is achieved in many ways. As shown in Figure 1, the students will learn about the multidisciplinary, multiscale, hierarchical framework for product design from the product-design faculty adviser, perhaps in the classroom. Elements of the framework needed for performing product design – model-based methods, rule-based methods, tools for simulation and optimization, databases for material properties, equipment performance, and so on, and experiments – will be covered. Each design team is expected to learn about the underlying science and technology for their product. This will be achieved by self-study guided by the domain-knowledge faculty adviser.

This combination of experiential learning, self-learning, formal learning, and peer learning in a group setting is expected to improve the students' learning experience. We seek to understand how to use these different ways of learning synergistically and effectively for teaching chemical product design.

Overall, the success of this approach can be judged by the utilization of the product-design case studies worldwide. In addition, each individual product-design case study will be assessed as follows:

- Benefit to human comfort, health, and convenience
- Impact on sustainability and social responsibility
- Potential economic impact
- Innovation
- Technically correct and an appropriate amount of details
- Breadth and depth of the report Feedback from students will be documented. Items will include:
- Motivation to self-learning
- Stimulation to pursue entrepreneurship

- The learning outcome of the perspective, methods, and tools for product design Feedback will also be sought from faculty participating in this guided product-design project:
- The effectiveness in integrating process design faculty with faculty engaging in engineering sciences in a typical chemical engineering department
- The effectiveness of the project-based approach to teach product design

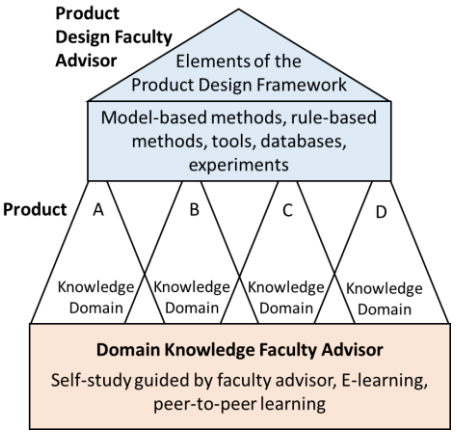

Figure 1. The students learn about how to perform product design and the domain knowledge underlying the product under consideration from the faculty adviser(s), E-learning, and so on. Each different product (of the four, A to D, shown here) is expected to involve a different knowledge domain although these domains are expected to overlap to some degree.

3. Conclusions

This manuscript documents our approach to generate a library of expert-driven, product-design case studies.

Reflections on embedding safety throughout the process engineering program

Michaela Pollock, Eva Sorensen*

Department of Chemical Engineering,UCL, Torrington Place, London, WC1E 7JE,United Kingdom
e.sorensen@ucl.ac.uk

Abstract

Safety is an important part of being a well-rounded, responsible process engineer. It not only covers fundamental scientific knowledge but also a way of thinking and culture in how engineers approach their work, and is continually developed throughout the working life of a process engineer. However, how this safety learning can start to be imparted to engineering students in an academic environment is a challenge for educators. In this work the systems approach that has been taken as part of UCL's Integrated Engineering Program (IEP) teaching framework is examined. Within this framework, safety is embedded into the curriculum from the start in Year 1 and is continually extended and advanced throughout the process engineering program. As the first cohort of students graduate we reflect on how this has been implemented and received.

Keywords: teaching, safety, embedded learning

1. Introduction

The significance of safety within process engineering is widely acknowledged in industry and education. However, the learning, and application of that learning, in an industrial and educational context is very different. In an industrial setting, where recent engineering graduates are applying their newly-gained fundamental knowledge to real-life problems within interdisciplinary teams of varying experience, it is easy to comprehend how the graduates can build on their fundamental knowledge to develop into well-rounded, safety-aware and responsible engineers. These real-life settings and awareness of the full context of safety, are challenging for educators to impart to students who are still developing their knowledge of core chemical engineering subjects and have limited if any industrial experience.

Ultimately, these challenges cannot be overlooked by educators aiming to prepare a young person for a career in engineering, as imparting an understanding and awareness of safety is a key learning outcome required by accreditation bodies globally. The IChemE's accreditation guidelines (IChemE, 2017) require graduating students to have gained an understanding of a variety of process safety learning outcomes, such as inherent safety, principles of risk assessment and methods of identifying process hazards. In addition to formally taught safety courses, the IChemE insists that students are instilled with appropriate attitudes to safety, health & the environment (SH&E). Similarly, the ABET criteria for chemical engineering programs (ABET, 2017) state that the curriculum must include the hazards associated with chemical, physical and/or biological processes. These open-ended and wide-ranging learning outcomes on safety are mirrored in numerous fundamental process safety textbooks, such as Crowl and Louvar (2011), who

propose that successful safety programs require several elements including fundamentals, experience and attitude.

The Department of Chemical Engineering at UCL offers both Bachelor and Masters programs in Chemical Engineering through its Integrated Engineering Programme (IEP) (Sorensen, 2016), with around 120-150 students per cohort. The IEP is a Faculty-wide, multidisciplinary program which started in 2014/15 and combines core disciplinary technical knowledge with interdisciplinary and/or research-based projects with strong emphasis on professional skills and academic learning connected with workplace learning. The program enables students to understand the fundamentals of their discipline, to practice the application of their core technical knowledge and to apply this to current complex global challenges such as energy, health *etc*. Students also have the opportunity to apply their fundamental learnings to industrially-relevant mini-design projects, known as scenarios. This focus on problem and/or project-based learning starts in Year 1 and continues throughout the program. As for most UK programs, most courses are compulsory in Years 1-3, and are taken by the entire cohort at the same time. It is therefore possible to properly plan the delivery of key concepts such as safety to ensure the material is introduced at the right time and that there is a clear progression from one course to the next or from one year to the next.

The IEP framework enables a systems approach to teaching safety to be undertaken. Firstly, from a depth perspective where safety is embedded into the curriculum immediately in Year 1 and the level of understanding is built upon in subsequent years. Secondly, from a breadth perspective, where different safety learnings are applied to an assortment of industrially-relevant problems throughout the program.

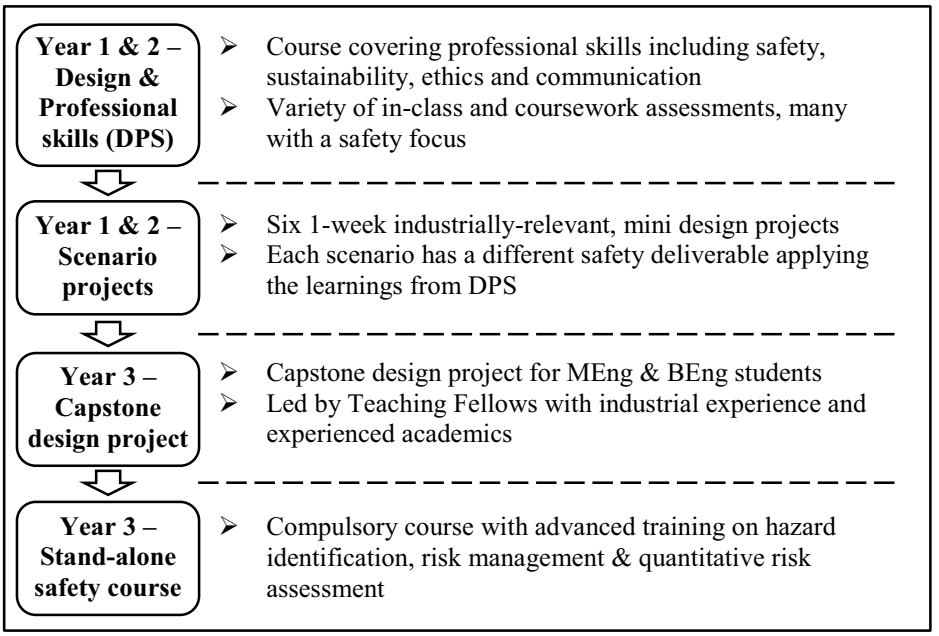

Figure 1: Illustration of how safety is embedded in the UCL Integrated Engineering Program (IEP) teaching framework.

Figure 1 illustrates how safety has been embedded throughout the IEP framework. In the remainder of this paper, the methods used to introduce and apply safety concepts in Years 1 and 2 are examined, and the approaches taken to extend this to advanced application and learning in Year 3 are then outlined. As the first cohort of students graduate from the IEP framework, reflections on embedding safety teaching and student feedback are examined, followed by conclusions on the approach.

2. Introducing safety concepts in Years 1 and 2

As soon as students arrive on campus they are introduced to the concepts associated with safety as one element of the 'Design and Professional Skills' course. Topics covered include risk, hazards, inherent safety and hazard evaluation techniques. Initially these concepts are introduced in Year 1 by considering everyday situations to which students can easily relate. For example, examining a photo of a staircase and considering safety strategies that can be adopted, or performing a HAZID (hazard identification) on everyday activities such as the commute of a cyclist in London. In Year 1, this is also extended to the context of the process industries through lecture examples which briefly introduce past accidents and utilise simple process examples such as an example of a HAZOP (hazard and operability study) on a fired heater. As in Shallcross (2013), assessment is introduced in terms of examining past accidents and considering issues that led to, and lessons learned from, the incident.

As students proceed through the second year of the IEP program, safety concepts and hazard evaluation techniques continue to be examined with a greater emphasis on process industries and their application to different stages in the process design timeline. As suggested by Shallcross (2014), brief 5 minute safety shares, which reflect industrial practice of focusing safety discussions at the start of meetings, are used to introduce safety topics covered in the lectures. Topics examined range from dangers in the home, major process incidents such as Bhopal and lessons learned from other industries such as the sinking of the Herald of Free Enterprise.

Supporting material for lecture content comes from traditional textbooks such as AIChE CCPS (2008) and Mannan and Lees (2012). This is supplemented by safety videos from the IChemE Safety Centre (ISC) (Kerin, 2016) and the Chemical Safety Board (CSB) (Horowitz and Gilmour, 2007) to highlight particular topics covered within lectures and to illustrate the context of process industries to students who potentially have not yet set foot on a process plant. One particular topic covered in the second year is hazards and control of exothermic reactions, fulfilling the recommendations from the CSB following the T2 Laboratories accident that awareness of reactive hazards is incorporated into the curriculum (Crowl and Louvar, 2011).

3. Applying safety learnings in Years 1 and 2

Ultimately, the subjects of engineering and safety are applied subjects. As such, students on the IEP program are given the opportunity to apply their safety learnings through a safety deliverable incorporated into each of the six industrially-relevant, week-long mini design projects, known as scenarios, which are completed in the first two years of the IEP degree program. As an example, in a scenario on air separation for the production of nitrogen for food packaging, students produced a safety newsletter examining a past accident involving cryogenic distillation and reported findings from a HAZID performed on their nitrogen production plant. The form of the deliverable, a safety newsletter,

replicated a common industrial safety document. In addition, this scenario increased students' awareness of technical documentation and standards through the freely available publications of the European Industrial Gases Association (EIGA) accessed via EIGA (2017).

The variety and format of the six scenarios completed during the first two years allows students to apply safety learnings on processes with which they are already familiar. This is representative of experiences of process engineers in industry where engineers perform hazard evaluations on processes well known to them as well as to unfamiliar processes. For example, in a Year 1 scenario, students performed a HAZOP on a reactor involved in styrene monomer production based on a process flow diagram (PFD) which they constructed from a process description provided in the student brief. In Year 2, the design of the styrene monomer process was further developed into a detailed PFD with some initial control strategies by teaching staff. The students were again asked to perform a HAZOP, this time on a distillation column and surrounding secondary units. By embedding safety into the curriculum, students are able to perform hazard evaluations on a process they have already encountered and on engineering documentation with varying levels of detail reflecting different stages in the process design timeline. Furthermore, students learn about fundamental chemical processes, such as distillation and reactors, and concurrently consider safety issues related to the design and operation of these units.

4. Advancing safety learning in Year 3

The safety learnings are further embedded in the third year in two parallel approaches, the capstone design project and a stand-alone Advanced Safety and Loss Prevention course. These courses, and their scheduling together, encourages in-depth learning of safety concepts through advanced application of hazard evaluation methods and deeper learning of the consequences of hazards, their quantification and safety management systems.

The capstone design project, which accounts for a quarter of the third year and where students work in teams of 6-7 students, is arranged in a manner so that students follow the development of a process from research and conceptual design, through preliminary, and then detailed design. As discussed in Towler and Sinnott (2012), the engineering information available, and the hazard evaluation methods that can be employed to assess the hazards related to the process, differ at every stage of the project. This is one of the key learnings for students where at every stage of the design project a different hazard evaluation, or safety element, is performed.

During the initial research and conceptual design stage, students investigate what is known to them in the form of a safety data sheet (SDS) review and are recommended to review literature on past accidents for similar processes. They then use this knowledge to perform a preliminary hazard analysis (PreHA) of the conceptual design in their design teams, focusing on potential hazards related to feedstock, major units, utility and support systems and other categories as relevant to the chosen project. This approach is flexible and allows students to focus on areas relevant to their process, for example, major units such as exothermic reactors in vinyl chloride monomer production or storage of feedstock in the conversion of biomass into bioethanol.

The design project then moves into preliminary design as students develop their process further with a detailed PFD and process simulation. At this stage, following formative and summative feedback on their PreHA study and their second year HAZOP workshop,

students perform a HAZOP on the process they are developing. Knowledge from the chemical review and any review of past accidents again aid in the hazard evaluation of the process and recommendations from the HAZOP often give an indication of potential control system requirements.

Students then move onto the individual component of the capstone design project where they are required to develop a detailed design of a major process unit, typically a separation unit, such as a distillation or absorption column, or a reactor unit. As they take their individual unit design through the process design stage and into detailed design, students develop a control system for their unit which they then represent on a piping and instrumentation diagram (P&ID). To complete the detailed design stage, students perform a safety integrity level (SIL) analysis where they quantitatively assess the reliability of their system. They identify the major hazards associated with their unit by looking back over findings from the PreHA, HAZOP and past accident reviews. For the selected major hazard they then identify a tolerable risk threshold for the hazard. To evaluate the reliability of their individual process unit design, students then develop a Fault Tree to identify the causes that can lead to the hazard and quantify the risk of the hazard occurring. Following comparison with the tolerable risk threshold, students then formulate recommendations of further actions, if any, required for the process design.

The safety teaching within the IEP framework concludes with a compulsory stand-alone Advanced Safety and Loss Prevention course extending the students' existing knowledge and awareness of safety. The course has a strong focus on risk management, management systems and quantitative risk assessment. The causes and physical effects of hazards are examined in detail and the course concludes by examining the concepts of reliability and availability. Assessment is split between 80% exam-based and 20% coursework-based.

5. Reflections on embedding safety within the IEP framework

At the end of 2016/17, as the first cohort of students were about to graduate with a Bachelor's in chemical engineering following the IEP framework, the students were asked for feedback on their perceptions of the IEP approach to embedding safety learning. Over 90 % of the respondents *Somewhat* or *Strongly* agreed with the statements that they understood the importance of safety in society in general, in chemical engineering and the concepts of inherent safety. When asked in which year they had been first introduced to the concepts of risk, hazard and accidents or had the opportunity to apply their safety knowledge, over 50 % of respondents indicated in their first year. While this does indicate that some further emphasis of safety teaching and its application is still needed in the first year, we can see that we are well on our way to achieving our goals of developing graduate engineers well prepared for a career in engineering with one student commenting "*courses are taught with a safety aspect in mind so that safety becomes part of our everyday critical thinking".*

6. Conclusions

In conclusion, embedding safety throughout the process engineering curriculum has been successfully achieved using a systems approach at UCL Engineering as part of the Integrated Engineering Program (IEP) teaching framework. This has been validated through the successful accreditation of the UCL IEP chemical engineering degree by the IChemE in 2016. Furthermore, student feedback has indicated significant understanding of the importance of safety in chemical engineering and in society in general. Finally, it

is important to emphasise that such an all-encompassing program can only be achieved through the efforts of staff, many of whom are chartered engineers, with a wide range of academic, industrial and lab experience which mirrors the wide-ranging background and experience of engineers that graduates will work with in future roles.

Advantages of Flipping Multiple PSE Courses (to the same students)

Daniel R. Lewin[a*] and Abigail Barzilai[b]

Abstract

In this paper, we present a case for injecting active learning methodology into PSE-related courses. In particular, we discuss the teaching of both the capstone process design course and the control course in flipped format, focusing specifically on the associated benefits and costs, both from the perspective of the teacher and from those of the students. While not all of the students have taken to the flipped approach, the vast majority agree that they learn more by flipping than by the conventional lecture-based approach. The bottom line is an increased average grade, a normal, unimodal grade distribution, accompanied by a reduced failure rate.

Keywords: Flipped Classroom, Capstone Design Course, Control Course, Learning Assessment, Active Learning.

1. Introduction

Most chemical engineering curricula feature at least two Process Systems Engineering components: a capstone process design course and a course on process dynamics and control. Often, these courses are taught in the same semester, which makes sense given their interrelated nature. In this paper, we present the benefits of taking an active-learning approach, employing flipping, to teaching these two courses, both from the perspective of the teacher and from those of the students.

Student engagement in the learning process is a prerequisite for a successful outcome. Deslauriers et al. (2011) and Bishop and Verleger (2013) present ample evidence that students who study in a learner-centered environment with an emphasis on active student engagement acquire a better conceptual understanding than their peers in a teacher-centered learning environment, where the emphasis is on transferring knowledge from teacher to learner. The lecture model is suitable for conveying simple information, but fails in response to the need to provide customized challenges and feedback required for a thorough understanding of complex problems. Student-centered environments are perceived by students as supportive to their learning and characterized by interaction between the lecturer and the students, active learning and the provision of effective feedback and time-management. These environments can accommodate different student skills and learning methods, enabling them to conduct discussions in the classroom and work in teams on projects, under conditions that ensure positive interdependence and personal responsibility, and were found to improve student achievements and learning experience, increasing class attendance and helping to reduce failure rates (Freeman, 2014).

As shown in Figure 1, our flipped classroom model (Lewin and Barzilai, 2017) features three main components: (a) On-line lessons, taking students up to three hours to cover at home in their own time, and in advance of the class-session. A lesson contains a

sequence of between 5 and 12 segments, with each segment comprised of a short video clip (up to 15 minutes per clip, with most being a lot shorter) and an associated quiz question; (b) A two-hour class-meeting in which portions of that week's on-line lessons which were found to have been difficult for most of the students are explained in more detail, but mostly allowing for in-class activities (i.e. clicker questions and collaborative open-ended problem solving); (c) A three-hour active tutorial session, in which groups of students solve classwork (previously called homework). This pedagogical model has been implemented in both the design and control courses.

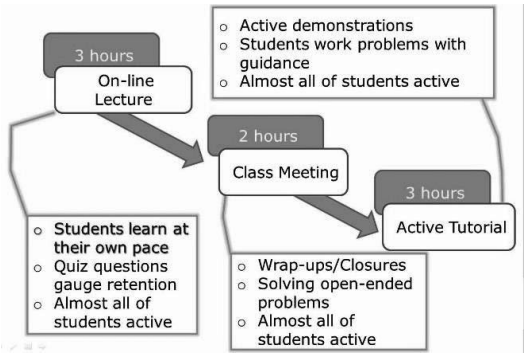

Figure 1: A weekly cycle of our flipped classroom model.

This paper summarizes the experiences after two years of "double-jeopardy," that is, after having two consecutive years of undergraduates take both the design and control courses in the same semester in flipped format, it having been suggested that a single flipped course is so exhausting for students that no more than one such course is recommended per semester. In particular, we shall analyze the students' opinions regarding their level of confidence in the materials taught, how they perceived the flipped approach impacted on their workload and well as the final results.

2. Curriculum and teaching objectives

The design course, closely following Seider et al. (2017), consists of four segments: (a) An overview of the design process itself, and including discussion of ethics, safety and environmental protection issues; (b) Plant economic analysis, focusing on capital cost estimation and profitability analysis; (c) Systematic design methods such as separation system synthesis methods and heat exchanger network synthesis; and (d) Plantwide control, HAZOP and HAZAN. An integral part of the design course is a design project, worth 30% of the total course grade, in which teams of five students compete with each other on the most profitable process for a given production rate of a target chemical, with 25% of the project grade proportional to the venture profit scored by each team. On completing the course, a successful student will be able to:

- Simulate a chemical process, including its optimization, using UNISIM.
- Perform an economic assessment of a chemical process.
- Synthesize a separation system.
- Synthesize a heat exchanger network (HEN) for a chemical process such that the maximum energy is recovered and/or the minimum number of exchangers is used.
- Prepare a Piping and Instrumentation Diagram (P&ID).
- Conceptually design a plantwide process control configurations using qualitative methods.
- Perform HAZOP/HAZAN analysis on a process based on its P&ID.

The control course provides the tools for developing dynamic process models (focusing only on lumped parameter systems), and the use of these models to develop process control systems. Taught in parallel with the design course and to the same cohort of students, the course largely follows Seborg et al. (2016), and consists of two parts, as illustrated in Figure 2. The first part of the course, taking six weeks of the semester, covers the modelling of process dynamics as well as mathematical analysis: Laplace transforms, open-loop transfer functions and linear dynamics. The second part of the course, lasting another seven weeks, covers control system design: frequency domain analysis, derivation of closed-loop transfer functions, stability analysis, root locus design, PID tuning, and cascade and feedforward control system design. On completing the course, the student will be able to:

- Formulate a lumped parameter model describing the process dynamics.
- Generate an approximate linear model of the process in its standard forms, either from fundamental models or empirical models fitted to plant data.
- Design a control system for the process that meets desired performance criteria.
- Use MATLAB/SIMULINK for the design and testing of control strategies.

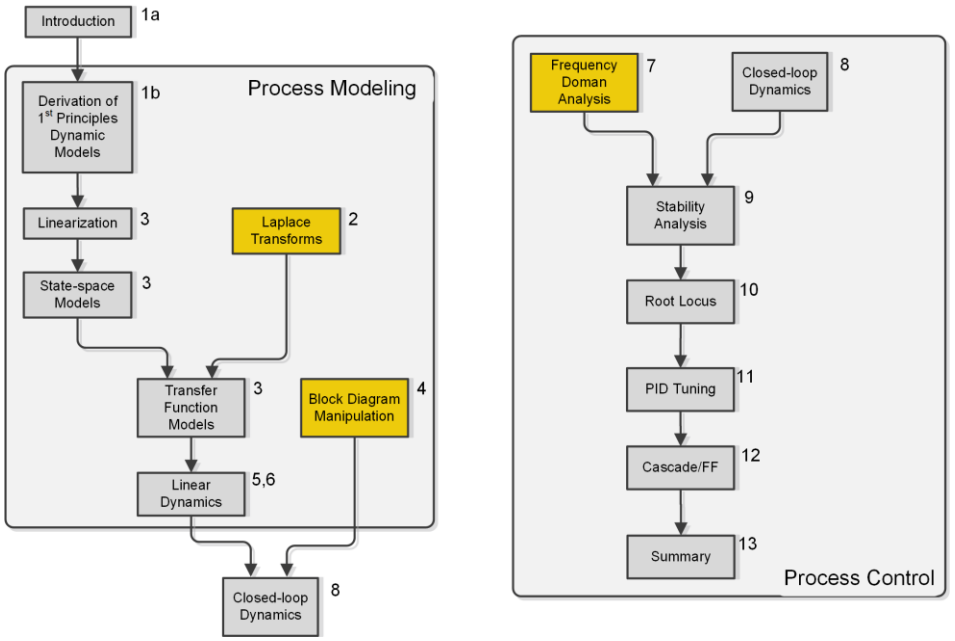

Figure 2. Flow diagram for control course (numbers indicate week of activity).

3. Differences between conventional and flipped teaching

For students to master a course, they need to apply themselves to independently working problem sets covering the course material. Traditionally at the Technion, this has been left to the student to do on his own at home. This leads to several problems: (a) Most of the contact time in the course involves students listening, first to the lecturer and then to the teaching assistant, during which most students are passive. Thus, the first time they are asked to be active is at home, where there is no help; (b) After submitting their solutions, typically if feedback is provided (often there is insufficient manpower available to do this effectively), it comes far too late to be of much use; (c) The feedback on student

performance is received by the lecturer too late for him to make the necessary corrections to his teaching.

A much better alternative is to convert the exercise sessions to "active tutorials," where students working in teams solve the homework in class time. This ensures that: (a) All students who participate in the sessions are actively involved in working problems; (b) Assistance can be provided by the course staff, and by the students themselves; (c) Both students, assistants and the lecturer all receive feedback in a timely fashion. In our experience, in every course in which the exercises have been switched to this mode, there has been a significant improvement in the performance of the students in the final exams. As an illustration, consider the depth of coverage possible in three weeks of the control course by keeping the students actively engaged, shown in Table 1.

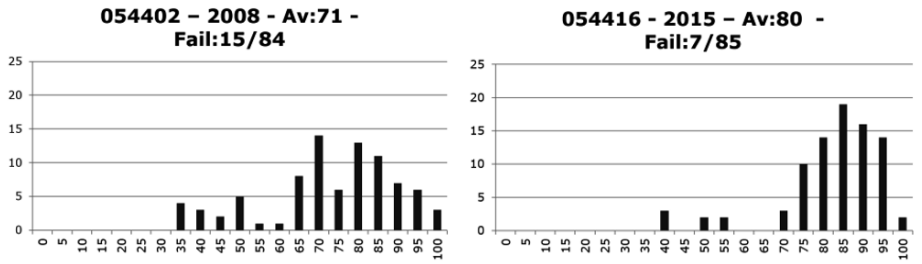
Table 1: Subjects and concepts taught and exercised in the three-week sequence between weeks 8 and 10 in the control course covering control system design.

Week	Subject	Concepts	Exercises
8	Closed-loop Dynamics	– Introduction to PID controller – Closed-loop transfer functions	– Computing actual closed loop transfer functions – Closed loop response using MATLAB/Simulink
9	Stability Analysis	– Stability tests (Routh Hurwitz, Direct, Bode) – Internal stability	– Practical examples – Controller tuning using MATLAB/Simulink
10	Root Locus	– Root locus method – Designing to meet specifications	– Designing for specifications – Open-loop unstable systems – Root locus design using MATLAB/Simulink

By design, flipped learning environments encourage continuous opportunities to assess student learning, both from the point of view of the student and of the lecturer. While watching the on-line lectures, the students participate actively, receiving immediate feedback on the on-line quiz questions, thus reinforcing their learning. They come to the class meeting where additional quiz questions are posed to them with clickers used to collect the responses of the entire class, and used to further drive discussion. Open-ended problem-solving further prepares them for the next step – the active tutorials, where they tackle classwork problems in cooperative effort. There are several features of this approach that can also provide the lecturer with on-going assessment of the degree to which course objectives are attained, providing opportunities to continuously improve and modify delivery. First of all, by observing the class performance on the on-line quizzes ahead of the class meeting, the lecturer can tailor the materials delivered to focus the discussion to items/issues that most of the class found the most difficult. Using clicker questions as CAT (class assessment techniques) in the class meeting, provides additional opportunities for both additional testing of student capabilities, as well as nurturing discussion of the results, providing for deeper understanding. Finally, the active tutorials are the ultimate test of the capabilities of the students to handle problems on their own, and the presence of the staff (assistants as well as the lecturer) enable a true assessment these capabilities to be ascertained well ahead of the final exam.

Figure 3 compares a typical grade distributions on the final exam before the design course was switched to active tutorials, with that obtained in the first flipped instance of the course, in which both flipping and active tutorials increased the amount of time students were actively engaged in their learning. It is clear that vast majority of the

students did very well in the course, as indicated by the increased average grade, and the reduced variance and number of failed students. Irrespective of how the lecturer performs, the very best students in the class will probably do well in any course, with the least capable students are likely to face unsurmountable difficulties. That leaves a huge number of students in the middle, whose performance can be significantly enhanced if the lecturer takes the time and makes the effort to reach out and motivate them. In our opinion, that is one of the yardsticks by which one should measure the degree of success, and the data in Figure 3 seems to confirm that the flipped approach achieves it.



(a) (b)

Figure 3: Typical final grade distributions for the design course: (a) before introduction of the active tutorials and flipping; (b) after introduction flipping and the active tutorials.

A word about the costs associated with the flipped approach is in order. While the total amount of time invested by the average student on a flipped course is the same as that expected in a conventional course (assuming the homework time is included), the same is not true for the load on the lecturer. The planning, and production of the on-line lecture videos as well as the on-line quizzes requires considerable time and attention from the lecturer, but this is mainly a one-time investment, and need not involve high costs. Indeed, as opinioned by Marlin (2017), "if you can prepare a PowerPoint, you can prepare an e-lesson for the internet." What is true for both students and lecturers, is that the time spent working together on the course is used far more effectively.

Table 2: Overall performance record for the design course over time.

Year	Mean (%)	STD (%)	Failure Rate	Remarks
2008	71	17	15/84 = 18%	
2009	75	16	6/68 = 9%	
2010	75	17	13/74 =18%	
2011	79	13	4/77 = 5%	First active tutorial
2012	82	11	7/80 = 9%	
2013	78	13	6/67 = 9%	
2015	80	13	7/85 = 8%	First flipped class
2016	76	20	9/71 = 13%	
2017	78	15	9/87 = 10%	

4. Teaching outcomes and student feedback

Table 2 summarizes the student performance in the design course since 2008, noting that the tutorial went "active" in 2011, and the course was switched to flipped format in 2015. It is noted that the move to more active involvement of the students resulted in increased average grade and a reduced failure rate. The reduction in the failure rate is often

accompanied by the transformation of a multimodal grade distribution (e.g., Figure 3a) into a normally distributed one (e.g., Figure 3b), as many of the poorer-performing students improve their mastery and thus become higher performers.

It is therefore fair to claim that flipping and active tutorial leads to improved class outcomes, but what do the students think? Student participants of our flipped courses are polled to ascertain their preference between the flipped/conventional approaches, and to gauge the level of their confidence in the course materials at each stage of the flipped approach. By the end of the courses, only a small minority of the students still think that the conventional approach is the most appropriate, in contrast to about two-thirds of the class that conclude that they prefer the flipped approach. Interestingly, usually about a quarter of the class are in strong disagreement that the flipped approach suits them, maintaining this opinion throughout the semester. It should be noted, though, that approximately half of these "die-hards" usually concede that they learn better using the flipped approach. The majority of the students consider the active tutorial component to be the most helpful in helping them attain mastery of course content.

5. Conclusions

Experience with the flipped-class approach indicates that overall, engagement with the materials and ongoing assessment throughout the semester improved the students' level of confidence in their mastery of the curriculum. This is principally because they come to class and to the tutorials better prepared than with the conventional version of the course. These observations could explain the improved performance in the final exams, as demonstrated. Table 2 shows the progressively increasing students' competence, as indicated by the sustained and improved average grade and reduced failure rates. This progression has been achieved in concert with the course's gradual transformation from conventional teacher-centered one (i.e., lecture-based) to student-centered ones (i.e., active tutorials and flipping). Having students take more than one flipped course in a semester does not overload them; in fact the teaching both the design and control courses together in this format only enhances the degree to which students engage as they also grasp the necessary synergy between the design and control of chemical processes.

Cyber Incident Exercise Admitting Inter-Organization for Critical Infrastructure Companies

Akihiro Tsuchiya*, Yuitaka Ota, Yuma Takayama, Tomomi Aoyama, Takashi Hamaguchi, Yoshihiro Hashimoto, and Ichiro Koshijima

Nagoya Institute of Technology, Nagoya 466-8555, JAPAN
a.tsuchiya.054@nitech.jp

Abstract

To improve cyber security awareness for Critical Infrastructure (CI) companies, Kaspersky Interactive Protection Simulation (KIPS) is provided by Kaspersky Lab. Through the KIPS exercise, participants simulate countermeasures while experiencing the effect of a cyberattack on a virtual CI company. However, an organizational structure that makes decisions relative to incident responses via communication between multiple departments is not explicitly specified in the KIPS exercise. Therefore, to increase awareness of the complexity of decision-making processes, a non-technical exercise method that divides a virtual company into headquarters and production plant administrator groups is proposed. The proposed exercise method was implemented using KIPS, and a trial was conducted with participants involved in CI companies.

Keywords: Industrial Control System, Cyber Security, Exercise, Risk Communication

1. Introduction

Cyberattacks on Critical Infrastructure (CI) have been recognized as a significant problem since the discovery of the Stuxnet worm in July 2010 [1]. The Stuxnet worm was primarily designed and developed to target an Industrial Control System (ICS). ICSs are used in gas pipelines, power plants, and chemical and petrochemical plants. The attackers designed Stuxnet to inflict damage by reprogramming programmable logic controllers (PLC) to control ICSs. After the discovery of Stuxnet, similar malware that targets ICSs has been discovered.

Cyber incidents that target ICSs are security, safety, and business problems. Such abnormal events affect physical devices, such as actuators and sensors. If a cyberattack results in manufacturing operations being shut down, a company will lose significant revenue. In addition, if a cyberattack targets systems that require safety operations, the operators will be endangered. For example, cyberattacks on an iron furnace have been reported [2]. In addition to safety risks, cyberattacks continue to pose serious financial risk for companies [3]. Therefore, cyberattacks should be prevented to ensure corporate resilience.

In addition to awareness of potential cyberattacks, the need for cybersecurity training has increased. The National Institute of Standards and Technology (NIST) specifies that incident response teams should be assigned and trained to develop incident response capabilities against cyberattacks. NIST SP 800-61 [4] describes the ability required for

an incident response as follows: “Managers should be technically adept and have excellent communication skills.” A capability for an incident response requires technical skill and non-technical skill. Several authorities have developed tabletop cybersecurity exercises to improve technical security awareness. Tomomi et al. described a technical exercise from the perspective of non-technical skills [5]. However, most security exercises focus on the technical aspects of incident responses. In other words, they are not designed to evaluate a team’s non-technical skills even though it is obvious that a team’s non-technical skills will affect overall performance.

In this paper, a tabletop exercise that involves participant communication skills and decision-making processes in a complex environment is proposed. The remainder of this paper is organized as follows. The basic exercise is explained in Section 2. The proposed exercise structure is described in Section 3. A prototype implementation and initial trial are discussed in Section 4, and conclusions are presented in Section 5.

2. Kaspersky Interactive Protection Simulation Exercise

2.1. Exercise Overview

The Kaspersky Interactive Protection Simulation (KIPS) was developed by Kaspersky Lab [6]. KIPS is a hybrid game with action cards and a game simulator that is intended to deepen the common understanding of the timeline of cyber incidents. Through KIPS exercises, players practically simulate an incident response while experiencing the effects of a cyberattack on a virtual CI company. Players acting as a security administrator for a virtual company determine countermeasures against cyberattacks within time and cost constraints. The goal of the game is to maximize revenue when responding to cyber incidents.

The KIPS exercise for multiple players comprises a game board, action cards, and a game console. The game board represents the plant and network configuration of the virtual company. Players use the game board to understand how the plant works and the devices related to the plant’s operations. The game board also includes space for enabled action cards. Once a player enables an action card, it is placed in an applicable space. Thus, players can observe which action cards have been used. An action card represents a set of cybersecurity countermeasures. There are thirty types of action cards, e.g., a network disconnection card. Each action card represents a countermeasure and shows the required time and costs. Some action cards are added in some cases. Player can combine action cards according to the situation, such as plant status, and the available budget and time. The game console is used to simulate the game, and it provides players with information about the virtual company. In addition, players send their selected action cards to a game moderator.

2.2. Scenario for CI Company

The KIPS provides two CI-related scenarios, i.e., a water purification plant and a combined cycle power plant. The water purification plant has two production lines, each of which comprises a precipitation tank, sand filter, disinfection tank, and drinking water tank. The power plant has two turbines, i.e., a gas turbine powered by burning fuel and a steam turbine powered by boiling water. The water is heated by exhaust gases. Then, the exhaust gas is emitted through a gas filter. In addition, the steam is changed to liquid water by cooling water.

Here, PLCs control both plant operations, and the PLCs are connected to a server in the control network. In the control network, there are various devices, such as a Human Machine Interface, a Data Historian, and an Engineering Workstation. Process data are sent to the headquarters over the Internet. The goal is to protect the devices using action cards.

2.3. Game Simulation

The game consists of a message phase, an action phase, a revenue phase, and a report phase. These four phases are cycled five times to complete the game. Prior to starting the four phases, the moderator explains the rules of KIPS and shows the participants threats of the same industry as news. The moderator operates a dedicated game console to advance each phase. In the message phase, players receive various information, such as news from the same industry and the status of the plant. Next, in the action phase, players evaluate the current situation and use action cards as countermeasures using the game console. The action phase is finished after the moderator has received action cards from all teams. The administrator console calculates each team's revenue according to their actions. The results of a team's actions and their revenue are sent to the applicable team in the report phase. Then, a card assistant distributes additional action cards to some groups that chose an action card which leads new event. In the report phase, all players review their team's result. Figure 1 shows game console of KIPS by four phases.

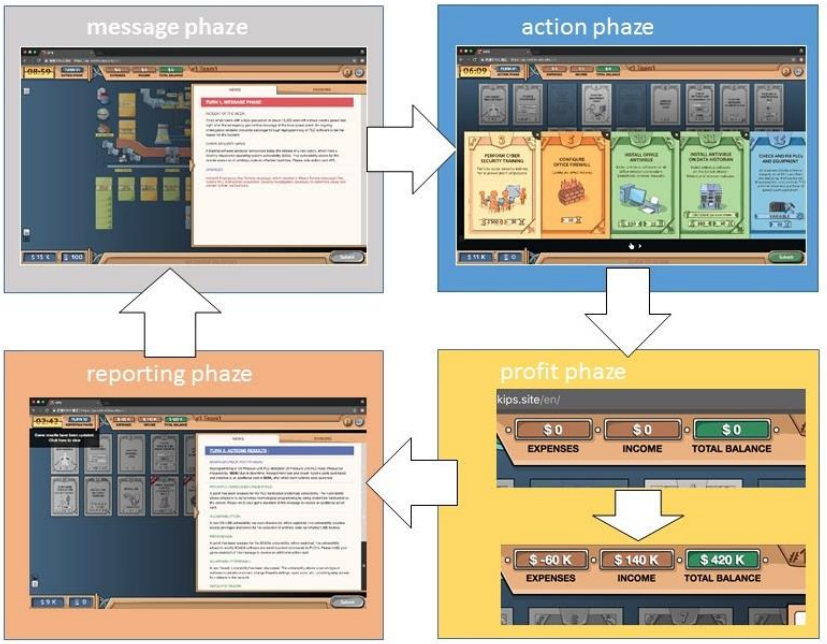

Figure 1 Game console of KIPS

At the end of the game, the moderator shows the total revenue and budget left after the five game cycles. In addition, bonuses are added to the revenue depending on the actions taken. The total revenue and remaining budget can be used to evaluate how security countermeasures contribute to the company's performance. Figure 2 shows the relationships among the KIPS stakeholders.

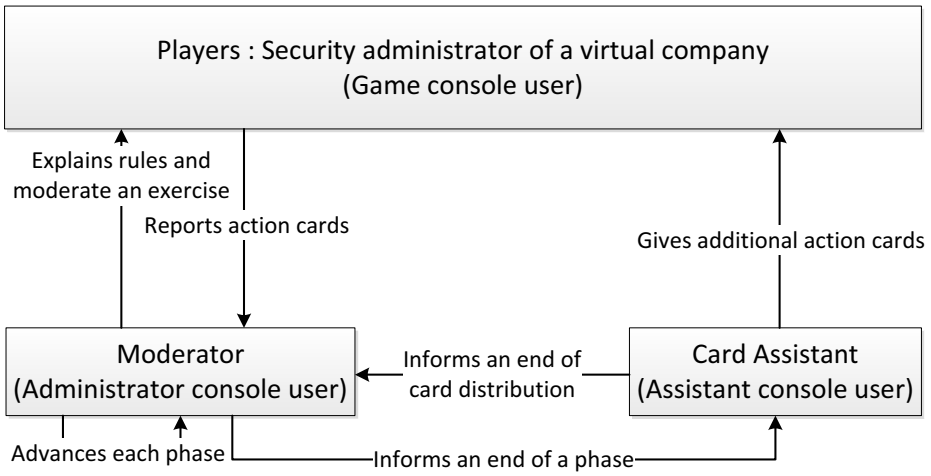

Figure 2 Relationships among KIPS stakeholders

3. Structure of Proposed Cyber Incident Exercise

3.1. Inter-organization cooperation

KIPS was designed to aware importance of inter-organizational incident response through game simulation. KIPS participants play the role of a security administrator. However, compared to real CI companies, an incident response is performed by several departments because both business and safety objectives should be considered simultaneously relative to a cyber incident. However, these objectives sometimes have a low affinity of a response due to differences among the policies of different departments. Therefore, we incorporate a cooperative inter-organization perspective into KIPS.

Therefore, we consider following mechanisms to design KIPS from the perspective of inter-organization cooperation.

- Separate one team into several groups

  An information gap is created by dividing a team into several groups. This information gap results in more complex decision-making scenarios. A group may communicate with other groups to acquire a group's unique information. Then, players should consider the nature of the current situation and what information is required for the given situation.

- Observe player decision making

  A mechanism to evaluate non-technical skills is required, and the decision-making process should be observable.

3.2. Proposed Exercise

To create the information gap within a team, players form two groups, i.e., a plant administrator group and a headquarters administrator group. The former is responsible for maintaining the safety and security of the plants. The objective of the plant administrator group is to maintain stable plant operations through five turns regardless of the nature of the cyber incident. On the other hand, the headquarters administrator

group is responsible for the overall network security, the company's budget, and its profit. The objective of the headquarters administrator group is to maximize revenue. Here action cards are distributed to the groups based on their role. One group does not initially know the information about the other group's action cards. Then, both groups discuss their actions through a chat system. The chat system enables us to observe the decision-making process because it records the communication.

In the proposed exercise, the chat system is used by both the players and facilitator. The facilitator provides information about the message phase with the plant and headquarter administrator groups at the start of the action phase. Each group receives only the information related to their responsibility; however, the players can obtain information from each other using the chat system. When players determine the action cards they will play, the headquarters administrator group notifies the facilitator of the cards' IDs. After the facilitator enters the selected action cards into the game console, the moderator uses the administrator console to proceed to the revenue phase. The administrator console shows the temporary revenue and budget available after the revenue phase. Then, the facilitator checks the result of each team on the game console and sends the results to each group. The card assistant then gives an additional action card to an applicable group that chose an action card which leads new event in the report phase. The moderator then oversees the next message phase and cycles the above process five times. Figure 3 shows the relationships among the stakeholders in the proposed exercise.

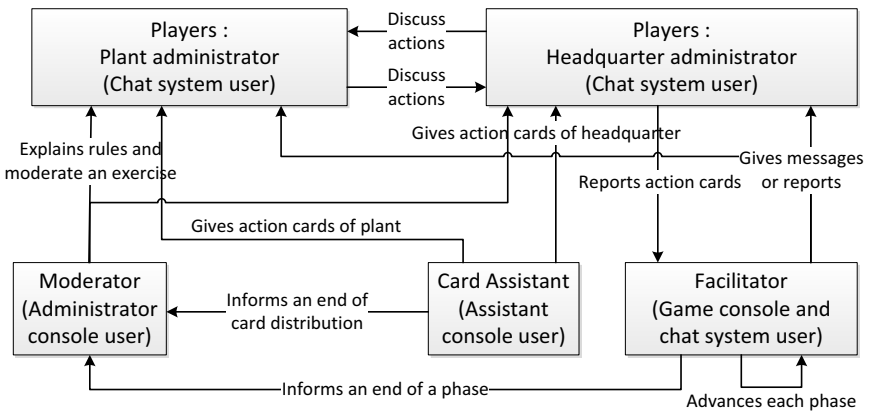

Figure 3 Relationships among stakeholders in proposed exercise

4. Implementation and Trial

4.1. Prototype Implementation

The water plant scenario was used for a prototype implementation. Here, 12 action cards were assigned as headquarters administrator cards and 18 action cards were assigned to the plant administrators.

Slack [7] was used as the chat system for the proposed exercise. Slack records user messages and can create channels for individual communication. Here, channel 1 was

between the headquarters administrators and the facilitator, channel 2 was between the plant administrators and the facilitator, and channel 3 was between the headquarters administrators and the plant administrators. Note that the facilitator could observe channel 3 to understand the teams' situations.

4.2. Trial

In September 2017, the proposed exercise was performed with 42 participants involved in CI companies. Seven teams were organized in this trial. Facilitator provide information with head quarter group and site group. Participants try a prototype game and evaluate if the game is good to make aware an importance of communication skill of incident response by a survey. As a result, 97% of the participants desired implementation of the proposed exercise at their company, which shows that this exercise is an effective evaluation tool.

5. Concluding Remarks

In this paper, we have proposed a new cyber incident exercise method that considers the complexity of decision making and communication skills. KIPS is an effective training tool for security awareness at CI companies; thus, we redesigned KIPS as an inter-organization exercise by implementing a chat system. An initial trial of the proposed exercise satisfied many participants who work at CI companies. In future, we plan to analyze the chat log of players that earned high revenue to determine effective communication processes.

Acknowledgement

Masato Matsuoka of Kaspersky Lab made significant contributions to our research. This research would not have been possible without his technical support and advice. We thank him for providing permission to use KIPS for the proposed exercise.

Supporting the use of PSE computational tools across a chemical engineering program

Mazaher Molaei Chalchooghi and Eva Sorensen*

Department of Chemical Engineering, UCL, Torrington Place, London, WC1E 7JE, UK
**e.sorensen@ucl.ac.uk*

Abstract

The use of Process Systems Engineering (PSE) computational tools across a chemical engineering curriculum is now an expectation rather than an exception, but may be challenging to deliver in a consistent and meaningful manner across an entire program. The Department of Chemical Engineering at UCL offers a variety of computational tools across our undergraduate programs, including MATLAB, GAMS, gPROMS ModelBuilder and ASPEN Plus. All modules across the program are expected to provide at least parts of the assignments in the form of PSE problems requiring the use of computation tools, often formulated in such a way that the students have a choice of tool to use. Our extensive use of computational tools is made possible by a dedicated faculty member whose sole responsibility is the development and delivery of regular lecture and tutorial material, support with assignments, as well as the development and maintenance of e-learning resources. In addition, we also have dedicated teaching assistants for each module who have domain expertise in the relevant tools, and who assist with tutorials and marking of assignments. Student feedback has shown that students highly value the extensive training in these commonly used tools, and that their leaning experience is made relevant by the application of challenging PSE problems.

Engineering education, process systems engineering, computational tools, e-learning

1. Introduction

Computational tools are now used extensively in most, if not all, chemical engineering programs. Most core modules or courses require some use of computational tools, from solving simple algebraic equations or complex differential equations systems, to plant design, control or optimization. Depending on the type of problem, and the licenses held by the department, the student can choose the most suitable tool from a variety of available commercial packages such as Excel, MATLAB, C++, Python, gPROMS, ChemCAD, ASPEN Plus *etc*.

The Department of Chemical Engineering at UCL offers both Bachelor and Masters programs in Chemical Engineering through its Integrated Engineering Programme (IEP) (Sorensen, 2016), with around 120-150 students per cohort. The IEP is a Faculty-wide, multidisciplinary program which combine core disciplinary technical knowledge with interdisciplinary and/or research-based projects with strong emphasis on professional skills and academic learning connected with workplace learning. The program enables students to understand the fundamentals of their discipline, to practice the application of their core technical knowledge and to apply this to current complex global challenges such as energy, health *etc*. This focus on problem and/or project-based learning starts in Year 1 and continues throughout the program. For each project, the students will be

working in teams of 6-8 students in solving an open-ended and complex problem. In Year 1, students will consider two five-week Engineering Challenges, which are considered alongside their other modules. Later in the year, and in Year 2, we suspend all other teaching for a week and work fulltime on a specific problem that is linked to the modules the students are currently studying. In total, six such scenarios are considered. In addition to providing practical examples of real-life problems within mass & heat transfer, thermodynamics, separation processes, reaction engineering *etc*., the scenarios also help develop the students' transferable skills such as team working, presentation, technical writing and time management as well as their professional skills in terms of understanding of, for instance, ethics, safety and sustainability.

One of the main aspects of the IEP is a strong emphasis on modelling and design, with two compulsory module or classes dedicated to mathematical modelling & analysis for all Faculty of Engineering Sciences programs in Years 1 and 2. The department continues this with another module on computational modelling & analysis in addition to a number of other modules through Years 2-4 (see Table 1). With this approach, the use of computational tools is embedded within the curriculum and within the individual modules. The students learn to solve problems based on traditional approaches, such as McCabe-Thiele diagrams, but also learn how to set up and run Aspen Plus simulations of standard unit operations, and more importantly, how to critically evaluate the results based on the assumptions made in the definition of the problem.

As for most UK programs, most modules are compulsory in Years 1-3, and are taken by the entire cohort at the same time. It is therefore possible to properly plan the use of a tool to ensure the material is introduced at the right time and that there is a clear progression from one module to the next or from one year to the next.

2. Integrating computational tools in undergraduate programs

The main computational tools used within our program are: MATLAB - for general purpose computation, GAMS - for solving algebraic equation systems and optimization, gPROMS ModelBuilder - for custom modelling of steady-state or dynamic mixed algebraic and differential equations, and Aspen Plus - for process flowsheeting and plant design. Other computational tools are mainly used for research in Year 4 such as ANSYS Fluent and STAR-CCM+ for computational fluid dynamics, and DynoChem scale up for process development.

Each tool is introduced in an introductory lecture that outlines the main capabilities of the tool, its usage in the chemical industries and beyond, as well as its basic features. The lecture is followed by one or more tutorials in a large cluster room where the cohort is split into smaller groups from 30 to 70 students. The tutorials are essential to ensure the students are able to first set up a basic problem and then gradually work though a number of problems of increasing complexity. The lecture is given by a dedicated faculty member who has extensive knowledge of each tool. The same person runs the tutorials but now supported by a number of teaching assistants, usually PhD students who are using the tool in their own research.

Table 1. Chemical engineering program at UCL (modules in grey are based on modeling and make explicit use of computational tools).

	Term 1	Term 2
Year 1 (Freshman)	Engineering Challenges	Transport Phenomena I
	Design & Professional Skills I	Thermodynamics
	Mathematical Modelling & Analysis I	Physical Chemistry
	Introduction to Chemical Engineering	**Computational Modelling & Analysis**
Year 2 (Sophomore)	Design & Professional Skills II	Design & Professional Skills II
	Mathematical Modelling & Analysis II	**Mathematical Modelling & Analysis II**
	Engineering Experimentation	**Particulate Systems & Separation Processes II**
	Process Heat Transfer	Chemical Reaction Engineering I
	Separation Processes I	Minor I
Year 3 (Junior)	**Process Design Project**	**Process Design Project**
	Process Dynamics & Control	Transport Phenomena II
	Chemical Reaction Engineering II	Advanced Safety & Loss Prevention
	Minor II	Minor III
Year 4 (Senior)	**Research Project**	**Research Project**
	Process Systems Engineering & Design	Elective
	Elective	Elective
	Elective	Elective

Extensive additional resources are available as e-learning resources and cover all the aspects of modelling that the students may encounter in their homework assignments and examinations, for instance, heat exchanger networks, column scheduling, pump sizing *etc*. The resources are mainly in the form of pdf versions of Powerpoint presentations and are available on the student intranet via Moodle to all students, researchers and staff within the department. Each module also has a dedicated Moodle site, with a dedicated Question & Answer Forum where students can ask questions related to the computational tool or their assignments, and where answers are provided by the teaching faculty to the entire cohort. If additional support is needed, which is very often the case, this is arranged on an as-and-when basis in the form of helpdesk sessions in a smaller computer cluster, again by the same faculty staff. The students can sign up for these via the relevant Moodle site.

2.1. MATLAB

MATLAB (Mathworks, 2017) is introduced to all Faculty of Engineering Sciences students in the first compulsory Mathematical Modelling & Analysis module in the first term. The module is taught by a number of academics from across the Faculty, with a weekly 2 hr Faculty lecture followed by a weekly 2 hr tutorial in the home department. The focus is very much on engineering problems, which by their nature can be described by a set of algebraic and/or differential equations. The students learn how to formulate the problems as well as the mathematical concepts required in solving them.

Whilst the lecture presents examples from across all engineering disciplines, the tutorials are based on problems from within the discipline.
MATLAB is used for a number of the assignments hence support needs to be available for nearly 800 students. This is provided at Faculty level involving teaching staff, but also a large group of specially trained teaching assistants. The use of MATLAB is continued in the second year in Mathematical Modelling & Analysis II, which runs over the entire academic year with a 2 hr lecture at Faculty level one week and a 2 hr tutorial in the home department the following week. In addition to the compulsory use of MATLAB in these two modules, students may use MATLAB in other assignments throughout their program, for instance in the design of reactors in Chemical Reaction Engineering or for detailed unit design in their capstone Design Project in Year 3. Support is provided by the department in the form of helpdesk sessions for such work but only at the request from students.

2.2. GAMS

The first Mathematical Modelling & Analysis module is followed by Computation Modelling & Analysis which is taught in the department and which follows on from the first module by demonstrating how larger systems of equations can be solved by computation tools rather than by hand or using MATLAB. The module is taught in two weekly two hour lectures with tutorials in addition some weeks. GAMS (GAMS, 2017) is introduced first and is used to solve steady-state problems consisting of a number of algebraic equations. The students are given assignments which must be completed as a combination of hand-calculations, Excel spreadsheets and using GAMS. Examples are to solve the mass balances on the form $\mathbf{A}\ \mathbf{x} = \mathbf{b}$ for a three column systems used to separate benzene, styrene, toluene and xylene, or to maximize the profit for a gas phase reaction system consisting of a mixer, a reactor, two separation units and a recycle stream. As for MATLAB, students may also use GAMS whenever they prefer for other assignments throughout their program.

2.3. gPROMS ModelBuilder

The department has used gPROMS (Process Systems Enterprise, 2017) in undergraduate teaching for about 15 years. Until four years ago, gPROMS was only taught in Year 4 as part of our advanced design project. With the introduction of the Integrated Engineering Program (IEP), it was decided to use gPROMS from Year 1 and to cover increasingly complex aspects of the tool term by term and year by year. gPROMS is now introduced in the second part of Computational Modelling & Analysis and is used to solve sets of differential and algebraic systems. Again, the students are given assignments which must be completed as a combination of hand-calculations and using gPROMS. An example is to solve a set of differential equations which describes an aquatic ecosystem and to analyze how pollutants have an impact on water, plants, soil and fish.

The use of gPROMS is continued in Year 2, and is incorporated into the two modules considering separation processes. In the first module, students use the tool to investigate the dynamic performance of, for instance, a distillation column stage subject to different disturbances. The students need to simulate and explain the dynamic responses based on their fundamental knowledge of volatility and mass balances for distillation. In the second separation module, students solve a problem related to Acetylsalicylic Acid (ACA) crystallization from Ethanol solution with a continuous MSMPR process. They

are free to choose which modelling tool they prefer and many use gPROMS for this instead of MATLAB or GAMS.

In Year 3, students consider Process Dynamics and Control, and again use gPROMS to investigate the dynamic behavior of a common unit operation such as a distillation column or a reactor. In Chemical Reaction Engineering, students solve a number of reactor design problems and many use gPROMS for this.

The fourth year advanced design project, Process Systems Modelling & Design, builds on the capstone project in Year 3 and considers more advanced design issues such as dynamics, optimization and design under uncertainty. gPROMS is the main tool for this and students consider different design options for a given process, for instance styrene production, and determine the optimal design for both a reaction section and a separation section. They investigate the impact of the main design parameters, such as reactor temperature, scheduling of the distillation columns *etc.*, and they consider the open-loop performance of the plant from both a safety and a production point of view and also propose a suitable control scheme for the overall plant. Some of students will also use gPROMS in their final year research project. gPROMS is the computational tool of choice for the department due to its robust capabilities in simulating large and complex equation systems, but more importantly because it is an easy tool to introduce students to, the learning curve is not too steep and it is easy to introduce the tool in bite-size portions throughout the program.

2.4. ASPEN Plus

ASPEN Plus (Aspentech, 2017) is the other main tool used in our program. The students are introduced to the tool in Year 2 and will solve small design problems in each of the two separation modules, e.g. designing a distillation column and consider the impact of tray efficiency on the design. The tool is used extensively in the capstone design project in Year 3, and in the advanced design project in Year 4, for flowsheeting and individual unit design. Some students will also use ASPEN Plus in their research projects.

2.5. Use of computational tools in Scenarios and research-based work

In addition to the regular modules and the assignments required for these, students also make extensive use of computational tools in the six week-long scenarios which run throughout Years 1 and 2. The open-ended problem descriptions are generally written in such a way that the students have a choice of which tool to use, which better mirrors the experience they will have as practicing engineers. All Masters' students will undertake a research project in their final year, and the majority of them will use a computation tool for this. In addition to the main tools mentioned above, they may also make use of tools developed in-house or more advanced tools such as STAR_CCM+ for CFD simulations.

3. e-learning Resources

Although all our computational tools are introduced and taught in formal lectures as well as supported by tutorials, extensive e-learning resources are also provided to further support the students as all the nuances and details of a computational tool cannot be conveyed in the form of lectures/tutorials. The e-learning material has been developed mainly in-house and aims to lead the students through different examples and to teach them different aspects of the tools that have not been fully covered during the face-to-face sessions. As an example, for ASPEN Plus we do not cover the detailed use

of all the available unit operations during the lectures/tutorials, but rather we give the students a brief overview in the face-to-face sessions and leave the details to the e-leaning material. We update the e-Learning material every year based on what we experience as being difficult for the students, as well as based on direct student feedback. The development of the e-learning material has primarily been done through student summer internships which we have run for three summers with a number of undergraduate students every year. This approach has worked well, as the student interns know better than teaching staff what they themselves found difficult and where more help and support is required.

4. Discussion

The use of Process Systems Engineering (PSE) tools across a chemical engineering curriculum may be challenging to deliver in a consistent and meaningful manner across an entire program. First and foremost, faculty that are experienced in the use of the tools is essential, as is teaching assistants with a good working knowledge. Secondly, there is a balance between teaching the tool via lectures and tutorials, based on student self-study using e-learning resources and books, or as a combination. There is generally limited time available on the time table to provide in-depth training, and there is often an expectation that tools such as MATLAB or ASPEN Plus are easy to pick up and require little support, however, from a student perspective, these tools are not intuitive and are often a challenge to learn, particularly for weaker students. As a result, the use of PSE computational tools are often not considered as widely as they could, and should, be. Our decision to have a faculty member dedicated to the support of computational tools has not only provided a much better service to our students but has also reduced the workload on colleagues who now receive proper help to formulate their PSE related assignments. One final year student comments: "*Across the years I have been at UCL I have been able to see the changes that has been made, and the course has definitely improved. It is particularly noticeable when looking at … and the quality and frequency of programming tutorials*."

5. Conclusion

The use of computational tools in a chemical engineering undergraduate program at UCL has been presented. All the main tools are directly embedded into the curriculum and are supported by lectures, tutorials and e-learning resources. This is made possible by a dedicated faculty member who delivers all the training across the program, who works with colleagues in integrating the use of PSE problems and tools, and who supports the students directly in their work.

Abstract

Sustainable manufacturing may be defined as the creation of manufactured products using non-polluting, energy and natural resources conserving, and economically sound and safe processes. Recently, there has been renewed interest in United States manufacturing and several industrial and governmental endeavours have been launched for sustainable manufacturing initiatives. To support such initiatives and to prepare the next generation of scientists and engineers, academic institutions have a responsibility to introduce educational programs and tools in the area of sustainable manufacturing. This work provides the engineering community with structured modules for introducing the topic of sustainable manufacturing in the curriculum. Working through an NSF funded SEES RCN program, the SMART CN project delivered 21 educational modules covering various aspects of engineering with the common theme of computer aided process design. This paper summarizes the concepts for module based learning, and a brief review of these educational modules for wider use and dissemination to the academic community.

Keywords: Sustainable engineering, Education for sustainable development, Sustainable manufacturing, Curriculum innovation, Module-based learning

1. Introduction

The Manufacturing Sector has been a key factor to influence a nation's growth. Over the past decade, United States has faced competitive trends due to global manufacturing competition. A shift towards fast implementation, frequent product transitions, just-in-time model-based manufacturing, and technical personnel shifting has been observed. Uncertain energy feedstock prices, potential environmental impacts and their associated burdens are a major source of concern for industries. The country has an ongoing effort

in restructuring their focus to revitalize the sector by investing in advanced manufacturing through several institutes operating under the umbrella of Manufacturing USA®. In academia, advanced manufacturing theory, alternative energy, nanotechnology, infrastructure resiliency, composite materials, etc. have become very active, but the connections to sustainability are not well defined. Research coordination between academic community industries are insufficient and lack depth. Thus, sustainable development of the manufacturing sector becomes an important topic for academia, industry and the government in the area of coordinated research. More importantly, it has become imperative to develop instructional material suitable for educating the next generation of engineers and scientists, while retraining the current workforce.

The term "sustainable development" was defined as "Development that meets the needs of the present without compromising the ability of future generations to meet their own needs" by the World Commission on Environment and Development's report Our Common Future[1]. One of the first efforts for education in sustainable development (ESD) was led by UNESCO[2]. New ideas in method and content were combined with existing ideas for the purpose of rethinking educational programs and systems and equip them to support unsustainable societies. ESD efforts have focused on topics like biodiversity, climate change, poverty reduction, disaster risk reduction, cultural diversity, sustainable lifestyles, gender equality, peace and human security, water, health promotion, and urbanization. Filho, et al. [3] discuss the key issues in introducing sustainable development in higher education in which were identified in Rio and the UN Decade of Education for Sustainable Development.

Perhaps the biggest challenge in implementing sustainability in education, particularly engineering education, is the ability to quantify sustainability concepts into mathematical expressions. Engineering Design courses typically act as the culmination point for various theoretical topics, and our approach to educating in sustainability focuses on quantification in this area Problems that consider the complexity, boundary, and various scales of manufacturing processes' and products' sustainability are considered for education modules in this paper.

A systematic modular structure is used to develop instruction ready material for sustainable manufacturing. This paper discusses the overview of development objectives, structure, content, and applicability of these modules. A detailed explanation of the theory and basis of the module development is given by Sengupta, et al. [4]. The modules are available from the Computer Aids for Chemical Engineering website for free download, along with a detailed paper on the needs of module based learning and its impact on higher education for teaching sustainability in manufacturing..

2. Background and Objectives

In recent times, the concept of learning and associated learning methods have gone beyond the definition of the university in terms of physical boundaries and flexible lecture class times accommodates a wider variety of students[5]. Addressing these changes, it becomes imperative to decide on the selection and construction of knowledge that needs to be represented in universities (epistemologically and from the perspective of learners). This also raises the need for the organization of this knowledge (institutionally and from the perspective of teachers) through effective ways of teaching and learning. Bridges [5] identifies five competing but eminent epistemological changes in higher education and focuses on the importance of deconstruction of the subject

where it is packaged in new ways to enable the modularization and offer flexible pattern of study. The modularization concept offers a three way impact: the deconstruction of traditional subjects as the epistemological units of study; the deconstruction of a time bound undergraduate course as the chronological unit of study; and the deconstruction of the single university as the topographical location of the unit of study.

The modularization of the units of learning in higher education enables the expression of two different educational principles. Firstly, a student-centred curriculum can be offered where a student can assemble a degree program according to their personal interests and aspirations. Secondly, it can satisfy the social expectation that university programs might serve more directly the needs of employers, where an employer guides the creation of modules best suited for their needs. Thus, the modularization concept has gained considerable impetus owing to the commitment to flexibility and student choice. A key consideration in involving the web helps to supplement the classroom experience, and provide unique learning opportunities only available through these online learning methods. These new trends in education have capability to reach a very wide audience by eliminating boundaries of classroom, geographical location, and even time. This brings the concept of flexibility in teaching and learning methods[6].

3. Module Structure and Use

Module based learning requires a focus on the quality of learning that can be achieved by students using them, and not on the specific content of the module and how they are intended to be taught. In the process of devising a module, the key is to forge educationally sound and logical links between learner needs, aims, learning outcomes, resources, learning and teaching strategies, assessment criteria and evaluation[7]. Svanström, et al. [8] discussed the key learning outcomes in education of sustainable development, which also apply to sustainable manufacturing.

The SMCS modules are designed for introducing basic and core concepts related to sustainable manufacturing, combine the concepts from the core modules to produce a methodology for sustainability analysis of manufacturing processes, and dedicated tools that incorporate some of these methods. The modules have flexibility to be combined with other courses and certainly carries the uniqueness of the module developers, who mostly were faculty consultants.

The modules were developed to have an overview of the module contents, a slide set for intended delivery or self- learning of the material, and case studies that provide the computer aided design component for the topics. A text document is provided which is intended to be a guide for both the instructor and the learner. It is assumed that the instructor will be well equipped with the traditional engineering concepts, but not conversant or expert in the sustainability aspects of a particular module. This document is aimed at connecting traditional engineering knowledge to the sustainability concepts provided by the module, providing the instructor with a starting point for engaging in a new topic related to sustainable manufacturing. The presentation slides for in-class delivery are intended to provide the instructor with a perspective of presenting the background information and the case studies with minimal modification. These slides can also be used as-is for self-learning. Finally, the case study files enable the instructor to deliver questionnaires or homework problems and the supporting design files or tools help to delve deeper into the topic for complete understanding of the module.

There are several possible ways to use these modules. Three such uses for education related to sustainable manufacturing have been envisioned. The first use is where these modules complement existing core courses in undergraduate or graduate studies. The second is where a dedicated course is proposed for introducing sustainable manufacturing, and can be complementary to engineering design. The third type is to cater to the needs of sustainability inclusion in a specific manufacturing sector of the industry.

4. Module Content and Description

Table 1 summarizes the key information for the modules available in the website till date. The modules reflect the outcomes of the SMART Roadmap Development Workshop in Cincinnati. These modules are broadly divided into Learning Tools, Case Studies and Methods, and Process Examples. A brief description of the modules is provided in the Table 2. There are 11 modules in this table, but 21 have been developed and will be made available soon.

Table 1 Summary of the SMART Education Modules

Module Name	Module Developer	Module Content
Learning Tools		
Early Stage Sustainability Analysis Tool - EarlySim	Akshay Patel, SustAnalyze and Utrecht University	Provides an early stage chemical process assessment tool. The tool can be used for sustainability assessment in the areas of economic constraints, environmental impact of raw materials, process costs and environmental impact, EHS index, and Risk aspects.
Case Studies and Methods		
Assessment of the Presidential Green Chemistry Award Winners using Green Chemistry Metrics	Christopher L. Kitchens, Clemson University	Evaluates the work that has received the Presidential Green Chemistry Challenge Award using green chemistry metrics, principles, and design strategies.
Life Cycle Assessment for Sustainable Manufacturing	Debalina Sengupta, Texas A&M University	Provides overview of life cycle assessment methodology as outlined in the ISO standards, Emphasize the utility for the LCA methods for manufacturing sustainability
Sustainability Metrics and Sustainability Footprint Method	Debalina Sengupta, Texas A&M University	Provides overview of methods to compute sustainability metrics. It also gives a method compute overall sustainability by aggregating metrics.
Green Chemistry to Manufacture Specialty Chemicals from Renewable Resources	Jeffrey R. Seay, University of Kentucky	Introduces the concept of green chemistry for green design of processes, gives three methods for assessing "greener" processes: The WAR Algorithm for potential environmental impact (PEI) of a process, Life Cycle Assessment, and inherently safe process design.
Sustainability Root Cause Analysis (SRCA)	Helen H. Lou, Lamar University	Demonstrates Sustainability Root Cause Analysis (SRCA) as a tool to determine the bottlenecks for a system's progress towards sustainability. The framework is built on the combination of Pareto chart and the Fishbone diagram, in conjunction with a set of

		sustainability metrics (economics, environmental and safety).
Optimization and Uncertainty for Green Design and Industrial Symbiosis	Urmila Diwekar, VRI and Yogendra Shastri, IIT Bombay, India	Demonstrates the use of optimization methods for sustainable manufacturing. Incorporates systems theory as a valuable tool to enable the integration of multi-scale, multi-disciplinary components using an informational and computational platform.
Atomic Layer Deposition Nano-Manufacturing Technology	Chris Yuan, University of Wisconsin, Milwaukee	Module on atomic layer deposition (ALD) focuses on the study of energy usage and exergy efficiency, simulate reactions inside ALD system and analyze ALD deposition and emissions.
Process Examples		
Optimal Design and Operation of Reverse Osmosis Desalination	Mingheng Li, California State Polytechnic	Specific energy consumption (SEC) in reverse osmosis (RO) desalination is considered for sustainability of the water treatment process. The module focuses on case studies that help in the optimal design for RO with the sustainability concerns in energy consumption addressed.
Sustainable Additive Manufacturing	Karl Haapala/Oregon State University	Provides a module that covers additive manufacturing as a means for sustainable manufacturing. This module explains the basics of additive manufacturing, and explores energy analysis as a metric to establish the benefits of AM.
Sustainable Mitigation of Carbon Dioxide to Chemicals	Debalina Sengupta, Texas A&M University and Sherif Khalifa, Drexel University	This module explores CO_2 mitigation strategies through the utilization of CO_2 into high value chemicals. A superstructure optimization model is formulated and solved for different scenarios.

5. Module Dissemination and Assessment Plan

These modules have been made available through the CACHE Corporation[9], and all future modules will also be disseminated through this website and the website of the Center for Sustainable Engineering[10]. These modules have undergone rigorous testing and review from the SMART team members, and are continuously updated based on reviews and responses from users. CACHE is a not-for-profit organization consisting of 21 universities and 7 industry members. Its purpose is to promote cooperation among universities, industry and government in the development and distribution of computer-related and/or technology-based educational aids for the chemical engineering profession. CACHE also operates short courses and research conferences on subjects of interest to the Process Systems Engineering community.

The Accreditation Board for Engineering and Technology requires well defined Program Educational Objectives, Student Outcomes, Assessment, and Evaluation planning of engineering programs[11]. The Sustainable Manufacturing Modules were described according to the terminology suggested by ABET. For the assessment of the modules, an assessment rubric was created to evaluate each module. Through a self-study exercise for graduate students from various institutions, this rubric was used to evaluate the modules on how effective were the modules in achieving the objectives and student outcomes; whether the modules were suitable as self-study material; and what basic information needed to be added to the modules for making them self-sufficient.

The modules were presented at AIChE Conferences, used in a two day tutorial for a larger group of students through lecture type delivery, and in the ASEE Summer School for Faculty to introduce them to the modules. A positive feedback was received for the modules from all these entities. Based on these assessment methods, the modules were considered effective to be made public.

6. Conclusions

The need for integrating a complex topic like sustainability and the need for introduction and assimilation in current engineering courses led to the Module based learning methods explained in this paper. Sustainable manufacturing case study modules having a computer aided design component were developed to highlight the various aspects for sustainable manufacturing as a part of the Sustainable Manufacturing Advances in Research and Technology Coordination Network. The specific module structures have been discussed and the suggested application of these modules has been proposed. Finally, the module content and dissemination plan have been discussed in this paper. The modules are self-contained sources of information that can be used by instructors and learners alike. The modules are freely available for download and use from the CACHE corporation website [9]. Users are requested to provide a feedback to the SMART executive team (authors of this paper) to improve these modules.

Abstract

Data-analytics is becoming a very influential tool for decision-making today both in industry and academia. The incorporation of data-driven concepts in the core chemical engineering curriculum would be very beneficial to our graduates, making them competitive in today's market. The main objective of this work is to develop tools and case studies that: (a) increase students' understanding and appreciation of data for decision making, (b) introduce students to basic data analytics and machine learning methods, (c) introduce students to basic data visualization tools, and (d) exhibit that the interactions between rigorous simulations and data could lead to improved solutions. This work shows that process design is an appropriate course for the introduction of this material, since students are at a senior level and have obtained the necessary mathematical background, and the development of process flowsheets using commercial simulators creates opportunities for inexpensive data generation to create many case studies.

Keywords: data-analytics, data-driven modelling, process design, simulation, optimization, machine-learning.

1. Introduction

Undoubtedly, we have entered an era, during which data are everywhere and the power and capabilities of data-driven decision-making is being increasingly adopted in many fields of engineering (Beck et al., 2016). The terms "data science", "data-analytics" and "Big-Data" have started to emerge in an increasing number of research papers and conference presentations from both academics and industry in chemical engineering (Venkatasubramanian, 2009, Qin, 2014). Data-scientists have the ability to combine statistics, mathematics and computer programming to capture data trends and find emerging patterns, via data pre-processing, visualization and analysis. Data-analytics is the science of applying algorithmic methods to raw data, in order to draw useful conclusions, which oftentimes may verify or disprove an existing insight. In this work, we aim to show how to incorporate data-analytics into the course of process design, since our main aim is to teach our students how to use information in the form of input-output data to validate existing insight, or gain new insight that would be hard to recognize without data-analytics. Due to the fact that data-sets are often extremely large, with high dimensionality and numerous measurements from advanced sensor technology, the term "Big-Data" has also been predominantly used to capture the volume, variety, velocity and veracity of data and data generation (Qin, 2014). The concepts that are described in this work do not require terabytes of data (which is less likely to be the case in most chemical engineering applications), but rather aim to introduce students to systematic data-driven decision-making tools, which can be applied to a wide range of data-set sizes.

This work is motivated by the vision that chemical engineers with a data-analytics background can make a significant impact, by knowing how to use data in tandem with their first-principle knowledge, to design better systems. A recent sample survey of data-related education showed that statistics and data-analytics do not currently have a big role in most chemical engineering programs (Braatz, 2015). This work will show examples of how process design can be one of the potential ideal courses in every undergraduate curriculum, through which one can introduce data-driven methods and tools, through simple case studies that can be formulated and solved using any simulation software, or process design project.

Three modules for teaching different aspects of data-analysis have been developed and are introduced in this paper. The first module aims to introduce students to multivariate analysis techniques for analysing noisy, unstructured data, and for identifying true dimensionality of data sets. The second module introduces students to the development of reduced-order regression models, using data from their simulations, in order to represent correlations of multiple inputs to outputs of interest. The final module allows students to experiment with data-driven optimization concepts, ranging from simple grid-search, to more sophisticated trust-region optimization. The modules are developed in Matlab and they are not reliant on a specific simulation package, as long as the simulation can communicate with Matlab via generation of text files. These modules are currently being taught and evaluated at the School of Chemical & Biomolecular Engineering at Georgia Institute of Technology, in the course of Process Design and Economics I.

2. Integration of Data-Analytics through the course of Process Design

Despite the acknowledged need to increase our students' understanding of statistics, data-handling, and data-analytics, it is often hard to create new courses that can be incorporated within the core curriculum, due to total credit-hour limitations. As a result, a very effective and efficient approach is to incorporate data-analytics within existing courses throughout the undergraduate curriculum. There are many opportunities for this seamless integration, since the concepts of empirical models, analytical methods and parameter estimation are all embedded within our core undergraduate courses already.

One very timely opportunity for integration of instruction of data-analytics is through the course of process design and economics. During this course, students are introduced to the complexity of decision-making when open-ended design problems need to be solved, using their accumulated knowledge in chemical engineering fundamentals and computer simulations. This course has the objective of teaching students how to develop rigorous simulations of their conceptual designs, generate alternatives, and finally, follow a trial-and-error approach to optimize their design with objectives that range from energy minimization to maximization of economic profitability measures, such as net present value (Seider et al., 2015). The most commonly used flowsheet simulators in process design course are ASPEN, gPROMS, ProMax, HYSYS, COCO, Unisim, and more (Adams, 2018).

The three modules that have been implemented within this course, are appropriately designed to follow the structure of the course, and supplement the learning objectives of the existing syllabus (Figure 1). In the first component, a data-analytics approach is introduced that helps students identify the true dimensionality of a data-set and to visualize the correlations in the data (Module 1). In the second case study, students are introduced to best practices and state-of-the-art methods in machine learning for fitting

multivariate regression models (Module 2) to represent a complex output as a function of a set of inputs. Finally, students are introduced to basic optimization formulations and solvers, and are asked to build their own adaptive optimization solver to identify optimal solutions of their rigorous design simulation (Module 3). Each module is described in more detail in the next subsections.

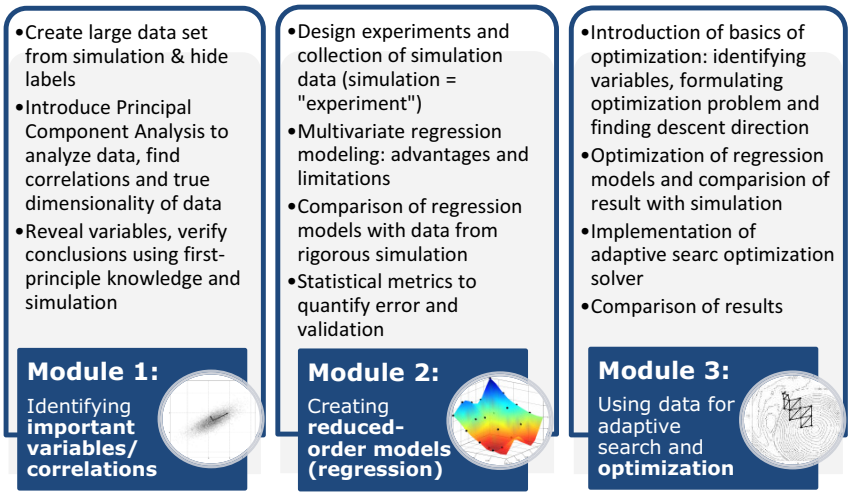

Figure 1. Summary of three modules for data-analytics in process design

2.1. Multivariate analysis for identification of correlations and dimensionality reduction

One of the first challenges that students face when they have completed a rigorous simulation of a fully integrated process, containing multiple units (i.e., reactors, separators, heat exchangers, pumps, compressors, etc.) is identifying which variables to tune, in order to achieve an improved operation. Teaching process design is challenging due to the fact that students may fall in the trap of blindly relying on the simulator, without attempting to use their first-principle insight for making informed perturbations to the system. The former is our first goal, and for this reason students are first expected to explore their design via trial-and-error and sensitivity analysis tools, in order to gain better understanding of the performance of the design, as well as to learn how to apply chemical engineering fundamentals to explain perturbation effects to the system.

However, even when students reach the point of understanding the effect of a single (or a few) key variables within a single unit to the outputs of that unit, it becomes more challenging to understand and quantify how changes in several variables across units, may propagate and affect the operation of other units within a fully integrated design with recycle streams. In addition to the above, it is true that a large fraction of our students in the future, may be faced with the challenge of trying to understand, analyse and predict the performance of a system, by using large historical data-sets.

Through the steps of Module 1 (Figure 2), we take advantage of the existence of large integrated simulations, for the given project statement in order to create a large data set, which aims to mimic a historical data set of a process design. More specifically, we select a large number (M_1) of manipulated design variables, feed conditions, and operating conditions from every unit in the design and identify a reasonable range of operation of these variables. In addition to the set of manipulated variables, we also select a set of

monitored variables (M_2) that may or may not be highly sensitive to the manipulated variables. We then randomly perturb the M_1 manipulated variables, in order to create a set of N simulated case studies of the design, and generate a data matrix $X = [N \times (M_1 + M_2)]$. Various sampling techniques can be used to generate the samples, such as Monte Carlo sampling or space-filling designs (i.e., Latin Hypercube sampling, orthogonal arrays) (Wang et al., 2006). Some of the columns (dimensions) of this data set are correlated (by design), but this is not revealed to the students. The module also has an option of adding noise to the data set X, in order to better mimic noisy historical data sets. After students are introduced to Principal Component Analysis (PCA) in a lecture (Jolliffe, 2002), they are provided with the data set and are asked to use PCA to identify correlated columns, as well as the true dimensionality of the data which they feel truly describes the variability in the data. Students are asked to complete exercises in which they generate score plots and are asked to identify correlated dimensions. Once these exercises are completed, the real labels of the data set are revealed, and students find that their conclusions based solely on data, often agree with their intuition. Through this exercise, it is truly fascinating to observe that his reinforcement of intuition helps students trust the data-driven approach. Other times, the data analysis points students towards a correlation that they did not identify through their trial-and-error approach, which they are always asked to explain using their engineering insight. Despite the fact that our aim is to introduce data-analytics, the most powerful learning outcome of this module is the realization that both rigorous simulation based on chemical engineering fundamentals, coupled with data-analytics can collectively lead to better analysis and understanding of complex systems.

Step 1: Indentify set of manipulated variables (M_1) (feed conditions, operating conditions, design parameters) and their ranges.
Step 2: Identify set of monitored variables (M_2) (outlet conditions, conversions, energy requirements, etc.) across units.
Step 3: Randomply perturb manipulated variables within their ranges, and perform $(N > M_1 + M_2)$ simulations, generating data set $X = [N \times (M_1 + M_2)]$.
Step 4 (optional): Add random noise to data set $X = X + \varepsilon$.
Step 5: Provide students with X, omitting labels/descriptions of data. Assignement includes PCA analysis of data, to identify correlations and reduce dimensionality.
Step 6: Collect results, reveal data labels and compare data-driven conclusions to engineering insight. [Questions posed: Did you verify your insight? Did you learn something new from data?]

Figure 2. Outline of steps of Module 1

2.2. Regression and interpolation using simulation data

Despite the fact that chemical engineering students oftentimes use empirical correlations, their understanding of regression does not often go beyond linear or polynomial regression in one dimension. Throughout the progression of a process design course, students can often benefit from using multidimensional regression models for analysis, visualization and optimization. One of the most commonly encountered example of the need to use regression functions (or else parametric models, surrogate models or metamodels) to represent phenomena is to allow for the incorporation of a rigorous model from a flowsheet simulator within a synthesis optimization formulation (Caballero et al., 2008). Through this module, students are taught about computer experimental design (Sacks et al., 1989), and subsequently they learn how to use the collected input-output data to minimize the least-squares error of prediction between the data and a variety of different regression functions: linear, quadratic, polynomial (Bhosekar and Ierapetritou, 2018) and more advanced state-of-the-art machine-learning inspired functions, such as

support vector regression (Smola et al., 1996). The importance of over-fitting and validation is conveyed to the students through a series of examples and comparisons of fitted models. The final assignment for this module is the collection of data from the actual simulation using a designed experiment; the fitting of a variety of regression models (Figure 3); the selection of the best model using statistical measures; plotting of the selected function in surface plots for visualization; and finally the validation of these fitted models for a set of data points that was not used to train them.

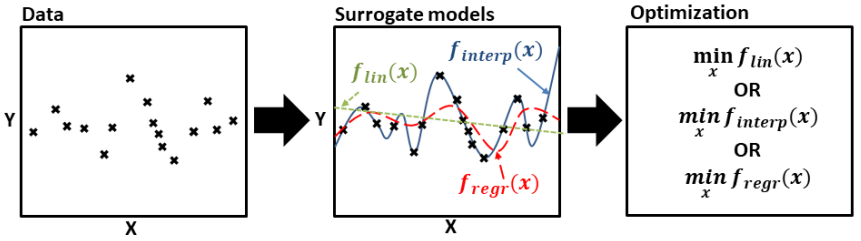

Figure 3. Concept of fitting parametric models (regression, interpolation) to data and finally using these functions for optimization.

2.3. Data-driven Optimization for flowsheet optimization

During the final lectures of the process design course, students learn about optimization fundamentals, such as identifying the degrees of freedom, formulating the objective function, formulating the constraints, linear optimization vs. nonlinear optimization, use and complexity of discrete variables to represent logical constraints, and formulation of synthesis problems. Students quickly identify the gap between being able to solve rigorous optimization problems, and the use of rigorous simulations. Several simulation packages contain built-in optimization solvers, through which a flowsheet can be optimized directly (i.e., ASPEN optimization tool). However, the goal of this work is to develop modules that are independent of a simulation platform, and also to teach the students the fundamentals of optimization by allowing them to develop their own simplified solver. During the first stage of this module, students are asked to use their results from Module 1 and Module 2 for the purpose of optimization. From Module 1, they have identified the most important and influential variables, while in Module 2 they have developed regression models. First, students use their fitted regression model to perform local optimization in Matlab (fmincon) (Figure 3). Subsequently, students have to simulate the identified optimum within their simulation software, in order to compare the accuracy of the result. Oftentimes, the predicted optimum is not identical to the optimal value obtained by the rigorous simulation. Thus, students quickly comprehend the concept of adaptively sampling their rigorous simulator in 'promising' locations, in an effort to identify better solutions. This teaching material starts with the simple concept of grid-search, and ends with the teaching of a more advanced trust-region-search algorithm towards descent directions (Boukouvala et al., 2016, Kolda et al., 2003). The students are asked to implement this algorithm, which iteratively exchanges data with their simulation in order to search for optimal locations. The advantage of implementing a customized solver, is the ability to account for simulation instances that fail to converge due to numerical issues, which may hinder the applicability of certain solvers. For simplicity, this analysis is performed for a relatively low number of optimization variables (~2-3), which have been previously identified to be significant. Finally, the students compare their results with in-built optimization solvers, if those are available.

Regardless of the result, through this exercise students truly understand fundamental optimization concepts, as well as the difference between local and global optimization

3. Conclusions

Three case studies have been presented, through which various data-driven analysis, modelling and optimization concepts are introduced to chemical engineering seniors, through the course of process design. The goal of these modules is to prepare graduates to enter the workforce, better equipped and competitive in today's Big-Data era, by introducing them to data-analytics tools that have gained significant applicability in industry and academia. The goal of the modules is to teach students how to use multivariate input-output data to improve their decision-making process, while never forgetting their chemical engineering fundamentals. These modules will continue to be tested and enhanced through additional case studies in the future, and will soon be made available to the community.

Abstract

In recent years, the risk that cyber incidents occur is increasing in Industrial Control System (ICS) which is the core function of Critical Infrastructures (CIs). As a result, companies holding CIs must improve the organization's incident response ability to cyber incidents. Because cyber incidents in ICS cause not only problems to cybersecurity but also problems to plant's safety and company's business, the company-wide response including not only the IT department but also the ICS department and management layer is essential. To smoothly promote this company-wide response, Incident Commanders who adjust between departments are essential. However, many companies holding CIs do not adequately educate Incident Commanders. Therefore, in this research, the authors developed the cyber exercise aimed at educating Incident Commanders.

Keywords: Cyber Security, Critical Infrastructure, Cyber Exercise, Incident Commander.

1. Research Background

In recent years, Cyberattacks to Industrial Control System (ICS), the core functions of Critical Infrastructures (CIs) such as power plants and chemical plants has been increasing year by year. In 2010, the uranium enrichment centrifuge fell into dysfunction at Iran's nuclear facility (Nobutaka Oguma, 2011) and the blast furnace was damaged in the German steelworks plant in 2014 (Motohiro Tsuchiya, 2015). Also, two large power outages occurred in Ukraine in 2015 and 2016 (Toshio Miyachi, 2016).

In Japan, the Tokyo Olympic and Paralympic Games are scheduled to be held in 2020. It is said that the 2012 London Olympic Games could have resulted in the loss of lighting at the opening ceremony site due to cyberattacks (BBC NEWS, 2013). For this reason, it is urgent for companies holding CIs in Japan to secure cybersecurity in ICS for the Tokyo Olympic and Paralympic Games (Nihon Keizai Shimbun, 2017).

Cyberattacks against ICS affect not only cyberspace but also the physical world. As a result, there are concerns about destruction of the equipment itself, leakage of dangerous substances, and explosion accidents. Also, in recent years as the sophistication of cyberattacks methods increases, preparing cybersecurity measures on the premise of receiving cyberattacks is regarded as important. One of the cybersecurity measures is a rapid and appropriate response by the organization to mitigate damage and bring the situation under control after cyberattacks occur. Thus, it is essential to formulate a response plan in advance for events caused by cyberattack (from now on referred to as

"cyber incidents"). For this reason, the authors have developed the cyber exercise to assist companies holding CIs in formulating their cyber incident response plans (Hidekazu Hirai, 2017).

2. Problem Setting

Even if companies holding CIs prepare the cyber incident response plan, it is not easy for companies holding CIs to implement cyber incident response plan that does not have experience. Cyber incidents in ICS cause not only problems with cybersecurity but also problems with plant's safety and company's business. Therefore, against cyber incidents in ICS, multiple departments such as IT department and ICS department must respond in parallel. However, when multiple departments respond in parallel, there may be errors in decision-making due to lack of information sharing among departments and conflicts due to differences in response objectives between departments. Therefore, under cyber incidents in ICS, Incident Commanders (from now on referred to as the "commanders") to coordinate and make decisions between departments are especially important. Many companies have Computer Security Incident Response Team (CSIRT) as commanders against cyber incidents in IT. However, few companies have specialized response teams against cyber incidents in ICS. Therefore, if cyber incidents occur in ICS, the leaders of divisions or departments in the existing organization may have to become commanders. However, it is challenging for anyone who has never experienced cyber incidents in ICS to properly perform the commander role. For this reason, companies holding CIs need to educate position who have to become commander under cyber incidents in ICS. Therefore, in this research, the authors will develop training for Incident Commander's educational support for companies holding CIs. However, in cyber incidents in ICS, abnormal situations in each company is unique to each company occurs. The role that commanders should be in cyber incidents varies widely from company to company, and therefore, the content of their training needs to be customized for each company. However, it is inefficient for us to develop customized training for each company. For this reason, the training is developed in this research must include the mechanism that each company can customize on its own. Thus, cyber exercise is developed in this research is training for commanders, including the mechanism that each company can customize in-house.

3. Cyber Exercise For Training Incident Commanders

3.1. Form of Training

To customize the training for each company, the training components need to be divided into parts that are common to all critical infrastructure companies and parts that must depend on the individual characteristics of each company. Customizing the training is to change the part of the training that depends on the individual nature of each company, which is a component of the training, into one that is unique to each company. To do this, training in the form of computer games is useful. Computer games consist of programs and data embedded in programs. For this reason, in computer games, the programs are a common part that can be used by all critical infrastructure companies, and the data can be viewed as a part that depends on the individuality of each company. Therefore, incorporating company-specific information into the data creates a customized computer game for each company. Therefore, the fact that the training is in the form of computer games is effective from the viewpoint that the training can be customized for each

company, and therefore, the training be developed in this research is in the form of computer games.

3.2. Requirements for the Computer Game

The purpose of the computer game is to enable participants to learn about the role of commanders and to perform that role properly. For this purpose, simulated training methods that allow participants to experience the role of commanders are useful. For this reason, it is essential to have mechanisms that allow participants to simulate the role of commanders in the computer game. To clarify what commanders should do cyber incidents to clarify the mechanism required for the computer game. Cyber incidents in ICS cause not only cybersecurity issues but also safety and business issues simultaneously. For this reason, not only IT departments, but also ICS departments, management, and others need to take action at the same time. To facilitate this company-wide response, it is necessary for the leaders of each department to act as commanders, to coordinate among departments, and to direct the company-wide response. To do this, each commander must perform the following:

- Collection of information on cyber incidents (information on damage status of ICS, network logs, operation status, etc.).
- Sharing information with other commanders and external organizations (customers and affiliates).
- Decision making based on information obtained and task instructions to workers and other commanders based on contents of decision making.

Thus, for the participants to simulate the role of commanders, the following mechanisms need to be established in the computer game.

- Mechanism by which more than one participant can participate in the computer game as another commander (ICS Director, IT Director, Management, etc.)
- Mechanism by which participants can collect information, share information, and issue task instructions as commanders.

To realize these mechanisms, the computer game with the configuration shown in Figure 1 is proposed.

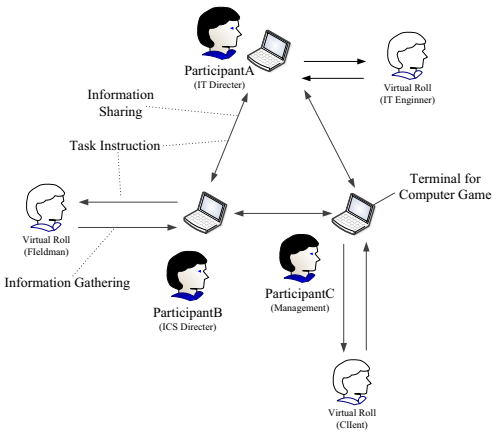

Figure 1 Composition of the Computer Game

Each participant has the terminal for the computer game and participates in the computer game as the separate commander. Each participant uses the terminal to collect information, share information, and issue task instructions among the participants. However, the commander needs to collaborate not only with other commanders but also with workers who are subordinates of the commander and external organizations (customers, affiliates, etc.). For this reason, it is necessary to prepare workers and external organizations as virtual roles on the computer game, which have the function of returning responses to collecting information, sharing information, and task instructions from participants. This allows each participant to interact not only with other participants but also with his subordinates and external organizations within the computer game. Also, to play the computer game, scenarios for proceeding the computer game is required. The game scenarios consist of cyberattacks scenario and an ICS state transition scenario affected by cyberattacks. Based on the game scenarios, virtual roles must respond to the participant. Participants understand the situation by using information from the virtual roles. The computer game also requires the mechanism whereby the instruction is reflected in the game scenarios when participants issue the task instructions to the virtual roles. For example, if the ICS Director instructs the fieldman to operate the ICS, then the status of the ICS in the gaming scenarios must change to the state in which the instruction is reflected. This mechanism is essential in the computer game, and with this mechanism, participants can aim for convergence of cyber incidents in ICS, which is the goal of the computer game. Thus, the requirements to be met by the computer game are as follows.

- Some participants can participate in the computer game as separate commanders.
- Each participant can collect information, share information, and perform task instructions to other participants and virtual roles.
- Based on the game scenarios, the virtual roles interact with the participants.
- Task instructions to the participants' workers are reflected in the game scenario.

Additionally, what is indispensable in training is feedback after training. In feedback, participants should assess whether they were able to adequately perform their commander roles, identify problems, and discuss remedial measures. However, to provide feedback, a workflow is required to record what the participants did in the computer game. Therefore, the computer game also requires the ability to output workflows.

3.3. Development of Prototype of the Computer Game

We developed the prototype computer game that satisfies the requirements described in the previous section. The programs of the computer game were described in Java.

Figure 2 is User Interface (UI) of terminals used by participants in the computer game. Participants can use this UI to collect information, share information, and issue task instructions. In UI, the communication sent and received is arranged in chronological order. Therefore, it is displayed on this UI when it communicates with other participants or virtual roles, or when itself receives communication from other participants or virtual roles. Pressing the buttons above the tray in which the communication in Figure 2 is arranged opens the box shown in Figure 3. When communication contents, address, etc. are set in this box and transmitted, the information is sent to the specified address.

Figure 4 shows an example of the result of a computer game.Artifact is output in workflow format, and records who, when, and what do. Participant training is not completed only by computer game execution. Training must include extracting the

current problem (slow decision on plant stoppage etc) based on deliverables and deciding how to improve the function of commanders. Also commanders training is not complete at once. Commanders cannot maintain its function unless it receives regular training. Commanders cannot maintain its function unless it receives regular training. And, further training provides new learning to participants every time. Therefore, it is important that Commander repeats training, always maintaining and improving functions.

Figure 2 User Interface

Figure 3 Box for Creating Communication

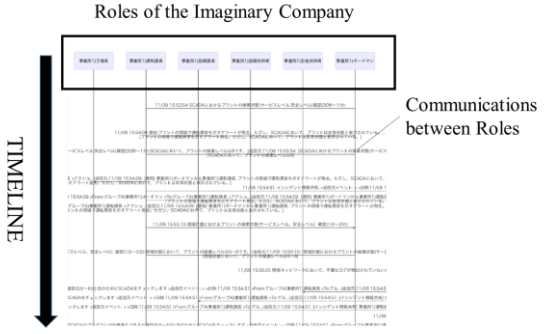

Figure 4 Typical Deliverable of the Participants

3.4. Implementation of Prototype of the Computer Game

In September 2017, the authors held the trial event of the prototype for 38 people from companies holding CIs. The data of prototype was developed based on the virtual

company used in the current cyber exercise. As commanders of the virtual company, participants experienced the prototype with the goal of convergence of cyber incidents.

In the post-implementation questionnaire, 17 out of 38 respondents answered that they would be trained on the question, "Can this game be used to train the Incident Commanders?" Therefore, it can be said that this game was evaluated as effective to a certain extent.

4. Conclusion

In this research, the authors developed the cyber exercise in the form of a computer game for educating incident commanders in CI owner companies. Through workshops with OT and cyber security experts, the developed prototype was successfully evaluated by using the participants' questionnaire. To apply this prototype to each company, it is necessary to customize the data to reflect the situation (such as the organization structure, the jurisdiction scope, the corporate culture and so on) of each company.

At present, however, the complexity of the data integrity makes it difficult to prepare unified template to simplify the customization. Accordingly, we will continue to develop the utility tools to promote our exercise.

Abstract

Industrial parks are competitive because of the concentrated utilization of resource and energy. In industrial parks, power plants are energy hubs to supply power and various levels of steam to other enterprises. However, it is still challenging to centralized produce and supply cold energy in industrial parks. We present a process superstructure for the retrofit of power plants to centralized produce and supply cold energy for industrial parks. The energy sources for refrigeration include cold energy from liquefied natural gas, pressure energy of natural gas and low-pressure steam in power plants. A mixed integer nonlinear programming model is formulated to optimize the process superstructure to minimize the total annual cost. The model is solved using the global solver BARON in GAMS environment. The solution results, total annual cost and different price of electricity are analyzed and compared. The best alternative is a hybrid central refrigeration system that includes different energy sources for chilling, and the power consumption of cold energy is reduced by 36%.

Keywords: Optimization, Mathematical modeling, Industrial park, Refrigeration.

1. Introduction

Energy conservation has been a routine behavior for process industries to reduce operating costs and emissions under the requirement of sustainable development (Zhang *et al.*, 2016). Industrial parks require considerable energy to transform crude feeds into final products. In industrial parks, power plants are energy hubs to supply power and various levels of steam to other enterprises. At the same time, most of the low-grade heat (LGH) is emitted directly. Using the unrecovered LGH to produce cold energy is an effective way to improve energy efficiency and reduce emissions for industrial parks.

Nowadays, due to the rising energy prices and stringent environmental protection requirements, the utilization of LGH is significantly investigated, such as absorption refrigeration (Ponce-Ortega *et al.*, 2011), desalination (Ammar *et al.*, 2012), and power generation (Lin *et al.*, 2014). Because of the high energy recovery efficiency of absorption chiller, absorption refrigeration is widely used to converting LGH for cooling. Wu *et al.* (2002) introduced a new method for synthesizing integrated refrigeration systems. Hammond and Norman (2014) used absorption chillers to convert heat energy for cold energy to fulfill chilling demand. Zhang *et al.* (2016) proposed a mixed integer nonlinear programming (MINLP) model to finish the optimization and economic analysis for the LGH utilization in petrochemical industrial parks and a good economic performance is

obtained. Salmi *et al.* (2016) presented a model to optimize an absorption refrigeration system using waste heat (WH) of ship as energy source. Wang *et al.* (2017) presented a model for the match between heat sources and absorption refrigeration to improve energy recovery efficiency of waste heat. Nevertheless, it is still challenging to centralized produce and supply cold energy in industrial parks.

In this study, the design optimization of central refrigeration systems (CRSs) using LGH and other energy sources in industrial parks is proposed. A MINLP model is formulated to optimize the process superstructure to minimize the total annual cost (TAC). An industrial case is then investigated and analyzed.

2. Problem Description and CRS superstructure

Natural gas power plants in industrial parks supply heat and electricity to other plants. However, cold energy is often separately produced and used in individual plants by using electricity. Thus, a CRS based on power plants is attractive for industrial parks to improve energy performance and profitability.

The typical flowsheet of natural gas power plants in industrial parks is shown in the upper part of Figure 1. The pressure regulating station, regasification station and low-pressure steam form the steam turbine can supply energy for refrigeration. The cold energy is then sent to cold sinks in industrial parks. In order to minimize the TAC, we need to determine: (1) which energy sources in the power plant is used for refrigeration? (2) which level of steam from the power plant is used for refrigeration? (3) how many refrigeration stations are built to produce cold energy? and (4) how much cold energy can be supplied from a refrigeration station to a cold sink?

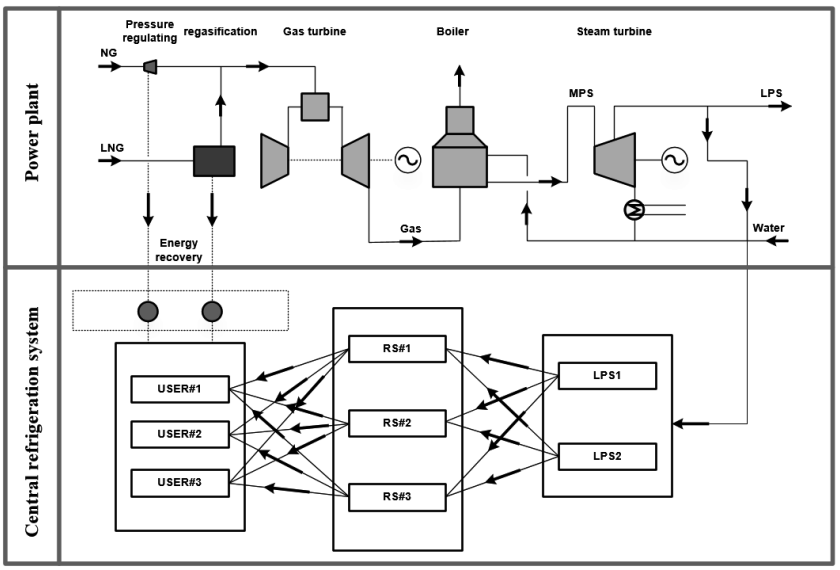

Figure 1. Flowsheet of natural gas power plants and superstructure of CRS

In order to address the above problems, a CRS superstructure is extracted and shown in the lower part of Figure 1. The possible flowsheets of CRS are represented as three levels. The first level is the configuration of energy sources from the power plant. We can use anyone of the three energy sources. The second level is refrigeration stations. A

refrigeration can collect energy from any sources, and convert it into cold energy, and then sent the cold energy to any cold sinks. The last level is cold sinks. A cold sink in industrial parks can receive cold energy from any refrigeration stations. Note that when different energy sources or flowsheets is employed, the operation of power plant varies.

3. Mathematic Modeling

A MINLP mathematical model is introduced in this section to optimize the superstructure. According the three levels of CRS superstructure, the mathematic model includes power plants, waste energy or low-grade heat recovery, refrigeration and pipeline network.

3.1 *Modeling for power plants*

Natural gas (NG) or liquid natural gas (LNG) after treatment enter into gas turbines to generate power and exhaust high temperature and pressure flue gas. Then, the flue gas goes into boilers to generate middle pressure steam. The middle pressure steam is introduced into steam turbines to generate power and obtain waste steam. Hence, the mass and energy balances of power plants are represented in Eqs. (1)- (5). Eq. (1) is the energy balance of fuel combustion. Q_{com} is the combustion heat of CH_4, F_{NG} and F_{LNG} are the mass flowrate of NG and LNG, respectively. $C_{CH_4,NG}$ and $C_{CH_4,LNG}$ are the mass fraction of CH_4 in NG and LNG, respectively. Q_{CH_4} is the low calorific value of CH_4. Eqs. (2) and (3) are the mass and energy balances for gas turbines, respectively. F_{air} is the mass flowrate of air enter gas turbine and F_{gas} is the mass flowrate of flue gas. Q_{gas} is the heat of gas from gas turbine, Q_{ele} is the power generated by gas turbine and Q_{loss} is the heat of low temperature flue gas. Eq. (4) is the model for boilers, and Eq. (5) is the model for steam turbines (Shang and Kokossis, 2004). In Eqs. (4) and (5), F is the mass flowrate of steam, ΔH_{steam} is the enthalpy of steam, TE_t is the power generated by steam turbine, D_t is the isentropic enthalpy drop of steam turbine, and α, β, δ and ε are correlation coefficients.

$$Q_{com} = (C_{CH_4,NG}F_{NG} + C_{CH_4,LNG}F_{LNG}) \times Q_{CH_4} \tag{1}$$

$$F_{gas} = F_{NG} + F_{LNG} + F_{air} \tag{2}$$

$$Q_{com} = Q_{gas} + Q_{loss} + Q_{ele} \tag{3}$$

$$Q_{gas} = [\alpha_b FBL_b^{max} + (1 + \beta_b)FBL_b] \times \Delta H_{steam} \tag{4}$$

$$TE_t = \frac{6}{5}\frac{1}{\delta_t}\left(D_t - \frac{\varepsilon_t}{F_t^{max}}\right)\left(F_t - \frac{1}{6}F_t^{max}\right) \tag{5}$$

3.2 *Modeling for recovery of waste energy*

The gas streams entering power plants include NG and LNG. NG is at high pressure and need to be decompressed at pressure regulating stations. The energy released from decompression processes can be recovered. The regasification of LNG also emits cold energy. The energy balance for the two processes are shown in Eqs. (6)-(7). Q_{NG} and Q_{LNG} are the capacity of refrigeration by NG pressure regulating and LNG regasification, respectively; CP_{NG} and CP_{LNG} are the specific heat capacity of NG and LNG, respectively;

T_{NG}^{in} and T_{NG}^{out}, T_{LNG}^{out} and T_{LNG}^{in} are the inlet and outlet temperatures of NG and LNG, respectively; η_{expand} is the efficiency of expander, and X_{NG} and Y_{LNG} are 0-1 variables to identify whether waste energy is recovered or not. Because of the throttling expansion for NG, the outlet temperature of NG can be calculated by Eq. (8). P_{NG}^{in} and P_{NG}^{out} are the inlet and outlet pressure of *NG*, respectively; k is the insulation index.

$$Q_{NG} = F_{NG} \cdot X_{NG} \cdot CP_{NG} \cdot \left(T_{NG}^{in} - T_{NG}^{out}\right) \cdot \eta_{expand} \tag{6}$$

$$Q_{LNG} = F_{LNG} \cdot Y_{LNG} \cdot CP_{LNG} \cdot (T_{LNG}^{out} - T_{LNG}^{in}) \tag{7}$$

$$\frac{T_{NG}^{in}}{T_{NG}^{out}} = \left(\frac{P_{NG}^{in}}{P_{NG}^{out}}\right)^{\frac{k-1}{k}} \tag{8}$$

3.3 *Modeling for refrigeration using steam*

Absorption chiller is widely used in refrigeration using low-grade heat. An absorption chiller is consisted of four main parts: generators, condensers, evaporators, and absorbers. We can model the absorption chiller by considering the energy balance in the four parts. The models of the four parts can be found in Literature 7. The total energy balance of the absorption chiller can be expressed in Eq. (9). Q_s^g is the energy of generator, Q_s^a is the energy of absorber, Q_s^c is the energy of condenser, and Q_s^e is the energy of evaporator. The coefficient of performance COP_s of the absorption chiller is represented in Eq. (10).

$$Q_s^g + Q_s^e = Q_s^a + Q_s^c \tag{9}$$

$$COP_s = \frac{Q_s^e}{Q_s^g} \tag{10}$$

3.4 *Objective function*

The TAC is used as the objective for the design of a CRS that covers all the cooling demands in industrial parks. The objective is represented in Eq. (11). TAC is the total annual cost, C^R is the investment of refrigeration stations, C^P is the investment of pipelines, C^E is the investment for valves and exchangers, C^D is the investment for expanders, θ is the equipment depreciation period, C^W is the cost for cooling water, P^C and P^E are the income for the cold energy and electricity, respectively. The correlation for the cost of equipment can be found in Literature 7.

$$\boldsymbol{min}\ \ TAC = \frac{C^R + C^P + C^E + C^D}{\theta} + C^W - (P^C + P^E) \tag{11}$$

4. Case Study

The MINLP model is applied to a case extracted from an industrial park at South of China. In the case, the total operation time per year is 8,000 hours, and there are two devices in the power plant to supply the energy and power to meet the industrial park's demand. The minimum annual demand of power in the entire park is 1.6 million MW. There are three

energy sources (the pressure regulating station, regasification station and steam turbine) in the power plant can be used for refrigeration. The specification of gas stream, the demand of chilled water from enterprises and the distances between cold sinks and refrigeration stations are all listed in Table 1.

Table 1. Basic data of the case

The original status for gas stream				The demand of cold energy sinks		
	Mass Flowrate	Temperature	Pressure		Quantity	Temperature
NG	20 t/h	273.15 K	4.0 MPa	User#1	10 MW	278.15 K
LNG	5 t/h	163.15 K	2.5 MPa	User#2	4 MW	278.15 K
				User#3	6 MW	278.15 K

The distances between steam turbines, sinks and refrigeration stations (m)			
	RS #1	RS #2	RS #3
Steam turbine #1	300	230	240
Steam turbine #2	300	230	240
User #1	2200	1200	3000
User #2	1300	470	1300
User #3	480	2200	1400

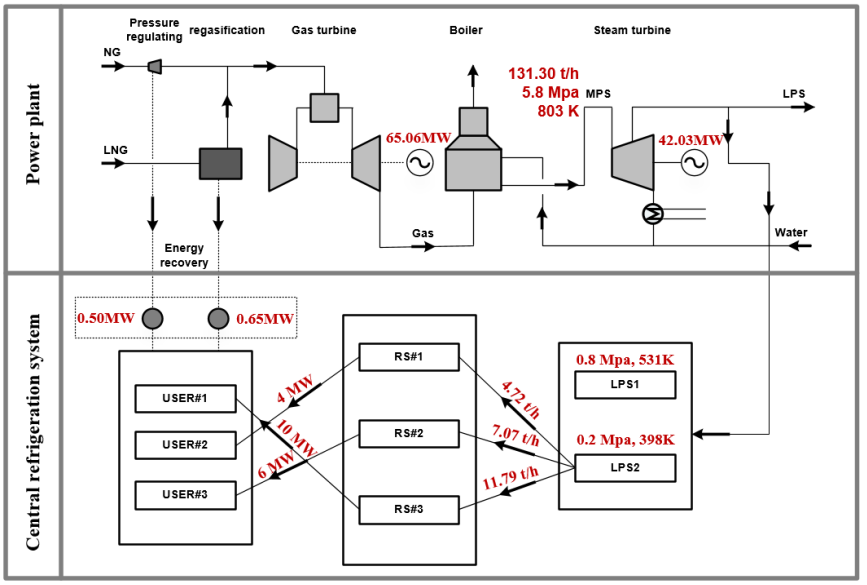

Figure 2. The optimal flowsheet and heat load of CRS

The MINLP model is coded in GAMS environments and solved using the global solver BARON, there are 217 variables and 22 binary variables, the computing time is 8s. The cold energy from pressure regulating stations and regasification stations is directly used by the power plant to produce chilled water. Low-pressure steam from steam turbine #2 is introduced into three refrigeration stations to produce chilled water. Cold energy from refrigeration station #1 is transferred into user #2, that from station #2 into user #3, and that from station #3 into user #1. The TAC of this case is $ 10.7 million dollars, the total power generated in the power plant is 1.7 million MW per year, the power can be generated by steam which is used to refrigeration is 2.55 MW and other solution results are shown in Figure 2.

5. Conclusions

A process superstructure was introduced for the design of CRSs based on natural gas power plants in industrial parks. A MINLP model was formulated to optimize the superstructure to obtain the minimum TAC. The model was applied to an industrial park. For 20 MW of cold energy, the total electricity consumption is 4.0 MW when using separate refrigeration processes, while the electricity generation in the power plant is only reduced by 2.55 MW when using the CRS. The CRS reduces the power consumption by 36%. The application demonstrates that the process superstructure and MINLP model can optimize the design of CRSs and improve energy efficiency.

Influence of Humic Substances on the Solubility and Crystallization Behavior of Calcium Phosphates during Crystallization from Digester Supernatant

Liubov Vasenko*, Haiyan Qu

Department of Chemical Engineering, Biotechnology and Environmental Technology, University of Southern Denmark, Campusvej 55, Odense M 5230, Denmark
liva@kbm.sdu.dk

Abstract

Conditional solubility of dicalcium phosphate dihydrate (DCPD) and hydroxyapatite (HAp) was determined in distilled water and in digester supernatant experimentally and compared with the modelling results with PHREEQC. Conditional solubility of both phases in digester supernatant increases at the pH values > 5 – 6, and for HAp this increase is more significant. It was confirmed that the increase in conditional solubility is caused by the presence of natural organic matter (especially humic substances) by determination of conditional solubility of DCPD and HAp in the solution of humic acid (10 mg/L). The obtained solid-liquid equilibrium data served as the background for designing the separation process for recovery of phosphorus from digester supernatant. A two-step process with fast precipitation and recrystallization was developed, from which DCPD, HAp or their mixture were obtained. However, it was observed that the presence of humic compounds significantly inhibited the crystallization of DCPD and HAp and affected the purity of the obtained products. Thereafter, a novel hybrid separation process was designed and developed. The new process consists of an oxidation and a crystallization steps. It could successfully overcome the negative effects of humic compounds. Either DCPD or HAp with the high purity could be produced with a P-recovery rate of about 90 %.

Keywords: Phosphorus recovery, Calcium phosphates, Reactive crystallization, Conditional solubility.

1. Introduction

Recovery of phosphorus from digester supernatant in wastewater treatment plants is one of the most promising ways toward phosphorus sustainability (Egle et al., 2015). Currently, the major product in such P-recovery processes is struvite, which is sold as a low-prise slow releasing fertilizer. Production of high-purity calcium phosphate (CaP) can ensure a broad application of the product (industry, fertilizers. feed additives etc.), and thus can improve the economy of the process. However, crystallization of calcium phosphates from digester supernatant is a challenging task due to the complicated equilibrium between different phases and the influence of operation parameters and presence of different impurities. It was reported that humic substances (HS) inhibit the crystallization of DCPD and HAp (Amjad, 1989; Freche et al., 1992). Song et al. reported that HS are removed from solution simultaneously with CaP crystallization by adsorption on crystals' surface (Song et al., 2006). HS can as well create complexes

with Ca^{2+}, reducing its availability for the formation of CaP. Previously we reported that the appearance of DCPD or HAp during crystallization depends on nucleation pH, which is strongly affected by Ca/P and NH_4-N/P ratios (Vasenko and Qu, 2017a). Moreover, presence of ammonia also affected the kinetics of the crystallization process.

A conceptual approach was suggested in the present work for the design and development of a hybrid separation process for recovery of high purity CaP products from digester supernatant. Firstly, the key impurities in the digester supernatant that influence the conditional solubility of CaP and inhibit their crystallization were identified. Then a two-step process of fast precipitation and recrystallization was developed and tested to minimize the effects of the impurities. Finally, a new hybrid process with oxidation and crystallization was designed. This process could produce high purity CaP with a high P-recovery rate at about 90 %, and thus has a great potential in application at wastewater treatment plants as a new P-recovery technology (Vasenko and Qu, 2017 b).

2. Materials and methods

2.1. Materials

Reagent grade DCPD and HAp were used for conditional solubility determination. pH adjustment was done using 37 % HCl and 23 % NaOH solutions. All mentioned reagents were purchased from Sigma Aldrich. Humic acid solution with the concentration of 10 mg/L was prepared from crystalline humic acid with assay > 95 % (purchased from Alfa Aesar). Solid and liquid separation after experiments were done with vacuum filtration using an Advantec Glass Fiber filter with a porosity < 0.45 μm.

2.2. Experimental determination of conditional solubility

The conditional solubility of two CaP phases was determined in distilled water, digester supernatant and humic acid solution with concentration of 10 mg/L at the room temperature. pH of 50 ml liquid aliquotes was adjusted to different values in the range of 1 – 13. An excess amount of DCPD or HAp was suspended in these aliquots for 24 hours to attain the solid-liquid equilibrium. Thereafter, solid phase was separated using vacuum filtration, final pH and the total concentration of phosphate ($[P^*_{tot}]$) and calcium ($[Ca^*_{tot}]$) in the liquid phase were determined. The conditional solubility was calculated using Eq. (1).

$$logP_s = log([Ca^*_{tot}] \cdot [P^*_{tot}]) \quad (1)$$

The values of logPs were plotted versus the final pH of solutions to graphically represent the dependence of conditional solubility on pH. All pH measurements were done with a PHM210 Standard pH Meter with reference Meter Toledo Routine sensor. The electrode was calibrated with standard IUPAC buffer solutions with pH 4.00 and 7.00 at room temperature before each experiment and was stored in a 3M KCl solution between measurements.

2.3. Determination of conditional solubility in distilled water using PHREEQC

PHREEQC software was used for the thermodynamical modeling of speciation during the dissolution of DCPD or HAp in distilled water at different pH values edited by the introduction of HCl or NaOH. Speciation equations were taken from the phreeqc.dat database. The equation for DCPD speciation was added manually to the program as it is

not in the phreeqc.dat database and was used with the activity based K_{sp} value (Patel, et al., 1974).

2.4. Analysis of liquid phase

Total phosphate and calcium concentrations in liquid phase were determined using ion chromatography equipped with a 761 SD Compact IC with an 813 Compact Autosampler by Metrohm. Anions analysis was performed using a Metrosep A Supp 5 - 150 (6.1006.520) column and the eluent is 3.2 mM Na2CO3/1.0 mM NaHCO3 + 10 % acetone. A column for cations analysis is Metrosep Cation 4 (6.1010.000) and the eluent is 1.7 nM Nitric acid/0.70 mM dipicolinic acid.

2.5. Analysis of solid phase

All solid samples were analysed with FT-Raman and PXRD in order to identify the CaP phase. A Bruker MultiRAM FT-Raman Spectrometer equipped with 1064 nm laser was used with the laser power of 100 – 400 mW. A Rigaku Miniflex 600 X-ray diffractometer with a Cu source of X-rays and a Ni filter was used for the PXRD analysis with the voltage of 40 kV, current – 15 mA, speed – 10°/min, step size – 0.02, 2Θ range: 2 – 70°. A demo version of Match! Ver.3. was used with a COD-Inorg database to analyse the PXRD patterns.

3. Results and discussion

3.1. Effect of humic substances on conditional solubility of DCPD and HAp

Conditional solubility of DCPD and HAp in water and in digester supernatant are shown in Fig. 1 together with the modelled results of PHREEQC. Analysis of the solid recovered after the solubility measurement confirmed no transformations between DCPD and HAp phases during the measurement. Conditional solubility of DCPD in digester supernatant only slightly increases at pH > 5 – 6 compared to its solubility in distilled water. For HAp the increase of conditional solubility is more significant at pH > 6, while for pH < 5 the decrease of its conditional solubility can be observed. This change of conditional solubility can be explained by the presence of different impurities in digester supernatant and their possible complexation with either calcium or phosphate ions as well as by the increase of the ionic strength of the solution.

In order to determine whether the presence of humic compounds can have an effect on conditional solubility of these two phases, the conditional solubility was measured in the solution of the humic acid with the concentration of 10 mg/L (Fig. 1).

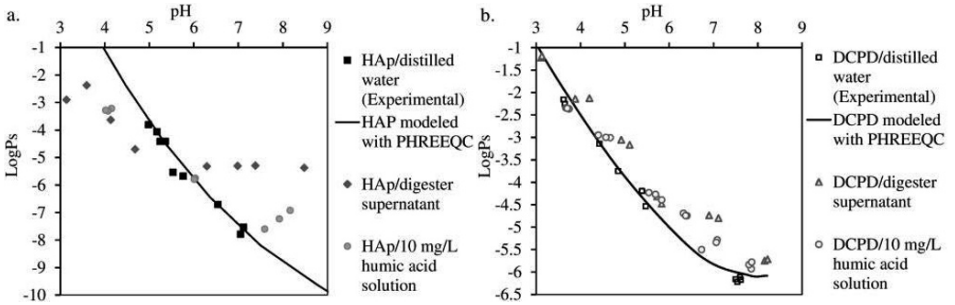

Figure 1. Conditional solubility of calcium phosphates in different media: a. HAp; b. DCPD.

Humic substances in digester supernatant have a major impact on the conditional solubility of HAp and DCPD, as the change of conditional solubility in digester supernatant follows the same trend as its change in the humic acid solution. It may also be true, that in digester supernatant the impact of humic substances is enhanced by the presence of other impurities such as carbonate etc. The change of conditional solubility described above can have a strong negative effect on the crystallization of DCPD or HAp as the yield of the crystallization process will be reduced. At the same time, the decrease in conditional solubility of HAp at pH below 5 may result in co-precipitation of mixture HAP and DCPD, due to the very similar conditional solubility of these two phases. Therefore, for the development of the robust technology, it is important to find the way to reduce the influence of humic substances.

4. Design of the P-recovery technology

4.1. Two-step fast precipitation/recrystallization technology

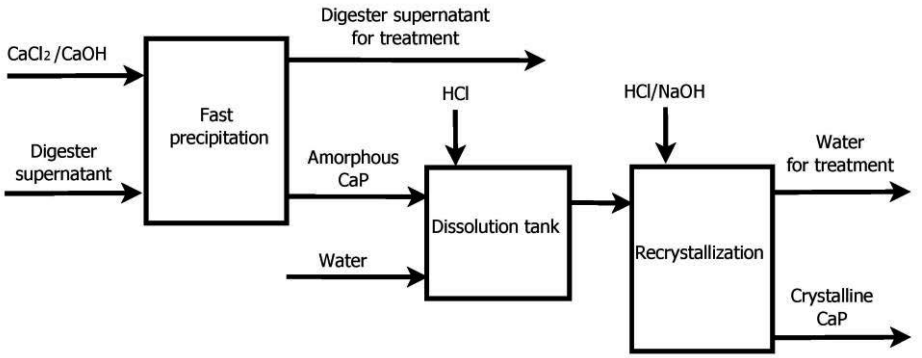

Figure 2. Two-step fast precipitation/recrystallization technology.

Based on the obtained solubility data a two-step process with fast precipitation and recrystallization was proposed, as it is shown in Fig 2. In this process, calcium is dosed to the digester supernatant at rather a high pH, so that amorphous CaP precipitates from the solution. The precipitation was performed within a short time so that the adsorption of humic substances onto the surface of CaP product can be minimized. Amorphous product later-on is dissolved in the water at low pH and can be re-crystallized into DCPD or HAp by controlling the operational pH and adding seeding.

This technology was tested in the laboratory scale (Vasenko and Qu, 2018). Aaby WTTP (Aarhus, Denmark) provided digester supernatant containing 0.008 mol/L of total-phosphate. Fast precipitation was performed at the initial pH of digester supernatant equal to 7.8 – 8.0 at Ca/P ratios 2 and 5 and total-phosphates concentrations 0.008 mol/L and 0.015 mol/L (increased by the addition of $NH_4H_2PO_4$). Batch recrystallization resulted in crystallization of HAp, DCPD or their mixture. Addition of DCPD seeding promoted crystallization of DCPD, but decreases the P-recovery rate, due to the higher solubility of DCPD than HAp. The highest obtained P-recovery rate was 69.5 % when HAp was crystallized from the solution. The drawback of this technology is that doubled amount of liquid waste is produced. Moreover, even though the products quality increases comparing to the direct crystallization of CaP from digester supernatant, it is a powder with light brown color that cannot be characterized as a high-purity product.

4.2. Novel hybrid technology

Based on the results obtained from the two-step process described above, a novel hybrid technology was developed. The novelty of this technology is that it takes the advantage of oxidation to degrade the NOM in digester supernatant and then crystallization is performed in an environment with minimal effects from the impurities (Vasenko and Qu, 2017b). This process is illustrated in Fig. 3.

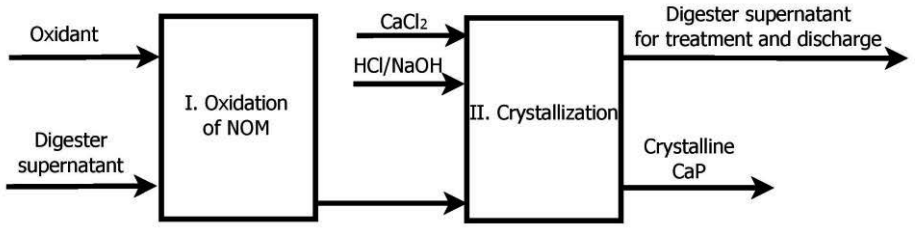

Figure 3. Hybrid oxidation/crystallization technology for high-purity CaP recovery.

During the oxidation step, digester supernatant is mixed with an oxidant for the time sufficient for degradation of NOM. Thereafter, crystallization of CaP is performed by dozing calcium to the oxidized supernatant and controlling the operational pH. This hybrid technology has been tested in laboratory scale with the application of H_2O_2 (20 ml of 30 w/w % per 1 L of digester supernatant) as an oxidant in combination with short ultrasound (US) treatment to enhance degradation of NOM. Sonication was on for 10 minutes at the beginning of oxidation step, which lasted for 24 hours. Thereafter, crystallization was performed with Ca/P=2 by dosing $CaCl_2$, adjusting pH until nucleation and keeping it stable throughout the process.

Optimization in terms of pH at oxidation step was performed with 4 pH values: 2.0, 3.9, 7.9 and 10.0. The color of digester supernatant was changing from dark brown to light yellow during the oxidation and the higher was the pH of oxidation the more significant was the improvement of the solution color. However, the performance of crystallization step was the highest, when the pH of oxidation was 7.9. At this condition, the highest P-recovery rate was achieved (89 %), and the purest product was obtained.

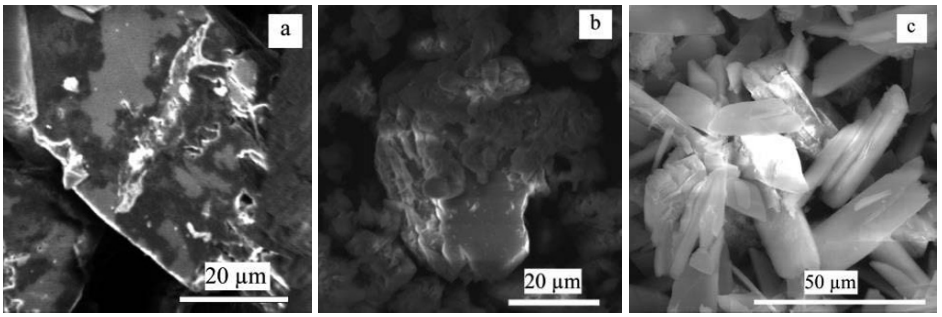

Figure 4. SEM images of selected samples: a. Direct crystallization of CaP from digester supernatant (Vasenko and Qu, 2017 c); b. Fast precipitation/recrystallization technology; c. Novel hybrid technology.

Improvement of the product quality especially the adsorption of HS on the CaP products can be observed from Fig. 4. On the surface of the DCPD product, crystallized directly

from digester supernatant, dark spots can be noticed, which are believed to be adsorbed HS (Fig.4.a). With the application of fast precipitation/recrystallization technology, no dark spots could be observed on the surface of the DCPD product, but the color of the crystals remains light brown (Fig. 4.b). When the novel hybrid oxidation/crystallization technology was used with the oxidation pH 7.9 white DCPD crystals with some minor amount of HAp were obtained (Fig. 4.c). ICP-MS analysis of the heavy metals contents in these products obtained with novel hybrid process indicated that the heavy metal concentration fulfils the EU requirement for food additives. These results proved the significant improvement in the purity of the products when the hybrid process is applied. Moreover, the amount of liquid wastes after the hybrid process is reduced compared to the fast precipitation/recrystallization technology.

5. Conclusions

The negative effect of humic substances on CaP crystallization from digester supernatant was proved by determination of conditional solubility of two target CaP phases in humic acid solution, digester supernatant, and distilled water. Based on the observation regarding the influence of humic substances on CaP crystallization, two processes were designed and tested in laboratory scale. The proposed two-step process with fast precipitation and recrystallization could slightly improve the quality of the produced CaP products. A more significant improvement of both the product quality and the P-recovery rate was achieved with the new hybrid process with oxidation and crystallization. There is a great potential of applying this new hybrid technology in phosphorus recovery in wastewater treatment plants.

Abstract

A methodology to design desalinated water supply systems including solar energy as an energy source option is proposed. The methodology consists of two stages and uses a MINLP model. The objective of the first stage is to minimize the total cost of the whole system, while the objective of the second stage is to minimize the greenhouse gases (GHG) emissions related to desalinated water transport by considering the opportunity of installing photovoltaic panels. The MINLP model considers the installation and operation costs of the desalination plants, pumping stations, pipes, and photovoltaic panels. Moreover, it quantifies the GHG emissions produced by the construction and operation of these elements. The mathematical methodology was implemented in the GAMS environment, and the BARON solver was used to obtain the optimal global solution. The design of a desalinated water supply system in the Atacama Desert was considered as a case study to validate the applicability of the methodology proposed. Result of the case study showed that the incorporation of photovoltaic panels in the desalinated water supply system not only reduces the GHG emissions, but also the total costs of the whole system.

Keywords: water supply system; desalination; solar energy; design; MINLP model.

1. Introduction

Nowadays, four billion people in different regions of the world are facing a severe water scarcity (Mekonnen and Hoekstra, 2016). This phenomenon occurs, among other factors, when the water demand is higher than the existing supply in a specific area and it gets more complicated in arid and semi-arid regions, where the water sources are limited or even non-existent. In these regions, seawater (SW) has been seen as an opportunity to satisfy the increasing demand due to economic development and population growth. Although SW could satisfy the quantity of water required by the population, it does not usually meet the required quality standards. To carry out the transformation process from SW to water with high-quality standards, a desalination plant is required.

Desalination plants have been present for several decades providing water for municipal and/or industrial use, commonly in the regions with water scarcity. There are several desalination technologies, however, reverse osmosis (RO) is currently the most used,

representing 63% of the current market (Gude, 2016). SW is a nonconventional water source, whereby the incorporation of desalination plants brings new economic and environmental challenges that should be included in the common water supply management problems. According to Ostfeld (2015), these problems can be classified into three aspects: (1) The layout of the topology or connectivity of the system; (2) the designed size of the system; and (3) the operation of the system.

Several methodologies have been proposed in the literature to face water supply management problems considering SW as a source of supply. Atilhan et al. (2012) developed a methodology based on a linear mathematical model for an integrated layout and operation of water supply systems. The layout includes different water sources, desalination plants, users, wastewater treatment facilities, and water storages. The solution determines the optimal operation of the water supply system and the optimal monthly allocation and storage of water resources. González-Bravo et al. (2015) introduced a methodology based on a nonlinear mathematical model. The objectives were to integrate SW desalination plants with power plants in the layout of water supply systems to maximize the gross annual profit from water and energy sales. González-Bravo et al. (2016) proposed a multi-objective methodology based on a nonlinear mathematical model to integrate SW desalination with power plants in the optimal layout of water distribution systems. The objectives of the study were the maximization of the gross annual profit, the minimization of the overall GHG emissions, and the quantification of jobs generated by the system.

The majority of the studies previously mentioned were focused on the layout of the system. This means: The determination of the system topology or connectivity. However, they did not consider the design of the system that is concerned in its size, mainly to the size of the diameter of the pipes, which has influence on the costs and energy consumptions related to the water transportation. In this context, Herrera et al. (2015) proposed a methodology of two stages based on a MINLP model to design desalinated water supply systems with the objective to determine the location and size of desalination plants, pumping stations, and pipes. In addition, Araya et al. (2016) proposed a methodology based on a MILP model to design desalinated water supply systems with the same objectives including the option to install energy recovery devices. Both studies considered the Atacama Desert as case study mainly for its complex topography (users located at long distances from the ocean and at high altitudes), which makes it challenging to design desalinated water supply systems. In this study, we propose a methodology of two stages based on a MINLP model to design desalinated water supply systems. The objectives of this the study are the minimization of the total cost of the whole system, and the minimization of the GHG emissions related to desalinated water transport. Although this problem can be solved using a multi-objective optimization approach, here, the costs are minimized initially in order to prioritize economic aspects of the system, and then we seek to minimize the environmentally negative effects related to energy consumption. The main novelty of the methodology is the capability to select the option to install photovoltaic panels to supply the energy required for the water transport. The water supply system design in the Atacama Desert is considered as a case study to validate the applicability of the methodology proposed.

2. Mathematical methodology

The first step of the methodology is to define a network that contains all potential layouts of the water supply system. The elements of the networks are the users that determine the

demand, the desalination plants that determine the supply, and the pumping stations that deliver the energy to the system to transport the water. The links of the network represent the pipes with a determined diameter, where the water could be transported. As this study deals with the layout and design of the water supply system, the pipe diameter can be selected from a set of several pipe diameters available. Then, the network is described as a mathematical function that will be optimized in two stages. The objective of the first stage is to minimize the total cost of the whole system determining the location and size of the desalination plants, pumping stations, and pipes to satisfy the water demands of the users. The objective of the second stage is to minimize the GHG emissions considering the opportunity of installing photovoltaic panels to supply the energy related to desalinated water transport.

In the MINLP model four main sets are used: The set of desalination plants (SO), the set of pumping stations (N), the set of users (SI), and the set of discrete pipe diameters (D). The pipes between nodes i, j of the network are established in the set FIJ, with defined distances ($L_{i,j}$) and height differences ($\Delta Z_{i,j}$). The main constraints of the MINLP model are the flow conservation constraints based on the continuity equation, the maximum production capacity of desalination plants, the water requirements of the users, the selection of pipe diameter where a disjunctive constraint is used, and the maximum velocity of water flowing into the pipes. One fundamental equation used in the model is the energy equation expressed in Eq. (1), which results in the hydraulic head ($H_{i,j}$) that is necessary to transport desalinated from one node to another. In this equation, the parameter H_j represents the pressure required in the terminal node, and $h_{n,j}$ represents the pressure loss in the pipe due to friction.

$$H_{i,j} = \Delta Z_{i,j} + H_j + h_{i,j} \qquad \forall\, (n,j) \in FIJ \tag{1}$$

Another fundamental equation used in the model is the power required in the pumping stations to carry out the desalinated water transportation (Eq. 2). The power is a function of desalinated water transport $Q_{i,j}$ from node i to j and the hydraulic head.

$$P_n = \frac{\rho \cdot g}{\eta} \cdot \sum_{j \in output} Q_{i,j} \cdot H_{i,j} \qquad \forall\, n \in N \tag{2}$$

The parameters g, ρ and η represent the gravitational acceleration, the mass density of fluid, and the total efficiency of pumping stations respectively.

Eq. (3) represents the economic objective function that seeks to minimize the total costs of the whole system (ECT), which include the capital and operational costs of the desalination plants ($ECSO_{so}$), pumping stations (ECN_n), and pipes ($ECP_{i,j}$).

$$ECT = \sum_{so \in SO} ECSO_{so} + \sum_{n \in N} ECN_n + \sum_{i,j \in FIJ} ECP_{i,j} \tag{3}$$

The GHG emissions related to desalinated water transport ($OMENCN_n$) are minimized in the second objective function (Eq. 4), where $y1_n$ and $y2_n$ are binary variables used as decision variables to solve the problem. The GHG emissions without the installation of photovoltaic panels ($OMENCN1_n$) are shown in Eq. (5), where T represents the quantity of hours a year using conventional energy as an energy source, and UNE is the unit value of GHG emissions in $kg\ GHG/kWh$ related to the water transport. If the solution of the problem selects to install photovoltaic panels, the binary variable $y2_n$ is activated and Eq. (5) is used to calculate the GHG emissions ($OMENCN2_n$). In Eq. (5), t represents the

percentage of the hours supplied with solar energy. The variable t is equal to EHS/T, where EHS represents the effective hours of sun available in the area under study.

$$OMENCN_n = y1_n \cdot OMENCN1_n + y2_n \cdot OMENCN2_n \quad \forall\, n \in N \tag{4}$$

$$OMENCN1_n = T \cdot UNE \cdot P_n \quad \forall\, n \in N \tag{5}$$

$$OMENCN2_n = (1 - t) \cdot T \cdot UNE \cdot P_n \quad \forall\, n \in N \tag{6}$$

3. Case study

The case study considered the design of a water supply system in the Atacama Desert. This area has relevant water scarcity due to the limited quantity of available water, the population growth, and mainly the economic development pulled by minerals production. In the Atacama Desert, more than 40 mining companies are operating and several more are in the process of being installed. Due to water scarcity, a large part of these mining companies must obtain water from the ocean, which is a problem because several of its operations are located at high altitudes, even at 2,000 meters above sea level. This problem increases the costs of the system, because of an increase the energy required for the water transportation. While some mining operations have used SW directly in their operations, most of them prefer to use desalinated water to not interfere with some of their processes and to expand their facilities. Therefore, a desalination plant is required. Another important aspect is that the Atacama Desert has one of the greatest solar radiations on Earth, which makes it a perfect area to apply the methodology proposed.

The case study considered RO plants and mining operations as desalination plants and users respectively, as shown in Figure 1. The case study includes three desalination plants, 18 pumping stations, and three mining operations. The elevation and distances from the ocean are included in Figure 1, where the dotted lines represent the potential pipes where the desalinated water could be transported (the continuous lines are the optimal solution). The desalinated water demands of each mining operation are 0.6, 1.0, and 0.9 m^3/s, and the maximum capacity of each desalination plant is 2.5 m^3/s. The set of pipe diameters includes three sizes considering commercial availability: 42" (~1 m), 48" (~1.2 m), and 60" (~1.5 m). Monocrystalline silicon photovoltaic panel was considered, and the costs of panels were based on the work of Mariaud et al. (2017).

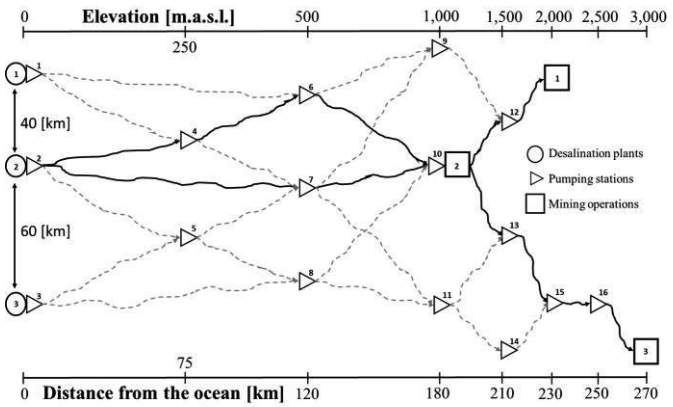

Figure 1: Conceptual representation of case study (dotted lines are potential pipes; the continuous lines represent the optimal solution).

4. Results and discussion

The mathematical methodology was implemented in the GAMS environment, and the BARON solver was used to obtain the optimal global solution. The whole model includes 1,443 single equations, 1,786 single variables, 116 discrete variables, and the solution of the first stage was reached in 2,451.83 seconds, while the solution of the second stage in only 1.81 seconds. The main results obtained are shown in Table 1. Stage 1 considered the minimization of the total costs of the system, while stage 2 considered the minimization of GHG emissions related to water transport. Three different effective hours of sun per day were considered in stage 2, and in each case, the solution selected the installation of photovoltaic panels to decrease the GHG emissions.

The results show that the total costs of the system decrease when the installation of photovoltaic panels is considered, even when the effective hours of sun are limited. Nevertheless, by decomposing the total costs we can observe that the capital costs of the system increase while the operational costs decrease.

Table 1: Results of the case study.

Stage		1	2		
Effective hours of sun			3	6	9
Total costs [million US$/y]	Whole system	361.87	353.59	345.31	337.02
Capital costs [million US$]	RO	1042.82	1042.82	1042.82	1042.82
	PS	261.62	261.62	261.62	261.62
	PIPES	462.48	462.48	462.48	462.48
	PP	0	30.99	61.98	92.98
Operational costs [million US$/y]	RO	73.33	73.33	73.33	73.33
	PS	101.11	88.47	75.83	63.19
	PP	0	1.07	2.14	3.21
GHG emissions by construction [Mt GHG]	RO	181.82	181.82	181.82	181.82
	PS	277.01	309.82	342.64	375.45
	PIPES	80.65	80.65	80.65	80.65
GHG emissions by operation [Mt GHG/y]	RO	261.78	261.78	261.78	261.78
	PS	652.48	570.92	489.36	407.80

RO: Reverse osmosis plants; PS: Pumping stations facilities; PP: Photovoltaic panels.

The increase in the capital costs is clearly due to the installation of photovoltaic panels. Whereas the decrease in the operational costs is because the operational costs of the photovoltaic panels are lower compared to the operational costs of the water transportation, when the energy is obtained from a conventional source. However, the cost to clean solar panels was not considered.

When the GHG emissions of water transportation are minimized, it a reduction of 81.56, 163.12, and 244.68 [Mt GHG/y] was obtained with 3, 6, and 9 effective hours of sun per day, respectively. However, the GHG emissions related to the construction of facilities increased due to photovoltaic panel installation, which is possible to appreciate in the quantities of GHG emissions due to the construction of the pumping stations, where the emissions related to photovoltaic panels were added. In this context, it is clear that the GHG emissions increase in the construction of the system, but the decrease in the operation is much more significant in quantitative terms.

5. Conclusions

A mathematical methodology to design desalinated water supply systems including solar energy as an energy source option was proposed. The methodology was applied to a case study in the Atacama Desert validating its applicability. The results of the case study showed that the incorporation of solar energy in the water supply systems reduces the GHG emissions and also the total costs of the whole system.

Life cycle assessment of bio-based sustainable polylimonene carbonate production processes

Dongda Zhang[a,*], Ehecatl Antonio del Rio-Chanona[a], Nilay Shah[1]

[a]*Centre for Process Systems Engineering, Imperial College London, South Kensington Campus, London SW7 2AZ, UK*
dongda.zhang11@ic.ac.uk

Abstract

Biomass derived polymers are considered as promising candidates to replace petroleum based polymers due to their potential environmental friendliness. To facilitate their application, in this study, a newly proposed biopolymer, polylimonene carbonate, was chosen as the representative to investigate the environmental impacts of the biopolymer production process. Different feedstocks (citrus waste and microalgae) were selected and a comprehensive process design from limonene oxidation to polymer synthesis was completed. Through life cycle assessment, effects of biomass treatment methods, energy integration, and use of solvents on the process environmental impacts were thoroughly discussed. It was found that for sustainable polylimonene carbonate synthesis, a more environmentally-friendly and energy-efficient limonene oxidation method should be developed. Based on the economic analysis, the polymer's cost was estimated to be around 1.36 to 1.51 $/kg, indicating its great potential as a substitute for petrol-based polystyrene. Moreover, this study found that both feedstock selection and biowaste treatment method significantly affect the process environmental impacts, and a carbon negative biopolymer can be achieved when the remaining waste is used for energy generation. Therefore, a new concept that considers CO_2 as an efficient solar energy carrier for future sustainable process design is proposed in this study.

Keywords: biomass, life cycle assessment, polylimonene carbonate, process simulation, economic analysis.

1. Introduction

Polymers are one of the most widely used commodities in both industry and daily life. With the rapid growth and development of advanced polymerisation technologies, a variety of polymers have been produced with substantial applications in different areas including electronics, healthcare products, toys, packaging materials, and coatings (Hottle et al. 2013; Zhu et al. 2016). To improve the process sustainability and mitigate environmental damages caused by the traditional polymer synthesis routes, more environmentally friendly raw materials, in particular biomass, have been chosen to replace fossil fuels for biopolymer production within the last two decades (Zhu et al. 2016; Miller 2013). For instance, a diversity of bio-based polymers such as polycarbonates, polyesters, and polyurethane (Hauenstein et al. 2016; Winkler et al. 2015) have been synthesised through different biomass feedstock including agricultural biomass, citrus wastes, and microorganisms.

Amongst different newly proposed biopolymers, polylimonene carbonate (PLC) has been given significant attention within the last five years due to its outstanding

characteristics compared to other candidates (Peña Carrodeguas et al. 2015; Hauenstein et al. 2016). For example, the precursor of PLC is limonene, a sustainable chemical that can be produced via different biomass feedstocks including orange peels and microalgae. Furthermore, CO_2 consumption is directly involved in the reaction steps for both limonene and PLC production, suggesting its promising potential as a carbon negative and environmentally friendly polymer. In addition, previous study has claimed that PLC has similar properties to polystyrene (Dalaeli et al. 2005), one of the most widely used fossil based polymers. However, the environmental impacts of the entire PLC production process ranging from feedstock selection to downstream PLC synthesis have not been explored so far, remaining the process sustainability, economic viability, and industrialisation feasibility an undetermined question. As a result, the current study aims to conduct a detailed PLC production process design and life cycle assessment to complete this open challenge and facilitate the industrialisation of PLC production.

2. Methodology

2.1. Process descriptions

The entire polylimonene carbonate (PLC) production process includes 4 operating sections (shown in Fig. 1, excluding limonene production): limonene production, tert-butyl hydroperoxide production, limonene oxide production, and PLC synthesis.

Limonene production from citrus and microalgae: Limonene is sold as a by-product from the orange juice industry because of its high content in orange peels (3.8 wt %) (Ciriminna et al. 2014). In a recent study (Roberts 2012), a citrus limonene production process was analysed from fertilising orange trees to final waste management. Therefore, this process is chosen as the standard route for limonene production from citrus in the current research (Roberts 2012). Meanwhile, microalgae been genetically modified to produce limonene (Davies et al. 2014; Jahandideh et al. 2017). In a very recent study (Johnson et al. 2016), a detailed process design for algal limonene and energy co-production was proposed. As a result, this process is selected to compare against the citrus limonene production process. In the algal process, limonene is considered as the major product, and algal biomass waste is sent to anaerobic digestion for hydrogen and methane production. The biogas is then used to generate electricity and heat. The detailed introduction of this process can be found in the recent study (Jahandideh et al. 2017). It is important to emphasise that in this study, the highest algal limonene productivity (Davies et al. 2014), 4.5 mg L^{-1} h^{-1}, is used to replace that used in the recent study, so that this process describes better the reality.

Limonene oxide and tert-butyl hydroperoxide production: Limonene oxide is the direct precursor for PLC synthesis. Tert-butyl hydroperoxide (TBHP) was recommended as a suitable oxidant for limonene oxidation because of its mild operating conditions (room temperature, 1 bar), high single-pass conversion (75 %) and selectivity (88 %) (Dalaeli et al. 2005). As this reaction has only been conducted under laboratory scale experiments, it is assumed that reaction selectivity and conversion efficiency in large scale systems are also identical. On the other hand, tert-butyl hydroperoxide (TBHP) is commercially derived from tert-butyl alcohol (TBA) oxidation by hydrogen peroxide. As TBA is the reduction product of TBHP in the limonene oxidation section, in practice only hydrogen peroxide needs to be provided to oxidise limonene, and TBA/TBHP actually acts as the electron carrier. The reaction happens at room temperature and 1 bar

in an acidic environment. The single-pass TBHP yield is high (90 %) (Bell & Vaughan 1953).

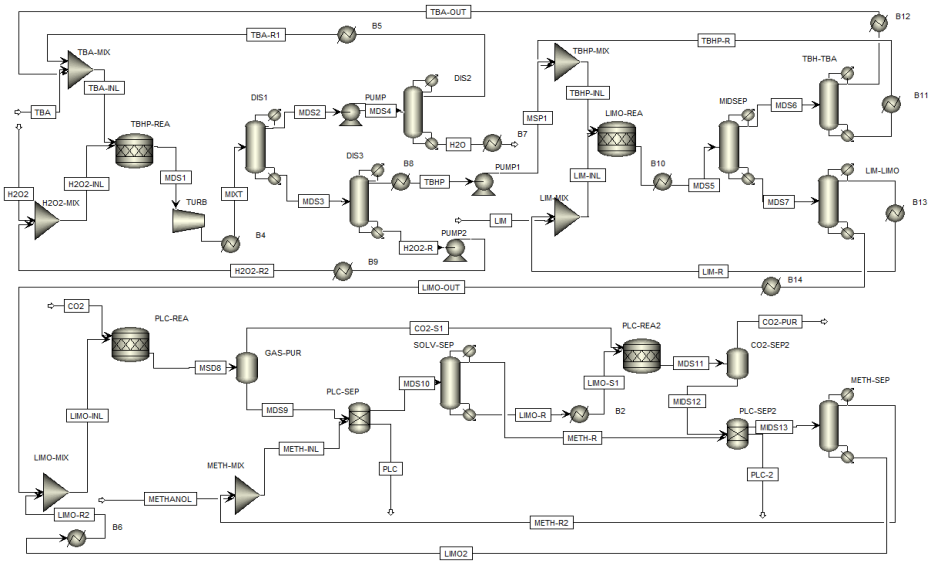

Figure 1: PLC production process (limonene oxidation, tert-butyl hydroperoxide production, and PLC synthesis)

Polylimonene carbonate production: Finally, PLC is synthesised by CO_2 and limonene oxide at a high pressure of 7 bar and ambient temperature (Dalaeli et al. 2005; Hauenstein et al. 2016). The single-pass conversion of this polymerisation process is 50 % (limonene oxide) (Dalaeli et al. 2005). The catalyst (a zinc based homogeneous catalyst) (Hauenstein et al. 2016) is dissolved in limonene oxide.

2.2. Life cycle assessment

A cradle-to-gate life cycle assessment is used to estimate the environmental impacts of PLC production processes (Yates & Barlow 2013). The primary goal of this LCA is to investigate whether the newly proposed biopolymer synthesis routes are environmentally friendly. In particular, to provide a realistic analysis for PLC production at its early research stage, two different biomass resources, microalgae and citrus wastes, are compared. More importantly, to explore the process carbon footprint and solar energy utilisation efficiency, different biowaste disposal scenarios are included in this study. The function unit of this LCA is set to be producing 21,600 tonnes PLC (eq. 15,000 tonnes limonene). In addition, when using citrus to produce limonene, only 1 % of environmental impacts is allocated to limonene, since it is a waste derived by-product and its production is much lower than orange juice (Roberts 2012). Whilst if the feedstock is algae, limonene should be regarded as the major product, since the process is particularly designed for limonene production (Jahandideh et al. 2017). As a result, an allocation factor of 66 % is given to limonene, and the remaining 34 % is allocated to the biogas derived through anaerobic digestion. From limonene oxide production to PLC production, the only by-product is water, which is assumed to be used inside the process. Thus, the environmental impacts are 100 % allocated to PLC.

2.3. Software

Process design and simulation (from limonene to PLC production) were executed in Aspen Plus V9. This aims to estimate energy consumption and mass balances in each process section. An analysis on the separation of limonene from orange peels has been completed in (Dalaeli et al. 2005), thus this is not included in the current simulation. Moreover, a preliminary evaluation of energy integration was conducted in this software to reduce the energy cost during the product separation sections (distillations), together with an approximation of process capital and operation costs. LCA was performed in Simapro 8.1, and the Ecoinvent 3.2 LCA database was used. The ReCiPe Midpoint method was used due to its wide applications (Roberts 2012; Keller et al. 2015).

3. Methodology

3.1. Effect of feedstock and biomass treatment method

To explore the importance of different feedstocks and biowaste treatment method on PLC production process environmental impacts, three scenarios are selected for comparison. These use citrus waste as cattle feed, algae biomass for energy production, and algae biomass as animal feed. Several conclusions are observed through LCA (Fig. 2). First, it is found that when biomass is sold as animal feed, no matter which feedstock is chosen for limonene synthesis, the PLC production process always emits CO_2 on a nett basis and has negative impacts to the environment (1.21 kg CO_2 eq./kg PLC and 11.99 kg CO_2 eq./kg PLC from the citrus and the algae process, respectively). Thus, biopolymer produced from these processes cannot achieve carbon negativity. On the contrary, when biomass is used for energy generation, it is found that not only is the biopolymer produced carbon negative, but also in most cases the process is environmentally friendly. This is because both algae and citrus are derived from solar energy and CO_2 via photosynthesis. Therefore, a significant amount of solar energy is stored inside biomass. For example, based on the recent work (Jahandideh et al. 2017), energy generated through anaerobic digestion (AD) in this PLC production process is 751.4 MJ kg^{-1} PLC (mainly electricity), over 30 times the energy required for the entire PLC production process (approximate 22.0 MJ kg^{-1} PLC, mainly heat). Hence, when algal biomass is converted back to CO_2, the stored solar energy is released and converted to electricity and heat. Thus, the obtained energy not only fulfils all the energy required for PLC synthesis, but can also be sent to electricity grids for other processes displacing other generation. However, if biomass is sold as animal feed, the stored solar energy will not be able utilised, and the process becomes less sustainable.

3.2. Effect of solvent, oxidant and energy integration

In this study, methanol is used as a solvent to precipitate PLC, and TBHP is used as the direct oxidant for limonene oxidation. As introduced before, both of them are recycled inside process without being emitted. Therefore, it is plausible to exclude the environmental impacts of these chemicals, since their purchase is one-off and their required amount is much lower than other chemicals. However, through LCA, it is found that although methanol only has negligible effect to the system, the use of TBHP shows a dramatic impact to the current process, in particular climate change, human toxicity, and ecotoxicity. For example, it causes a 156.7 % and 1603.4 % increase on climate change and human toxicity, respectively, in the citrus based PLC production process. This clearly suggests that although TBHP/TBA is recycled inside the process and only employed as the electron carrier to facilitate the oxidation-reduction reaction

between limonene and hydrogen peroxide, its use due to its current synthesis route could significantly aggravate the environmental impacts of PLC production process. As a result, more environmentally friendly routes should be developed for TBHP/TBA synthesis, and more effort should be given to research focusing on the direct reaction between limonene and hydrogen peroxide. In addition, it is found that through energy integration, in total 20.8 % of energy input can be saved within the PLC production process. Nonetheless, apart from the mild improvement on climate change (6.2 %) and ozone depletion (15.2 %), for most environmental categories, energy integration does not lead to distinguishable benefit to the process. This indicates that energy integration may not serve as the best option to improve the current process environmental-friendliness, and meanwhile could increase the process investment cost due to the addition of heat exchangers and other auxiliary equipment.

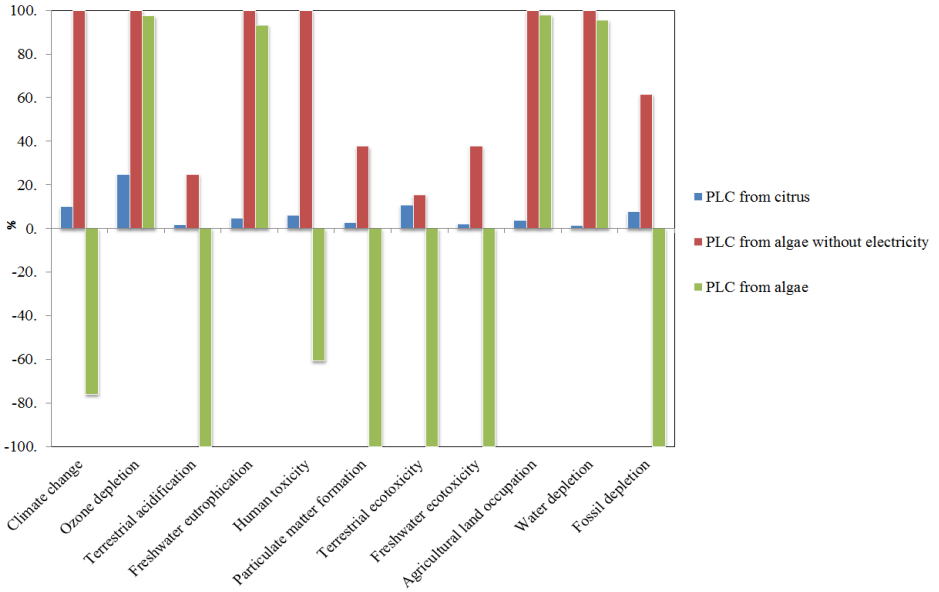

Figure 2: LCA of PLC production with different feedstocks and waste treatment methods. “PLC from algae” is the process where biomass is used to generate energy.

3.3. Process economic analysis

Finally, a brief analysis on the cost of different PLC production routes is carried out in this study. Process capital and operating costs are estimated from Aspen Plus V9, and prices of raw materials are obtained from manufacturer websites and recent studies (CO2 price is assumed to be zero) (Dalaeli et al. 2005; Johnson et al. 2016). From the study, it is estimated that the cost of PLC is around 1.36 to 1.51 $/kg, depending on the limonene feedstock. This result is higher than the price of polyethylene (0.91 S/kg), but falls within the price range of polystyrene (1.2 to 1.6 $/kg), a traditional commercial polymer that has similar properties to PLC but based on conventional fossil resources. Overall, based on the current process design, life cycle assessment, and process economic analysis, it is concluded that there is a great potential to replace fossil fuel based polystyrene by biomass derived PLC in the future.

4. Conclusion

Eventually, from the current research, a new concept is proposed for future sustainable process design, which is compared to exclusively focusing on the limited amount of biowaste derived sustainable chemicals as well as their downstream processing efficiencies, it is more crucial to identify the most effective way to maximise the utilisation efficiency of the huge amount of solar energy stored inside biowaste. In other words, this concept suggests that compared to only considering CO_2 derived biomass as the feedstock for sustainable chemicals synthesis, it is more important to also consider these biomass as an efficient solar energy storage to systematically optimise the process energy and materials utilisation efficiency.

Abstract

Dilute algae are often grown in raceways or bioreactors by photosynthesis using carbon dioxide in flue gas. After being harvested, algae oil must be extracted before being transesterified to biodiesel. This process, which generates a carbon-neutral, renewable, liquid fuel, has been shown to be competitive with other liquid fuel sources (Silva et al., 2014). Herein, we introduce the use of carbon dioxide microbubbles to lyse algae cell walls, releasing triglyceride oils, combined with their transesterification using methanol in a single vessel. To obtain more reliable multiphase equilibrium calculations to predict the phase distribution (often vapor-liquid-liquid), we use the SAFT equation-of-state (the latest PC-SAFT in ASPEN PLUS and gSAFT in gPROMS) with new experimental data, where necessary. This permits the use of an extended kinetic model to compute biodiesel production rates. At lower temperatures and intermediate pressures, carbon dioxide causes methanol to dissolve in the triglyceride phase and triglyceride to dissolve in the methanol phase, increasing the transesterification reaction rate. This brief paper describes the status of our research without providing the detailed model and results.

Keywords: multi-phase equilibrium, SAFT EOS, algae biodiesel, transesterification, supercritical CO_2.

1. Introduction

1.1 Background

Increasingly, fossil fuels are being replaced with sustainable and renewable alternatives like microalgae, for the production of transportation fuels like biodiesel. Microalgae offer several advantages as compared to fossil-based counterparts including carbon-neutral re-use of CO_2. Biodiesel, comprised of fatty-acid methyl esters (FAMEs), is produced from the transesterification of triglycerides with methanol, yielding the glycerol byproduct.

In our earlier work (Silva et al., 2014), a process was designed to carry out transesterification using a solid-base catalyst at 1 atm with rate data regressed in a kinetic model. Using cost estimates from the Aspen Process Economic Analyzer (APEA) and industrial quotes, a cash flow analysis was performed for an entire carbon sequestration-to-biodiesel production train, yielding a competitive biodiesel selling price of $4.34/gal.

Subsequently, Silva et al. (2016) demonstrated that transesterification of algal oil (triglycerides) using methanol is accelerated using supercritical CO_2 at moderate temperatures and pressures. Recently, we have introduced the carbon dioxide in microbubbles to lyse the algae cell walls, releasing triglyceride oils. Our research focuses on the intensification/combination of these two processes to reduce the energy consumption and capital costs of processes to generate biodiesel. Initially, we are carrying out more reliable multiphase equilibrium calculations to predict the phase distribution (as simple as a single supercritical phase or as complex as V-L_I-L_{II}) using the SAFT equations-of-state. It has been shown experimentally in the laboratory (Soh et al., 2014, 2015) and using simulation software (ASPEN PLUS and gPROMS – Silva et al., 2016) that at intermediate pressures, CO_2 causes triglyceride to dissolve in the methanol phase, significantly increasing the transesterification reaction rate. But, additional data are needed to improve estimates of the rates. Also, smaller methanol/triglyceride ratios are needed, yielding a triglyceride phase that dissolves methanol.

They used an approximate single-reaction, kinetic mechanism, as shown in Figure 1. This model included just six chemical species: triolein, methanol, methyl oleate, glycerol, CO_2, and water. Their large methanol/triolein molar ratios simplified the experiments, but were commercially unrealistic. Note that Freedman et al. (1984) report the industrial use of methanol/triolein molar ratio = 6 and Maeda et al. (2011) report even smaller molar ratios for methanol/canola oil. Also, because algae grow profusely in dilute aqueous media, the presence of water cannot be avoided.

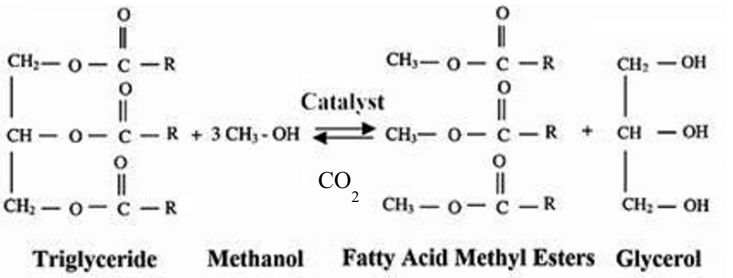

Figure 1. A single reversible transesterification reaction to convert triglycerides into biodiesel

In this paper, the mechanism is extended to include three reversible reactions (R_1, R_2, and R_3 in Figure 2) with eight chemical species, including diolein and monoolein. In our earlier work, a crude model was used, the Redlich-Kwong equation in ASPEN PLUS, which is not suitable in the critical region (Silva et al., 2016). To compute concentrations of diolein and monoolein in three phases at equilibrium, routine liquid density and liquid vapor pressure measurements are underway. These data are being regressed to obtain pure-species PC-SAFT and gSAFT parameters. Additionally, we are measuring LLE and VLE data for binary mixtures including diolein and monoolein. Their binary interaction parameters are being regressed to improve the multi-phase equilibrium calculations. Note that pure-species parameters for PC-SAFT were published by Perez-Cisneros et al. (2016), but have not yielded realistic LLE and VLE results in our ASPEN PLUS calculations.

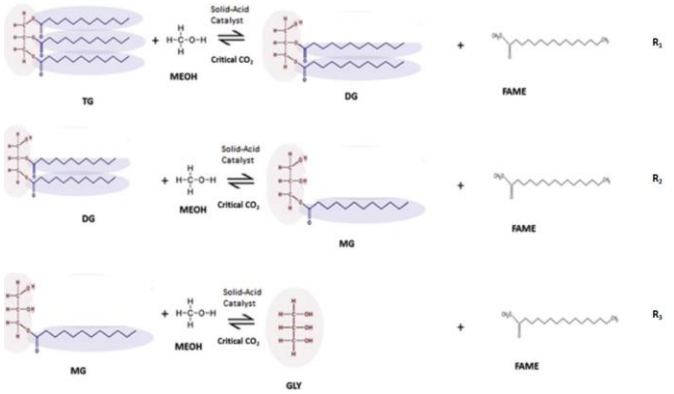

Figure 2. Kinetic mechanism involving three reversible reactions. TG is triglyceride (triolein), MEOH is methanol, DG is diglyceride (diolein), FAME is fatty-acid methyl-ester (methyl oleate – biodiesel), MG is monoglyceride (monoolein), GLY is glycerol, and critical CO_2 is in or near the critical region

2. Multiphase Kinetics Model

To model a batch reactor, involving up to three phases (V, L_I, and L_{II}), for each phase, the mass balances are expressed:

$$\frac{d[C_i]}{dt} = \nu_{R_{j,i}} * r_j \tag{1}$$

where i is the species counter in reaction (R_j), j = 1, 2, 3, and the intrinsic rates of reaction are expressed in:

$$r_1 = k_{1\mathrm{f}}[cat]^{n_{1\mathrm{f}}}[triolein][methanol] - k_{1\mathrm{r}}[cat]^{n_{1\mathrm{r}}}[diolein][methyl-oleate]$$

$$r_2 = k_{2\mathrm{f}}[cat]^{n_{2\mathrm{f}}}[diolein][methanol] - k_{2\mathrm{r}}[cat]^{n_{2\mathrm{r}}}[monoolein][methyl-oleate]$$

$$r_3 = k_{3\mathrm{f}}[cat]^{n_{3\mathrm{f}}}[monoolein][methanol] - k_{3\mathrm{r}}[cat]^{n_{3\mathrm{r}}}[glycerol][methyl-oleate] \tag{2}$$

where $k_{j\mathrm{f}}$ is the forward rate constant, $k_{j\mathrm{r}}$ is the reverse rate constant, [cat] is the catalyst concentration, $n_{j\mathrm{f}}$ is the exponent of the catalyst concentration in the forward direction, $n_{j\mathrm{r}}$ is the exponent of the catalyst concentration in the reverse direction, $[C_i]$ is the concentration of species i, and $\nu_{Rj,i}$ is the stoichiometric coefficient of species i in reaction R_j. In the absence of catalyst, the n coefficients are zero.

Prior to each time-step, when integrating mass balances (1) for each phase, the concentrations in the three phases and phase volumes are computed by minimizing G (Gibbs free energy). It is necessary to check for phase stability using the Gibbs tangent-plane distance criterion, as discussed by Silva et al. (2016). These calculations are completed using PC-SAFT in ASPEN PLUS and gSAFT in gPROMS, as summarized in Section 3. Experimental concentration measurements for the three phases (see Section 4) in the batch reactor are being taken to regress the rate constants in Eq. (2).

3. Equations of State (EOS)

3.1 PC-SAFT EOS

The EOS is formulated in terms of the Helmholtz free energy, as shown in:

$$\frac{A}{Nk_BT} = \frac{A^{ig}}{Nk_BT} + \frac{A^{hc}}{Nk_BT} + \frac{A^{disp}}{Nk_BT} + \frac{A^{assoc}}{Nk_BT} \quad (3)$$

where the ideal-gas contribution is augmented with hard-chain, dispersion, and association contributions. Although the PC-SAFT model is based on advanced molecular theory, only three pure-species parameters (m, σ, and ε) are required to model both phase equilibria and bulk properties of hydrocarbon mixtures.

3.2 SAFT-γ Mie

Like PC-SAFT, SAFT-γ Mie is formulated in terms of Helmholtz free energy. However, its formulation includes monomeric functional-group interactions, rather than a dispersion contribution:

$$\frac{A}{Nk_BT} = \frac{A^{ig}}{Nk_BT} + \frac{A^{mono}}{Nk_BT} + \frac{A^{chain}}{Nk_BT} + \frac{A^{assoc}}{Nk_BT} \quad (4)$$

In our current work, we examine the performance of the PC-SAFT and SAFT-γ Mie approach for the description of a broad variety of properties of pure fluids (such as liquid density and vapour pressure for diolein and monoolein) and binary mixtures including phase behaviour (VLL, VL, LL). Comparisons of the calculations are made with the experimental data in the development of the group parameters and for predictions of properties not used in the characterization of the groups.

4. Experimental

4.1. Vapor pressure measurement: Transpiration method

Vapor pressures of monoolein and diolein were determined using the method of transference in a saturated stream of inert gas and applying the Clausius-Clapeyron equation. A sample of approximately 0.5 g was mixed with glass beads (0.25 g) and placed in a U-tube 10 cm long and 0.5 cm in diameter having a thermostadt. A preheated helium stream was passed through the U-tube at different temperatures at the flow rate of 8 dm^3 h^{-1} which ensured that the carrier gas was in saturated equilibrium with the coexisting liquid phase in the saturation tube (Emel'yanenko et al. 2007). The material was transported in a cold trap upon bubbling through the isopropanol solvent and analyzed by supercritical fluid chromatography-mass spectroscopy (SFC-MS).

4.2. Liquid density measurement

Density was measured using a 5 mL pycnometer and a thermostatically controlled water bath was used to control the temperature (Ihmels and Lemmon, 2007).

4.3. Vapor-liquid equilibria

A 500 mL bulb connected to a condenser is being used to measure VLE. The bulb is heated from below with an electric heating jacket, and cooling water is circulated around the condenser at 7°C. The well-insulated apparatus is stirred by a magnetic stirrer in the liquid phase and heated to allow boiling and equilibration for 1 hour. Samples were collected and analyzed by SFC-MS.

4.4. Liquid-liquid equilibria

The binary pairs involving diolein and monoolein were added at equal mass loadings to a 10 mL separatory funnel that was used for equilibrium and sampling (Silva, et al., 2016). The top and bottom phases were sampled using a pipette and stopcock, respectively. The collected samples were analyzed by SFC-MS.

Recently, PC-SAFT calculations were repeated using ASPEN PLUS Version 10 for the triolein-water binary pair. As shown in Figure 3, good agreement is obtained with the experimental data (better than obtained by Silva et al. (2016).) Similar comparisons have been completed and, as needed, improved experimental measurements are planned for ternary LLE.

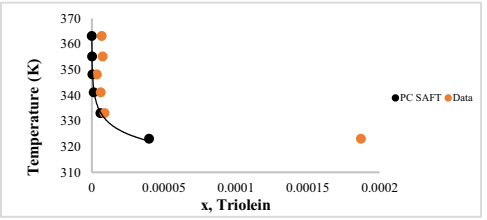

Figure 3. LLE – triolein in water at 1 atm

5. Microbubbles for Oil Extraction

Traditional methods for cell disruption include bead milling, microwave-assisted, sonication, hydrodynamic cavitation, and atomic force microscopy (AFM.) Recently, microbubbles have been proposed as promising candidates for improving cell-disruption efficiency and reducing energy requirements. In this regard, Krehbiel et al. (2014) showed that ultrasound cell disruption, with low-frequency waves (at ~10 kHz), increased by up to 58-% through the addition of microbubbles, with peak disruption occurring in the vicinity of 10^8 microbubbles/mL. The fluid motion due to the bubbles and shock waves that accompany bubble collapse lead to algal cell disruption (Krehbiel et al., 2014).

Methods for lipid extraction have energy requirements varying from $3.3 \times 10^7 – 5.3 \times 10^8$ J/kg of dry biomass. Furthermore, conventional cell disruption techniques often lead to negative net energy balances for biofuel production. To circumvent this, microbubbles are expected to advance significantly the efficiency of algal-cell disruption.

Of special note, supercritical CO_2 (SC-CO_2), for intensification of extraction and transesterification, shows great promise for replacing traditional organic solvents. SC-CO_2 accelerates the formation of the FAMEs in the transesterification reaction between two immiscible phases, oil and methanol, in a shorter extraction time compared with the use of organic solvents (Soh and Zimmerman, 2011). So, in this work, we describe the potential of CO_2 microbubbles for lipid extraction by cell disruption and as a co-solvent for the transesterification reaction that converts lipids into biodiesel. Experiments are planned to carry out extraction and transesterification in a single vessel. Also, calculations are underway to locate reactor temperatures and pressures that reduce the selling price of methyl-oleate (biodiesel) below $4.34/gal, as estimated using a basic-solid catalyst at 82°C and 1 atm (Silva et al., 2014).

6. Conclusions

To improve process design, a three-reversible reaction model involving diolein, monoolein, and triolein using PC-SAFT and gPROMS has been developed. It will improve kinetic modelling of the intensified extraction/transesterification process by enabling multiphase equilibria involving VLLE. This will permit an accurate determination of the phase distribution when triolein is present in sufficiently large quantities to create a second liquid phase. Binary VLE and LLE data for the eight species are used to obtain binary interaction parameters in PC-SAFT and cross parameters in SAFT-γ Mie. Herein, for the triolein-water binary, improved agreement of LLE calculations using PC-SAFT in ASPEN PLUS with experimental data has been achieved (compared with the calculations of Silva et al. (2016).) Additional comparisons are planned for other binary pairs, and where appropriate, additional experimental data will be measured. Furthermore, capital cost estimates and energy requirements for the intensified extraction/transesterification process are being computed.

Abstract

The conversion and storage of renewables into useful and transportable energy vectors is an outstanding challenge in transitioning to a sustainable energy future. Ammonia and methanol are two promising vectors due to their proven production and transportation infrastructures. Individual processes consuming fossil fuels have been improved and optimized over the years, but there is no clear path forward for incorporating renewables or their coproduction. In this work, we introduce a deterministic global optimization-based process synthesis framework to determine the minimal cost for the coproduction of ammonia and methanol from hardwood biomass and natural gas. This will provide the guideline for future studies into solar and wind energy. A process superstructure with several competing technologies and integration routes is modeled and described. A customized branch-and-bound algorithm is used to solve the resulting mixed-integer nonlinear nonconvex optimization model. Results indicate that the biomass incorporated processes are cost-competitive with pure fossil fuel based processes, and the integration of ammonia and methanol production leads to 4-7% savings.

Keywords: Biomass, methanol, ammonia, process synthesis, global optimization

1. Introduction

Reducing mankind's dependency on fossil fuels in favor of an increasing share of renewables is an important shift for realizing a sustainable energy supply chain. While a transition to fully renewable energy production looks possible in the future, there will likely be a transition period, where renewables like solar, wind, or biomass are integrated alongside fossil fuels into the energy supply chain. In this respect, converting renewables into energy vectors that can efficiently store and transport the energy is a priority for creating an economically attractive sustainable energy supply chain (Floudas et al. 2016).

Although hydrogen is a promising energy vector to store renewables due to its high gravimetric energy storage density (33 kWh/kg), its low volumetric storage density (3 Wh/L under ambient conditions) makes storage and transportation problematic. Either extreme pressures or cryogenic temperatures are required for gaseous or liquid state storage, respectively. These two extreme storage conditions have motivated investigation into alternative energy vectors that can store hydrogen in their chemical structures, such as ammonia, methanol, liquid organic hydrogen carriers (LOHCs), and metal hydrides (Teichmann et al. 2012). Among these energy vectors, ammonia has a high capacity for hydrogen storage, 17.6 wt.% based on its molecular structure and a hydrogen volume

density of 105.0 kg/m^3, which is about 45 % higher than that of liquid hydrogen, which is reported as 71.2 kg/m^3. Similarly, methanol has 12.6 wt.% hydrogen based on its molecular structure and its liquid hydrogen volume density is 99.8 kg/m^3 (Thomas and Parks, 2006).

In addition to the high hydrogen content of ammonia and methanol, their storage and transportation infrastructures are also well-established. Therefore, we focus here on a transition-period ammonia and methanol coproduction plant in which both natural and biomass are used as feedstocks. Future studies will investigate solar and wind integration. Coproducing ammonia and methanol has received much attention. In 2017, Haldor Topsoe opened up the first such plant in Russia. Both production processes utilize syngas generated from steam reforming of methane, but the syngas quality in each is quite different. While methanol production desires a stoichiometric ratio of H_2/CO, ammonia production involves more complex gas purification steps to prevent oxide species from poisoning the catalyst in its synthesis converter. Typical ammonia processes also emit more CO_2 than typical methanol processes. However, ammonia contains more hydrogen per mass in its chemical structure than methanol does. Therefore, there are interesting tradeoffs to be investigated in the integrated process.

In order to determine the economic and technical feasibility of incorporating biomass into an integrated ammonia and methanol production, a global optimization-based process synthesis approach is used to determine the optimal process topologies while minimizing the annualized cost of energy carrier production. A superstructure of process alternatives is modeled as a large-scale mixed-integer nonlinear optimization (MINLP) model, with simultaneous heat, power, and water integration. The nonconvex MINLP model is solved to global optimality by using a branch-and-bound global optimization algorithm.

2. Biomass/Natural Gas to Ammonia and Methanol Process Superstructure

2.1 Natural Gas Reforming

Natural gas can be converted to raw syngas via a primary reformer, a secondary reformer or both. The primary reformer is a typical steam methane reformer, and the secondary reformer is an autothermal reformer. Both reforming routes are governed by the steam reforming and water-gas shift reactions shown in Eqs. (1) and (2). The primary reformer operates at 40 bar and three discrete temperatures (800 °C, 850 °C, and 900 °C). The secondary reformer operates at 39.5 bar and three distinct temperatures (900 °C, 950 °C, 1000 °C). In the secondary reformer, either highly pure oxygen from an air separation unit (ASU) or input air is added to partially oxidize the natural gas. Non-syngas and non-hydrocarbon species are assumed to be inert in the reformers. Syngas from both reformers are sent to the syngas purification section or methanol synthesis section.

$$CH_4 + H_2O \leftrightarrow CO + 3H_2 \quad (1)$$

$$CO + H_2O \leftrightarrow CO_2 + H_2 \quad (2)$$

2.2 Biomass Gasification and Bio-Syngas Cleaning

The hardwood-type biomass is delivered to the refinery as wood chips with a moisture content of 45 wt.%. Biomass is dried and lockhopped with compressed CO_2 at 31 bar. This mixture is then fed to the gasifier which operates at 30 bar and at either 900, 1000, 1100 °C. Oxygen and steam are also fed to the gasifier to facilitate char gasification. The effluent is sent to two cyclones to remove the ash. Unreacted char is either recycled to the

gasifier or sent to the tar cracker. The effluent of the tar cracker contains some sulfur and needs to be treated before being sent to ammonia or methanol synthesis sections. The bio-syngas stream is first cooled down to 35 °C and then sent to a NH_3/HCl scrubber. This is followed by a two-stage Rectisol acid gas removal unit and a Claus plant. The removed CO_2 is either recycled, sent to sequestration, or vented. Clean bio-syngas can either be sent to methanol synthesis section, the reformers to convert the light gases into syngas, to another WGS reactor, or the syngas purification section.

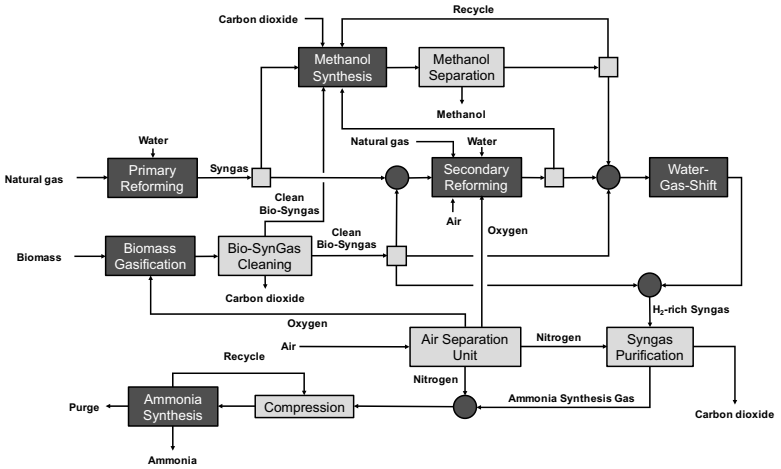

Figure 1. Process superstructure for Biomass/Natural Gas to Ammonia and Methanol

2.3 Methanol Synthesis

Clean syngas from biomass gasification and natural gas reforming is sent to the methanol synthesis section. Methanol synthesis section consists of two reactor configurations that are used together or separately. The first option is to use a once-through methanol reactor (OTMR) without recycle, and the second option is methanol synthesis reactor (MSWR) with recycle. The reactors serve two purposes: (i) methanol production and (ii) CO_x removal from syngas. The effluent of OTMR is flashed to separate methanol product from unreacted syngas. The unreacted syngas can either be sent to MSWR to produce more methanol or to the ammonia synthesis section. MSWR effluent is sent to a separation unit to separate methanol and unreacted syngas. A recycle loop configuration is used to increase the methanol conversion. Hydrogen-rich off-gases from MSWR can be purified and sent to ammonia synthesis section. Both reactors operate at 45 bar and 250 °C and reach equilibrium conversion according to the reactions shown in Eqs. (2) and (3).

$$CO + 2H_2 \leftrightarrow CH_3OH \tag{3}$$

2.4 Syngas Purification

Since oxygen containing species (e.g. CO_x, H_2O) are poisonous for the iron catalyst used in the ammonia converter, they need to be removed. Syngas coming from biomass gasification or natural gas reforming and H_2-rich streams from the methanol synthesis section are mixed and sent to a two-stage WGS reactor to further increase the H_2 yield (according to Eq. 2) and remove the CO_x species. After water is removed in a flash unit, an aMDEA process is used to remove 99.9 % of CO_2. This effluent can then be either washed with liquid N_2 to remove all the species but H_2 and N_2, sent to a methanator unit

where all CO_x species are converted to inert CH_4, or sent to a pressure swing adsorption (PSA) unit to remove impurities. Make-up nitrogen supply is available from an air separation unit to adjust the inert free ammonia syngas to the desired H_2/N_2 ratio.

2.5 Ammonia Synthesis

Five production trains are employed to have different converter options operating at distinct pressures (85.5, 130, 170, 210, and 250 bar). A single reaction shown in Eq. (4) takes place in the ammonia converter.

$$N_2 + 3H_2 \rightarrow 2NH_3 \tag{4}$$

The ammonia converters are not modeled as equilibrium converters, since industrial reactors do not reach equilibrium. Instead, the reactors are modeled through a data-driven approach using 25 industrial and experimental studies. Ammonia conversion is calculated as a function of operating temperature, pressure, and input compositions as shown in Eq. (5). The parameter estimation problem is formulated and solved in GAMS.

$$X_{NH_3} = A \cdot T + B \cdot P + C \cdot y_{H_2} + D \cdot y_{N_2} + E \cdot y_{NH_3} + F \cdot y_{inert} + G \tag{5}$$

The due to low single-pass conversion (20-35 %) multiple recycle options are used. The converter effluent is cooled to ambient conditions before being refrigerated to condense NH_3. A letdown vessel is used to flash out the liquid ammonia. The ammonia in the vapor effluent of the letdown unit is recovered with a water scrubber/distillation system. Inert gases are purged and the unreacted gases are recycled to the ammonia converter.

2.6 Utilities

The process superstructure includes alternatives for oxygen and hydrogen production. A comprehensive wastewater treatment network is also implemented. Simultaneous heat, power, and water integration ensures minimal utilization of external utility and maximum utilization of waste heat within the process (Elia et al., 2010).

3. Deterministic Global Optimization

3.1. Objective Function

The complete mathematical model representing the integrated ammonia and methanol process is a large-scale non-convex mixed-integer nonlinear program (MINLP). The objective function in Eq. (6) is to minimize the overall cost of hydrogen production, and all terms are normalized with respect to the total production of hydrogen in metric tons.

$$MIN \sum_{F \in Feed} Cost_F + Cost_{El} + Cost_{Seq} + \sum_{U \in Units} Cost_U \tag{6}$$

3.2. Branch-and-Bound Algorithm

Within each node in the branch-and-bound tree, a mixed-integer linear program (MILP) is first solved using CPLEX to determine a lower bound on the original MINLP by underestimating nonlinear terms with linear relaxations. Concave cost functions are approximated using piecewise linearization. Bilinear terms are relaxed using piecewise McCormick envelopes. The solution of the MILP provides initial starting points for the upper bound problem. By fixing binary variables at these starting points, a nonlinear program (NLP) that forms an upper bound on the original MINLP is created and then

solved using CONOPT (Baliban et al., 2012). More detailed discussions about global optimization theory and algorithms are given in textbooks by Floudas (1995, 2000).

4. Computational Studies

The process synthesis model is used to examine three case studies to observe the effect of coproduction on the optimal breakeven H_2 price and process topologies. The total output of the plant is set to 500 MT/day of H_2 containing energy vector. The cases are denoted as A-500 (ammonia-only), M-500 (methanol-only), and C-500 (ammonia-methanol coproduction). From mass conversion, 500 MT/day of H_2 translates to 2,830 MT/day of ammonia production in the A-500 plant and 4,000 MT/day of methanol production in the M-500 plant. For coproduction of ammonia and methanol, the product ratio is left as a decision variable. The greenhouse gas emissions (GHG) are restricted, such that they do not exceed more than 50% of the values produced by typical ammonia and methanol plants. The overall cost breakdown for all cases are shown in Table 1.

Table 1. Overall Cost Breakdown.

Contribution to Cost ($/kg of H_2 equivalent)	A-500	M-500	C-500
Biomass	0.57	0.95	0.61
Natural Gas	0.23	0.19	0.36
Water	0.01	0.01	0.00
Investment	0.99	0.91	0.90
CO_2 TS&M	0.00	0.02	0.02
O&M	0.26	0.24	0.24
Electricity Use	-0.03	-0.24	-0.20
Breakeven Price	2.03	2.08	1.94

The results indicate that coproduction of ammonia and methanol decreases the breakeven price of producing ammonia and methanol individually. The C-500 study shows that the optimal ratio in the product energy vector mix are 1,020 MT/day of ammonia and 2,560 MT/day of methanol. A mass balance indicates that 36% of the H_2 is stored in ammonia and 64% is stored in methanol. Converted breakeven prices to ammonia and methanol bases for the A-500 and M-500 plants are $360.33/MT and $254.80/MT, respectively.

It is observed that the A-500 and C-500 plants use a hybrid feedstock of biomass and natural gas, whereas the M-500 plant uses only biomass as feedstock. The M-500 and C-500 plants also use natural gas for electricity generation. Since the net electricity consumption values are negative, all the plants are producing electricity and this excess can be sold back to the grid.

The optimal process topologies are shown in Table 2. The A-500 plant uses both natural gas reformers and a biomass gasifier operating at 900 °C to produce syngas. The M-500 plant utilizes only biomass for its feedstock. It has a higher temperature gasifier, operating at 1100 °C to produce the methanol synthesis gas. OTMR and MSWR configurations are implemented together. The C-500 plant inputs both biomass and natural gas as feedstocks. Clean bio-syngas and primary reformer effluent are mixed and sent to OTMR, followed up by the MSWR. After methanol is produced, the unreacted and unrecycled synthesis gas is sent to the ammonia synthesis section. Liquid nitrogen wash technology is always selected over the methanator and PSA to obtain a pure ammonia synthesis gas, and a low-pressure ammonia synthesis loop is always preferred.

Table 2. Optimal Process Topologies.

Technology	A-500	M-500	C-500
Biomass Gasifier Temp.	900 °C	1100 °C	1100 °C
Primary Reformer Temp.	900 °C	-	900 °C
Secondary Reformer Temp.	1000 °C	-	-
OTMR	-	Y	Y
MSWR	-	Y	Y
ASU	Y	Y	Y
aMDEA	Y	-	Y
Liquid Nitrogen Wash	Y	-	Y
Methanator	-	-	-
PSA	-	-	-
Ammonia Converter Pres.	85.5 bar	-	85.5 bar
Fuel Combustor	Y	-	Y
CO_2 Sequestration	-	Y	Y

5. Conclusion

This paper introduced novel renewable processes for coproduction of ammonia and methanol as hydrogen containing energy vectors. A process superstructure consisting of several competing and commercial processes is modeled and solved to global optimality using a tailored deterministic global optimization branch-and-bound algorithm. Three examined case studies focused on plants that produce energy vectors in the form of ammonia and/or methanol that contain the same amount of H_2 that is equivalent to producing 500 MT/day of H_2. Coproduction of ammonia and methanol as energy vectors is found to lower the production cost of separate ammonia or methanol production plants between 4-7%. The reported breakeven prices for H_2 is cost-competitive.

Abstract

The development of computational tools in the process industry is essential to achieve sustainable production systems. In this work, we present a framework which incorporates sustainability principles applied to the design and optimization of chemical processes. The methodology incorporates life cycle assessment, surrogate modeling, objective-reduction techniques, multi-objective optimization, and the use of Data Envelopment Analysis (DEA) as multi-criteria decision analysis tool. In particular, the use of DEA facilitates the post-optimal analysis of the Pareto front by filtering the number of designs and ranking them without the need to define explicit weights. Additionally, DEA also provides improvement targets for those designs identified as suboptimal. This characteristic is particularly appealing as it can guide retrofit efforts towards the most effective actions when benchmark processes are compared against the best technologies available. The capabilities of the framework are demonstrated in a case study based on the production of methanol from CO_2 and hydrogen.

Keywords: Sustainable process design, life cycle assessment, multi-objective optimization, objective-reduction, data envelopment analysis.

1. Introduction

The generation of renewable and cleaner production systems is essential to achieve sustainable development. In the process industry, this is observed in the increasing implementation of processes which consume less energy and resources while releasing lower amounts of waste and emissions. In other words, the development of new processes and technologies is now driven by sustainable criteria. However, the implementation of these new technologies will very likely take place in the coming decades creating also the need to improve the performance of current facilities.

Given the impact it has over the chemical industry and related industries, process systems engineering plays a key role to attain sustainable development (Reklaitis, 2014). In this context, we can identify three main stages to achieve a sustainable design: modeling and assessment of the process, optimization, and multi-criteria decision analysis. In the first stage, sustainability metrics are defined and incorporated within a modeling technique following either equation-oriented or sequential modular approaches. In the second stage, the design task is posed as a multi-objective optimization (MOO) problem that seeks to minimize or maximize the sustainability metrics previously selected. Typically, these metrics are in conflict with each other due to the existence of inherent trade-offs between them. As a result, their optimization results in a set of optimal solutions also known as Pareto frontier. In a third stage, this Pareto frontier is analyzed in order to select the best

design. Typically, this analysis is performed by stakeholders who are assisted by multi-criteria decision analysis (MCDA) tools.

In this work, we present a framework for the optimal design of sustainable chemical processes that combines life cycle assessment, surrogate modeling, objective-reduction techniques, multi-objective optimization, and MCDA tools within a unified framework. The main novelty of the framework, additional to the integration of approaches, is the use of Data Envelopment Analysis (DEA) to assess Pareto optimal designs. The use of DEA allows us to further screen and rank alternatives without the need of defining explicit weights. More precisely, in the context of process design DEA allows to: (i) filter and rank the Pareto solutions; and (ii) provide clear insight into how to enhance suboptimal solutions such that they achieve an optimal performance.

2. Methodology

The methodology proposed to generate sustainable processes is shown in Figure 1.

2.1 Flow sheet modeling and assessment

While the framework is general enough to accommodate any metric, the sustainability assessment proposed focuses on economic and environmental criteria. As standard practice, we propose to use the total annualized cost (TAC), as it is widely applied in process design. The environmental performance is assessed via LCA as described by the International Organization for Standardization (ISO-14040). Depending on the scope of the analysis, the process can be assessed from cradle-to-gate, cradle-to-grave or cradle-to-cradle, and allocation of environmental burdens can also be considered for those processes where more than one final product is generated.

As for the modeling, we primarily focus on commercial simulators based on the sequential modular approach. When complex or computationally expensive models are implemented in the simulator, the optimization task becomes challenging as convergence problems, numerical difficulties, or large use of computational resources may arise (e.g. modeling reactive distillation columns, reactors with complex kinetics, several recycling streams, etc.). In such cases, we propose the use of surrogate models to facilitate the solution of the model and enhance the optimization stage.

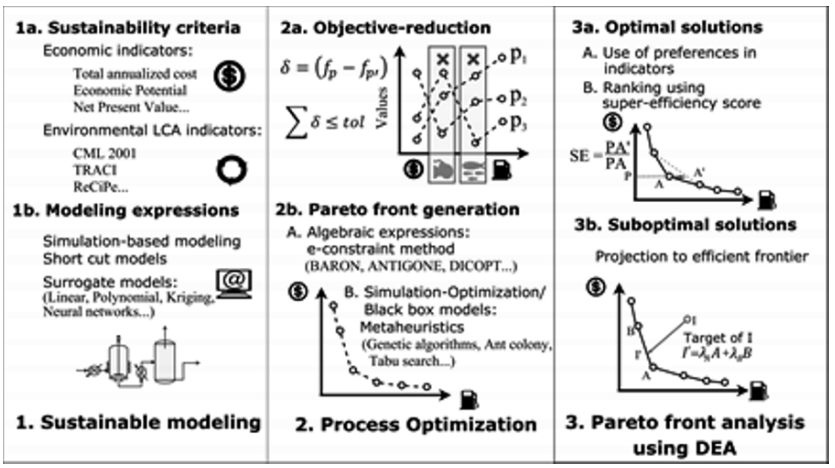

Figure 1. Framework for the optimal design of sustainable processes.

2.2 Process Optimization

To enhance the performance of the optimization solver and improve the quality of the Pareto frontier generated, we first apply an objective-reduction technique based on the MILP formulation introduced by Guillen-Gosalbez (2011). The advantage of this formulation is that the dominance structure of the Pareto set is preserved by maintaining a delta error δ below a given tolerance each time an objective is omitted.

During the optimization, we focus on the use of Multi-Objective Genetic Algorithms (MOGA's) given that they can be easily coupled not only with simulators/black box models but also with models based on algebraic expressions. However, other approaches can also be applied, such as the ε–constraint method.

2.3 Pareto frontier post-analysis using Data Envelopment Analysis (DEA)

DEA is a linear programming (LP) technique that quantifies the relative efficiency of a group of comparable decision-making units (DMUs), each consuming multiple inputs to produce multiple outputs. In the context of process design, a DMU refers to one process being assessed under multiple sustainability criteria.

The solution of the DEA model provides efficiency scores for all DMUs. Those units having an efficiency score of one are considered as efficient while those units having an efficiency score less than one are inefficient. Given the nature of DEA, the units identified as efficient form the convex envelope of the system, which can be considered as an efficient frontier. By projecting the inefficient units into the frontier, it is possible to determine improvement targets that would make them efficient. In this context, the most applied projections in DEA are the input and output oriented models. Herein, we present the input-oriented model (Banker et al., 1984), which aims to minimize the inputs (e.g. total annualized cost, global warming potential, etc.) while maintaining the same level of outputs (e.g. profit, amount of products and by-products produced, etc.). The input-oriented model is expressed as follows:

$$\max \sum_{r=1}^{s} u_r y_{ro} - u_o \tag{1}$$

$$\sum_{l=1}^{m} v_l x_{lo} = 1 \tag{2}$$

$$\sum_{r=1}^{s} u_r y_{rj} - u_o - \sum_{l=1}^{m} v_l x_{lj} \leq 0; \quad j = 1, \dots, n \tag{3}$$

$$u_r, v_l \geq 0; \quad \forall l, r; \quad \theta_o \; unconstrained$$

where multipliers v_l and u_r denote weights given to inputs x_l and outputs y_r, respectively. In the model, these multipliers are optimized in order to maximize the efficiency value of a given DMU_o rather than being defined by decision-makers. In this model, it is also possible to apply preferences in the multipliers by imposing additional constraints.

Enhancement of technologies. This characteristic is particularly appealing when we are comparing different processes or technologies. For instance, when we aim to compare a current production process against emerging technologies. In such cases, DEA not only identifies the process having the best practices ($\theta_o = 1$) but also provides improvement targets for the alternatives having the worst performance ($\theta_o < 1$). These targets are obtained by solving the following model, which is a reformulation of Eqs. 1-3:

$$\min \theta_o - \varphi \left(\sum_r s_r^+ + \sum_l s_l^- \right) \tag{4}$$

$$\sum_j \lambda_j x_{lj} + s_l^- = \theta_o x_{lo}; \quad l = 1, \dots, m \tag{5}$$

$$\sum_j \lambda_j y_{rj} - s_r^+ = y_{ro}; \quad r = 1, \dots, s \tag{6}$$

$$\sum_{j=1}^{n} \lambda_j = 1 \qquad j = 1, \dots, n \tag{7}$$

$$\lambda_j, s_l^-, s_r^+ \geq 0; \quad \forall i, j, r; \quad \theta_o \; unconstrained$$

where φ is a non-Archimedean infinitesimal value used to enforce the variables to be strictly positive; s_r^+ is a slack variable representing the additional amount of output r required by DMU_o to become efficient; s_l^- is a slack variable denoting the additional amount of input l to be reduced to become efficient; and λ_j are the linear weights used to project the inefficient units onto the efficient frontier. When $\theta_o = 1$ and $(s_r^+ + s_l^- = 0)$, the DMU is said to be strongly efficient. If $\theta_o = 1$ but $(s_r^+ + s_l^- \neq 0)$, the DMU is deemed as weakly efficient. If $\theta_o < 1$, the DMU is inefficient.

The improvement target for input l in a given design is expressed as:

$$\sum_{j=1}^{n} \lambda_j x_{lj} = \theta_o x_{lo} - s_l^- \tag{8}$$

Ranking of efficient (optimal) solutions. The ranking of optimal solutions is achieved by using a super-efficiency model, which is essentially the same as the one described in Eqs. 4-7, but in which the summation of lambdas excludes the efficient unit being assessed:

$$\sum_{j=1, j \neq j'}^{m} \lambda_j x_{lj} + s_l^- = \theta_j x_{ljj'}; \quad l = 1, \dots, m \tag{9}$$

$$\sum_{j=1, j \neq j'}^{s} \lambda_j y_{rj} - s_r^+ = y_{rjj'}; \quad r = 1, \dots, s \tag{10}$$

In an input-oriented model, the super-efficiency can be seen as the input savings achieved by an efficient DMU. These savings are measured by the extent to which the efficient frontier changes when such unit is removed. As a result, the model provides a super-efficiency score $\theta_{SE,j'}$ that is always greater or equal to one and can be used to further discriminate efficient units.

3. Case study: Methanol production from CO2 and hydrogen

The capabilities of the framework are shown in the assessment of the production of methanol from CO_2 and hydrogen. The base case is taken from Perez-Fortes et al. (2016).

Step 1: Flow sheet modeling and assessment. The sustainability of the process was assessed from cradle-to-gate defining 1 kg of methanol as functional unit. The indicators considered were the total annualized cost (TAC) and those included in the LCIA methodology CML 2001 (10 environmental indicators). The detailed process was first modeled in Aspen-HYSYS and then used to build a surrogate model using neural networks. A total of 10 continuous and 2 integer variables were considered for the

optimization of the process: CO_2 and hydrogen flow rates, temperature and volume of the reactor, recycling ratio of the flash gases, amount of purged being burned to recover heat, methanol recovery, inlet temperature of the feed to the column, distillation column pressure, reflux ratio, number of trays and feed tray.

Step 2: Process optimization.

The objective reduction was performed using an exhaustive exploration of the MILP formulation presented by Guillen-Gosalbez (2011) using a delta error $\delta = 0$. The results indicated that five out of the 11 objectives were required to keep the approximation error desired: total annualized cost (TAC), global warming potential (GWP), eutrophication potential (EP), human toxicity (HT), and photochemical oxidation (PO).

The optimization of the surrogate model was executed five times using a Multi-Objective Genetic Algorithm considering only the indicators included in the reduced space. A total of 137 non-repeated solutions were obtained, from which 126 points converged and were feasible in the original model in Aspen-HYSYS.

Step 3: Pareto front analysis using DEA. The Pareto front analysis included the 126 designs obtained from the MOO and the base case design taken from Perez-Fortes et al. (2016). After solving Eqs. 4-7, only ten out of the 127 designs were identified as efficient, including the base case (s_1 to s_9 and BC). These results show how a significant number of solutions were first ruled out by applying the concept of efficiency in DEA.

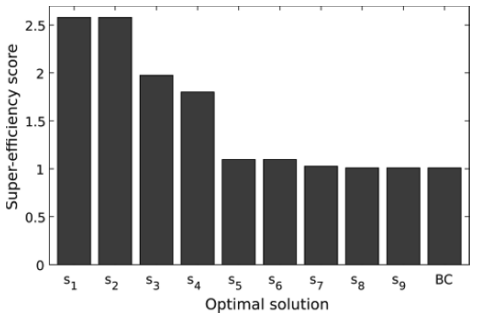

Figure 2. Super-efficiency score for the optimal designs identified as efficient.

To rank the efficient solutions, we calculated the super-efficiency score by solving Eqs.4, 7, 9 and 10. The ranking of the efficient solutions is shown in Figure 2. In this case, the super-efficiency model provided the same score for designs s_1 and s_2, indicating that a further analysis between those solutions has to be done to select the most suitable design.

In DEA, it is also possible to determine preferences in the sustainable indicators by imposing constraints to the multipliers u_r and v_l and including them in the model presented in Eqs. 1-3. To show this capability, we included the following constraint in our analysis:

$$v_{TAC} \geq v_{GWP} \geq v_{HT} \geq v_{EP} \geq v_{PO} \tag{11}$$

The efficient designs identified by solving Eqs. 1-3 and 11 are shown in Figure 3. In this case, only four designs were efficient and the base case was classified as inefficient. To identify the improvement targets for design BC, we solved Eqs. 4-8 and retrieved the values of λ_j. From the solution of the model, design BC had to be reduced to the level of solution s_1 in order to become optimal when constraint 11 is imposed.

Analyzing the best solutions identified by DEA, we found that hydrogen and CO_2 were the main contributors to the total value of the TAC and HT indicators (>90 %). In the case of GWP, hydrogen and CO_2 contributed by ≈80% while the remaining percentage was equally attributed to cooling water, heat recovery and emissions (≈6% in each case). EP

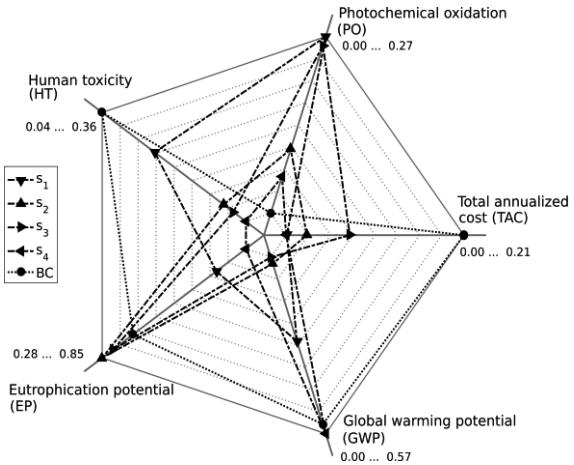

Figure 3. Normalized values for the efficient units and design BC in the reduced space when constraints in the multipliers are included.

and PO were mainly explained by the emissions generated in the process (>90% and >70%, respectively). Finally, the full methodology pointed designs s_1 and s_2 as the most sustainable options when no constraints were included in the indicators. The main difference between both designs was the higher consumption of hydrogen in design s_2, which also caused the TAC indicator to increase and was the reason to identify it as inefficient when constraints in the multipliers were included.

4. Conclusions

We introduced a framework for the optimal design of sustainable chemical process that combines life cycle assessment principles, surrogate modelling, objective reduction techniques, multi-objective optimization and DEA. The methodology was applied to the production of methanol from CO_2 and hydrogen, where all the stages of the methodology were evaluated. The application of DEA as multi-criteria analysis tool allowed us to narrow down the number of Pareto points and to establish improvement targets for those designs showing the worst performance. The same methodology allowed the ranking of optimal solutions, which facilitates the comparison between different designs. Finally, the achievement of sustainable development in the chemical industry can be facilitated by the development and application of computational tools such as the one presented in this work. This, not only by assessing new processes and technologies but also by identifying improvement targets for current suboptimal designs.

Abstract

This paper presents a systematic approach to synthesize optimal water distribution networks (WDN) taking into account the water requirement of consumers based on a multi-stakeholder approach. A structural representation is developed to satisfy the water requirements of all users without taking into account water concessions in the region, but considering the depletion of groundwater and surface water, to generate an integral water distribution network. A rigorous mathematical formulation is developed as a mixed-integer linear programming model to transform the water distribution problem into an optimization task that seeks to minimize the overall cost of the water supply network. The proposed optimization model was applied to the Sonoran water scarcity problem from Mexico, where the optimal water distribution network was obtained, based on a multi-criteria approach taking into account the industrial, domestic and agricultural users. The obtained results show that the proposed model can satisfy economic, environmental and social aspects, where the distribution of water is equal for all users without affecting natural resources. Also, the results show economic advantages due to the sales of water.

Keywords: Water management; Water distribution network; Optimization; Multi-Stakeholder Criteria.

1. Introduction

Water scarcity is becoming the major environmental issue affecting many regions of the world. Climate change and temporal variations between water recharge have intensified this problem, and combined with the increased water demand for domestic, agricultural, industrial and energy production, it has resulted in the overexploitation of water resources around the world (UN-Water, 2017). The water scarcity problem has affected large regions around the world, so that, the distribution of limited water resources for agricultural, domestic, industrial and environmental uses, requires the complete integration of demand and supply, taking into account sustainable considerations.

The synthesis of water distribution networks (WDN) based on optimization still requires the development of enhanced optimization models, efforts have been made to generate robust models that consider environmental, social and economic issues. For example,

Liu et al. (2011) proposed a mixed-integer linear programming (MILP) problem taking into account the production, distribution, and storage of desalinated water in a macroscopic case. Athilan et al. (2012) introduced a mathematical model for the synthesis of macroscopic WDN, where the authors considered fresh water, underground water, seawater, and desalinated water accounting for monthly demand fluctuations and wastewater treatment. Napoles-Rivera et al. (2015) developed a mathematical formulation for the optimal synthesis of WDN considering environmental and economic issues, the model considers dams, springs, deep wells and rainwater harvesting as main sources to satisfy industrial and domestic demands. Alnouri et al. (2015) considered the water-energy nexus by the development of a deterministic MILP problem used to obtain the optimal WDN and allocation of power-desalination technology taking into consideration seasonal variations through the year obtaining significant cost reductions. Gonzalez-Bravo et al. (2017) introduced a mathematical model for the synthesis of WDN involving power-desalination plants for water-stressed areas, in which the authors considered sustainability aspects in terms of energy and water preservation. Araya et al. (2017) presented a mixed-integer nonlinear programming (MINLP) problem for the synthesis of WDN taking into consideration the location of new desalination plants and energy recovery devices in regions with a complex topography.

This paper presents an optimization approach to perform a multi-objective optimization of integrated water distribution networks, the proposed optimization model is a decision-making tool based on multi-stakeholder theory, which takes into account the economic and environmental points of view, the characteristics of the water sources (availability of water, minimum and maximum water level, and over-exploitation status), as well as the characteristics of the consumers (seasonal variations on water demand), in order to generate a water distribution network that does not affect the sustainability of water resources. The model also considers the integration of energy issues related to the generation of water, based on power-desalination technology.

2. Proposed approach

It is important to differentiate between the minimum and the desired water supply. The first one represents the water needed to meet the basic requirements of the user and it is non-negotiable. The second one represents the water needed to cover all requirements of the user. Therefore, the social objective is to minimize the difference between the supply and the desired demand of the user, reducing the level of dissatisfaction. The proposed optimization model is based on stakeholder theory. The main idea of this model is to satisfy water demands of multiple users accounting for the dissatisfaction of each part, the water demands, as social objective functions, involve the water demands of domestic users, industrial users, and agricultural users, where the water demands can be satisfied by the existing water in dams, rivers, aquifers, deep wells, storage tanks and also the possible installation of water desalination plants. Each of the participants in the decision-making process expresses different level of preference over the objectives considered for the final configuration and operation of the system. The presented modelling approach allows defining an optimal solution that reaches a trade-off between the multiple criteria of the stakeholders and reducing the possible conflicts. The model also takes into account the water depletion of natural resources (dams and aquifers) based on a minimum and maximum amount of water to be extracted, these values depend on the natural recharge through the year. In addition, the model includes economic (profit), and environmental (CO_2 emissions) objective functions.

3. Mathematical formulation

The proposed equations include mass balances for aquifers, deep wells, dams, central stations (domestic, agricultural and industrial), storage tanks, new desalination plant, pumping cost, piping cost, solar collector equations, and water resource depletion equations. Additionally, the optimization model includes equations to account the existence of power desalination plants, capital and operating cost.

The water demands can be satisfied by the volume of water in central stations (h), plus the water in existing storage tanks (s^E) and new storage tanks (s^N).

For domestic users:

$$domdem_{r,t} = h_{r,t}^{dom} + \sum_p s_{p,r,t}^{E,dom} + \sum_q s_{q,r,t}^{N,dom}, \qquad \forall r \in R, \forall t \in T \tag{1}$$

The water demands for domestic users can be set using a minimum value, this value depends on the minimum amount of water that can be sent to the user to satisfy the domestic water demands, and it is stated as follows:

$$domdem_{r,t} \geq \mathrm{ddem}_{\mathrm{r,t}}^{\min} \qquad \forall r \in R, \forall t \in T \tag{2}$$

At the same time, the desired water demand that can be received by the domestic users can be stated as a maximum value, this value depends on the desired amount of water that can be sent to the user to satisfy the domestic water demands, as follows:

$$domdem_{r,t} \leq \mathrm{ddem}_{\mathrm{r,t}}^{\mathrm{desired}} \qquad \forall r \in R, \forall t \in T \tag{3}$$

Similarly, for industrial users:

$$inddem_{o,t} = h_{o,t}^{ind} + \sum_p s_{o,p,t}^{E,ind} + \sum_q s_{o,q,t}^{N,ind}, \qquad \forall o \in O, \forall t \in T \tag{4}$$

$$inddem_{o,t} \geq \mathrm{idem}_{\mathrm{o,t}}^{\min} \qquad \forall o \in O, \forall t \in T \tag{5}$$

$$inddem_{o,t} \leq \mathrm{idem}_{\mathrm{o,t}}^{\mathrm{desired}} \qquad \forall o \in O, \forall t \in T \tag{6}$$

For agricultural users:

$$agrdem_{g,t} = h_{g,t}^{agr} + \sum_p s_{g,p,t}^{E,agr} + \sum_q s_{g,q,t}^{N,agr}, \qquad \forall g \in G, \forall t \in T \tag{7}$$

$$agrdem_{g,t} \geq \mathrm{adem}_{\mathrm{g,t}}^{\min} \qquad \forall g \in G, \forall t \in T \tag{8}$$

$$agrdem_{g,t} \leq \mathrm{adem}_{\mathrm{g,t}}^{\mathrm{desired}} \qquad \forall g \in G, \forall t \in T \tag{9}$$

The economic objective function ($Profit$) seeks to maximize the total annual profit, which includes water sales and tax credit reduction, minus the total annual cost.

$$maxProfit = Water\ Sales + TCR - TAC \tag{10}$$

The environmental objective function ($OGHGE$) seeks to minimize the overall greenhouse gas emissions. In this case, we take into account the GHGE for fossil fuels and biofuels, the emissions for the solar collector is assumed to be zero, which is stated as follows:

$$Min\, OGHGE = \sum_{f}\sum_{u}\sum_{t}\left[GHGE_{f}^{fossil} \cdot Q_{f,u,t}^{fossil} \right] + \sum_{b}\sum_{u}\sum_{t}\left[GHGE_{b}^{biofuel} \cdot Q_{b,u,t}^{biofuel} \right] \tag{11}$$

4. Multi-stakeholder decision-making strategy

The optimal solution must be selected from the feasible solution space, which is obtained using the coordinates of the utopia point (UP), the UP point represents the optimal values of all objective functions (the UP is infeasible); the feasible solution also includes the Nadir solution (NS), which represents the opposite values of the UP, this region is obtained using lower bounds (LB) and upper bounds (UB) of the proposed objective functions. By scaling the objective functions using the UP and NS, the following equations are obtained:

Economic objective function:

$$\varphi = \frac{Profit^{UB} - Profit}{Profit^{UB} - Profit^{LB}} \tag{12}$$

Environmental objective function:

$$\tau = \frac{OGHGE - OGHGE^{LB}}{OGHGE^{UB} - OGHGE^{LB}} \tag{13}$$

Social objective function:

$$\psi_{e} = \frac{domdem_{e}^{UB} - \sum_{t} domdem_{e,t}}{domdem_{e}^{UB} - domdem_{e}^{LB}}, \qquad \forall e \in E \tag{14}$$

Where e represents any water consumer (either agricultural, domestic and industrial user). The social objective function allows selecting either one or e user demands to be prioritized, in order to evaluate the optimal solution (notice that the number of prioritized users increases the dimensions of the problem)

The compromise solution (CS) is to reduce the absolute distance between the utopia point (UP) and the objective functions, this solution will satisfy all parts and must be a feasible optimal solution, according to the following equation:

$$0 \le \varphi \le 1 \tag{15}$$

$$0 \le \tau \le 1 \tag{16}$$

$$0 \le \psi_{e} \le 1, \qquad \forall e \in E \tag{17}$$

By assigning weights to the CS function and taking into account k number of stakeholders, where each stakeholder has an individual solution (FSH_{k}), in this way these weights represent the level of individual priorities of each stakeholder:

$$FSH_{k} = w_{k}^{eco}\varphi_{k} + w_{k}^{envi}\tau_{k} + w_{k}^{soc}\sum\nolimits_{e}\psi_{k,e}, \qquad \forall k \in K, \tag{18}$$

where the average solution (AS) takes into account the contribution of each stakeholder as follows:

$$AS = \frac{\sum_{k=1}^{k} FSH_k}{CARD(k)} \tag{19}$$

Then the compensated solution of the problem seeks to minimize the average of the dissatisfactions and the main function, this solution represents the compensated solution of the involved stakeholders.

$$\min \left| CS - FSH \right| \tag{20}$$

5. Results

The water scarcity problem of Hermosillo Sonora in Mexico is presented to show the applicability of the proposed approach for designing a WDN, in this region the overexploitation of groundwater and surface water over the years has led to problems among the inhabitants of the driest regions by the dispute of this resource. In 2012, the inhabitants of one of the driest regions in Mexico (Hermosillo Sonora, near to the Sonoran Desert) faced a critical situation of water supply due to the low rainfall of the region. Later in 2014, a mining company of the region spilled 40,000 cubic meters of copper sulfate leachate in one of the most important rivers in the area, which deteriorated the water situation in the region.

The proposed model was coded in the software GAMS and it was solved using the solver BARON (Brooke et al., 2017). The model includes 10,724 equations and 10,910 continuous variables, and 764 binary variables, in this case, the average CPU time was 14,652 s in a computer with an i7 Intel core processor at 3.20 GHz and 32 GB of RAM. The model was solved taking into account environmental and economic points of view, then the most critical user of the case study was involved (domestic user from Hermosillo Region) as a priority to evaluate the differences between both scenarios. First, the evaluation of the net profit and the overall GHGE is presented in Figure 1, this figure presents an optimal economic solution in point A (1660 MM$/y and 1.45×10^7 tonCO_2eq/y) and the optimal environmental solution in point B (424 MM$/y and 1.36×10^7 tonCO_2eq/y). In the optimal economic solution, the power plant is installed at the Hermosillo Beach at the first period to supply the water deficit to the Hermosillo Region, (403×10^6 m^3/y). In this case, the prioritized users (domestic users from Hermosillo region) receive a total of 94.08×10^6 m^3/y, which represent the minimal requirement of water by the users. By applying the model prioritization through the multi-stakeholder optimization model for the domestic users from Hermosillo region, the total volume of water received by this user is 164.64, m^3/y, which represents 42% more water for this users, this increased volume inflicts directly over the net profit by reducing its value to 1493 MM$/y, which represents 11% less than the optimal economic solution. Also, the preservation of natural water resources is observed by maintaining the water levels through the year, and this is obtained because of the installation of the power-desalination plant.

6. Conclusions

This paper has presented a new optimization approach for the integrated synthesis of WDN, the proposed formulation takes into account economic and environmental impacts, as well as water demands as social objective, the problem was solved based on a multi-stakeholder theory which allows increasing the volume of water required by water-stressed users. This new formulation allows finding the optimal solution ensuring

the water demands of the most critical users. The results have shown important social, economic and environmental benefits that satisfy the involved stakeholders.

Abstract

Development of predictive environmental property models is increasingly becoming crucial as stringent regulations for substances with high global warming and ozone depletion potentials are being introduced. This contribution presents new environmental property models using two group contribution (GC) based approaches for the prediction of ozone depletion potential (ODP), global warming potential (GWP) and Daphnia magna lethal concentration (LC50, 48 hr), concentration of the test chemical in water (mg/L) that causes 50% of Daphnia magna to die after 48 hours. First, the classical group contribution approach, in which a property of interest is estimated from regression models that make use of available information about the chemical structure of a given compound (i.e. functional groups), is applied to develop models for selected properties using robust regression with outlier treatment. Second, a hybrid approach using only the first order GC-defined functional groups as predictors is presented to develop a number of data-driven models (a feedforward neural network (ANN) and a radial basis function network (RBFN), regression tree, etc.). Performance of the different models in predicting ODP, GWP, and LC50 is assessed for various industrially relevant chemicals and compared with results of the classical GC method. The experimental data for the selected properties is collected from the databases of Environmental Protection Agency (EPA) and the fifth assessment report of the Intergovernmental Panel on Climate Change (IPCC). The results showed that hybrid approach presents significant improvement on estimation accuracy for the considered environmental properties. This flexible approach builds on the basis of GC theory and extends it with nonlinear surrogate models to better describe the property of interest, which makes it a promising method to improve accuracy of property models in the wider domain of process systems engineering.

Keywords: predictive modeling, group contribution method, radial basis function network, artificial neural networks, environmental properties.

1. Introduction

The increasing legislative regulations as well as social awareness drive (bio)chemical, pharmaceutical and food industries to design sustainable processes with minimum environmental footprint. Performing sustainability assessment of manufacturing processes requires life cycle analysis, which among others rely on databases of environmental impact properties. There is a lack of sufficient data on the environmental properties such as ozone depletion potential, global warming potential and toxicity

endpoints like Daphnia magna LC50 (48 hr) for the majority of compounds. Development of these predictive property models is crucial for the process synthesis, design, and analysis of sustainable processes. GC based predictive property models are widely used in the literature. Frutiger et al. (2015) recently presented a methodology for the development of these models and applied it to the estimation of heat of combustion. Hukkerikar et al. (2012) estimated thermophysical and environment-related properties of pure components using GC methods. These methods have the advantage of being simple in model structure and capable of estimating new chemicals not used in training dataset. Approaches based on surrogate models like ANN using different pre-determined descriptors, also exist. Wernet et al. (2009), for example, developed ANN models to predict life cycle assessment related parameters including GWP using molecular weight and number of certain atoms in the molecular structure. Though these surrogate modelling approaches usually lack a close form expression of model structure, they are very effective at capturing nonlinearities that might be present in the datasets. In this contribution, by combining the best of the two modeling approaches, we introduce a hybrid approach building on the GC method by using its first order functional groups as predictors and utilizing the advanced model structure of surrogate models like ANNs to improve the predictive accuracy of the property models.

2. Theory

The classical group contribution method decomposes each chemical compound into first, second and, third order functional groups based on its molecular structure. Number of each different functional group present in a compound is used as predictors in a multiple linear regression model without any attempt to reduce the number of parameters in the model as the method tries to characterize the contributions from each different group. For instance, a certain function of the property of X to be predicted can be written as a function of contributions of first (i), second (j), and third (k) order groups as in the Eq.(1),

$$f(X) = \sum_i N_i C_i + \sum_j M_j D_j + \sum_k E_k O_k \quad (1)$$

where C_i, D_j, and O_k are fitted contribution factors and $N_i, M_j,$ and E_k are the number of times these groups appear in the compound. It was concluded in Frutiger et al.'s study that addition of higher order groups (second and the third) did not improve the accuracy of the predictions. Therefore, in this study, only the first order contributions are considered.

3. Methodology

3.1. Data collection

The experimental property data for GWP and ODP (100 years timeline for both) were collected from a recent paper from Huijbregts et al., and the data for LC_{50} were collected from the Ecotoxicology Database (ECOTOX) of U.S. Environmental Protection Agency. Available data for GWP covers chlorofluorocarbons, hydrochlorofluorocarbons, hydrofluorocarbons, chlorocarbons and hydrochlorocarbons, halons, fully fluorinated species, halogenated alcohols and ethers, whereas for ODP available data is much more limited, to those of chlorofluorocarbons, hydrochlorofluorocarbons, and halons. Before proceeding with model development, an

outlier treatment function is applied to the data, which trims the observations that are more than 1.5 interquartile ranges above the upper quartile or below the lower quartile. This ensures the developed model are robust to the outliers in the data. To determine the predictors for the multiple linear regression model, an occurrence matrix of each specific group present in the each different compound is generated using ICAS© software, which requires canonical SMILES expression of compounds. A robust regression using a nonlinear least squares solution algorithm (trust region reflective algorithm of MATLAB's lsqnonlin solver) is performed to calculate group contribution factors. The following functions are applied to the investigated properties.

$$f(GWP) = \log(GWP) = \sum_i N_i C_i \tag{2}$$

$$f(ODP) = \log(ODP) = \sum_i N_i C_i \tag{3}$$

$$f(LC_{50}) = -\log(LC_{50}) + LC_{50_0} = \sum_i N_i C_i \qquad with\ LC_{50_0} = 2.97 \tag{4}$$

Using the occurrence matrix and contribution factors as described in above equations, the first order GC predictions are obtained. An assessment on the goodness of fit of different models is made using the R^2 metric, which can be interpreted as the proportion of variability in property data that can be accounted for by the set of predictors in the model. A good estimate of the generalization potential of the developed models can be obtained using cross-validation. To account for that, one fifth of the data was held out as a test sample, and the model was trained on the remaining data. Performance measures, such as root mean squared error (RMSE) and mean absolute error (MAE), are calculated for the test set as shown in Eq. (5) and (6) respectively.

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_i^{exp} - y_i^{pred})^2} \tag{5}$$

$$MAE = \frac{1}{N}\sum_{j}^{N} |y_j^{exp} - y_j^{pred}| \tag{6}$$

When developing predictive models on datasets with strong clusterization, it is crucial to select a training set that is representative of the overall data trends. This problem can be addressed with the use of stratified sampling approach, which takes into account the clusters in the data and generates training and test samples preserving percentage of clusters for each set. This was the case with GWP data, and therefore a representative training set was created using this approach.

3.2. Description of neural networks based approach

Neural networks have gained a renewed interest among property modellers after their successful implementation in numerous other scientific and engineering problems such as function approximation, pattern recognition, etc. Recently, Mondejar et al. (2017) applied neural networks to predict thermophysical properties (critical temperature, critical pressure, normal boiling point, etc.) of a group of compounds using a GC based molecular groups as predictors. As the number of data available is so limited for the properties of interest in this study, our approach only uses the first order groups to keep the complexity of the models at a reasonable level.

Basically, a feedforward neural network (the kind of network where information flows only in one direction from inputs to targets) comprising of one hidden layer and one output layer (each with different number of neurons) was developed using the Neural Network toolbox of MATLAB software (Mathworks Inc.). Given the training data, each layer in the network adjusts its internal weights using a training algorithm and generates an output using a transfer function. The output of the output layer gives the network response. Development of an optimal network configuration for each property is achieved following a grid search approach. Each different combinations of three different transfer functions (i.e. logarithmic, tangential, and linear sigmoid functions) with three different training algorithms (i.e. Bayesian regularization backpropagation, Levenberg-Marquardt backpropagation, and scaled conjugate gradient backpropagation) was tested for different numbers of neurons in the hidden layer. As the initial assignment of weights and bias are random, each different network configuration is repeated 10 times. The configuration giving the lowest RMSE on the test set (the same set used for GC) was chosen. To prevent the network from overfitting, the number of network parameters is kept below the number of data points. Finally, the network performance is also compared with other popular machine learning algorithms such as regression trees, radial basis function networks using built-in MATLAB functions. Also applied is a piece-wise linear regression model using multivariate adaptive regression splines (MARS) method, for which the toolbox of Jekabsons (2016) is used.

4. Results and discussions

Performance results of first order group contribution based models trained on full data sets are summarised in Table 1. The predictors defined by GC models are able to explain the variations in the investigated properties with an acceptable accuracy (R^2 higher than 0.6) using a multiple linear regression model without the intercept term. However, cross-validation performance scores of GC models were not as satisfactory as the training performance. Table 2 shows performance metrics of holdout cross-validation results of GC based models in comparison with other methods. Compared to other methods, a significant reduction in the root mean squared error of GWP predictions (from around 2000 to 1196) was achieved using the hybrid approach with ANN. Similar reductions in RMSE were also observed for ODP and LC50 data.

Table 1. Summary of performances of first order GC-based models trained on full data sets.

Property	Number of data points used	Number of predictors	R2	MSE	RMSE	MAE	ARE
GWP	109	30	0.8544	1.72e+6	1311	689	13.92
ODP	30	16	0.9934	0.011	0.033	0.020	0.26
LC50	305	115	0.7983	0.4532	0.673	0.477	14.9

Figure 1 shows the comparison of the predictions attained using GC and neural networks based approaches with the experimental GWP and ODP data. GC method severely underestimates some of the compounds in GWP data while the neural network more closely follows the experimental data points.

Figure 2 shows the comparison of GC and ANN models for LC50 data prediction. Both models have some over and under estimates. The results suggest that the set of functional groups used in the model building are not able to explain the variations in LC50 data as well as they did for the other properties.

Table 2: Holdout cross-validation performance of GC models compared with other methods.

	GWP (kg CO2eq/ kg GHG)			ODP (kg CFC11-eq/ kg ODS)			LC50 (-Log10 mol/L)		
Model	R2	RMSE	MAE	R2	RMSE	MAE	R2	RMSE	MAE
GC	0.68	2002	940	0.35	0.90	0.50	0.39	1.37	0.95
MARS	0.60	2126	1835	0.32	0.40	0.33	0.34	1.34	1.05
RBFN	0.70	1968	1387	0.64	0.34	0.29	0.28	1.70	1.35
TREE	0.44	2553	1560	0.24	0.44	0.31	0.51	1.14	0.82
ANN	0.88	1196	741	0.97	0.06	0.03	0.74	0.77	0.55

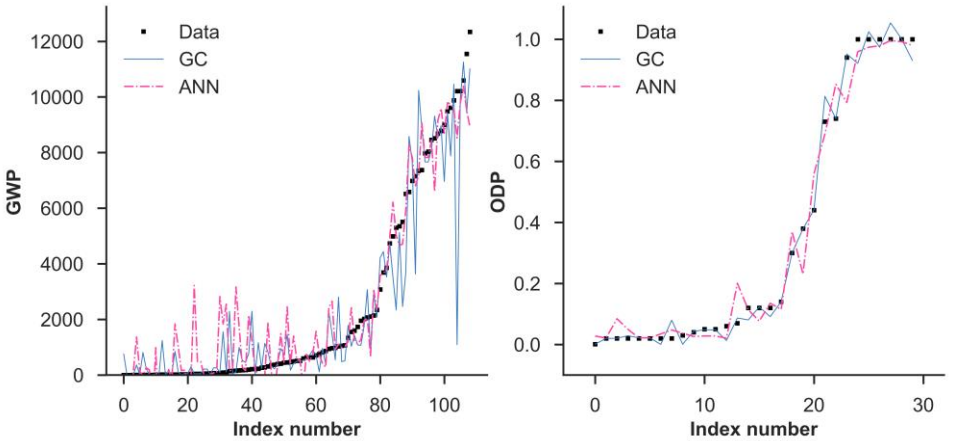

Figure 1: Comparison of group contribution method (line) and artificial neural network (dashed line) based method for predictions of the global warming potential data (left) and ozone depletion potential data (right). ANN models more closely follow the data points.

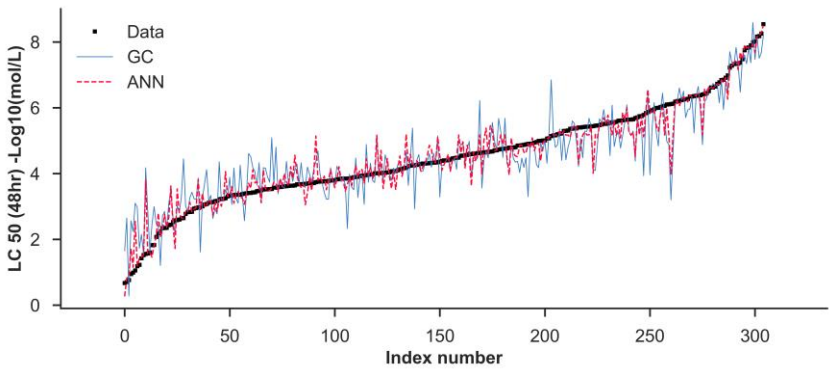

Figure 2: Comparison of group contribution model (line) and hybrid model using ANN (dashed line) for predictions of the full Daphnia magna LC50 dataset.

5. Conclusions

Predictive property models were developed for global warming potential, ozone depletion potential, and Daphnia magna lethal concentration 50 using the latest available data from the literature. First order functional groups defined by classical group contribution method are able to model the data, however, generalization potential of these models are found limited using holdout cross-validation. Compared to a multiple linear regression model as applied in GC methods, we have shown that a feedforward artificial neural network model using the same first order functional groups as inputs has better cross-validation performance for each of the investigated properties, also outperforming other tested surrogate models. This suggests that it is possible to describe relationships between first order functional groups and predicted environmental properties using an artificial neural network model with a better prediction accuracy.

Abstract

Hydrogen (H_2) is one of the most important raw materials in the chemical and refinery industries. H_2 is also regarded as a future "energy vector" due to its potential to act as an ultraclean fuel in the heat, power, and transport sectors. Therefore, development of efficient, low carbon routes to produce H_2 is essential to meet its current and growing demand. In particular, this has placed an imperative on improving the efficiency of steam reforming of hydrocarbons (SRH), this process being considered the most feasible and economic route to large scale H_2 production. The water gas shift reaction (WGS) is one of the most important stages of SRH, but is equilibrium limited and requires improvements in energy efficiency. In this study, we demonstrate that the overall efficiency of the WGS can be improved by removing CO_2 in situ and co-feeding alcohols such as methanol and ethanol. The feasibility of this novel concept is investigated by conducting thermodynamic analyses of the alcohol reforming/WGS (alcohol-to-shift) reactions for H_2 production alone and with simultaneous CO_2 adsorption (sorption-enhanced, SEalcohol-to-shift). To this end, a non-stoichiometric approach based on the minimisation of the Gibbs free energy is used. The results show that adding alcohols to the feed facilitates autothermal operation of the shift unit and significantly increases the amount of H_2 produced. The H_2 productivity can be further enhanced by adsorbing CO_2 in situ. The theoretical studies presented here are carried out under relevant operating conditions for SRH and aim to serve as a guideline for future work on alcohol-to-shift processes enhanced by adsorption.

Keywords: Hydrogen, WGS, alcohol reforming, sorption-enhancement, CO_2 adsorption

1. Introduction

Hydrogen (H_2) is considered to be a future "energy vector" playing a key role in the mitigation of climate change, which is one of the biggest energy challenges facing the world today (Committee on Climate Change, 2016). In particular, the use of H_2 as an ultraclean fuel in the transport, power, and heat sectors has the potential to provide deep carbon emission reductions. Contrary to fossil fuels that produce more than 180 gm/kWh CO_2 equivalent after combustion, H_2 has no emissions at the point of use. In addition, H_2 is an important raw material for many valuable chemicals (*e.g.* ammonia

and methanol), and it is widely used in hydrotreating processes to increase the yield of light fractions obtained from heavy oils and to meet increasingly strict environmental regulations (Iruretagoyena and Montesano, 2018). Hydrogen can be produced from a variety of sources and routes although the cheapest is steam reforming of methane and other hydrocarbons (SRH), [$CH_4 + H_2O \leftrightarrow 3H_2 + CO$]. A typical SRH plant includes a reformer followed by a water gas shift (WGS) stage, [$CO + H_2O \leftrightarrow H_2 + CO_2$] and a purification section. Steam reforming is strongly endothermic and the heat of reaction has to be supplied to the system, which accounts for a significant part of the production costs. Consequently, emphasis has been given to the development of processes that minimise the energy input, *e.g*. autothermal reforming (Zennaro et al. 2013) and to the improvement of reformer designs. However, while the energy efficiency of the reformer has increased significantly in recent years, in industry there has been little progress on improving the efficiency of the shift stage. One of the few attempts to enhance the performance of the WGS section is the methanol-to-shift (MtoS) process developed by Haldor Topsøe, which combines the exothermic WGS and the endothermic methanol decomposition [$CH_3OH \leftrightarrow CO + 2H_2$] and methanol reforming [$CH_3OH + H_2O \leftrightarrow CO_2 + 3H_2$] reactions, aiming to minimise the energy losses while boosting the H_2 productivity (up to 25 %). (Nielsen et al. 2009)

The efficiency of the WGS can also be significantly enhanced by the so-called sorption-enhanced water gas shift reaction (SEWGS), which combines the WGS with in situ removal of CO_2 using a solid adsorbent (Jang et al. 2012). This shifts the equilibrium towards the products thereby increasing the production of H_2. Additional advantages of SEWGS include lower consumption of steam, improved energy efficiency and capital cost reduction through process simplification. In this contribution, we investigate the feasibility of combining the methanol-to-shift process with CO_2 adsorption (i.e. SEMtoS). The analysis of the shift section is based on a typical composition of the effluent from a steam methane reformer (Rostrup-Nielsen, 2008). The effects of temperature, pressure, steam and methanol addition, fraction of CO_2 adsorption and energy efficiency of the shift systems are investigated. An advantage of using methanol as energy carrier in the process is that methanol is produced in very large scale at places where natural gas is cheap, and in the future is expected to serve as a vector for renewable hydrogen. The suitability of co-feeding ethanol (ethanol-to-shift, EtoS), a renewable fuel, in the WGS unit is also explored. This study extends the research on methanol-to-shift reported previously (Iruretagoyena, 2016)

2. Methods

2.1 Equilibrium calculations

An algorithm to calculate the chemical equilibrium of the WGS and alcohol-to-shift reactions with simultaneous CO_2 adsorption was developed following a non-stoichiometric approach based on the minimization of the Gibbs free energy (Iruretagoyena, 2016). The non-linear algebraic system, involving Lagrange multipliers, was solved in MATLAB (R2013a) using the in-built routine *fsolve* and the *code newtons* (Yang et al. 2005). A particular equation was written for carbon dioxide to account for the fraction, *f,* of CO_2 removed by adsorption, Eq. (1). In addition, a subroutine was developed to calculate the fugacity coefficients of each species in the gas mixture using the *Soave-Redlich-Kwong* equation of state. To validate the methodology used in this study, a comparison was made with published experimental

equilibrium data available for the forward and reverse water gas shift, methanol decomposition, methanol synthesis, MtoS and SEWGS (Nielsen et al. 2009, Graaf et al. 2016, Stevens Jr. et al. 2010).

$$\Delta G^{f}_{CO_2} + RTln\left(P\frac{n_{CO_2}(1-f)}{\sum_{i=1}^{N} n_i - n_{CO_2} f}\right) + RTln\phi_{CO_2} + \lambda_C + 2\lambda_O = 0 \quad (1)$$

2.2 Species in the alcohol-to-shift units

The free energy minimisation approach used here requires the specification of the species that are in chemical equilibrium in the system, i.e. methanol, ethanol. carbon monoxide, hydrogen and water. If a well-designed catalyst is used, the formation of by-products can be maintained at trace levels as reported by Nielsen et al (Nielsen et al. 2009). Therefore, the formation of by-products such as methane, dimethyl ether and formic acid is not considered in the present study.

2.3 Description of the simulated shift stage

The shift stage consists of an equilibrium reactor in which WGS alone or in combination with alcohol steam reforming takes place. To assess the energy efficiency of the section, besides the energy balance of the shift reactor, the heat that is removed from the effluent of the reformer and transferred to the water or alcohol streams if they are co-fed to the reactor are included. In the sorption-enhanced cases, a heat of adsorption of 17 kJ molCO_2^{-1} was assumed (Ding and Alpay, 2000). The equilibrium calculations presented in this study assume that CO_2 is the only species that is adsorbed on the surface, which is a good approximation to real adsorption systems using layered double oxide as adsorbents (Ding and Alpay, 2000, Iruretagoyena, 2014). The feed to the WGS reactor considered in our case study corresponds to the effluent from a heat exchange reformer operating at 20 barg and 1,173 K with a steam to carbon ratio 2.5:1, Table 1 (Rostrup-Nielsen, 2008).

Table 1. Feed composition to the shift section

Compounds	Composition (mole %)
H_2O	26.1
H_2	54.0
CO	12.3
CO_2	4.5
N_2	0.9
CH_4	2.2
Flow (Nm^3/h)	530

3. Results and discussion

3.1 Methanol-to-shift

The combination of WGS and steam reforming of methanol increases the productivity of H_2 in the range of temperatures relevant in the conventional WGS catalytic process (573-773 K), Figure 1a. Methanol is transformed to H_2 and CO, which is then shifted to produce even more H_2. The H_2 productivity shows a maximum between 523 K and 593 K, an operation window where both reactions, i.e. WGS and methanol steam reforming, are thermodynamically favourable. The operating pressure in the WGS alone has little impact on the equilibrium product distribution of the WGS since there is no change in the number of moles during the reaction. On the contrary, for the MtoS, the

thermodynamic constraints on methanol steam reforming at low temperatures can be compensated for by reducing the operating pressure due to the twofold increase in the number of moles, Figure 1b. In industry, it is more efficient to increase the pressure of natural gas rather than H_2, since smaller volumes need to be compressed. Consequently, the optimal operating pressure of a steam-methane reformer is typically around 20 barg (Rostrup-Nielsen, 2008).

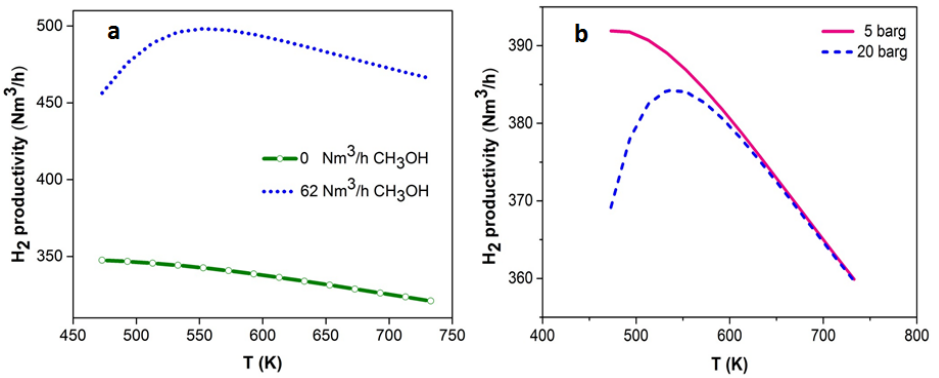

Figure 1. (a) Effect of methanol addition (20 barg). (b) Effect of temperature and pressure (CH_3OH: 16 Nm^3/h)

Besides the increase in the amount of H_2 produced, the main advantage of the MtoS process over WGS is to achieve autothermal operation of the shift unit which is not possible with the WGS alone. The heat released by WGS compensates the heat consumed by the steam reforming of methanol. It is worth nothing that for a given syngas composition, the amount of H_2 produced autothermally at equilibrium depends solely on the reactor temperature, Figure 2. This can be attributed to the fact that the partial pressures of the species have a negligible effect on the equilibrium conversion of WGS so the amount of methanol that needs to react does not depend on the pressure of the system. On the other hand, less methanol needs to be added at low pressure to achieve autothermal operation due to the more favourable thermodynamics for methanol reforming. Slightly higher H_2 productivities are obtained over the whole range of operating temperatures if the methanol feed to the MtoS reactor is replaced by a mixture of water and methanol. This stems from the decrease in the partial pressures of the species involved in the methanol decomposition, and from the shift of the WGS equilibrium towards CO_2 and H_2 due to an increased concentration of water.

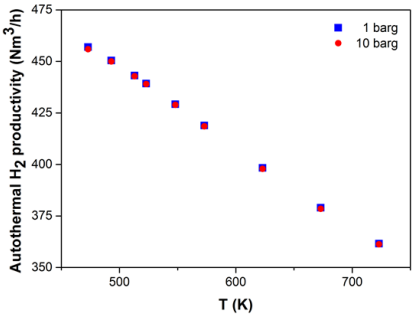

Figure 2. H_2 productivity under autothermal conditions (range of CH_3OH required for autothermal operation: ~20-60 Nm^3/h)

3.2 Sorption-enhanced methanol-to-shift

The maximum in the hydrogen productivity for the MtoS process between 523 K and 593 K, corresponds to the temperature window in which both WGS and methanol reforming are favourable. Therefore, adsorption of CO_2 becomes useful above ~523 K to overcome the WGS equilibrium limitations and to benefit from high reaction rates. When the MtoS process is conducted in the presence of a solid adsorbent, there is a marked increase in the hydrogen productivity as the fraction of CO_2 adsorbed, *f*, increases, and for different values of *f*, the maximum H_2 productivity is centered between 523 K and 593 K, Figure 3. Pressure has little effect on the H_2 productivity of SEMtoS at high temperatures, whereas low pressures favor the production of H_2 at temperatures below 623 K.

Under sorption-assisted conditions, the heat balance in the MtoS reactor must include the contribution of CO_2 adsorption. Considering a heat of adsorption of 17 kJ molCO_2^{-1} (Ding and Alpay, 2000) it is found that there is a methanol to carbon monoxide feed molar ratio that allows autothermal operation. This ratio decreases slightly in the temperature range relevant for SEMtoS. Due to the endothermicity of the steam reforming of methanol, the amount of methanol that needs to be added increases significantly at low temperatures.

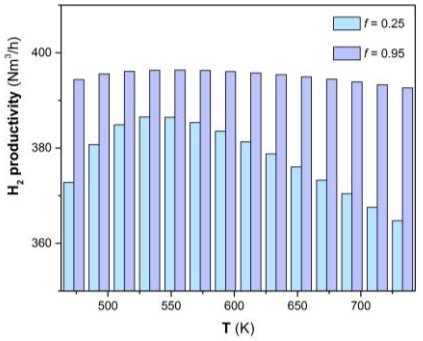

Figure 3. Effect of temperature on the H_2 productivity, SEMtoS (20 barg, 16 Nm^3/h CH_3OH)

3.3 Sorption-enhanced ethanol-to-shift

Analyses analogous to those described above for SEMtoS were conducted for sorption-enhanced ethanol-to-shift (SEEtoS). The overall results show a similar optimal operating window (i.e. ~523 K to 773 K). In this temperature range, the removal of CO_2 shifts the equilibrium towards the products, thereby increasing the production of H_2. A comparative study between SEMToS and SEEToS using the same carbon to CO feed molar ratio shows that the product distribution of both systems is approximately the same in the temperature range of interest. Moreover, the production of H_2 is only marginally higher in the methanol-system compared to that of the ethanol-system. Interestingly, an energy analysis shows that for both SEMtoS and SEEtoS, there is an amount of alcohol added which enables autothermal operation. However, if methane is produced at equilibrium as by-product, the system is not energy efficient at temperatures below 673K, i.e. the overall heat of reaction of SEWGS is lower than that of the sorption-enhanced alcohol-to-shift systems under the same operating conditions. Therefore, it is very important to use highly selective catalysts in the processes (Nielsen et al. 2009).

4. Conclusions

In this study a non-stoichiometric approach based on the minimization of the Gibbs free energy was used to assess the thermodynamic feasibility of sorption-enhanced alcohol-to-shift systems. SEMtoS and SEEtoS are promising strategies to enhance the productivity of H_2 while ensuring that the energy efficiency of the WGS is improved. The amount of H_2 produced in the SEalcohol-to-shift processes shows a maximum between 523 and 593 K, an operating window where the WGS and alcohol steam reforming reactions are thermodynamically favored. The adsorption of CO_2 in situ enhances the H_2 productivity more than other strategies to shift equilibrium (e.g. increasing the amount of steam in the feed or reducing the pressure of the shift units). A major advantage of the SEalcohol-to-shift systems compared to SEWGS is the ability to achieve autothermal operation of the shift unit, which is not possible with the WGS alone. The heat released by WGS and CO_2 adsorption is compensated by the heat consumed in the steam alcohol reforming reactions. The systems are not energy efficient if methane is produced at equilibrium as by-product.

Abstract

The effect of applied shear stress on *Botryococcus braunii*, in the presence of solvent is important to further understanding the mechanisms behind in-situ solvent extraction and will be critical in the design and scale up of an effective extraction process. This paper looks at the effect of various mixing rates on colony structure and culture photosynthetic activity in the presence of heptane. Partial colony disruption was found to occur at shear rates of 335 s^{-1}, with the main mechanism of disruption believed to be microeddies generated by turbulence around the impeller. Photosynthetic activity was seen to drop by 55 % during the extraction period requiring a short recovery time of 3 days, reaching 66.5 % of its original value. These results provide valuable insight and data on the shear limits of *B. braunii* required in the design of a repeated milking process and will assist in the design and scale up of a viable milking process.

Keywords: Shear rate, Botryococcene, Microalgae, Lipid production, Solvent extraction.

1. Introduction

Botryococcus braunii is a fresh water, green microalgae, which forms colonies supported by an extracellular matrix (ECM) rich in long chain hydrocarbons of a nature which make them ideal as a source of biofuel (Banerjee, Sharma et al. 2002, Weiss, Roth et al. 2012). Historically the production of high value products from microalgae has followed a four-step process involving; biomass cultivation, harvesting/dewatering, extraction, and separation. This may work with the production of high value products; however, biofuels require larger volumes of product. Furthermore, while *B. braunii* may have a relatively high lipid content, it is a slow growing microalgae (Cabanelas, Marques et al. 2015). This is where methods such as in-situ solvent extraction become attractive. The ability of *B. braunii* to store these lipids extracellularly make them accessible for solvent extraction, with minimal damage to the cell wall, after which *B. braunii* cells can regenerate lipid stores for future extraction events (Frenz, Largeau et al. 1989).

Generally cell cultures require little agitation to achieve effective mixing, reducing the shear generated from impellers (Pol and Tramper 1998). However, higher mixing rates are required for effective solvent dispersion in a solvent extraction process. For large scale culture, the increased power input from can generate turbulent microeddies around the impeller. As average microeddy length drops below the cell diameter, cells can become damaged and rupture (Papoutsakis 1991, Pol and Tramper 1998, Mardikar and Niranjan 1999).

Solvent toxicity is likely to weaken colonies and increase the effect of these microeddies on culture viability, making this an important factor to consider in design of an effective non-destructive extraction process. There are five factors to consider in solvent selection; Biocompatibility, Downstream processing, Extraction efficiency, Cost and Safety (Jackson, Bahri et al. 2017). Solvents with high biocompatibility tend to have low extraction efficiencies resulting in the requirement of increased volumes and exposure periods (Miazek, Kratky et al. 2017). As the exposure period is increased the effect of solvent toxicity is increased resulting in cell mortality. Larger volumes and contact periods also result in increased process costs when considering scale up and economic viability. A solvent which has a reasonable extraction efficiency with an acceptable toxicity which does not result in irreversible damage to the culture is required for a viable large-scale process.

For this study heptane has been chosen due to a balance of biocompatibility (Frenz, Largeau et al. 1989, Moheimani, Cord-Ruwisch et al. 2013) and extraction efficiency, with ease of downstream separation and relatively low cost (Jackson, Bahri et al. 2017). The purpose of this paper is to observe and understand the effect of hydrodynamic shear on *Botryococcus braunii* during the solvent extraction process and the effect it has on culture activity and recovery.

2. Materials and Methods

2.1. Culture conditions:

Botryococcus braunii (BOT-22, B Race), originally obtained from The AOACC culture collection, Tsukuba, Japan, was used for this study. Culture conditions were identical to that of Moheimani, Matsuura et al. (2013). Culture density was maintained at 1.3 – 1.5 gL^{-1}.

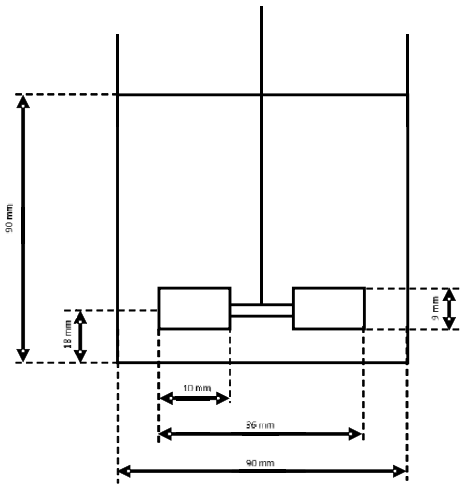

Figure 1 – Extraction vessel dimensions.

Figure 1 shows the dimensions of the vessel used for lipid extraction. For effective extraction it is important to keep turbulence to a minimum whilst still achieving sufficient solvent dispersion. To determine the minimum required mixing rate, tests were completed with water and heptane, increasing the mixing rate to a point where solvent dispersal is achieved. Eq. (1) was generated to select mixing rates for this work.

$$N_{min} = 21.5R + 289 \qquad 1.33 < R < 9 \qquad (1)$$

Where; R is the ratio of water to heptane and N_{min} is the minimum impeller speed necessary to achieve solvent dispersion (rev.min^{-1}).

Each 2-hour extraction was run in triplet. Photosynthetic activity was measured at 20-minute intervals for the duration of the experiments. Lipid and biomass content was measured directly before and after extraction. Heptane was added to the culture at time zero and topped up every 20-minutes throughout all extractions.

An R value of 2.33 and mixing rate of 500 rpm was used for the second round of experiments with a solvent contact period of 4 hours. Culture activity was measured half hourly during the extraction period and daily post extraction. CO_2 addition pre/post extraction was maintained at 1 Lmin^{-1} (1 % CO_2). Light was supplied to one side of the flask at 77 ± 0.4 μmol photons m^{-2}s^{-1}. Both light and CO_2 cycled on a 12 hr on: 12 hr off cycle.

Culture activity was measured using F_V/F_M as explained by Moheimani, Matsuura et al. (2013). 6 ml of sample was used for all activity samples. Samples taken during the extraction phase were replaced with fresh culture. All samples were diluted (6 ml sample : 9 ml fresh media) and dark adapted for 30 minutes prior to measurement.

2.2. CSTR shear rate correlation

Rushton, Costich et al. (1950) produced power curves for many stirred tank reactor setups correlating vessel power number (N_P) with Reynolds number (N_{Re}), one of these being an unbaffled reactor with a 6 bladed Rushton turbine, much the same as what was used in this study. Using these correlations the power draw generated by the agitator can be determined, which can then be used to calculate the shear rate imposed on the system (Coker 2001). Alternatively, the power requirement can be modelled using a complex set of equations taking into account; the vessel dimensions (height, diameter, number of baffles, width of baffles, height of baffles), impeller dimensions/type (blade length and width, number of blades, impeller diameter) and the characteristics of the fluid to be agitated (Furukawa, Kato et al. 2012). These equations can be used similar to that of Coker (2001) to obtain the power draw from the system and shear rate, leading to a correlation between shear rate (γ, s^{-1}) and mixing rate (N, rpm). For detailed equations and related correlations refer to Furukawa, Kato et al. (2012).

Eq. (2) (Coker 2001) and (3) (Furukawa, Kato et al. 2012) are the resulting correlations from the two methods described. Averaging these two equations gives Eq. (4), which was used for shear rate calculations on this system.

$$\gamma = 0.8603N - 81.677 \qquad 330 < N < 600 \qquad (2)$$
$$\gamma = 0.8440N - 101.280 \qquad 330 < N < 600 \qquad (3)$$
$$\gamma = 0.8522N - 91.479 \qquad 330 < N < 600 \qquad (4)$$

3. Results

In all extractions, once the heptane was added the culture activity steadily decreased over the extraction period, levelling out around 0.3 (approx. 40 % of the original value). At an R value of 4 and mixing rate of 380 rpm, very little loss in culture photosynthetic activity is seen with a reduction in activity of 9.7 %. At this mixing rate, a substantial portion of the solvent was still sitting on the surface, undispersed, resulting in reduced

culture/solvent contact. When increased to 400 rpm a significant drop in activity resulted in a final reduction of 52 %. As this was increased to 500 rpm, the initial drop in activity was much greater, reducing by 32 % after 40 minutes compared to 11 % at 400 rpm. There was no significant difference between the final activity at mixing rates of 500 and 600 rpm.

Table 1 – Reduction in culture activity after 2 hours of solvent contact.

Mixing rate	***380 rpm (232 s^{-1})***		***400 rpm (249 s^{-1})***		***500 rpm (335 s^{-1})***		
Culture/Heptane	400/100	350/150	500/0	400/100	500/0	400/100	350/150
R	4	2.33	-	4	-	4	2.33
Loss in activity	9.7 %	26.4 %	2.3 %	52.3 %	1.2 %	54.4 %	54.9 %

There was a clear initial drop in culture condition at 500 rpm at both R values of 4 and 2.33 which was not seen at 380 or 400 rpm. At a mixing rate of 380 rpm solvent dispersion was inefficient with an R value of 4, resulting in reduced solvent contact and a much lower reduction in activity. As R was reduced to 2.33 the culture was seen to be under more stress with the activity dropping by 26 % over the two-hour extraction period. Little difference could be seen in the culture performance at R values of 4 and 2.33 at a mixing rate of 500 rpm, indicating solvent dispersion is complete. In the absence of heptane, the culture was completely un-harmed.

Colony observations were made post extraction at a mixing rate of 500 rpm and culture/heptane ratio of 2.33. As to be expected, the effect of heptane on colony structure is clear. Large colonies post-extraction were less common with more single/double cells present in the culture. The colonies which were still intact were smaller and had a yellow/brown tinge to them indicating the production carotenoids in response to stress (Ambati, Ravi et al. 2010). With the extraction of lipids and hydrocarbons from the ECM, the strength of the colonies was compromised, increasing the cultures sensitivity to hydrodynamic shear. There are also what appear to be lipid globules surrounding the colony, indicating small tears in the ECM retaining sheath (Figure 2C).

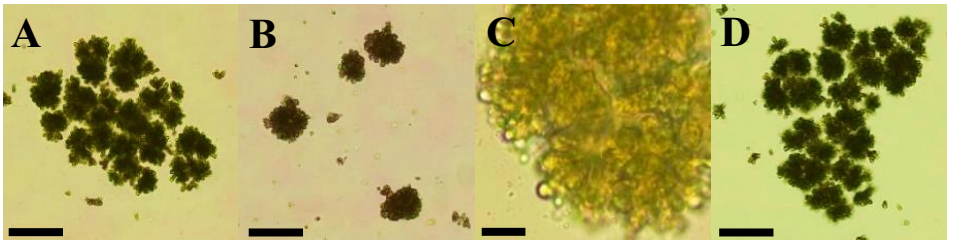

Figure 2 – Experiment 1.74 (500 rpm, R = 2.33); culture condition pre-extraction (A), directly after extraction (B, C) and 24 hours after extraction (D). Scale; A, B, D = 100 µm, C = 20 µm.

After just 24 hours of CO_2 exposure, the colonies returned to their original size/colour (Figure 2D). The extraction period at 500 rpm was extended to 4 hours with little further reduction in photosynthetic activity observed, showing the algae are biocompatible with heptane and can withstand prolonged exposure. The fact that the culture activity does not drop much in the second half of the extraction suggests the algae are stressed but are not dying, likely to be a result of colony disruption. Post extraction cultures recovered to an activity of 0.58 where it remained for the 6 days it was monitored.

4. Discussion

Botryococcus braunii has shown a strong tolerance to mixing rates of up to 500 rpm. At the lower mixing rates (N < 400 rpm) solvent dispersion was not complete with a portion of solvent remaining on the surface of the culture. This resulted in reduced contact and lower reductions in culture activity. At 500 rpm solvent dispersion was almost immediate, with culture activity dropping much quicker, stabilizing at 38 % of the original value after two hours. Solvent contact with the colony weakened the colony outer sheath, making colonies more susceptible to hydrodynamic shear. This resulted in the breaking up of colonies into smaller sub colonies and in some cases single/double cell aggregates (Figure 2B). While complete colony disruption can result in culture death (Hou, Park et al. 2014), the level of disruption in this case was not enough to do so.

As colonies are disrupted and split into more smaller colonies, the resistance to microeddies generated by shear forces around the impeller is expected to increase. The Kolmogorov scale can be used to model minimum microeddy length (η, m) (Eq. (5) and (6), (Papoutsakis 1991)).

$$\eta = (v^3/\varepsilon)^{1/4} \tag{5}$$

$$\varepsilon = P/\rho V \tag{6}$$

Where; v is the fluid kinematic viscosity (m^2s), ε is the rate of energy dissipation into the fluid body (m^2s^{-3}).

If the microeddy size is equal to, or less than that of the cells being mixed, damage is likely to occur (Papoutsakis 1991, Pol and Tramper 1998). At the mixing rates used in this work, the minimum microeddy sizes observed were 45-66 µm. At 500 rpm the eddy size calculated is 50 µm, which is much smaller than the large colonies seen pre-extraction (> 400 µm, Figure 2A), resulting in the breaking up of colonies into the smaller colonies seen post extraction (45-100 µm, Figure 2B). The size of these colonies suggests they would also be compromised, which is seen in the lipids leaking from the ECM (Fig. 3D), and a portion of the colonies which have been completely broken up, resulting in free floating single/double cells. Individual cells are much smaller than 45 µm and would be unaffected by the shear rates imposed in this work. The loss in activity must therefore be attributed to the break-down of colonies via mechanisms described by Papoutsakis (1991). Increasing the period of exposure is likely to lead to increased loss of lipids from the ECM and further colony disruption, which in this case would increase extraction efficiencies. Unfortunately, *B. braunii* cells have been seen to struggle once separated from the colony (Hou, Park et al. 2014), too much disruption is likely to result in increased cell mortality requiring an extended recovery phase.

5. Conclusions/Recommendations

The shear limits of *Botryococcus braunii* obtained in this work are vital in the design and scale up of an effective non-destructive extraction process. A mixing rate of 500 rpm (335 s^{-1}) at culture/solvent ratio of 2.33 proved to be optimal with a reduction in activity of 55%. At this mixing rate colonies were under enough stress to release lipids from the ECM while cellular activity was maintained for a quick recovery. The presence of solvent had a dramatic effect on the cultures shear tolerance which must be considered in the process design. The shear limits observed in this paper can be utilized in alternate extraction vessel design and modeling saving a great deal of time and resources in process

feasibility studies. Furthermore, this gives an initial starting point required for further work on long term repetitive extractions reducing the number of variables to be tested.

Abstract

While utilizing plant-derived resources has emerged as a key toward sustainability, systems should solve systemic problems that cannot be easily coped with because of their far-reaching and potentially unpredicted influence. In this study, we have tackled the systemic problems in plant-derived production through a case study on sugarcane-derived production. First, we developed a process model that can simulate mass and energy balance in a cane sugar mill considering agricultural and industrial technology options based on the site investigation, literature search and data analysis. Using the developed process model, a simulation-based analysis was conducted targeting Tanegashima, which is one of the sugarcane-farming areas in Japan. Some alternatives that a single decision maker or technology have never found were generated. Finally, the potential of this approach to generate scenarios for reaching the alternatives was confirmed through a scenario-planning meeting involving actual engineers in a cane sugar mill. It can be concluded that a simulation-based approach can be a strong tool to intensify plant-derived production through solving the systemic problems across agriculture and industry.

Keywords: Interdisciplinary approach, sugarcane, bioethanol, combined production

1. Introduction

Plant-derived resources have emerged as key alternatives to fossil resources for production of fuels and chemicals. There have been innumerable number of studies on the development of technology for converting plant-derived resources into the products within the industrial field (e.g., Vohra et al., 2014; Humbird et al., 2011). The benefit of these technologies, however, could be affected by the agricultural process as a raw material acquisition stage of plant-derived production. Unlike mining of fossil resources, agriculture has some unique characteristics that restrict the yield, composition and availability of plant-derived resources such as intervention of farmers and vulnerability to weather, insects and diseases. The method for the design of systems encompassing agriculture and industry is needed.

It is challenging to change agriculture and industry simultaneously because of the unclear relationship between them and existing limitations such as current land use, equipment in the plant, infrastructure or regulations. For example, in Japanese cane

sugar industry, it is not easy to transform from single sugar production to combined sugar and ethanol production even if the latter is acknowledged as better. While some high-yielding sugarcane cultivars that increase both sugar and ethanol production have been developed (Ohara et al., 2009), their adoption is challenging because of their high impurities that deteriorate the efficiency of sugar crystallization processes. In recent years, a technology has been developed to mitigate the unpleasant effect from the impurities and to support the introduction of the high-yielding cultivars (Ohara et al., 2012). However, it may be still hard for sugar mills to decide the technology introduction without building consensus with farmers in advance.

There are sometimes systemic problems, which cannot be clearly attributed to specific causes and, therefore, are difficult to be solved systematically in plant-derived production. The systems often become complex because of their lying on two different type of systems, i.e., agriculture and industry, which are different in decision makers, time scales, uncertainties and data availability. Because communication between them is insufficient, one player sometimes makes a decision that has far-reaching and potentially unpredicted influence on others' decisions and the performance of the systems. Although mere rational decision makings from the viewpoint of each player cannot always avoid systemic problems, appropriate communication within the systems may overcome them to adapt the new environment (Checkland and Scholes, 1990).

Over the decades, a simulation-based analysis has leveraged its expertise in synthesizing data to model real complex systems and to support decision makings (Klatt and Marquardt, 2009). Multi-scale modelling has been a recent challenge for the design of the systems having different temporal and spatial scales (Garcia and You, 2016). It should be a strong tool to design the systems of plant-derived production overcoming the differences between agriculture and industry, which have been obstacle to quantitative discussion.

In this study, we tackle systemic problems in plant-derived production through a case study on sugarcane-derived production with a simulation-based analysis. First, we develop a process model that can simulate mass and energy balance in a cane sugar mill considering agricultural and industrial technology options based on the site investigation, literature search and data analysis. Then, a scenario-planning meeting is conducted involving actual engineers in a cane sugar mill to verify the effectiveness of the model to generate scenarios for reaching new alternatives.

2. Materials and method

2.1. Requirements for systems design through solving systemic problems

Figure 1 shows the requirements for systems design in plant-derived production. To solve systemic problems, we propose two phases as described below: systematic approach through modelling and systemic approach with scenario-planning meeting with the model.

To avoid systemic problems, each player should recognize how his/her decision influence the whole system. It is necessary to develop a tool for analysing agricultural and industrial processes quantitatively through collecting and synthesizing data and knowledge that are dispersed across the systems. Since agriculture and industry are different in time scales, uncertainties and data availability, modelling them in an

integrated manner would be one of the challenges which process systems engineering should tackle with.

Just because a model is developed to help players to search alternatives considering agricultural and industrial options simultaneously, it does not follow that they are easily implementable for three reasons. First, the easiness of the transition highly depends on the order of options because each option would more or less have an impact on other options. Second, we should not overlook that some options need a period of time. For example, it takes several years for an unspecified large number of farmers to change the cultivar, while the constraints from externals such as regulations may change, encouraging or discouraging the player to take other options. Third, there may remain subjects that only simulation-based analysis cannot bring to light because the range of discussion with the model is limited by data availability and uncertainty from model structure. A method of planning the systems transition is needed to achieve the alternative.

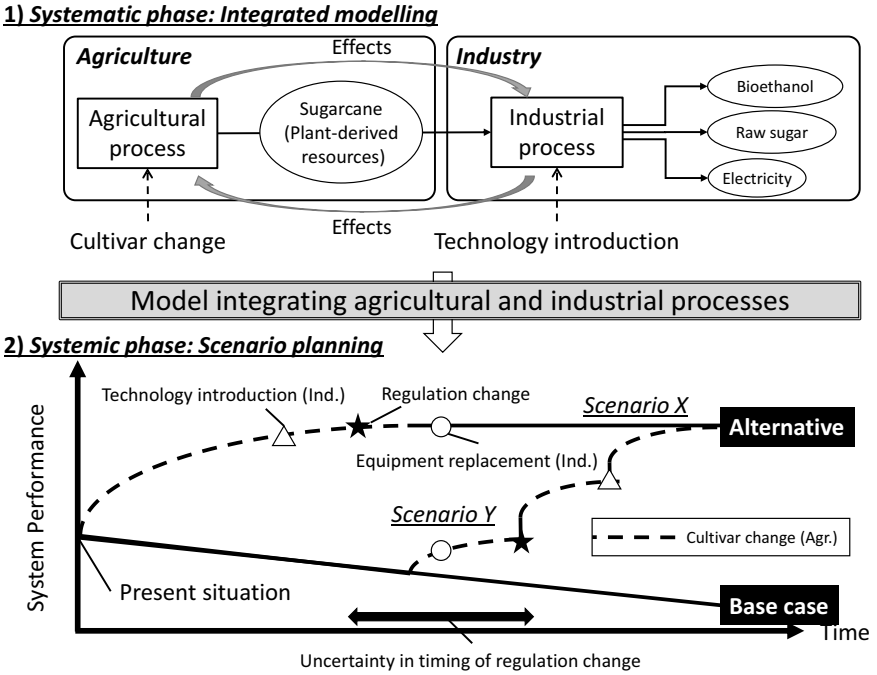

Figure 1 Requirements for systems design solving systemic problems in plant-derived production

2.2. Modelling and scenario-planning meeting

A process model that can simulate mass and energy balance in a cane sugar mill considering agricultural and industrial technology options has been developed (Ouchida et al., 2017a) and extended to analyse the effect of introducing a novel technology on the systems (Kikuchi et al., 2017). Data and information for modelling were collected through detailed investigations of actual sugar mills and literature search. This model could be a tool for promoting communication between agriculture and industry.

As a method of planning the systems transition, a scenario-planning meeting using the model was proposed in this study. A scenario-planning approach is a method for

clarifying the path to the goal and enhancing the ability to deal with uncertainties by considering the multiple possible future situations (Amer et al., 2013). A scenario-planning meeting was held on a sugar mill to generate the practical scenario to achieve the alternative.

3. Results and discussion

3.1. Development of model integrating agricultural and industrial processes

Figure 2 shows the examples of systems performances visualized by the model. Productivity, energy efficiency, lifecycle greenhouse gas emissions, economy and circulation of nitrogen, phosphorus and potassium can be evaluated considering both agricultural and industrial options simultaneously (Ouchida et al., 2016; 2017a). It also enables the implementation analysis of a technology on the systems (Kikuchi et al., 2017) and the operational decision support in the sugar mill considering the fluctuation in the quality of feedstock derived from uncertainties in agriculture (Ouchida et al., 2017b). This model has a potential of generating alternatives that a single decision maker or technology have never achieved.

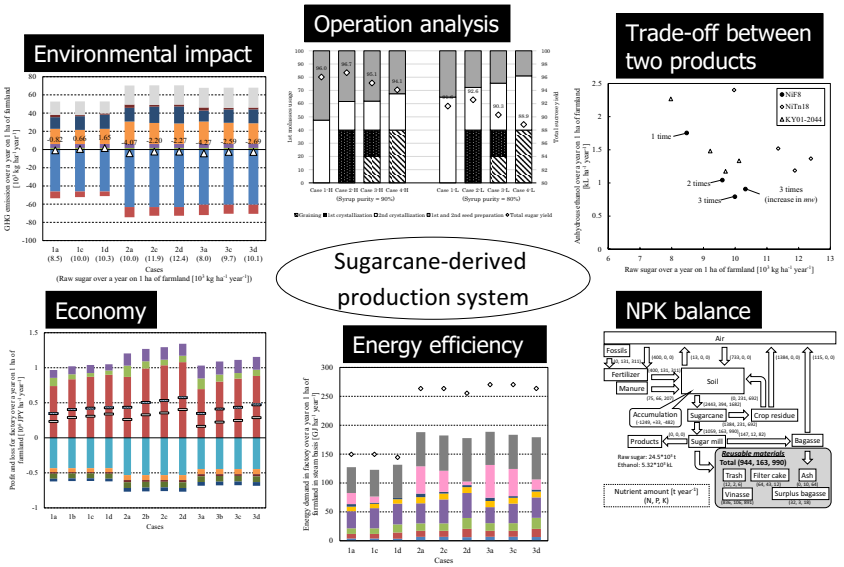

Figure 2 Visualization of systems performance in sugarcane-derived production by model.

3.2. Scenario-planning supported by model

Involving actual decision engineers in a cane sugar mill, a scenario-planning meeting was held on a cane sugar industry in Tanegashima, which is one of the islands in Japan. Tanegashima has 2,500 ha of sugarcane farmland and a sugar mill, which produces only raw sugar and the processing capacity of which is 1,500 t day^{-1}. Since the farmland area is shrinking year by year as the number of population decreases, some measures are needed to avoid the collapse of the cane sugar industry.

The model indicated that a set of key options to the systems transition are the cultivar change to the high-yielding cultivar, the replacement of the present back-pressure steam turbine with a condensing-extraction steam turbine to improve power conversion

efficiency, and starting to sell electricity. Based on the preliminary investigation on Tanegashima, it was found that the timings of the rise in the electricity price and the renovation of the turbine are crucial to the overall scenario plan. Because it is uncertain when the timing of the price rise comes, multiple scenario plans should be prepared.

One of the plans generated is shown in Figure 3. In this case, the timing of the renovation comes after the price rises and, consequently, electricity selling is highly motivated. Therefore, the mill should prepare for enhancing the benefit of electricity selling by cultivar change or energy saving before the renovation.

The feasibility of the scenario plans was discussed with actual engineers. Some obstacles to the implementation were extracted and the solutions for avoiding them were discussed. For example, an increase in the amount of bagasse by cultivar change will arise other problems such as the increase in labour loads of farmers in harvesting and the difficulty in the management of its storage. Such discussion has not appeared in the past. It can be expected that an iterative procedure of modelling and scenario planning will blush up the scenarios to make them more practicable.

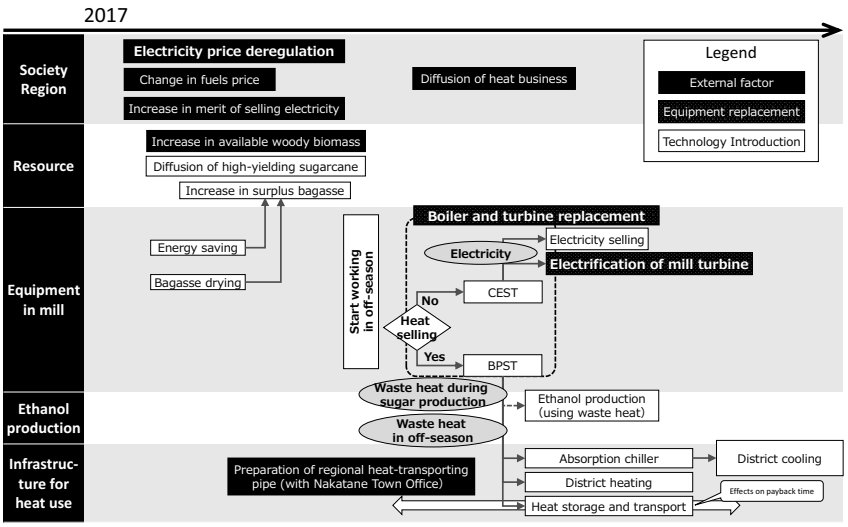

Figure 3 A scenario plan generated for the cane sugar mill and farmers in Tanegashima.

4. Conclusions

Through a case study on sugarcane-derived production, it was revealed that an integrated modelling of agricultural and industrial processes and a scenario-planning meeting using the model were effective to solve systemic problems in plant-derived production. In spite of the uncertainties, data availability and model limitations, a simulation-based approach can support alternative generations considering both agricultural and industrial options. In addition, actual decision makers can proceed to the next step through finding new challenges and generating alternative scenarios for avoiding them. In conclusion, modelling and scenario-planning meeting could deepen the discussion and contribute to solving systemic problems in plant-derived production. It can be expected that the development of the framework for conducting these procedure iteratively will intensify plant-derived production seamlessly.

Abstract

Coal or biomass gasification can be used to produce methane rich syngas and the heating value of this gas depends on methane concentration. In this research we use computational fluid dynamics (CFD) to optimize a fixed-bed gasifier to produce methane as a fuel. Only a limited amount of what is required to model gasification is available today in literature and most models fail to capture the intricate operations of a gasifier, but CFD can use this limited information to provide further information on parameters that cannot be easily and safely measured through experimentation.

Gasifier hydrodynamics, tar production, heat and mass transfer coefficients, and pressure drops are the principal areas requiring research for the modeling and optimization of a fixed-bed gasifier. A CFD model using the Euler–Euler model in ANSYS Fluent was developed to model the effect of composition and temperature on the production of tar and methane.

The results show that lower temperatures favor methane production. The devolatilization rate increases with increasing fluid solid interactions, heat and mass transfer rates. However, this lowers the methane production and hence the thermal efficiency of the gasifier. Thus, the use of CFD to optimize a fixed-bed gasifier does not only extend our knowledge of gasification and its components but moves us closer to providing the much-needed sustainable energy solutions that are easily affordable and accessible.

Keywords: Fixed-bed Gasifier Optimization, Coal and Biomass Devolatilization, Computational Fluid Dynamics Modeling, Energy Efficiency.

1. Introduction

Africa especially Sub-Saharan Africa still battles with a lack of basic service provision and a lack of basic infrastructure required to connect people to sustainable energy supplies (Butera et al, 2016; Musango, 2014). Substitute natural gas from biomass gasification could provide a solution but updraft gasifiers currently used in the gasification process are limited by their small processing throughput, and large production of waste water (Chen et al, 2011).

Tar is one of the major waste products in gasification with updraft gasifiers producing about 50mg/nm^3 compared to the required minimum of 0.1mg/nm^3. Tar production is determined by the reactor temperature, pressure, gasification medium and equivalence ratio. Passing the syngas through an external combustor before recycling it, was found to

reduce the amount of tar produced in a downdraft gasifier to minimum levels of about 0.1mg/nm^3 of tar (Susanto et al, 1996, Basu, 2010). This method has not been applied to an updraft gasifier. The purpose of this study was to use purely computational methods to simulate the impact of recycling syngas on tar and methane production in a 0.8x0.5 m^2 steel drum fixed-bed gasifier currently available at the University of South Africa.

2. Model Development

2.1. Literature Models

Most of the methane and the tar produced in a fixed-bed gasifier is assumed to come from devolatilization. Yoon (1978) studied the limits of operation of a moving-bed gasifier using a triangular diagram based on mass and energy balances. He assumed devolatilization to be thermally neutral and the inlet gas temperature to be equal to the outlet gas temperature to avoid tar condensation but focused on the combustion region of the gasifier. Hobbs et al (1992) attempted a comprehensive model of the fixed-bed gasifier removing most of the assumptions used in previous models. The devolatilization reaction was modeled using the functional group process. Tar was treated as a single species that has variable composition dependent on location in the reactor. Brundu et al (2009) considered a one-dimensional kinetic model of a fixed-bed gasifier and carried out a review of gasifier studies. They attempted using iron to reduce tar production during coal gasification. Their study modeled coal devolatilization using a global model. Murgia et al (2012) designed a comprehensive model of an air blown updraft gasifier using devolatilization data from the chemical percolation model.

2.2. Experimental Setup to be Modeled

The experimental gasifier currently stands on a raised palette and is fed compressed air from a compressor. Coal is charged from the top of the gasifier and gas is released through an outlet that is connected to a flare. The gasifier does not have a steam inlet. In our simulation, coal was charged into the gasifier forming a packed-bed. This result was achieved in ANSYS Fluent 18.2 using the region patch option and using the multiphase Euler–Euler method for the gas and solid phase. The simulation had two inlets, one for the compressed air as in the original gasifier and the other as a recycle inlet.

Two cases were run, with the first case involving zero input of syngas from the recycle stream. In ANSYS Fluent this was achieved by converting the feature type of the recycle inlet from a velocity inlet into a wall. The other case had the recycle inlet with a velocity specified together with the compressed air inlet. Syngas samples were used as the recycle inlet species composition. Changes within the gasifier in temperature, pressure, tar and methane concentrations were measured. The gasifier model was generated using design modeler and meshed using the parameters described in Table 1 below.

Table 1: Gasifier Model Parameters

Measurement	**Value**	**Source**
Density (kg/m^3)	Incompressible mixture	This study
Void fraction	0.465	Murgia et al, 2012
Particle diameter (m)	0.05-0.08	This study

Coal mass flow rate (kg/s)	Fixed bed	This study
Air velocity (m/s)	5	This study
Steam mass flow rate (kg/s)	0	This study
Wall temperature (°C)	42	Murgia et al, 2012
Bed height (m)	0.6	This study
Reactor length (m)	0.8	This study
Reactor width (m)	0.5	This study
Inlet and outlet pipe diameters (m)	0.02	This study

3. Hydrodynamics and Reaction Modeling

3.1. Hydrodynamic Model Selection

A purely theoretical computational fluid dynamics model was used to analyze the variation of methane production in a fixed-bed gasifier with temperature and pressure. The coal material used in this study was Jetson coal, with material parameters obtained from studies by Murgia et al (2012).

An Euler–Euler model was applied in this research and not the Lagrangian model to describe the behavior of coal, because the Lagrangian method was found to be more computationally expensive compared to the Euler–Euler method. The Lagrangian method is well suited for particles that are in motion such as found in an entrained bed gasifier but cannot adequately describe particles in a packed bed as in the case of the 0.8x0.5 m fixed-bed gasifier used in this research.

The Euler–Euler method applied in this model describes the phases as interpenetrating continua and this is ideal to describe fluidized bed gasifiers and in the case of a fixed bed gasifier it is more adequate for dense particle systems.

The Euler–Euler model in ANSYS does not provide an inbuilt model for the devolatilization process as the Lagrangian method does and so this study modelled devolatilization using coal as a mixture that contains three species namely char (solid carbon), volatiles and ash. All the volatiles in the coal are assumed to form methane, water, carbon dioxide, tar, carbon monoxide and char. The reaction kinetics data for the rest of the reactions within the gasifier are obtained from Hobbs et al (1992).

3.2. Computational Fluid Dynamics Modelling

ANSYS Fluent calculates the multiphase flow by solving the governing equations using numerical methods. The reactions that occur within the gasifier are included within the simulation through rate of reaction terms in the equations. Four main governing equations are solved. The mass conservation equation, the species mass conservation equation, the momentum conservation equation and the energy conservation equation.

The Euler–Euler method describes both the solid and gaseous phases as continuous phases. Therefore, the continuity equation is given by:

$$\frac{\partial(\rho\varepsilon)}{\partial t} + \Delta \cdot (\rho\varepsilon u) = \sum_{j=1}^{N} R_j \quad (1)$$

The conservation of mass of each species i is described by:

$$\frac{\partial(\rho\varepsilon Y_i)}{\partial t} + \Delta \cdot (\rho\varepsilon Y_i u) = \sum_{j=1}^{N} R_{ji} \quad (2)$$

The momentum balance equation is:

$$\frac{\partial(\rho\varepsilon u)}{\partial t} + \Delta \cdot (\rho\varepsilon uu) = \Delta \cdot S + \rho\varepsilon g - \sum_{k=1}^{N} I_{ki} \quad (3)$$

The energy balance is given by:

$$\rho\varepsilon Cp[\frac{\partial(T)}{\partial t} + u.\Delta T] = -\Delta q - Hk - \Delta Hr \quad (4)$$

3.3. Reaction Kinetics Modelling

The reactions that occur in the gasifier and the rate of reaction terms that are included in the simulation of the governing equations are listed in table 2 below:

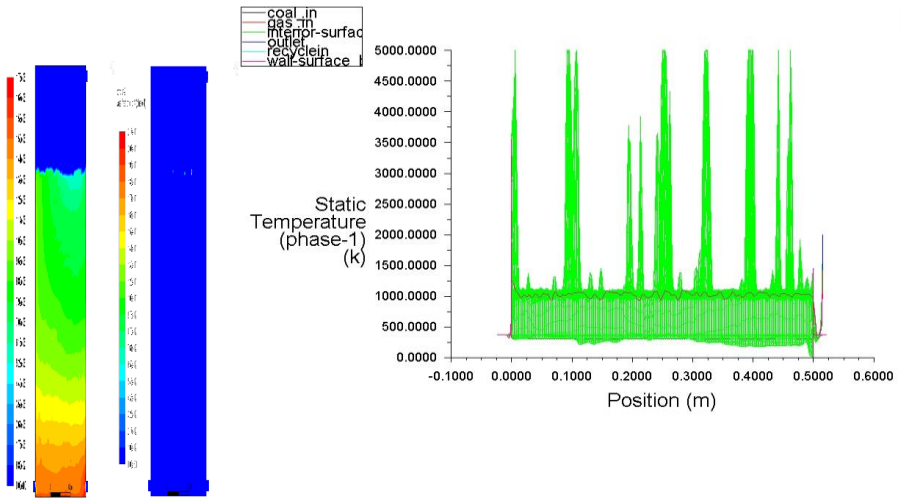
Table 2: Model Reactions and Parameters

Reaction equation	**Pre-exponential factor (m/sK)**	**Activation energy (E/R)**	**Source**
Char + 0.5 O_2 = CO	2.30	11,100	Hobbs et al, 1992
Char + CO_2 = 2CO	589	26,800	Hobbs et al, 1992
Char + H_2O = CO + H_2	589	26,800	Hobbs et al, 1992
Char + H_2 = CH_4	0.589	26,800	Hobbs et al, 1992
CO + 0.5 O_2 = CO_2	2.30	11,100	This study
CO + H_2O = CO_2 + H_2	589	26,800	This study
CH_4 + 0.5 O_2 = CO + 2H_2	2.30	11,100	This study
Coal = Char + Tar + H_2O + CO_2 + CH_4 + CO	$1.14x10^5$	8900	Murgia et al, 2012
Tar = Char +H_2O+CO_2+CH_4+CO	$1.14x10^5$	8900	this study

In this study we assumed that the reaction rate data for the oxidation of carbon monoxide, the water-gas shift and the oxidation of methane have reaction rates similar to those of the heterogeneous reactions. Therefore, literature values (Hobbs et al, 1992) were used for these reactions.

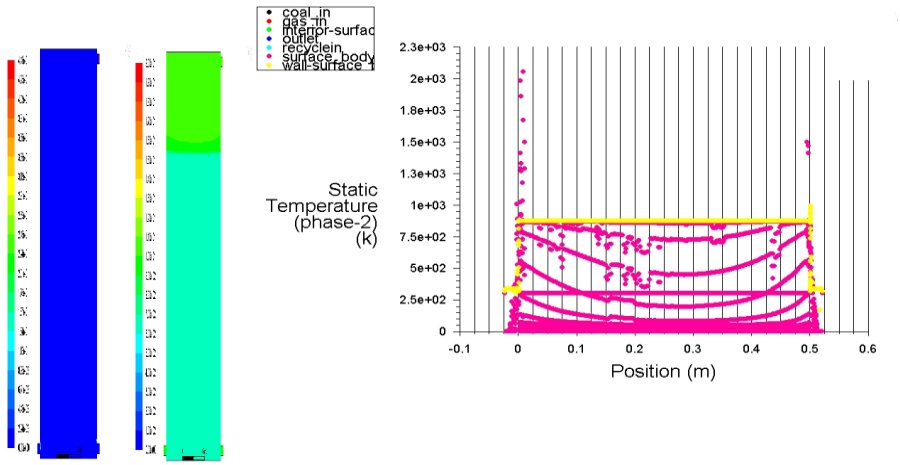
4. Results and Discussion

The CFD model results obtained for the two cases considered in this study are presented in Figures 1 and 2.



Tar methane temperature

Figure 1: Model results with zero input of syngas from the recycle stream



Tar methane temperature

Figure 2: Model results with input of syngas from the recycle stream

The results in Figures 1 and 2 should show that lower temperatures favor methane production. In the first case higher temperatures were achieved than in the second case. More methane was produced in the second case than in the first case with the opposite

occurring for tar. This suggests that the inclusion of syngas into the case reduced gas–solid interactions, heat and mass transfer within the reactor thus, reducing devolatilization and other gasification reactions. The devolatilization rate should increase with increasing fluid solid interactions, heat and mass transfer rates. However, as shown in the first case this lowers the methane production and hence the thermal efficiency of the gasifier.

5. Conclusions

The use of CFD to optimize a fixed-bed gasifier does not only extend our knowledge of gasification and its components but moves us closer to providing the much-needed sustainable energy solutions that are easily affordable and accessible. Recycling syngas into an updraft gasifier is limited by the gas–solid interactions which ultimately reduce the performance of the gasifier.

Abstract

The aim of this work is to identify profitable and environmentally benign technological paths connecting phosphorus (P) recovery with macroalgae based hydrothermal liquefaction (HTL). For this purpose, a thorough literature review of relevant technologies in different fields of application was carried out. Together with a citation network analysis (CNA) a framework comprising qualitative and quantitative information about process significance, conditions, material and energy flows for a comprehensive list of potentially involved technologies was developed. On the basis of this information framework, processes were combined into a superstructure of options for P-recovery from macroalgae based HTL. Based on criteria such as technology maturity and severity of process conditions, two different but not mutually exclusive approaches for utilizing HTL waste streams were identified: exploiting the carbon and/or the nutrients potential of the streams. The process layout selected consists of hydrothermal liquefaction, catalytic hydrothermal gasification (CHG), incineration of solid residues, acidic leaching of incineration ashes, crystallization and precipitation of P in form of magnesium ammonium phosphate (struvite), methane steam reforming and biocrude upgrading through hydrotreatment. The selected layout's model was based on HTL reaction kinetics (kinetic constants extrapolated from experiment data and verified with laboratory results from HTL of macroalgae Ulva Lactuca collected from several sites of the Swedish coast) and on performances averaging (according to literature sources) for the other sub-processes sections. Net revenues as high as 21 $\$/t_{dry\ macroalgae}$ were predicted, coming mainly from upgraded oil and a small part from struvite, while including material and energy costs for operating the system. This revenue is highly affected by the cost of the macroalgae feedstock. Finally, environmental aspects and constraints related to the process, were addressed and evaluated with the cumulative energy demand (CED) indicator, which resulted stable around 34 $MJ_{eq}/kg_{products}$.

Keywords: Hydrothermal liquefaction; Phosphorus recovery; Macroalgae.

1. Introduction

Phosphorus (P) is a biologically indispensable nutrient and its largest use is by far in fertilizers (Desmidt et al., 2015). Today almost all P is produced from phosphate rock, but the mining process is not sustainable due to the negligible mineral P regeneration rate compared to the current and the future predicted exploitation. Moreover, world phosphate rock natural reserves are unevenly distributed, with more of 70 % situated in Morocco and the Western Sahara region (Desmidt et al., 2015), making P a geopolitically strategic

element. Phosphorus recovery and/or removal is both implemented at large scales and well documented for the treatment of municipal waste waters, but in the context of hydrothermal liquefaction (HTL) both large scale experience and literature is limited. Thus, the motivation for this work was to investigate such a possibility. In fact, the biomass feed of HTL can have considerable P contents, and only a small amount of it ends in the biocrude; the rest is distributed in the HTL aqueous and solid phases which are considered waste streams. In addition, phosphorus causes eutrophication of aquatic environments and therefore P-rich streams often must be treated prior to disposal.

2. Literature review and citation network analysis

P-recovery technologies can be categorized by the P source (aqueous, solid, sludge or ashes) or by the physical principle (mechanical, chemical, biological or thermal). These processes often consist of P concentration stages and/or heavy metal (HM) removal treatments, but in most cases, precipitation is required to effectively recover useful P-containing compounds. If not precipitated, P can be concentrated in different matrices such as ashes, adsorbents, metal slags and filters, or diluted in aqueous phases and used for cultivation of yeasts or microalgae. Commercial values of the recovered P can be associated to its potential as a fertilizer. Struvite is acknowledged as a slow releasing source of highly bioavailable-P (Desmidt et al., 2015) and therefore precipitation of struvite has been preferred to other phosphorus compounds in this work. The principles of P-recovery in wastewater treatment (WWT) can be applied to HTL even though the streams vary in composition. Moreover, besides nutrients recovery, HTL waste streams can be employed for energy recovery or further exploited for biofuels production. The set of material- or energy-recovery processes integrated to macroalgae based HTL outlines the superstructure shown in Figure 1. Citation network analysis (CNA) of the reviewed literature was carried out to prioritize information sources, assess the technological

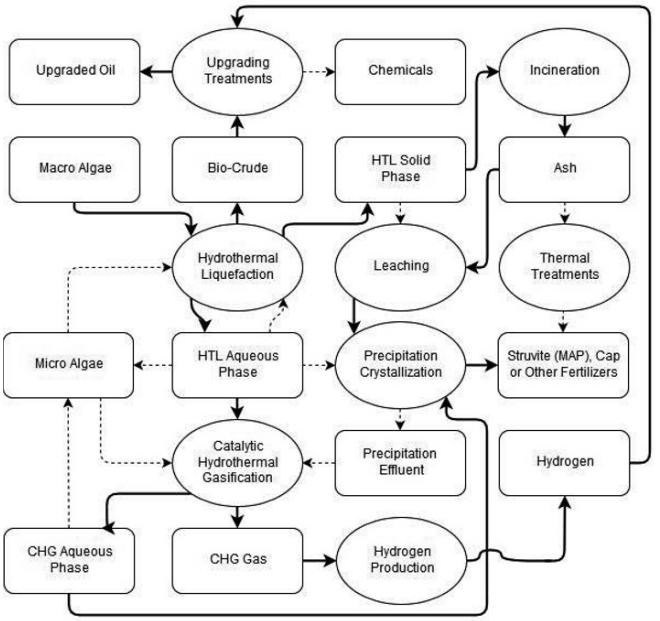

Figure 1: P-recovery for macroalgae HTL superstructure. Ovals and rectangles represent respectively sub-processes and materials. Bold arrows represent the pathway chosen in this work.

maturity of each process and highlight eventual technological affinities within the superstructure. An example of how to interpret the CNA is given in Figure 2: the temporal distribution of the sources was considered as an indicator of technological maturity, whereas the number of studies shared by two different technologies and the citations across sources of different fields were interpreted as indicators of technological affinity. Direct use of the HTL aqueous phase as a nutrients supplement for microalgae cultivation medium was initially taken into account as a valid option and successively discarded for its high costs and its poor affinity with P-recovery shown in the CNA.

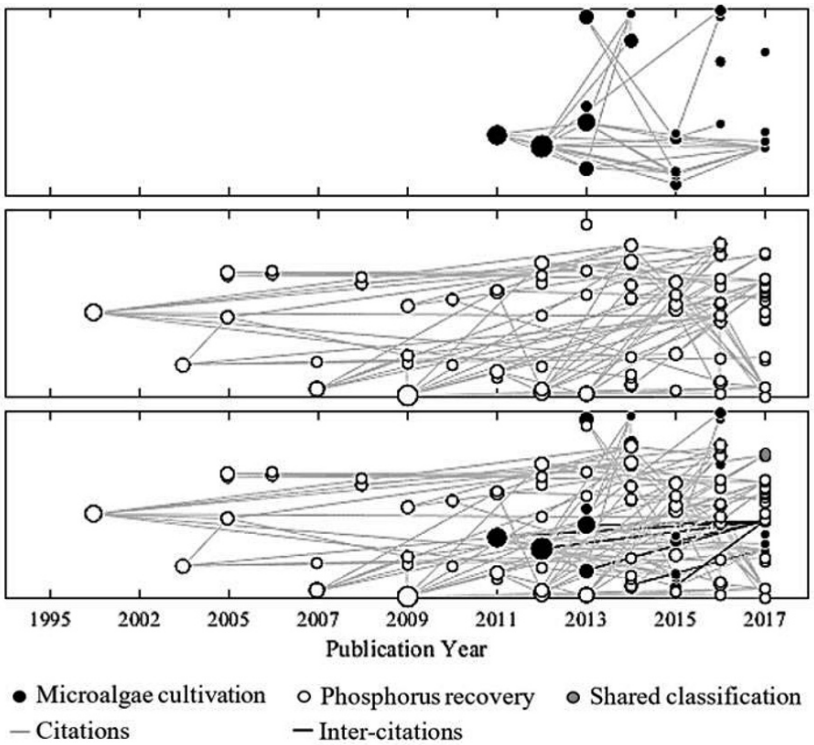

Figure 2: Citation network analysis for microalgae cultivation (top), P-recovery (center) and a combination of the two (bottom). Each circle represents a literature source, and its size is a measure of the number of times it has been cited (i.e. an indicator of its relevance for the analysis). Gray circles refer to literature sources combining microalgae cultivation and P-recovery. Gray lines represent citations within the same field, whereas black lines represent inter-citations. Gray circles and black lines are indicators of technological affinity.

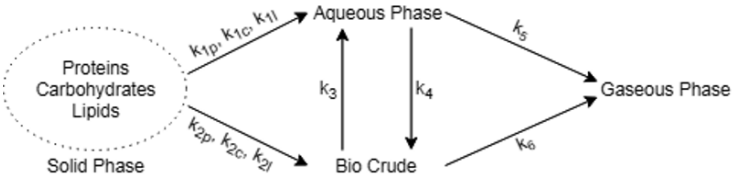
3. Methodology

3.1. HTL kinetic model

To predict the HTL output yields, the general HTL kinetic model developed by Valdez et al. (2014), shown in Figure 3, was updated using a broader set of experimental data retrieved from different sources. The experimental set-ups presented subcritical water condition and a total solid content ranging between 10 % and 20 %, whereas they differed for feedstock biochemical composition, process temperature and residence time. Two different sets of kinetic constants were calculated: for residence times shorter than 15 min and from 15 min to 90 min. Then, the results "*Y*" were merged together according to Eq.(1).



$$Y = Y_{k,\theta<15} \cdot f(T,\theta) + Y_{k,\theta>15} \cdot \left(1 - f(T,\theta)\right) \quad (1)$$

Figure 3: Reactions framework for hydrothermal liquefaction proposed by Valdez et al. (2014).

Where Y_k is the result calculated from the respective set of kinetic constants, and f is a function of T and θ (respectively the HTL temperature and residence time expressed in °C and minutes) bounded between 0 and 1 used for weighting the results according to the pertinent HTL setting. The mathematical expression of $f(T,\theta)$ is given in Eq.(2).

$$f(T,\theta) = \left[1 - \frac{1}{1+\left(\frac{T}{400}\right)^{0,6}}\right] \cdot \frac{1}{1+\left(\frac{\theta}{90}\right)^{0,6}} \quad (2)$$

The reason of this is that using only one set of kinetic constants for the whole span of residence times produced unrealistic results for HTL residence times below 15 minutes.

3.2. P-recovery

HTL aqueous phase undergoes catalytic hydrothermal gasification (CHG) as described by Jones et al. (2014). The main product of CHG is a methane-rich gas which is used for hydrogen production through steam reforming as described by Barthe et al. (2015). Hydrogen is then used to upgrade the biocrude by the hydrodeoxygenation process as reported by Jones et al. (2014). HTL solid phase is incinerated and the P remaining in the ash is then released by acidic leaching at a pH below 2. The P dissolved in the leachate and in the CHG aqueous phase is then precipitated and recovered through pH adjustments with sodium hydroxide and addition of magnesium chloride. Part of the effluent is neutralized and recirculated as process water for the leaching, whereas the rest is sent to WWT. Energy recovery has been performed through heat integration and pinch analysis. Prices and environmental impacts for material and energy flows were retrieved from Ecoinvent database v3.3 except for catalysts prices which were extrapolated from rates from online suppliers. The system operating parameters were then optimized to maximize the net revenues. Furthermore, life cycle environmental aspects were assessed through the Cumulative Energy Demand (CED) indicator.

4. Results and discussion

The results of the HTL model for the macroalgae Ulva Intestinalis having the same biochemical composition given by Neveux et al. (2013) are shown in Figure 4. These results were validated by comparison with the HTL measurements provided by (Raikova et al., 2017). The costs and the maximized revenues for three different options are shown in Figure 5. Option 1 was previously described in section 3.2. In Option 2 and 3 no leaching is performed (ash is disposed of) and in Option 3 the CHG is not performed (HTL aqueous phase directly fed to the precipitation step). The cost of performing the ash leaching is equal or even higher than the value of the struvite recovered from it, but the

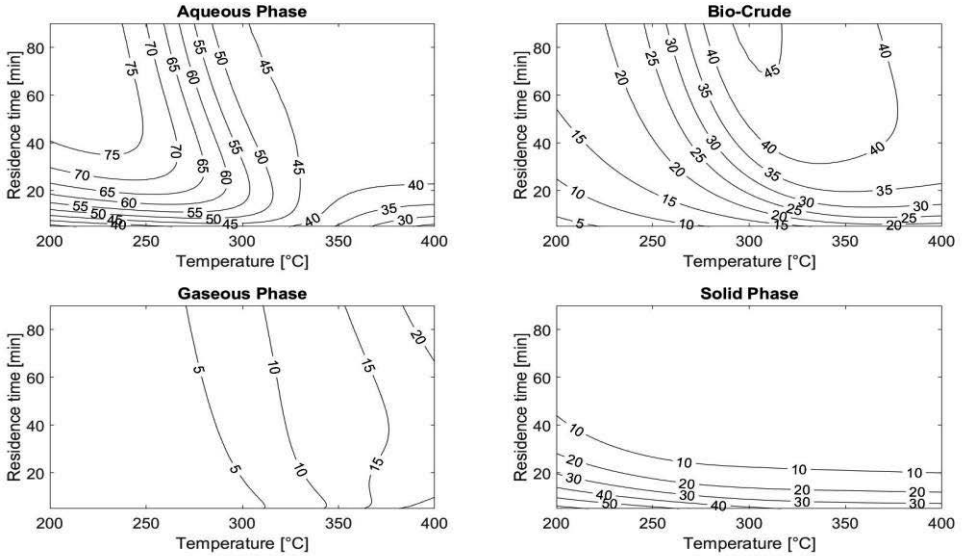


Figure 4: Predicted HTL yields as a percentage of the original dry, ash free feedstock mass.

P-content in the ash plays a key role in this assessment. Not performing the CHG leads to a substantial net revenues loss, as the aqueous phase total organic carbon (TOC) converted in the CHG becomes a cost for the waste water treatment, but might be counteracted by a reduced system capital cost. All the scenarios are heavily affected by the feedstock cost which accounts for more than 60 % of the total costs (the feedstock price being 93 $/t$_{dry\ macroalgae}$). The struvite production, peaking at 7.2 kg/t$_{dry\ macroalgae}$, has a marginal impact on the profits, but pays back its related operative costs. The CED of the three scenarios resulted stable around 34 MJ$_{eq}$/kg$_{products}$ (about 15 MJ$_{eq}$/kg$_{products}$ less

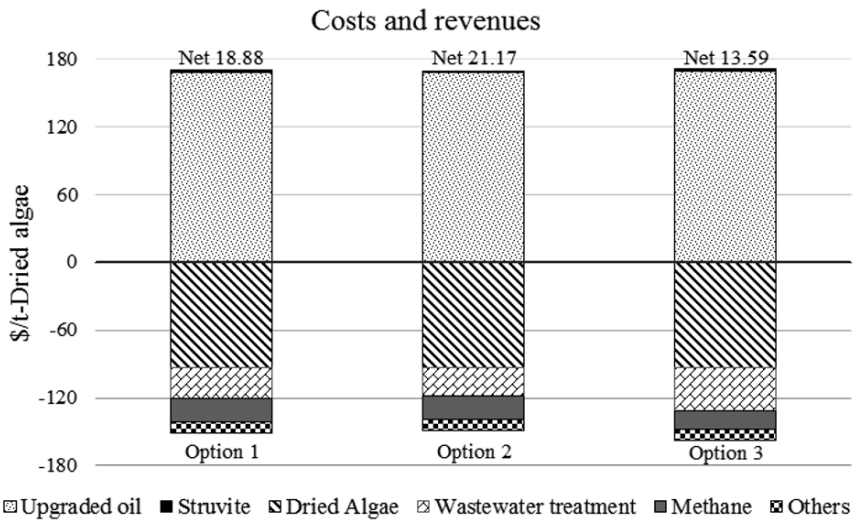

Figure 5: Operating costs and revenues for three different system scenarios.

than producing the same goods in a traditional way). Heavy metals contamination of struvite was not considered, but depending on the HM content of the feedstock a removal step could be necessary prior the precipitation (burdening on capital and operating costs and on the CED).

5. Conclusions

P-recovery could be effectively achieved from HTL waste streams treatments, diversifying the HTL product outputs. From a superstructure of process options supported by CNA and experimental data, cost effective process configurations were prioritized. Besides the phosphorous content and price of HTL feedstock, also the heavy metal content plays a key role in the economic and environmental assessment. To get more reliable results, it is important to include a capital cost analysis: for the same feedstock flow, a shorter HTL residence time would penalize the biocrude production but could substantially reduce the capital investment. Moreover, some of the most influential variables, such as the macroalgae price or the HTL yields, should be further verified. Some socio-economic factors could also affect the price setting. Main benefits include a reduced reliance on terrestrial biomass and enhanced energy security. Hindering factors are the early use of immature technology, which in combination with general negative public perception and conflicts with shipping lanes and anchorage space caused by the algae cultivation may pose significant risks for a smooth process learning period.

A Data-Driven Approach for Design and Optimization of Energy Storage Systems

Lanyu Li, Xiaonan Wang*

Department of Chemical and Biomolecular Engineering, National University of Singapore, Singapore 117585 Singapore
chewxia@nus.edu.sg

Abstract

Energy storage systems are becoming an essential support for modern living. Since it is important but challenging to select the best energy storage technologies for the applications, this work aims to develop a data-driven optimization approach for energy storage selection as a decision-support tool for the decision makers. Technical suitability, economic feasibility and environmental impact were considered as objective criteria for selection and an augmented ε-constraint was used to find the efficient solutions for the multi-objective optimization problem of energy storage selection. A case study on arbitrage and voltage support applications was conducted. The optimal technologies for the applications was generally consistent with the common choices in literature. This model can be applied to the more complicated energy storage selection processes with more technologies, objectives and constrains taken into account.

Keywords: energy storage, technology selection, optimization, economic, environment

1. Introduction

Energy storage systems (ESS) play a critical role in the transformation from the current fossil fuel dependent energy systems to a low carbon-emitting, environmental-friendly and sustainable energy landscape, since they not only provide essential support for promoting the development of multiple evolving technologies in the energy sector such as renewable energy utilization, distributed micro-grid, and electric vehicles, but also offer a lot of benefits when integrated into the grid (Wang et al. 2015; Zhao 2016; Wang et al., 2017). Owning to the substantial research effort, a lot of energy storage technologies have been developed and their applications can be found across the power grid falling into the categories of customer energy management, transmission and distribution (T&D) support, and bulk power management (Huff et al., 2013). As it is shown in Figure 1, each of these technologies has its unique characteristics that make it only compatible with certain applications. As more and more energy storage technologies and applications are developed, it is necessary to develop a convenient tool for energy storage selection.

Although the development, characteristics and applications of energy storage technologies are widely discussed in review papers and technology roadmaps, only few publications have discussed the quantitative methods for energy storage selection. ES-select is the most comprehensive energy storage selection tool which is able to rank the energy storage technologies by their feasibility scores calculated by a weighted sum of technology feasibility, installation cost, maturity, and location feasibility (KEMA, 2012). Similarly, Raza et. al (2014) developed the sustainable index approach for energy storage

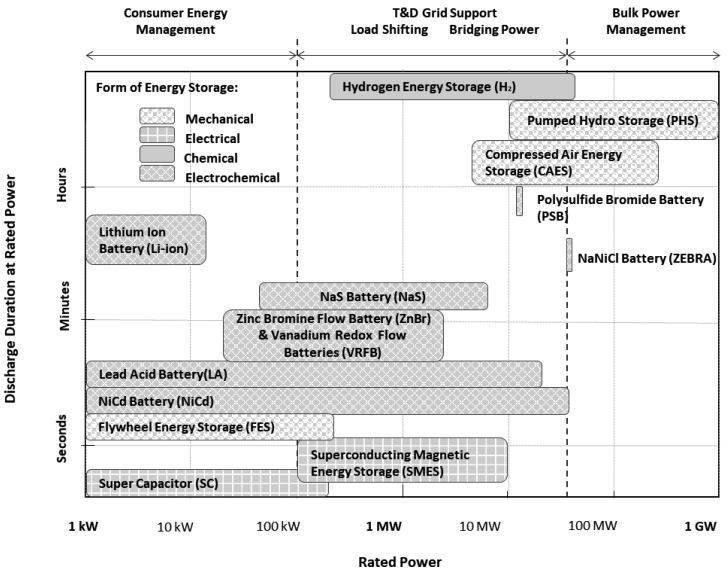

Figure 1 Characteristics of different energy storage technologies (adapted from Lawson, 2017)

technology selection for renewable energy application by ranking the technologies after assigning index to the evaluated factors and calculating a total score using the weighted sum of the normalized factors. Walker et al. (2016) used an AHP approach to study the feasibility of using different types of emerging chemical energy storage technologies for several key grid scale EES applications. However, the methods mentioned above belong to a priori methods where decision makers need to assign weighting factors and scores to evaluate the suitability of the technology for the applications, which is subjective and require a great deal of experience and expertise of the decision makers.

In this study, a data-driven multi-objective optimization approach, which is a posteriori method where efficient solutions of the problem are generated for decision makers, is proposed for the selection of energy storage technology. It is more convenient for decision-makers, especially those who is lack of expertise in this field, to select the technologies when the all possible optimal alternatives are generated by the optimization approach, compared with the previous a priori methods. In the following sections, the method and model for energy storage selection will be presented in Section 2. A case study and the results will be presented and discussed in Section 3, and conclusions and future work provided in Section 4.

2. Method

Three major criteria including technical suitability, economic feasibility, and environmental impact are considered for the selection of the energy storage technology. In this section, the detailed description of each of the criteria is given.

2.1. Technical Suitability

Generally, the two main characteristics that establish the potential set of suitable applications for a specific storage technology are rated power (P) and rated energy (E) (European Commission, 2017). In the current work, power and discharge duration are

selected to be the main factors for the technical suitability assessment because it is more common to use discharge duration (t_D) to represent rated energy as the relationship between them is:

$$E = P \cdot t_D \tag{1}$$

The technical feasibility (*TF*) for the matching between energy storage technology and application is evaluated by an overlapping coefficient (*OVL*). When the distribution density functions of the characteristics for both the technology (f_1) and the application (f_2) are known, the probability that an energy storage technology can be used for the application is the area under the two density functions, that is, the overlapping coefficient. It can be calculated by (Larson, 2014):

$$OVL = \begin{cases} \int_{R_n} \min[f_1(x), f_2(x)]dx, & \textit{Continuous distribution} \\ \sum_x \min[f_1(x), f_2(x)], & \textit{Descrete distribution} \end{cases} \tag{2}$$

Then the calculated *OVL* for the characteristic of the technology can be plug into Eq.(3) to calculate the total technical feasibility. w_P and w_D are weights for the factors and $w_P = w_D = 0.5$ since it was assumed that the power and discharge time which decides the total energy per charge cycle are equally important technical factors.

$$TF = w_P \times OVL_P + w_D \times OVL_{t_D} \tag{3}$$

2.2. Economic Feasibility

By assuming that different technologies bring the same revenue for a specific application, the economic performance can then be simplified to the cost of the energy storage system. A typical way of cost analysis for energy storage systems is using levelized cost of storage (*LCOS*). Recently, Zakeri and Syri (2015) conducted a thorough review and analysis on the levelized cost of energy storage system. Their method of cost analysis is commonly recognized and used in this model. The equations are shown below:

$$CRF = \frac{i(i+i)^T}{(i+i)^T - 1} \tag{4}$$

$$C_{OM,a} = C_{FOM,a} + C_{VOM} \cdot n \cdot t_D \tag{5}$$

$$C_{R,a} = CRF \cdot \sum_{k=1}^{r} (1+i)^{-kt} \cdot \frac{C_R \cdot t_D}{\eta} \tag{6}$$

$$C_{DR,a} = C_{DR} \cdot \frac{i}{(1+i)^T - 1} \tag{7}$$

$$C_{CAPEX,a} = CRF \cdot C_{CAPEX} = CRF \cdot (C_{PCS} + C_{ESS} \cdot t_D + C_{BoP}) \tag{8}$$

$$LCOS = \frac{C_{LCC,a}}{n \cdot t_D} = \frac{C_{CAPEX,a} + C_{OM,a} + C_{R,a} + C_{DR,a}}{n \cdot t_D} \tag{9}$$

where *CRF* is the recovery factor, *i* is the interest rate during the lifetime *T*, n is cycles per year, and η is cycle efficiency. C_{OM}, C_R, C_{DR}, C_{CAPEX}, C_{Lcc} are operation and maintenance cost (containing fixed and variable O&M C_{FOM} and C_{VOM}), replacement cost, discharge and recycle cost, capital cost, and life cycle cost, respectively. Subscript *a* denotes annual values.

2.3. Environmental Impact

The environmental impact of the system is not only the impact that is induced during the operation of the system, but also the amount resulted from its manufacturing, disposal and decommissioning processes. A lifecycle impact assessment (LCIA) involving the major environmental impact of the system throughout its lifecycle is a systematic and common way to evaluate the environmental impact of a system. In this study, ReCiPe point as a commonly used endpoint LCIA evaluation method, is adopted as indicator for the environmental performance of the technologies. The data and method is based on the energy storage system LCA study conducted by Oliveira et al. (2015), where the environmental impacts on climate change, human toxicity, particulate matter formation and fossil depletion were assessed and aggregated into a single ReCiPe endpoint in hierarchist version using European normalization and average weighting set.

2.4. Model Formulation

This work aims to identify one optimal energy storage technology that has high technical suitability, low cost and low negative environmental impact for a given application. To achieve this goal, a multi-objective optimization method is applied and the formulation of the problem is shown in Eq.(10), where z_i is a binary variable with 1 meaning selecting the technology i and 0 otherwise.

$$\begin{cases} \max\ T(z_i) \\ \min\ C(z_i) \\ \min\ E(z_i)) \end{cases} \quad \text{where} \quad \begin{cases} T(z_i) = \sum_{i=1}^{p} z_i \cdot TF_i \\ C(z_i) = \sum_{i=1}^{p} z_i \cdot LCOS_i \quad s.t.\ \sum_{i=1}^{p} z_i = 1 \\ E(z_i) = \sum_{i=1}^{p} z_i \cdot LCIA_i \end{cases} \tag{10}$$

The model is implemented in GAMS as a Multi-objective Mixed Integer Programming (MOMIP) problem using CPLEX solver. An augmented ε-constraint method proposed by Mavrotas (2007) is used to produce the efficient solutions to the problem.

2.5. Data Collection and Model Implementation

The considerable projects for different energy storage technologies generate a large amount of data describing the technical, economic and environmental features of the energy storage technologies and applications. In order to carry out an effective selection of the technologies for an application, descriptive statistics can be used to capture the main features of the technology and the applications from the abundant data. In this study, it is assumed that the distribution of the technologies and the applications for different characteristics follows normal distribution and the average value of the characteristic for each technology or application is used to represent the population. The data for economic and technical features of the energy storage technologies are mainly from Zakeri and Syri (2015) and the environmental impact data of the technologies are from Oliveira et al. (2015) and other data sources.

3. Case Study and Discussion

3.1. Technologies and Applications for the Case Study

Two bulk energy management applications, arbitrage and grid voltage stability, were chosen to be the application scenarios for this study. As is shown in Table 1, these two

applications have distinct technical features as arbitrage requires long discharge duration, while voltage stability application requires fast response and short discharge duration.

Table 1. Characteristics of the energy storage applications

	P (MW)	t_D	Cycles (per year)	Lifetime (y)
Arbitrage	10-300	2-10 h	350	25
Voltage stability	10-500	1 s	10	25

Figure 1 shows the basic information about the large variety of the energy storage technologies and their key technical characteristics (i.e. rated power and discharge duration) that are investigated in this case study.

3.2. Results for the Case Study

Figure 2 shows the evaluation of the key criteria, which are TF_i, $LCOE_i$ and $LCIA_i$, in the optimization process for the selection of energy storage technologies. The optimal set of efficient solutions of energy storage technologies for each application was returned by the multi-objective optimization as it is shown in Table 2. The most economically feasible, most technically suitable and least environmentally influential technologies for the applications highlighted in Table 2 can be obtained by individual optimization of each objective or interpreted from Figure2. The efficient solutions other than the above discussed cases are the one that has the advantage of compromised technical, economic and environmental performance, such as SC and VRFB for arbitrage application.

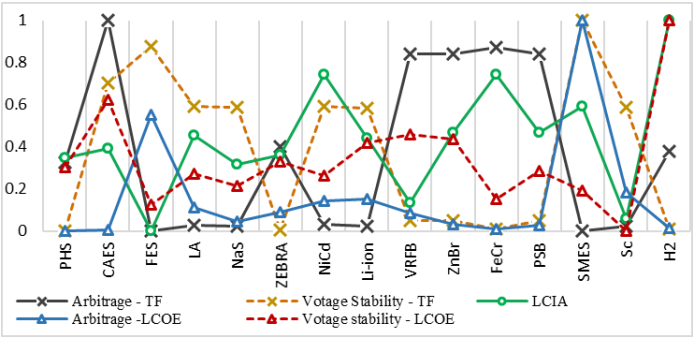

Figure 2. Trend for TF_i, $LCOE_i$ and $LCIA_i$ with varying technologies for arbitrage and voltage stability applications, where values are normalized.

Table 2. Efficient solutions returned by the optimization of energy storage technologies selection model for the arbitrage and voltage stability applications.

	Highest technical suitability	Lowest cost	Lowest environmental impact	Other efficient solutions	
Arbitrage	CAES	PHS	FES	SC	VRFB
Voltage stability	SMES	SC	FES	-	-

In general, CAES and PHS are energy storage technologies with large global deployment capacities and they are suitable for large-scale energy storage such as arbitrage, flow batteries are also good candidates for applications with discharge duration for more than 5 hours, and FES, SMES and SC are typical energy storage technologies with fast response and they are suitable technologies for short-duration energy storage. Therefore,

the results for voltage stability application are reasonable. But the FES and SC appear to be not technically suitable for the arbitrage application. They are included in the efficient solution set mainly because they are at the low end of environmental impact. In short, the result of the optimization is reliable and consistent with the recommended selections in the literature.

4. Conclusions and Future Work

This work developed an optimization approach to identify the optimal energy storage technology for a specific application. Several objectives including minimizing cost, maximizing technical suitability and minimizing environmental impact of the selected technology were considered in the selection process. An augmented ε-constraint method was used to find the pareto-optimum for the model. The result from the optimization for a case study on utility-scale applications was reasonable and this model can be applied to the larger system with more technologies and constraints. Although technical feasibility is modelled as an objective to be maximized in this conference paper, some technical requirements, such as the suitable range of the rated power and discharge duration for the applications, usually appear to be prerequisites for the selection. Therefore, as future work, several key technical requirements will be formulated as constraints in a journal article extended from on this paper.

Comparative study on LCA co-product allocation method of bioethanol production in the development from sweet sorghum stem

Haoyu Liu, Tong Qiu*

Department of Chemical Engineering, Tsinghua University, 100084 Beijing, China
qiutong@tsinghua.edu.cn

Abstract

The biofuels technology in development stage have totally different separation and recycling of co-product compared with industry products, for which the greenhouse gases (GHGs) and energy consumption (EC) associated with different co-product allocation method of life cycle analysis (LCA) could apparently change. This study explores the impact of different co-product allocation method of fuel ethanol from sweet sorghum stalks using advanced solid state fermentation (ASSF) in china. The scenario analysis is utilized to predict the industrial application and recycling of co-product. The result reveal that apparent differences exist in different allocation method. Hybrid allocation is recommend to deal with different co-products. The performance of ASSF will be further improved by recycling the co-product and separation technology.

Keywords: Life-cycle analysis, Co-product allocation, Biofuels, Scenario analysis

1. Introduction

China is currently the world's largest oil consumer and GHGs emitter (EIA. 2014). Bio–ethanol derived from energy crop has been promoted by the Chinese government because of its capacity to reduce fossil consumption and GHGs emissions(Hao, Dunn et al. 2013). Ethanol from corn started being produced in 2002 and china has become the third largest producer and consumer of bio-ethanol, after the United States and Brazil(Ding, Yang et al. 2017). However, the concern about food safety promote the government to impose a ban on expanding maize and other grain-based bio-fuel production(Hong, Yuan et al. 2009). The study of second-generation biofuels has become an international trend to address these problems, while how to calculate the emission and reuse the non-energy co-product in the production process is the biggest controversy of non-food feedstock(Giarola, Shah et al. 2012).

Sweet sorghum stalks (SSS) have recently received attention as one of the most promising second-generation crop for bioethanol production in China because of its high photosynthetic efficiency, high biological yield, strong resistance, wide adaptability rich, as well as clean and relatively low production cost(Wang, Chen et al. 2014). The advanced solid state fermentation (ASSF) technology for fuel ethanol production from SSS was developed by the Chinese scientists. The pilot plant of this new technology is successfully applied in Inner Mongolia, located in northern China, where is estimated that there may be as many as 4.4 million hectares of land suitable for SSS planting, occupying 13% of this land(Han, Wang et al. 2010).

However, there are two controversy problems about ASSF: whether it is environment friendly and whether it is energy saving. Life cycle analysis is a tool to assess these problems. Tian, Y. S. established energy consumption and GHGs and other impact facts about ASSF, and the results showed SSS-based bioethanol making feasible from the view point of energy production(Tian, Li et al. 2011). Ding, N. reported that ASSF has advantages in terms of energy consumption but lack superiority in the GHGs(Ding, Yang et al. 2017). The different results are lead by the different co-product allocaiton of LCA they used. Because of the two kinds of co-product (the sweet sorghum grain and the dried distillers) existed in the production process, lack of systematic and suitable allocation method will strongly influence the GHGs and energy consumption results.

In recent years, a wide variety of co-product allocation method of biofuels has been proposed. Although the ISO14040 advocates the displacement method, and the mass, energy, market method are also adopted for different situations in studies(Wang, Hong et al. 2011). Jong compared the well-to-wake GHG emission performance of multiple renewable jet fuel conversion pathways and explored the impact of different co-product allocation method, and recommend using energy and economic allocation (for non-energy co-products)(Jong, Antonissen et al. 2017).Compared to the industry products, they discussed, the new biofuels technology, like ASSF, is deficient in separation and recycling of co-product, and the uncertainty of given process parameters is obvious. Error will be apparent in the result of LCA without solving these problems. The importance of this problem was also discussed by experts(Report, 2014).

Thus, the differences of ASSF laboratory data using multiple allocation methods is compare in this article. Four allocation methods are combined to analyze the uncertainty of the two kinds of non-energy co-product. Scenario analysis is utilized to predict the industrial application effect and reusage of biofuels in development stage, and the process replacement method is used to simulate the product heat transfer network and recycling. This life cycle process covers data from Chinese SSS-based bioethanol used ASSF. The energy consumption and GHG emissions are examined through the overall process. The result indicate that the scheme of co-product allocation has significant impact on the conversion period. Compared to the case of industrial applications, the effectiveness of the results is enhanced improved, the formation of a multi-scene analysis results is useful for policy makers.

2. Methods

2.1. LCA framework

A cradle-to-gate LCA was performed with GaBi ts Education software. The analysis focused on determine the energy consumption and GHGs of ASSF-based ethanol produced by the pilot plant in Inner Mongolia, to compare the results with different co-products allocation method and to find an eco-friendly heat transfer network and recycling.

2.2. System boundary and functional unit

The stages considered and the calculation logic of the energy consumption and the GHGs of the entire process is present in the Figure 1, including the plant cultivation, production and transport process. Effects of fertilizer emissions and land use change will not be considered for the moment due to the data given in the IPCC Guidelines have large deviations. The assessments were compared on the basis of their GHG emissions in g

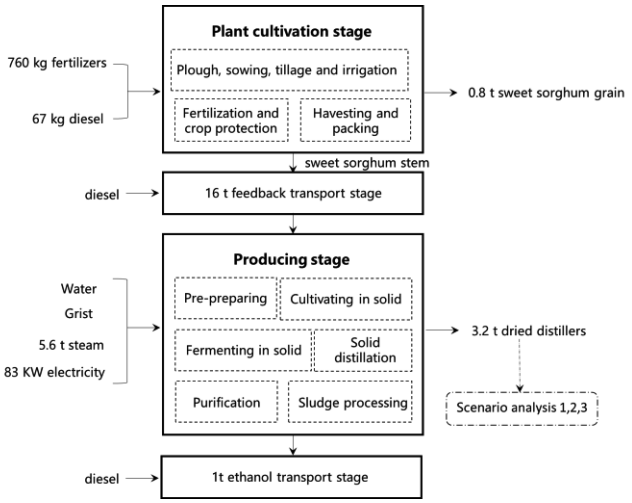

Figure 1. Product system boundary of this study.

CO2 per MJ_LHV_bioethanol and energy consumption MJ per MJ_LHV_bioethanol means of bioethanol produced from sweet sorghum stem in higher heating value.

2.3. Product system description

The ASSF technology in the lab mainly include pre-preparing, cultivating in solid, solid-state fermentation, solid distillation, purification, sludge processing. While there isn't sludge processing to deal with co-product in the pilot plant. An average of 1 t of ethanol produces 3.2 t of dried distillers, which is the biggest co-product produced in the pilot process.

2.4. Method to deal with two kinds of co-products

Three different means is suitable for this system: energy, mass and economic method. While benefits and disadvantages exist for each method. The non-energy coproduct is not suitable for energy allocation. For instance, the commercial crop, sweet sorghum grain, can't be valued by burning to get the energy. The mass allocation is limited to material products and cannot be used on immaterial products such as electricity. The third method economic allocation may be affected by the price fluctuations, geographical location or market distortions, especially for the non-commoditized products.

2.5. Scenarios for reusing the co-products

For the further applications, the distillers that can be used for forage or biogas will be comprehensive utilized. We gain the data from the pilot plant and the farmers. The possible systems for recycle the co-product, dried distillers, are divided into 3 scenarios: Scenario 1: Half of the dried distiller produces steam achieving self-supplied though burning, the other half is used to get biogas, biogas residue and biogas slurry turn to be fertilizer; Scenario 2: All the dried distiller are burned to achieve steam supply, Waste water is used to product biogas; Scenario 3: All dried distiller produce biogas, where need extra coal. The biogas is used to produce steam, while biogas residue and biogas slurry is used as fertilizer.

Table 1 Parameter about ASSF

Item Parameter	Value	Item Parameter	Value	Item Parameter	Value
Planting		**Pre-preparing**		**Cultivation**	
Nitrogen fertilizers (kg/ha)	600	Sweet sorghum stem (t/ha)	16	Electricity (kw)	15
Phosphorus fertilizers (kg/ha)	160	Electricity (kw)	41	Steam in 100℃ (t)	0.1
Diesel used in farming (kg/ha)	67	Steam in 100℃ (t)	0.1	Grist	0.17
Sweet sorghum stem (t/ha)	60	**Distillation and purification**		**Transport**	
Co-product: sweet sorghum grain (t/ha)	3	Electricity (kw)	6	Distance (farming and plant) (km)	25
LHV of SSS (MJ/kg)	4.56	Steam in 140℃ (t)	5.5	Distance (plant and market) (km)	300
LHV of grain (MJ/kg)	27.27	co-product: dried distillers (t)	3.2	Ethanol heat value	29.29
Fermentation		Water	264		
Electricity (kw)	21				

2.6. Life cycle inventory

Based on the investigation with the technology developer and farmers, open LCI databases and references, the LCA parameter is showed in the Table 1.

3. Result and discussion

3.1. Energy consumption and environment emissions

The contribution of different energy inputs and different processes to the energy consumption and the environment emissions are showed in the Figure 2. The total energy efficiency is 1.27MJ/MJ. The distillation and purification unit exhibits high contribution to EC due to the high steam input. Including the emission of all the co-product, the total GHGs is 116 g CO_2 /MJ and the ratio of stages is similar to the EC. To reduce the GHGs, we can consider enhancing the separation efficiency or using co-product to supply energy. Besides, the plant size is also to a factor that influence the consumption of coal.

3.2. Comparison between allocation methods

In this case, there are two process need to be allocated: the allocation of SSS and grain during plant cultivation stage, and the allocation of bioethanol and dried distillers during production stage. To illustrate the impact of two kinds of co-product, Figure 3 shows that the emissions for the SSS-based bioethanol range between 30 and 84 g CO_2 /MJ for different allocation methods. Huge sensitivity exists in the energy allocation for the grain and dried distillers, as is not the direct fuel. In the first stage, economic allocation is considered to be the best choice because the SSS will be waste if not used to fabricate

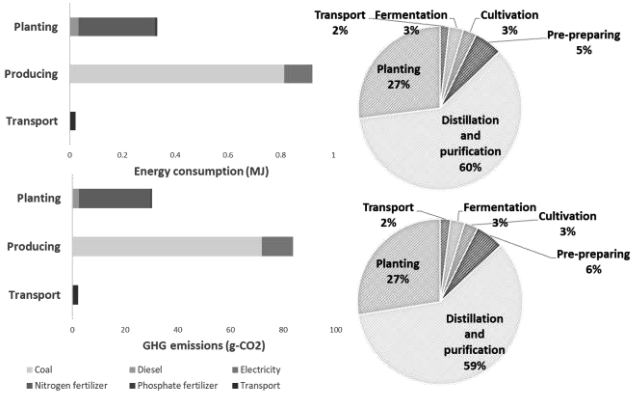

Figure 2. GHG emission and energy consumption in each production process of ASSF.

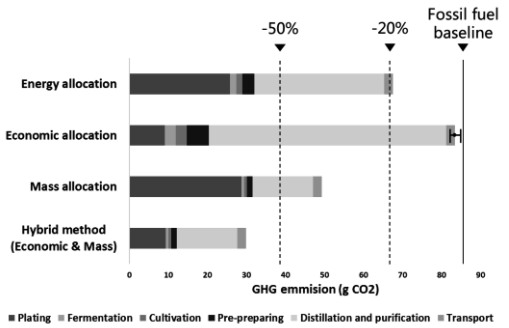

Figure 3. GHG emissions for ASSF using different allocation methods.

bioethanol. The factory can get SSS with a low price and the non-energy grain gain a big share. The mass allocation is most suitable for the ethanol production stage, in which the stem is not the main crop but a co-product and no one will buy distillers. So a hybrid allocation way, in which the first stage used economic allocation and the second stage used mass allocation, is utilized to prove the importance of allocation. To conclude, choose a suitable allocation way is important in LCA study.

3.3. Scenario analysis for the recycling of the co-product

Figure 4 shows that energy consumption and GHGs are greatly improved in each scenario, in which recycling the distillers will get the unexploited energy due to the low conversion ratio of the stem. The high energy efficiency in the scenario 2 by directly burning lead the negative emissions. Scenario 1 and 3 can be enhanced by using high-efficient biogas conversion method. From the scenario analysis we can draw the conclusion that comprehensive utilization about the co-product especially like dried distillers will be apparently positive to the environment impact.

4. Conclusion

The life cycle analysis about the ASSF in the Inner Mongolia is conducted in this study. Different allocation method (energy, economic, mass allocation) is utilized to illustrate the importance of how to calculate the co-product (especially the non-energy co-product). The effect and uncertainty of the biofuels in the development stage is compared by the scenario analysis, using process replacement method. Compared the single allocation and hybrid allocation, the biggest differences are found for non-energy product in the two process of production, which is more suitable for the mass allocation and economic allocation. With the idealized hybrid allocation, the result of GHGs in the ASSF is 30 g CO_2 /MJ. Scenario analysis showed the systematic and comprehensive utilization of

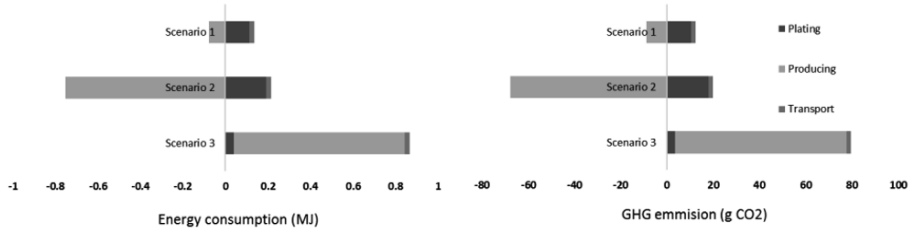

Figure 4. Three scenario analysis for reusing the co-product.

co-product will improve the environment impact. Reusing vinasse as the fuel and better separation of the product could significantly enhance the energy efficiency. Further study can focus on the scale of the heat transfer network in the pilot plant to recycle the co-product, the formation of a multi-scene analysis results is useful for producer and policy makers.

Abstract

We visualized the network between design variables and product functions in a supply chain of product for sustainable packaging design. The multi-functional product design affects multiple processes in the supply chain including consumption process, while there are trade-offs between product functions because enhancing one functionality for sustainable supply chain could decrease another functionality. Visualizing the relationships between product functions and design variables as network structure supports to grasp the trade-offs in the design stage and to perform sustainable process and product design. Several case studies were performed to verify the proposed network structure, and design condition of the case studies was to decrease the content losses in consumption process. As a result, the proposed network structure reflected the difference of the product function and identified the loss reduction to decrease total environmental impacts by scenario analysis of consumption process.

Keywords: process and product design; food packaging; life cycle assessment; sustainable consumption and production; scenario analysis.

1. Introduction

Packaging has a lot of functions to provide benefits for stakeholders in a supply chain of a product, such as productivity, preservation of its content and usability. There are various requirements for product functions in the supply chain, and a packaging designer takes the requirements into account. To ensure different functions of the packaging, the packaging designer performs process and product design concurrently, and expressing product functions by packaging design affects multiple processes beyond production line. Linking packaging design with logistics is significant to develop a sustainable supply chain (García-Arca et al., 2017), which indicates that boundary expansion supports sustainable packaging design. In addition, consumption process needs to be included into the design boundary because there are high impacts from consumption process. For example, in a case of breakfast cereals, milk as an input of consumption process has a large contribution to CO_2 emission in a supply chain as well as the ingredients of the product (Juswani et al. 2015).

Packaging functions can prevent one of the crucial topics for global sustainability: food losses. Food losses are highly dependent on consumption process and cause environmental impacts (Wikström et al., 2014). We also presented the relationship between consumer behaviours and environmental impacts by scenario analysis (Yokokawa et al., 2018), and the effects of some of the packaging functions were

indicated. However, there remains a need to develop a support tool for the designer to obtain the effects of their decision-makings, i.e., decisions of product and process design variables for realizing product functions, on the supply chain.

The objective of this study is to visualize the network structure among process and product design variables and product functions in the supply chain of product for sustainable packaging design. The relations among variables and product functions were modelled, then they were structured by a matrix and visualized as a network structure. The proposed network structure was applied to milk in carton as a case study to show applicability of the network structure for packaging design.

2. Network visualization of design variables and product functions

2.1. Modelling the relationships

Design variables and product functions are regarded as attributes allocated to a supply chain. These attributes in the supply chain of packaging and its contents were identified, and the relationships were modelled by Eqs. (1)–(3):

$$I_l = g_l(\boldsymbol{V}, \boldsymbol{F}, \boldsymbol{P}) \tag{1}$$

$$F_m = h_m(\boldsymbol{V}, \boldsymbol{P}) \tag{2}$$

$$P_n = k_n(\boldsymbol{F}, \boldsymbol{P}) \tag{3}$$

$$\boldsymbol{I} = (I_1, I_2, \dots), \boldsymbol{V} = (V_1, V_2, \dots), \boldsymbol{F} = (F_1, F_2, \dots), \boldsymbol{P} = (P_1, P_2, \dots)$$

where I_l, V_j, F_m, P_n are the l-th objective function, the j-th product design variable, the m-th product function, and the n-th process design variable, respectively. Objective functions can be economic indicators such as cost, and environmental indicators such as life cycle CO_2 emission. From Eqs. (2) and (3), process design variables and product functions interact with one another. These equations prescribe the rules of visualization of relationships among attributes, and they represent a superstructure of the relationships among attributes and objective functions. The modelling reflects the multiple effects of the variable changes on the supply chain into the assessment of objective functions.

2.2. Structuring the relationships as a matrix

The relationships between one attribute to another modelled as Eqs. (1)–(3) were structured as a square matrix in which all attributes, i.e. $\boldsymbol{V}$, $\boldsymbol{P}$ and $\boldsymbol{F}$, are aligned in the row and column.

Figure 1 shows an excerpt of the matrix and the procedure to use the matrix for packaging design. In four steps shown in Figure 1, the spread of multiple effects on the supply chain by design change to fulfil one function is illustrated. As shown in the Step I, after deciding a product function to be enhanced (column F_5) to satisfy a request from the supply chain, the packaging designer seeks design variables for functionality enhancement. The shaded cells indicate the existence of relationships between the attributes. In this case, the rows V_1 and P_2 have relations with the column F_5. Then, as shown in the Step II, the designer can identify the effects of design change on the other functions. In this case, a design change of V_1 affects on F_9 as well as F_5. As shown in the Step III, the designer can identify

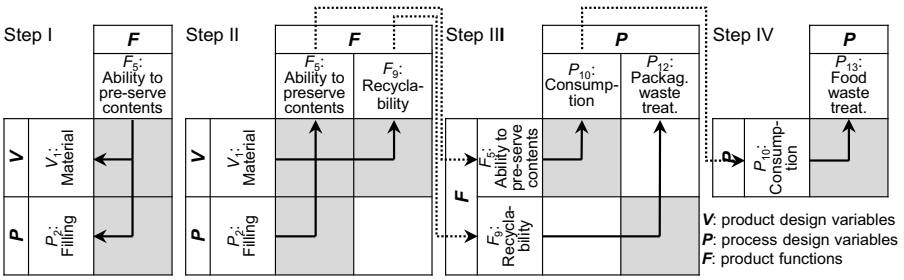

Figure 1 Excerpt matrix and one case of the multiple effects of changing product variables on other attributes.

the effects of functionality changes on process design variables. The changes of functionality, F_5 and F_9, affect on the consumption and end of life treatment P_{10} and P_{12}. Finally, as shown in the Step IV, the designer can identify the effects of the identified process design variables on other process design variables. The change of consumption P_{10} affects the end of life treatment P_{13} in the same manner as the Steps II and III.

2.3. Visualizing the relationships as a network

Network structure was developed to visualize all relationships between attributes and the places where the attributes are expressed. Figure 2 shows a part of the network structure based on the matrix in the case of Figure 1. The cross direction from left to right of Figure 2 indicates the stream of the supply chain, and the upper, lower and middle rows of Figure 2 indicate a packaging part, its content part and product part in the supply chain respectively. The relationships prescribed by Eqs. (1)–(3) are represented as nodes and arrows. Nodes surrounded by an oval, a square and two concentric ovals represent attributes ***V***, ***P*** and ***F*** respectively, and an arrow indicates the relationship, h_m and k_n. That is why an attribute at the start point of an arrow affects an attribute at the end point of the arrow. There are some double-headed arrows between process design variables and product functions, e.g. the arrow between "Filling" and "Ability to preserve contents" in Figure 2, because the decision order of these attributes differs among the cases. In Figure 2, the effects of decision-making, i.e. material selection, is shown as the arrows, while the requests are indicated by following the arrows conversely. The latter indicates the Step I shown in Figure1, and the former indicates the other Steps.

The relationships between attributes visualizes the experts' tacit knowledge, and the network structure contributes to concurrent design of process and product considering the

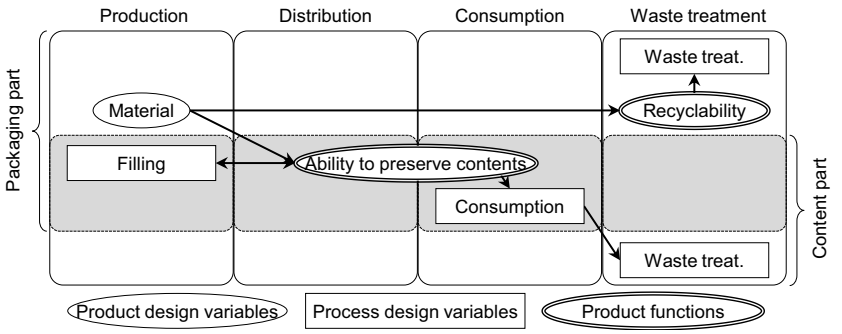

Figure 2 A part of network structure to visualize the relationships between the attributes.

trade-offs between product functions in the supply chain. For example, to enhance the ability to preserve contents F_5, packaging designers decide on packaging materials V_1 changing from packaging materials with high permeability to those with low permeability. It is certainly a decision to enhance the ability to preserve contents, but it decreases packaging recyclability F_9 as a consequent result of additional materials to packaging waste treatment process P_{12}. Environmental assessment based on the network structure can show the life cycle CO_2 emission of the product I_2 considering the trade-offs between product functions. The results support stakeholders to make a sustainable decision for sustainable process and product design.

3. Case study

We performed several case studies in different types of product design by using the network structure. In this paper, we present the case of milk products in carton to demonstrate the applicability of the proposed network visualization. To integrate various consumer behaviours, the design condition was set as food loss prevention in consumption process. Figures 1 and 2 represent the relationships focused on in the case of milk products. Life cycle assessment approach was adopted for evaluating environmental impacts, and life cycle CO_2 emission was set as an objective function in this case study because CO_2 emission is one of the reliable environmental indicators. The effects of the product functions were analysed by reflecting product characteristics in life cycle environmental analysis.

Table 1 shows product characteristics of milk products in this study. Refrigerated milk is a conventional product employing the carton packaging which consists of paper and polyethene. This type of the products is distributed with refrigeration through the supply chain till consumption, and the expiration date is one or two weeks. To prevent food losses, non-refrigerated milk has an extended expiration date by adding aluminium into the carton and increasing the sterilization temperature at the filling process. This product design is shown as a variable identification for functionality enhancement in the Step I. Figures 1 and 2 shows that packaging materials and filling process affect the ability to preserve food and the packaging recyclability at the same time. Finally, this decision on these changes affects the downstream of the supply chain including consumption process, and the non-refrigerated milk can be stored at normal temperature before opening.

The criteria for assessment of milk products was set as one litre of milk consumption by reflecting food characteristics. Food losses are derived from short/little consumption of food, and consumers do not take the same volume of nutrition as a result of the disposal of edible parts. When there are food losses, consumers purchase additional products to compensate for the losses. The model integrating food losses is represented by Eq. (4):

Table 1 Product characteristics of milk products in the case study.

	Refrigerated milk	Non-refrigerated milk
Packaging	Carton made by paper and polyethylene	Carton laminated with aluminum
Max temperature at sterilization [°C]	130	150
Storage condition before open	Refrigeration	Normal temperature
Expiration date [day]	7	60

$$E(x)^{product} = \left(E^{product} + xE^{\text{loss}}\right)/(1-x) \quad (4)$$

where x [–], $E(x)^{product}$ [kg CO_2eq/L-milk consumption], $E^{product}$ [kg CO_2eq/L-milk production], and E^{loss} [kg CO_2eq/L-milk] are the loss rate of food products which is defined as the rate of the losses to the provided food, the life cycle CO_2 emission of a product per consumption when the value of the loss rate is x [–], the CO_2 emission of a product per production, and the CO_2 emission of loss treatment process, respectively. This equation is unbounded when all contents are discarded (x=1) because unlimited purchase of products is needed for a certain amount of consumption.

Figure 3 shows the results of the environmental assessment comparing refrigerated milk containing one litre of milk (RF) and non-refrigerated milk containing one litre of milk (NR) based on Eq. (4). In the case of no food loss, the functionality enhancement increases the total CO_2 emission from the supply chain as a result of the additional use of aluminium for packaging. Meanwhile, because the CO_2 emission from the production of milk has a large contribution, food losses increase the total CO_2 emission. Therefore, a balance between the increased CO_2 emission by functionality enhancement and the effects of functions, i.e. food loss reduction, needs to be quantitatively evaluated and compared for sustainable packaging design. In other words, a break-even point on the increased CO_2 emission needs to be identified for decreasing the total CO_2 emission by food loss reduction. A previous study (Yokokawa et al., 2018) introduced an indicator, break-even rate of food loss, φ [–], to represent the break-even point. The break-even rate of food loss is given by Eq. (5):

$$\varphi = \left(E(0)^{\text{NR}} - E(0)^{\text{RF}}\right)/\left(E(0)^{\text{NR}} + E^{\text{loss}}\right) \quad (5)$$

The value of the break-even rate of food loss was 4.6 % in this study comparing NR with RF. The result shows NR has less CO_2 emission than RF has when enhancing the ability to preserve food reduces more than 4.6 % of the loss rate.

Food losses are dependent on consumer behaviour, and the value of the loss rate differs among consumer behaviours. Scenarios reflected various consumer behaviours to identify the food loss rate in the scenarios by setting the design variables of consumption process like consumption rate. For example, when the food losses were dependent on consumption rate r_{M} [L/day] and expiration date d_{expire} [day], the food loss rate was represented by Eq. (6)

$$x = \begin{cases} 1 - r_{\text{M}} d_{\text{expire}} / M_{\text{edible}} & \left(r_{\text{M}} d_{\text{expire}} \le M_{\text{edible}}\right) \\ 0 & \left(r_{\text{M}} d_{\text{expire}} \ge M_{\text{edible}}\right) \end{cases} \quad (6)$$

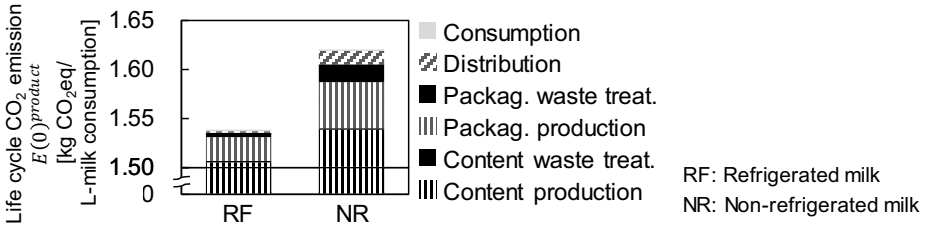

Figure 3 Environmental assessment results of refrigerated milk and non-refrigerated milk.

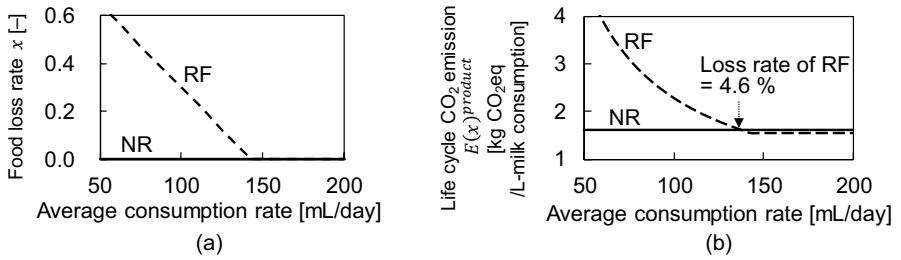

Figure 4 Scenario analysis results of consumer behavior comparing refrigerated milk (RF) and non-refrigerated milk (NR) in two indices (a) food loss rate (b) CO_2 emission

where M_{edible} [L] is the total edible parts of provided food. Figure 4 shows the scenario analysis results of milk products based on Eqs. (5) and (6). Figure 4(b) presents that the break-even rate of food loss is a useful indicator to identify the scenarios where NR is better for the environment than RF is. In this case, NR is effective for consumers who consume less than 136 mL/day of milk in decreasing the life cycle CO_2 emission.

4. Conclusions

We visualized the relationships between design variables and product functions in the supply chain of packaging and its contents for sustainable packaging design. By a case study, the applicability of the developed network structure of the relationships was presented. Including the losses of contents from consumption process into the evaluation shows the significance of integrating the effects of the product functions in the supply chain. This study can support packaging designers to make sustainable decisions by grasping the effects of their decisions on the supply chain.

Semantically-enabled CAPS platform: Towards a generic and dynamic formulation for the synthesis and optimisation of value chains

Eirini Siougkrou*, Foteini Barla and Antonis C. Kokossis

Department of Chemical Engineering, National Technical University of Athens
9 Heroon Polytechniou Street, 157 80 Athens, Greece
esiougkrou@mail.ntua.gr

Abstract

A dynamic Computer-Aided Process Synthesis (CAPS) platform is developed able to offer high-throughput discovery and analysis of information for a wide range of users based on ontology engineering. The services that have been designed for the platform consider a range of user roles, including three main categories of services. (a) Basic services, such as search and upload of conversion pathways and models, (b) integration with external tools and databases, and (c) custom-made services that include synthesis and optimisation of value chains. The platform is further developed to enable a customised formulation for the optimisation of the value chains. A general formulation of the model equations is introduced, where each process unit is considered to be a black box described by inlets, outlets and generic functions that define the relationship between inlets and outlets. The user can define the form of the model equations in the ontology and then the model equations are transferred from the ontology to a mathematical form through a disjunctive programming formulation. Representative services of the semantic platform are illustrated for the case of the waste biorefinery.
Keywords: ontology engineering, repository, synthesis of value chains, optimisation of value chains

1. Introduction

The existing and developing resources in the CAPE (Computer-Aided Process Engineering) community can vary significantly in origin, type and scale; experimental data, algorithms, mathematical models, technology models, flowsheets, property models, executable files, etc.. A computational tool able to systematically store, retrieve and manipulate that knowledge and at the same time accessible to both experts and non-experts would be very beneficial. Ontology engineering can be the ideal base for the development of such a tool, as it can provide the means for high-throughput storing and processing of information.

Ontology engineering has been applied recently to several process engineering problems, such as process synthesis and optimisation (Kokossis et al., 2016; Barla et al., 2016; Magioglou et al., 2014) and industrial symbiosis (Cecelja et al., 2015). The current work anticipates the challenge to develop a dynamic platform able to host and integrate developments in the process engineering community. Ontologies are selected to model knowledge and process information services, such as synthesis and optimisation of value chains. The resources will be shared and will support dynamic updates and upgrades offering services to the users.

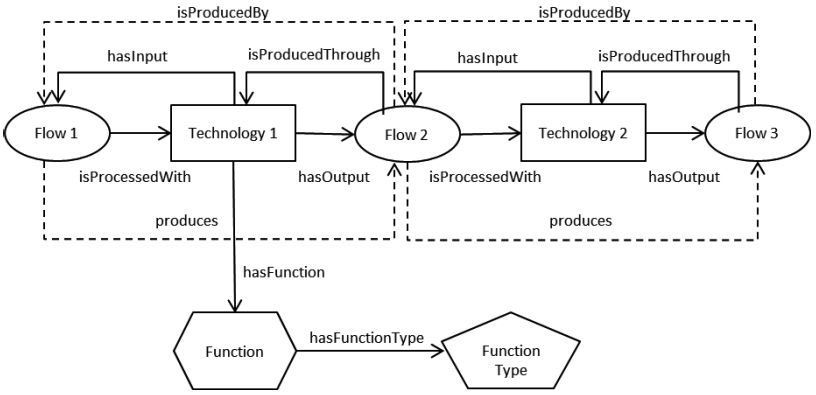

Figure 1. A representative pathway of the developed ontology and the defined object properties (relations). Different shapes correspond to different classes.

2. The CAPS platform

The platform is based on an ontological representation of the conversion pathways. The ontology comprises of four main classes; Flows, Technologies, Functions and Function types. Object properties are defined to describe the relations among the classes, as shown in Figure 1.

2.1 Services

Basic services

Basic services include Search and Upload of data, pathways and models. The users are able to search for existing pathways and technology models in the platform. In addition, new pathways and technology models can be added to the platform through a user-friendly interface. The new data that are uploaded are automatically integrated into the ontology and all possible connections with the existing data are made, possibly creating new knowledge. The user is also able to search for data to external databases that are linked via the CAPS platform.

Customised services

Customised services include the synthesis and optimisation of value chains, as well as integration with external databases and tools.

Synthesis of value chains

The Value Chain Builder is based on algorithms that have been developed to synthesise value chains from predefined feedstock/s or/and product/s. The algorithms make use of the object properties that connect the individuals of the ontology and are based on SPARQL commands. The corresponding steps are given in Figure 2. The steps that are followed for building value chains for preselected feedstock are the following:

Step 1. The Feedstock is selected.

Step 2. The flows that are contained in the value chains are found; all Intermediates and Products that *are produced by* the preselected Feedstock are found.

Step 3. The technologies that can connect the Feedstock and the Intermediates and Products that were found in Step 2 are found; the technologies that *have input* the

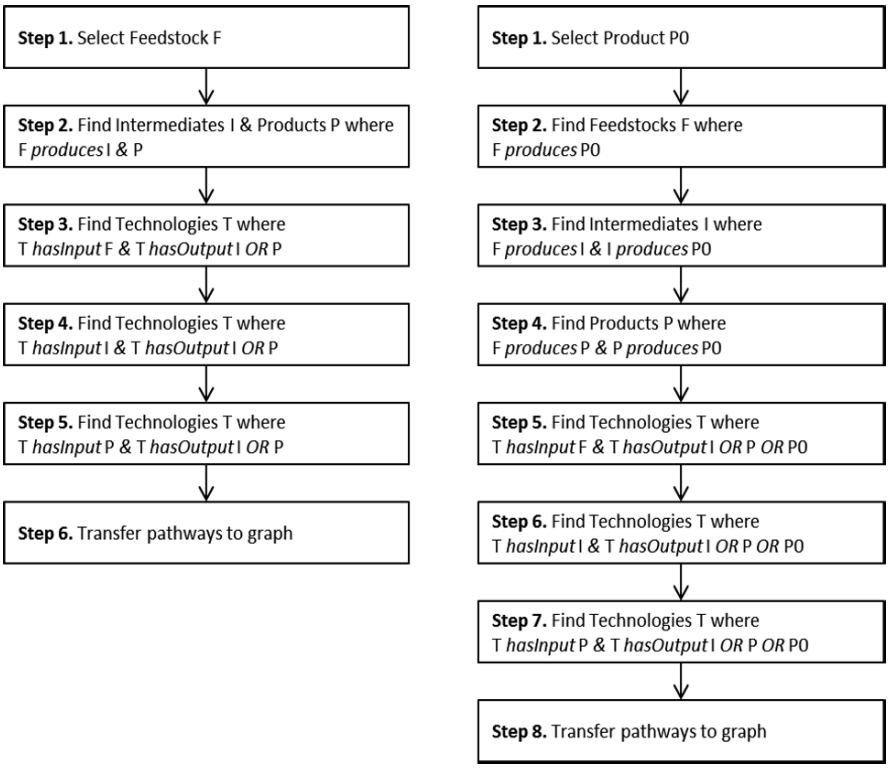

Figure 2. Algorithms for the building of value chains for selected Feedstock (left) and Product (right).

Feedstock *and have output* the Intermediates *or* Products found in the previous step are defined.

Step 4. Next, the technologies that can connect the Intermediates found in Step 1 and the other Intermediates and Products that were found in Step 2 are found. Thus, the technologies that *have input* the Intermediates *and have output* other Intermediates *or* Products are found.

Step 5. Similarly, the technologies that can connect the Products found in Step 1 and the Intermediates and other Products that were found in Step 2 are found. The technologies that *have input* the Products *and have output* other Intermediates *or* Products are defined.

Step 6. All pathways are transferred to a graph in the form of a superstructure.

The algorithm for preselected product has been developed in a similar way (Figure 2). The algorithms can be easily extended to consider also intermediates or combinations of flows, such as preselected feedstock and product, or feedstock and intermediate.

Optimisation of value chains

Once the desired value chain is obtained, the question that arises is "what is the optimal pathway?" This question can be answered by the Value Chain Optimiser, that provides

the optimal path of the value chain, for user-defined objective function and constraints. The Value Chain Optimiser, previously presented in Barla et al. (2016), has been further developed to consider a customised formulation of the optimisation problem. A generalized formulation of the optimisation problem is presented, enabling the use of user functions for selected technology models. Each technology block is described with inputs, outputs and functions that link the corresponding flows (f_i in Figure 3). These flows can be mass and energy flows, whereas the functions can be mass balances, energy requirement equations, environmental and cost constraints.

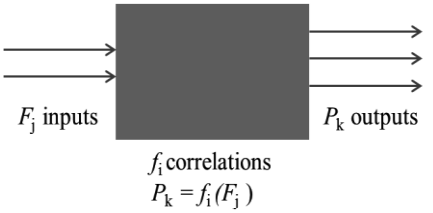

Figure 3. A technology unit represented by inputs (F_j), outputs (P_k) and relations f_i that connect them.

The optimisation problem is formulated as a Mixed Integer Non Linear Programming (MINLP) problem (equations 1-3), where the objective function (in this work, the total cost) is minimized subject to equality and inequality constraints. The equality constraints include model equations such as mass balances, energy requirements, cost and environmental models. The inequality constraints can be feedstock and product specifications or requirements.

$$\min \quad Obj\,(\boldsymbol{x}, \boldsymbol{y}) \tag{1}$$

$$\text{s.t.} \quad \boldsymbol{h}\,(\boldsymbol{x}, \boldsymbol{y}) = 0 \tag{2}$$

$$\boldsymbol{g}\,(\boldsymbol{x}, \boldsymbol{y}) \leq 0. \tag{3}$$

The optimization model is an extension of the formulation by Kokossis et al. (2015). The model equations are now defined using a disjunctive formulation, as

$$f_{l,i} = \begin{Bmatrix} \neg\, Z_{l.i} \\ \text{default eqn} \end{Bmatrix} \vee \begin{Bmatrix} Z_{l.i} \\ a_{l,i}x_l + b_{l,i}{x_l}^2 + c_{l,i}{x_l}^{d_{l,i}} + e_{l,i}y_l \end{Bmatrix} \tag{4}$$

where subscript l defines the technology unit and i defines the equation type, that is i={conversion, energy, cost, environmental, etc.}. $Z_{l.i}$ is a Boolean variable that is true, if the user has defined equation i for technology l. Thus, when an equation is not defined by the user, the corresponding equation by Kokossis et al. (2015) (default eqn in equation (4)) is used, while when a user-defined equation exists, the generalised formulation is used as shown in the second part of equation (4). Parameters a, b, c, d and e are values defined by the user, and x is the depending variable. y_l is a binary variable that represents the existence of technology l. As it is obvious from the equation, the user can enter linear, polynomial and exponential model equations. Non-zero parameters define the function type. Naturally, the equation is easily extended to include other forms of equations. The platform offers the possibility to use the default optimisation formulation (Kokossis et al., 2015), customised forms of equations, and any combinations of default and customised equations.

Integration with external tools and databases

The CAPS platform supports the integration of external tools, such as property or data models (e.g. LCA models, cost models). In addition, the platform is able to search for information to external databases and integrate internal and external data.

2.2 Implementation

The application platform has been developed upon Yii framework, a high-performance PHP framework using the Model-View-Controller (MVC) software design pattern. This web-based system lies on a private Linux Web Server provided by GRNET NOC's ViMa service ("ViMa," n.d.) and is part of IPSEN Tools, a collection of tools developed by the Industrial and Process Systems Engineering (IPSEN) group at the National Technical University of Athens. IPSEN tools are available in the URL *http://tools.ipsen.ntua.gr*. The architecture of the platform, as shown in Figure 4, contains three main separated layers, the presentation layer (the front end), the logic layer and the data access layer (the back end). The presentation layer provides the functionality for the user interface in order to interact with the data layer for both input and output.

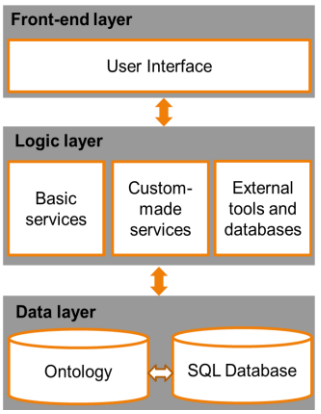

Figure 4. The architecture of the developed platform.

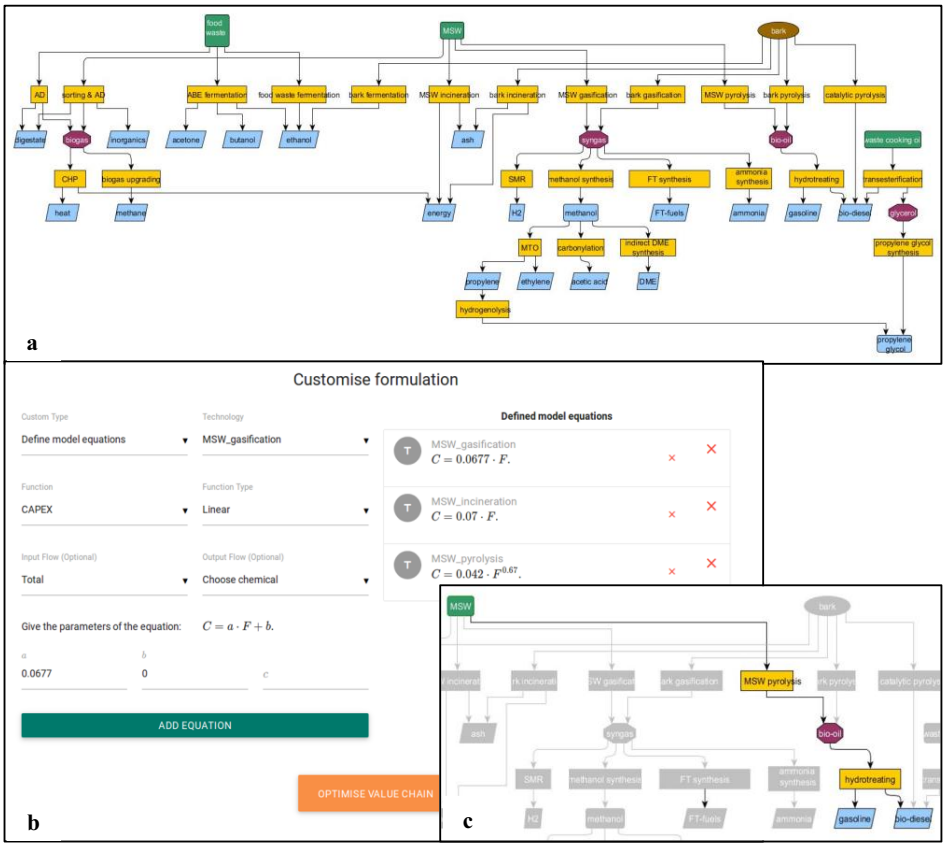

Figure 5. (a) The value chain produced for MSW, food waste, waste cooking oil and bark. (b) The interface of CAPS platform for customised optimisation formulation. (c) The optimised path.

3. The case of the waste biorefinery

The case of the waste biorefinery has been selected to demonstrate some of the functionalities of the platform. In this example, the user is looking for the optimised path for a defined set of feedstocks. Thus, the user firstly selects feedstocks to be included in the value chain; municipal solid waste (MSW), food waste, waste cooking oil and bark. The Value Chain Builder synthesises the value chain for the aforementioned feedstocks, as shown in Figure 5a. Next, the user chooses to "Optimise the Value Chain" for an amount of 500 Mt/year available total feedstock. In the next step, the user is called to choose between default and customised formulation. The default formulation corresponds to the use of existing models in the platform's database. The user selects customised formulation and defines the cost equations (Mountraki et al., 2016) for the technologies MSW_fast_pyrolysis, MSW_incineration and MSW_gasification (Figure 5b). The resulting optimal path is shown in Figure 5c, where two products are selected, gasoline and bio-diesel.

4. Conclusions

A dynamic platform has been presented that supports the integration and manipulation of knowledge in process systems engineering community. The platform stands as a repository of existing data, as well as a tool for the synthesis and optimisation of value chains. The development of the CAPS platform has been based on ontology engineering and its services include basic services, such as search and upload of data, and customised services for building and optimising value chains. A generalised formulation of the model equations for the optimisation has been presented, where the optimisation model can be customised according to user definitions. The user can partly define the model equations or data without needing to create a new optimisation model from scratch. The functionality of the developed tool has been demonstrated to a waste biorefinery example.

Abstract

This work presents a new computer-aided thermomorphic solvent system (TMS) design methodology for the recovery of homogeneous catalysts that incorporates quantitative structure-activity relationships (QSAR) to predict various environmental, health, and safety (EHS) criteria using modern software packages. The quantum chemical method Conductor-like Screening Model for Real Solvents (COSMO-RS) (Klamt, 1995) is used for predicting catalyst solubility and the liquid-liquid equilibrium behavior of potential TMS designs. This methodology is then exemplified on the hydroformylation of 1-decene using the rhodium-Biphephos (Rh-BPP) transition metal catalyst and several green TMS designs were identified. Two of these TMS were then selected for experimental validation of both their LLE behavior and reaction performance.

Keywords: computer-aided molecular design (CAMD), COSMO-RS, green solvents, homogeneous catalysis

1. Introduction

The use of TMS has been shown to be a simple yet effective separation strategy in the recovery of homogeneous catalysts. Recently, a computational framework for a priori TMS design that incorporated predictions of catalyst solubility was developed (McBride and Sundmacher, 2015a) and experimentally validated (McBride et al., 2016) based on the quantum-chemical method COSMO-RS (Klamt, 1995). This design strategy was exemplified on the hydroformylation of 1-dodecene using the rhodium-Biphephos (Rh-BPP) homogeneous transition metal catalyst. Several potential TMS systems were identified and promising candidate systems were experimentally validated. Three of the considered TMS were very successful in recovering the catalyst and facilitating the reaction. Generally, the best performing TMS designs found consisted of mixtures using dimethylformamide (DMF) and alkanes in the range of C_8 – C_{14} as the polar and nonpolar component solvents, respectively.

However, a TMS consisting of DMF and decane has already been used in long-chain olefin hydroformylation research for several years. Since catalyst leaching remains economically high using this TMS (McBride and Sundmacher, 2015b), an alternative recycling strategy using a series of counter-current extraction stages using additional DMF was investigated. An evaluation of this separation strategy as part of an overall process optimization predicted that improved recovery of the catalyst at more

economical conditions is possible than previously (McBride et al, 2017). Nevertheless, due to its developmental toxicity, DMF is a solvent that should be substituted with a safer, more benign alternative. Continued use of this solvent is also in direct opposition to the idea of green and sustainable chemistry. Therefore a new computational strategy has been developed to find replacement solvents for DMF that are considered green and that would be suitable for recovering the catalyst as part of a multi-stage extraction.

2. Screening Method

This new method is based on the previous TMS design strategy first presented by McBride and Sundmacher (2015a), but with two major differences. Since it is known that an extraction process can be used to recover leached catalyst lost after the first decantation step (McBride et al., 2017), a solvent with lower catalyst recovery performance than DMF can be used. This allows one to explore a larger solvent search space than in the previous framework, increasing the potential to find a green solvent to replace DMF. Additionally, the simple prediction of the presence of a miscibility gap using binary LLE predictions has been replaced by a complete prediction of the ternary LLE for the reaction and separation stages at several temperatures. Although there are still inherent inaccuracies in the LLE predictions, they should provide an improved approximation of phase separation after the reaction which is also strongly correlated to catalyst leaching.

Since it is only of interest to replace DMF and that it was found previously that alkanes containing eight to 14 carbon atoms were the best choice for nonpolar solvents, it was decided that decane should remain fixed as the nonpolar solvent in the present work. This also has the benefit of reducing the amount of decane formed as a by-product due to the hydrogenation of 1-decene during the reaction. Thus, the focus here is to find a suitable and green solvent to replace DMF as the solvent used to recover the rhodium-Biphephos catalyst, which also simplifies the TMS design procedure by limiting our search to a single component solvent in the TMS. One of the challenges in green chemistry is finding feasible substitutes for currently used solvents. Fortunately, there are several methods that allow one to predict different EHS characteristics, such as persistency and carcinogenicity. The modern software packages VEGA (Benefenati et al, 2013) and EPI Suite (US EPA, 2017) are two such tools that enable one to make computationally based predictions of the EHS criteria for molecules simply by using their SMILES structures as the basis for QSAR-based models.

To start, two different lists of potential solvents are considered: those molecules included in COSMObase (ver. 1301 COSMOlogic GmbH) and a list containing known green solvents collected from Moity et al. (2012).

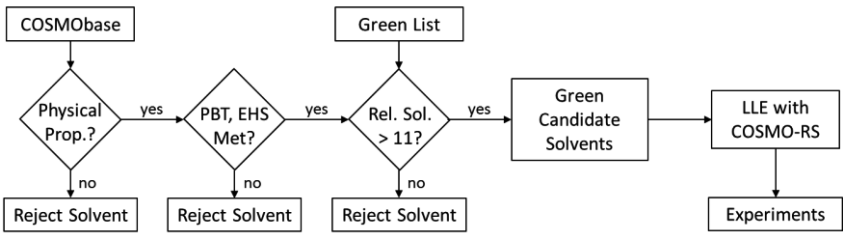

Figure 1. Screening methodology for green TMS design.

Table 1. Models used for each EHS characteristic and constraints on PBT criteria taken from US EPA TRI for substances of low concern.

Property	**Model (Software)**	**Limit**
Persistence	Biowin3 (Vega)	< 60 days
Bioaccumulation	CAESAR (Vega)	< 1000
Toxicity	ECOSAR (EPISuite)	< 10 mg/L
Carcinogenicity	CAESAR (Vega)	No
Mutagenicity	CAESAR (Vega)	No
Developmental Toxicity	CAESAR (Vega)	No

Those molecules provided by COSMObase are to be screened using physical property constraints and their predicted EHS criteria.The solvents included in the green solvent list are used directly in the LLE calculation step. A flowchart depicting this screening process is shown in Figure 1.

2.1. Predicted EHS Properties

In this framework, six molecular properties concerning EHS are considered: the persistence, bioaccumulation, and toxicity criteria (PBT), as well as predictions about whether each molecule is carcinogenic, mutagenic, or developmentally toxic. The screening is conducted using the values provided in Table 1 as constraints on the PBT, which have been set by the US EPA Toxics Release Inventory (TRI) Program. Predictions made for carcinogenicity, mutagenicity, and developmental toxicity are either yes or no decisions. The individual models for each property used in this work are also provided in Table 1 along with the software package used.

2.2. Relative Solubility

The second aspect considered is the relative solubility of the catalyst ligand in each potential green solvent. This is possible using COSMO-RS as implemented in the COSMOtherm software (Eckert and Klamt, 2016). Relative solubility has been shown to be a qualitatively acceptable measure for comparing the potential solvation power of a solvent for a specific solute and this was corroborated for the present catalyst in our previous work (McBride et al., 2016). The relative solubility compares the predicted chemical potential of a solute in a solvent at infinite dilution, which is an acceptable assumption for the catalyst ligand due to its very low concentration in the reaction mixture. To remove those solvents predicted to have poor solubility for the catalyst, a minimum value of 11 is selected as the cut-off value for the relative solubility (higher is better). For reference, DMF is predicted as having a relative solubility of 12.49. All calculations for relative solubility and the following LLE predictions were made using the BP_TZVPD_FINE_C30_1601 parameterization.

2.3. Liquid Phase Equilibrium

A requirement of the TMS is that a homogeneous mixture exists during the reaction and that a biphasic mixture forms upon subsequent cooling. For those solvents with suitable EHS characteristics and good relative solubility, ternary LLE calculations are predicted using COSMOtherm at 25 °C to obtain information about the potential ability of the mixture to separate. Care must be taken here as predictions of LLE behavior are

notoriously inaccurate for some substances, especially for mixtures containing more than two components. A similar calculation is performed for the ternary mixture consisting of the TMS and 1-decene at 100 °C to predict the degree of homogeneity in the reactor. These predictions were found to be unreliable and quite restrictive and therefore left as a consideration for future improvements to the TMS design method.

3. Results

3.1. Screening Results

First, those solvents that are contained within the COSMObase (ver. 1301, COSMOlogic GmbH) are considered. The only physical property constraint used in this example is a restriction on molecular weight (< 200 g/mol), which leaves 6261 candidates. After screening the molecules using the criteria outlined in Section 2.1 and 2.2 and evaluating the phase equilibrium behavior of each resulting ternary system as outlined in Section 2.3, only three molecules remain. These are listed in Table 2 on the left-hand side. Similarly, only three solvents included in the green solvent list were found to have acceptable LLE predictions. These are also presented in Table 2. Two solvents were then selected for experimental validation primarily based on price and accessibility: dimethylsuccinate (DMS), which was found in both lists, and tetrahydro-4h-pyran-4-one (THPO).

Table 2. List of potential solvents to replace DMF in the TMS using COSMObase (left) and from the green solvent list (right) taken from Moity et al (2012).

Molecule (COSMObase)	**Rel. Sol.**	**Molecule (Moity et al.)**	**Rel. Sol.**
2,7-Octanedione	13.49	Dimethylglutarate	12.05
Tetrahydro-4h-pyran-4-one	12.88	Dimethylsuccinate	11.87
Dimethylsuccinate	11.87	Glycerol-1-methyl monoether	11.33

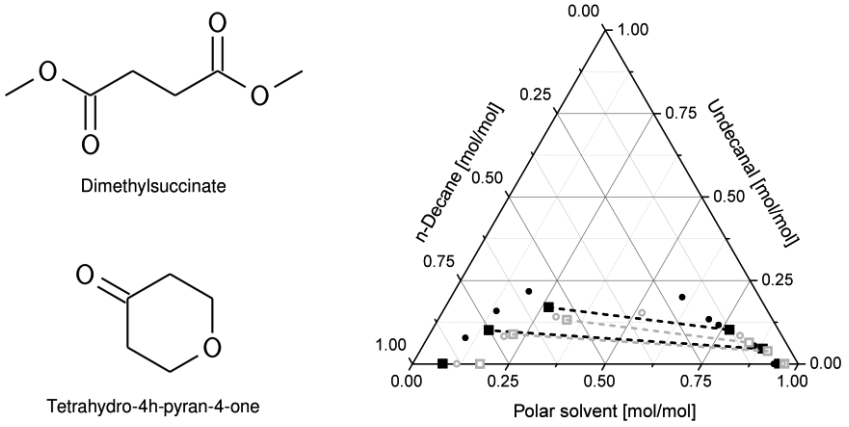

Figure 2. LLE (■) and cloud point measurements (●) for decane, undecanal, and DMS and LLE (□) and cloud point measurements (○) for decane, undecanal, and THPO at 25 °C. The molecular structures for both solvents are shown on the left.

3.2. LLE Measurements

Due to the uncertainty in predictions of LLE, they are measured directly. This ensures that one knows whether the mixture leaving the reactor forms a biphasic mixture upon cooling. This was performed on each mixture at 25 °C using a series of predefined compositions as well as by performing cloud point experiments. The results of these experiments are displayed in Figure 1. Additionally, several typical reaction mixtures of 1-decene, decane and the two polar solvents were heated to 100 °C and no phase separation was observed. Both solvents show acceptable LLE behavior for use in a TMS for the hydroformylation of 1-decene.

3.3. Reaction Experiments

The hydroformylation of 1-decene was performed in both TMS mixtures to confirm that they can facilitate the reaction. Each reaction was performed in a 1 L semi-batch reactor filled with 600 mL liquid. An equimolar synthesis gas feed was designed to maintain the pressure at 19 bar, which failed to do so due to very high reaction activity. This caused the pressure to fall to 6 bar using the TMS with DMS. A reduction in the catalyst amount by two-thirds was then used for THPO as a direct result of the high pressure loss during the first reaction. Despite this, the pressure still fell to 11 bar with THPO. Since our concern was in proving the feasibility of using these solvents in the reaction, further optimization of the reaction conditions was not pursued at this time.

The reaction profiles for both TMS are shown in Figure 3. In both cases, despite the differences in catalyst amounts used, the reaction proceeds rapidly towards a high conversion to the undecanal product. These preliminary investigations show that the hydroformylation can be efficiently performed in both TMS compositions. However, when using the TMS with THPO, a yellow substance formed during the reaction which may be caused by catalyst instability or degradation in the presence of THPO.

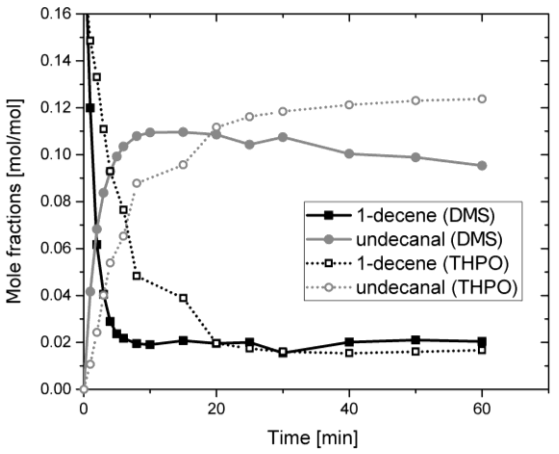

Figure 3. Mole fractions of 1-decene and undecanal during the reaction. The reactions were carried out at 105°C and 19 bar with 1-decene/decane/polar solvent = 0.20/0.48/0.32 mass ratios, H_2:CO = 1:1, catalyst/1-decene = 1:2000 for DMS, catalyst/1-decene = 1:6000 for THPO, and Rh/ligand = 1:5. All ratios given in mol/mol except for reactants and solvents.

4. Conclusions

This work presents a new framework for green solvent selection in TMS design used in replacing DMF as the currently used solvent in a TMS for catalyst recovery. The method was applied to the hydroformylation of 1-decene using the homogeneous rhodium-Biphephos catalyst. By considering the EHS criteria, catalyst ligand solubility, and LLE behaviors, several green solvents were identified. The LLE and reaction performance in two of these TMS designs were then experimentally validated. It was shown that performing the hydroformylation of 1-decene in a green TMS is not just feasible but functional. Future work will focus on a more detailed analysis of the catalyst recovery in a single separation stage and using a series of extractions. The effect of the solvents on the reaction performance is also to be considered in more detail, especially the reason why by-products formed when using THPO.

5. Acknowledgement

jose.oduque@hotmail.com

Abstract

The life cycle assessment method was applied to identify the stages of the industrial water production system in an oil refinery and analyze the energy demand, carbon footprint and water footprint in order to propose scenarios for improvements. Based on the data collection carried out in the field, the inventory of the product system was elaborated in Simapro software with the ecoinvent database. Impact assessment methods applied were Cumulative Energy Demand (CED), Intergovernmental Panel on Climate Change (IPCC) (2013) and Available Water Remaining (AWARE). It was noticed that water losses represent 59% and electricity consumption 0.92 kWh per m^3 of distributed water. The proposed scenarios to use more efficient frequency inverters in water uptake, water capture in the nearest place and water losses reduction combined resulted in 28% water losses and 0.33 kWh of electricity consumption per m^3 of distributed water. The proposed scenarios combined also reduced CED by 51%, carbon footprint by 47% and water footprint by 39%. The proposed actions are part of the rationalization and eco-efficiency strategies of water use in oil refineries.

Keywords: Life Cycle Assessment, Energy Demand, Carbon Footprint, Water Footprint, Water Supply.

1. Introduction

Investigations on the IPCC climate scenarios from 2070 to 2100 for the State of Bahia in Brazil observed the largest reduction in precipitation on the coast, approximately 70%, and the highest temperature increase in the Northwest and North of the State by 5◦C (Tanajura et al., 2010). Water and energy rationalization are fundamental to achieve Sustainable Development Goals by 2030. About 2% to 3% of the world's energy consumption is used to capture, treat and distribute water to supply industries and homes (ASE, 2002). Water losses in uptake, treatment or distribution stages of water supply chain can occur by inadequate operation, lack of maintenance, depleted pipes and process management with low efficiency. Iwanek et al. (2016) argue that deteriorated infrastructure in the water supply chain causes leaks that reduce water carrying capacity, increase energy demand, cause system component failures, increase maintenance and operating costs, constant disruptions supply and reduce reliability. Therefore, the goal of this study was to assess the energy demand, carbon footprint and

water footprint of the industrial water supply chain to support the environmental management and operational costs reduction.

2. Methodology

The application of Life Cycle Analysis (LCA) followed the methodological structure recommended by ISO 14044 (2006). Data were collected from the oil refinery's water supply system in the foreground inventory (gate to gate) and the ecoinvent database version 3.3 was used in the background inventory (cradle to gate) in Simapro software version 8.4. The impact assessment methods were Cumulated Energy Demand (CED) (Jungbluth and Frischknecht, 2010), Carbon Footprint (IPCC 2013 - 100 years) and Water Footprint (Boulay et al., 2017).

The water supply system is the conventional type, composed of surface water uptake, treatment, storage and distribution. The water uptake uses three sets of motor-pump with a flow rate of 700 $m^3\ h^{-1}$ that pumps water to the Water Treatment Plant (WTP). There are three water catchment points, Catu river (245 $m^3\ h^{-1}$ or 35% of the total), Paraguaçu river (175 $m^3\ h^{-1}$ or 25% of the total) and São Paulo river (280 $m^3\ h^{-1}$ or 40% of the total). The electricity consumption of each set of motor-pump is 0.20 kWh m^{-3} for Paraguaçu river, 0.40 kWh m^{-3} for Catu river and 0.07 kWh m^{-3} for São Paulo river. In 2015 the total volume of water uptake was 6,117,984 m^3. The water supply system operates 24 h dia^{-1}. The WTP is composed of flocculation, decantation and filtration processes. The distribution of water flows by gravity. The reference flow adopted was 1 m^3 of distributed water. In this way, the amount of auxiliary materials and electricity consumption of the water supply system are presented in Table 1.

Table 1
Foreground inventory for 1 m^3 of distributed water

Stage	Amount	Unit	*GSD^2
Uptake			
Chlorine	0.030	kg	1.05
Electricity	0.54	kWh	1.07
Treatment			
Aluminum Sulfate	0.26	kg	1.05
Sodium Carbonate	0.12	kg	1.05
Polyelectrolyte	0.0026	kg	1.05
Electricity	0.38	kWh	1.07
Chlorine	0.025	kg	1.05
Sludge	0.020	m^3	1.09
Infrastructure	3.07E-9	unit	3.28
Distribution			
Electricity	0	kWh	-

*GSD^2: square geometric standard deviation.

Electricity consumption and water losses were identified as the largest contributors to the impact categories considered in this study. Therefore, improvement scenarios together with scenarios of water uptake per source were analyzed in order to identify

opportunities for environmental improvements. Seven additional scenarios were set for comparison with the Base Scenario.

- Inverter Scenario: considered the use of modern frequency inverters to reduce electricity consumption in uptake by 20%;
- Loss Scenario: considered the reduction of water losses in uptake to 5% and treatment to 20%;
- Combined Scenario: refers to the combination of Inverter Scenario and Loss Scenario;
- Paraguaçu Scenario: considered water uptake only from Paraguaçu river;
- Catu Scenario: considered water uptake only from Catu river;
- São Paulo Scenario: considered water uptake only from São Paulo river;
- São Paulo Combined Scenario: refers to the combination of Combined Scenario and São Paulo Scenario.

3. Results and discussion

The Base Scenario of the water supply system consumes 0.92 kWh of electricity per m^3 of distributed water. Fig. 1 shows the water balance of the oil refinery water supply system per stage.

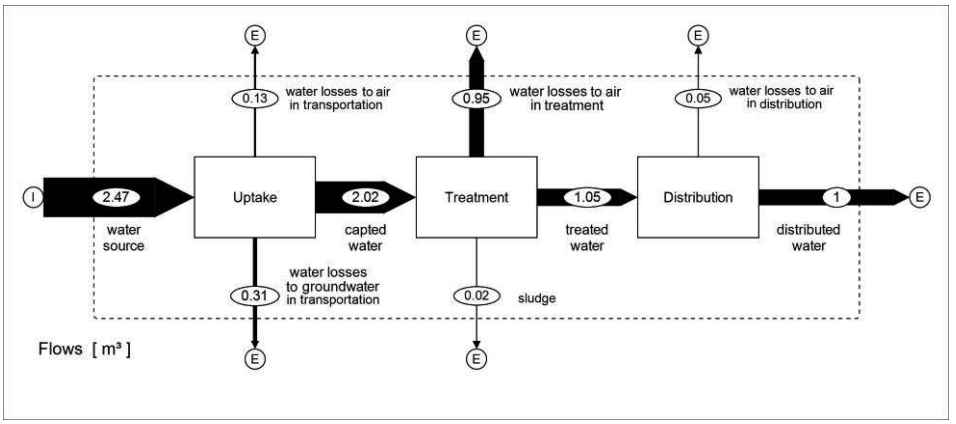

Fig. 1 Water balance along the water supply system (Base Scenario)

It was identified that each m^3 of distributed water requires 2.47 m^3 of water in uptake stage, 2.02 m^3 of water in treatment stage and 1.05 m^3 of water in distribution stage. Therefore, water losses represent 59% along the supply chain, considering 18% in the uptake stage, 48% in the treatment stage and 5% in the distribution stage. Water losses along the water supply system occur due to pipeline leakage, evaporation and sludge generation. The impact contributions of the water supply system are presented per life cycle stage for each scenario (Fig. 2, Fig. 3 and Fig. 4).

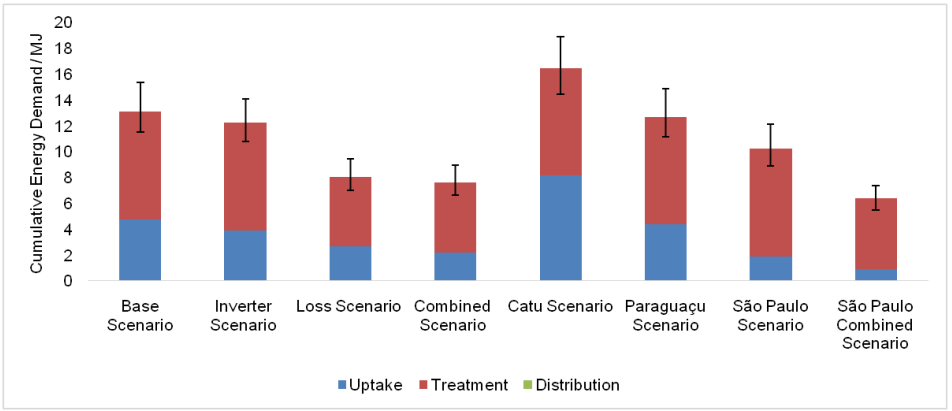

Fig. 2 Impact contribution of Cumulative Energy Demand with uncertainty (background and foreground) of 1 m³ of distributed water per stage along the life cycle for each scenario

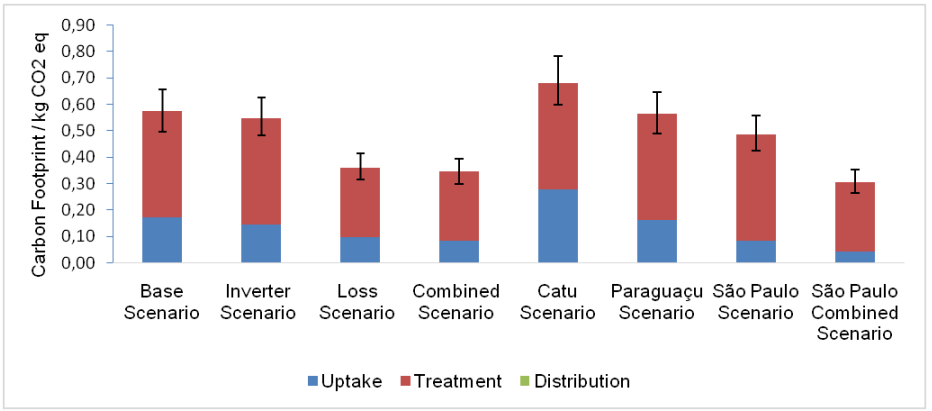

Fig. 3 Impact contribution of Carbon Footprint with uncertainty (background and foreground) of 1 m³ of distributed water per stage along the life cycle for each scenario

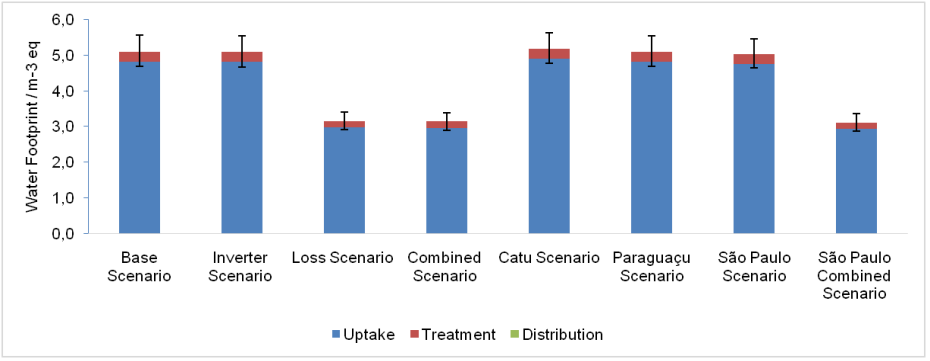

Fig. 4 Impact contribution of Water Footprint with uncertainty* (foreground) of 1 m³ of distributed water per stage along the life cycle for each scenario

*Uncertainty was only considered from foreground data due to inconsistencies presented in water flows from background data.

The largest contributions per stage of the water supply system were treatment stage for CED and carbon footprint, and uptake stage for water footprint. The distribution stage did not present significant impact contributions as infrastructure was considered in treatment stage and no energy was consumed at this stage. The main contribution to CED in the Base Scenario was electricity consumption (54%) of water uptake and treatment. The Inverter Scenario reduced CED by 6% and carbon footprint by 5% with the insertion of frequency inverters in the motor-pumps. On the other hand, Loss Scenario reduced the amount of water uptake from 2.47 m^3 to 1.39 m^3 that also reduced the electricity and chemical inputs. In this sense, the Loss Scenario reduced CED, carbon footprint and water footprint by 38% compared to Base Scenario. The Combined Scenario presented impacts slightly smaller than Loss Scenario, as the Inverter Scenario had a small contribution to impact reduction. The scenarios per water catchment points presented larger impacts for a distant source (Catu Scenario), average impacts for a medium distance source (Paraguaçu Scenario) and smaller impacts for a nearer source (São Paulo Scenario). São Paulo Scenario presented as an optimal point of water uptake with smaller energy consumption in relation to other catchment points. Therefore, the São Paulo Combined Scenario reduced CED by 51%, carbon footprint 47% and water footprint by 39%. Water management requires knowledge of the availability and demand of water resources to establish priority actions for water conservation. If the refinery plant reduces its water demand significantly it could be supplied by nearer water sources, reducing environmental impacts and operational costs. The climate change may also pressure water availability, as mentioned by Tanajura et al. (2010), therefore water rationalization along with alternative water sources should be considered.

4. Conclusion

The study analyzed the water balance, energy demand and environmental impacts of water supply system in an oil refinery with LCA methodology. The largest contributions in the energy demand, carbon footprint and water footprint were related to uptake and treatment stages, such as water pumping, electricity consumed in the water treatment and water losses. Some opportunities to improve energy efficiency and reduce water losses were identified, as well as water uptake from nearer sources. Energy and water efficiency along the supply chain is key to reduce environmental impacts and increase water availability for multiple uses. Thus, this study supports decision making aimed at reducing costs and improving environmental aspects of water supply systems.

Optimal Design of an Ambient Air Vaporizer using Numerical Model and DIRECT Algorithm

Yongkyu Lee [a], Jonggeol Na [a], Wonbo Lee [a*]

[a]*School of Chemical and Biological Engineering, Seoul National University, Build. 302, 1, Gwanak-ro, Gwanak-gu, Seoul (08826), Republic of Korea*
wblee@snu.ac.kr

Abstract

The ambient air vaporizer (AAV) using ambient air as heat source was environment-friendly method to vaporize LNG. The main problem of the vaporizer is performance degradation caused by frost formation on surface of tube. Determining the appropriate value of design variables under given climate is a critical issue. In this paper, design optimization in the vaporizer is performed using DIRECT algorithm whose result is compared with the result obtained by GA. Time series dataset including temperature and relative humidity of air for a year is categorized using k-means clustering. Finally, the optimal design shows 23.4 % improved performance of AAV and defrosting time is drastically reduced.

Keywords: Ambient air vaporizer, DIRECT algorithm, K-means clustering

1. Introduction

Ambient air vaporizer (AAV) is the most simple type of liquefied natural gas (LNG) vaporizer. The vaporizer do not require external power because it utilizes ambient air to vaporize LNG. Because cryogenic LNG is flowing through the internal section of finned tubes, water-vapour in the air is condensation and frost layer is accumulated at the surface of the finned tubes.[1, 2] The heat transfer efficiency of the vaporizer is reduced by thick frost layer, so defrosting time is typically required repeatedly.

Frost growth on the tube surface is generally known to be highly influenced by atmospheric temperature and humidity, but there is little research into the effects of AAV structures.[3-5] Frost growth is determined by the water-vapour density difference between air stream and frost surface. Weather condition such as relative humidity and temperature is related to the water-vapour density of air stream. But, water-vapour density on the frost surface is affected by the factors like cryogenic LNG, finned tube, etc. Hence, proper design of the AAV structure assists in maximizing heat transfer efficiency of the vaporizer.

Global optimization problems can be generally classified into stochastic and deterministic algorithms. Stochastic algorithms are based on the random generation of points, while deterministic optimization algorithms use a predetermined sequence of points to search for the global optimum.[6, 7] DIRECT, which is shorthand for Dividing Rectangles, is a deterministic global optimization algorithm. Given enough function evaluations and a highly sensitive stopping criteria, DIRECT will always find the global optimum of a function within a given domain.

Numerical AAV model simulate heat transfer from air to cryogenic LNG, mass transfer from air to frost layer and frost growth. The behaviour of the heat and mass transfer phenomena depends on the initially set structure and operation condition. The numerical

model which was validated by pilot-scale experimental data was used to simulate frost growth and temperature profile of LNG. The thickness and density of frost and temperature change of LNG in a vaporizer tube with time and position are predicted using simulation results.[5]

This paper proposes an optimal design of AAV that can vaporize LNG while minimizing the formation of the frost layer and defrosting time in a given climate condition. Climate conditions including temperature and relative humidity of specific region were categorized under k-means clustering. K-means clustering algorithm partitions the data set into k-clusters with the dual objective of making each cluster as compact as possible and the k-clusters as separated as possible. [8, 9] With the clustered data set, DIRECT algorithm and GA (genetic algorithm) were also used to find optimal design of AAV, which shows the difference in convergence speed and optimal point of design structure. Finally, the simulated results which were calculated under optimal design variables were compared with the results from original design variables. The comparison results shows proposed optimal design structure is more efficient than original design with a year's climate data.

2. Ambient air vaporizer model

The numerical model of the vaporizer calculate LNG temperature profile in fin tube of AAV, the thickness and density of frost layer on the tube surface and water-vapor in the air stream which flows outside. Input parameters includes climate data of a year at Incheon, Korea and structure related variables such as thickness and height of fin, tube radius and fan capacity. The climate data of a year was categorized under K-means clustering and centroid values of temperature and relative humidity represents each cluster. Hence, each cluster has its own representative climate condition and weight which was determined by ratio of the number of samples contained in the cluster to total data samples. For optimizing design variables, operating time until the temperature of outlet LNG becomes below -20 °C is defined as duration of AAV. The sum of duration at each cluster is defined as objective function which should be maximized at given design variables.

2.1. Numerical model of the vaporizer

The flowchart of numerical model is shown Fig. 1. First, the number of control volumes and time steps was defined, which was essential procedure for iterative techniques. The operation condition including temperature and humidity of air and temperature and flowrate of LNG is introduced. These parameters used to determine the properties like thermal diffusivity, convective heat transfer coefficient and density. Heat transfer model which calculates heat flux from air stream to LNG and mass transfer model which calculates growth of frost layer are solved based on previously obtained properties. In heat transfer model, heat fluxes and overall heat transfer coefficient affects the enthalpies of air and LNG. In mass transfer model, temperature of frost surface and mass flux of water-vapor determine the frost thickness and density. These two types of model are simultaneously solved and the results from the models are saved for current time step and control volume. The procedure is iteratively performed until the target control volume and time step reaches given values. The detailed explanation including equations and validation is contained at the paper of Lee et al. 2017. [5]

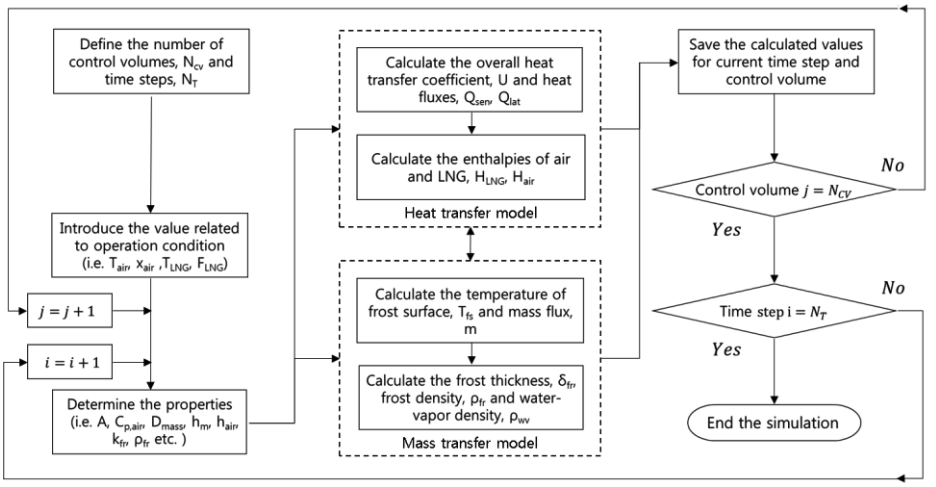

Figure 1. Flowchart of the vaporizer model

2.2. K-means clustering for categorized climate data

Climate condition of the region where the vaporizer was installed was a critical factor. The duration of AAV operation is mainly affected by the factor and the design of vaporizer structure should be considered under the factor. But temperature and relative humidity depend on location and season and are different at every hour of the day. Hence, the climate data with similar values should be grouped and the representative value of the group are selected for evaluation the design variables. K-means clustering is method for finding group which has similar features. Each group has its own centroid which represents the group. So it is simple method for grouping unlabeled big data. The data of a year have information of temperature and humidity every minute and the number of data points is 527,040. Figure 2. shows climate condition of a year in Incheon, Korea.

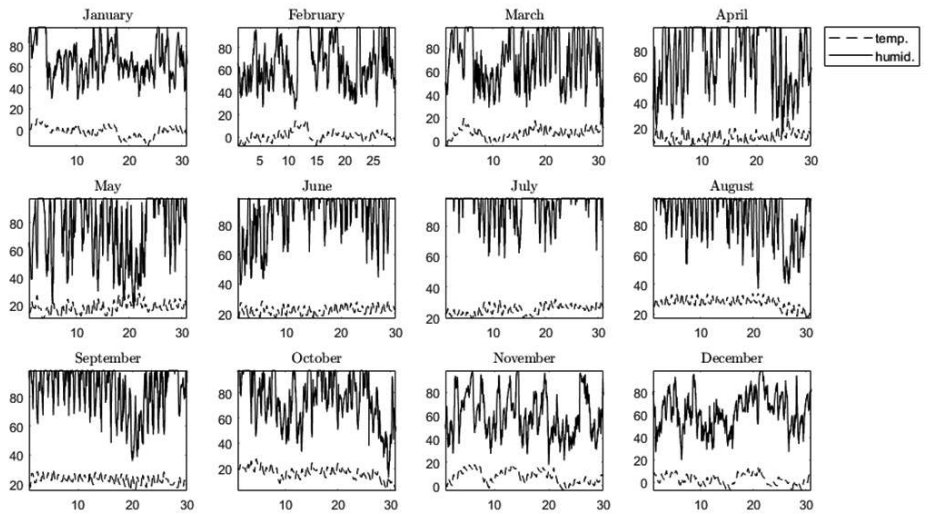

Figure 2. The data of a year in Incheon, Korea in 2016.

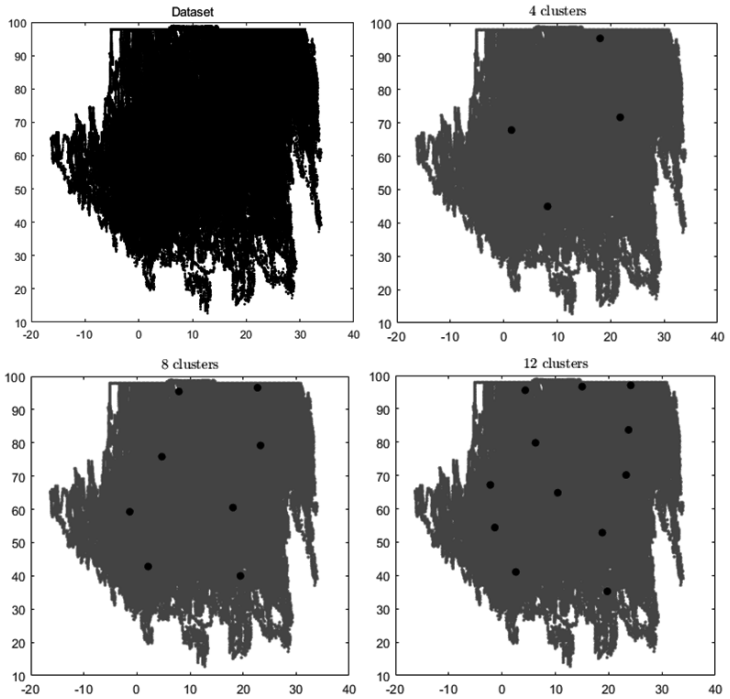

Figure 3. The dataset and centroids by k-means clustering (left-top: dataset, right-top: 4 clusters, left-bottom: 8 clusters, right-bottom: 12 clusters)

4 clusters, 8 clusters and 12 clusters are obtained by k-means clustering algorithm. Figure 3. shows the climate dataset and centroids of clusters.

2.3. Optimization formulation

There are no constraints in optimization problem. But the problem has multiple local optimum because of the complexity of numerical model. The Eq.(1) shows the optimization problem. $f(\vec{x}, w, C)$ is the objective function at which $\vec{x}$ means the design variables, w is weight which was ratio of the number of target cluster's data samples to the number of total data samples and C is temperature and relative humidity of air of clusters centroids. $g(\vec{x}, C_i)$ indicates the duration of validated model operation under $\vec{x}$ and C_i condition. Optimal design variables vector $\vec{x}$ was searched to maximize the sum of product of weight and duration. The boundary conditions of design variables $\vec{x}$ are [2000, 0.005, 0.05, 0.001] for lower bound and [4000, 0.02, 0.15, 0.005] for upper bound. The values in vectors indicate fan capacity, tube radius, fin height and fin thickness in order.

$$\underset{\vec{x}}{maximize} \quad f(\vec{x}, w, C) = \sum_{i=1}^{N_c} w_i g(\vec{x}, C_i) \tag{1}$$

$$s.t.: \quad LB_i \leq x_i \leq UB_i, \quad i = 1, 2, 3, 4$$

3. Optimization result and discussion

3.1. Optimal design of the vaporizer

Proposed optimization problem was solved by GA and DIRECT algorithm. The convergence rates of both algorithms are shown Figure 4. DIRECT algorithm approaches to the optimal point faster than GA at first. But the total iteration steps to optimal point is almost same. The weight of the objective function makes the optimal values almost same in different cluster size.

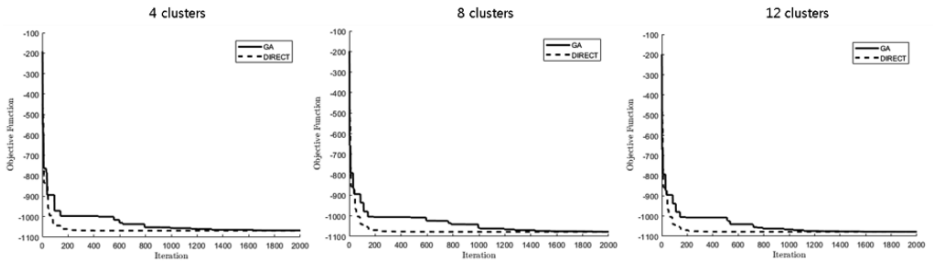

Figure 4. The convergence rate of GA and DIRECT algorithm

Table 1. shows the design variables of optimal solution of DIRECT algorithm at various clusters because DIRECT gives better solution than GA. Tube radius and fin thickness are converged at upper bound. Fan capacity at optimal solution is reduced as the number of clusters increases and fin height is converged near 0.1 m. The results show that proper design of fan capacity and fin height for specific climate is the critical for performance of AAV.

Table 1. The design variables of various conditions

	Fan capacity [m^3/min]	Tube radius [m]	Fin height [m]	Fin thickness [m]
Original	4000	0.0105	0.085992	0.0025
4 clusters	3738	0.0200	0.099826	0.0050
8 clusters	3492	0.0200	0.104100	0.0050
12 clusters	3357	0.0200	0.099588	0.0050

3.2. Comparison of performance in different designs

Figure 5. shows the ratio of operation time to a year. The number of clusters don't affect the results much but comparison of results between original design and optimal design shows 23.4 %, 22.4 %, and 22.6 % increase in operating time respectively. Although 12 clusters reflects better the overall climate than 4 clusters, optimal solution from 4 clusters deliver the best performance.

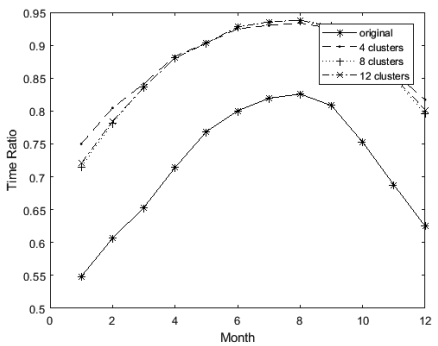

Figure 5. The ratio of operation time to a year

It shows the limitation of the clustering method when dealing with time series data. Figure 6. shows that optimal design provides outstanding performance and vaporizes LNG while minimizing the frost growth and defrosting time.

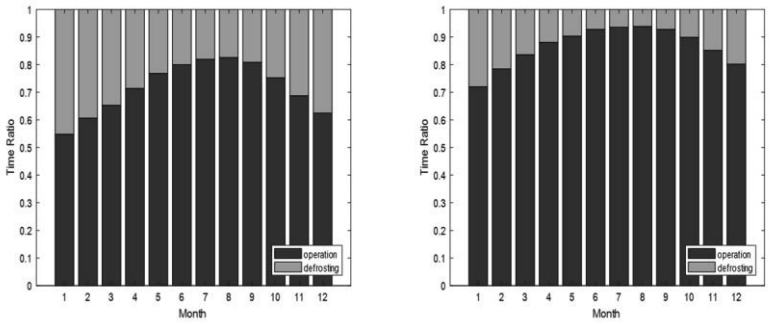

Figure 6. The ratio of operation time to defrosting time (left: original design, right: optimal design – 4 clusters)

4. Conclusions

The optimal design of AAV is proposed using K-means clustering method for data processing and GA and DIRECT algorithm for solving optimization problem. As the number of clusters increases, each cluster better reflects the overall climate. But many clusters does not guarantee optimal design of the vaporizer because clustering method is not best option for treating time series dataset. However, all optimal design shows better performance than original design under climate for a year. The ratio of operation time for clusters increases by 23.4 %, 22.4 %, and 22.6 % respectively. It means the vaporizer can be operated long time with short defrosting time.

Thermoeconomic design of biomass biochemical conversion technologies for advanced fuel, heat and power production

Maxime Alexandre Vigot[a], Theodoros Damartzis[a*], François Maréchal[a]

[a]*Industrial Process and Energy Systems Engineering (IPESE), École Polytechnique Fédérale de Lausanne (EPFL), 1951, Sion, Switzerland*
theodoros.damartzisl@epfl.ch

Abstract

The current work addresses the design and assessment of different biomass conversion pathways based on anaerobic digestion for the efficient transformation of the raw materials to a variety of products, including bio-SNG, heat and power. Using a generic superstructure-based approach, various conversion pathways can be synthesized in the context of a MILP optimization problem that aims to minimize the total process cost. A comprehensive methodology is utilized, able to produce a large variety of process alternatives. Heat integration is employed among all designed cases to best exploit the process thermal streams and minimize the energetic needs. Four indicative flowsheet designs are presented and assessed here, regarding their energetic consumption as well as their associated revenues.

Keywords: anaerobic digestion, biogas, bio-SNG, heat and power production, fruit and vegetable residues.

1. Introduction

Recent fluctuations in the prices of fossil fuels as well as the overall shift towards renewable energy have led to the intensification in the design and employment of biomass-based conversion technologies. The latter, together with the high available biomass potential constitute the enhancement of the role of biomass in the global energy mix as well as the development of efficient conversion technologies to support the chemical transformation to energy and fuels a necessity.

Biomass conversion technologies allow the transformation of raw biomass to a variety of gaseous, liquid or solid fuels as well as the simultaneous production of heat and power for energy services supply. Biomass-produced fuels can substitute nearly any kind of conventional fuel, decreasing the associated greenhouse gas emissions. However, the current high investment costs, together with the relatively low conversion efficiencies hamper the quick propagation of these technologies and limit the utilization of biomass to direct combustion in order to maintain a profitable operation (Codina Girones et al., 2017). On the other hand, the drawbacks associated with the efficiency limitations during the chemical transformation of biomass can be easily compensated by an effective reformulation of the conversion path, including the employment of a variety of sub-processes that increase the overall efficiency.

Anaerobic digestion (AD) is a biochemical process for the conversion of a wide variety of wet biomass (i.e. animal manure, sludge from wastewater treatment plants (WWTP),

household or industrial residues containing significant levels of humidity etc.) into biogas, a mixture of CH_4 and CO_2 (Ward et al., 2008). Biogas can be then upgraded to bio-SNG or used as fuel for heat and power production. Anaerobic digestion also produces a sludge residue, which includes the undigested part of the biomass. The latter can be directly used as soil amendment of further treated for methane or energy production as well as the extraction of the contained nutrients in the form of phosphorus, nitrogen and potassium (Abubaker et al., 2012).

A large variety of possible pre-treatment steps can be used enhance the digestibility of the biomass by either chemically intervening to the system's biochemistry (Passos et al., 2017) or simply increasing the effective area for digestion with simple size reduction of the raw material. Similarly, the upgrading of biogas into a stream of pure CH_4 is realized with the employment of a number of techniques that include the separation and removal of CO_2 from the gaseous mix, the conversion of CO_2 into CH_4 or even a combination of the two (Singhal et al., 2017). The solid digestate can also be processed in a number of ways including drying and reuse as fertilizer (Alburquerque et al., 2012) or further treated in order to recover the contained carbon material (Tambone et al., 2010). Finally, depending on the employed conversion and upgrading technology, the produced stream of either biogas or bio-SNG can be further treated for energy recovery in gas boilers, cogeneration units of even injected into the natural gas grid, provided that the specifications are met.

The large number of possible options in all processing stages between the raw materials and the end products creates a plethora of conversion chains that differentiate in terms of conversion efficiency as well as total process cost. This work aims towards the systematic identification, development and assessment of efficient pathways through which biomass is effectively converted to a number of potential products based on anaerobic digestion. This complex problem is handled within a generic framework that utilizes a process superstructure approach for the representation of the possible conversion pathways as well as their synthesis from a list of available technologies that act as building blocks. The efficient design of the arising conversion pathways is established through the use of a MILP optimization formulation that aims to minimize the total capital and operating expenses of the process. Process integration considerations are further employed to ensure the minimization of the energetic demands in the designed plants and further enhance the process economics through the efficient design of the heat exchanger network. Thus, the emerging solutions can be easily assessed for their economic performance and decisions regarding the selection of the most suitable conversion pathway based on the type of raw biomass used and intended product can be facilitated.

2. Methodology

To address the problem of designing an economic and energy efficient process for the treatment of biomass through anaerobic digestion, a process superstructure was formulated consisting of the possible options representing the employed technologies. The arising superstructure is schematically depicted in Figure 1. The considered technologies revolve around the processes of pre-treatment, conversion to biogas, upgrading of biogas and provision of services.

Pre-treatment of biomass involves the mechanical, thermal or chemical processing of the raw material in order to facilitate the digestion process. Mechanical pre-treatment

methods usually resort to size reduction in order to expose a larger area to the methanogenic bacteria and increase the rate of conversion. On the other hand, thermal pre-treatment methods involve the processing of the biomass at elevated temperatures for a specified amount of time in order to enhance the solubility of organic waste constituents and subsequently promote the hydrolysis step. Finally, chemical methods aim towards the initial breakdown of the organic matter via the addition of alkaline or acid solutions.

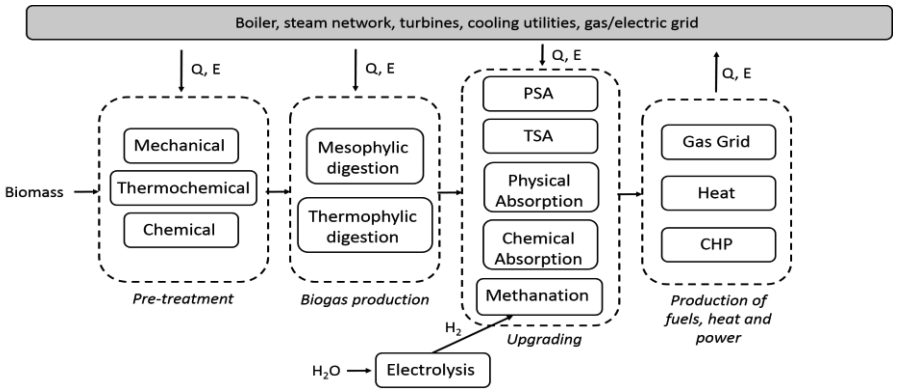

Figure 1. Biomass conversion superstructure.

The considered conversion of biomass to biogas involves two scenarios; utilizing either mesophilic or thermophilic bacteria. The major differences between the two involve the operating conditions such as temperature and retention time but also affect the CH_4 content of the biogas.

A number of different biogas upgrading methods are considered as shown in Figure 1. PSA and TSA exploit the pressure and temperature effects on the CO_2 adsorption equilibrium, respectively, creating an alternating cycle of adsorption and desorption in suitable solid materials. Membrane separation is based on the gas dissolution and diffusion into polymeric materials, responsible for selectively allowing the passing of certain gases, thus achieving the separation of a gaseous mixture. Solvent-based CO_2 capture processes involve the physical or chemical entrapment of CO_2 in usually packed absorption / reactive absorption columns. Depending on the employed solvent, various regeneration and operating costs apply for these processes. Finally, direct methanation involves the reaction of CO_2 with H_2 in moderate temperature and pressure for the production of additional CH_4. Subsequently, the product of upgrading can either be directly subjected into the natural gas grid of further converted to heat and/or power using turbines, fuel cells or advanced cogeneration units.

The addressed problem is formulated as a MILP optimization focusing on the minimization of the total process expenses that account for the annualized capital and operating costs of each designed process, further implementing heat integration considerations to account for the minimization of the heating/cooling requirements. The methodology is implemented in the OSMOSE process integration platform (Bolliger, 2010), where the mathematical programming is defined using AMPL. The employed optimization scheme can be seen in Figure 2, showing the information exchange between the various modeling layers.

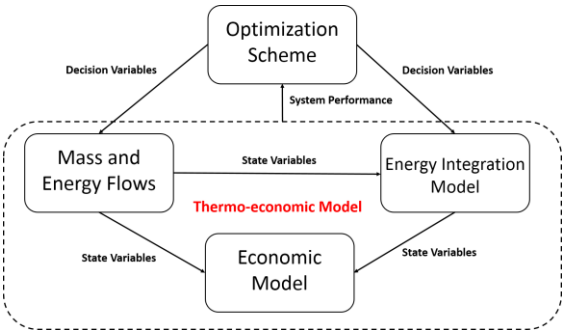

Figure 2. Optimization scheme

3. Case study

Fruit and vegetable residues with a total solids (TS) content of 10 % wt. have been selected as the raw material. The volatile solids (VS) content of the biomass is 86 % wt (Gunaseelan, 1997) and the plant capacity was set to 12500 kg/day.

Four indicative scenarios are presented here as part of the attained solutions. The first two scenarios are depicted in Figure 3 and differentiate by the end services. Specifically, in FS-1, the methane from the upgrading step is directly inserted to the natural gas grid, while a SOFC is used in FS-2 to convert it to electricity. Both flowsheets neglect the use of a pre-treatment step as is was not deemed economically viable, while they employ a biofiltration step for the cleaning of the biogas impurities as well as PSA for the upgrading step. In both cases, the reactor is a handled as a thermophilic digester with an operating temperature of 55 ºC and a retention time of 20 days, a typical value for the thermophilic digestion of food waste (Mir et al., 2016). The PSA utilizes a pressure of 8 bars to achieve the desirable separation.

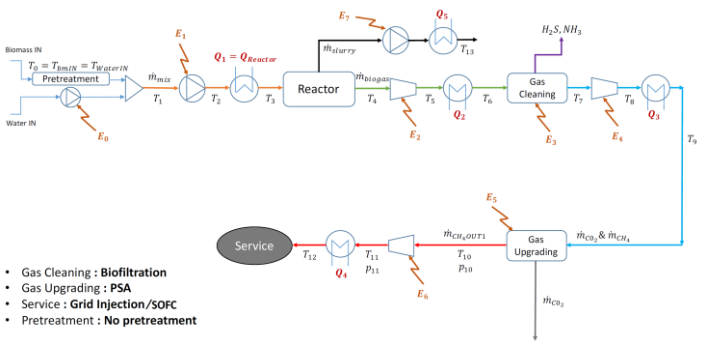

Figure 3. Schematic representation of scenarios FS-1 and FS-2.

Figure 4 shows the designed flowsheets FS-3 and FS-4. In these, a methanation reactor operating at 220 ºC and 20 bars is used to convert the captured CO_2 into extra methane and enrich the final methane yield prior to grid injection or further treatment. The required H_2 for the reaction is obtained from water electrolysis using renewable energy sources, in the form of solar energy. However, in this study, the electrolyzer design and economics were not taken into consideration. Like the first two flowsheets, FS-3 and

FS-4 differ in the end services, with FS-3 producing a bio-SNG stream that is injected into the gas grid while FS-4 employs a fuel cell for power generation. The operating principles of the digester and PSA are the same as the respective ones in FS-1 and FS-2.

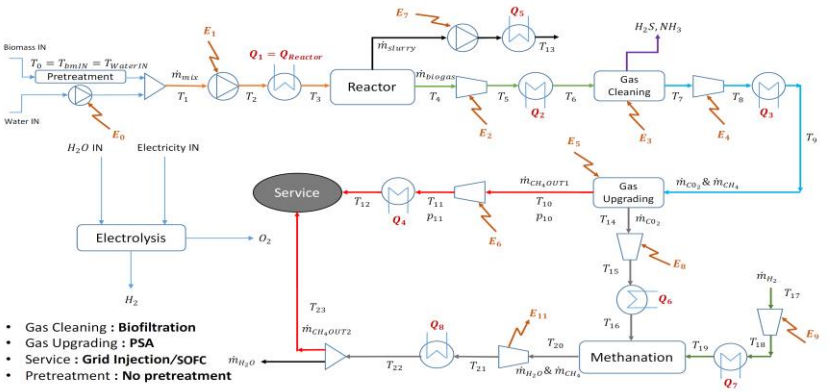

Figure 4. Schematic representation of scenarios FS-3 and FS-4.

In all four cases, the obtained heat from the heat exchangers is sufficient to fulfill the energetic needs of the process regarding heating, eliminating the need for an extra boiler, while in the cases of power generation the latter is partly used to supply the necessary power in the pumps, motors and compressors of the process. Cooling, on the other hand, is still necessary to reduce the temperature of the intermediate process streams.

Table 1. Operating expenses and revenues for the four reported flowsheets.

	FS-1	FS-2	FS-3	FS-4
Expenses (in €)				
Process Water	1966.27	1966.27	1879.39	1879.39
Electricity	25352.85	0	37066.63	0
Revenues (in €)				
SNG	59270.6	0	93854.96	0
Electricity	0	70010.27	0	112626.71

Table 1 summarizes the energy consumption in the four designed flowsheets as well as the obtained revenues from the distribution of bio-SNG or electricity into the respective grids. The process water used to create the slurry fed into the digester is smaller in the cases where methanation is used. This is because the water produced by the reaction is assumed to be used in the process after a condensation step. It can be seen that the power demands in the cases where a SOFC is used are fully satisfied by the product of the process itself, disregarding the need for grid imported power. These include the energy demands for the compressors, motors, pumps as well as the operation of the cooling tower. Finally, the option of using a methanation reactor significantly increases the production of bio-SNG through the recovery of extra methane leading to increased revenues, both in the case of grid injection as well as in the case of power generation.

4. Conclusions

A comprehensive methodology for the design and thermoeconomic assessment of biochemical biomass conversion technologies was presented. A generalized superstructure approach, encompassing the various intermediate processes that lead from the raw materials to the end products, coupled with a MILP optimization problem, has led to the design of a variety of process alternatives. A case study is shown here, accounting for the transformation of fruit and vegetable residues to bio-SNG, heat and power and four indicative solutions are presented. Heat integration has allowed the minimization of the heating demands in the processes and a variance is observed among the final revenues depending on the type of the end services as well as the conversion path used. The employment of a methanation reactor for the enrichment of the produced bio-SNG has led to improved attained revenues in the range of 58 % for the case of bio-SNG production and 61 % for the case of power generation.

Abstract

The following work aims to estimate the production of biogas in the liquid and gaseous phases in an anaerobic reactor by means of simulation. For this, the ADM 1 model modified by Mendes et al. (2016) is used to represent the simultaneous removal of carbon and nitrogen (SRCN) from a fishery effluent. Henry equation, originally used to represent thermodynamic equilibrium, is hereby replaced by a method that aggregates more robust equations, available in the simulator Aspen Plus. Therefore, the validity of Henry's law is tested by applying an equilibrium condition that considerate liquid phase modeling by means of eNRTL method. The results show that when applying the thermodynamic method, the gaseous concentrations for CH_4, N_2, H_2 and acetic acid are lower than those foreseen by ADM 1, and the presence of these dissolved components in the liquid phase is indicated. That way, it is verified that the consideration of equilibrium condition is fundamentally important for anaerobic digestion process, besides indicating the need for more in-depth studies about the influence of this consideration in the process.

Keywords: anaerobic digestion, equilibrium conditions, ADM 1, modeling.

1. Introduction

Anaerobic processes allow treatment of effluents with low sludge generation and production of biogas (renewable energy). Less space is needed for operation and it's applied to the treatment of both diluted and concentrated effluents. In this process, about 70 - 90 % of the influent COD is converted to biogas, leaving the reactor in the gaseous phase. A portion ranging from 5 – 15 % is converted to biomass, and about 10 – 30 % of the influent COD is converted neither into biogas or biomass, so this portion composes the liquid phase leaving the reactor as non-degraded material (Chernicharo, 2007). In this portion, some dissolved gases such as N_2, CO_2 and especially methane gas (CH_4) are found.

In this sense, anaerobic digestion presents itself as a potential source of greenhouse gas emissions, since CH_4 and CO_2 have high polluting potential and may be emitted by the process. Particularly in relation to CH_4 gas, besides the pollution potential, its loss in the liquid phase leads to the reduction of energy potential of the system (Lobato, 2011).

This concern motivated several authors to investigate the presence of CH_4 dissolved in both diluted and concentrated wastewater. The results of the studies indicate a large variation in the dissolved amount. Souza et al. (2011), observed values around 36-41% for domestic water treatment, and other authors reported by Crone et al. (2016) found

values of 11-100% at different temperatures, concluding that the concentrations of dissolved methane may be many times higher than those values predicted by Henry's law, in a supersaturation state. In this sense, it's necessary an accurate modeling of this process, based on biochemical fundamentals in order to predict the biogas production. Also, it's important to do a reliable consideration of the liquid-vapor phase equilibrium, aiming a correct calculation of the gaseous solubility. This approach allows a closer representation of the real situation.

In light of this, the present work uses the gas production data predicted by the Anaerobic Digestion Model N.1 (ADM 1) for the wastewater treatment of salmon effluent in a CSTR proposed by Mendes et al. (2016) and implemented in Matlab/Simulink. Together with ADM 1, it is proposed to improve the thermodynamic representation of the process by using a simulation tool, Aspen Plus. Therefore, it is possible to verify the prediction of biogas formation, and the presence of dissolved gases (mainly CH_4) in the liquid phase, after the application of a thermodynamic method.

2. Anaerobic Biodigestion Modeling and the Representation of Equilibrium

Knowing the complexity of the anaerobic digestion process, Batstone et al. (2002) proposed a generic model to control the operation and prediction of biogas, the ADM 1. It is composed of biochemical and physical-chemical reactions, represented by acid-base and gas-liquid transfer reactions. The gas liquid equilibrium is represented by Henry's Law. Despite being used, this law does not present great relevance in relation to gas transfer, indicating how much the liquid-gas system is far from equilibrium. (Souza, 2010). Mendes et al. (2016) proposes a modification to represent the simultaneous removal of carbon and nitrogen (SRCN) in anaerobic-anoxic reactor.

Batstone et al. (2015) ponders the need to consider the solubility of the gases, including methane. Since this gas has a low mass transfer coefficient, it ends up being released with the final effluent. It is also necessary to consider the influence of electrolytes, since these ions interact with stronger and far-reaching forces than those of the neutral molecules. In addition, because of the different functional groups, the effluent will have a high non-ideality. Consequently, Henry's Law will be significantly different for this case over those with very low electrolyte concentrations. (Sandler, 2006).

Since the equilibrium conditions control the entire reaction mechanism that occurs between species in reactor, it becomes essential to apply a more robust thermodynamic method to the model in order to obtain results closer to reality.

3. Methodology

For integration between the ADM1 model proposed by Mendes et al. (2016) and the external simulator, ActiveX tool was used. Due to consideration of acid-base pairs, the chosen method on the thermodynamic simulation was "Electrolyte-NRTL" (eNRTL), implemented as ELECNRTL. This is a comprehensive electrolytic method since it handles solutions of very low concentrations up to high concentrations. It applies a modified Debye-Rueckel equation, able to represent long and middle range interactions. Furthermore, it takes Redlich-Kwong equation for predict the vapor phase properties and Henry's Law for modeling the gases solubility. This method also handles short range interactions. (Aspen Technology, 2013; Biernacki, 2014).

This way, ADM1 for SRCN is integrated from an initial instant t to a final instant t+1, step by step, until it reaches the steady-state. In each instant of time, Matlab communicates with the simulator estimating the compounds distributions between gaseous and liquid phase, the equilibrium conditions. Figure 1 shows a schematic representation of the integrated model developed, as well as the flow of required information and data for the simulation.

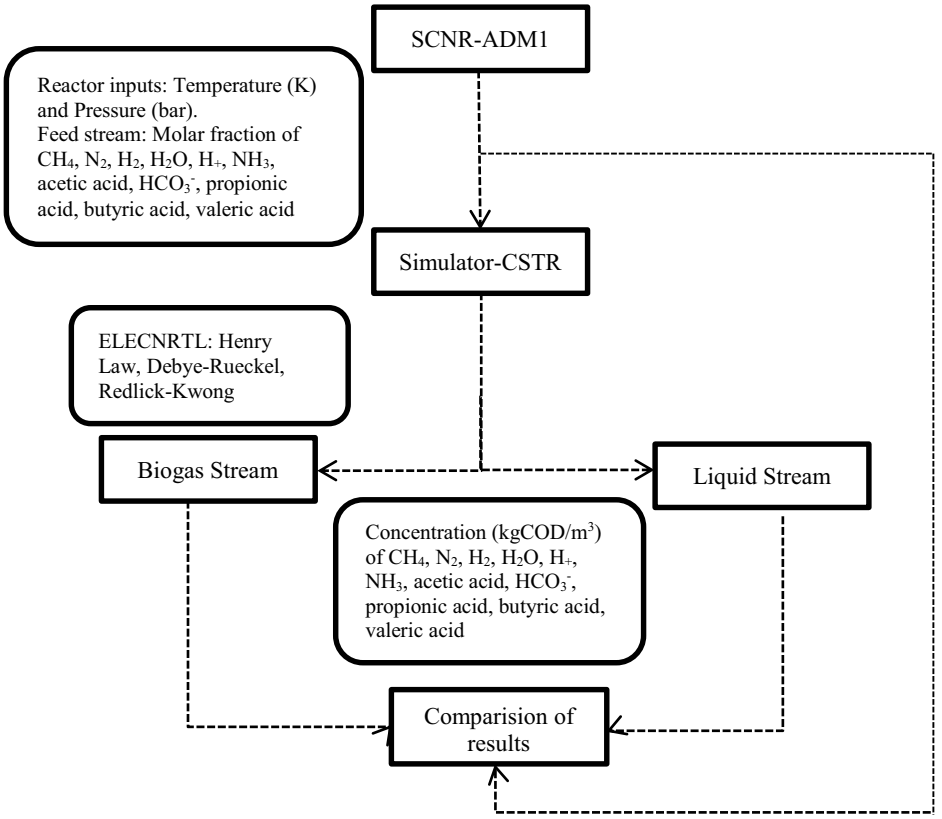

Figure 1- Representative scheme

4. Initial results

Figure 2 shows the prediction results using the proposed method for equilibrium. The concentration is given in kgCOD.m^{-3} and time is given in hours. In letter a, the predicted concentration of produced CH_4 from ADM 1 is shown. It may be noted that ADM 1 indicates a biogas production with a concentration of 0.1897 kg COD m^{-3}. When the thermodynamic equilibrium is represented by the simulation tool, a lower concentration is obtained that makes up the gaseous phase, 0.0953 kgCOD.m^{-3}, with a portion remaining in the liquid phase 0.0073 kg COD.m^{-3}. Letter b shows the behavior for Nitrogen, the final product of the denitrification process, occurring from the oxidation of ammonia to nitrate, and subsequent reduction from nitrate to nitrogen. It is interesting to note that nitrogen oxides have an inhibitory effect on methanogenesis, since there is a substrate competition between fermentative, methanogenic and denitrifying bacteria.

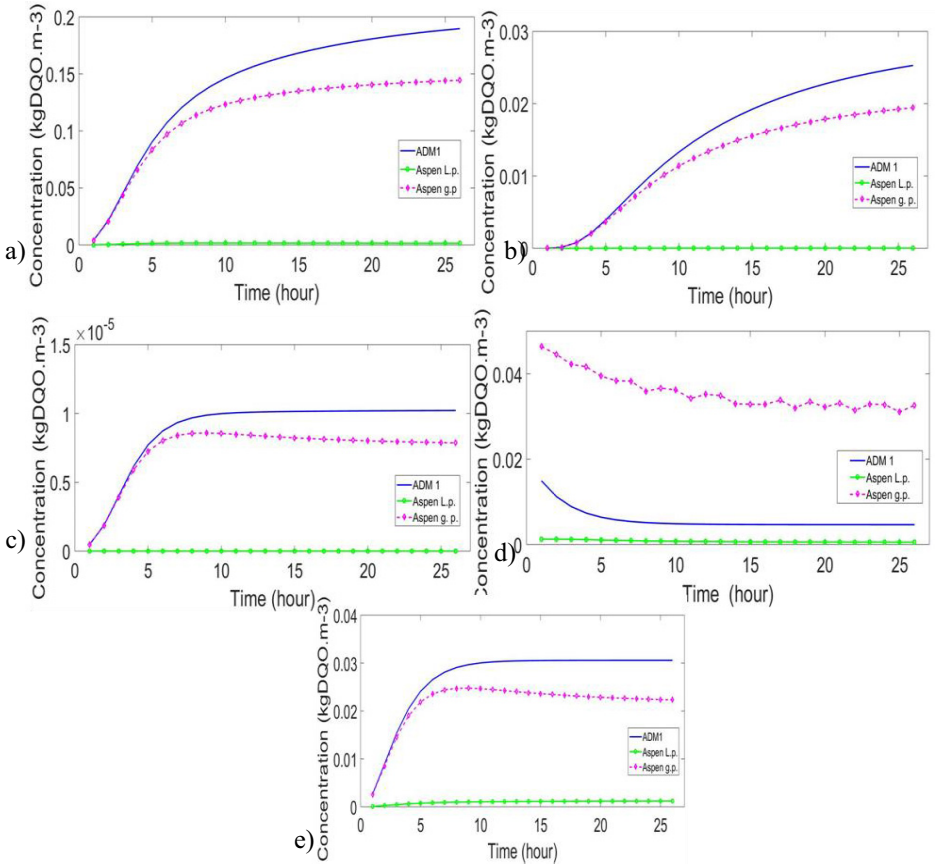

Figure 2- Results for prediction of concentration in each instant t: a) CH_4 b) N_2 c) H_2 d) CO_2 e) Acetic acid

By the figure, it is possible to notice that the behavior for gaseous phase remained the same, but the simulation with the thermodynamic model eNRTL once again found a lower gas concentration (0.0136 kgCOD.m^{-3}) and a small concentration in the liquid phase (1.1414e^{-4} kgCOD.m^{-3}). For Hydrogen, figure c, the same behavior as the previous compounds is observed. It is noted in the beginning of the process, the acidogenesis of the products resulted from hydrolysis, noticing a rapid increase in the hydrogen concentration. H_2 is also formed in acetogenesis from organic acids, along with CO_2 and acetic acid. The concentration becomes constant while the hydrogen is consumed by the homoacetogenic to form acetate and later by the methanogenic for the formation of CH_4, where the hydrogenotrophic bacteria will use it as energy source.

For CO_2, letter d, it is verified that the prediction using the thermodynamic model eNRTL did not progress with the same tendency of the ADM 1. Initially, this gas is formed and consumed in acetogenesis and after it is a product of methanogenesis from acetate, whereas it is consumed in methanogenesis from H_2. The trend simulated using the new thermodynamic model exhibits a worrying behavior since it confirms a

concentration higher than expected for the gaseous phase and a considerable concentration for the liquid phase. This could be due to numeric method or the influence of consider it as an important integral acid-base pair. This dilution in liquid phase can cause a drop in pH, since in water CO_2 is maintained as carbonic acid. With decreasing pH, CO_2 is dissolved as a neutral molecule, but with increasing pH it forms carbonic acid that ionizes. (Serrano, 2011).

The acetic acid, letter e, follows the same trend proposed by ADM1. Since it is one of the main components of the process, once after being formed in the acidogenesis it is used by the methanogenic bacteria to produce CH_4. Ammonia, propionic acid, valeric acid, butyric acid and carbonic acid had much lower concentrations than those predicted by ADM 1, besides the fact that they did not present behavior following the trend of the original model. Except for ammonia and carbonic acid, the acid-base reactions for volatile acids were not specified by the thermodynamic model because their ions are not present in the simulator databases and, for the implementation, a great number of information is necessary. In any case, they have a low dissociation constant and therefore, their higher or lower concentration does not strongly affect the result, and may have a negligible acid-base effect. (Serrano 2010)

Pauss et. al. (1990) considers the importance to considerate steady-state (as considered in the simulation), when no variation occurs in flow, temperature or pressure. In this case, normally, the concentration of dissolved gases is close to equilibrium values. About the highly soluble gases as CO_2, H_2S and NH_3, they are likely to be in thermodynamic equilibrium, even with low mass transfer coefficient. About the poorly soluble gases, as CH_4, N_2 and H_2, they are far from the equilibrium. In fact, the effluent here considered presents many compounds that affirm its non-ideality.

This discussion raises important considerations involving evidences cited for previous authors and possibly confirm that effluent may being eliminated before reaching the equilibrium, once high values of dissolved methane was measured. Even if this effluent goes to others steps of post treatment (as indicated) and if the methane is transferred from liquid to gaseous phase, it would be emitted to atmosphere. This investigation needs more steps to confirm how much this evidences and purposes is correlated.

5. Conclusion

This work allowed to visualize the influence of consideration about thermodynamic equilibrium in the model, using an electrolytic method. It is a significant approach, especially for CH_4, since its loss also characterizes energy loss of the system, as well as environmental damages. For further steps, new investigations must be carried out by adding all the acid-base reactions in the simulator, considering each functional group and investigation if in this case, methane is in supersaturation condition, as previously reported. The work ends as a finding that thermodynamic equilibrium does indeed provide a reliable representation of the results, indicating a deeper investigation is needed to validate this observation. Besides, it is an advance in ADM1 usage by improving its results with a rigorous thermodynamic approach, since it may allow a precise improvement in ADM1 values, ensuring a strict representation of this process.

Abstract

Demand responsive operation of chemical processes has recently become the focus of significant research. While various operational scheduling solutions have been proposed to realize demand response (DR) objectives, the possibility of plant flowsheet reconfiguration in real-time has rarely been addressed. In this work, we compare the different deterministic design solutions of a work-heat exchanger network under varying electricity prices. We present a heuristic design that allows for reconfigurability during DR events using a superstructure formulation to conceptualize a DR-enabled process design.

Keywords: Demand Response, Work-heat Exchange Network, MINLP, Flowsheet Reconfiguration.

1. Introduction

The fluctuation of electricity prices, caused by changing demand and generation profiles during a specific period, is already playing a significant role in industrial energy management strategies, and this is likely to continue with the growing share of renewables in future energy systems. The challenge of decreasing the impact of volatile electricity price profiles evoked concepts like demand response (DR), where electricity consumption is adjusted depending on its price during a specific period. While a higher electricity price encourages consumers to lower their demand, low prices are an incentive to increase it. As a result, fluctuating electricity price profiles are smoothed benefiting both the energy providers and the consumers.

DR has been discussed recently in the context of chemical process systems (e.g., Chmielewski 2014; Harijunkoski et al. 2014). Primarily, the focus has been on the scheduling of process operations, typically by increasing or decreasing production rates during the day or by shifting production load among specific units (Kwag and Kim, 2012; Mitra et al., 2012; Wang and Li, 2013; Wang et al., 2014). Wang et al. (2015) also presented a proactive approach for operational reconfiguration of heat exchanger networks (HENs) under varying electricity prices and renewable energy resource availability to satisfy DR objectives. Compared with operational DR solutions, the

design of DR-enabled chemical processes has received limited attention, and has focused mainly on air separation units (Pattison and Baldea, 2014), where variable capacity operations are accounted for during the process design step. The design of a process network, allowing varied operating levels as well as enabling the optimal process flowsheet reconfiguration under different DR scenarios is a novel concept. Intuitively, reconfiguration suggests the purchase of more (redundant) process equipment which generally results in a higher capital investment. Whether the economic benefits from DR operation can compensate for the higher investment and thereafter reduce the overall cost remains an open research question.

In this work, we propose a heuristic study of an existing work-heat exchanger network (WHEN) model (Huang and Karimi, 2016) to demonstrate the concept of a reconfigurable flowsheet subject to DR objectives. We first obtain the optimal design solution under different electricity prices; then an ad-hoc method is introduced to explore the generation of a design that can switch flowsheet configurations to accommodate DR objectives.

2. WHEN Modeling and Optimization

While air separation processes are significant energy consumers, several other processes have also been identified as potential candidates due to their high electricity consumption, including pulp and paper, aluminum, chlor-alkali, cement, and steel (Paulus and Borggrefe, 2011). Another promising technology is the combination of work exchanger networks (WENs) with heat-exchanger networks (HENs), which also utilize energy-intensive equipment. Similar to HENs in which heat-exchangers are used to have process stream meet temperature targets, a WEN is equipped with single-shaft-turbine-compressor (SSTC) units for transferring work from high- to low-pressure process streams. Razib et al. (2012) first introduced a superstructure-based mixed-integer nonlinear programming problem (MINLP) model to include the SSTC into the work recovery. Based on their study, Onishi et al. (2014) further developed a MINLP formulation to include heat integration. However, their model includes highly nonlinear equipment cost functions and a number of big-M constraints. Huang and Karimi (2016) proposed an alternative formulation to address these issues, yielding a more efficient model for WHEN synthesis.

The WHEN model consists of three parts, including the set of equations describing the HEN and WEN modules and their connections. In this work, the WEN model is taken from Huang and Karimi (2016) and the HEN model is based on a formulation proposed by Yee and Grossmann (1990). The connection of HEN and WEN is achieved by considering the outlet temperature of a HEN stage as the inlet temperature of the subsequent WEN stage, while the pressure drop in the HEN is neglected. The objective is to minimize the total annualized cost (TAC), including the capital (CAPEX) and operational (OPEX) costs.

The WHEN model results in a MINLP problem. Its highly nonlinear characteristics preclude the guarantee of obtaining a global optimum, and in this work, a heuristic, ad-hoc method was used for finding the local optima with GAMS/SBB. Various scenarios are developed and following the adjustment of the initialization and electricity prices, the optimizations are run consecutively. While other solvers, i.e. DICOPT, are also useable for MINLPs, SBB showed the best performance in terms of computation time and obtaining feasible results.

3. Case Study

3.1 Process description

To test the WHEN model formulation and confirm the scenario assumptions, the data of example 3 in Huang and Karimi (2016) are used for evaluating a LNG process. This case study deals with the work and heat integration between two gaseous and one liquid process streams. For the liquefaction of natural gas (NG), the feed stream has to be compressed and thus is considered as a low-pressure (LP) stream in the WEN, while it is regarded as a hot stream in the HEN since it is more energy efficient to compress cold streams. In contrast, the liquid nitrogen used to cool down NG is supposed to be a high-pressure (HP) and cold stream. Liquid CO_2, a side-stream of the LNG process, is considered to be a no-pressure-change stream (NPCS) to be heated, and is not involved in the WEN. All process data are taken from (Huang and Karimi, 2016), while this paper focuses on a varying electricity price structure to demonstrate how DR objectives are met. Furthermore, since selling back electricity to the grid is allowed and would generate a revenue, the electricity selling price is assumed to be 50 % of the purchase price. For evaluating off- / mid- / and on-peak scenarios, three different electricity price levels are assumed. As time of use (TOU) electricity price, the following distribution was assumed: \$0.07/kWh for 11 h/d (midnight to 11 am), \$0.15/kWh for 7 h/d (11 am to 6 pm) and \$0.30/kWh for 6 h/d (6 pm to midnight).

4. Results and Discussion

First, the MINLP problem is solved using the TOU electricity price structure. As a result, the optimal configurations for the different periods are obtained as shown in Table 1. While an off-peak electricity price leads to the use of a valve for expanding HP, a utility turbine is chosen for higher prices. Since the utility turbine is assumed to be much more expensive than a valve, its use has to be economically compensated by the generated revenue, which is the case when the electricity selling price is high.

Although the configurations for mid- and on-peak process look similar (Figure 1), their loads and process stream connections are slightly different. Specifically, in the WEN the utility and SSTC turbine are in reversed order, and in the HEN the number of heaters is higher in the mid-peak scenario.

TAC [$/y]		124,699	116,842	-251,328

*0: Used but no load; - : not used

To gain further insight into the DR behavior of the WHEN, we consider and evaluate the following scenarios:

1. Use one of the optimal configurations (Fig. 1) throughout the entire day, recognizing that each configuration would be suboptimal during the other two periods.
2. Commit to the purchase of all equipment under all three configurations and allow for the reconfiguration of the flowsheet among the available equipment, switching configurations as electricity price changes. From the CAPEX standpoint, this is the worst case scenario. We will refer to this as the WHEN superstructure.
3. Create a WHEN *suprastructure* that modifies each optimal configuration in an ad-hoc fashion so that the modified configurations have more common equipment. When all such equipment are combined, one still has a reconfigurable flowsheet but much less capital commitment than the WHEN superstructure. This comes at the expense of likely increased OPEX during the realization of various electricity price levels.

For evaluating the total cost of using a single configuration for the entire time (on a daily basis), the binary variables of the WHEN are fixed as suggested by the solutions and run under the other two electricity purchasing and selling prices.

The WHEN suprastructure is achieved by fixing the HEN equipment, while the binary variables of the WEN remain as decision variables. This scenario was used since a single WEN configuration under a varying electricity price showed high TAC, so one HEN was assumed to lower the cost. Though a slight decrease of the cost was achieved (see Table 2), it could be different for other electricity price profiles due to the heuristic nature of this approach. Furthermore, although only the HEN equipment was fixed under different electricity prices, the WEN configuration is almost the same in mid- and on-peak periods.

The results of the above scenarios are summarized in Table 2. One can see that when using a single configuration for the entire day, the mid-peak configuration has lowest cost, while the WHEN suprastructure is slightly cheaper compared to the WHEN superstructure. Although the CAPEX and OPEX for the off-peak configuration are the lowest, the total cost is higher than the mid-peak and on-peak configurations since no revenue is generated due to the low electricity selling price.

Table 2: Daily cost of all configurations.

Cost [$/d]	Off-Peak Configu-ration	Mid-Peak Configu-ration	On-Peak Configu-ration	WHEN Superstructure	WHEN Suprastructure
CAPEX	350	1,040	1,041	1,066	1,037
OPEX	6	347	347	295	269
Revenue	0	1,069	1,063	887	836
Total	356	318	325	474	470

Table 3: Stream loads of WHEN suprastructure.

Equipment	Stream(s), Stage	Load [kW]		
		Off-Peak	Mid-Peak	On-Peak
SSTC turbine	HP1, s1	125.7	71.2	71.2
SSTC compressor	LP1, s1	125.7	71.2	71.2

Cooler	LP1	-	98.4	98.4
	LP2	383.4	31.3	31.3

4. Conclusions and Future Work

In this study, the concept of a reconfigurable design for process flowsheets under varying electricity profiles was introduced and demonstrated using a WHEN case study. The preliminary results show that different electricity purchasing and selling prices highly influence the WHEN configuration while the use of the single mid-peak configuration for the entire time yields the lowest TAC. We note that the current results are ad-hoc solutions, and no global optima is presumed to be obtained, meaning that under other assumptions the WHEN superstructure could have lower TAC. Further research needs to be conducted, focusing on other electricity price profiles, cost data and scenarios using a broader variety of process streams. While the MINLP problem of work-heat integration between two gaseous and one liquid process stream is a relatively simple example, a higher number of streams would result in more complex models, which are difficult to solve. More importantly, a rigorous solution of the optimal network reconfiguration needs to be formulated.

Abstract

Software tools for process simulation and optimization have increasingly been used in industry to design and operate complex, highly interconnected plants. This allows the design of industrial plants to be profitable and to meet quality, safety, environmental and other standards. The aim of this work is to create a platform to simulate industrial sugarcane first generation process. Brazilian sugarcane industry is a well known process with many parameters available from industrial and literature data. The current first generation process seems to have reached the state of art and not great improvements seams to emerge nowadays. However engineering research has dedicated great efforts recently to improve efficiency through the use of industrial and agricultural residues. Most of these studies are related to the use of lignocellulosic material and vinasse. In this context an easy and simple platform has been developed to provide reliable outputs that could provide data for the studies of viability, social and environmental impacts when an additional process are interconnected to the first generation plant. The model has been validated using industrial data in order to attain the most realistic outputs.

Keywords: Sugarcane, biofuel, biogas, process simulation.

1. Introduction

In Brazilian sugarcane industries, several studies have been carried out as an attempt to use agricultural residues like straw (Dias, et al., 2012) or industrial residues like vinasse (Longati, et al., 2017) and bagasse (Furlan, et al., 2012) to sum up with new co-products or improve the whole sector more efficiently (Junqueira, et al., 2011) These new processes can be understood as an interconnected plant to the current first generation process where materials and utilities are shared. (Fonseca, et al., 2017). Indeed, there is a synergetic interaction between the new and the main process which could result in better overall energy balance. (Furlan, et al., 2012) The objective of this work is to develop a model for quantitative simulation of a feasible ethanol and sugar conversion process that uses these residues as raw materials and is interconnected to the first generation process.

2. Process Overview

The development of this computational platform follows the process configuration presented in Fig 1, which is a typical sugarcane mill. Each step represents an area at the sugar mill industry and each area has a number of unit operation processes. In Fig 1, "cane reception and extraction" is the process where the sugarcane feed is reduced into

small pieces and the sugar bearing cells is ruptured to facilitate the subsequent extraction process. The size reduction is generally achieved through the use of rotating knives and swing hammer shredder in the cane conveying system. In the case of billeted cane, mechanically harvested, it can be fed directly into a shredder without any knifing. For sugarcane juice extraction, two systems are used: milling tandem or diffuser. In Brazil, the preference has been for the mill extraction process which consists of a set of four to six mills. This step produces two streams: bagasse and juice.

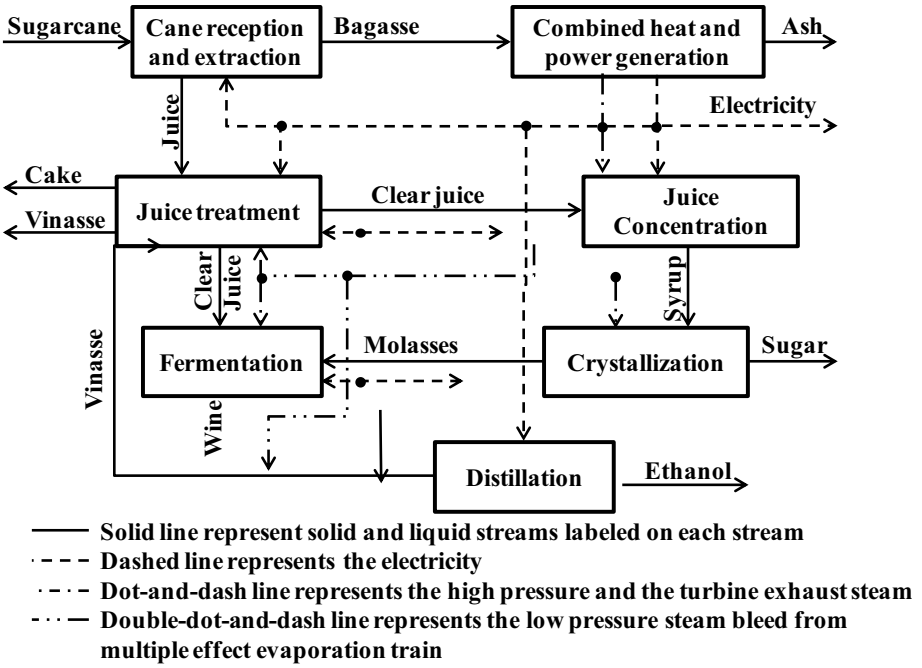

Figure 1 - Schematic flowchart of a sugarcane industry

Juice after mill contains several impurities which must be removed prior to fermentation or concentration. This process takes place at "juice treatment" area where these impurities are removed using a set of unit operations which basically consist in heating, pH adjust, settling the precipitate formed in the body juice and filtering.

Clear juice must be concentrated to achieve a suitable brix to start the crystallization process, about 60 % (w/w) sucrose. This concentration is obtained using multiple effect evaporators, which use the exhaust steam from the turbines and produce lower pressure steam used as utility in the process.

Concentrated juice, called syrup, is further concentrated in a vacuum boiling pan until it becomes supersaturated. Finely ground sugar crystals suspended in alcohol are introduced into the vacuum pan as seed crystals around which sucrose is deposited. These crystals then grow until they are ready to be discharged. Maximum recovery of sucrose by crystallization cannot be achieved in one step. Various crystallization schemes can be employed. In Brazil, two-boiling scheme is the most used, because it is not necessary to completely exhaust molasses since ethanol is produced using it.

Must for alcoholic fermentation is a mixture containing molasses and clear juice. This mixture uses a biological process that converts sugars such as glucose, fructose, and

sucrose into cellular energy, producing ethanol and carbon dioxide as a side-effect. The overall chemical reaction for alcoholic fermentation is:

$$C_{12}H_{22}O_{11} + H_2O + enzyme \rightarrow 2\ C_6H_{12}O_6 \rightarrow 4\ C_2H_5OH + 4\ CO_2$$

In the first step of alcoholic fermentation, the enzyme invertase cleaves the glycolic linkage between the glucose and fructose molecules. This process usually takes place in a fed batch fermentation process. When fermentation finishes the fermented wine is centrifuged to remove yeast (*Saccharomyces cerevisiae*) which is recycled to the next fed batch while wine with ethanol content about 8 ºGL is sent to next process.

Ethanol is recovered from wine in the distillation process. Fuel ethanol or hydrous ethanol 93 wt% is produced by a simple distillation process while anhydrous ethanol 99.3 wt% for mixing with gasoline is produced by azeotropic distillation with cyclohexane or monoethyleneglycol or by absorption on molecular sieves. Vinasse rich in nutrients is used in fertirrigation of the sugarcane fields.

Sugarcane bagasse is burnt in the boiler, producing steam that is expanded in turbines coupled with electric generators. Steam exhaust from the turbines is used as thermal energy at the evaporation area. The surplus steam (not consumed in the process) is used in condensing steam turbines to maximize the electricity production. Therefore sugarcane mill is self-sufficient in electricity and can sell surplus to the grid.

3. Model

The model-based simulation framework involved two main parts: (1) mass and energy balances; (2) constitutive equations.. The in-house model was implemented in MatLab®.

Sugarcane, biomass feedstock for the first generation process, can be represented by 3 main parts: (1) the insoluble part includes fibrous and other insoluble materials like soil, which in this text is called 'Fibre'; (2) water which is about 70 % of the total sugarcane; and (3) soluble solids like sucrose, other sugars, some proteins, some salts, etc., which is usually called 'Brix'. Consequently mass balance is applied for the three parts (Eqs 1 to 3).

$$\sum_{i=1}^{n} Fibre_{in} - \sum_{i=1}^{n} Fibre_{out} = 0 \quad (1)$$

$$\sum_{i=1}^{n} Brix_{in} - \sum_{i=1}^{n} Brix_{out} = 0 \quad (2)$$

$$\sum_{i=1}^{n} Flow_{in} - \sum_{i=1}^{n} Flow_{out} = 0 \quad (3)$$

For the energy balance, Eq. 4, thermodynamic properties of water were obtained adjoining packages from IPAWS. Specific heat of juice is given by Eq. 5 (Hugot, 1986) and specific heat of fibre is given by Eq. 6 adapted from Hatakeyama et al (1982)

The parameters for the constitutive equations come from industrial or literature data, or from equipment modelling (Rein, 2007). This equation and its parameters depend on the type of operation, for example, overall coefficient and area is the needed parameters for

heat exchangers; mud concentration is the parameter for the juice clarification process; and so one.

$$\sum_{i-stream}^{n-stream} (Flow_i \cdot cp_i \cdot T_i)_{in} - \sum_{i-stream}^{n-stream} (Flow_i \cdot cp_i \cdot T_i)_{out} = 0 \quad (4)$$

$$cp_j = \left(1 - \left(0.6 - 0.0018 \cdot T + 0.08 \cdot (1 - P)\right) \cdot Brix\right) \cdot 4.187 \quad (5)$$

$$cp_b = 1.364 + 5.06 \cdot 10^{-3} \cdot (T - 76.85) \quad (6)$$

The model is then comprised by three independent equations from mass balance are obtained: Fibre balance, Brix balance and overall balance or water balance and the energy balance. Consequently, the number of parameters and constitutive equations depends on the number of unknown variables. Usually feed stream is known and the outflow is unknown, consequently, the number of parametric equation needed will depend on the number of streams out of the 'unit operation'.

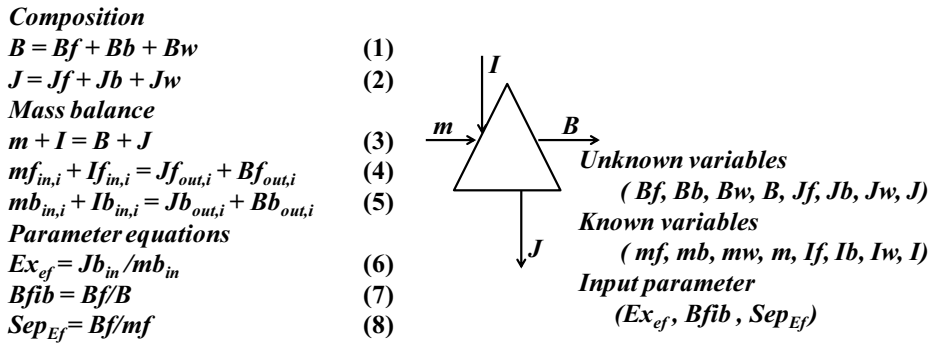

Figure 2 - Schematic flowchart of a sugarcane industry

Several configurations have been proposed (Rein, 2007). This platform aim to allow the user to customize the configuration in many ways one requires. Consequently this model deals with each unit operation as a separate algorithm. Fig 2 shows an example of one unit operation.

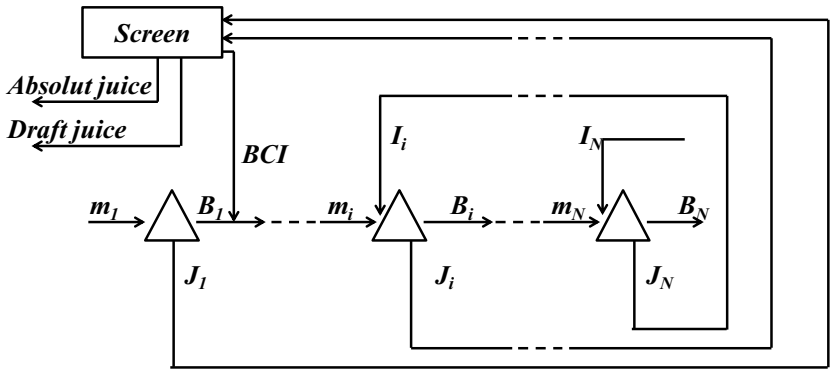

Figure 3 - Schematic flowchart of a sugarcane industry

Another script is used to call a given unit operations by identifying recycling loops to solve each area individually as shown in Fig 3. The result from one unit operation becomes the input for the next unit operation.

Flowsheet analysis or simulation is complicated because the mass and energy balances are tightly coupled between different unit operations and consequently between areas. This problem were stated in a standard form of a "Direct Substitution Method", which uses a fixed point relation $x^{k+1} = g(x^k)$ (Biegler, et al., 1999, p. 268), where x is for instance the stream flow rate and $g(x)$ is the corresponding algorithm to calculate this stream and x_0 is the initial guess. The convergence of this method depends on the relation:

$$|\lambda| = \frac{|x^{k+1} - x^k|}{|x^k - x^{k-1}|} \tag{7}$$

Where $|\lambda|^{max}$ is the Euclidean norm and a necessary and sufficient condition for convergence is that $|\lambda|^{max} < 1$. The fixed point methods developed for recycle convergence are strongly influenced by the structure of the flowsheet and the choice of the tear streams. The algorithm proposed by Biegler et al. (1999) was used to find the partitions and precedence ordering of resolution.

4. Results

Fig 4 shows the synergetic effect of producing sugar and ethanol simultaneously and Table 1 shows specifications and operating conditions used in this simulation. When both sugar and ethanol are produced, the steam consumption in first generation process is reduced while surplus power generation increase against industrial mix. Industrial mix is the step to decide which product is going to be produced using the sucrose from juice: ethanol or sugar. In this configuration, steam form the first effect of the multiple effect evaporation train is bleed and directly injected in a distillation column. It is observed that when at about 60 % of cane is used to produce sugar, the steam consumption is the lowest and consequently the energy production is the highest. This occurs because great amount of water has to be taken off the sugar juice in order to concentrate it for the crystallization process and the water withdrawn as steam from the sugar juice is used in the distillation process. For higher sugar production, the steam used to concentrate the juice is predominant while for a lower sugar production

Table 1 - Specifications and operations conditions used in this simulation

Sugarcane	1000 t/h
Fibre % Cane	13.0%
Sucrose wt%	15.0%
Bagasse	265 t/h
Extraction efficiency	97.7
Boiler steam pressure and temperature	67 bar / 520ºC
Boiler efficiency	79%
Back pressures turbine overall efficiency	82%
Condensation turbine overall efficiency	73%

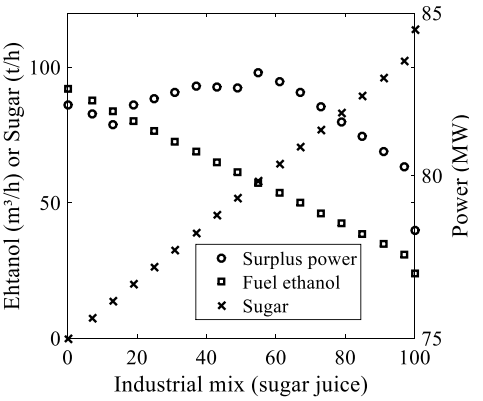

Figure 4- Ethanol Sugar and Power production

distillation it is major responsible for the overall heat consumption and it is necessary to concentrate ethanol juice using one effect evaporator which increases the overall steam consumption when compared to multiple effect evaporation.

It is important to say that, at this scenario, even when the whole sugarcane juice stream is sent to the sugar process, ethanol is still being produced using molasses. Nevertheless the behaviour showed at Fig 4 is valid for this configuration of equipments and operation streams. Consequently, changing the configuration would change the result even keeping the same parameters and specifications or vice-versa.

5. Conclusion

A typical sugar and ethanol process has been presented. Assumptions and results of the simulation have been carefully validated using industrial data to reflect the reality. Consequently a platform simulation has been developed to provide reliable outputs that could provide data for studies of technical and economic viability and social and environmental impacts when any new process is interconnected to the first generation plant, by sharing materials, utilities and products. Research will continue using agricultural residues (straw) or industrial residues (vinasse and bagasse) to sum up with new co-products or improve the whole sector more efficiently.

Abstract

In this research an innovative energy-saving process using chemical absorption by a metal solid in a circulating fluidized bed has been proposed. To recirculate of all process heat, the reaction heat that accompanies absorption is successfully supplied through a heat pump to achieve thermal decomposition in a regenerator, leading to large energy saving of the process. Absorption and fluidization experiments were conducted to determine the process conditions and requirements of the proposed process. An energy balance of the proposed process was simulated using the experimental data by a commercial process simulator. The simulation results indicate that the proposed CO_2 separation process has large energy-saving potential as compared with conventional counterparts.

Keywords: CO_2 capture, Energy saving, Process design

1. Introduction

Carbon capture and storage (CCS) is considered to be the most significant strategy to control the greenhouse gas effect and mitigate climate change. Among CCS, CO_2 separation is the most energy-intensive component: 75%–80% of the total cost of CCS is consumed for CO_2 separation (Goto et al., 2009). It is therefore necessary to reduce the energy consumption of the CO_2 separation process to promote development of CCS technology (Figueroa et al., 2008).

Mainly three CO_2 capture ways are applicable to the power plants, namely post-combustion, pre-combustion and oxy-fuel combustion. The most widely used for CO_2 separation among these three ways is chemical absorption using amine-based solutions, because of the reversible and continuous nature of the chemical reaction (Ali et al., 2016). In fact, an aqueous alkaline solution has been commercially used for absorption of acidic or sour gases (Arias et al., 2016). In the conventional absorption process using amine solutions, thermal energy is supplied from the bottom of the regenerator, which utilizes reaction heat for regeneration of the solutions and heat of vaporization for stripping.

Concurrently, the authors have developed an energy-saving process design: that of self-heat recuperation (Kansha et al., 2009). By applying self-heat recuperation to thermal processes, whole process heat can be circulated in the process with equivalent work of minimum exergy destruction of heat transfer (Kansha et al., 2013). Following this design, CO_2 gas separation processes based on self-heat recuperation for both post- and pre-combustion power generation systems have been developed (Kishimoto et al., 2011, 2012). In these processes, all of the process heat circulates in the process by using heat

pump, resulting in large energy savings. Although this technology contributes large energy savings, absorption using aqueous solutions requires additional energy for vaporization for the stripping step. To avoid the need to supply vaporization heat, some researchers have investigated the use of solid absorbents. However, the reaction temperatures of these solid absorbents are relatively high to apply heat-pump systems (Kato et al., 2002). It is therefore difficult to recirculate all process heat. In fact, many of these solid absorbents are used for chemical looping combustions integrated into the power generation (Cormos et al., 2015).

In this research, a new energy-saving process using chemical absorption by metal oxide in a circulating fluidized bed with reaction heat circulation by a heat pump is proposed. The energy-saving potential was evaluated by simulation based on experimental data.

2. Proposed CO_2 Separation Process

Figure 1 shows the conceptual design of the proposed process using chemical absorption by metal oxide particles (Kansha et al. 2017). The feed mixture containing CO_2 and other gases is fed as stream 1 and supplied to an absorber through a blower (stream 2). This absorber is a fluidized bed, in which the fluidized particles are selected zinc oxide (ZnO) fluidized by the feed gas in consideration of the reaction temperatures. CO_2 reacts with the ZnO particles to zinc carbonate ($ZnCO_3$) particles. This reaction heat is transferred to a heat-pump system where the temperature of the heat is elevated. The unreacted gases are exhausted from the absorber as stream 3. $ZnCO_3$ particles from the absorber are fed to a regenerator with a carrier gas (stream 4). In the regenerator, the reverse reaction, thermal decomposition ($ZnCO_3 \rightarrow CO_2 + ZnO$), takes place by supplying absorption heat through the heat-pump system. ZnO particles are resupplied to the absorber as stream 5. CO_2 gas is separated from the particles (stream 6 → stream 7). Stream 7 is the separated CO_2 gas. A portion of the CO_2 produced is supplied to the moving-bed regenerator through a blower to reduce friction between the particles and wall (stream 8 → stream 9). Therefore, this process does not require the stripping step and all process heat including reaction heat can be recirculated by heat pump and fluidized particles.

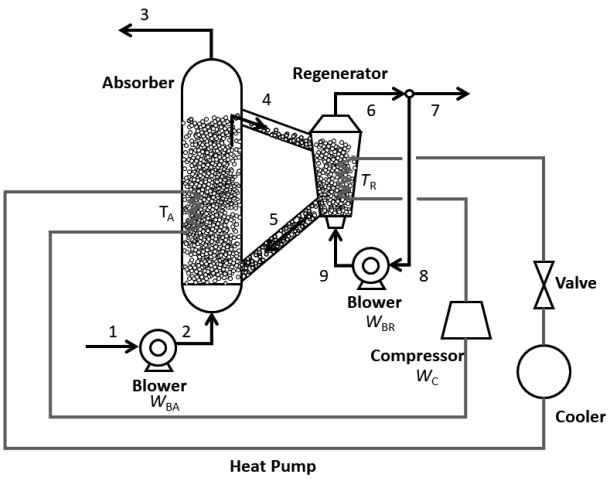

Fig. 1. Flow diagram of the proposed process

3. Experimental Test work and Results

To determine suitable reaction conditions for the proposed process, the CO_2 absorption reaction experiment was conducted using experimental setup shown in Figure 2. ZnO powder (Wako Pure Chemical JIS Special Grade, Wako, 5 g) was pre-treated by heating at 250 °C in a test tube under pure nitrogen (N_2) flow to ensure the desorption of any CO_2 from the atmosphere. The heater was set to the selected reaction temperature under pure N_2 flow. After stabilizing the temperature, the CO_2 flow valve was opened and CO_2 was mixed with the N_2 flow. The feed compositions were ensured by means of flow controllers (FCST 1005LC-4F2-F10, Fujikin). The exhaust gas composition was analysed by Fourier Transform infrared spectroscopy (Nicolet™ iS™ 5 FT-IR Spectrometer, Thermo Fisher Scientific) each minute.

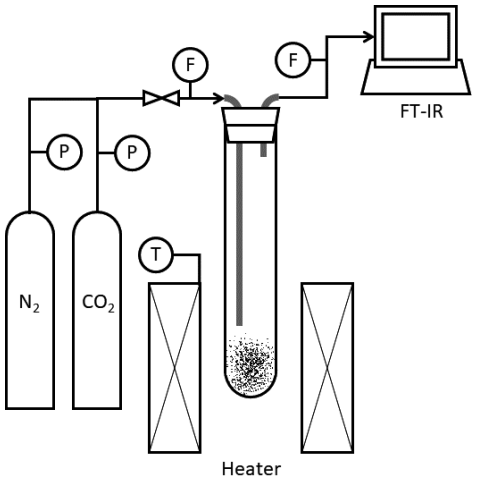

Fig. 2 Experimental setup for absorption reaction

Figure 3 shows one of the results of this experiment to see the extent of reaction for absorption as a function of time at the different reaction temperatures (80 °C, 100 °C, 120 °C), using the heater to ensure isothermal reaction conditions. The N_2 flow rate was set to 10 mL/min and the CO_2 flow rate was set to 4.0 mL/min (29%). It can be seen from Figure 3 that these reaction temperature changes did not significantly affect the reaction rate and all of reaction was completed within 25 mins. It is well known that the conversion ratio appeared to be affected according to Le Chatelier's principle. This absorption reaction is exothermic reaction. Thus, it was expected to reduce the reaction rates with temperature increase. However, the effect was too small to accurately observe in this experiment. It can be said from these results that the absorption reaction temperature can be set lower than 120 °C. By the way, only less than 2.5% of the ZnO was converted to $ZnCO_3$ due to the limited contact area between ZnO powder and CO_2 gas in the test tube. It was therefore necessary to expand the contact area in order to absorb CO_2 effectively.

From these experiments, it appeared appropriate to set the reaction temperature of the absorber to 120 °C; however, it was necessary to increase the contact area of ZnO with CO_2 to increase the conversion ratio of absorption. In addition, we considered that the rate of thermal decomposition in the regenerator was relatively fast compared with that of the absorption reaction.

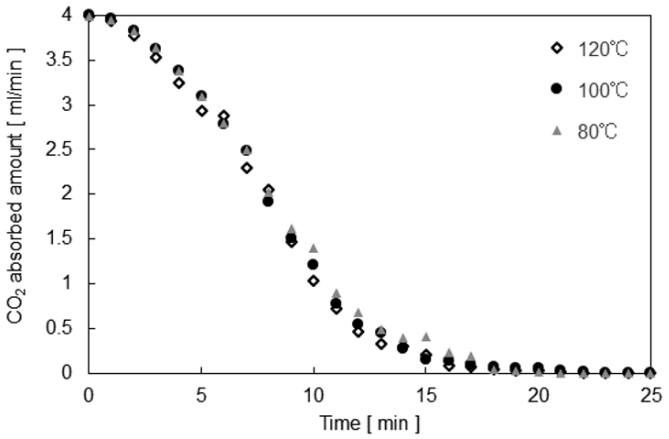

Fig. 3 Rate of CO_2 absorption as a function of time for different reaction temperature

A fluidized bed was therefore selected for the absorber and a moving bed for the regenerator. Although a fluidized bed requires additional energy for the blower that supplies the fluidizing gas, it is well known that heat transfer inside the bed is enhanced and a uniform bed temperature is achieved, leading to good heat transfer from the absorption reaction to the heat-pump system.

To investigate the additional energy required for the blower (W_{BA}), the minimum fluidizing gas velocity was determined using an experimental fluidized bed. The bed was made of glass and had a cylindrical shape with an inner diameter of 50 mm and height of 500 mm. ZnO particles with an average diameter of 40 μm were used as the fluidized medium (457 g, bed height of unfluidized condition was 120 mm). According to the pressure drop changes for different fluidizing gas velocities and observation of this experiment, the minimum fluidizing gas velocity (U_{mf}) was determined to be about 2.6 L/min.

4. Simulations

To examine the energy required for the proposed process, a simulation at steady-state conditions was conducted using PRO/II Ver. 10.0 software (Schneider Electric). The Soave–Redlich–Kwong equation was selected for the thermodynamic data and an adiabatic efficiency of 80% was initially assumed for the heat-pump compressor. The same simulations were also conducted assuming 60% adiabatic efficiency to be close to actual adiabatic efficiency of the compressors. Water was selected as a representative working fluid in the heat-pump system. The reaction temperature (T_A) in the absorber was assumed to be 120 °C, from the experimental test work; the temperature of the thermal decomposition in the regenerator (T_R) was assumed to be 200 °C, from the equilibrium of the reaction between ZnO and CO_2 using the Materials-Oriented Little Thermodynamic Database for PC (MALT, Kagaku Gijutsu-Sha). The bed temperature was assumed to be uniform due to the properties of a fluidized bed and the reaction was assumed to take place isothermally. We therefore assumed that the heat-pump system successfully received the reaction heat of adsorption and provided reaction heat for thermal decomposition in the regenerator. The minimum temperature differences between the heat-pump system and each beds were assumed to be 10 and 20 K. The blower duty for the fluidized bed was calculated from the assumptions of $2.0U_{mf}$ (=5.2

L/min) for the fluidized gas velocity, 0.6 kPa of pressure drop in the fluidized bed acquired from previous experiments. In addition, 10% of conversion ratio in the absorber was assumed. The blower duty (W_{BR}) of the moving bed was neglected due to its negligible influence and heat loss was neglected. The energy required for the process at each temperature for 80 and 60% adiabatic efficiencies are summarized in Tables 1 and 2.

Table 1 Energy required for the proposed process assuming 80% adiabatic efficiency of the heat-pump compressor and blower

Temperature of heat pump at absorber [°C]	110	100
Temperature of heat pump at regenerator [°C]	210	220
Work for heat pump (W_C) [MJ/kg-CO_2]	0.56	0.70
Work for blower (W_{BA}) [MJ/kg-CO_2]	0.04	0.04
Total Work (W_C+ W_{BA}) [MJ/kg-CO_2]	0.60	0.74

Adiabatic efficiency: 80%

Table 2 Energy required for the proposed process assuming 60% adiabatic efficiency of the heat-pump compressor and blower

Temperature of heat pump at absorber [°C]	110	100
Temperature of heat pump at regenerator [°C]	210	220
Work for heat pump (W_C) [MJ/kg-CO_2]	0.75	0.93
Work for blower (W_{BA}) [MJ/kg-CO_2]	0.05	0.05
Total Work (W_C+ W_{BA}) [MJ/kg-CO_2]	0.80	0.98

Adiabatic efficiency: 60%

From the simulation results, the energy required for the proposed process was from 0.60 to 0.98 MJ/kg-CO_2 with 60 or 80% adiabatic efficiency of the compressors at steady state. These values are less than 1/4 of that required for conventional CO_2 gas separation processes using amine-based absorption (4.1 MJ/kg-CO_2) (Kishimoto et al., 2011, 2012). According to the temperature range of this process, it can be expected to apply for post-combustion CO_2 capture. Although it is necessary to conduct further investigations for installing the proposed process to an actual power plant such as integrating with a scrubber system for separation of other gas mixtures or other processes in a power plant, and optimization of process conditions, it can be said that this process has a great potential for energy saving CO_2 separation for power generation.

5. Conclusion

An innovative energy-saving CO_2 chemical absorption process, integrating a circulating fluidized bed and heat pump, is proposed. The energy-saving performance of the proposed process was evaluated both experimentally and by simulation. In fact, this process required for less than 1/6 of conventional CO_2 separation. Thus, it can be said that the proposed process has a great potential for CO_2 separation with further investigations.

Abstract

The insertion of renewable sources in the world energy matrix is a promising pathway to reduce greenhouse gas (GHG) emissions in the future. Brazil is one of the leaders in the use of renewable energy, pioneering new biofuel technologies and presenting an electricity matrix based on hydroelectric power. Due to its vast territory, Brazil presents a high heterogeneity regarding natural resources availability and socioeconomic conditions, resulting in regions with different electricity supply and demand profiles. Hydropower, biomass and wind power account respectively for 61.40%, 8.77% and 6.71% of the Brazilian total installed capacity. However, the high dependence on hydroelectricity exposes the country to risks associated with variations on the hydrological regimes. The renewable alternatives to hydroelectricity in the country - biomass and wind power - can increase the reliability of the system and the choice of the optimal power mix is a challenge.

This study analyzes the optimal Brazilian electricity mix based on a portfolio model considering regional supply and demand characteristics. The main drivers to analyze the problem are the generation and transmission costs and the regional supply and demand. At an aggregate level, the results show that bioelectricity is the most economical option among the thermal sources. The results motivate the analysis of land use for biomass crops, the development of new technologies to increase the harvest productivity and establishment of policies to attract investments on bioelectricity.

Keywords: electricity generation, portfolio theory, renewable sources, Brazilian electricity sector.

1. Introduction

The global electrical energy demand may increase by a factor of seven over the next five decades (Siirola, 2012). As a developing country, Brazil presents a high potential for electricity consumption growth. Forecasts from the Empresa de Pesquisa Energética (EPE) – shows that in 2026 the country's demand for electricity will be 43.6% higher than in 2016 (EPE, 2017). The Brazilian electricity mix is predominantly renewable but due to recent droughts there has been an expressive increase in the demand for fossil fuels for thermopower generation. Thus, an important question is: how to expand the

Brazilian electricity capacity to attend the demand growth considering renewable sources.

The Brazilian grid is made up of four interconnected electricity subsystems with more than 99% of the electricity generated in the country being delivered through the national interconnected system (Operador Nacional do Sistema (ONS), 2017). Hydropower is the main generation source, corresponding to 61.40% of the total installed capacity (Agência Nacional de Energia Elétrica (Aneel), 2017). Other important renewable sources are biomass and wind, representing 8.77% and 6.71% of the country's installed capacity. Fossil fuels account for 16.76%, nuclear 1.24% and importation from Paraguay, Argentina, Venezuela and Uruguay 5.04% (Aneel, 2017). Natural gas plays an important role to guarantee the system reliability. Brazil uses fossil fuel power plants to overcome the variability on the hydro, wind and biomass supply, with natural gas representing more than 48% of the fossil installed capacity (Aneel, 2017).

As the hydro potential in many regions is already saturated and most of the country's remaining potential is situated far from the centres with the highest demand, high investments on transmission lines would be required to attend the demand growth. Moreover, the operation of hydropower plants depends on the hydrological conditions, exposing the system to the risk of electricity shortfalls during drought periods. Consequently, the expansion of other sources to meet the growing demand is needed and the choice of such sources is a challenge.

One approach to determine the amount of expansion for each energy source is through Modern Portfolio Theory (Markowitz, 1952). Originally designed to find portfolios of financial assets with minimum risk, this approach has been adapted to many applications, including electricity portfolios (Awerbuch and Berger, 2003).

Expressive regional differences with respect to natural resources availability, level of industrialization, socioeconomic conditions and climate influence the operation of the whole Brazilian system. Therefore, it is possible that transmission constraints and limits on the amount of generation in different regions of the country may affect the overall participation of each generation source. Such issues are considered in the present study through the development of optimization models. The objective is to find electricity matrices with minimum cost risk, to meet the demand forecasted by EPE for the year 2026 (EPE, 2017).

The models consider two risk measures: the variance of costs, as in the original work of Markowitz (1952), and the β-CVaR, a tail risk measure proposed by Rockafellar and Uryasev (2000) defined as the expected cost, above a fixed β-percentile. The decision variables - x_{ij}^{k} - are the amount of electricity generated through source k, in the supply subsystem i, to be sent to the consumption subsystem j.

Recent discoveries of natural gas reserves in the Brazilian pre-salt, the effort to maintain high shares of renewable sources and improvements on bioelectricity generation technologies suggest four different scenarios to be analysed regarding the costs of electricity generation: Scenario 1 considers industry experts costs estimation, Scenario 2 and 3 assume respectively that natural gas and biomass generation costs maintains 20% lower than in Scenario 1, and Scenario 4 considers that both natural gas and biomass generation costs maintain 20% lower than in Scenario 1.

Section 2 presents an overview of the Brazilian power sector. The portfolio models are described in section 3 and the results are presented in section 4. Section 5 concludes this study.

2. Brazilian Power Sector

The Brazilian power sector comprises four interconnected subsystems allowing electricity exchanges between regions. As regions with electricity surplus can supply regions with deficit of electricity, it increases the reliability of the whole system. Moreover, it is possible to take economic advantages of this structure by generating electricity where the generation costs are lower, even when the consumption centre is far from the supply source. The national grid accounts with more than 150,000 kilometres of transmission lines (ONS, 2017).

To maintain and expand the system, generation and distribution companies pay a tariff for the use of the transmission system. This tariff is calculated by the government and the total amount must be enough to cover expenses and to provide profits to the transmission companies. Moreover, generators located farther from the consumption centres pay higher tariff values to compensate their need for extensive lines.

The great size of the Brazilian system makes the management of both generation and transmission costs important to provide affordable electricity prices to the population. Therefore, the costs considered in the models are the sum of the levelized cost of electricity, which is the present value of operation and maintenance (O&M), investment and fuel costs incurred during the lifetime of a powerplant divided by the amount of electricity generated during this period, and the tariff for the use of transmission system.

3. Model Description

The objective is to find minimum risk electricity mixes under two risk measures: the variance and the 95%-CVaR of the total costs. The generation sources considered are hydro, nuclear, wind, biomass, natural gas, oil and coal. Due to investment costs already incurred in hydro and nuclear powerplants currently in operation (sunk costs), these sources were grouped in two categories: old and new plants. It is assumed that old hydro and old nuclear plants have their effective generation capacities fully used. Due to the investment costs, it is also assumed that the only nuclear plant under construction in Brazil, Angra III, will use the estimated effective capacity. As to guarantee supply security, the government contracts a minimum amount of thermoelectricity. The model constraints are linear and described as follows:

a) After transmission and distribution losses are discounted, demand must be attended;

b) Generation through each source for each region is bounded to lower and upper limits;

c) The expected cost is bounded from above;

d) Each region must generate a minimum amount of thermal electricity, which is given by the sum of generation through biomass, natural gas, coal and fuel oil;

e) The amount of electricity sent from one region to another cannot exceed the transmission capacity.

The total cost – T - of the system is the sum of the costs - $Cost_i^k$ - over all sources, supply regions and consumption regions (Eq.(1)).

$$T = \sum_i \sum_j \sum_k Cost_i^k x_{ij}^k = \sum_i \sum_j \sum_k (invest^k + O\&M^k + fuel^k + transm_i) x_{ij}^k \quad (1)$$

Investment, O&M, fuel and transmission costs were considered independent from each other. Different sources are independent with respect to investment and O&M costs. The fuel costs cross-correlation matrix estimated by Awerbuch and Berger (2003) was adopted. The regions were considered independent with respect to the transmission costs. Investment and O&M costs for each source, and transmission costs for each region were assumed to be random variables uniformly distributed. Fuel costs were assumed to be normally distributed.

The model formulation is:

$$\min_{\boldsymbol{x} \in X} \big(risk(\boldsymbol{x}) \big) \quad (2)$$

The set X considers linear constraints. The risk measure is quadratic if the model adopts variance as risk measure, and it is linear in case CVaR is adopted (Rockafellar and Uryasev, 2000).

4. Results

The optimal solutions when transmission constraints are considered are presented in Figure 1 for Scenarios 1 and 2. Except for the solutions with lowest expected costs, there was no significant difference between the optimal solution regarding the use of transmission constraints. The optimal generation mix for Scenarios 1, 3 and 4 were similar, therefore Scenarios 3 and 4 are not shown in Figure 1. For each expected cost level (x-axis) the optimal composition (the y-axis) are shown. Although the amount of generation from each source varies according to the region, indicating the importance of regional public policies, only the aggregated results are presented in this study.

The results obtained through CVaR and variance minimization are respectively shown in the top and bottom of Figure 1. The main differences between the optimal solutions result from the risk measure considered. Due to fuel costs, the expected costs of thermopower sources are higher when compared to other sources. Even when the costs obtained by wind and new hydro power are higher than their respective expected values, they are still lower than the expected costs of thermopower sources. Therefore, as CVaR minimizes the expected cost of the matrix, given that the cost is above a fixed percentile, it does not favour the insertion of thermoelectricity, which is included in the matrix at the lower bound level to assure supply security. On the other hand, the minimization of variance concerns to minimize deviations from the matrix expected cost value and does not consider how high is the resulted expected cost, which results on the insertion of thermoelectricity above the lower bound level.

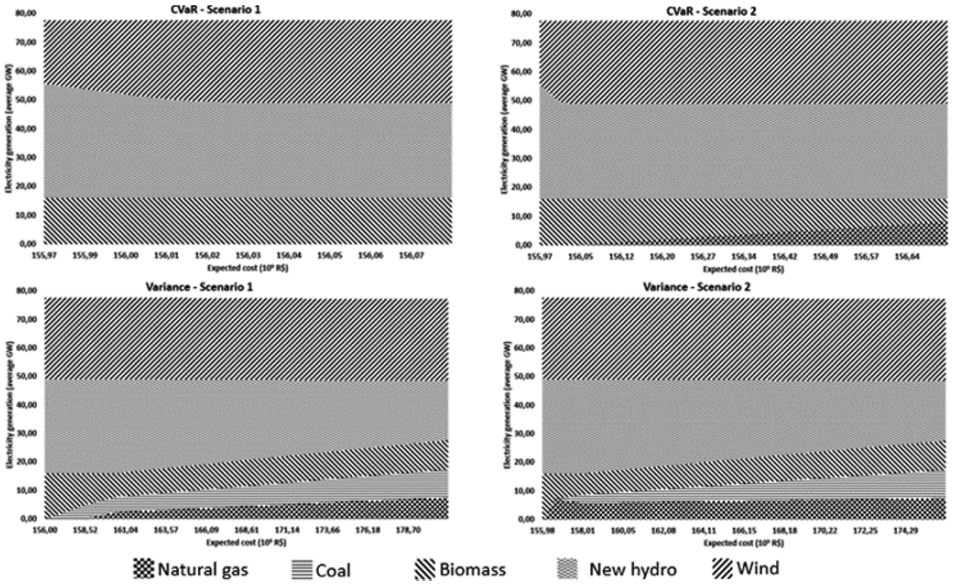

Figure 1: Efficient electricity matrices compositions.
Source: Own elaboration.

All the solutions indicate a high share of wind power in the matrix. This result is aligned with the increase from 2,501 average megawatts in 2015 to 3,809 average megawatts in the electricity generated through wind in 2016 (ONS, 2017). The trade-off expected cost versus cost risk favours the use of wind even compared to hydropower. As a result, for higher expected costs and lower risk solutions, the amount of wind generation grows as substitution to hydropower.

In Scenario 1, under CVaR risk measure, the only thermopower source included in the matrix is biomass. However, if the cost of electricity from natural gas is reduced by 20% and its variance is maintained constant, its expected cost becomes just 2% higher than biomass and it is included in the matrix. When considering variance as the risk measure, Scenario 2 also presents a higher participation of natural gas when compared to Scenario 1.

5. Conclusions

Based on portfolio theory, the four models were applied to find possible efficient electricity matrices to meet the estimated Brazilian demand for 2026. Operational constraints such as limited generation potential for each source in each region, transmission capacities and distribution and transmission losses were considered. Regional differences on the demand were also considered.

Variance and CVaR were adopted as risk measures. With the probability density functions adopted for the costs, it was shown that efficient solutions in terms of variance differ from efficient solutions in terms of CVaR. However, they are similar with respect to indication of high participation of wind, hydropower and biomass.

Biomass was predominant among the thermopower sources. The solutions obtained were very similar regardless transmission constraints were considered or not. Also,

there is no significant change in the solutions when biomass cost is 20% lower than the costs estimated by industry experts. This reduction would only maintain the predominance of electricity generated through biomass among other thermopower sources.

As there was no upper bound for bioelectricity, its predominance raises issues regarding the debate food versus energy. It also indicates that the creation of government policies to incentive investment on bioelectricity is an adequate path to be followed. Moreover, the development of new technologies to generate bioelectricity more efficiently may be crucial to keep renewable sources predominant in the Brazilian power sector.

Under the scenario where the discovery of natural gas reserves in the Brazilian pre-salt layer would cause a 20% reduction on the electricity cost generated by this source, natural gas has an augmented participation on the matrix. As a result, it substitutes part of the bioelectricity generation. Therefore, it can be concluded that in case of land unavailability or lack of bioelectricity investors, natural gas would be the most economical thermopower source to be used instead of biomass.

As a continuity of this research, a multi-period optimization model can be developed to incorporate temporal fluctuations on energy availability.

Including Ecosystem Services in Sustainable Process Design across Multiple Spatial Scales

Tapajyoti Ghosh[a], Xinyu Liu[a], Bhavik R. Bakshi[a*]

[a]*William G Lowrie Department of Chemical and Biomolecular Engineering,The Ohio State University,Columbus, Ohio,USA.*

bakshi.2@osu.edu

Abstract

This work aims to combine process design, supply chain design (SPD), technology choices, hybrid life cycle assessment (LCA) as well as incorporation of ecosystem services in a comprehensive optimization model. While most work on sustainable supply chains couples process life cycle assessment as an addendum to the optimization model, the Process to Planet – Techno Ecological Synergy (P2P-TES) framework seamlessly integrates the engineering process as well as the supply chain design module into the hybrid LCA matrix structure. Inclusion of process design results in simultaneous optimization of both the production process as well as the supply chain network. Choice of technology options in the life cycle model provide the freedom to supplier to choose between pathway alternatives for promoting sustainability in the supply chain. Additionally, this framework includes the role of ecosystem services at the local process level as well as in all the other scales of the hybrid life cycle model. Inclusion of ecosystem services in the optimization framework results in opportunities where technological systems can harness ecological systems to offset the environmental impacts and verifies if the manufacturing process as well as its entire supply chain network is within the ecological carrying capacity of nature and satisfies a necessary condition for sustainability.

Keywords: Supply Chain design, sustainability, optimization, process, ecosystem services.

1. Introduction

Sustainable process design has made enormous advances in the last decade and industries, governments as well as consumers are leaning towards technologies and products whose production and use have low environmental impact. Major chemical industries are aiming for eliminating toxic chemical use, environmental impacts, reducing human risks and improving social conditions not only locally but over the entire supply chain. While LCA methods have been popular for gauging environmental impacts, their application in the field of supply chain design has been limited. Studies which deal with "green supply chains" keep LCA separated from the design problem and apply it as an analytical tool for environmental impacts (Borghi et al. 2014). There have been few studies where supply chains for biofuels have been designed while satisfying environmental objectives. Mele et al. (2009) studied optimal planning of bioethanol and sugar production supply chains while You et al. (2012) considered the design of sustainable cellulosic biofuel supply chains. Aguirre (2009) studied the design of maleic anhydride production supply chain. Both these studies coupled LCA within the optimization framework. To the best of our knowledge, none of the existing work

considers ecosystem services in the purview of the design problem. In this study, we present a novel P2P-TES optimization framework that extends the boundaries of supply chain design by integrating process design, supply chain design and ecological services within the scope of the design problem. An additional advantage of P2P-TES is that it preserves the matrix structure of conventional LCA, making its application simpler and more generalized. Individually, the Process to Planet (P2P) framework (Hanes and Bakshi, 2015) brings in the capability of process design, SPD, LCA and choice of technology while the Techno-Ecological Synergy (TES) framework (Bakshi et al. 2015) provides the foundation for coupling of process, life cycle and economy with the ecosystem services. Using a corn ethanol biorefinery network, an application of P2P-TES framework for process design, supply chain design, and choice of technology is demonstrated. Changes in the decision variables on consideration of ecosystem services within the optimization problem is also demonstrated.

2. Methodology

The framework is built to be analogous with the matrix form of conventional life cycle assessment to promote ease of usability, integration with environmental impact indicators and generalization for applicability to a wide range of problems.

2.1 Background

The mathematical formulation of Conventional LCA is presented as

$$Xm = f \tag{1}$$

where X is the technology matrix that contains information about the life cycle network, flows between activities and linear models of the activities. m is the scaling factor matrix that decides the sizes of the activities to satisfy a certain final demand f of a product on the entire system by society. The environmental impact is given by

$$g = Bm \tag{2}$$

where B is the interventions matrix with information regarding environmental impact of each activity within the system. The P2P framework, while preserving the structure of conventional LCA allows incorporation of economy scale as well as process design in an optimization framework as shown in Fig. 1. It has three separate scales – economy, value chain (for life cycle models) and equipment (for process engineering design model). The framework can be represented mathematically as

$$\overline{\underline{X}}\,(\{z\})\,\overline{\underline{m}} = \overline{\underline{f}} \tag{3}$$

where $\overline{\underline{X}}$ represents a multiscale technology matrix that includes life cycle model information, economy scale as well as engineering design variables z for the fundamental engineering models. Similarly, $\overline{\underline{m}}$ and $\overline{\underline{f}}$ represent the multiscale scaling vector and multiscale final demand that contain the sizes of the three separate scales and their separate final demands. The overbars and underbars are used to represent its multiscale nature. Environmental impact from this multiscale framework is given by

$$\overline{\underline{g}} = \overline{\underline{B}}(\{\mathrm{z}\})\,\overline{\underline{m}} \tag{4}$$

where $\overline{\underline{B}}$ is the multiscale environmental interventions matrix containing impact information for activities at all three scales.

2.2 P2P-TES mathematical framework

The P2P framework is modified to include ecosystem services information resulting in the P2P-TES framework which is written as

$$\begin{bmatrix} \underline{\overline{X}}(\underline{\overline{z}}) & \underline{\overline{C}}(\underline{\overline{z}}) \\ \underline{\overline{B}}(\underline{\overline{z}}) & \underline{\overline{S}}(\underline{\overline{z}}) \end{bmatrix} \begin{bmatrix} \underline{\overline{m}} \\ \underline{\overline{m}}_e \end{bmatrix} = \begin{bmatrix} \underline{\overline{f}} \\ \underline{\overline{f}}_e \end{bmatrix} \tag{5}$$

In contrast to P2P framework, engineering process variables z has been replaced by $\underline{\overline{z}}$ which includes $\underline{z}$ supply chain design/choice of technology and $\overline{z}$ economic policy design variables. $\underline{\overline{S}}(\underline{\overline{z}})$ is ecosystem services matrix that holds data pertaining to ecosystem activities modelled as unit operations at different scales. $\underline{\overline{m}}_e$ is the ecosystem scaling matrix that determines ecosystem sizes whereas $\underline{\overline{f}}_e$ is the multiscale ecosystem final demand matrix. The final demand of ecosystems can be envisaged as the requirement of technological systems to reduce environmental impact, such as carbon dioxide sequestration and is obtained by subtracting the demand of ecosystem services from supply. Ideally, if $\underline{\overline{f}}_e$ is 0, it means no environmental impact as ecosystem service supply becomes equal to the demand. $\underline{\overline{C}}(\{\underline{\overline{z}}\})$ is the management matrix that models flows from technological systems to ecosystems for maintenance. The net environmental impact is obtained from

$$\underline{\overline{g}} = \sum_i \underline{\overline{f}}_e^i \tag{6}$$

which represents the total final demand of ecosystem services. It is different from the previous frameworks since we are interested in not only the direct environmental impact but after ecosystem services have been considered and resulted in impact remediation. The dotted arrows in Fig. 1 represent the flow to and from ecological systems.

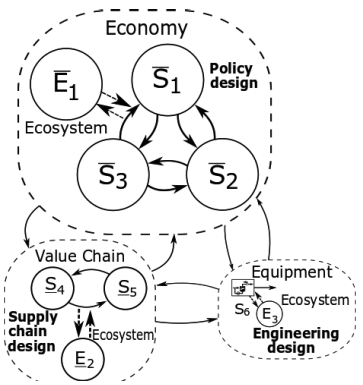

Figure 1: P2P-TES Framework showing economy, value chain and equipment scale with ecosystems.

As seen from Fig. 1 different modules of the P2P-TES framework entail different design problems. Variables at equipment scale constitute engineering design problem, at the value chain scale establish a supply chain design problem, while variables at economy scale forge a policy design study. With environmental impact assessment and ecosystem services included at all three scales, P2P-TES creates the foundation of a comprehensive, yet coherent and systematic tool which can undertake various challenges as mentioned earlier.

2.3 Optimization Formulation

The optimization problem based on the P2P-TES framework can be multifaceted with multiple objectives based on user preference. For the purposes of this paper, we define a multi-objective scenario, with minimization of environmental impact and maximization of economic profitability of the engineering process through

$$Minimize \begin{cases} \Sigma_i \overline{\underline{f}}_e^i \\ -NPV(\{z\}) \end{cases} \quad (7)$$

subject to constraints,

Eq. 3, $\mathrm{H}(\{z\}) \geq 0$, $\overline{\underline{\mathrm{m}}}_{\mathrm{e}} \geq 0$, $\overline{\underline{m}} \geq 0$, $S(\{z\}) \geq 0$

$\mathrm{H}(\{z\})$ represents the engineering design, comprising process variables, mass, energy balances etc. $S(\{z\})$ represents the ecosystems modelled as unit operations and should also comply with physical mass flow laws. Eq. 3 forms the core equation for P2P-TES framework while the sizes of technological and ecological systems should be non-negative. Solving the optimization problem determines the engineering process design variables z, supply chain design and/or choice of technology variables $\underline{z}$ and policy design variables $\overline{z}$.

3. Case Study

In this article, we demonstrate P2P-TES application on a corn ethanol distribution network. The goal of the study is to design the ethanol manufacturing process, the supply chain as well as choose between farming objectives. Major constraints imposed on this network are demand of food and energy by the society. As seen from Fig. 2, we consider a land area divided into 18 grid regions. Each of these regions are attributed to their own available agricultural area, population dependant food and biofuel demand. The demand and production of materials are concentrated at the centroid of grids. Each of the 18 grid regions can be a possible location of a biorefinery whose total number is constrained at 6 as because we estimated 6 refineries would be enough to satisfy the entire corn ethanol demand of this area. The white regions are assumed to practice no till corn farming while the grey regions practice farming with conventional till. The biorefineries as well as consumers have the option of choosing between the different farms available at the 18 grids for meeting their fuel and food demand respectively. Combination of rail and truck transportation modes was considered from centroid to centroid distances for material movement. Environmental impact considered in this study is nitrate loading in water from farming and refining activities. The optimization problem was set up to minimize the environmental impact as described by

$$Minimize \ \Sigma_i \overline{\underline{f}}_e^i \ or \ \overline{\underline{B}}(\overline{\underline{z}})\overline{\underline{m}} + \overline{\underline{S}}(\overline{\underline{z}})\overline{\underline{m}}_e \quad (8)$$

Design variables included process parameters for corn to ethanol conversion in biorefinery, quantity of corn supply from the different farms to the individual biorefineries and consumer, binary variables to determine the location of biorefineries and scaling variables to determine the total consumption from individual farms. The corn to ethanol production technology assumed a wet milling process with 15 projected design variables which included temperature of steam jets, flow concentrations and recovery rates in distillation columns. Ecosystems considered in this case study are wetlands which are modelled as bioreactors and can take up the nitrates in the run-off water from technological activities. Limited amount of areas in each grid region is available for conversion to a wetland ecosystem. The final optimization problem is an MINLP consisting of 8541 equations, 10915 single variables and 36 discrete variables. The non-linearities in the model mostly come from the engineering superstructure module of the biorefineries. It is solved using BARON on GAMS optimization platform in an 8300 core Intel Xeon Cluster.

3.1 No-ecosystem scenario

In this scenario, ecosystems are not considered in the optimization problem. The objective function minimizes the nitrate runoff from the farms and the biorefineries. Solving this problem resulted in placement of biorefineries in the grids as shown in Fig. 2 (top). From the network plot in Fig. 2 (top), it is observed that all the grid regions practicing no till agriculture is chosen for satisfying food and fuel demand. The network plot depicts the quantity (width of interconnecting curves) of flow of corn from farms to biorefineries and consumers (interconnecting curves between farms and refineries, farms and consumers) along with the flow of ethanol from refineries to consumers (interconnecting curves between refineries and consumers). However, the total corn production of these 6 regions are not enough for satisfying the total food and fuel demand. Thus, additional farming regions are selected for corn production. However, the optimization solution expands no till practicing farms to their largest possible production bounds before sourcing corn from farms practicing conventional till.

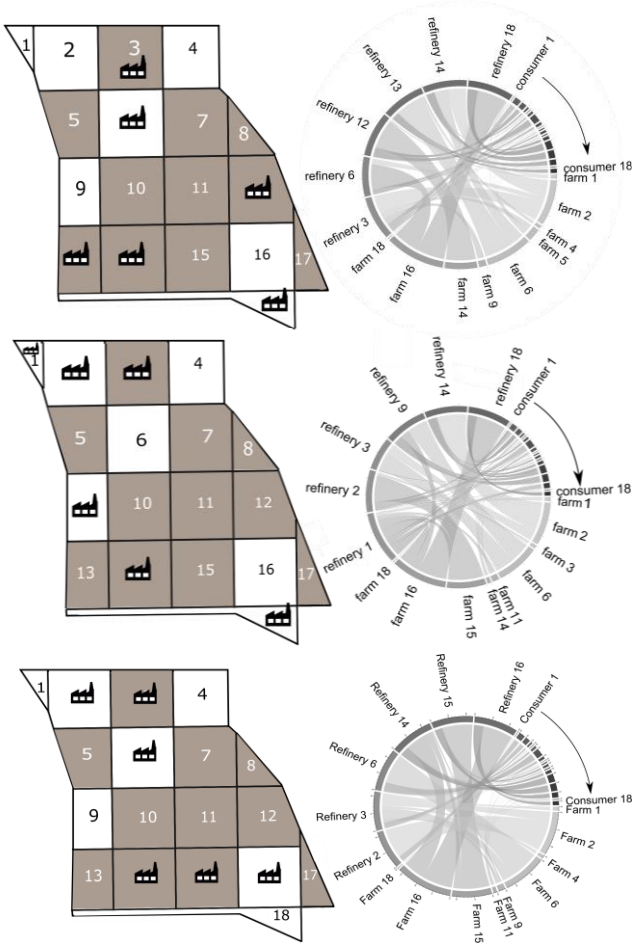

Figure 2: Distribution of biorefineries in the grids and network plot for product flow connections for (top) no-ecosystem scenario, (middle) with-ecosystem scenario and (bottom) transportation cost reduction scenario. Consumers 2-18 have not been labelled due to space constraints.

3.2 With-ecosystem scenario

In this scenario, land area is available at the farms for conversion into wetlands. These wetlands, modelled as flow reactors can consume nitrate loaded water, treat it naturally and supply clean water to the watershed. The amount of land area available is barren or shrubs land and is determined randomly for the 18 grids. Solving this optimization problem, the distribution of refineries is obtained as shown in Fig. 2 (middle). Total nitrate loading in water was reduced by 22%. From the network plot in Fig. 2 (middle), it is observed that for this scenario, along with some no till faming grids, conventional till practicing regions

3,11,14,15 are chosen for production of corn. This is due to the construction and maintenance of wetlands in these regions which are large enough to take up a huge amount of nitrate in the water. Thus, the net nitrate emissions for these regions are lower than obtained from till agriculture. Farming in regions 4 and 9 are not longer viable because they have relatively less area available for wetlands and results in larger nitrate emissions compared to the selected regions.

3.3 Transportation cost reduction scenario

In this scenario, the objective function is modified to reduce cost of transportation of products between different sectors. Ecosystems are considered in this analysis and the nitrate loading in water is fixed to the amount obtained from the previous with-ecosystem scenario. The distribution of biorefineries for this scenario as shown in Fig. 2 (bottom) is such that both transportation of corn from farms to biorefineries and farms to consumers as well ethanol transportation cost from biorefineries to consumers is reduced. The network plot in Fig. 2 (bottom) clearly depicts this change. More interconnections are seen between activities in the same grid (Farm 2 – Refinery 2, Farm 6 – Refinery 6 etc.). Biorefineries also tend to be located near high ethanol demand centres. (Grids 14,15,16.)

4. Conclusion

In this article, we present a novel framework that can solve a process design, supply chain design, technology choice optimization problem and considers ecosystem services within its analysis. The inclusion of ecosystem services provides a metric for sustainability where we may claim that the supply chain does not exceed the carrying capacity of ecological sources and may be environmentally sustainable. The case study effectively demonstrates how this framework can be applied for determination of process parameters and facility locations of the biorefineries, choice of farming technologies and consideration of wetland ecosystems.

Long-Term Energy Storage: What is the Need and is Ammonia a Solution?

Richard M. Nayak-Luke[a], René Bañares-Alcántara[a*]

[a]*University of Oxford, Dept of Engineering Science, Parks Road, Oxford OX1 3PJ, UK*

Abstract

Ammonia production contributes 1.3% of global carbon dioxide emissions (IEA 2016, Philibert 2017). In the context of global emission targets and growing demand, decarbonisation of this process is environmentally imperative. Ammonia can also have a significant additional role as a seasonal electrical energy storage vector, and the potential requirement for this could be substantial. We present a method to calculate a first estimate for the optimum size of an electrified ammonia production plant (at the process level), the required renewable energy (RE) supply, and the levelised cost of ammonia (LCOA) for islanded operation with a hydrogen buffer. A model was developed to quantitatively identify the key variables that impact the LCOA (relative to a ±10 GBP/t change in LCOA): levelised cost of electricity (±0.89 GBP/MWh), electrolyser CAPEX (±65 GBP/kW), minimum Haber-Bosch (HB) load (±12% of rated power), maximum rate of HB load ramping, and RE supply mix. Using 2025/2030 estimates results in a LCOA of 588 GBP/t for Lerwick, Scotland. The application of the model can guide and improve the production of carbon-free ammonia in the future.

Keywords: Ammonia; Electrification; Haber-Bosch; LCOA; Seasonal storage.

1. Introduction

On a global scale, carbon dioxide emissions are increasing at a rate of 2.4% per annum (IEA 2016). These emissions originate from four main sectors: electricity, heat, transport and industry, the last being the most commonly overlooked. With chemical production predicted to account for 14% of industrial emissions by 2050 (Philibert 2017), it is an environmental imperative to identify and decarbonise those chemicals produced in significant quantities and with high dependency on fossil fuels (for both energy and feedstock). Ammonia is a prominent example, with a current global production of c.180M t/y and, due to the 95% of its hydrogen feedstock coming from fossil fuels, and generation of 420M t/y of carbon dioxide emissions (1.3% of the global amount) (IEA 2016, Philibert 2017). Primarily driven by population growth, this is predicted to increase to c.270M t/y of ammonia by 2050 (Philibert 2017, UN 2017). Currently about 85% of ammonia produced is used as fertiliser.

In recent years ammonia has been re-considered as a potential energy vector for use in three other sectors: electricity, transport and heating. Ammonia can provide a grid service for seasonal energy storage. There has been significant integration of renewable energy (RE) sources onto existing electrical networks. To date this has mainly been in response to binding national/regional targets (e.g. EU Renewable Energy Directive), but the substantial falling cost and significant availability of RE resources also drives it (IPCC 2011). However, as calculated in (Denholm and Hand 2011) and proven in practice by

the application of Germany's Energiewende (Ehlers 2015), increasing RE penetration on networks requires an increased network flexibility for successful integration. To gain quantitative understanding of the supply-demand balancing problem and to facilitate identification of the impact that key variables (such as RE penetration) have on the storage required we have defined the storage duration index (SDI) (Eq.1).

$$\text{SDI} = \left(\begin{matrix} \text{Fraction of demand met by} \\ \text{energy that has been stored} \end{matrix} \Big/ \begin{matrix} \text{Normalised variance from} \\ \text{uniform duration storage} \end{matrix} \right) \quad (1)$$

The SDI condenses the storage requirement information from the storage profile (Figure 1) into two non-dimensional numbers that relate to the magnitude of storage use and duration of storage use respectively. This enables the quick identification of the impact that variables have on the storage requirements. Using this tool and data from the Met Office (Office 2006) and ELEXON (ELEXON 2017) we have investigated the impact that RE mix and penetration would have on an electricity network in Lerwick, Scotland. From these results, shown in Figure 2, we have three conclusions for this location: increased RE penetration increases the requirement for storage, increased RE penetration leads to a reduction in the short-term storage bias, and the RE mix has a large impact on storage requirements which is exacerbated by RE penetration.

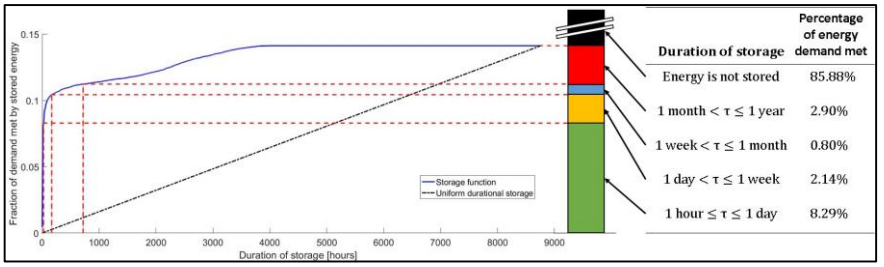

Figure 1: Storage profile against the duration of storage for Lerwick with 60% RES penetration and 50% Wind:50% Solar power supply

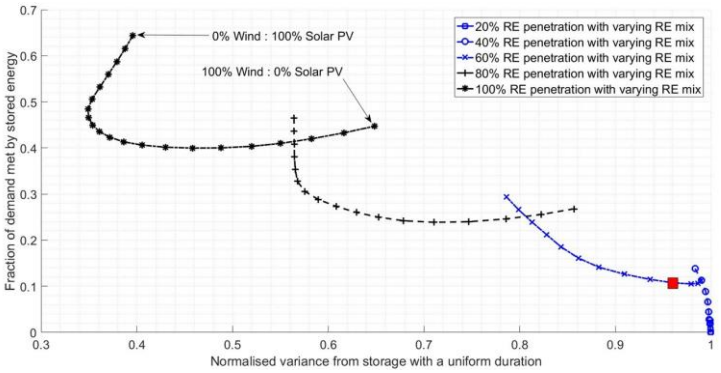

Figure 2: The impact of RES ratio (Wind:Solar PV energy supplied) and RES penetration on the system's storage duration index (SDI)

We also investigated the viability of an islanded 'green' ammonia production process, i.e. using a Haber-Bosch (HB) process fed with hydrogen produced by water electrolysis and nitrogen from air separation powered entirely by RE. We modelled the production process in MATLAB at the process level accounting for the intermittency of RE (i.e. fluctuations

≥ 1 hour), a gap in the knowledge base recently identified by the IEA (Philibert 2017). Few studies on process analysis of electrified ammonia production have been published. The four most important RE studies dealt with intermittency differently so LCOA estimates vary (in GBP/t NH_3, Eq.2): 447-942 (Morgan 2013), 264-528 (Beerbühl, Fröhling et al. 2015), 504-609 (Bañares-Alcántara, Dericks III et al. 2015) and 524-1771 (Tunå, Hulteberg et al. 2014). To stabilise the supply Morgan and Tunå et al. used dispatchable sources such as the grid or biomass, whereas Beerbühl et al. and Bañares-Alcántara et al. assumed islanded systems that had hydrogen and ammonia "buffers" respectively. Our analysis presented here goes beyond: it provides a method applicacable to any location and quantitatively identifies the key variables affecting the LCOA.

Section 2 outlines the modelling assumptions and methodology, Section 3 describes the model's calculations, Section 4 presents the results and their significance. Section 5 summarises the key conclusions and identifies areas for future development.

2. Methods (modelling methodology)

The model was written in MATLAB®. The model, when provided with RE supply profiles, outputs the optimum size of the electrolyser, air separation unit (ASU), HB process and hydrogen storage (see Figure 3). Optimisation of additional variables such as the RE mix and HB operating variables (maximum rate of load ramping and minimum process load) is also possible. The model uses RE supply data with thirty minute or hourly granularity to accommodate electrical settlement periods in the UK (the most commonly available data granularity). This limits the accuracy of the final results unless sub-minute variations are taken into account using dynamic modelling. The ASU and HB processes are lumped together (ASU/HB) for power allocation to simplify the problem, a reasonable assumption due to the small power demand and capital cost (CAPEX) of the ASU relative to the HB process, and particularly the electrolyser.

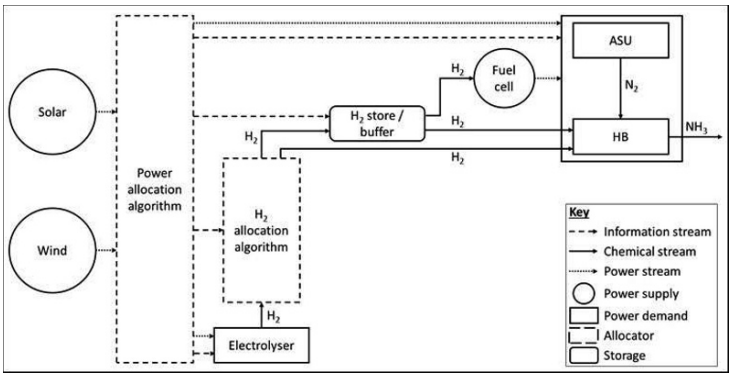

Figure 3: Process block diagram including power, chemical and information flows

3. Calculation

In order to identify the key variables that impact LCOA (Eq.2) and its sensitivity to them, the model was run with (2000-2016) Met Office wind and solar MIDAS data which have a granularity of one hour (Office 2006). The use of historical data, instead of an artificial statistical dataset, and its long time coverage enabled the model to provide more realistic results. We decided to perform our investigation using data for Lerwick, Scotland for two

reasons: plentiful wind power (thus enabling a high electrolyser average load factor (Philibert 2017)), and a predicted increase of curtailed RE energy in the regional network (see ITM's BIG HIT project for further details (Hyde 2017)).

$$\text{LCOA} = \frac{\text{Cost of production}}{\text{Mass of ammonia produced}} \quad (2)$$

To facilitate the comparison of different cases, we constrained the supply power to an average of 100 MW rather than fix the plant production rate (in t/day of ammonia); the simulation then finds the optimal size plant that minimises the LCOA. For Lerwick the LCOE from renewables was taken as 67 and 80 GBP/MWh for wind (BEIS 2016) and solar photovoltaic (BEIS 2016) sources respectively. The solar data is provided in power per unit area, so it does not require pre-conditioning. However, the wind speed provided in the MIDAS data is converted first to a hub height of 80 m using the wind profile power law (and roughness level taken as 0.03), then converted to power using the power profile of the Vestas V90 3.0 MW turbine with an air density of 1.225 kg/m^3. The cut-in and cut-out speeds were taken as 4 and 25 m/s respectively.

The identification of the key variables that determine the LCOA value was achieved by performing sensitivity analyses on numerous variables, prioritised when possible (if they were cost of production variables), by their fraction of total production cost. Having identified five key variables (discussed further in Section 4) that significantly impact LCOA, we performed more detailed sensitivity analyses. Analysis of production cost variables held the size of the plant (all component processes) constant and changed linearly the value of the variable. However, analysis of production process variables allowed the size of the plant (each individual component process) to change, allowing the model to find a better plant size (and its corresponding RE supply mix) if one is available, thus providing an impact on LCOA together with individual process sizing.

4. Results

The five key variables have the most significant impact on LCOA:

- Production cost variables (those that dominate OPEX and CAPEX values)
  i. Levelised cost of electricity (LCOE)
  ii. Electrolyser CAPEX per kW of rated power
- Production process variables (those that influence the mass of ammonia produced)
  iii. RE sources ratio (dependent on RE profiles, i.e. geographical location)
  iv. ASU/HB process minimum power consumption (P_{MIN})
  v. ASU/HB process maximum ramping rate (maximum difference in power for contiguous time intervals)

The production cost variables, as shown in Figure 4 for LCOE, have significant impact on the LCOA: a change in LCOE ±0.89 GBP/MWh results in a change of ±10 GBP/t NH_3. In turn, a change in the electrolyser CAPEX per kW rated power of ±65 GBP/kW has the same effect on the LCOA, i.e. ±10 GBP/t NH_3. The significance of these variables is widely acknowledged, but has only been previously quantified in (Beerbühl, Kolbe et al. 2014) (using a dispatchable electrical supply) and in (ISPT 2017) respectively. The results presented here corroborate Beerbühl's result of ±0.97 GBP/MWh resulting in ±10 GBP/t NH_3, and correlate well with ISPT's finding that a significant reduction in

electrolyser CAPEX (to 300 GBP/kW) is needed to make the process economically viable. We have benchmarked our analysis in Figure 4 against ammonia as a commodity (showing the global ammonia prices between 2002-2014) and as it is converted to retail electricity (prices of 0.12 GBP/kWh with a 50% ammonia-to-electricity efficiency).

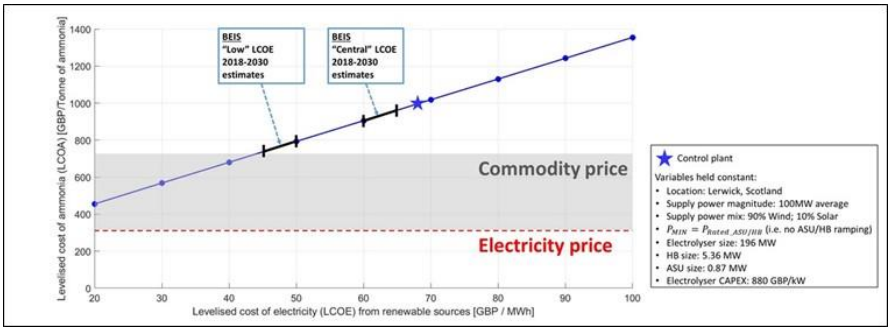

Figure 4: LCOA sensitivity to LCOE

In contrast, the process variables (shown in Figure 5) have been ignored to date and their impact had not been quantified previously. Figure 5 shows the benefits of a flexible HB process and the limitations that the process must be able to operate within, i.e. ramping faster than 5% of rated power/h, to enable these benefits to be realised. The ramping bottleneck within the process would most likely be the catalyst. These results can provide some technical requirements for future catalyst development in an electrified ammonia process.

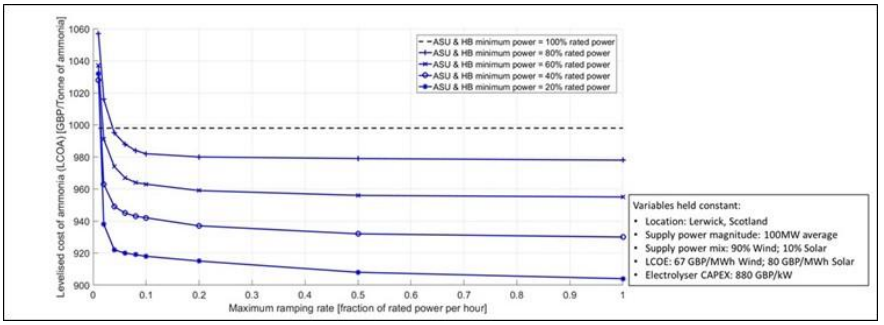

Figure 5: LCOA sensitivity to ASU & HB process minimum power and maximum ramping rate

5. Conclusions

The outline of a model implemented in MATLAB® has been presented which, for a given location, will design a 'green' ammonia plant with the optimum size (at the process level), RE mix and operation schedule. In response to a recent IEA challenge (Philibert 2017), this model makes possible detailed plant design in combination with RE supply sizing for any given location, and facilitates further optimisation (through dynamic analysis) by providing a good initial solution. The model has enabled us to identify the five most significant variables to produce 'green' ammonia, and to investigate the LCOA's sensitivity to each of them. In practice, a combination of these improvements in a suitable geographical location (i.e. with favourable supply profiles) has the potential to become the first economically viable decarbonised process substitute to conventional ammonia production.

Production cost variables

i. Levelised cost of electricity (LCOE): ±0.89 GBP/MWh results in ±10 GBP/t NH_3
ii. Electroyser CAPEX per kW rated power: ±65 GBP/kW results in ±10 GBP/t NH_3

Production process variables

iii. RE sources ratio: has a significant impact on the LCOA and optimum plant size
iv. ASU/HB process minimum power (P_{MIN}): ±12% change of rated power results in ±10 GBP/t NH_3
v. ASU/HB process maximum ramping rate (LCOA insensitive to > 4% rated power/h)

2025/2030 predictions for these variables (LCOE = 45.7 GBP/MWh (BEIS 2016), electrolyser CAPEX = 308 GBP/kW (Colella, James et al. 2014), $P_{MIN} = 20\%$ rated power and a maximum ramping rate of 6%) estimates LCOA as 588 GBP/t NH_3. This work shows how electrifying chemical production processes using intermittent RE affects process sizing and plant operation. Future work will integrate component level analysis of the synthesis loop, accounting fluctuations < 1 hour for RE and use machine learning to manage the predictability of RE.

Abstract

Taking into account the high efficiency of solar thermal collectors and the fact that heating demands represent around 80% of the total energy needs in residential buildings, it is of interest to integrate solar thermal systems to supply HVAC services. However, both solar energy and HVAC needs have strong daily and seasonal variations, and require an efficient long term storage solution. The underground represents an efficient storage medium, which can compensate the latter mismatch; in winter, surplus heat can be extracted to satisfy the strong demand, while in summer, the rejected heat from cooling systems – in addition to the heat produced from the solar thermal collectors can be reinjected in the ground, therefore achieving long term energy storage.

Low temperature district energy networks do not only supply heating and cooling to districts, but they also have the ability to harvest heat from renewable or low temperature waste heat sources and to integrate with long term heat storage systems, such as ground storage. This work looks at the integration of low temperature CO_2 networks with solar thermal and geothermal storage to provide energy services. Solar thermal collector areas of 12.5 m^2/cap are required for typical urban centers to close yearly energy balance in the ground.

Keywords: ground long-term storage, solar thermal, low temperature district networks, geothermal probes

1. Introduction

In the 20th century geothermal energy started being harvested on a large scale for heating, industry and electricity generation. Although the worldwide use of geothermal energy amounts to 49 TWh/year of electricity and 53 TWh/year for direct use, the total potential of this resource is estimated at 2,000 TWh/year for electricity generation and 7,000 TWh/year for direct use (Groupe de travail PGG 2011). Clearly, the current use of geothermal energy represents only a very small fraction of the real potential.

One way of exploiting geothermal energy would be by extracting the heat from the ground using vertical geothermal probes (VGP) (Focaccia and Tinti 2013). VGPs are composed of one or more polyethylene U-shaped pipes, in which a heat transfer fluid flows in a circuit. The fluid heats up when it goes down the tube and transports the heat from the underground to the heating system found at the surface.

Vertical geothermal probes exploit a low temperature heat source, and are usually at a depth of no more than 300-400 m. The probes are further connected to heat pumps (HPs) which allow, with a moderate amount of electricity, to increase the temperature of

the fluid up to 35 to 45°C for heat delivery at low temperature (e.g. for space heating (SH)) or up to 60°C to produce domestic hot water (DHW) (Steiger and Kees 1981). Providing thermal services using vertical geothermal probes requires external energy (usually in the form of electricity) not just for the heat pump, but also for the pump used to circulate the heat transfer fluid inside the probe. In addition to heating, VGPs can also be used to produce cooling in summer. In this case, the heat transfer fluid evacuates the excess heat from the building in the underground, recharging the ground which was cooled down during the heating season (Wiggs 2008). Cooling services can be provided either directly or via a refrigeration cycle. In the case of direct cooling, this natural cooling technique has two advantages: it saves a considerable amount of electrical energy (i.e. used by commercial AC) and it recharges the ground with heat during summer.

However, the temperature of the ground where the probe fields are must be equilibrated over the year, since generally the heating is not equal to the cooling demand. In this work, a solar system is coupled to the network in order to close the energy balance in the ground. A typical urban center using CO_2 as the heat transfer fluid is used as case study. Celine Weber *et al* (Weber and Favrat 2010) introduced the idea of distributing CO_2 in the district energy networks at an intermediate temperature below the critical pressure of 7.4 MPa. The system has been integrated with geothermal probes for heat extraction (Suciu et al 2017), but a low temperature water source was used for heat injection. In this work, the heat injection is done using geothermal probes and the gap between the heat extraction from the ground and the heat injection into the ground is filled using heat available from solar thermal collectors. The solar thermal collector area required to close this energy balance for a typical urban center is assessed.

2. Methodology

2.1. CO_2 based district energy networks

A detailed description of the refrigerant based network using CO_2 as the heat transfer fluid is given by (Weber and Favrat 2010) and possible energy conversion technologies have been investigated by (Henchoz 2016). The decentralized energy technologies used are (i) heat pumps for SH and DHW, (ii) heat exchangers for air cooling, and (iii) vapor compression chillers for refrigeration. The centralized energy technologies used are: a central plant which balances the network (in the form of a lake or geothermal probes), photo-voltaic (PV) panels, a solid oxide fuel cell (SOFC) – solid oxide electrolysis cell (SOEC) co-generation unit, and a boiler-steam network installed at the waste incinerator. Interested readers are referred to (Suciu et al 2017) for further details. A schematic representation of the fully integrated system can be observed in Figure 1.

The system is integrated with geothermal probes for heat extraction and injection and with solar thermal collectors to close the balance on the heat extracted from the ground (i.e. additional heat injection). The problem is formulated as a mixed integer linear programming (MILP) problem and is targeting the optimal utility selection (and sizing) (Marechal et al 2003). The objective function is the minimization of the operating cost and the main constraints are the heat cascade equations and the resource balance equations.

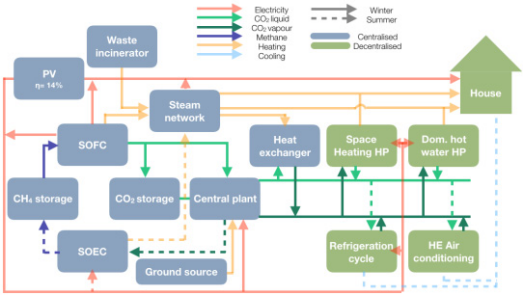

Figure 1. Schematics of CO_2 DEN

2.2. Geothermal extraction and injection

The ground storage is modeled as a fully stratified tank (Figure 2), with the temperature at the bottom fixed at T_{bottom} = 30°C and the temperature at the top fixed at the ambient temperature T_{amb}. The storage level changes by moving the thermocline up and down. The ground storage tank is modeled as a long-term storage unit:

$$SL(t+1) = SL(t) + \dot{Q}_{in} - \dot{Q}_{out} + \dot{Q}_{loss,env} \quad (1)$$

with $SL(t)$ the storage level at time t, $\dot{Q}_{in}$ the heat flow in the ground (eject heat from the network and heat from solar thermal), $\dot{Q}_{out}$ the heat flow out of the ground (heat required by the network) and $\dot{Q}_{loss,env}$ the heat losses to the environment:

$$\dot{Q}_{loss,env} = \hbar_{air} \cdot \dot{A}_{ground} \cdot (T_{bottom} - T_{amb}) \quad (2)$$

with $\hbar_{air}$ = 50 W/(m²·K) the heat transfer coefficient of air (Bergman and Incropera 2011) and A_{ground} the cross-sectional area of the ground influenced by the geothermal probe. The cross-sectional area was computed using:

$$A_{ground} = \pi \cdot \left(\frac{D_{ground}}{2}\right)^2 \quad (3)$$

with D_{ground} = 4 m (Bianchi 2006) the diameter of the ground influenced by the geothermal probe. In order to compute the electrical power required to extract heat from the ground, first the pressure drop in the pipe was computed using the friction factor f, the fluid density ρ_{H_2O}, the fluid velocity v, the probe height $\hbar_{probe}$, and its hydraulic diameter $D_{\hbar}$= 0.04 m (Groupe de travail PGG 2011):

$$dP = \frac{f \cdot \rho_{H_2O} \cdot v^2 \cdot \hbar_{probe}}{2 \cdot D_{\hbar}} \quad (4)$$

Additional details on the different parameters can be found in (Bergman and Incropera 2011). The probe height was computed assuming a geothermal gradient of 30°C/km (Amblard 2015). Using the pressure drop, the mass flow of the fluid $\dot{m}$, its density ρ_{H_2O}, and an average geothermal pump efficiency $\eta_{geot\hbar}$ = 0.8 (Self, Reddy et al 2013), the geothermal energy of extraction is calculated:

$$\dot{E}_{pumping} = \eta_{geot\hbar} \cdot \frac{dP \cdot \dot{m}}{\rho_{CO_2}} \quad (5)$$

The number of geothermal wells needed is found using:

$$N_{probes} = \frac{\max(SL)}{C_{ground} \cdot (T_{bottom} - T_{amb}) \cdot h_{probe} \cdot A_{ground}} \quad (6)$$

with C_{ground} = 2009.8 kJ/(m^3·K) (Groupe de travail PGG 2011) the volumetric capacity of the ground.

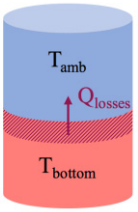

Figure 2. Schematics of stratified geothermal model

And the average temperature in the ground $T_{avg,ground}$ is computed as:

$$T_{avg,ground} = \frac{SL(t) \cdot T_{bottom} + (\max(SL) - SL(t)) \cdot T_{amb})}{\max(SL)} \quad (7)$$

2.3. Solar thermal collector

The solar thermal collector efficiency is modeled as a quadratic performance curve, depending on the external temperature T_{amb}, the incoming irradiation intensity GI $[\frac{W}{m^2}]$, a maximum efficiency η_0, and two experimental parameters a_1, a_2 (Duffie and Beckman 2013):

$$\eta = \eta_0 - a_1 \cdot \frac{T_m - T_{amb}}{GI} - a_2 \cdot \left(\frac{T_m - T_{amb}}{GI}\right)^2 \cdot GI \quad (8)$$

The heat transmission coefficient a_1 describes the thermal losses. The higher this value, the more losses the collector has. The coefficient a_2 is used to calculate the coefficient of heat transmission dependent on temperature. The average monthly solar thermal efficiency varies between 30 – 45%.

3. Results and discussion

The results are divided in three scenarios. In the first scenario, the heat from the environment is provided by a lake, in the second scenario it is provided by geothermal probes (coupled to solar thermal), and in the third scenario, besides geothermal probes and solar thermal, also the waste incineration plant is included. The number of probes/household (4 capita), the m^2/cap of PV panels and m^2/cap of solar thermal panels required for full autonomy are shown in Figure 3.

The m^2/cap of PV panels required decreases when geothermal probes are used instead of a lake since the electricity required for pumping is smaller than the electricity required in a central plant heat pump using lake water as a source. The m^2/cap of PV and solar thermal panels and the number of probes/ household (4 capita) decreases from 23.5 and 13.5 m^2/cap and 0.34 probes/household to 22.4 and 12.5 m^2/cap and 0.32 probes/household when the waste incineration plant is included, since the steam network integrated at the waste incinerator produces a part of the electricity required and of the low temperature heat which is used to vaporize CO_2 (instead of using heat from the geothermal probes).

The real potential for PV/solar thermal for a typical urban center of 11 m^2/cap (Figure 3) (Faessler et al. 2011) is not enough for full autonomy, so other sources of heat and electricity should be considered, such as wind, hydro energy or the electricity mix, and ground or waste water, respectively.

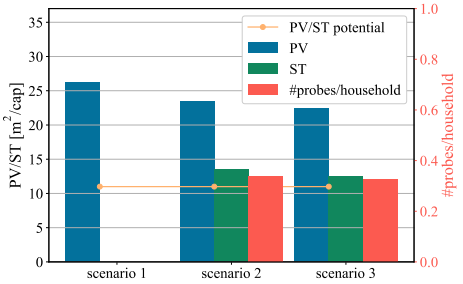

Figure 3. PV/ST area and #probes/household for a typical urban city

The heat flow profiles in and out of the ground are shown in Figure 4. One can see that heat is extracted from the ground between October and February, when the heat demand is high and injected in the ground in summer, when there is waste heat available from cooling and the solar thermal heat production is high.

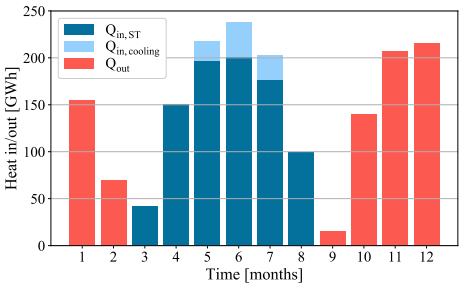

Figure 4. Heat flow in/out of the ground

The average temperature in the ground and the heating demand (space heating and domestic hot water) are shown in Figure 5. One can observe that in winter the heating demand is high, so heat is extracted from the ground and consequently the average temperature in the ground decreases, while in summer the heating demand is low, but the solar thermal heat production is high and therefore the average temperature in the ground increases.

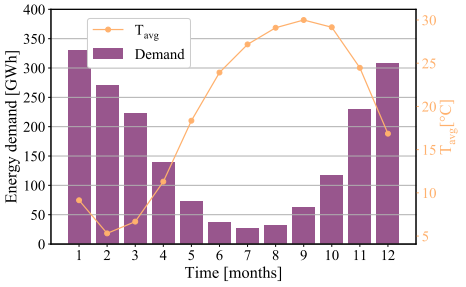

Figure 5. Average temperature in the ground and heating (SH and DHW) demand

4. Conclusion

This work studies the integration of low temperature CO_2 based district energy networks with geothermal probes as a ground energy source and solar thermal collectors as a heat source for the heat pumps and for the ground (to close the yearly balance). Three scenarios are studied depending on the source of the heat from the environment and on whether the waste incineration plant is considered or not. The PV area required for autonomy reduces when geothermal probes are used, since their electricity consumption is lower than that of a water source heat pump, and the PV and solar thermal areas and number of probes decrease when the waste incineration plant is included, since part of the electricity and of the heat required to vaporize CO_2 are produced by the steam network integrated at the waste incinerator.

The real potential for PV/solar thermal panels of 11 m^2/cap is not sufficient for autonomous urban centers, so other clean energy sources are suggested, such as wind or hydro as an electricity source and ground or waste water as a heat source.

Abstract

The objective of this work is to develop computational tools to identify optimal configurations when integrating a large number of solar cells under shady or faulty conditions. The photovoltaic module that will be considered in this analysis consists of 96 cells connected in series, where an equal number of solar cells, called a string, is connected to a bypass diode. Both event-driven Monte Carlo simulation and Multi-Attribute Utility Theory are used to evaluate the effect of the number of bypass diodes on the photovoltaic module maximum power point, and to find the optimal configuration needed to minimize performance losses under uncertain shading conditions. The optimal cell configuration is established when the total value function of the module is maximized. Ideally, it was found that the optimal situation corresponds to having one bypass diode connected to each cell in the module; however, by factoring in diode cost, it was found that one bypass diode wired to each group of four solar cells was economically more practical.

Keywords: Solar energy, Modeling, Monte Carlo simulation.

1. Introduction

Current trends in electrical power generation and energy storage research highlight the promise of micro- and nano-scale devices (Fan et al., 2015 and Krogstrup et al., 2013). Performance issues arise when integrating these devices, as design and performance mismatch between devices can cause deviation from the expected performance in a highly nonlinear manner. The tera- and giga-scale levels of integration necessary for producing and storing macroscopic levels of energy from nano-scale devices necessitates device integration strategies that are resilient to the inevitable faults and variability that will arise in the individual devices. Thus, new computational tools are needed to support the design, integration, and (advanced) manufacturing of these energy systems. As a first step towards developing simulation-based design tools for the integration of nano-scale energy devices, we will examine the problem of determining the optimal strategy to integrate a large number of photovoltaic (PV) solar cells under shady or faulty conditions as a proxy for our primary simulation objective.

When one cell in an array of PV cells is shaded, its voltage polarity may reverse resulting in power consumption instead of production, leading to hotspot formation, reduced overall power, and even PV module damage. Bypass diodes can be used to route current around shaded or faulty cells to partially recover the lost performance. In this paper, we focus on modeling tools useful for optimizing the number and placement of these diodes within a PV cell array.

Rao et al. (2014) investigated the effect of different interconnection schemes on the output of a PV array under partial shading conditions; the potential benefits of bypass diodes, however, was not included in their analysis. Vemuru et al. (2012) examine the effect of random shading of a PV array on the output power. They concluded that the power of the randomly shaded array is reduced significantly when no bypass diodes are used, as opposed to having a fixed number of bypass diodes in the array for the same shading conditions. Silvestre et al. (2009) used the Pspice simulation environment to study the effect of bypass diode configuration on a PV module. They presented a finite number of simulation cases in which selected cells were shaded, and demonstrated how the configuration of a fixed number of bypass diodes affected the results.

In this work, we introduce the stochastic effects and uncertainty generated by shading, which simulate real-life operating conditions. We use event-driven Monte Carlo simulations, in which each event corresponds to a separate shading case. An advantage of our choice of MC simulation is that it can be extended to any shading pattern caused by trees, falling tree leaves, standing birds, close-by buildings, and even passing clouds, once the statistical distribution of the shading effect is known or can be approximated.

2. Model and Simulation

2.1. Governing Equation

The PV module considered in this analysis consists of 96 PV cells connected in series, where strings (subsets of the full set) of solar cells are wired in parallel to a bypass diode, as shown in Figure (1). The extended diode equation, Eq.(1), is used to model the current-versus-voltage characteristics of each PV cell (Silvestre et al., 2009). The last term in the equation describes the diode avalanche breakdown at high negative voltages of the cell (Ben Or and Appelbaum, 2013).

$$I = XI_{ph} - I_o\left[exp\left(\frac{V+IR_s}{mV_{th}}\right)-1\right]-\left(\frac{V+IR_s}{R_{sh}}\right)\left[1+a\left(1-\frac{V+IR_s}{V_b}\right)^{-\beta}\right] \quad (1)$$

The diode equation parameters and their values used in this analysis are: photocurrent I_{ph}=2.443 A, dark saturation current I_o=2.935×10^{-12} A, series resistance R_s= 14.49×10^{-3} Ω, shunt resistance R_{sh}=3872 Ω, diode ideality factor m=1, thermal voltage V_{th}= k_BT/q = 2.61×10^{-2} V, breakdown voltage V_b= -25 V (Silvestre et al., 2009), and bishop's term parameters a=2×10^{-3} and β=4 (Silvestre et al., 2009). These parameters are intended to approximate a SANYO HIP-205BA3 PV module. In this simulation, the shaded cells are assumed to be 50 % shaded (X=0.5).

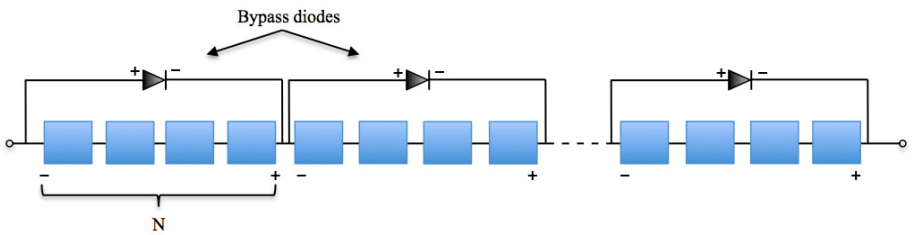

Figure (1): Schematic diagram showing the system's configuration.

2.2. Calculating the current of a string with shaded cells

To calculate the current I of a string of N solar cells wired in series, we define C_t as the number of shaded solar cells in the string, V_1 the voltage across an unshaded cell, and V is the total voltage of the string to find the voltage across a shaded cell as

$$V_{sh} = \frac{V - (N - C_t)V_1}{C_t} \tag{2}$$

Substituting V_1 and V_{sh} into Eq.(1), we obtain two diode equations: one for unshaded cells, and the other for shaded cells. Because the currents of PV cells connected in series are identical, we can set both equations equal to each other to find one function of I, V, and V_1. This equation can be solved numerically to find current values I at different string voltages V. However, for every V value we assume, we have two unknowns, I and V_1, and hence, a two-dimensional iterative loop is used. For a known value of V, first we assume I = 0, and using a Newton procedure, we find the corresponding value of V_1. Then the inner loop will re-calculate the value of I as a function of the previous V_1 and I values. The next iteration would use the most recent V_1 and I values to solve for V_1 again, and then I is re-examined in the inner loop. The stopping criterion corresponds to reaching converged V_1 and I values. This procedure is carried out for each value in the vector V, resulting in I-V data for the shaded string.

2.3. Monte Carlo Simulation

For the MC simulation, both the number of partially shaded solar cells and their position are considered random variables. The number of shaded cells is assumed to follow a uniform distribution ranging from 1 to 5 shaded cells, and the position of the shaded cells also follows a uniform distribution ranging from cell 1 to cell 96. The position of the shaded cell is important since it determines the number of shaded cells in each string, and the number of strings with shaded cells.

We developed a MATLAB program to calculate the output maximum power point for each run of the MC simulation. At the start of the program, we have a vector of values for the voltage ranging from 0 to the open circuit voltage of the string. The main idea is to determine at each voltage point whether the bypass diode for each string would be activated or not under the shading conditions randomly provided. We assigned 12 cases representing the number of bypass diodes (1, 2, 3, 4, 6, 8, 12, 16, 24, 32, 48, 96), and for every case, we run the MC simulation for 1,000 shading events, each with different random number of shaded cells and random positions, to obtain the module maximum power point P_{max}, its standard deviation, and standard error.

For each value of the voltage, we calculate its corresponding current following the model presented in sections 2.1 and 2.2. The string with the highest current will force the shaded strings to pass the same current. As a result, the bypass diode will be activated if the shaded strings resulted in a negative voltage.

When recalculating the voltage of the shaded strings, we might encounter high values of negative voltage (close to cell breakdown voltage), and the Newton procedure converges slowly or sometimes even diverges (Quaschning and Hanitsch, 1996). Hence,

in some cases, the bisection method is used to estimate the initial guess for the Newton procedure. A summary of the simulation algorithm is shown in the SysML activity diagram in Figure (2).

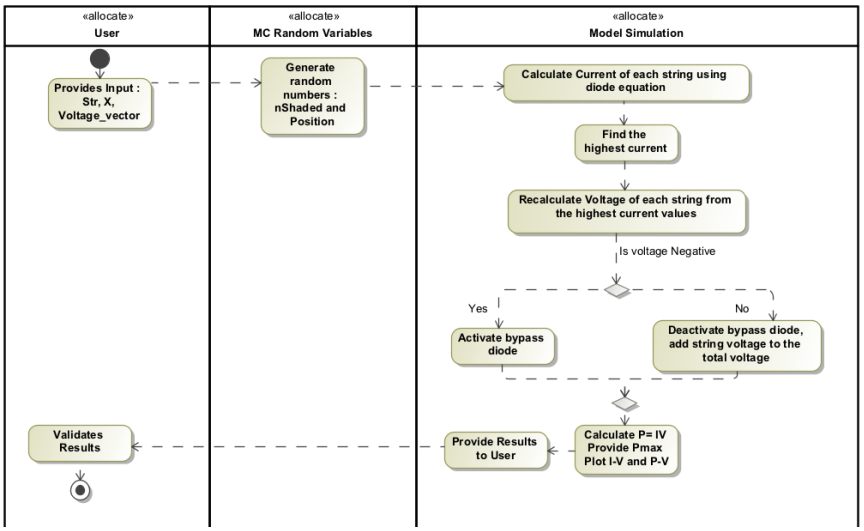

Figure (2): Simulation Algorithm Activity Diagram. Note that "Str" is the number of strings.

2.4. Multi-Attribute Utility Theory (MAUT)

Because the MC simulation results clearly demonstrated the effectiveness of using the highest number of bypass diodes (Fig. 4), we next considered the cost of adding the bypass diodes to make the final design decision. Hence, MAUT was used, with a linear additive utility function, and a weight (w) of 0.6 for cost value function, and 0.4 (1-w) for performance value function. The cost of each diode was set to be \$3, an approximate cost of Microsemi Active Bypass LX2400 (Microsemi, 2017). The cost value function V_c was normalized to be between 0 and 1, with a value of 1 corresponding to having no bypass diode, and a value of 0 corresponding to having the maximum number of bypass diodes (96×\$3=\$288). The performance value function V_p was also normalized to be between 0 and 1, with a value of 1 for the maximum power value among all bypass diodes, and 0 for the minimal power value among all bypass diodes. The total value function V(C,P) is given in Eq.(3).

$$V(C,P) = wV_c(C) + (1-w)V_p(P) \tag{3}$$

3. Analysis and Results

To examine the effect of the number of bypass diodes on the module performance, the module is simulated with only one shaded cell. As seen in Figure (3), as the number of bypass diodes increases, the output power will also increase, minimizing performance losses compared to the unshaded case. Hence, the effect of the shaded cell is minimized with increasing the number of bypass diodes.

The MC simulation results are provided in Figure (4). As the number of bypass diodes increases, the maximum power also increases. This result is expected since increasing the number of diodes decreases the number of illuminated PV cells bypassed. Even though increasing the number of bypass diodes may lead to increased leakage currents in these diodes, this effect is highly compensated by the positive benefits of adding the diodes.

For the MAUT analysis, Figure (5) shows the normalized total utility value function calculated. For the given diode cost and weights on each attribute, the optimum configuration is achieved by using 24 bypass diodes, at which P_{max} is 119.31 ± 0.20 W, and the total diode cost is $ 72.

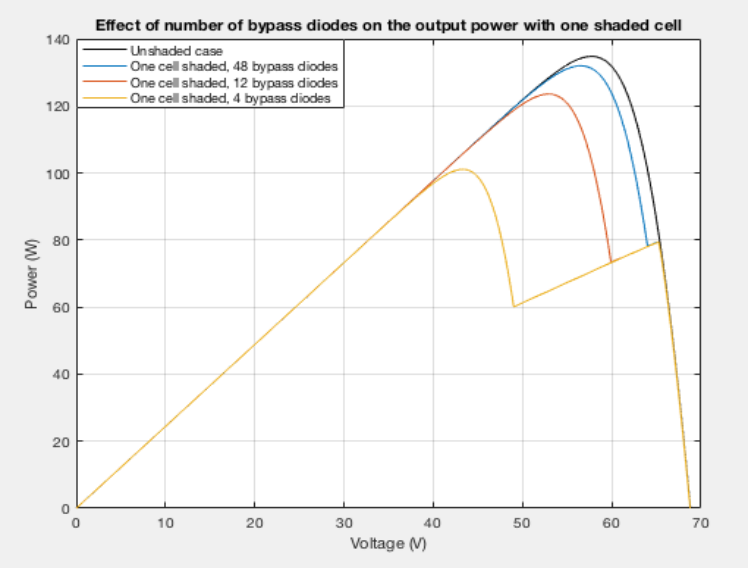

Figure (3): P-V curve for one shaded cell at different bypass diodes

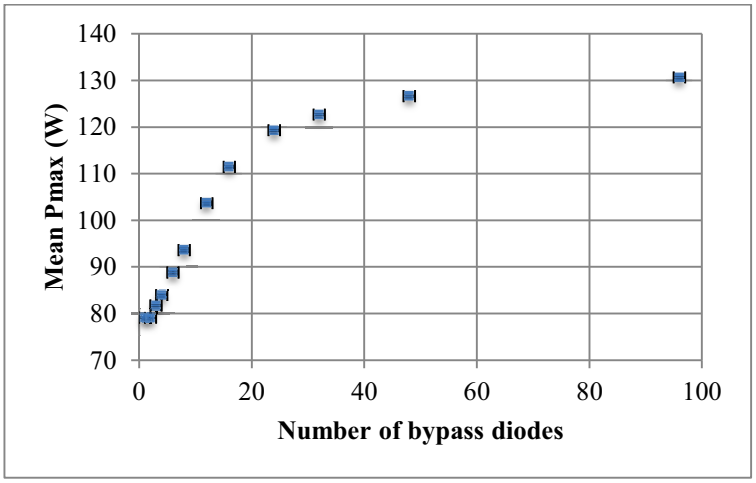

Figure (4): MC simulation results for each bypass diode case.

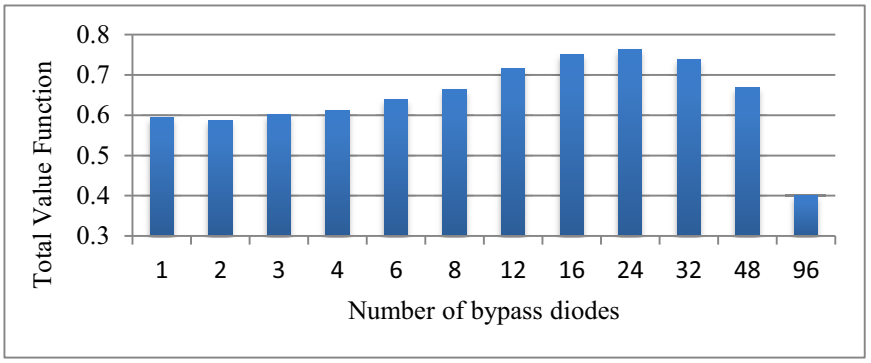

Figure (5): MAUT total value function

4. Conclusion

A computational algorithm was developed for optimizing PV cell network design. In this study, the effect of using bypass diodes in a PV module with shaded cells was examined. Ideally, it was found that the optimal situation corresponds to having one bypass diode connected to each cell in the module; however, by factoring in diode cost, it was found that one bypass diode wired to each group of four PV cells was economically more practical.

The algorithm presented in this work was able to find the optimum configuration of bypass diodes for any module with PV cells wired in series. The MC simulation allows for consideration of different shading patterns once the statistical distribution of the shading effect can be approximated. The approach developed in this paper can be extended to include randomly distributed manufacturing and other defects.

Comparative Study on Heat Transfer Efficiency of CRR Based on Entropy Analysis and Entransy Analysis

Li Xia, Yiting Zeng, Yuanli Feng, Xiaoyan Sun, Shuguang Xiang*

College of Chemical Engineering, Qingdao University of Science & Technology, Qingdao 266042, China
xsg @ qust. edu. cn

Abstract

The heat transfer efficiency of continuous reforming unit (CRR) is studied based on entropy analysis and entransy analysis. By calculating the entropy change and entransy of cold and hot streams, the transfer efficiency of entropy and entransy is obtained respectively. When the minimum temperature difference increases, the entropy transfer efficiency increases. It appears contrary to the principle of minimum entropy generation. When the minimum temperature difference increases, the entransy transfer efficiency decreases. It is proved that the greater the temperature difference, the lower the heat transfer ability. The theory of entransy can avoid the violation of the minimum principle of entropy production. Thus, compared with the entropy analysis, the entransy analysis has obvious advantages in analyzing the heat transfer efficiency of the CRR unit.

Keywords: entransy, entransy dissipation, entropy, heat transfer, the heat transfer efficiency, heat exchanger networks

1. Introduction

Many theories have been developed for the analysis of energy utilization efficiency of heat exchanger networks (HENs), such as entropy analysis and entransy analysis.

Bejan (1996) proposed the principle of minimum entropy production. However, when studying non equilibrium thermodynamics, it is found that the principle of minimum entropy production does not satisfy fourier law (Bertola and Cafaro, 2008). Guo et al. (2007) introduced the new physical quantity called entransy to describe the heat transfer capacity of objects. In recent years, some scholars have introduced the idea of entransy into HENs synthesis (Xia et al., 2016), such as heat exchanger design (Xia et al., 2017a), graphical method (Chen et al., 2012), computing the entransy transfer efficiency for the petrochemical unit (Xia et al., 2017b).

The entropy analysis and entransy analysis can describe the irreversibility of the heat transfer process. For the analysis of energy utilization efficiency of CRR unit, which is better? Then, the two methods for the HENs of the CRR unit were further compared.

2. Model of entropy analysis and entransy analysis

2.1. Entropy analysis model of HENs

The entropy analysis is based on the second law of thermodynamics. Select the N_h (hot streams) and N_c (cold streams). There is no heat loss and shaft power in the process of heat exchange. There is no fluid phase transition in the process. The heat flow rate of hot stream is CP_h and the heat flow rate of cold stream is CP_c. The temperature range from T_{in} to T_{out}, the entropy of hot and cold streams can be written as:

$$\Delta S_{h,i} = CP_{h,i} \ln \frac{T_{h,i,out}}{T_{h,i,in}} \tag{1}$$

The enthalpy change is:

$$\Delta H_{h,i} = CP_{h,i}(T_{h,i,out} - T_{h,i,in}) \tag{2}$$

$$\Delta H_h = \sum_{i=1}^{h_n} \Delta H_{h,i} \tag{3}$$

At ambient temperature T_0, the ideal work can be written as:

$$W_{id,c,i} = -CP_{c,i}(T_{c,i,out} - T_{c,i,in}) + T_0 CP_{c,i} \ln \frac{T_{c,i,out}}{T_{c,i,in}} \tag{4}$$

$$W_{id,h,i} = -CP_{h,i}(T_{h,i,out} - T_{h,i,in}) + T_0 CP_{h,i} \ln \frac{T_{h,i,out}}{T_{h,i,in}} \tag{5}$$

$$\Delta W_{id,c} = \sum_{i=1}^{c_n} \Delta W_{id,c,i} \tag{6}$$

$$\Delta W_{id,h} = \sum_{i=1}^{h_n} \Delta W_{id,h,i} \tag{7}$$

Because the efficiency of the second law of thermodynamics is

$$\eta_{II,0} = \frac{W_S}{W_{id}} = \frac{W_{id} - W_L}{W_{id}} \tag{8}$$

The ideal work done by hot stream from T_{out} to T_{in} is W_{id}. The difference between the ideal work given by the hot stream and the cold stream is W_L, which can be written as:

$$W_L = \Delta W_{id,h} - \Delta W_{id,c} \tag{9}$$

Therefore, the entropy transfer efficiency is:

$$\eta_{II,0} = \frac{W_{id,c}}{W_{id,h}} = \frac{\sum_{i=1}^{n} T_{m,h,i}(T_0 - T_{m,c,i})}{\sum_{i=1}^{n} T_{m,c,i}(T_{m,h,i} - T_0)} \tag{10}$$

$$T_{m,h,i}=\frac{T_{h,i,out}-T_{h,i,in}}{\ln\frac{T_{h,i,out}}{T_{h,i,in}}},T_{m,c,i}=\frac{T_{c,i,out}-T_{c,i,in}}{\ln\frac{T_{c,i,out}}{T_{c,i,in}}} \tag{11}$$

2.2. Entransy analysis model of HENs

The entransy analysis can be used to describe the efficiency of heat transfer (Xia et al. 2017c).According to the hypothesis of the model of a two-stream heat transfer process with entransy theory (Xia et al., 2017c), the HENs generally with constant pressure and constant volume, the constant volume specific heat of C_V and constant pressure specific heat C_P are approximately equal (Gesellschaft, 2010).

The entransy of hot and cold streams can be expressed as:

$$E_H=\sum_{i=1}^{h_n}E_{h,i},\ E_C=\sum_{i=1}^{c_n}E_{c,i},\ E_{h,i}=\frac{1}{2}CP_{h,i}(T_{h,i,in}^2-T_{h,i,\mathrm{out}}^2),\ E_{c,i}=\frac{1}{2}CP_{c,i}(T_{c,i,\mathrm{out}}^2-T_{c,i,in}^2) \tag{12}$$

The entransy dissipation can be written as:

$$\Delta E=\sum_{i=1}^{h_n}E_{h,i}-\sum_{i=1}^{c_n}E_{c,i}=\frac{1}{2}\sum_{i=1}^{h_n}CP_{h,i}(T_{h,i,in}^2-T_{h,i,out}^2)-\frac{1}{2}\sum_{i=1}^{c_n}CP_{c,i}(T_{c,i,out}^2-T_{c,i,in}^2) \tag{13}$$

Therefore, the efficiency of the entransy is:

$$\eta_0=\frac{E_C}{E_H}=\frac{\sum_{i=1}^{n}CP_{c,i}(T_{c,out,i}^2-T_{c,in,i}^2)}{\sum_{i=1}^{n}CP_{h,i}(T_{h,in,i}^2-T_{h,out,i}^2)} \tag{14}$$

Where CP denotes heat capacity flow rate, CP=mass flow m × constant pressure specific heat C_p.

3. Comparison of entropy analysis and entransy analysis for CRR unit

The pretreatment process of CRR unit is shown in figure 1. The reforming process of CRR unit is shown in figure 2.

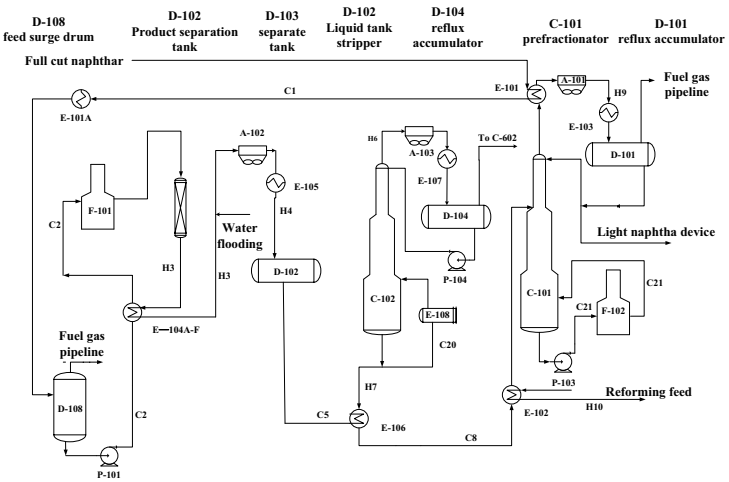

Figure 1.The pretreatment process of CRR unit

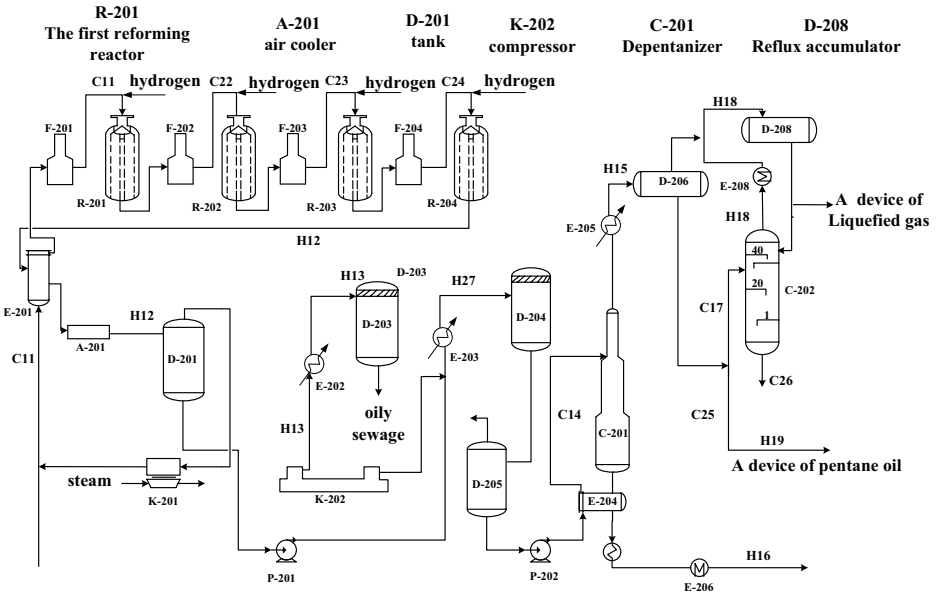

Figure 2. The reforming process of CRR unit

Extract the data of hot and cold streams, including hot and cold utilities. The extracted streams data include initial temperature, target temperature, heat capacity flow rate and heat load. The data of hot and cold streams is shown in table 1 and table 2.The environmental temperature T_0 is 298.15K, and the pressure is 0.1013MPa. The results calculated by entropy analysis and entransy analysis are shown in table 3 and table 4 respectively.

Table 1 The data of hot streams

Stream	Stream description	Supply Temperature [K]	Target Temperature [K]	CP [kW·K^{-1}]
H3A	reactor streams	278	215	53.2
H3B	reactor streams	215	144	100.5
H4	Streams mixed with water injection	109	40	61.3
H6	The stream of stripping tower	114	41	8.6
H7	The stream of stripping tower	189	112	46.3

4. Conclusions

The heat transfer efficiency of the CRR unit is analyzed by entropy analysis and entransy analysis. The main conclusions are as follows:

(1) The entropy analysis and entransy analysis can describe the irreversibility of heat transfer processes. Entropy analysis pays more attention to the work of hot streams under completely reversible conditions. The entropy can not calculate the energy loss.
(2) When the minimum temperature difference is 15 K, 20 K and 25 K respectively, the entropy transfer efficiency is 62.703%, 63.008%, 63.305%. The result is a clear violation of the minimum principle of entropy production. However, the entransy transfer efficiency is 75.90%, 73.97%, 72.11%. The theory of entransy can avoid the violation of the minimum principle of entropy production.
(3) The calculation of entropy, the ideal work, the entropy transfer efficiency is related to the ambient temperature in the entropy analysis. The calculation of the entrancy and the entrancy transfer efficiency is independent of the ambient temperature in the entrancy analysis. The entrancy analysis is more convenient than entropy analysis.

Abstract

The modern industrialized world is generating a huge amount of wastewater containing a variety of micro-pollutants which is discharged into rivers and oceans leading to disruption of the biological ecosystem. The reverse osmosis (RO) process is one of the most promising technologies to produce high-quality recycling water at a reasonable cost. In this work we develop a new mathematical model to predict the performance of the RO process for the removal of several organic and non-organic compounds from wastewater simultaneously. The realistic operating conditions ensuring high rejection of multi-compounds is explored via the simulation of the RO process first. The model is then used for optimising the operating conditions of the process while maximising the rejection and permeate recovery.

Keywords: RO Process, Wastewater Treatment; Modelling; Simulation; Optimisation; Multi-compound rejection.

1. Introduction

The main concern of any industrial wastewater is the existence of several organic and non-organic compounds which are harmful to human beings and marine life. Despite the availability of several wastewater treatment methods such as adsorption, biological, oxidation, and electrochemical process; the Reverse Osmosis (RO) process has demonstrated its competitive performance at a reasonable cost for the removal of these compounds. Several previous studies modelled the spiral wound RO process considering the removal of a single organic contaminant from wastewater (Sundaramoorthy et al., 2011; Al-Obaidi et al., 2017). However, only a few attempted the modelling of the spiral wound RO process for the removal of several organic and non-organic compounds from waste water. Al-Bastaki (2004) developed a lumped model to study the performance of a spiral wound RO process for removing Na_2SO_4 and methyl orange dye from wastewater. Note however, the development of a distributed model for the spiral wound RO process for the removal of multi-compounds simultaneously from wastewater has not been considered yet and is the main focus of this work. Also note, in the absence of experimental data in the literature for multi-compounds removal from wastewater, the model developed in this work has been validated against experimental data available for the removal of a single compound (chlorophenol) from wastewater. The model is then used to examine the rejection of organic and non-organic compounds under various operating parameters which in turn evaluates the process performance. This is followed

by embedding the model in a multi-objective optimisation framework to simultaneously maximise the rejection and the total permeate recovery.

2. RO Process Model

In this work RO filtration system of Sundaramoorthy et al. (2011) is used to investigate the simultaneous removal of multi-compounds from wastewater. Table 1 shows the new one-dimensional model equations for the process based on solution-diffusion model and the film theory. See Al-Obaidi et al. (2017) for a similar model but for single compound rejection. Due to the multi-compounds nature of the wastewater, the contribution of all of them to the osmotic pressure was considered in the new model. The model is validated using experimental data of chlorophenol removal from wastewater (Sundaramoorthy et al., 2011) which shows a very good agreement in terms of rejection and recovery of water (Fig. 1). The process model shown in Table 1 can be written in the compact form: f(x, u, v) = 0, where x is the set of all algebraic variables, u is the set of decision variables and v denotes the constant parameters of the process. The physical properties of seawater were used to calculate the diffusivity (D_b), viscosity (μ_b, μ_p) and density (ρ_b, ρ_p) due to low concentration of wastewater. The characteristics of the membranes used are given in Table 2. Five organic compounds and three inorganic species are assumed to be in the wastewater. The solute transport parameters (B_s) of the selected compounds were gathered from the literature and given in Table 3.

3. Process simulation: Effect of operating parameters

Fig. 2 shows the variation of feed pressure, osmotic pressure, and water flux along the membrane length (x-axis). The feed pressure decreases along the x-axis due to pressure drop caused by the friction. This in turn reduces the water flux as a result of decreasing diving force. An increase of total osmotic pressure along the x-axis is noticed due to increasing accumulated concentration of the solutes at the membrane wall.

The variation of inlet feed concentration of the pollutants found in wastewater is expected. Therefore, the RO process performance is investigated here using a range (350 to 500 ppm) of each pollutant concentration carried out at fixed feed flow rate, pressure, and temperature. Fig. 3 shows the effect of increasing feed concentration of each component on the rejection and total permeate recovery. In the selected range of 350 – 500 ppm of solute feed concentration, there was no considerable effect on the rejection. However, increasing the feed concentration of all the components causes a continuous reduction in permeate recovery due to increased osmotic pressure.

Table 2. Membrane specifications and geometry (Ion Exchange, India)

Parameter	Value
Membrane material	TFC Polyamide
Feed and permeate spacers thickness (t_f, t_p)	0.8E-3 m, 0.5E-3 m
Module length and width (L, W)	0.934 m, 8.4 m
Water Permeability Constant (A_w) and friction factor (b)	9.5188E-7 $\left(\frac{m}{atm\ s}\right)$, 8529.45$\left(\frac{atm\ s}{m^4}\right)$

Table 3. Physical and transport parameters of the eight selected organic compounds

Compound	B_s (m/s)	Membrane	Reference
Dimethylphenol	1.5876E-8	Ion Exchange, India	Srinivasan et al. (2011)
Chlorophenol	8.4680E-8	Ion Exchange, India	Sundaramoorthy et al. (2011)
Phenol	6.5367E-7	Permionics, India	Srinivasan et al. (2010)
Methyl orange dye	3.2000E-9	FilmTec SW30	Al-Bastaki (2004)
Aniline	4.1900E-6	DESAL-3B	Hidalgo et al. (2014)
Ammonium	1.1696E-7	SEPA-SSIC	Bódalo et al. (2005)
Cyanide	2.1861E-6	DESAL-3	Bódalo et al. (2004)
Sulphate	3.9869E-8	SEPA-SSIC	Bódalo et al. (2003)

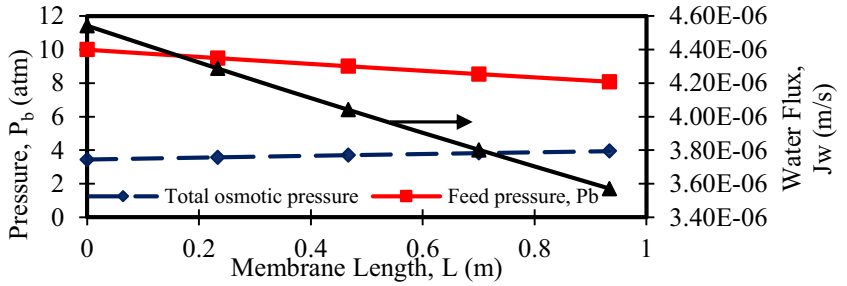

Fig. 2. The variation of operating parameters along the membrane length

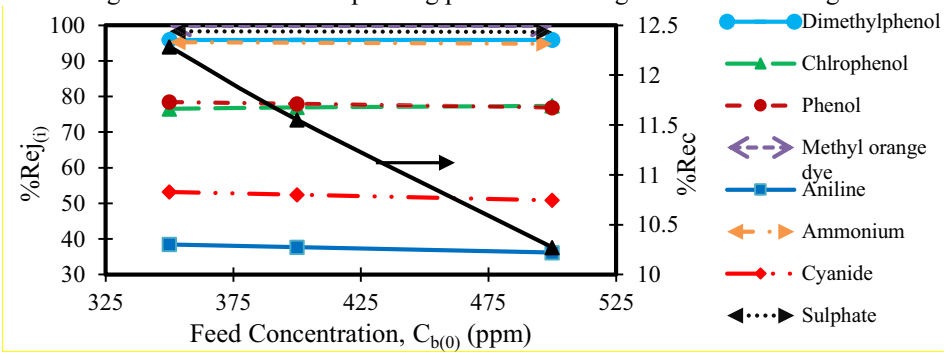

Fig. 3. Effect of compound concentration on rejection and recovery rate (operating conditions: 2.583E-4 m³/s, 10 atm, 30 °C)

Fig. 4 shows the impact of temperature on the removal of all compounds and permeate recovery. Increasing temperature causes more flexibility of membrane chains resulting in increasing convective transport by elevating the water flux. Also, it is noticed that diffusion transport increases due to increase in temperature, which is accompanied by a continuous reduction of average density and viscosity of the mixture. The effect of inlet feed pressure is shown in Fig. 5. Increasing the pressure from 10 to 20 atm causes an increase in the rejection due to increase in water flux, which dilutes the permeate. However, it seems that there is an optimum pressure which would maximise rejection of some of compounds. The impact of feed flow rate is shown in Fig. 6. The increase of feed flow rate from 2E-4 to 2.583E-4 m³/s causes a little increase in the rejection parameter but a remarkable decrease in permeate recovery. Increasing the feed flow rate causes a reduction in the osmotic pressure as a result of decreasing the membrane wall concentration. Increasing the feed flow rate from 2.583E-4 to 3E-4 m³/s causes a little

decrease in rejection and steady decrease in the permeate recovery. The reduction of permeate flux is due to reduction of wastewater residence time inside the module.

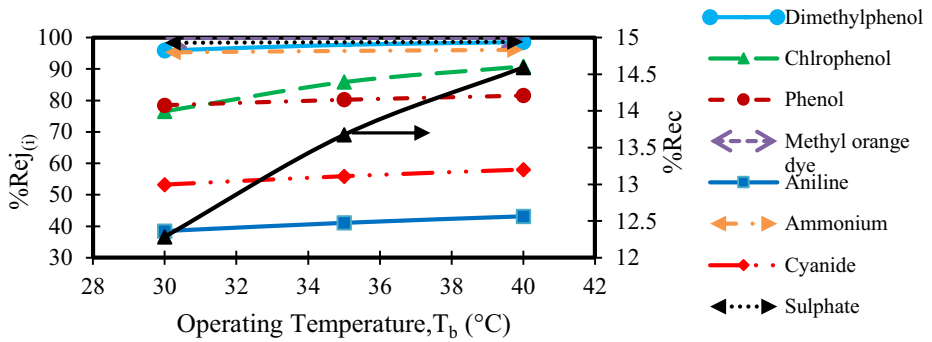

Fig. 4. Effect of operating temperature on rejection and recovery rate (operating conditions: 2.583E-4 m³/s, 10 atm, 350 ppm)

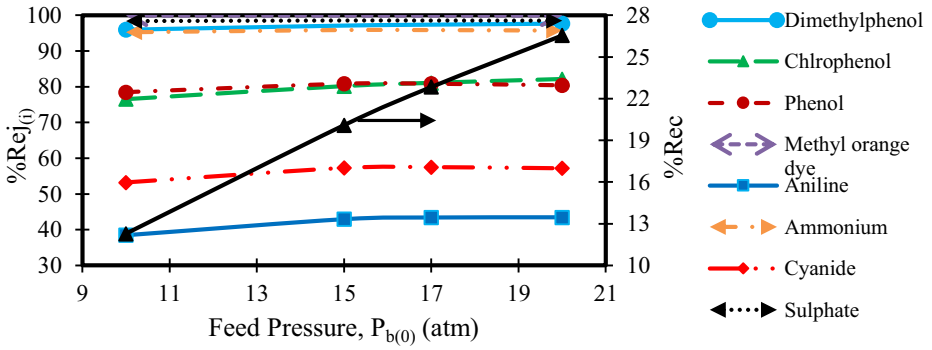

Fig. 5. Operating pressure verses rejection and recovery rate (operating conditions: 2.583E-4 m³/s, 30 °C, 350 ppm)

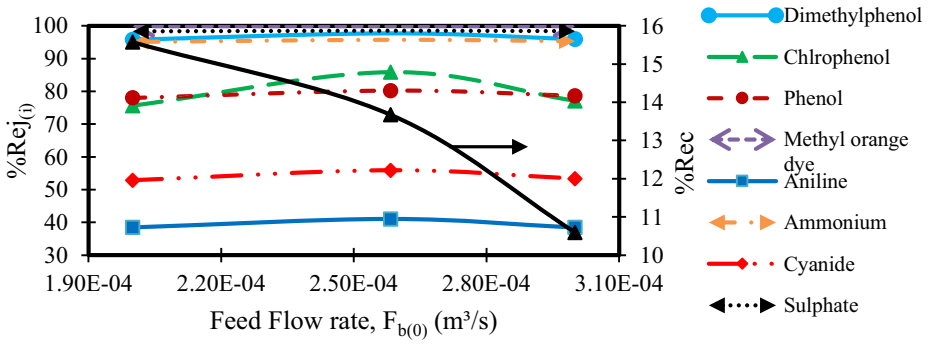

Fig. 6. Effect of operating feed flow rate on rejection and recovery rate (operating conditions: 10 atm, 30 °C, 350 ppm)

4. Process optimisation

The multi-objective function is presented below:

Max $P_{b(0)}$, $F_{b(0)}$, T_b	$Rej_{(i)}$, Rec
Subject to: Equality constraints - Process Model	f(x, u, v) = 0
Inequality constraints: Inlet pressure	$5\ atm \leq P_{b(0)} \leq 20\ atm$
Inlet feed flow rate	$1E-4\ \frac{m^3}{s} \leq F_{b(0)} \leq 1E-3\ \frac{m^3}{s}$
Operating temperature	$20\ °C \leq T_b \leq 40\ °C$

The optimal values of feed flow rate, pressure, and temperature are 7.4515E-4 m³/s, 20 atm and 40 °C respectively. The maximum permeate recovery is found to be 13.54%, while the maximum rejection of the compounds are: <Dimethylphenol, Chlorophenol, Phenol, Methyl orange dye, Aniline, Ammonium, Cyanide, Sulphate> = < 99.269, 94.922, 86.477, 99.923, 51.430, 97.253, 66.252, 99.045>. The optimisation approach leads to an increased rejection of all the selected components compared to what have been presented in Figs. 3- 6. However, the low value of permeate recovery is due to the impact of osmotic pressure of eight compounds.

5. Conclusions

A new one-dimensional model is developed for a spiral-wound RO process which is used to evaluate the impact of operating conditions on the rejection of several organic and non-organic compounds from wastewater and permeate recovery. The simulation results confirmed the importance of feed pressure and temperature to drive high performance of RO process. Finally, the multi-objective optimisation problem finds the maximum values of the rejection of all the compounds and permeate recovery.

Food and bioenergy: capturing the synergies and conflicts in the design of value chains through spatio-temporal multi-objective optimisation

Sheila Samsatli*

Department of Chemical Engineering, University of Bath, Claverton Down, Bath BA2 7AY, United Kingdom
*s.m.c.samsatli@bath.ac.uk

Abstract

An MILP model was developed for biomass value chains that can maximise synergies and minimise conflicts within the food-energy-water-environment nexus. The model accounts for the spatial dependencies of the system, at a 50 km level, with a long planning horizon from 2010 to 2050 with seasonal time steps. A scenario was presented in which the model was used to examine competition between food and energy for arable land in the UK. Results suggest that the demands for food can be met along with 10% of total energy demands from bioenergy but food production must move to different locations to make way for bioenergy.

Keywords: biomass value chains; food vs. energy; land use and resource allocation; spatio-temporal supply chain optimisation; GIS analysis.

1. Introduction

Biomass can be used to produce electricity, heat and transport fuels to help meet energy and emissions targets, diversify energy supply and create growth and jobs (Demirbas, 2009). Biomass and bioenergy are intricately linked with the food-energy-water-environment nexus. Biomass production and utilisation involves chains of activities, including growing the feedstocks, transporting them to processing facilities, converting them to various products and so on. Each of these activities can have profound environmental, economic and social impacts. Effective and careful management of all activities in biomass supply chains (Samsatli and Samsatli, 2018) is crucial to ensure that the production and utilisation of biomass are sustainable, do not contribute to global warming and maintain the balance between all of the elements in the nexus. Many biomass supply chain optimisation models have been developed over the last decade (see reviews of De Meyer et al. (2014), Mafakheri and Nasiri (2014), Yue et al. (2014) and Mitchell (2000)). However, nearly all of these models did not account for the interaction of the biomass supply chains with the nexus. The aim of this work is to develop a spatio-temporal (Samsatli and Samsatli, 2015) mixed integer linear programming (MILP) model that can determine the important decisions concerning the design and operation of biomass value chains and identify sustainable chains that are synergistic with the nexus.

2. Problem statement

Many different types of biomass can be grown and converted to many different products. There are many decisions that need to be determined simultaneously, such as: what biomass types to grow, where and when to grow them; what energy services/products to generate (e.g. heat, biofuels, electricity, chemicals); what processing technologies to use, where to locate them, when to invest in them; centralised or distributed processing; whether or not to densify/pre-process biomass before transportation; how to transport

biomass and distribute products to customers; and how to manage inventory (as the production of most types of biomass is seasonal and not available all year round).

3. Mathematical model

The model considers a planning horizon from 2010 to 2050, with 10-year time steps, $d \in \mathbb{D}$, in order to model the investment in and retirement of technologies and land use changes, as well as seasonal time steps, $t \in \mathbb{T}$, in order to capture the seasonal production and storage of biomass. For the spatial representation, the UK is divided into 50 km × 50 km square cells, with each cell, $i \in \mathbb{I}$, characterised by: the area of each type of land cover available for growing crops, existing technologies, transport distances between each pair of cells and existing transport infrastructures. The total land area is divided into three categories, $c \in \mathbb{C}$, according to the existing land use: arable, grassland and forest (CEH, 2015). In Figure 1, the black circles are the total area of the three categories while the grey circles are the area of each individual category. These categories correspond closely to the different types of biomass that can be grown, e.g. wheat and other arable crops, energy crops such as Miscanthus and forestry. The yields for the different crops will depend on the category of land on which they are grown. These categories are also used to restrict crops to certain land categories, e.g. disallowing production of arable or energy crops on existing forest. Further, these land categories are required in order to track land use change and its associated emissions over the decades. The use of land can be limited according to various constraints, such as suitability for cultivation and harvesting, as well as social and environmental constraints. Specifically, constraints can be applied to exclude the following land areas in an optimisation run: elevation > 250 m; slope > 15 %; topsoil organic carbon > 30%; urban areas, roads and rivers; parks, scheduled monuments and world heritage sites; designated areas and cultural heritage areas; natural and semi-natural habitats; areas of outstanding natural beauty; and woodlands. Figure 1 shows how much area is available without any constraints and with all of the constraints applied.

3.1. Objective function

The objective function, to be minimised is given by Eq. (1).

$$Z = \sum_{d \in \mathbb{D}} \sum_{m \in \mathbb{M}} \omega_m \left(I_{dm}^{\mathrm{BP}} + I_{dm}^{\mathrm{TI}} + I_{dm}^{\mathrm{TO}} + I_{dm}^{\mathrm{Q}} + I_{dm}^{\mathrm{RP}} + I_{dm}^{\mathrm{SI}} + I_{dm}^{\mathrm{SO}} + I_{dm}^{\mathrm{RD}} - I_{dm}^{\mathrm{R}} \right) \quad (1)$$

Each term in the parentheses represents an impact in decade d on metric m. These are: biomass production, technology investment, technology operation, transportation, resource purchase, storage invesment, storage operation, resource disposal and revenue from sales of resource. The set of metrics $\mathbb{M}$ comprises costs and GHG emissions, including CO_2 and other emissions such as NO_x, SO_x and PMs.

3.2. Constraints

The resource balance, given by Eq. (2), considers various source and sink terms for each resource, $r \in \mathbb{R}$, in each cell, $i \in \mathbb{I}$. These include production of biomass, production of a resource through a conversion technology, transportation of resource into and out of each cell, compulsory demand satisfaction, purchase/import of a resource, sale of any bi/co-products and disposal of any waste resources that cannot be sold. The resource balance also tracks the inventory of stored resource, accounting for any losses in storage. The biomass produced, in oven-dry tonnes per season, is given by Eq. (3), where A_{rcid} is the area allocated to production of biomass type $r \in \mathbb{R}^{\mathrm{B}}$ on land class c in cell i during decade d and Y_{rcidt} is its yield potential in season t. M_r in Eq. (2) is the moisture content of biomass type $r \in \mathbb{R}^{\mathrm{B}}$. If wheat is grown in order to use just the grain in further processes, then an amount of straw can also be collected. The factor ϕ_{cid} defines the mass

of straw that can be collected if 1 odt of wheat grain is harvested, assuming that only half of the straw left in the field can be recovered (Eqs. (4) and (5)).

If wheat is grown, other crops must be rotated with it to maintain soil quality (Eq.(6)). The crops that can be rotated with wheat are defined by the set $\mathbb{R}^{\mathrm{WR}}$; y_r^{WR} is the number of years that wheat can be grown for each year of the rotation crop.

The total area allocated to crops in each cell, i, on each land class, $c \in \mathbb{C}$, is restricted by the maximum available area, $A_{cid}^{\max}$ (Eq.(7)).

The rate of operation of a conversion technology, $p \in \mathbb{P}$, is restricted by the total installed capacity in any cell, i, and the fraction of the year that it is available (e.g. accounting for maintenance and other downtime), a_{pd} (Eq.(8)).

The capacity of installed technologies is determined by a set of investment constraints (Eq.(9–11)). C_{pid} is the total installed capacity of technology p in cell i in decade d. It is equal to the installed capacity in the previous decade (or the initial capacity, for the first decade) plus any newly installed capacity, CI_{pid}, minus the capacity that is retired, CR_{pid}. CI_{pid} is constrained by the minimum and maximum capacity of a new technology, $C_{pd}^{\min}$ and $C_{pd}^{\max}$, multiplied by the number of new technologies installed, NI_{pid}. The retired capacity is calculated from the invested capacity and a "retirement fraction", $\psi_{pdd'}$, which defines the fraction of capacity that retires in decade d of technologies that were invested in decade d'; it also includes the retirements of existing technologies, CR_{pid}^{0}.

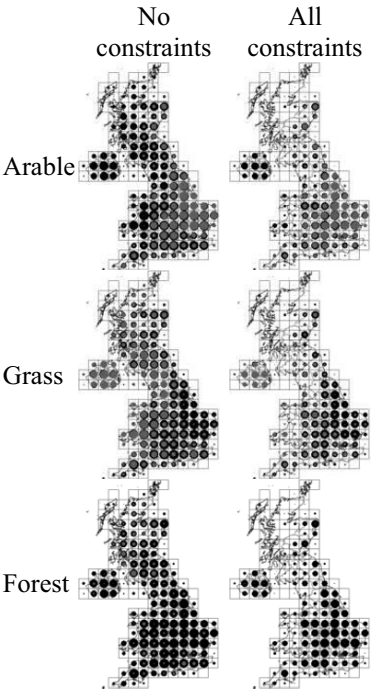

Figure 1. Available land area with and without constraints applied. Black circles: available area; grey circles: area of the land cover type.

$$C_{pd}^{\min} NI_{pid} \leq CI_{pid} \leq C_{pd}^{\max} NI_{pid} \qquad \forall p \in \mathbb{P}, i \in \mathbb{I}, d \in \mathbb{D} \tag{10}$$

$$CR_{pid} = CR_{pid}^{0} + \sum_{d'} CI_{pid'} \psi_{pdd'} \qquad \forall p \in \mathbb{P}, i \in \mathbb{I}, d \in \mathbb{D} \tag{11}$$

4. Case study

Scenario: bioenergy can satisfy up to 10% of the total UK energy demand, with a trajectory from 2010 to 2050 given in Figure 2 (Samsatli et al., 2015). Only arable crops are considered: wheat, oilseed rape and sugar beet, which are the major food crops produced in the UK. Wheat has to be rotated with either oilseed rape or sugar beet: 2 years of wheat for every year of rotation crop. In order to capture the competition for arable land between food and energy, the model will determine the allocation of arable land for production of crops for either food or bioenergy. All of the land constraints discussed in Section 3 are applied. Food, energy services (i.e. heat, electricity and transport fuels) and by-products can be sold at market price to maximise the net present value (NPV) of the overall system. Figure 3 presents the value web superstructure diagram for wheat, which shows the wide range of products that can be produced from this resource: different types of transport fuel, electricity and heat as well as various by-products (e.g. DDGS from ethanol and butanol production, which can be sold as animal feed). Similar value web diagrams exist for oilseed rape and sugar beet but are not shown due to limited space. The model will choose what crops to grow and what products and by-products to generate but all demands for food (equivalent to current production) must be met. The model will determine the best locations for food and energy production. The aim is to determine: the design and operation of the value chains to maximise the NPV; how much land area is required and where to plant the crops; how much of the energy service demands can be met; in what form the energy will be; etc.

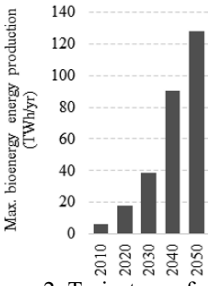

Figure 2. Trajectory of max bioenergy production (Samsatli et al., 2015).

5. Results and discussion

Figure 4 shows the wheat production from 2010 to 2050. Over the decades, additional wheat is grown for bioenergy and this has displaced some of the food production, which has moved to other locations. As the circles for bioenergy appear and grow over the decades, some of the circles for food disappear (e.g. in the central part of the country) while the other circles for food increase in size. In all decades, the same amount of wheat is produced for food but in different locations – this suggests that bioenergy will have local and regional impacts on food production. Bioenergy production starts in the eastern part of the country in 2020 and then in the later decades expands towards the northern and southern western parts of the UK and then grows westward. The spatial distribution of oilseed rape follows that of wheat as it is the main crop rotated with wheat. Large amounts of the oilseed rape are being used for energy, since its demands for food are much lower than those for wheat. There is also a small amount of sugar beet produced – mostly for food. Figure 5(a) shows the optimal biomass value chains in 2010. Oilseed rape is used for food as well as heat and electricity by converting it first to rapeseed oil, which is then used in internal combustion (IC) engine combined heat and power (CHP) plants. Additional value is obtained from the rapeseed meal (by-product from oil extraction), which is sold for animal feed.

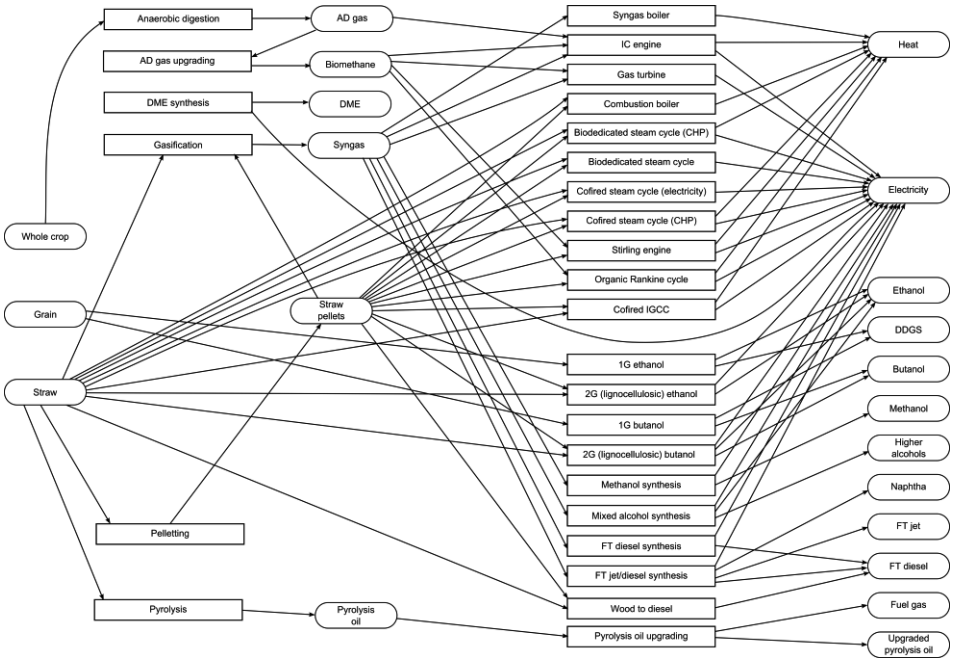

Figure 3. Value web network superstructure for wheat.

The map in Figure 6(a) shows the location of the oil extraction and the IC engine CHP plants. Both technologies are in the same location so only oil extraction can be seen on the map. The blue arrow represents the transport of the rapeseed oil. In this decade, all of the wheat grain produced is used to satisfy its food demands. Some of the straw from wheat production is sold as animal bedding and the remainder is used in CHPs for heat and electricity. In the 2050s, the limit on the amount of bioenergy that can be produced is much larger (see Figure 2) and the amount of wheat grain produced for bioenergy is almost the same as the amount grown for food (see Figure 4). Figure 5(b) presents the optimal value chains in 2050, where large amounts of wheat grain are used to produce butanol. The by-product DDGS is sold as animal feed. Figure 6(b) shows the location of the butanol plants: wheat is harvested in different locations and transported to the butanol plants. Wheat straw is used in a combination of biomass and syngas boilers to produce heat, the syngas being produced by the gasification of straw. Some straw is sold as animal bedding but because of the large amount of wheat grain produced in this decade, there is an excess of straw beyond its market demand that cannot be used for heat, the demands for which are also being met by the rapeseed oil. Sugar beet is only grown to meet its demand for food. The structure of the chain for oilseed rape did not change from 2010 but the amount of energy produced from this chain increased significantly. Overall, the optimal value chains result in an NPV of £96bn with a GHG emissions saving of 729 million tonnes over the 40 year planning horizon.

6. Conclusions

A multi-objective, spatio-temporal MILP model was developed to optimise the strategic design and tactical operation of biomass value chains. The model was used to examine food vs. energy scenarios in the UK and the results indicate that the UK has sufficient arable land to satisfy demands for main food crops (wheat, sugar beet and oilseed rape) and the target of meeting 10% of the energy demands through biomass. However, food

production is moved to other locations in order to give way for energy production, suggesting local and regional impacts of bioenergy on food production. By-products (wheat straw, DDGS, rapeseed meal, sugar beet pulp) can have a significant contribution to the profitability and emissions reduction of the whole value chain. Overall, exploiting the synergies between food and energy production can result in profitable value chains with negative GHG emissions.

Dewatering Screw Pressing: Model Development and Sensitivity Analysis for Process Understanding

Franco Mangone[a*], Adrián Ferrari[a], Soledad Gutiérrez[a]

[a]*Chemical and Process Systems Engineering Group – Chemical Engineering Institute - Engineering School – Universidad de la República, Julio Herrera y Reissig 565, PC 11300, Montevideo, Uruguay*

Abstract

Dewatering screw presses (DSP) are a type of dewatering unit for sludge, which operate by compressing the material and letting water permeate to the outside. This is desirable to reduce downstream transportation costs, since sludge is often an unwanted product and needs to be disposed of. No simple mathematical models for DSP were found in open literature, and so one is proposed and analyzed in this work. Sensitivity and identifiability analysis are carried out in order to select the best parameter set for future parameter estimation.

Keywords: Dewatering screw press, sensitivity, identifiability.

1. Introduction

Sludges often result from separation processes, and they broadly represent a problem for industries because of the need to handle them. This of course has a cost, whether if the sludge is transported to a final disposal site, or if it is subjected to any kind of further treatment. Due to its high moisture content (> 90%), removing water from sludge can be advantageous in order to reduce downstream transportation costs.

To accomplish this goal, several methods and equipment exist, for instance the centrifuge decanter, dewatering tubes, diverse filter-type units, etc. Dewatering screw presses (DSP) are one of the options available for dewatering, and consist of a drum to which sludge is fed, and that also allows water to squeeze to the outside. The material is transported and compressed by an internal screw conveyor, providing the necessary potential for dehydration. Process understanding and modelling will be the main focus of this work.

2. Sludge behavior

The sludge dewatering process is more complex than an ideal sedimentation and it involves the need of additional pressure in order to dewater the material further once a certain threshold concentration is reached, called the *gel point* (ϕ_g).

This phenomenon is described by Buscall and White (1987) in a theory called "Compressive Rheology", which explains that the two parameters that describe sludge dewatering are its resistance to compression, and the permeability to water of the material. Intuitively, the former should increase and the latter should decrease as the solids concentration (ϕ) rises, and the authors describe numerical values that account for both phenomena and should follow those trends, which are the compressive yield stress, $P_y(\phi)$, and the hindered settling factor, $r(\phi)$. Both will be incorporated in is contribution.

3. Model description

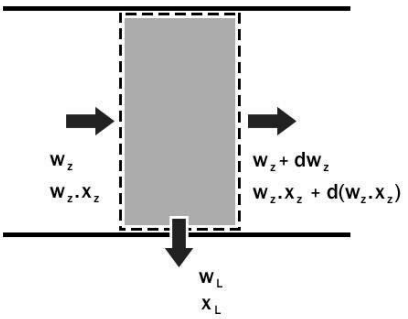

Figure 1. Selected control volume for mass balance

To start developing a mathematical description of the equipment, some assumptions need to be made. Initially, it is assumed that the composition of the sludge across a section of the unit will be uniform because of how the fluid is being pushed forward by the screw conveyor. This equates to saying that it resembles a plug flow behaviour, and in this sense Figure 1 shows the corresponding mass balance, where w_z is the total cake mass flow (kg/s), x_z is the mass solids fraction (dimensionless), and w_L and x_L represent the clarified liquid's total flow and solids content respectively.

3.1. Constitutive equation

With a plug flow structure assumed, the balances in a differential control volume can be analysed. The process is similar to a filtration, because of how water escapes through a semi-permeable drum wall that retains the solids inside of the unit, which is depicted in Figure 1. However, as a filtration-based model is not described in the original theory of Buscall and White (1987), a different approach is presented here by considering the work of Ruth et al. (1933) on filtration processes, who developed Equation (1):

$$\frac{dV}{A.dt} = \frac{\Delta P}{\mu.(R_m + R_c)} \tag{1}$$

Where dV/dt represents the permeate volumetric flow (m^3/s), A the filtration area (m^2), ΔP the differential pressure applied to the system (Pa), μ the water viscosity (Pa.s), and finally R_m and R_c being membrane (the equipment wall in this case) and cake resistance (m^{-1}) respectively. The original equation describes a non-steady state phenomenon and can be adapted to our model by substituting the dV/dt term with suitable process variables, namely w_L. At first sight, this equation does not incorporate the parameters described by Buscall and White (1987), but since the properties of the sludge are not dependent on the selected dewatering method, then the parameters in different models for cake formation should be related (De Kretser et al. 2003).

First, the pressure drop used in the filtration model can be represented by an applied pressure (P_T, the total pressure applied by the screw) minus the atmospheric pressure, since the permeate escapes to the outside of the drum. When the gel point is reached, extra pressure will be needed to continue dehydrating the formed cake, and, as a consequence, the original ΔP will be reduced by a certain amount. This is where it is possible to incorporate the P_y variable.

On the other hand, the parameter that accounts for permeability is clearly R_c, so it should be somehow related to the hindered settling factor. Matteson and Orr (1987) demonstrated that R_c can be defined as a function of a specific cake resistance α, in accordance with Equation (2):

$$\alpha(\phi) = \frac{R(\phi)}{(1-\phi).\mu} \tag{2}$$

Where $R(\phi)$ is the hindered settling factor multiplied by a set of constants, and ϕ is the volumetric solids fraction (dimensionless). At this point it might be helpful to clarify that ϕ and x_z which are both a function of z (position along the unit), are a measure of concentration and can be mutually related.

3.2. Parameters

All that remains is to define the functional expression of $P_y(\phi)$ and $R_c(\phi)$ in order to complete the constitutive equation for the model. Many authors have carried out studies to achieve this purpose, for instance Channel and Zukoski (1997) who state that P_y can be expressed as Equation (3):

$$P_y(\phi) = P_{y,0}.\left[\left(\frac{\phi}{\phi_g}\right)^n - 1\right] \tag{3}$$

Where $P_{y,0}$ is a pre-exponential factor which has the same units as P_y, expressed in Pa, and n is an exponential factor that accounts for the "microstructure" of the sludge. Note that ϕ_g is introduced as a fitting factor, since P_y should be zero for concentrations lower than or equal to the gel point.

For cake resistance, by finding a function that describes the hindered settling factor it is possible to propose a function for R_c by using Equation (2). Landman and White (1992) proposed and verified a functional description of $r(\phi)$, and when combined with (2) it is possible to obtain Equation (4):

$$R_c(\phi) = R_{c,0}.\frac{1}{\left(1-\frac{\phi}{\phi_{cp}}\right)^m} \tag{4}$$

Where $R_{c,0}$ is simply the set of constants that results from combining Equation (2) with the results found by Landman and White (1992), and ϕ_{cp} is a "random close-packing limit" that expresses a maximum possible concentration for the sludge, which has an empirical value of 0.64 (Berryman, 1983).

3.3. Mass balance

By performing a global and solids mass balance on the selected control volume, and adequately substituting the result of the former in the constitutive equation, the two model equations that allow for numerical simulation of the system can be obtained:

$$\frac{dw_z}{dz} = -\frac{\Delta P.\rho.\pi.D}{\mu.(R_m + R_c)} \tag{5}$$

$$\frac{dx_z}{dz} = \frac{dw_z}{dz} \cdot \frac{(x_L - x_z)}{w_z} \quad (6)$$

It is assume that x_L is this fraction of x_z, since no information was found regarding this variable. A value of 5% will be used, which is close to standard for this kind of equipment, and therefore we assign this percentage to a variable *C* so that $x_L = C.x_z$. The functional relationship between these two variables might be more complex, and that can be the focus of further model improvements if this proves to be influential.

4. Simulation, analysis, and discussion

All simulations were performed in the software Matlab R2010a, using the parameter values shown in Table 1.

The model should show an asymptotic behaviour for w_z and x_z. The cake flow rate should decrease until reaching a minimum value, which means no more dewatering occurs, and the opposite should happen for the solids fraction. Results are shown in Figure 2, supporting these conceptualizations.

4.1. Sensitivity analysis (SA)

Due to the lack of experimental data, sensitivity and identifiability analysis will be carried out in order to correctly select the parameter subsets for further estimation. Local (differential) sensitivity is defined as the derivative of a target output with respect to a model input or parameter. The values are then normalized in order to compare dimensionless sensitivities obtained for different outputs and from different inputs/parameters (Sin et al., 2010).

Table 1. Parameter values used for model simulation

Parameter	Value	Units
ϕ_g	0.07	-
m	5	-
n	5	-
C	0.05	-
P_T	9000	Pa
$P_{y,0}$	1000	Pa
R_m	$1.0x10^{11}$	m^{-1}
$R_{c,0}$	$1.0x10^{11}$	m^{-1}

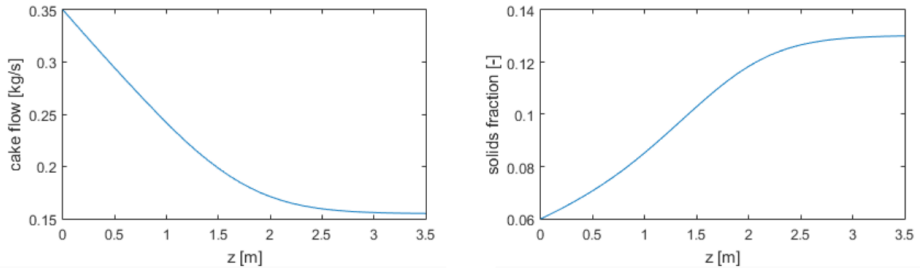

Figure 2. Cake flow (left) and solids fraction (right) simulation results for the developed model

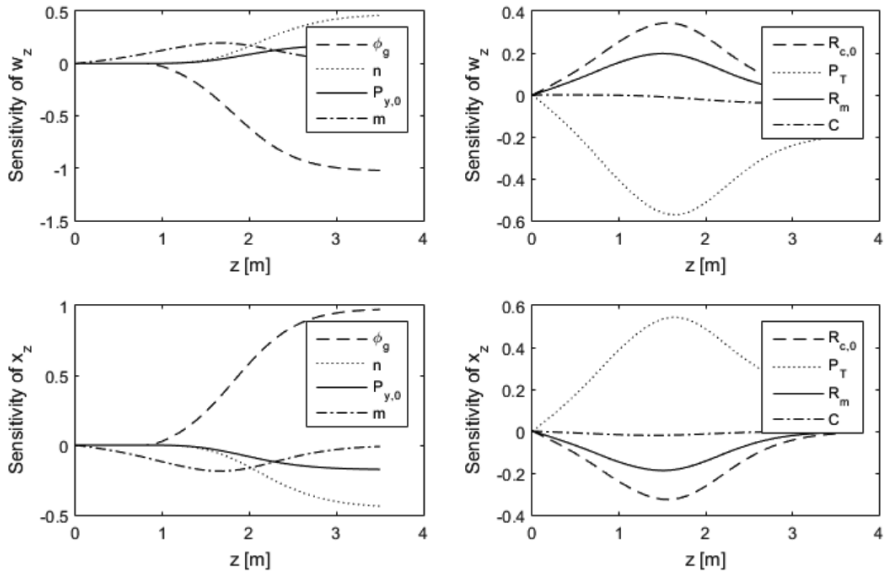

Figure 3. Dimensionless sensitivities to every parameter for each process output

In this case, the target outputs will be cake flow rate and solids content. To calculate the sensitivities, a positive and negative deviation of 0.1% around the nominal condition applied for all parameters (Sin et al., 2010). SA results are shown in Figure 3. Low sensitivity to C can be observed, meaning that this parameter will not be influential on the model. In addition, the results provide evidence about some degree of over-parameterization in the system, indicated by the similarity in some sensitivity trends, which represent correlation between parameters. These could represent difficulties in obtaining unique estimates for the parameters (Sin et al., 2010), hence identifiability analysis becomes necessary to identify an adequate subset for parameter estimation.

4.2. Identifiability analysis (IA)

This implementation was based in the collinearity index calculation in accordance to Sin et al., (2010) using the local SA results. Parameter subsets are analyzed and their linear correlation is evaluated through a measure called collinearity index (γ). A high value of γ means more correlation between the considered parameters. The analysis is used to find the largest size identifiable subset assuming a threshold γ value for the identifiability. Table 2 summarizes the obtained results for IA.

Results indicate that a maximum of two parameters are identifiable assuming a threshold of 5 for the collinearity index. In order to select an adequate subset for further analysis, the one with the lowest index can be chosen. The ranking of identifiable subsets is resumed in Table 2. The minimum collinearity index corresponds to the subset (n, R_m), meaning that after parameter estimation a minimal correlation between them would be expected, obtaining the best possible unique estimators. Nevertheless, it is important to consider the physical meaning of the parameters. Only two of them are DSP specific, P_T and R_m, while the rest can be proven to be material properties related (De Kretser et al., 2003). This means that they can also be determined via other experiments on the sludge itself, and not using data from DSP operation since they are

not strictly process related. Consequently, (P_T, R_m) could be selected for parameter estimation since it is also an identifiable subset.

Table 2. List of largest size identifiable subsets of model parameters

Parameter subset	Collinearity index	Parameter subset	Collinearity index
(ϕ_g, m)	1.0432	($P_{y,0}$, m)	0.9627
(ϕ_g, $R_{c,0}$)	0.9819	($P_{y,0}$, $R_{c,0}$)	0.9142
(ϕ_g, P_T)	1.2591	($P_{y,0}$, P_T)	1.1444
(ϕ_g, R_m)	0.9527	($P_{y,0}$, R_m)	0.8909
(n, m)	0.9155	(m, P_T)	4.7968
(n, $R_{c,0}$)	0.8754	($R_{c,0}$, P_T)	3.9556
(n, P_T)	1.0802	(P_T, R_m)	3.4781
(n, R_m)	**0.8560**		

5. Conclusion

A mathematical model for DSP, including the sludge behavior, was developed and implemented in Matlab. It was shown that the model follows the expected tendencies. SA results indicate the presence of some degree of over-parameterization, and thus suggest a potential for model reduction, which can be a future challenge. IA results indicated that a maximum of two parameters are identifiable. DSP specific parameters, such as P_T and R_m, can be selected to be obtained by parameter estimation from process data, while the sludge properties could be determined via other non-process related experiments. Important factors such as cake thickness variation throughout the length of the tube and dynamic conditions are not considered in this study and should be the focus of further work in order to develop a model that more accurately describes the process.

Abstract

The land use allocation problem is an important issue for a sustainable development. Land use optimization can have a profound influence on the provisions of interconnected elements that strongly rely on the same land resources, such as food, energy, and water. However, a major challenge in land use optimization arises from the multiple stakeholders and their differing, and often conflicting, objectives. Industries, agricultural producers and developers are mainly concerned with profits and costs, while government agents are concerned with a host of economic, environmental and sustainability factors. In this work, we developed a hierarchical FEW-N approach to tackle the problem of land use optimization and facilitate decision making to decrease the competition for resources and significantly contribute to the sustainable development of the land. We formulate the problem as a Stackelberg duopoly game, a sequential game with two players – a leader and a follower (Stackelberg, 2011). The government agents are treated as the leader (with the objective to minimize the competition between the FEW-N), and the agricultural producers and land developers as the followers (with the objective to maximize their profit). This formulation results into a bi-level mixed-integer programming problem that is solved using a novel bi-level optimization algorithm through ARGONAUT. ARGONAUT is a hybrid optimization framework which is tailored to solve high- dimensional constrained grey-box optimization problems via connecting surrogate model identification and deterministic global optimization. Results show that our data-driven approach allows us to provide feasible solutions to complex bi-level problems, which are essentially very difficult to solve deterministically.

Keywords: Food-Energy-Water Nexus, Bi-level Optimization, Land Use Optimization, Data-Driven Optimization

1. Introduction

A combination of rapid population growth, urbanisation, and economic development has spurred an overwhelming increase in world demands for food, energy, and water. With the availability of those goods being constantly decreasing, it is essential, now more than ever, to tackle effectively this issue.

This phenomenon can be linked to an economic theory called "The tragedy of the commons" (Lloyd, 1833), that refers to a situation within a shared resource system where individual users acting independently according to their own self-interest behave contrary to the common good of all users by depleting or spoiling that resource through their collective action (Hardin, 1968). Water, energy and food can be regarded as common resources, that can be overused and under-maintained. To add to the complexity, water, energy and food are interconnected resources forming what we referred to as Food-Energy-Water Nexus. For example, to produce food we need energy in the form of fertilizers or electricity, and water for irrigation. To produce clean water, we need energy for cleaning, and to produce energy we need water for cooling, and food if we were to use biofuels.

Even though we know that a holistic approach is required to tackle the problem of FEW increasing demand, the objectives of individual companies or organizations are usually based on short term profit.

To tackle this issue, Ostrom, E., 1990 discussed that enabling governments at multiple scales to interact with community organizations so that we have a complex nested system can give solutions to 'the tragedy of commons' problem. In other words, governments can shape strategies that lead organizations into actions that would avoid or limit stresses on the FEW Nexus. This can be done through rules and regulations, or subsidies that drive the objective and actions of the individual organizations towards the common good. This leads to a hierarchical system, with the government deciding (at the highest decision level) the rules, regulations and subsidies to motivate organizations towards deciding on their actions (at a lower decision level) to achieve the government's objective, i.e. best sustainable long-term FEW-N solution.

In this work, we attempt to model and solve hierarchical systems as the one described above. We are focusing on the case of land use allocation which is an important issue for sustainable development and its optimization can have a profound influence on the provisions of interconnected elements that strongly rely on the same land resources, such as food, energy, and water. In Section 2 the Land Use allocation case study is explained and the hierarchical model is developed and presented. In Section 3 a novel data-driven algorithm for the solution of the complex hierarchical problem is presented, while the solution for land use problem is presented in Section 4. Section 5 concludes this paper.

2. Land Use Allocation Problem

The chosen case study is a land use allocation problem that involves a fictional piece of land owned by an organization. The organization will invest in this land, and may choose different types of developments, which can involve a mixture of both agricultural and energy production land processes, consisting of solar energy, wind energy, fruit production, vegetable production, and livestock grazing. The interest of the land developer is to maximize its profit, while the interest of the government that rules this piece of land is to minimize the stresses on the FEW-N. This leads to a hierarchical optimization problem.

We are formulating this problem as a Stackelberg duopoly game (Stackelberg, 2011), a sequential game with two players – a leader and a follower. The government agents are

treated as the leader, and the land developer as the follower. The formulation of this problem as a bi-level problem is presented in Eq. (1).

$$\begin{aligned} &\min \ \ FEW\ Nexus\ Stress \\ &s.t. \ \ Goverment\ Budget \\ &\quad \max \ \ Developer's\ Profit \\ &\quad s.t. \ \ Land\ Properties\ , Developers\ Budget, Land\ Process\ Models \end{aligned} \tag{1}$$

2.1. Government's Optimization Problem – Leader's Problem

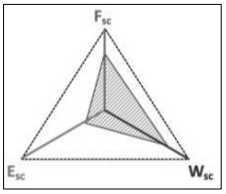

Figure 1 FEW metric

As mentioned before the government's move is only constrained by its budget. The objective of the government is to limit the stresses between food energy and water. While the importance of the FEW-N has been widely accepted, a quantitative index assessing the integrated FEW-N performance is rather lacking (Garcia et al. 2016). In this work, we have defined a FEW-N metric that aggregates FEW elements into a single 'geometric' metric, that can be used by the government as an objective.

The metric system involves scaling the quantitative value for each FEW element, to values between 0 and 1. A value of 0 indicates the worst possible scenario for a given element while a value of 1 implies the converse. The bounds on each element were determined by minimizing and maximizing the Land use allocation problem with each element as an objective. The three scaled elements are then used to create the geometric shape illustrated in Fig. 1. The area of the triangle formed corresponds to the FEW metric, the bigger the area the better the FEW Nexus solution.

$$\begin{aligned} FEW_{metric} = \Bigg[&\frac{Etotal - Emin}{Emax - Emin} \times \left(1 - \frac{Wtotal - Wmin}{Wmax - Wmin}\right) + \frac{Etotal - Emin}{Emax - Emin} \\ &\times \frac{Ftotal - Fmin}{Fmax - Fmin} + \left(1 - \frac{Wtotal - Wmin}{Wmax - Wmin}\right) \times \frac{Ftotal - Fmin}{Fmax - Fmin} \Bigg] \frac{\sin 120}{2} \end{aligned} \tag{2}$$

where Etotal, Ftotal are the total energy and food produced by the system correspondingly and Wtotal is the total water consumed by the system. Emin and Fmin are the minimum amount of energy and food that can be produced, and Wmin is the minimum amount of water that can be consumed. The same follows for Emax, Fmax, and Wmin.

For this case study, the government is using subsidies for each FEW sector. Therefore, the optimization problem of the government is as follows:

$$\begin{aligned} &\max_{sub} \ \ FEW_{metric} \\ &s.t. \quad sub_X \leq bg \quad \forall x = E, F, W \end{aligned} \tag{3}$$

where $sub_F, sub_E,$ and sub_W are the amount of dollars the government is subsidizing food, energy and water respectively.

2.2. Land Developer's Optimization Problem – Follower's Problem

As mentioned before the objective of the land developer is to maximize its profit. To achieve this, the land developer must take into account the characteristics of i) each land process, ii) the land itself, and iii) the subsidies given by the government. The specific case study for this work, assumes a fairly small piece of land in a climate similar to that of Texas, split into 8 evenly sized square plots, each with different properties. These properties, shown below in Table 1, define the limitations on which land processes can occur on each plot, and thus portray the specific situation of the assumed land developer.

Also, seasonal differences in climate can greatly impact the characteristics of the land as a whole, and change the appeal of various processes. These seasonal differences contribute to changes in a) energy profit based on consumers' demands, b) cost of transporting water due to availability, c) efficiency of the different systems in different weathers, and d) minimum water requirements for crops (due to rainfall), which are all modeled in the process. Therefore, the model includes parameters for each season that reflect the variations in energy and crop production efficiency, demand for energy, water cost, and water availability during different periods of the year.

For agricultural processes, the amount of water and energy used for the agricultural processes determines their yield (Table 2). The amount of Energy produced by solar and wind are only varied by land properties and seasonal changes. When both land properties and seasonal changes are at their optimal the amount of energy produced by one land piece is 50kW and the amount of energy produced by wind turbines is 1000kW.The profit gained from agricultural processes is proportional to the yield, whereas the profit from the energy processes is proportional to the kW produced.

The model also allows wind energy and agricultural processes to be developed on the same piece of land.

The model was developed in GAMS and it consisted of 1,723 equations, 216 integer variables and 1,107 continuous variables. The detailed model can be provided upon request as it was excluded from the document due to page restrictions.

Table 1 Land Properties

	Land Section Number							
	1	2	3	4	5	6	7	8
Good soil	√	√	√	√	×	×	√	√
Adequate sun	×	×	√	√	√	√	√	√
Adequate wind	√	√	√	√	√	√	×	×
Water available	×	×	×	×	√	√	×	√

Table 2 Yield of agricultural processes

Agricultural land use type	Yield (tonnes)
Fruits	$10E + 10^{-4}W$
Vegetables	$10E + 15^{-4}W$
Livestock	$E + 40^{-4}W$

3. Solution Method: ARGONAUT

A novel data-driven solution algorithm was developed for the solution of the large scale bi-level mixed-integer programming problem. The main idea behind the algorithm is to approximate the bi-level problem into a single level problem by collecting data from the optimality of the lower level problem. The main steps of the proposed algorithm are illustrated in Fig. 2.

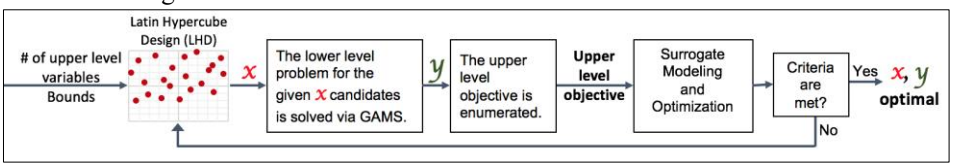

Figure 2 Illustration of the main steps of the Data-Driven Bi-level algorithm

3.1. Data-Driven Solution Method

The proposed algorithm is tested with different constrained data-driven optimization strategies, and AlgoRithms for Global Optimization of coNstrAined grey-box compUTational problems (ARGONAUT) (Boukouvala et al., Boukouvala and Floudas, 2017) was chosen for the solution of the hierarchical FEW Nexus problem. The selection of solver was based on its ability to perform constrained optimization on black/grey-box problems with a global optimization strategy. The ARGONAUT algorithm performs global optimization on general constrained grey-box problems by providing accurate surrogate formulations to each unknown equation while incorporating adaptive parallel sampling, bounds tightening and variable selection within the algorithm for improved accuracy in obtaining the global solution.

3.2. Benchmarking

This algorithm was tested by solving the challenging set of bi-level test problems from Mitsos et al. 2017. The developed algorithm was able to converge to the global solution for 72% of the test problems, and was able to find feasible local solution for the rest of problems.

4. Results and Discussion

Using ARGONAUT as the data-driven solution method the results in Table 3 were attained. It is observed that different government strategies are able to give the same upper level objective with the same land development solution (Fig. 3). One can choose the strategy that poses the lowest expenditure for the government, i.e. Run 10. It is worth noting that without any governmental subsidies the FEW metric would have been 20.4% less than the optimal calculated with the subsidies, and with solar energy being developed in sections 7 and 8 instead of fruit production.

5. Conclusions

It is evident that the developed model and approach constitutes a greatly effective means of optimizing land use through a Food-Energy-Water Nexus approach. The flexibility, robustness and scalability of the model facilitates its application to a real-life case study, with the various parameters and variables being redefined to fit the desired situation, and the solutions made to fit a client's demands. This strong adaptability to real world situations can thus help create more sustainable methods of agriculture and energy production in a world where demands for resources are constantly increasing, whether this be on a local, regional or national scale.

Abstract

Water and energy are two of the most pressing problems faced by the world today. Osmotic membrane processes such as Reverse Osmosis (RO) and Pressure Retarded Osmosis (PRO) can help alleviate both of these challenges. This work focuses on systematic optimization of a two-stage RO-PRO process for energy-efficient seawater desalination which integrates RO for desalination and PRO for power generation into a single process. RO-PRO is of great significance at the water-energy nexus given that water production, pump energy consumption, and hydraulic/osmotic energy recovery are essentially intertwined. The optimization problem is formulated to minimize the Specific Energy Consumption (SEC) subject to specified total membrane area and total water recovery. By solving the optimization model, the best design (e.g., allocation of membrane area among different units) and operating conditions (e.g. applied pressure in each membrane unit) are simultaneously determined. It is shown that the proposed two-stage RO-PRO is energy-efficient than single- and two-stage ROs as well as one-stage RO-PRO.

Keywords: Optimization, Water-Energy Nexus, Reverse Osmosis, Pressure Retarded Osmosis

1. Introduction

Energy and water are the top two grand challenges faced by the world (Smalley, 2003). The most modern industrial water desalination technology employs reverse osmosis (RO), which consumes roughly 0.5 kWh/m^3 and 3.5 kWh/m^3 electricity for groundwater and seawater sources, respectively. In seawater RO (SWRO), pump energy consumption accounts for a major portion of the total cost, which motivates research and development in energy-efficient RO (Zhu et al., 2009). For example, employing energy recovery devices (ERDs) has drastically reduced the pump energy consumption by recovering hydraulic potential energy in the RO brine (Stover, 2007).

Recently, Pressure Retarded Osmosis (PRO) has emerged as an osmotically driven membrane process that can generate power from a salinity gradient (Achilli, et al. 2009). The RO brine, due to its high osmotic pressure, is naturally suitable for this application if low-salinity impaired water is also available. The PRO and SWRO can be integrated into a RO-PRO process in which the power produced in the PRO may partially subsidize the power required by the SWRO. The research efforts are particularly encouraged by recent development of high-performance membranes with desired structural, mechanical, and permeative properties suitable for PRO applications (Han et al., 2017).

A RO-PRO membrane process is an interesting problem at the energy-water nexus (Gabriel et al. 2016, Garcia et al. 2016, Li et al. 2018). In the RO-PRO, water production, pump energy consumption, and hydraulic/osmotic energy recovery are essentially intertwined. Process systems engineering plays a very important role in the system-level understanding and optimization of such a process, which may guide experimental investigations undertaken by many research groups across the world.

2. Optimization Model

The schematics of two membrane process - RO for water desalination and PRO for power generation, are shown in Figure 1. The feed water in PRO is usually from low-salinity impaired wastewater resources and the draw solution could be seawater or brine from a SWRO process.

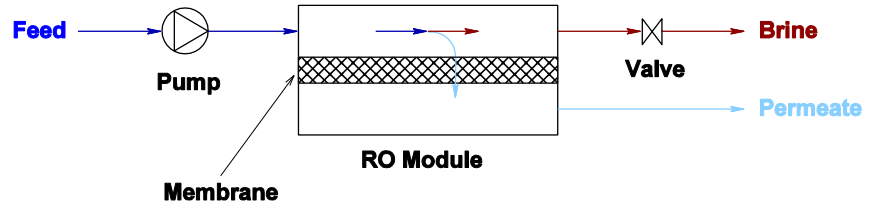

Fig. 1 Schematics of (a) RO for seawater desalination and (b) PRO for power generation.

A detailed description of transport phenomena in commercial spiral wound membrane units may require Computational Fluid Dynamic simulations (Li et al., 2016). If ignoring the effects of pressure drop and concentration polarization, both membrane processes shown in Fig. 1 can be described by the model shown below (Li, 2010; Li, 2015):

$$dQ = dA \cdot L_p \cdot (Q_0\pi_0/Q - P) \quad (1)$$

where Q, π and P are the flow rate, osmotic pressure, and hydraulic pressure of the solution with the higher salinity. A and L_p are membrane area and hydraulic permeability, respectively. Subscript 0 represents membrane inlet. An analytical solution to Eq. (1) can be derived as follows (Li, 2010; Li, 2015):

$$\gamma = \alpha\left[(1-q) + \alpha \ln \frac{\alpha - 1}{\alpha - q}\right] \quad (2)$$

where $\alpha = \pi_0/P$, $q = Q_1/Q_0$, and $\gamma = AL_p\pi_0/Q_0$. Subscript 1 represents membrane outlet. Eq. (2) clearly reveals the nonlinear coupling amongst the design parameter γ, the operating parameter α, and the performance parameter q. In RO, the fractional recovery Y = 1-q. Both α and q are less than 1 in RO and greater than 1 in PRO.

Concentration polarization is an important phenomenon that reduces water flux across the membrane. External concentration polarization may be supressed by optimizing flow conditions and spacer designs. However, internal concentration polarization, which occurs only in the PRO but not in the RO, cannot be easily mitigated. To account for this detrimental effect, an efficiency factor η_{PRO} is introduced so that the actual volume gain ratio in PRO *q-1* is only a fraction of the value predicted by Eq. (2).

In the RO community, Specific Energy Consumption (SEC) is a very important term describing pump power consumption per unit flow of the permeate product. If normalized by the feed osmotic pressure, it becomes a dimensionless quantity, or NSEC. Similarly, NSEP denotes the power produced by the PRO per unit flow rate normalized by the draw solution osmotic pressure. The author's group have demonstrated that employing multi-stage designs and increasing the total dimensionless membrane area γ_{total} ($\gamma_{total} = A_{total}L_p\pi_0/Q_0$) reduce NSEC in RO and enhance NSEP in PRO, as shown in Fig. 2.

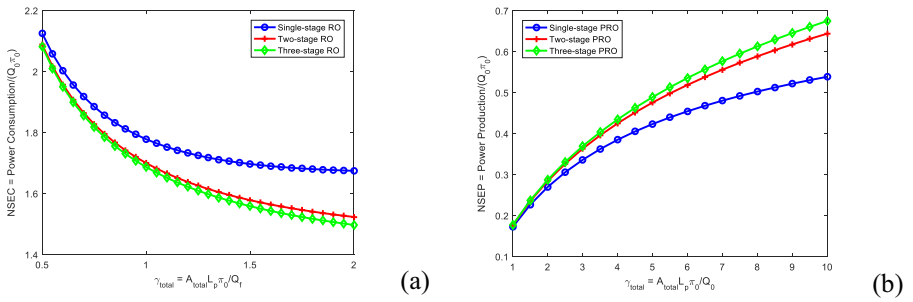

Fig. 2 Effects of total dimensionless membrane area γ_{total} and number of stages on (a) NSEC in RO at 40% recovery (Li, 2011) and (b) NSEP in PRO (Li, 2018).

Motivated by this, a two-stage RO-PRO process is proposed in this work for potential energy-efficient seawater desalination. As shown in Fig. 3, seawater is pressurized by several ERDs in addition to a feed pump before entering the first stage of RO. The concentrate from the first stage of the RO is pressurized further via a booster pump and sent to the second stage for additional water recovery. The osmotic and hydraulic energies in the RO brine are then recovered by the PRO and ERD systems downstream. The first two ERDs are necessary in order for the hydraulic osmotic pressure ratio at the inlet of each PRO to reach its optimal value which is unknown priori (Li, 2015; Li, 2017).

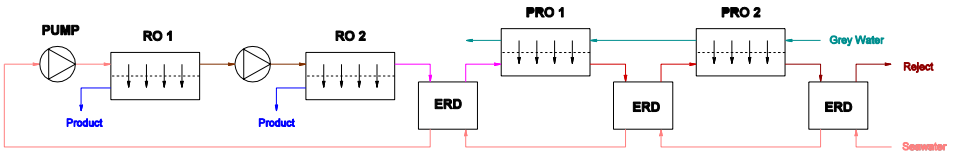

Fig. 3 Schematic of a hybrid two-stage RO-PRO process for energy-efficient seawater desalination.

The RO is a mature technology while the PRO is still under development. In this work it is assumed that both RO and PRO membranes have comparable permeative properties and costs per area. The optimization model is formulated to minimize the NSEC by simultaneously adjusting design parameters γ_j and operating parameters α_j while maintaining the total water recovery Y_{total} and total dimensionless area γ_{total}:

$$
\begin{aligned}
\min_{\alpha_j,\gamma_j,q_j} \eta_{pump} NSEC &= \frac{\frac{Y_1}{\alpha_1} + \frac{1-\eta_{ERD}(1-Y_2)}{\alpha_2} - \frac{\eta_{ERD}(q_3-1)}{\alpha_3} - \frac{\eta_{ERD}(q_4-1)}{\alpha_4}}{Y_{total}} \\
s.t. & \\
0 &= \gamma_j - \alpha_j \left[Y_j + \alpha_j \ln \frac{1-\alpha_j}{1-Y_j-\alpha_j} \right], j = 1,2 \\
0 &= \gamma_j - \alpha_j \left[1 - q_j^{ideal} + \alpha_j \ln \frac{\alpha_j - 1}{\alpha_j - q_j^{ideal}} \right], j = 3,4 \\
0 &= (q_j - 1) - \eta_{PRO}(q_j^{ideal} - 1), j = 3,4 \\
0 &= \gamma_{total} - \left[\gamma_1 + \gamma_2(1-Y_1)^2 + \gamma_3(1-Y_1)^2(1-Y_2)^2 + \gamma_4(1-Y_1)^2(1-Y_2)^2 q_3^2 \right] \\
0 &= 1 - (1-Y_1)(1-Y_2) - Y_{total} \\
0 &\leq \gamma_j, j = 1,\ldots,4 \\
0 &\leq \alpha_j, j = 1,2 \\
0 &\leq 1 - \alpha_j, j = 1,2 \\
0 &\leq \alpha_j - 1, j = 3,4 \\
0 &\leq \alpha_1 - \alpha_2(1-Y_1) \\
0 &\leq \alpha_4 q_3 - \alpha_3 \\
0 &\leq Y_j, j = 1,2 \\
0 &\leq 1 - Y_j, j = 1,2 \\
0 &\leq q_j - 1, j = 3,4
\end{aligned}
\tag{4}
$$

where η_{pump} is the pump efficiency, η_{ERD} is the ERD efficiency, subscripts 1, 2 represent RO stages, and 3,4 PRO stages. The optimization model is solved using constrained nonlinear optimization function `fmincon` in Matlab.

3. Results and Discussion

The optimization is carried out at different values of dimensionless membrane area γ_{total} (0.4-2), overall water recovery (30% and 50%) and PRO efficiency (70% and 100%). The optimization results of two-stage RO-PRO (RO2PRO2) are compared with those in one-stage RO (RO1), two-stage RO (RO2) as well as one-stage RO-PRO.

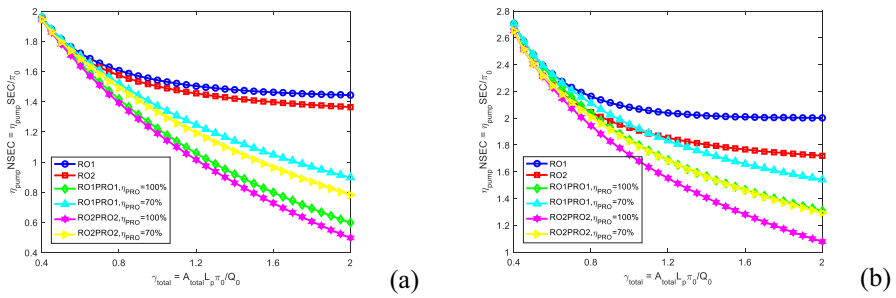

Fig. 4 Optimal NSEC in different membrane configurations under different η_{PRO} (70% and 100%) and different water recoveries Y_{total} (a) 30% and (b) 50%.

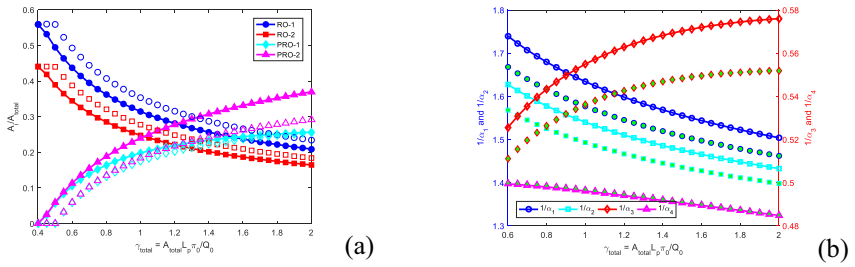
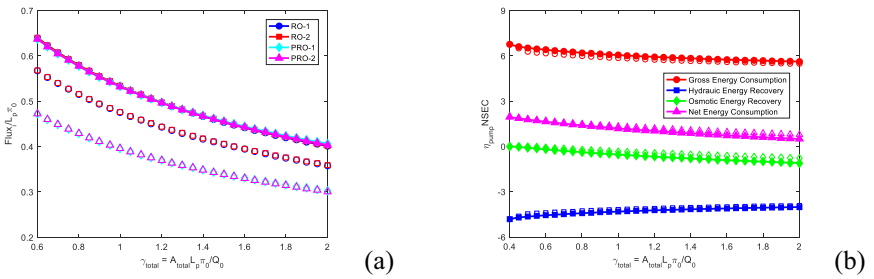
It is seen from Fig. 4 that the two-stage RO-PRO is the most energy-efficient configuration at fixed values of Y_{total} and γ_{total}. Moreover, the RO-PRO configurations keep the downhill trend of NSEC as γ_{total} increases. This implies that additional investment in membrane area and/or advances in membrane technologies may lead to a substantial reduction in SEC. It is worth noting that a representative value for γ_{total} in industrial SWRO plants is about 0.8 (Li, 2013). Mitigating the detrimental effects in PRO is very beneficial in the RO-PRO configurations, especially when water recovery is low.

Optimal allocation of membrane area and dimensionless applied pressure among all four membrane units are shown in Fig. 5. If γ_{total} is small, the PRO units are eliminated by the optimization model, and the two-stage RO-PRO collapses to a two-stage RO. When γ_{total} gets larger, the fraction of membrane area in the PRO units for energy recovery increases while that in the RO units for water recovery reduces. This is because $1/\alpha_1$ and $1/\alpha_2$ approach values closer to 1, or the RO moves towards its thermodynamic limit, and its energy efficiency approaches a plateau (as shown by the red and blue curves in Fig. 4). Therefore, the benefit of energy saving in RO resulting from additional membrane area is not as much as that of energy recovery in PRO from the same additional membrane area. Fig. 5 also implies that if the detrimental effects in PRO are small, membrane area allocation shifts from RO to PRO. Moreover, it allows a larger hydraulic pressure ($1/\alpha_3$) to be applied in the first PRO stage, enhancing osmotic energy recovery (Li, 2017).



(a) (b)

Fig. 5 Optimal (a) membrane area and (a) pressure among all membrane units in two-stage RO-PRO under different η_{PRO} (100%, solid symbols and 70%, hollow symbols) at 30% water recovery.



(a) (b)

Fig. 6 Optimal (a) dimensionless flux and (b) dimensionless energy consumption (positive) and recovery (negative) in two-stage RO-PRO under different η_{PRO} (100%, solid symbols and 70%, hollow symbols) at 30% water recovery.

The optimal flux in each membrane unit at a 30% water recovery is shown in Fig. 6(a). If the detrimental effects in PRO can be completely eliminated, it appears that all membrane units should have about the same flux to minimize the SEC. The presence of detrimental effects in PRO leads to a reduction of water flux in not only PRO, but RO as well.

The objective function $\eta_{pump}NSEC$ in Eq. (4) is in fact the sum of several terms including the gross energy consumption (or $(Y_1/\alpha_1 + 1/\alpha_2)/Y_{total}$), hydraulic energy recovery, (or $-\eta_{ERD}(1 - Y_2)/\alpha_2/Y_{total}$), and osmotic energy recovery (or $-\eta_{ERD}[(q_3 - 1)/\alpha_3 + (q_4 - 1)/\alpha_4]/Y_{total}$). The relative magnitude of these terms and their sum are shown in Fig. 6(b). It appears that the osmotic energy recovery by PRO is by no means close to the hydraulic energy recovery if γ_{total} is no greater than 2. Because of competition between the ROs and the PROs, the osmotic energy recovery can only be partially done. Considering the presence of detrimental effects in PRO, its value may be even smaller.

4. Conclusion

RO-PRO designs continue the downhill trend in the NSEC vs γ curve, so that advances in membrane technology, and/or additional investment in membrane, will bring about a further substantial reduction in SEC in SWRO. Two-stage RO-PRO offers more savings than single-stage RO-PRO, especially at higher recoveries. However, the osmotic energy recovery is much lower than the hydraulic energy recovery in RO-PRO processes if $\gamma \leq 2$. Therefore, even if the RO-PRO technology is commercialized, the SWRO industry may still not observe an energy saving on the same magnitude of the one brought about ERDs, unless a breakthrough in membrane technology allows a large γ in plant design.

Energy Network Optimization in an Oil Refinery

Elif Mete[a], Metin Turkay[b*]

[a]*TUPRAS R&D Center, Turkish Petroleum Refineries, Korfez, Kocaeli, 41780 Turkey*
[b]*Koc University, Rumelifeneri Yolu, Sariyer, Istanbul, 34450 Turkey*
mturkay@ku.edu.tr

Abstract

Management of energy is a critical factor in refinery operations, having a significant impact on the production costs. The effective management of the energy system in the refinery can improve the economic performance significantly. The energy demand in refineries changes continuously in the presence of changing crude oil properties, operation conditions of process units, and cost of fuels. We present a decision support system to manage the complex energy network of the refinery by determining the optimum operational combinations of the equipment for minimizing the energy costs. In addition to operational optimization of the energy network, we also examine the impact of policy decisions through scenario analysis. We show that around 3.5 % cost reduction is possible without capital investment.

Keywords: energy network optimization, utility systems, mixed-integer programming

1. Introduction

The production of refined petroleum products is highly energy intensive. Although refinery processes involve both energy generating and consuming operations, extra energy is required to keep operational stability. Most of the refineries operate its own utility system to satisfy the energy demand. Refinery energy production expenses comprise a significant portion of the refinery budget. Effective energy management is essential to improve the effectiveness while minimizing the operational costs in a very competitive environment. However, because of the complexity of energy network, the decision-making process is a very problematic task. In addition, the energy demand for refining operations changes time due to varying crude oil properties and operating conditions. Optimization in the energy network system minimizes the operation cost and allows to get the most value from the existing system.

Important researches and contributions have been addressed for the problem of utility system optimization. One of the first important studies in this field has been published by Papoulias and Grossmann (1983). A MILP model was proposed in their study to the synthesis of utility systems with fixed steam and electricity demands. Bruno et al. (1998) states a MINLP approach for structural and parameter optimization in utility systems. The optimization algorithm decides the configurations and loads of the equipment but also the operating conditions like enthalpies and efficiencies.

In the study of Iyer and Grossmann (1997), a MILP mathematical model is developed to determine the optimum operational combinations of the equipment at minimum cost of operation. The objective function takes into account changeover costs for units. In solution, a shortest path algorithm is preferred instead of branch and bound to shorten the computation time. The study of Velasco-Garcia et al. (2011) accounts the cost of

shut-downs and start-ups of utility operating units, as well. A SMILP model approach proposed for varying utility demand of process.

Zhang et al. (2008) presented an overall optimization model for process and utility operation. In the traditional approach for oil refinery-wide production planning, utility system and process system are optimized, separately. LP models of the process units are developed first to obtain a planning strategy. Production planning model determines crude oil selection, product and allocation of utilities. Secondly, the utility system is optimized to meet the energy demean at minimum operational cost. The production planning model is much more complicated than the utility optimization model. By separating these two models, the interrelationship between them is simplified and the global optimum result may not be achieved. Therefore, the utility model and process model are composed together to increase the optimization model efficiency.

Micheletto et al. (2008) developed a MILP model for utility plant optimization of RACAP Refinery in Sao Paulo, Brazil. The objective function is minimization of operation cost of the overall plant. The mathematical model can be simplified from MINLP to MILP, because each header temperature and pressure are taken as constant. They also. stated that MILP modelling gives very accurate optimization results.

Turkay et al. (2004) illustrated the strategic benefits of collaboration among different cogeneration systems in a single period Setting. This approach was extended to cover the investment decisions to facilitate collaboration and two-way exchange with the energy grid. (Soylu et al., 2006). Ozturk and Turkay (2016) showed that incorporation of new technologies to reduce the Green House Gas emission can be analysed to provide insight into long-term energy system planning using multi-objective mixed-integer optimization.

In this paper, power generation equipment in the refinery is analyzed thermodynamically to determine the variables that have an impact on the equipment efficiency. A mathematical programming model is developed to represent the energy demand of the refinery with the minimum production cost of energy. The model is formulated as an MILP problem and includes all operational constraints, mass and energy balances, demand satisfaction constraints, efficiency models and operational status of the equipment. All energy consuming/producing equipment in the refinery are defined in the model. The interactions between refinery units and the utility plants are taken into consideration. In addition to optimization of the operations in the energy network we examine two scenarios where the energy policy changes are examined in detail. The approach that is presented in this paper had been tested for one year in online and real-time decision-making purposes.

2. The energy network model

Although typical refineries have a single utility plant, the refineries with high Nelson Complexity Index (Nelson, 1976) usually has more than one utility plant due to high production capacity and investments to upgrade these refineries that span several decades. Tupras Izmit Refinery has a Nelson Complexity Index of 14.5 with two interconnected refining facilities and three utility plants. The first refining facility (F1) contains two utility plants (PA and PB) whereas the second refining facility (F2) contains one utility plant (PC). PA has four boilers to produce very high-pressure steam, four steam turbines to generate electricity, a gas turbine and heat recovery units. PB has four boilers to produce high-pressure steam that is used in back pressure turbines to

drive pumps and compressors in the refinery. PC contains two sets of gas turbines and heat recovery units to generate ultra-high-pressure steam that is used to generate electricity in turbines. In addition, deaerators and preheaters are also present in PC that also produce low-pressure steam to be used in pumps and compressors. The excess steam produced in F2 can be used in F1 and it is possible to transfer electricity between two facilities. It is also possible to exchange electricity (both ways) with the national grid.

All of the major units in these three utility plants are modelled using the conservation of energy, conservation of mass and real-time data from the process monitoring system. We present the model for the gas turbines in this section. A gas turbine is a type of combustion engine that is used to transform fuel energy to mechanical energy. This mechanical energy drives a generator to produce electricity. There are 3 main parts in a gas turbine: the compressor where the pressure of the incoming air is increased, the combustor that burns the fuel and produce high-pressure and high-velocity gas, the turbine where the high-pressure gas is expanded to produce work which is used to drive the generator. In the compression process, the compression ratio is calculated using,

$$r_p = Pr_2/Pr_1 \tag{1}$$

where r_p is the compression ratio, Pr_1 and Pr_2 are the inlet and outlet pressures respectively. The isentropic efficiency of the compressor (nc) is estimated with:

$$n_c = (T_{2s} - T_1)/(T_2 - T_1) \tag{2}$$

where T_{2s} is the isentropic compressor outlet temperature and T_1 and T_2 are compressor inlet and outlet temperatures respectively. Then, the work of compressor (W_c) can be calculated from:

$$W_c = C_{pa}T_1\left(r_p^{\gamma_a-1/\gamma_a} - 1\right)/n_m\, n_c \tag{3}$$

where C_{pa} is the specific heat of air, γ_a is a constant (=1.4), n_m and n_c are mechanical and isentropic efficiency of the compressor respectively. The energy balance in the combustion chamber can be expressed as,

$$m_a C_{pa} T_2 + m_f HV_f + m_f C_{pf} T_f = (m_a + m_f)TIT \tag{4}$$

where m_a and m_f are the mass flow of air and fuel, C_{pf} is the specific heat of the fuel, HV_f is the heating value of the fuel, T_f is the temperature of the fuel, TIT is the turbine inlet temperature. Then, the shaft work in the turbine section (W_t) can be expressed as,

$$W_t = C_{pf}\, TIT\, n_t \left(1 - \frac{1}{r_p^{\gamma_g-1/\gamma_g}}\right)\Big/ n_m \tag{5}$$

where n_t is the turbine efficiency and γ_g is a constant with a value of 1.33. The net work in the gas turbine system is the difference between W_t and W_c. In addition to the fundamental equations above, the efficiency of the gas turbines are directly affected by different factors including air temperature at the compressor inlet, air humidity, fuel

characteristics, steam and water injection during combustion. The process data were used to perform a regression analysis for power production in the gas turbines. The agreement between the process data and the regression model is very high as shown in Fig.1.

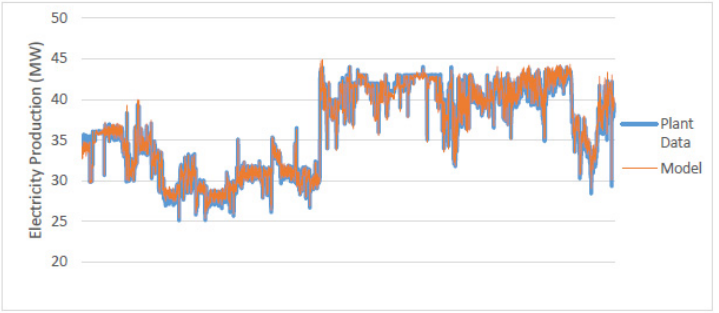

Fig.1 Comparison between the regression model and the plant data.

After the mathematical models for every major equipment are constructed, the optimization model for the entire energy network is assembled. The objective function is defined as the minimization of the operating cost that is subject to all material and energy conservation laws, equipment characteristics and efficiencies and electricity trade (buy/sell) options and emission limits and penalties. The binary variables are used to model the on/off status of the major equipment during the operations.

3. Results

The optimization problem is routinely solved to support online real-time decision-making regarding the operation of the energy network of the refinery. Typical MILP model for this purpose includes 28,104 variables (190 are 0-1 variables) and 10,656 constraints. The optimization is based on hourly operation plans.

3.1. Base Case

In order to assess the validity of the optimization results and analyse the benefits from the optimization approach by satisfying the electricity and steam demand in the two facilities of the refinery. The optimization of the energy network favors the most efficient equipment and allocates higher loads to them and shuts down some of the boilers. The optimal operation decreases the fuel gas consumption and the natural gas consumption increases. In order to eliminate the problem of drastic changes in the operation of the energy network, the furnace operations were not changed so the fuel consumption at each furnace remains unchanged. The green house gas emission levels are also calculated considering the operation before and after the optimization. By optimizing the energy network, the total energy of consumed fuel in the utility plants is decreased from 427.53 Gcal/hr to 418.97 Gcal/hr. This decrease also decreases CO_2 emissions from 101.1 ton/hr to 99.1 ton/hr while SO_2 emission is kept at 0. The total cost of operations includes demineralized water production cost and fuel cost consumed in the energy production. The overall savings for the base case are calculated as 2.51 %.

In addition to this regular decision support in the operations, the system is also used for scenario analysis to support policy decisions.

3.2. Scenario 1: Electricity buy/sell

Most of the refineries prefer to generate the electricity in their own utility plants for the continuity of their operations. The impact of electricity exchange with the national grid is analyzed in this scenario. The electricity buy/sell prices were obtained from the national grid web site and the option to meet the electricity demand of the refinery fully or partially from the national grid is considered as well as selling electricity if the refinery demand is satisfied and generating additional the electricity to sell to the national grid is economically advantageous. When selling electricity is economically favorable, the steam demand in the refinery stays the same and all of this demand is satisfied, electricity generation in gas turbines increase to 2.5 MW, the fuel gas consumption is reduced by 14.73 % and the natural gas consumption increases by 3.5 %. The total energy of consumed fuel in the utility plants is reduced from 427.53 Gcal/hr to 418.97 Gcal/hr and the CO_2 emissions are reduced from 101.1 ton/hr to 99.8 ton/hr. The total operating cost of the energy production is decreased by 2.75 %.

A sensitivity analysis study is carried out to examine the effect of the electricity price on the electricity trade with the maximum electricity trade limits for buying and selling are determined as 15 MW. Figure 2 shows the optimum amount of electricity purchased or sold at the corresponding electricity price. It is more profitable to buy electricity from the national grid for the prices under the approx. 105 TL/MW.

Fig.2 Sensitivity of electricity trade with respect to electricity price.

3.3. Scenario 2: Rolling drives

In this scenario, the rolling equipment are involved in the optimization algorithm; sparing the rolling drives allows multiple operational configurations of the units. For the least cost operation, it is important to choose the optimal set of drives to operate. Switching sparing drives for optimization changes the steam and electricity demand of the refinery. In addition, the electricity trade is not limited to 15 MW as in the previous scenario. The main difference in this case is the switching of 9 rolling drives that powered by steam to electricity. Thus, the electricity demand of the refinery increases by 0.49 MW, while HP steam demand decrease by 44.88 ton/hr. The total fuel gas consumption in the utility plants is decreased, while total natural gas consumption is

increased. The CO_2 emission level is reduced from 101.1 ton/hr to 98.9 ton/hr. The overall saving in the total operating cost is 3.451 %.

4. Conclusions

In this paper, a mathematical model for optimization the operations of the complex energy network in the refinery is presented. The problem is formulated as a mixed-integer linear program with the objective function of minimizing the total energy production cost. The mathematical model includes all operational constraints, mass and energy balances, demand satisfaction constraints, efficiency models and operational modes of the equipment in the energy network. The developed approach is analyzed and tested on real plant data of the Tupras Izmit Refinery. The online utility demand of the refinery is determined by receiving live plant data for steam, fuel, condensate, BFW, and electric system metering devices via plant information system. The problem is modeled in GAMS and solved by CPLEX solver for online real-time decision support.

In scenario analysis, two optimization cases are conducted to analyze the policy decisions in the operation of the refinery. The main objective of these optimization studies is to validate the extent of the developed model for policy analysis and to evaluate the economic impact of the optimization. In addition, a detailed sensitivity analysis is carried out to examine the effect of the electricity price on the electricity trade. Up to 3.5 % cost reduction is achieved comperes to base cases.

Abstract

This work proposes a mathematical optimization model for the design of a biorefining system through an efficient supply chain considering economic (minimization of the total annual cost) and environmental objectives (minimization of the overall CO_2 emissions), through the water-energy-food nexus. The proposed model is a mixed-integer linear programming (MILP) problem, which includes the material flow analysis (MFA) technique in order to simulate the changes that take place in a watershed system impacted by the implementation of the biorefining system and determine the water consumption caused mainly by the production of the feedstock and for the operation of the biorefineries. The methodology is configured to account for the uncertainty inherent to prices of feedstocks and products, biofuel demands, biomass requirements, weather conditions, grain production, etc. Finally, a case study located in Mexico is solved for a set of scenarios with the purpose of illustrating the capabilities of the approach. The results show the trade-offs among the considered objectives impacted by the uncertainty in the biorefinery system.

Keywords: Biorefinery, optimization, supply chain, material flow analysis, uncertainty.

1. Introduction

Nowadays, biofuels have been recognized as potential options to partially replace fossil fuels due to the decrease in the production projections for fossil fuels, and the stricter environmental legislations for the use of them, which have produced huge environmental impacts during decades. In spite of the economic advantages that fossil fuels have with respect to renewable alternatives, biofuels offer several environmental advantages including the reduction of the carbon footprint on a life cycle basis and the enhancement of renewability and sustainability. A biorefinery is an industrial processing plant where value-added chemicals and/or biofuels are produced using different renewable raw materials (grains and starch crops, agricultural residues, food waste, forestry materials, etc.). The design of a biorefinery is based on the optimal use of natural resources. For example, Khalidi et al. (2016) defined the pathways for producing biofuels. Because the biorefinery design is a complex task, which interacts with many other sectors, the entire associated supply chain must be simultaneously considered. Cucek et al. (2014) proposed a method for synthesizing a biorefinery supply chain through a mixed-integer linear programming model. Murillo-Alvarado et al. (2013) proposed a methodology dealing with the selection of feedstocks, products,

processing routes and processes for the separation of products for a biorefinery. Recently, López-Díaz et al. (2017) developed a mathematical model to incorporate a supply chain for the production of biofuels with a material flow analysis (MFA) approach with the purpose of designing an integrated biorefinery system with the environment to implement a study for the water-biofuel nexus. It should be noted that none of the previously reported methods have considered the relationship between the water and food nexus in the design of biofuels supply chains. Therefore, this work presents a superstructure to account for the interaction of the water-food nexus in the design of a biofuel supply chain, which incorporates the MFA technique to track the impact of the wastewater streams on the environment and to quantify the overall water requirements of the project). The proposed approach considers simultaneously the optimal location of a set of biorefineries, the type and amounts of feedstocks and biofuels (attempting to satisfy a given demand), the overall CO_2 emissions (including the CO_2 fixed by the crops during their growth period), the use of resources (water and land requirements), the routes of transportation and distribution for raw materials and biofuels, and the types of processing technologies. The optimization approach is driven by economic (maximization of the total annual cost) and environmental (minimization of the overall greenhouse gas emissions) goals. Furthermore, the optimization model accounts for the interactions by the sale of grains associated with the feedstock production.

2. Model formulation

A superstructure was proposed to consider the relationships between the agricultural products and the production of biofuels as well as the implication with food production in the cultivating sites. Additionally, the scheme is able to determine the impact in the watershed in terms of the consumption and discharges of effluents. One of the most important contributions is the consideration of the involved uncertainty in the model, because a large number of parameters are uncertain including the water availability, weather conditions, raw material prices, and biofuel prices. The proposed optimization model is described as follows:

2.1 Watershed model

2.1.1 Watershed at initial conditions before the implementation of the biorefining system. In this balance, the flowrate in reach *r* includes discharges and extraction to the watershed from the agricultural, biorefinery and urban activities surrounded the watershed as well as the weather condition (precipitation and evaporation).

$$Q_{r,s}^{Out} = Q_r^{In} + P_{r,s} + D_{r,s} + H_{r,s} + \sum_{t=1}^{N_{(t)}} FT_{r,t,s} + \sum_m w_{m,r,s}^{Discharge-feedstocks} + \sum_k w_{k,r',s}^{Discharge-biorefinery} - \sum_m w_{m,r,s}^{Used-feedstocks} - \sum_k w_{k,r',s}^{Used-biorefinery} - L_{r,s} - U_{r,s}, \qquad \forall r, \forall s \tag{1}$$

2.1.2 Overall water balance for each tributary of the watershed. The tributaries are little rivers that flow into the watershed, the balance considers the interaction in the reaches directly.

$$FT_{r,t,s} = S_{r,t}^{Untreated} + S_{r,t}^{Treated} + I_{r,t,s} + P_{r,t,s} + D_{r,t,s} - L_{r,t,s} - U_{r,t,s}, \qquad \forall r, \forall t, \forall s \tag{2}$$

2.2 Modelling of the biorefining system

In the design of the corresponding supply chain are estimated the capacities of process operation, biomass production, cultivating area, demand of water, logistic of distribution, etc.

2.2.1 Production at the cultivating fields.

$$f_{m,r,s}^{Prod-feedstock} = \alpha_{m,r,s}^{fedstock}\left[a_{m,r}^{exist} + a_{m,r}^{new}\right], \qquad \forall m, \forall r, \forall s \tag{3}$$

2.2.2 Activation of binary variables for biorefineries.

$$F_{m,r',s} \le \mathrm{F}_{\mathrm{m,r'}}^{\max}\, y_{r',s}^{Biorefinery}, \qquad \forall r', \forall s \tag{4}$$

2.2.3 Production of biofuels.

$$P_{k,m,r',s}^{Bio} = \alpha_{k,m,s}^{Bioref} F_{m,r',s}, \quad \forall k, \forall m, \forall r', \forall s \tag{5}$$

2.2.4 Products obtained in markets.

$$\sum_{r'} P_{k,r',j,s}^{Prod-market} \le P_{k,j,s}^{Prod-market-Max}, \qquad \forall k, \forall j, \forall s, \forall r' \tag{6}$$

2.3 Gains and costs

In the economic objective, the capital and operation costs are considered in the total annual cost for biorefineries and the agriculture activity.

2.3.1 Gains obtained by the selling of products.

$$G_s^{Products} = \sum_k \sum_{r'} UC_{k,s}^{Product} P_{k,r',s} \tag{7}$$

2.3.2 Gains obtained by selling grains.

$$G_s^{grains} = \sum_m \sum_r UC_{m,s}^{Grains} f_{m,r,s}^{\mathrm{Prod-grains}}, \ \forall s \tag{8}$$

2.3.3 Capital cots for biorefineries.

$$CapCost_s^{Biorefineries} = k_F\left[\sum_m \sum_{r'} FC_{m,r'}^{Biorefinery} y_{r',\mathrm{s}}^{Biorefinery} + \sum_m \sum_{r'} VC_{m,r'}^{Biorefinery}\left(F_{m,r',\mathrm{s}}\right)^{\sigma_{m,r'}^{Biorefinery}}\right], \ \forall s \tag{9}$$

2.3.4 Operating costs for biorefineries.

$$OpCost_s^{Biorefineries} = \sum_m \sum_{r'} UC_{m,r'}^{Biorefinery} F_{m,r',\mathrm{s}}, \ \forall s \tag{10}$$

2.4 Objective functions

The first objective is economic that is defined as the net gains in the supply chain, then the environmental objective functions represent the total used water and emissions.

2.4.1 Total annual profit

$$Profit_s = G_s^{Products} + G_s^{Grains} - CapCost_s^{Biorefineries} - OpCost_s^{Biorefineries} - OpCost_s^{Feedstocks} - OpCost_s^{Water-biorefineries} - OpCost_s^{Water-feedstocks} - TCost_s^{Feedstocks} - TCost_s^{Grains} - TCost_s^{Products} \quad (11)$$

2.4.2 Total water requirement

$$Water_s^{required} = \mathrm{Q}_{s\ \mathrm{final}}^{\mathrm{Initial}} - Q_{s\ final}, \quad \forall s$$

2.4.3 CO_2 emissions

$$CO2_s^{total} = CO2_s^{prod} P_s^{biototal} - CO2_s^{abs} \mathrm{A}_s^{total}, \quad \forall s \quad (12)$$

3. Results and discussion

The proposed model was coded in the General Algebraic Modelling System (GAMS) as a mixed-integer lineal programing problem. A case study was solved to evaluate the capacities of the proposed model considering the installation of a biorefinery system in the center region of México. The Balsas river is considered as watershed to study the behavior of the water resources, which was divided in 23 fixed reaches defined accounting for studies by the National Water Council (CONAGUA, 2016). The total biofuel demands are presented as requirements by ten markets (important cities along the watershed), where the ten percent of the total energy demand is satisfied by biofuels. A biorefinery can offer a wide platform of products, but for this case only was considering the bioethanol and biodiesel productions. For this system, the agricultural information such as soil conditions, potential cultivation area, crop yields, demand of water by crops, etc., are provided by SAGARPA (2016). The considered biorefineries are configured to use second generation biomass in the production of biofuels in specific agricultural residues of corn, wheat, sorghum and sugar cane to produce bioethanol, and jatropha and oil palm to produce biodiesel. The case study works with the next distribution of prices: $US 0.45/L and US$0.66/L for bioethanol and biodiesel respectively, for agriculture products as grains of corn wheat, sorghum we have $US 140/t, $US 142/t, $US 138/t, $US 30/t, and for sugar cane, jatropha, and oil palm $US 4000/t and $US 304/t provided by World Bank database. In this case, some parameters for products and feedstocks, weather conditions like precipitation, evaporation and filtration as well as some agricultural parameters are modeled under uncertainty. In Excel®, n-scenarios are generated through the Latin hypercube sampling method under certain probability of distribution using a normal distribution of 90% and 95%. Then, fifty scenarios were generated using Monte Carlo simulation to determine the optimal design of the supply chain necessary for defining the location and operation of the biorefinery system.

The problem was analyzed considering four situations; pessimist and optimistic conditions for the profit and for the consumption of water in the project. Then, the multi-objective optimization problem was solve using the solver CPLEX with 309,650 continuous variables, 23 binary variables, and 84,947 constraints. The CPU time depends on each scenario, where the corresponding solution for the analyzed specific scenario is presented in Table 1. The time horizon is a year with an investment time of ten years. With the purpose of making a wide analysis, it is selected 3 specific scenarios: the first has 20% of probability, the second has 70% of occurrence and finally the scenario 3 has 94% of occurrence. The model also was analyzed for economic and environmental expected and pessimistic conditions.

Table 1. Case study solutions.

Case	CPU TIME (s)	OPTIMAL SOLUTION
Maximizing Mprofit	2426	US$6.79x10^8/y
Maximizing Wprofit	90.4	US$6.44 x10^8/y
Minimizing Mwater	244.7	0.639 m^3
Minimizing Wwater	27.05	0.016 m^3

Figure 1 shows the results for the scenarios maximizing the expected profit and the worst or pessimistic profit against the demand of water under these conditions. In this sense, Figure 2 presents the configuration for the solution at scenario with 94% of probability of occurrence (point 3). The expected profit is \$US 7.58 x10^8 /y, and the required fresh water is 3.24 x10^7 m^3/y, where there are required 7 biorefineries to satisfy the biofuel demands in the markets. The total biofuel production is 6.71 x10^7 L/y of bioethanol and 8.66 x10^7 L/y of biodiesel. Comparing with the worst or pessimist case, the profit was obtained with a value of US\$ 7.32 x10^8 /y and the fresh water consumption increases to 3.25 x10^7 m^3/y. This scenario requires a new cultivating area of 19 377 ha to satisfy the biomass demands. The decision about how much of specific crop can be required as biomass depends of the land characteristics, cost of farm and harvesting, as well as the transportation logistic. The supply of the markets is satisfied considering the interaction between the agricultural, food and biofuel to define an efficient supply chain and optimal location of a biorefinery system.

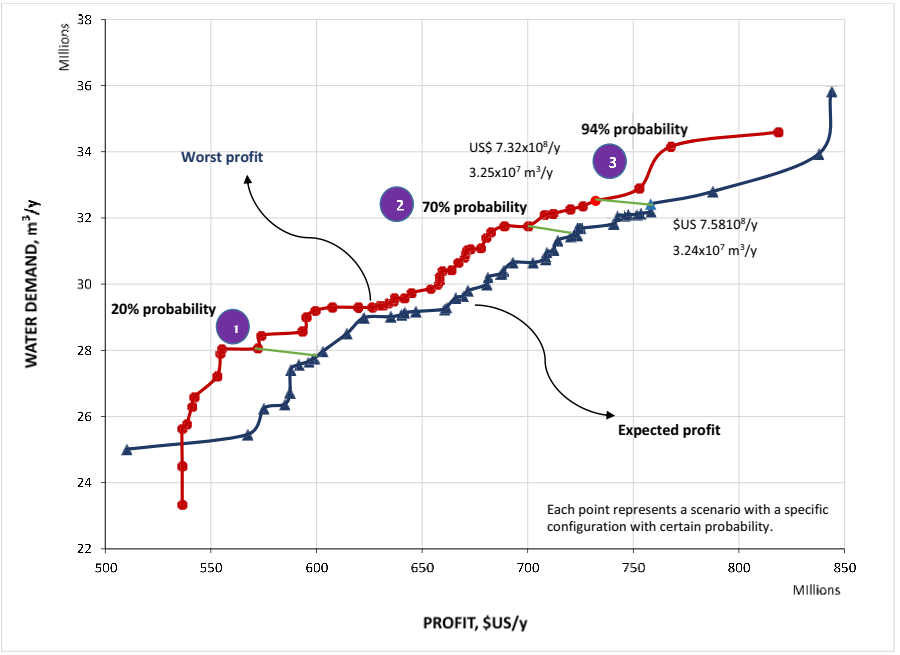

Figure 1. Pareto curve for the profit vs water demand.

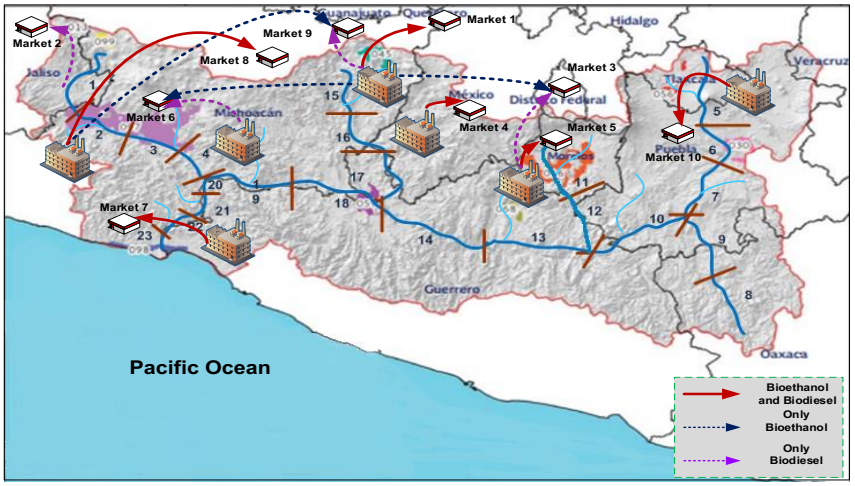

Figure 2. Optimal configuration for the biorefinery system in scenario 3 for expected profit.

4. Conclusions

The proposed optimization approach determines the location, operation and logistic of distribution for biomass and biofuels, as well as new cultivation areas, fresh water demand, the impact on the watershed by design and efficient supply chain for the biorefinery system considering simultaneously economic and environmental objectives. The biofuels have proved to be a potential energy alternative but the disadvantage is found in the nexus that this sector has with the food sector. The cultivation of new land to cultivate biomass can be compromised by food production and in some cases the impact on the watershed for extraction and discharges by agricultural and industrial uses is greater that the benefit of greenhouse emission. This work is a powerful tool for decision makers to have a more complete analysis for the production of biofuels.

Abstract

Surrogate modeling (also referred to as metamodeling) has attracted increased attention from researchers in various fields of engineering due to its use in computationally expensive engineering tasks such as Monte Carlo based global sensitivity analysis and process design optimization. However, the applications of surrogate models in the field of wastewater treatment modeling have not been extensively explored in the literature. In this work we present a systematic methodology for construction of powerful surrogate models to be used for the global sensitivity analysis of Benchmark Simulation Model 1 (BSM1) plant. A quasi-random design of experiments technique, Sobol sampling, is employed to generate an experimental design, which is further used to build surrogate models. A class of advanced metamodeling algorithms such as sparse polynomial chaos expansion (PCE) using least angle regression, Kriging interpolation, polynomial chaos Kriging (PCK), radial basis function (RBF) interpolation, multivariate adaptive regression splines (MARS), and a multilayer perceptron type feedforward neural network (ANN) are applied. The generalization error of the developed models has been estimated using holdout cross-validation with coefficient of determination (R^2) and root mean squared error (RMSE) being used for evaluation of model predictive accuracy and model selection, respectively. The framework was further investigated for its suitability in a Monte Carlo based global sensitivity analysis using Sobol' method. The results obtained suggest that by following the framework, ANN and Kriging type surrogate models can effectively be constructed and used to estimate Sobol' sensitivity indices of WWTP design parameters.

Keywords: surrogate modelling, wastewater treatment modelling, design of experiments, metamodeling, global sensitivity analysis.

1. Introduction

Wastewater treatment plant (WWTP) design is motivated towards meeting effluent quality requirements, which are regulated by governmental and intergovernmental bodies. Among the most important effluent discharge limits are chemical oxygen demand (COD), total nitrogen (TN), total suspended solids (TSS), and ammonium (SNH) concentrations. In the WWTP community, significant effort has been invested into developing activated sludge process mechanistic models and benchmarking of wastewater treatment plant control strategies, which produced widely used Activated Sludge Models (ASMs) and Benchmark Simulation Models (BSMs) (Gernaey *et al.*,

2014). Regarding the use of surrogate models in the community, Raduly *et al*. (2007) developed artificial neural networks for rapid performance evaluation of WWTPs. Moral *et al*. (2008) developed an ANN for ASM. However, none of them focused on performance comparison of different type of surrogate models. In this work we present a new systematic framework for efficient construction of plant-wide surrogate models using advanced surrogate modeling and data-driven algorithms including Kriging, polynomial chaos expansions, and neural networks from a process design point of view. In what follows, we describe our modeling approach of WWT process, and the surrogate model construction framework with an end use application of a global sensitivity analysis.

2. Surrogate Modeling

MARS is a powerful nonparametric regression algorithm using two-sided truncated basis functions to explain the relationships between the predictor and response variables. More details about this algorithm can be found in Friedman (1991). Originally developed for scattered multivariate data interpolation, RBF is an exact interpolation algorithm (model predictions goes through the training data points) using various basis functions such as biharmonic, multiquadric, inverse multiquadric, thin plate spline, and Gaussian. Jekabsons implemented MARS (2016) and RBF (2009) in MATLAB environment, which were used for this study. Marelli and Sudret (2016) developed UQLab framework for uncertainty quantification, which also implemented surrogate modeling algorithms including Kriging and polynomial chaos expansions using least angle regression, and polynomial chaos Kriging. More explanations about how these algorithms work can be found in the user manuals of the framework. As these algorithms allow defining many configurable model parameters, we employ a grid search approach to find the optimum set of parameters, which performs a combinatorial optimization by screening over each different combinations and finding the model with minimum root mean square error on the test sample. The same approach is also used for finding optimum MARS and RBF models. A multilayer perceptron type feedforward neural network comprising of one hidden layer (with different number of neurons) and one output layer was developed using the Neural Network Toolbox of MATLAB (Mathworks Inc.). The grid search is also used to find the optimum number of neurons in the hidden layer, transfer functions (i.e. logarithmic, tangential, and linear sigmoid functions), and training algorithms (i.e. Bayesian regularization backpropagation, Levenberg-Marquardt backpropagation, and scaled conjugate gradient backpropagation).

3. Methodology

The BSM1 model has a relatively simple plant layout consisting of a five-compartment activated sludge reactor (two anoxic tanks followed by three aerobic tanks) and a secondary settler. From a process design point of view, we create an initial input space with five design-related parameters taken from Sin *et al.* (2009). These include hydraulic residence time in the anoxic tank (HRT_{an}) (varied between 1 and 7 hours), volume ratio (VR) of anoxic tank to aerobic tank (varied between 0.2 and 0.8), ratio of external recycle flowrate to influent flowrate (RR_e) (varied between 0.4 and 1.4), ratio of internal recycle flowrate to influent flowrate (RR_i) (varied between 2.8 and 4.2), and wastage flowrate (Q_w) (varied between 300 and 450 m^3/day). To reach a steady state,

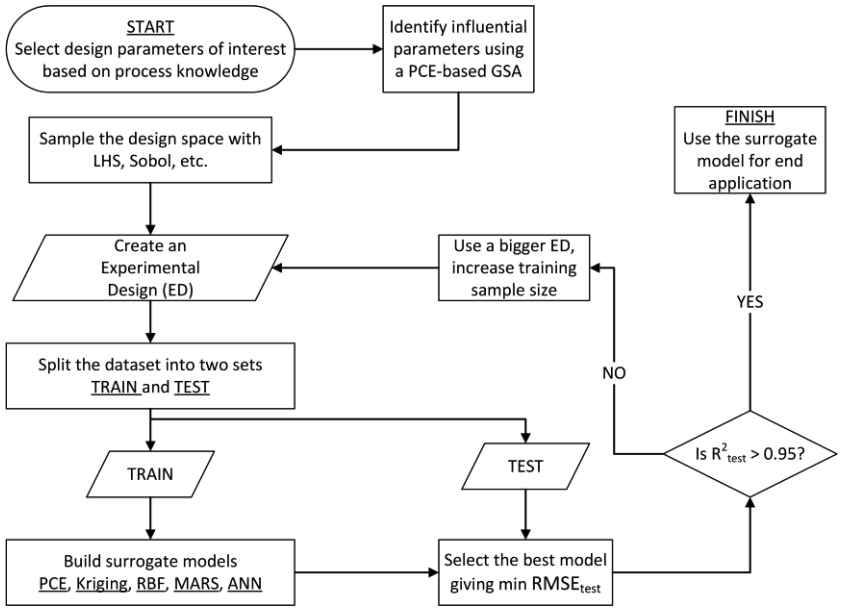

Figure 1: Systematic framework for developing surrogate models to be used in WWTP modeling

the BSM1 model is simulated for 150 days using the dry weather influent file. Model outputs of interest included effluent quality indices , such as COD, TSS, TN, and SNH.

Figure 1 shows the methodological framework used to build the surrogate models. After deciding on the design parameters, in order not to include an uninfluential parameter in the design space, the framework proposes to perform a PCE-based global sensitivity analysis, following from Sudret (2008) whose ground-breaking work showed the effectiveness of PCE models in the global sensitivity analysis. This step can be achieved with a relatively small experimental design (ED) size of 200. With the new design parameters sampled between their ranges of variation using the quasi-random Sobol sampling algorithm, the framework creates a larger ED (size of which is 1000 in this case) and splits it into training set size of 500 and a global test set size of 500. The global test set was never shown to any of the algorithms during training and just used for estimating the generalization error of the models (holdout validation). By doing so, one can make sure to avoid overfitting, a challenge faced when models perform well on training sample but not on the test sample. For cases where such large test sample sizes are unaffordable, 5-fold or 10-fold cross-validation techniques can also be used. The framework further splits the training sample into smaller sub-training samples and builds surrogate models. The grid search uses unused training sample to optimize models from each algorithm whereas the global test sample provides performance score comparison of different algorithms. The computational cost of building these models depends on the training sample size and the complexity of the original model as well as the adopted computing strategy. In order to test the usability of the final developed models, a variance based global sensitivity analysis (Sobol method), which produces first and total order Sobol' indices, is performed. The theory behind evaluation of these indices can be found in Saltelli (2008). Basically, first and total indices respectively indicate individual and total effects of inputs on the variance of the model outputs.

4. Results and Discussions

As stated in the methodology, we first performed a PCE-based global sensitivity analysis, results of which are shown in Figure 2. Since they directly relate to the effective size of aerobic and anoxic tanks, HRT_{an} and VR are found to be the most influential parameters in terms of their effects on the model outputs, whereas the internal recycle ratio played no significant role on any of the outputs. Hence this was excluded from further analysis. These results also agree well with those obtained in Sin *et al.* (2011).

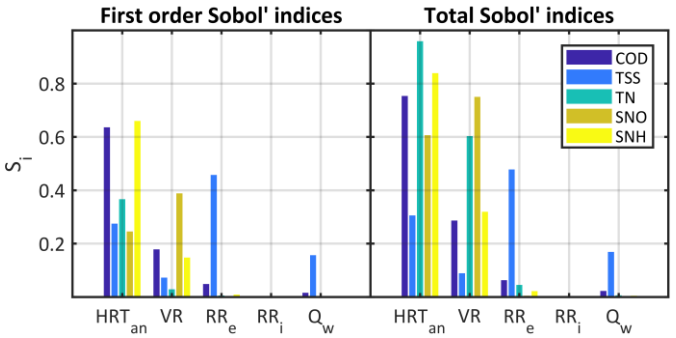

Figure 2: PCE-based global sensitivity analysis results for models outputs of interest.s.

Table 1 shows performance test scores of the developed surrogate models for the model output of COD. Scores are tabulated for training sample sizes of 100, 200 and 400 and the test sample was kept the same size of 500. Kriging and ANN type models outperform the other type of models. Table 2 shows performance scores obtained for the model output of SNH, which exhibits strong nonlinearities with the model inputs. Kriging and ANN models show good results even for the training sample size of 100. All the models show improvement as the training sample size increases.

Table 1: Performance scores of surrogate models developed for COD model output

Model type	$N_{training} = 100$		$N_{training} = 200$		$N_{training} = 400$	
	R^2_{test}	$RMSE_{test}$	R^2_{test}	$RMSE_{test}$	R^2_{test}	$RMSE_{test}$
PCE	0.88	1.33	0.89	1.19	0.95	0.78
Kriging	0.98	0.40	0.99	0.28	0.99	0.21
PC-Kriging	0.86	1.54	0.94	0.84	0.97	0.45
MARS	0.88	0.96	0.95	0.62	0.98	0.35
RBF	0.73	1.78	0.76	1.41	0.80	1.25
ANN	0.98	0.45	0.99	0.31	0.99	0.29

Table 2: Performance scores of surrogate models developed for SNH model output

Model type	$N_{training} = 100$		$N_{training} = 200$		$N_{training} = 400$	
	R^2_{test}	$RMSE_{test}$	R^2_{test}	$RMSE_{test}$	R^2_{test}	$RMSE_{test}$
PCE	0.62	9.04	0.84	5.47	0.84	5.55
Kriging	0.95	3.04	0.97	2.53	0.99	1.59
PC-Kriging	0.95	3.13	0.96	2.88	0.98	1.73
MARS	0.89	4.64	0.92	3.96	0.93	3.73
RBF	0.54	9.31	0.56	9.12	0.57	8.96
ANN	0.98	2.10	0.98	1.76	0.99	1.57

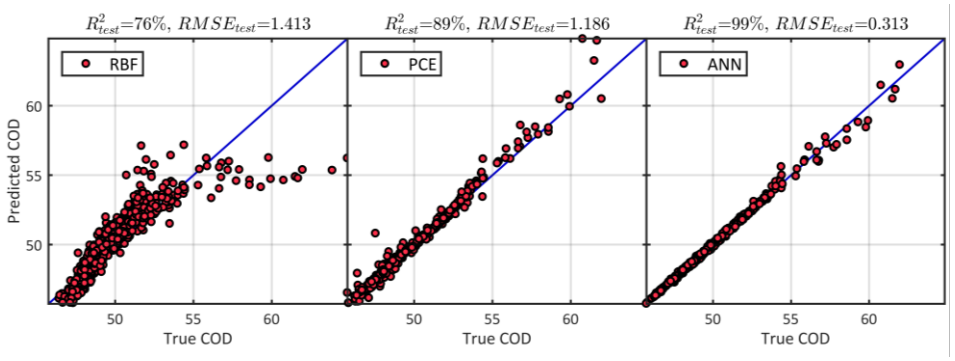

Figure 3: Predictions of RBF, PCE, and ANN type surrogate models trained on a sample size of 200 are compared for the original model response of COD.

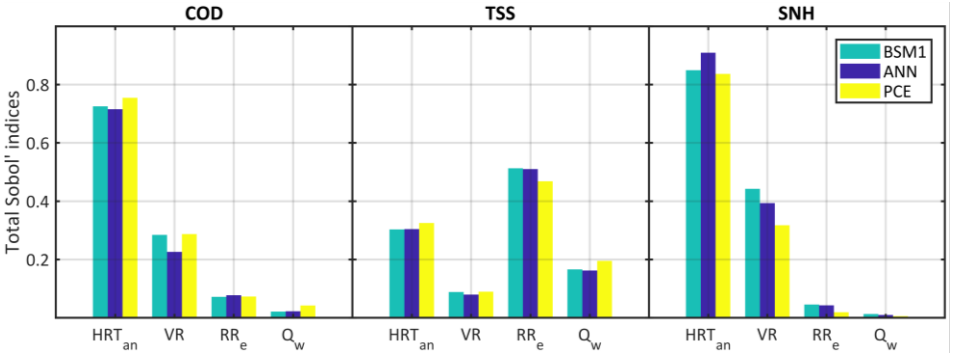

Figure 4: Total Sobol' sensitivity indices are calculated for the model outputs of COD, TSS, and SNH using both the original model (BSM1) and the surrogate models of type ANN and PCE.

Figure 3 shows a comparison of predictions of RBF, PCE, and ANN models for the model output of COD. RBF overpredicts lower responses and underpredicts higher responses. Figure 4 shows total Sobol' sensitivity indices for COD, TSS, and SHN outputs obtained using the original model (BSM1) and two surrogate models (ANN and PCE). A sample size of 2000 is used with Sobol' sampling strategy. This results in 12000 runs of the original model and the ANN model, which was parallelized using 20 MATLAB workers (CPU threads). Advantageously, the PCE model does not require any new model runs after its creation to compute these sensitivity indices. Table 3 shows the computation time comparison of these simulations and the speedup gain obtained due to the use of surrogate models. Although the time required to perform a single original model run was no more than ten seconds and the power of parallel computing was used, performing a global sensitivity analysis with the original model costed several hours. Use of surrogate models instead resulted in significantly lower computation time.

Table 3: Computation time of global sensitivity analysis are compared for different models.

Model used	Computing power used	Computation time (sec)	Speedup
BSM1	20 MATLAB workers in parallel	15890	1x
ANN	20 MATLAB workers in parallel	94	169x
PCE	1 MATLAB engine in series	7	2270x

5. Conclusions

In this work, we have presented a new systematic framework, which can be used to build plant-wide surrogate models for wastewater treatment plants using advanced surrogate modelling algorithms. The list of algorithms tested included artificial neural networks, polynomial chaos expansions, Kriging, among others. For predicting effluent COD and ammonium, Kriging and neural networks type surrogate models are found to be the most effective. A training sample size 100 was found to be enough to build models with test R^2 values above 0.95. Also important is the results obtained from the use of surrogate models in the case of a global sensitivity analysis, which revealed very close results compared to the ones obtained using the original model, yet with much faster computation times.

Abstract

Solar energy, though promising as the energy source for a fossil fuel-deprived future, is a dilute resource and harvesting it requires vast tracts of land. In this study, we develop an extensive process system model for land requirement analysis in each of the 48 contiguous states of the United States for a solar powered economy to address the likely land competition. Land requirement analysis in this study takes into account several issues that are usually ignored. Efficiencies of major energy conversion steps from primary energy to end use are accounted and intermittent solar availability, actual solar farm output and land availability are all considered. In addition, we prefer local photons for local use for consideration of minimizing transmission loss and energy security. Under this preferred scenario, our land requirement analysis shows that 16 of the 48 contiguous states have insufficient available land and that the land competition for energy and food will be intense. Thus, in a solar economy, land use intensification will be required to avoid conflict between our competing land use needs.

Keywords: solar, PV, land, requirement

1. Introduction

Solar energy is our most ubiquitous and promising renewable energy resource that has the potential to meet our future energy demands due to its sustainable availability and abundance (Lewis and Nocera, 2006). Replacing fossil resources with solar power provides an opportunity to eliminate much of the world's pollution, greenhouse gas emissions, and energy security challenges. However, solar energy is a dilute source with power density several orders of magnitude lower than fossil fuels (Smil, 2015). Harnessing solar energy therefore requires vast tracts of land. A number of studies have envisioned a fossil fuel-deprived future powered by solar energy. In most of these previous studies, land availability is not a constraint to the feasibility of a solar powered future. For example, Turner (1999) has estimated that no more than 1 % of the land in the United States, if used for photovoltaics (PV), could provide all the energy needed for the entire country. While these researchers are optimistic about the total solar economy, several recent land requirement analyses have raised the concern in land availability in some densely populated countries. MacKay (2013) has suggested that transition to a total solar economy in Britain would require land area similar to the area of the entire country and that several other high-density, high-consuming countries, such as Japan and Germany, are facing the same challenge. A recent land requirement analysis by Capellán-Pérez et al. (2017) over 40 countries around the world has also pointed out that it could be physically infeasible for many densely populated countries to domestically harness renewable energy to maintain the current energy consumption.

According to these recent land requirement estimations, countries with relatively low population density, such as the US, have sufficient land for solar farms to meet all energy demand.

However, the US is large country where coastal areas are densely packed while other states have relatively less population and energy demand. We would like to see if solar photons could locally fulfil the energy demand. In this work, an extensive systems model for detailed land requirement analysis is developed for each of contiguous 48 states of the US for a full solar economy. In our system model, electricity demand in a solar powered future is first estimated according to current end use energy consumption and energy conversion efficiencies. To take into account the intermittency of solar availability, storage capacity of solar production should be included and various storage methods are deployed. We use the actual PV production data reported (NREL, 2013) to calculate the land area requirement. Furthermore, available land for PV installation is limited; only part of the miscellaneous and urban land could be directly utilized for PV. Considering all the issues stated above, we find out that currently available land is insufficient for many states in the US, which suggests that land competition will be intense in a full solar economy. Novel concepts will be needed to meet food and energy needs in a "Full Earth" maintained by primarily solar energy.

2. System model for land requirement and analysis for a full solar economy

2.1. Methodology for estimating electricity demand in a solar powered future

For the purpose of this study, PV panels are the only devices harnessing solar energy and converting it to electricity supplied to end uses. Therefore, most end use systems are to be electrified for the transition and we need to estimate the total electricity demand (E_{total}^{future}) for electrified end use systems through detailed modeling of each end-use sector (Figure 1). Currently, fossil fuels are either supplied directly to end use sectors or converted to electricity before consumed. In our model, we treat power generation as a separate sector and only direct primary energy consumption is considered for the residential, commercial, industrial and transportation sectors. The systems that might not be feasibly electrified would be powered by synthetic fuels, which are originated from biomass under our assumption. In addition, fossil fuels consumed as feedstocks are also replaced by bio-fuels. The bio-fuel production is also treated as a stand-alone sector.

For the electricity generation, current electricity generated from fossil fuels (EIA, 2016[a]) will be replaced by electricity from solar energy (Eq. (1)).

$$E_{electricity}^{future} = \text{Actural electricity generated from fossil fuels} \quad (1)$$

For other end-use sectors, the basis for estimating the electricity demand is to assure that the end-use energy consumptions are the same for current and future scenarios under different energy conversion efficiencies. The calculation paradigm is expressed by Eq. (2)

$$E_i^{future}\eta_i^{future}\eta_{transmission}^{future} = \sum_j E_{i,j}^{current}\eta_{i,j}^{current} \quad (2)$$

where the subscript *i* refers to the end-use, *j* refers to the fuel and $E_{i,j}^{current}$ refers to the current primary energy consumption from fossil fuel *j* for use *i*. The efficiencies for various end uses and fuels are listed in Table 1.

Table 1: Efficiencies for various end uses and fuels

Sector	End-use (i)	Fuel (j)	$\eta_{i,j}^{current}$	$\eta_{i,j}^{future}$
Residential	Residential	Natural gas, petroleum, coal	65 %	95 %
Commercial	Commercial	Natural gas, petroleum, coal	65 %	95 %
Transportation	Light duty vehicle	Motor gasoline, LPG	14.8 %	75 %
Transportation	Truck	Diesel	20.2 %	75 %
Industrial	Industrial heat	Natural gas	80 %	95 %
Industrial	Industrial heat	Petroleum	80 %	95 %
Industrial	In-house electricity	Natural gas	46 %	-
Industrial	In-house electricity	Petroleum	35 %	-

The primary energy consumption data for each of the end-uses can be acquired from EIA (EIA, 2016[b]) and according to the efficiencies listed in Table 1 we can estimate the electricity demand for a future solar economy. Note that the electricity transmission loss is taken to be 4.7 % and therefore a $\eta_{transmission}^{future}$ value of 95.3 % is accounted (EIA, 2016[a]).

Now what has been left out is the means of transportation that could not feasibly be electrified and the industrial feedstocks. The fractions of these fossil fuels (e.g. 25.2 % of the natural gas going to industrial sector is for feedstock) are shown in Figure 1. The conversion process from biomass to bio-fuels requires hydrogen to get rid of the oxygen in biomass and the hydrogen is assumed to come from water electrolysis. The electricity required for water electrolysis ($E_{bio-refineing}^{future}$) is added to the total solar electricity demand. Therefore, the total electricity demand is calculated by Eq. (3)

$$E_{total}^{future} = E_{electricity}^{future} + E_{bio-refineing}^{future} + \sum_{i,j} E_{i,j}^{future} \quad (3)$$

where *i, j* are listed in Table 1.

2.2. Intermittency of solar energy, PV output and land availability

One of the essential challenges of solar energy utilization is the intermittency of solar availability. In the US, the average solar availability is only 4.8 hours per day, which means that all the solar electricity demand must be produced in 1/5 time of a day (Lewis and Nocera, 2006). The electricity produced in the solar available time period needs to be stored. Currently, the battery storage efficiency varies in the range of 75 - 94 % (Gençer and Agrawal, 2016) and carbon storage cycle has an efficiency of 55 – 58 % (Al-Musleh et al., 2014). We adopt a mixed energy storage method and the overall system storage efficiency is taken to be 65 %. Considering the intermittency and the storage efficiency, the corrected total electricity for a solar economy can be calculated by Eq. (4) where $f_{solar\ available}$ refers to the fraction of solar available time in a 24-hour day, which is 20 % here.

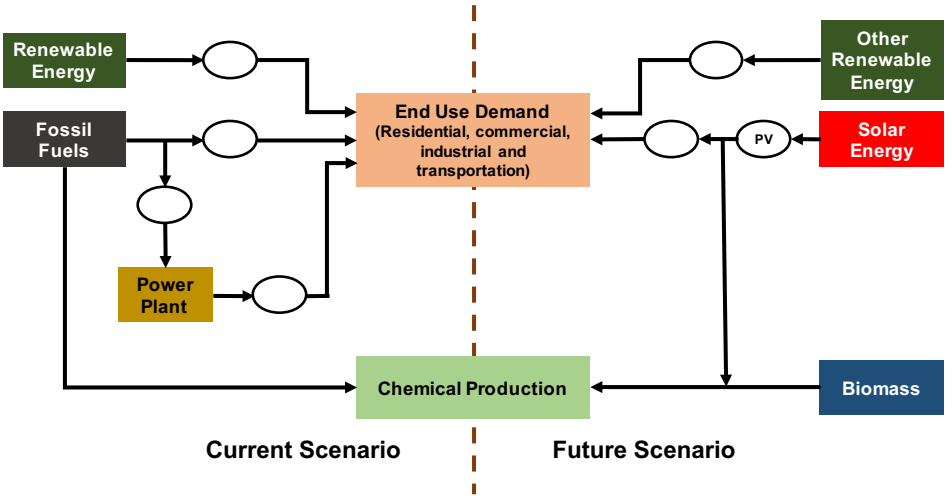

Figure 1: The energy supply infrastructure of current and future scenarios. The current end use demand will be maintained by solar energy in the future. Ovals in the figure indicate the energy conversion efficiency.

$$E_{corrected}^{future} = E_{total}^{future} f_{solar\ available} + E_{total}^{future}(1 - f_{solar\ available})/\eta_{storage} \quad (4)$$

A reasonable PV output number is crucial for our land requirement analysis. Although the maximum solar cell efficiency reported to date can be up to 46 % (NREL, 2017), the actual PV power output from PV parks is generally much lower. Instead of estimating PV power output by looking at the solar flux and PV efficiency as in most of the previous studies, we use actual production data of existing PV parks. An average power production of ~7 W/m^2 is reported for PV installations that are greater than 1 MW in size (Ong, 2013) and we take this number for our land requirement analysis. In addition, we average the total electricity demand over the total time of a year to obtain the total power output requirement (P^{future}) for a solar economy (Eq. (5)).

$$P^{future} = \frac{E_{corrected}^{future}}{Total\ time\ of\ a\ year} \quad (5)$$

Then we can calculate the land requirement for each of the contiguous states as we know the total power output requirement and power output density for PV parks ((Eq. (6)).

$$Land\ area = \frac{P^{future}}{power\ output\ density} \quad (6)$$

3. Miscellaneous and urban land are insufficient

Land area available for PV installation is only limited to certain types of land. Agriculture land (croplands, grassland pastures and ranges) cannot be used for PV installation as food production will be harmed by PV panels. Forest-use land and special-use land (national and state parks, etc.) are also unsuitable for PV for the consideration ecosystem protection. Agriculture land, forest-use land and special-use land account for 93.2 % of the total land of the US. Only part of urban-use land can directly be used for rooftop PV and other miscellaneous land (marshes, deserts and

other barren land generally of low value for agricultural purposes) is currently available for PV parks.

If we compare the land area requirement estimated in Section 2 and the area of miscellaneous and urban land for each of the contiguous 48 states in the US (Figure 2), we can see that there are 16 states that need more than 50 % of the miscellaneous and urban area. For Wyoming, West Virginia and Texas, even more than 100 % of the miscellaneous and urban land are required for PV. What we have to note is that 50 % is a rather high utilization ratio, especially for urban area. Existing studies have shown that only a small percentage of urbanized area could be covered by solar panels, generally no more than 10 %, with acceptable solar conversion efficiency (Capellán-Pérez et al., 2017). Therefore, for the highly urbanized coastal areas, such as California and New Jersey, the land challenge could be more severe. Clearly, a significantly large number of states will not able to meet their need locally and will have to import energy from other parts of the country. Alternatively, options to use other land areas such as agricultural land should be explored. This could be challenging as current practice of using photovoltaics on farmland is known to hurt food production or alter crops that can be grown (Armstrong et al., 2016).

Moreover, our energy demand estimation is based on the energy consumption data for the year of 2014. With population growth and economic development, the energy demand could be higher in the future, which would require more land dedicated for power production. In addition, population growth would require more land for human activities. Therefore, the land competition will more challenging in a full earth. To resolve this land issue for the realization of solar economy, additional land apart from urban and miscellaneous land will be locally required.

4. Conclusions

To transition to a full solar economy, an extensive systems model is developed accounting for harnessing solar energy as electricity, its storage, transportation and use. The model is then used for detailed land requirement analysis in each of the contiguous 48 states of the Unites States to examine the possible land usage for energy. Results show that for a future solar economy, 16 states are likely to require more than 50 % of the miscellaneous and urban land for solar power generation. Our results are in sharp contrast to the common understanding that only small land areas will be needed in a future solar economy to satisfy entire energy need. These results show a need for innovation in land use intensification including the possibility of using farmland while causing no reduction in food production.

Modeling and Design of a Solar-Assisted High-Performance Direct Contact Membrane Distillation System

Mahdi Mohammadi Ghaleni[a], Abdullah Al Balushi[a], Mona Bavarian[a], and Siamak Nejati[a*]

[a]*University of Nebraska-Lincoln, Department of Chemical and Biomolecular Engineering, 820 N 16th Street, Lincoln, NE 68588*
snejati2@unl.edu

Abstract

Hollow fiber membrane (HFM) modules have recently drawn considerable attention in membrane distillation (MD) because of their high packing density compared to other type of modules. In this work, a mathematical model is developed to study the impact of design and process parameters on both permeate flux and energy efficiency of hollow fiber membrane modules. The membrane module is integrated with a heat exchanger to utilize the heat of waste brine . Also, a solar collector is integrated in the system to increase the temperature of feed stream before entering the module. The simulation data were in good agreement with the experimental results. We found that the close-packed configuration provides the maximum permeate flux and energy efficiency for the module when the inter-spacing parameter, the ratio of the fiber radius to the center-to-center distance between neighboring fibers, is properly adjusted. The simulation results suggested that the permeate flux for this system can be enhanced as high as 18% by choosing the close-packed configuration and adjusting the inter-spacing parameter such that neighboring fibers are not in contact with each other.

Keywords: membrane distillation; hollow fiber membrane; solar energy; water desalination, modeling and simulation.

1. Introduction

Water scarcity is a severe universal problem, demanding new methods for desalination of saline resources such as seawater and brackish water [1–4]. Membrane distillation (MD) is an emerging technology for producing freshwater. In MD, a hydrophobic membrane acts as a physical barrier between a cold (distillate) and a warm stream (saline water). The membrane is typically made of a hydrophobic material allowing the water vapor to pass through but hinders the liquid flow. The driving force for vapor permeation is the difference in vapor pressure across the membrane induced by the temperature gradient.
Although MD is a promising technology, it has not been commercially developed for water desalination mainly because of the lack of high-performance materials and modules specifically designed for MD. Among the different membrane modules, hollow fiber membrane modules offer the best performance because of their high packing density, high mechanical strength, and small footprints [5, 6].
In the present work, a mathematical model is developed to simulate the membrane distillation process, operated in direct contact mode, in a hollow fiber membrane module. The effect of different packing configurations and design parameters on the module

performance were investigated. The membrane module is integrated with a shell and tube heat exchanger to utilize the heat of brine in the system. Also, a solar collector is used to provide the thermal energy needed for heating of the feed stream.

2. Mathematical Model

We built a three-dimensional (3D) mathematical model to simulate a coupled system of momentum, heat, and mass transfer in a hollow fiber membrane module using COMOSL Multiphysics software.

2.1. Membrane Distillation Model

In the DCMD process, two water streams including the saline and distillate streams pass through the lumen and in the shell side of the module. The hydrodynamic behavior of the system can be modeled by solving Navier-Stokes equations for an incompressible fluid [6,7]. Figure 1 shows the schematic of a single hollow fiber membrane in its control volume, the location of feed (in the shell) and distillate (in the lumen) streams, as well as a diagram of a laboratory-scale solar-assisted membrane distillation process.

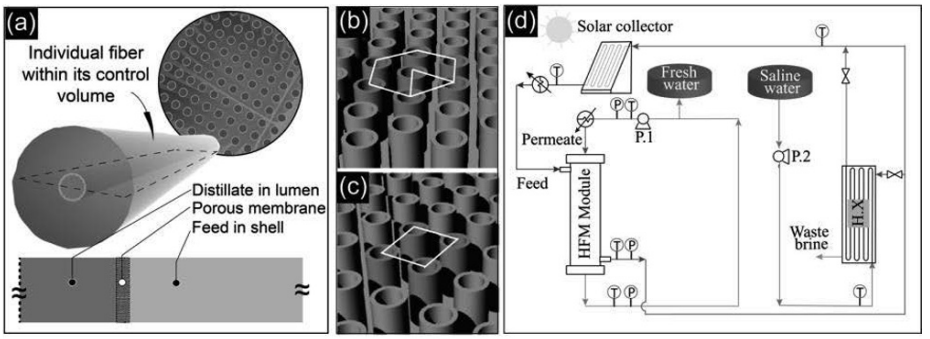

Figure1. The schematic of the hollow fiber membrane module configuration and a lab-scale membrane distillation setup. (a) an individual fiber in its control volume (the cross-section representation is not to scale); (b) hollow fiber membranes in the close-packed configuration; (c) hollow fiber membranes in the square configuration; (d) the schematic of a lab-scale solar-assisted membrane distillation process.

2.1.1. Energy Transfer

The energy balance equation for the feed and distillate streams includes both convection and conduction terms [8]. The heat is transferred between feed and distillate streams by conduction through the membrane.The energy transfer equations were written for the three subsystems of the saline stream, membrane, as well as distillate stream.

2.1.2. Mass transfer

The vapor transfer in the hollow fiber membrane can be described using two primary diffusional terms, Knudsen and molecular diffusion, whose significance can be determined using the membrane pore size and mean free path of molecules [8,9].

The mass transfer equation in the hollow fiber membrane in the radial direction can be defined as [8]:

$$J = -\frac{D_{eff}}{RT_m}\Delta p_w \quad (1)$$

where, Δp_w is the gradient of the partial pressure of water vapor across the membrane, determined using Antoine's equations [6,10].

The effective diffusion coefficient can be defined as follow [9,11]:

$$D_{eff} = \frac{\varepsilon}{\tau}\left(\frac{1-\frac{\bar{p}_{w,pore}}{P_t}}{D_{w-a}} + \frac{1}{D_{kn}}\right)^{-1} \tag{2}$$

where, ε and τ are porosity and tortuosity of the hollow-fiber membrane; D_{w-a} and D_{kn} are molecular and Knudsen diffusion coefficients, respectively [8,12]:

$$D_{w-a}\left[m^2 s^{-1}\right] = \frac{1.895\times10^{-5}\ T_m^{2.072}}{P_t} \qquad 273\ [K] < T_m < 373\ [K] \tag{3}$$

$$D_{kn} = \frac{4d_p}{3}\sqrt{\frac{R_g T_m}{2\pi M_w}} \tag{4}$$

$\bar{p}_{w,pore}$ in equation (2) is the average partial pressure of water in the pore. It can be determined using Antoine's equations at the average temperature of the membrane (T_m)– the average temperature of feed and distillate streams at the membrane interface.

2.2. Heat Exchanger and Solar Heater

A shell-tube heat exchanger can be utilized to preheat the feed entering the system using the heat of waste brine. The effective heat transfer area of the heat exchanger was assumed to be equal to 1.22 m^2. The overall heat transfer coefficient, U, was calculated to be equal to 1500 W/m^2K [13]. The feed recirculating in the system is mixed with a constant amount of preheated fresh feed (to control the salinity in the feed line) and flows through a solar collector before entering the hollow fiber membrane module. The heat transfer rate, Qc, gained by the feed in the solar collector is given by:

$$Qc = \dot{m}_f C_{p,f}\left(T_{co} - T_{ci}\right) \tag{5}$$

where, $\dot{m}_f$ and $c_{p,f}$ are the mass flow and specific heat of the feed, respectively; T_{co} and T_{ci} are the outlet and inlet temperatures of the feed from and to the collector, respectively.

The instantaneous efficiency of the solar collector, η, is defined by the following equation:

$$\eta = \frac{Qc}{A_c G_T} \tag{6}$$

where, A_c is the collector area, and G_T is the averaged solar irradiance on a tilted surface. The efficiency of solar collector is related to the optical properties of the collector, as well as the ambient conditions during the operation. The following correlation is used to find the efficiency of solar collector [14]:

$$\eta = \eta_0 - a\frac{T_{cm} - T_a}{G_T} - b\left(\frac{T_{cm} - T_a}{G_T}\right)^2 \tag{7}$$

where, η_o, a, and b are constants that can be found experimentally. T_{cm} and T_a are the mean temperature in the collector and the ambient temperature, respectively. The parameters η_o, a, and b are provided by the manufacturers of the collectors. In this study, the parameters of "Apricus ETC-30" collector that has a gross area of 4.4 m^2 ($\eta_o = 0.46$, $a = 0.802$, and $b = 0.005$) were used [14]. Accordingly, the efficiency of the solar collector was calculated to be 0.4299 for an averaged solar irradiance, G_T, of 800 W/m^2 and ambient temperature of 25°C.

3. Results and Discussions

3.1. *Effect of packing configuration*

Two different packing configurations—close-packed and square— were considered to investigate the effect of packing on the performance of hollow fiber membrane modules. Figure 2.a shows the normalized permeate flux for the two packing arrangements. The results indicate that the permeate flux for the close-packed configuration is on average 18% higher than that of square configuration.. Figure 2.b also displays the temperature difference between membrane surface and bulk flow at the feed side for both close-packed and square configurations. This temperature difference can be translated into the temperature polarization parameter (θ) — an important parameter in MD showing the temperature gradient existing between bulk flow and membrane-flow interface. The feed-side temperature polarization of the two different configurations was calculated using the following equation [6]:

$$\theta = \frac{T_{mf} - T_{md}}{T_f - T_d} \tag{8}$$

Where T_f and T_d are the bulk temperature of feed and distillate streams, respectively. Also, T_{mf} and T_{md} are the temperature of the membrane at the feed and distillate sides, respectively.

The calculations showed that the temperature polarization of both configurations remains almost constant along the length of the membrane. However, the temperature polarization issue is less for the close-packed configuration; the value of θ for close-packed and square configurations (module length=20 cm) was 0.90 and 0.85, respectively, where the value of unity is an ideal case. For this reason, the close-packed configuration was selected to further study the effect of system parameters on the permeate flux and thermal efficiency.

To determine the effect of the packing design on the performance of close-packed configuration, a dimensionless parameter (R/a), the ratio of outer diameter to the center-to-center distance of hollow fiber membranes, is defined. The R/a parameter is equal to 0.5 when the fibers are adjacent to each other. In this case, significant active surface areas in the module will be unavailable. Additionally, this condition results in a significant pressure drop and flow misdistribution due to spatial constriction. The simulations were performed for different R/a parameters. Figure 2.c shows that, for all fiber diameters tested, the increase in the R/a does not affect the permeate flux, because the process is mass transfer limited at R/a value of less than 0.45. The permeate flux drops when R/a reaches the values higher than 0.45. This observation can be attributed to the overlapping thermal boundary layers and that the increase in the transmembrane thermal conduction, pushing the process towards a heat transfer limited regime at R/a=0.5.

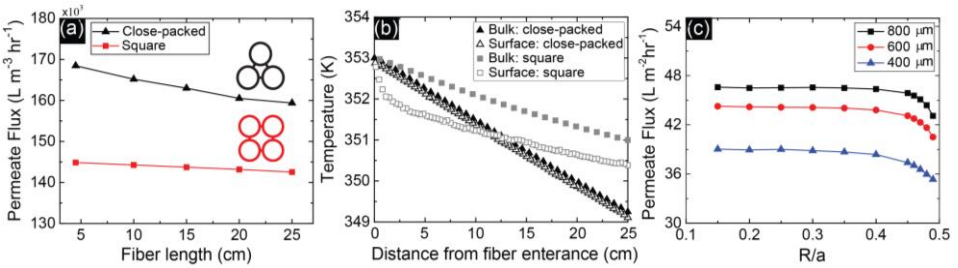

Figure 2. (a) Effect of packing configuration on the permeate flux; (b) membrane surface and bulk temperature of fiber with 25 cm length in close-packed and square configurations. (c) The effect of fiber-to-fiber spacing on the normalized permeate flux for membranes with various diameters. Here, R is the outer radius of the membrane; a is the center-to-center distance of neighboring fibers. The feed and distillate inlet temperatures are 17 °C and 80 °C, respectively. The fiber porosity and tortuosity are set at 74% and 2.5, respectively. For (a) and (b), the membrane outer and inner radii were kept constant at 400 μm and 300 μm, respectively.

4. Comparison of experimental and computational results

Feed temperature is one of the most critical parameters in the MD process because it influences water partial pressure gradient existing across the membrane. Figure 3.a shows the effect of feed temperature on the permeate flux for two different hollow fiber membranes. The results indicate that the permeate flux increases with feed temperature. The modeling results were in good agreements with the experimental data when the tortuosity parameter was set to be equal to 2.5 and 8. The effect of tortuosity and feed temperature on the permeate flux of the system is also shown in Figure. 3b. The permeate flux increases with the increase in the feed temperature and the consequent increase in the temperature gradient across the membrane.

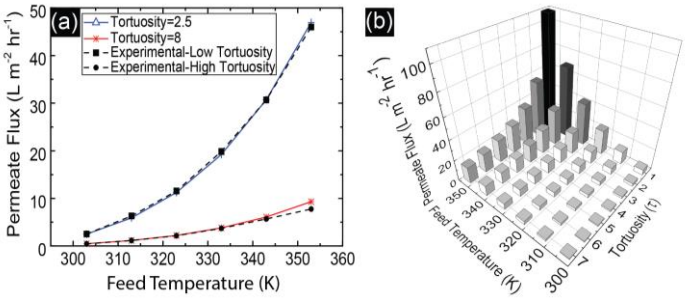

Figure 3. (a) Comparison between experimental results for the permeate flux of two hollow fiber membranes with low and high tortuosity and the prediction of the model for the membranes in a close-packed configuration[15]; (b) effect of feed temperature and tortuosity on the permeate flux.

5. Concluding Remarks

We developed a multiphysics model to investigate the impact of design and process parameters on both permeate flux and energy efficiency of hollow fiber membrane modules used in a direct contact membrane distillation (DCMD) process. The simulation

results showed that the permeate flux for this system can be enhanced as high as 18% by choosing and fine-tuning the packing configuration of the hollow fiber membranes. It was found that the close-packed configuration provides the maximum permeate flux and energy efficiency for the module, if the ratio of the fiber radius to the center-to-center distance between neighboring fibers, is properly set.

Abstract

This work proposes one kind of closed wet cooling tower (CWCT) equipped with longitudinal finned tubes, and develops a two-dimensional numerical model using FLUENT. The Navier-Stokes and *k-ε* equations are applied to calculate the vapor flow and Reynolds stress. Important operational/structural parameters such as the inlet air angle and velocity are analyzed by the multi-fields synergy theory, in which the increment in synergy degree between the velocity field, temperature field and humidity field can enhance the heat and mass transfers. The results show that the increase in fin number, inlet air velocity and decrease in fin height are conducive to the distribution uniformity of vortex and air turbulence in CWCT, which improves the field synergy degree between the velocity, temperature and humidity. With the alteration of air inlet angle, the field synergy degree is optimal at the angle of 45°, in which the heat transfer coefficient and mass transfer coefficient are about 1.15 times and 1.5 times of those of 30°, respectively. Moreover, the field synergy principle revealed that near the fin where the thermal boundary layer is thin, the α of the fin tube cases were about 1.2~1.5 times.

Keywords: closed wet cooling tower; CFD simulation; heat transfer enhancement; multi-field synergy

1. Introduction

Closed wet cooling tower (CWCT) is one type of cooling system that widely used in chemical engineering, buildings, metallurgy enterprises and so on (Xie et al, 2017). With the largely increasing consumption of energy and water in the process industry, improving the thermal performance and water-saving of CWCTs has received substantial concerns. Up to now, various studies have been conducted to investigate the heat and mass transfer process in CWCTs. These investigations mainly focused on exploring the optimal design and operating conditions (Xia et al, 2011) of CWCTs equipped with different tubes(M. Sarker et al,, 2009), such as plain tubes, finned tubes and oval tubes, et al. For example, Hasan and Sirén (2005) compared the oval tube with a plain tube in the CWCTs by experiment researches, and they concluded that the oval tubes were better than the plain tubes by 1.93~1.96 times in terms of the combined thermal-hydraulic performance index. Compared to time-consume by experimental measurements, numerical simulation by CFD has become a helpful tool in thermal hydraulic design and analysis of cooling towers. Hasan and Gan (2002) found that CFD results agree well with the analytical results when the air flow is simulated with an air

supply from the bottom of the tower. Jiang et al. (2013) further revealed that the heat and mass transfer driving forces of a cross-flow CWCT were fairly uniform by establishing a two-dimensional CFD model. The heat transfer enhancement in CWCTs mainly focuses on optimizing operating conditions and novel designed CWCTs with special tubes, e.g. oval tubes. The heat transfer enhancement of the CWCTs installed with longitudinal fin tubes is rarely reported.

Guo *et al.* (1998, 2005) proposed field synergy theory to analyze the convection heat transfer by relating the velocity and temperature gradient fields. Field synergy theory provides theoretical basis for the development of enhanced heat transfer technology. According to field synergy theory, the intensity of convective heat transfer can be changed with the alteration of synergy degree of velocity field and heat flow in the CWCT. Thus, it is important to find a relation between heat transfer enhancement and multiple fields (velocity field, humidity field, temperature filed) for a better application of field synergy principle in CWCTs.

The objective of this study is to investigate the heat and mass transfer performances of CWCTs equipped with longitudinal fin tubes using the field synergy theory. The operating conditions of CWCTs are discussed and analyzed in detail, including the air flow angle and inlet air velocity. On this basis, an optimization model is built for the process of heat and mass transfers. The influence of process parameters (velocities of airflow, humidity, and heat exchange surface characteristics) on the heat and mass transfer performances can be thoroughly analyzed.

2. Theory and model

2.1 field synergy principle

Field synergy theory (Guo et al, 1998) is used to analyse the thermal performance in CWCTs from a local point of view. For a two-dimensional steady simulation, the energy equation can be written as follows:

$$\rho c_p (u\frac{\partial T}{\partial x} + v\frac{\partial T}{\partial y}) = \frac{\partial}{\partial y}(k\frac{\partial T}{\partial y}) \tag{1}$$

The heat source term of the conduction equation is expressed as follows:

$$-q = \frac{\partial}{\partial y}(k\infty\frac{\partial T}{\partial y}) \tag{2}$$

This analogy between convection and conduction heat transfer implies that tube wall heat flux can be obtained by the integration of the convective term in the thermal boundary layer. Integrating Eq. (1) over the thermal boundary layer and writing the convective part in the scalar product form, is given by:

$$\vec{u}\cdot\nabla\vec{T} = \left|\vec{u}\right|\left|\nabla\vec{T}\right|\cos\theta \tag{3}$$

where θ is the synergy angle. It is observed that one of the ways to enhance the heat transfer is to increase the scalar product of the velocity and the temperature gradient, either by reducing the synergy angle θ.

2.2 Governing equations

The species transport models are adopted to simulate the concentration of different species such as humidity in the CWCT, and the general format of the convection-diffusion equation to solve the mass fraction of different species is provided as follows:

$$\frac{\partial}{\partial t}\left(\rho Y_i\right)+\nabla\cdot\left(\rho\vec{v}Y_i\right)=-\nabla\cdot\vec{J}_i+S_i \tag{4}$$

This work employs DPM to simulate the spray water by tracking a large number of droplets, whose momentum governing equation follows the form of Newton's Second Law:

$$\frac{d\vec{u}_p}{dt}=F_D\left(\vec{u}-\vec{u}_p\right)+\frac{\vec{g}\left(\rho_p-\rho\right)}{\rho_p}+\vec{F} \tag{5}$$

2.3 Performance parameters

The performance parameters depend on the geometry and flow conditions in CWCTs. the heat and mass transfer of CWCTs can be described by the heat transfer coefficient α and the mass transfer coefficient β, respectively.

The heat transfer coefficient is expressed as:

$$\alpha=\frac{m_{\mathrm{a}}c_{\mathrm{pa}}}{A}\ln\left(\frac{t_{\mathrm{w}}-t_{\mathrm{a,in}}}{t_{\mathrm{w}}-t_{\mathrm{a.out}}}\right) \tag{6}$$

where m_{a} is the mass flow rate of the dry air, and t refers to the temperature .

The mass transfer coefficient is given by:

$$\beta=\frac{m_{\mathrm{a}}}{A}\ln\left(\frac{i_{\mathrm{w}}^{'}-i_{\mathrm{a,in}}}{i_{\mathrm{w}}^{'}-i_{\mathrm{a.out}}}\right) \tag{7}$$

where i_{a} refers to the enthalpy of the air, the subscripts w refers to the process water, and A is the heat or mass transfer area, respectively. The thermal performances of CWCTs equipped with plain and longitudinal fin tubes are investigated and compared. Specific parameters are shown in Figure 1.

3. Solving model

The FLUENT software was applied for the present numerical simulations, and the governing equations were solved by the finite volume method using the SIMPLE algorithm, and the convective terms in governing equations were discretized by the QUICK scheme with second-order precision. In addition, the convergence criterions, namely the normalized residuals are less than 10^{-4} for the momentum equations and 10^{-6} for the energy equation. The quantity and quality of the meshes are of great important to the accuracy and time of the simulations. In order to generate the most appropriate grid and capture the exact heat and mass transfer, the structured meshes were employed in the computational domain, shown in Figure 2.

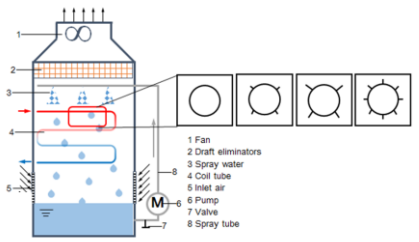

Figure 1 Schematic of the closed wet cooling tower

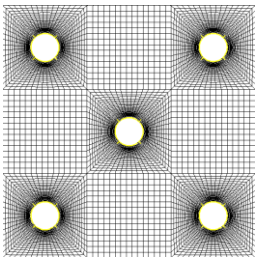

Figure 2 Mesh generation

4. Results and discussion

4.1. Influence of inlet air angle

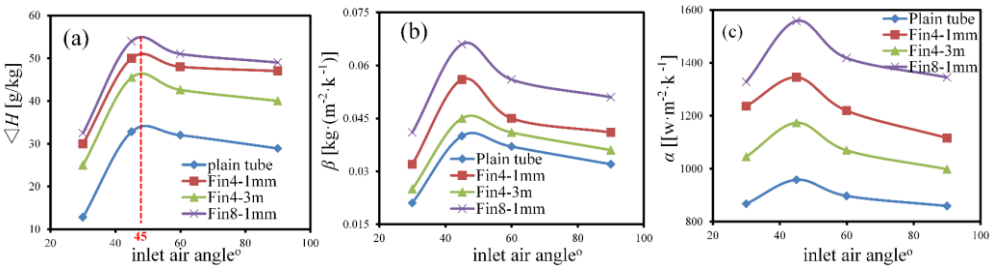

Figure 3 Influences of inlet air angle on (a) humidity difference (ΔH), (b) air-water mass transfer coefficient β, and (c) heat transfer coefficient α

Through numerical simulation, the influences of the inlet air angle on the heat and mass transfer coefficients (Eqs. 10~11) have been investigated under the operating conditions as follows: inlet air temperature 293 K, inlet air velocity 1 m/s, process water temperature 323 K. As depicted in Figure 3 (a~c), the humidity difference(ΔH), mass transfer coefficient(β) and heat transfer coefficient (α) show increasing trends with the inlet air angle ranging from 30° to 45°. However, when the inlet air angle exceeds 45 °, all these performances decrease with the increase in the inlet air angle, indicating that 45 ° is potentially a critical value with respect to the inlet air angle. Moreover, the α and β for the fin tubes are higher than that of plain tubes and these differences become more significant under different fin numbers. The the fin tube case is around 75% higher than that of the plain tube case at the the inlet air angle of 45 °. This is mainly due to the fact that the synergy angle gradually decreases with the inlet air angle ranging from 30° to 45°. This phenomenon can be further explained by the synergy effect of multiple fields in Figure 4 and 5, in which we present the coupling of temperature, humidity and velocity field at the the inlet air angle of 45 °. As shown, the temperature and humidity distribution of the fin tube between the wall surface and bulk airflow can change more rapidly in comparison with those of other tubes. The field synergy degree is optimal at the angle of 45°, in which the heat transfer coefficient and mass transfer coefficient are about 1.15 ~1.5 times than other angles.

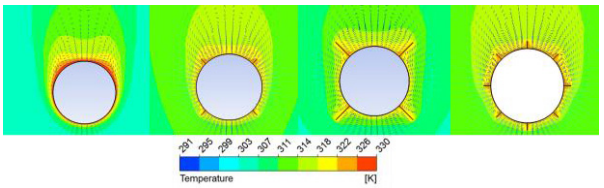

Figure 4 Coupling of temperature field and velocity vector field

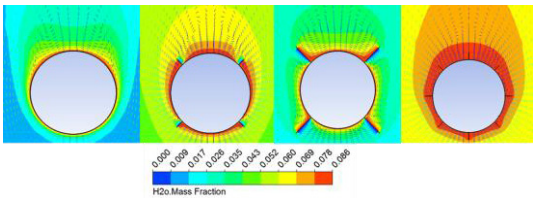

Figure 5 Coupling of humidity field and velocity vector field

4.2. Influence of inlet air velocity

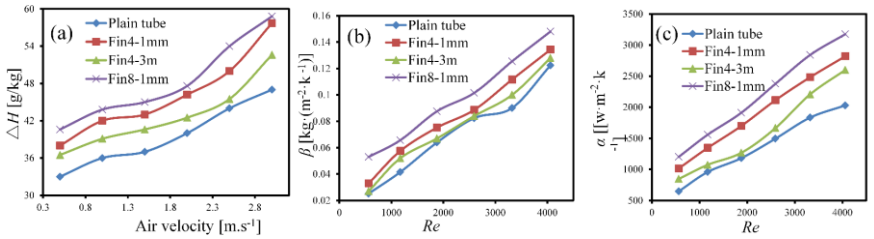

Figure 6 (a~c) shows the humidity difference($\triangle H$), mass transfer coefficient(β) and heat transfer coefficient (α) of the four tube cases with respect to a variable inlet air velocity.

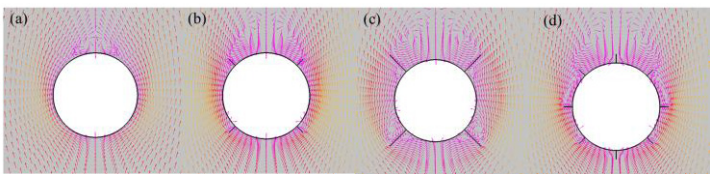

Figure 7 velocity vector field: (a) plain tube, (b) fin4-1mm, (c) fin4-3mm, (d) fin8-1mm

One of the objectives of this study is to explore the influence of inlet air velocity on the heat transfer enhancement of CWCTs. The higher air flow velocity can enhance the heat transfer rate from the spray water to air in the process of the countercurrent contacting of vapor-liquid phase. This enhancement helps to decrease the temperature of the outlet process water to the wet-bulb temperature of the inlet air. Thus, with the rise in air flow velocity, as shown in Figure 6(a~c), the α of fin and plain tube cases increases around 62% and 68%, respectively. Moreover, the α of the fin tube case is about 1.2~1.5 times that of the plain tube case, this is because the fins on the outer surface which leads to a reduction in the synergy angle compared to the plain tube, can effectively disturb and accelerate the movement of falling film. Herein, that is, the Reynolds number and heat transfer coefficient are enhanced, especially in the case of high speed airflow. This phenomenon can be further explained by the synergy effect of velocity fields shown in Figure 7, in which the air velocity of the fin tubes close to the wall surface have the

stronger turbulence intensity among these tubes cases investigated. Overall, we can conclude that the increase in inlet air velocity has a positive effect on the heat and mass transfer in CWCTs.

5. Conclusions

A numerical study had been carried out using plain tubes and fin tubes to enhance the thermal performance of the CWCT. The influences of structure and operating parameters were discussed and the main conclusions have been achieved: The effect of operational/structural parameters including the inlet air angle and velocity were systematically analyzed with the field synergy principle. The α of the fin tube cases was the highest when the air air angle at a critical value 45^o. The field synergy principle revealed that near the fin where the thermal boundary layer is thin, the α of the fin tube cases were about 1.2~1.5 times that of the plain tube case, and the increases of β of the fin tube cases were around 150%.

Abstract

In this work, we address the optimization of an integrated microalgae-based biorefinery through the formulation of a mixed integer nonlinear programming model (MINLP) for the production of astaxanthin and co-products (renewable fuels, bioplastics and green chemical products) reducing the dependency of external energy sources. The proposed model is implemented in GAMS to maximize net present value. Numerical results show the economic feasibility of microalgae-based nutraceuticals production in an integrated biorefinery under the water-food-energy-waste nexus concept (NPV: 336 MM$). Gross profit of the optimal integrated biorefinery is $8,434 per kg of astaxanthin, approximately 30% higher than the obtained when astaxanthin is produced as a single product, with no considerations on water-food-energy and waste nexus.

Keywords: biorefinery, microalgae, nutraceuticals, optimization.

1. Introduction

In the last years, the water-food-energy nexus concept has been promoted as a tool for achieving sustainable development accounting the relationship among these three resources (García & You, 2017). From a nexus perspective, integrated biorefineries, mainly the ones that involve second and third generation feedstocks (Martín & Grossmann, 2017), can help to solve some water-food-energy issues. For instance, developments on algae cultivations as a biorefinery feedstock have promising prospects to address these concerns (Martinez-Hernandez & Samsatli, 2017). Furthermore, many recent emerging waste management technologies lead to incorporate the management of waste streams to the nexus concept, contributing in this way to the global challenges context presented by water-food-energy nexus.

The worldwide nutraceutical market has been increased due to current population and the health trends (Sabol et al., 2017). Astaxanthin global market is estimated at 280 t in 2014 and is further projected to reach 670 t by 2020. Nutraceuticals are food or part of food playing an important role in normal physiological functions that maintain healthy human beings. Powerful antioxidants with application in nutraceuticals, pharmaceuticals, cosmetics and food industries, such as the natural ketocarotenoid astaxanthin, can be obtained under the integrated biorefinery concept.

In this sense, we address the optimization of an integrated microalgae-based biorefinery for the production of astaxanthin including the possibility of co-produce renewable fuels, bioplastics and green chemical products. We also incorporate a potential anaerobic digestion process in order to reduce waste streams and mitigate the dependency of energy sources by means of a combined heat and power cycle.

2. Process Description

The proposed superstructure, shown in Figure 1, involves the production of natural astaxanthin from the microalgae *Haematococcus pluvialis* as well as different route alternatives in order to make it sustainable, under the water-food-energy-waste concept. Main processes are described below.

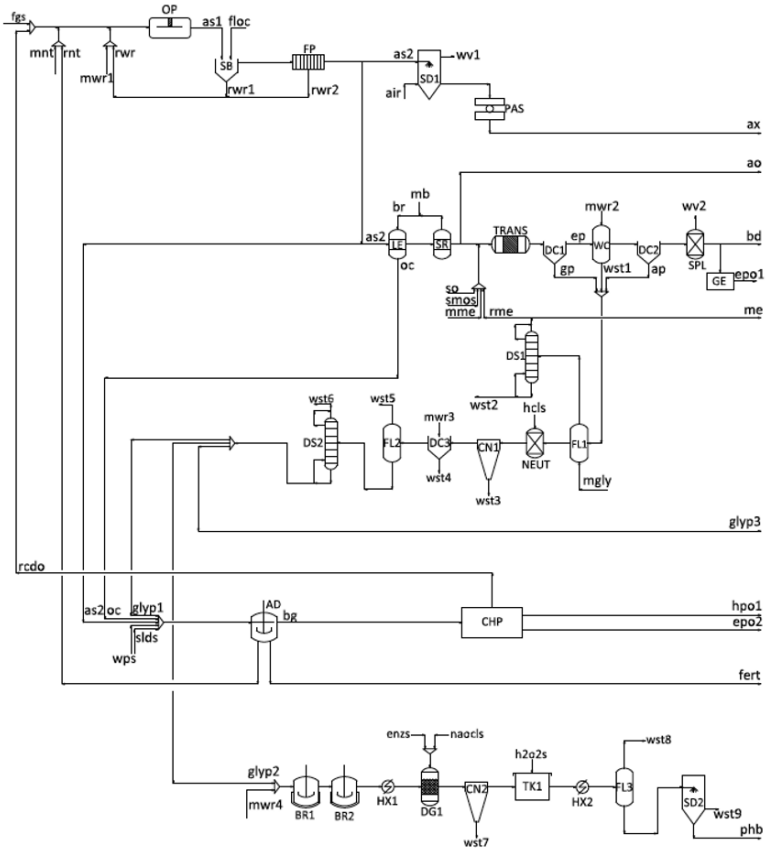

Figure 1. Integrated microalgae-based biorefinery superstructure

2.1. Astaxanthin production process

In this work the cultivation of *Haematococcus pluvialis* in open ponds (OP) is taken into account due to their capability of astaxanthin accumulation, under certain culture conditions. Carbon dioxide can be fed from neighbouring industries flue gases and from process streams, reducing GHG emissions. Nutrients, mainly phosphorous and nitrogen, are incorporated to the cultivation system from residual process streams and/or from external sources. After harvesting (SB) and dewatering (FP) the algae biomass is dried in a spray dryer (SD1) and then cracked by a bed airflow pulveriser (PAS) to obtain the final product.

2.2. Energy, water and waste management

The integrated biorefinery is proposed to be thermal energy self-sufficient and at least 20% of the electrical energy consumption is imposed to be from renewable sources,

aligned with state policies in Argentina. In order to reduce the dependency of external energy sources, biodiesel and its subsequent transformation to electric energy (GE) is proposed from microalgae and/or soybean oil. A combined heat and power cycle (CHP) to transform biogas generated by the anaerobic digestion of substrates is considered in the superstructure in order to satisfy energy constraints. Potential substrates include microalgae biomass, residual microalgae biomass from lipid extraction (oil cake), sludge from waste water treatment plant and waste paper. Water from residual streams in harvesting and dewatering steps as well as a nutrient-rich stream from the anaerobic digestor (AD), are fed back into the microalgae cultivation system, thus reducing external nutrients and water requirements. The potential inclusion of an anaerobic digestor can help into the reduction of waste streams not only from the process, but also from external sources (sludge and waste paper).

2.3. Transportation fuel and packaging

The proposed model considers bulk and packed product transportation from the facility location to a distribution center. Biodiesel can be used as transportation fuel and the requirement amount is considered as a lower bound on biodiesel production. Biodiesel is produced from soybean and/or microalgae oil transesterification (TRANS), with glycerol as a by-product. Glycerol is mostly used for food, cosmetics and pharmaceutical products, but can also be used as raw material for higher added value products as poly(hydroxybutyrate) (PHB). PHB is a biopolymer produced by microorganisms, with similar properties to fossil fuel based polymers. In this work, PHB production must be, at least, the required for main product packaging. Crude glycerol is also included as potential raw material.

2.4. Product portfolio

Under the concept of integrated biorefinery, it is well known that revenues can be increased by producing and selling one or more value-added products that enlarge the existing product portfolio. The development of product portfolio leads to several benefits, such as adjustment of supply to the market, using process flexibility. Potential co-products include: algae oil, biodiesel, purified glycerol, methanol, fertilizers from the anaerobic digestion process and PHB.

3. Mathematical Modelling

The proposed superstructure is formulated as an MINLP problem and implemented in GAMS (Brooke, 2013). The model includes mass balance constraints, energy and correlation constraints, detailed equipment design and cost capital correlations, integer constraints and economic objective function.

3.1. Mass balance constraints

Mass balances are formulated for each unit in the superstructure shown in Figure 1. For reactive units (θ') mass balances are formulated as follows:

$$f_{r,j}^{\theta'} = \sum_{k \in K} f_{\theta',j}^{k} + \sum_{h \in H} \xi_{j,s_h}^{h} \cdot C_h \cdot \sum_{k \in K} f_{\theta',s_h}^{k} \quad \forall\, j \in J \tag{1}$$

where $f_{r,j}^{\theta'}$ is the mass flowrate of component j from reactive unit θ' to outlet stream r, in kg j/day. $f_{\theta',j}^{k}$ is the mass flowrate of component j from inlet stream k to reactive unit θ',

in kg j/day. ξ_{j,s_h}^{h} is the mass coefficient between components j and s_h for the reaction h, in kg$j$/kg s_h. s_h is the limiting reactant for reaction h. C_h is the limiting reactant conversion for reaction h. f_{θ',s_h}^{k} is the mass flowrate of component s_h from inlet stream k to reactive unit θ', in kg s_h/ day.

3.2. Energy balance constraints

The energy consumed by each process unit is represented by Eq. (2), as follows:

$$EC_{\vartheta} = ECR_{\vartheta} \cdot m_{\vartheta} \tag{2}$$

where EC_{ϑ} is the energy consumption of unit ϑ (it includes θ and θ' units), in kWh/day. ECR_{ϑ} is the energy consumption ratio of unit ϑ, in kWh/kg. m_{ϑ} is the mass flowrate relative to unit ϑ, in kg/day.

3.3. Cost capital constraints and equipment design correlations and

Capital cost for equipment related to the anaerobic digestion section, microalgae cultivation step, combined heat and power cycle and astaxanthin production process has been calculated using the six-tenths rule. Cost equations involved in the remaining section of the integrated biorefinery and detailed equipment design correlations for each unit have been formulated following the methodology presented by García Prieto et al. (2017).

3.4. Integer constraints

Potential units in the proposed superstructure are associated to binary variables y_i. Big M constraints are formulated in order to establish the existence (y_i=1) or non-existence (y_i=0) of the unit.

3.5. Inequality constraints

Upper bounds of the main variables involved in the process are shown in Table 1.

Table 1. Major model constraints

Variable		Upper bound
CN_{op}	Maximum Carbon: Nitrogen ratio	25
$-CN_{op}$	Minimum Carbon: Nitrogen ratio	-20
wsp_{AD}	Available waste paper	38,500 t/y
sld_{AD}	Available sludge	12,700 t/y
NER_{EE}	Minimum electric energy self-supplied	5
NER_{HE}	Thermal energy self-sufficiency	1
PHB_{prod}	Industrial scale of a PHB plant	10,000 t/y
$-PHB_{prod}$	Minimum requirement for packaging	-2,520 t/y
BD_{prod}	Industrial scale of a biodiesel biorefinery	47,500 t/y
$-BD_{prod}$	Minimum requirement for transport	-198.25 t/y

Particularly, net energy ratio (NER) constraint is given for ensure a minimum of self-supplied energy. For electric and heat NER calculations (NER_{EE} and NER_{HE}), the following equations are implemented in the model.

$$NER_{EE} = \frac{EE_{C_{bd}} + EE_{C_{ast}} + EE_{C_{pha}} + EE_{C_{AD}}}{EE_{P_{bg}} + EE_{P_{bd}}} \quad (3)$$

$$NER_{HE} = \frac{HE_{C_{bd}} + HE_{C_{ast}} + HE_{C_{pha}} + HE_{C_{AD}}}{HE_{P_{bg}}} \quad (4)$$

where, $EE_{C_{bd}}$, $EE_{C_{ast}}$, $EE_{C_{pha}}$, $EE_{C_{AD}}$, $HE_{C_{bd}}$, $HE_{C_{ast}}$, $HE_{C_{pha}}$, $HE_{C_{AD}}$, are the electric and heat energy consumed in biodiesel, astaxanthin, PHA and anaerobic digestion process, respectively. $EE_{P_{bg}}$ and $HE_{P_{bg}}$ are the electric and heat energy obtained by biogas generation and $EE_{P_{bd}}$ is the electric energy given by biodiesel production.

3.6. Objective function

Net present value (NPV) is the objective function given by Eq. (5). It includes total capital investment (I), which involves fixed capital and working capital (10% of fixed capital). Furthermore, the objective function considers revenues from sales (Rev), manufacturing cost (C_{manuf}), raw materials cost (C_{rawmat}) and utilities cost (C_{utilit}), in \$/y. In order to take into account time value of money, each cash flow is discounted back to its present value (a^{-1}) considering a project lifetime of 15 years and a discount rate of 10% (Ramos et al., 2017).

$$NPV = -I + a^{-1}.\left(Rev - C_{manuf} - C_{rawmat} - C_{utilit}\right) \quad (5)$$

4. Numerical Results

The MINLP model has 601 continuous variables and 7 binary variables, with 961 constraints. It was solved with DICOPT (CONOPT and CPLEX) in 65 s. The optimal configuration and the numerical results for 12 t/y of astaxanthin production, corresponding to NPV maximization, is shown in Figure 2. The NPV and gross profit of the integrated biorefinery is 336 MM\$ and 8,434 \$/kg astaxanthin, respectively. $\boldsymbol{NER_{EE}}$ and $\boldsymbol{NER_{HE}}$ are 2.134 and 1, respectively, for the optimal configuration. If astaxanthin is produce as a sole product and no renewable energy and materials are considered, NPV for the production of the same amount of astaxanthin is 377 MM\$ and a gross profit of 6,419 \$/kg astaxanthin.

5. Conclusions

In this work, a detailed MINLP model for an integrated microalgae-based biorefinery is formulated to determine the optimal process configuration, based on NPV maximization. Optimization results show the economic feasibility of astaxanthin production in an integrated biorefinery under the water-food-energy-waste nexus concept, with a gross profit of 8,434 \$/$kg_{astaxanthin}$, 30 % higher than the obtained when astaxanthin is produced as a single product. The nutraceuticals and co-products sales (renewable fuels, bioplastics and green chemical products) allow obtaining a NPV of nearly \$ 336 MM. Even that this NPV value is lower than the one where astaxanthin is a sole product (377 MM\$), this could be reverted with a higher project lifetime. Our future work is to develop a bicriteria

optimization problem, including not only the economic benefits but also de environmental impact.

Abstract

Efficient land use in agricultural systems is a complicated decision-making problem with resource competitions and conflicting objectives. Systematic thinking based on food-energy-water (FEW) nexus is a necessity for modeling and optimization of the systems. However, challenges arise in making decisions while encountering conflicting objectives, limited data and coupling components. To address these challenges, we developed a global optimization-based land allocation framework, which provides an adaptive data-driven modeling method based on limited realistic data to predict yields for production components, a FEW index to help solve the multi-objective optimization problem and carry out assessments. Computational results indicate that the framework can provide valuable production models and a comprehensive FEW index to select strategies for optimal land allocation and limit stresses in the FEW nexus.

Keywords: land use, nexus, data-driven modeling, global optimization

1. Introduction

Agricultural land use optimization is a complicated process as it consists of allocating not only various species to different areas but also activities and resources based on different strategies of land allocation (Bergstrom et al., 2013). It often involves policy-makers, stakeholders, spatial factors, constraints, dynamic conditions and multiple components, which need systematic thinking for modeling and optimization. To achieve a better understanding of the relationships among nexus elements and make optimal decisions, all these challenges have to be addressed. (Miralles-Wilhelm et al., 2016).

Complications arise form conflicting interests over different stakeholders, such as profit, food demand, environmental penalty, and use efficiency of resources. Data limitation is another complicating factor. Many studies focus on modelling the production components as complicated model sets that take into consideration many factors such as climate change and biological properties (Memmah et al., 2015). However, modeling

with increasing considerations need more data and parameters, which is often unrealistic for application purposes or optimization (Jones et al., 2017). Since agricultural systems with multiple components need a model family to represent production processes, the FEW nexus interactions among them also need to be quantified to facilitate nexus wide decision making.

These challenges call for systematic modelling and optimization methods that can make nexus wide decisions for the systems. In this work, we develop a global optimization-based land allocation framework, which includes an adaptive modelling method based on limited realistic data for predicting production components, and a series of FEW index for achieving multi-objective solutions and quantitative assessments.

2. The Modeling and Optimization Framework

Figure 1 briefly illustrates the framework for a land use allocation problem in agricultural systems. The tasks of the problem are to decrease the stresses between land resources (food-energy-water) and maximize the benefits based on land conditions and balance the interests from different stakeholders. The resulting multi-objective optimization problem can be solved by a three-step method.

Step 1: Data collection and pre-processing. Data in the system includes input-output data from production units, economic data from social surveys, and other conditions, such as climate and soil data. The data pre-processing includes outlier detection, data normalization, data grouping based on FEW flow for production units.

Step 2: Adaptive Data-driven modelling. As the input-output data have been processed, the most important step is to simulate the output variables response to changes in the input variables for production components. These models are constructed by using a data-driven modelling method. Take crop models as examples, a number of simulated experiments are defined based on local conditions (soils, climate, irrigation, crop properties and sowing dates). By parametrically modifying the amount of input variables X, such as water, fertilizer and seeds applied to a crop in each simulated experiment, simulators can estimate its yield response $F^{sim}(X)$. The resulting input-output data points $s \in S^{modeling}$ can be fitted to yield prediction models M.

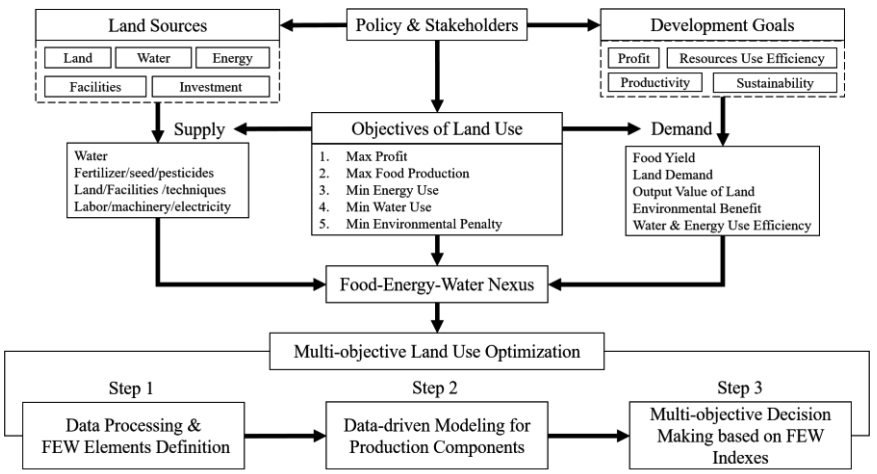

Figure 1. Framework of land use optimization.

For model M with certain size K, parameters α_k are estimated by minimizing the sum of absolute model error $e_n(X_n)$ over training data points $n \in \mathrm{S}^{\mathrm{train}}$ (Cozad et al., 2014). The optimization problem formulations are as follows (Eq. (1)):

$$
\begin{aligned}
&min \sum_{n \in \mathrm{S}^{\mathrm{train}}} |e_n(X_n)| \\
&\text{s.t.} \quad F^{sim}(X) = \sum_{k=1}^{K} \alpha_k f^k(X), k = 1, 2, \ldots, K \\
&F_n^{obs}(\mathrm{X_n}) = F_n^{sim}(X_n) + \epsilon_n(X_n), n = 1, 2, \ldots, N_1 \\
&\mathrm{ER}(X_m) = \frac{1}{N_2} \sum_{m \in \mathrm{S}^{test}} |F_m^{sim}(X_m) - F_m^{obs}(X_m)| / F_m^{obs}(X_m), m = 1, 2, \ldots, N_2 \\
&e_n(X_n) \geq \epsilon_n(X_n), \ \mathrm{e_n(X_n)} \geq -\epsilon_n(\mathrm{X_n}) \\
&\sum_k y_k = \mathrm{K}, \ \mathrm{y_k} \in \{0,1\}, -\mathrm{M}y_k \leq \alpha_k \leq M\mathrm{y}_k
\end{aligned}
\tag{1}
$$

The surrogate function $F^{sim}(X)$ is a linear combination of K nonlinear basis functions. $F^{obs}(X)$ is the observed output data from simulating experiments. By solving this MIP problem with increasing size K until the test error ratio $\mathrm{ER}(X_m)$ meet the tolerance, candidate size K of model M can be obtained. This modelling procedure is repeated for I times by using 10-fold cross validation methods. Candidate K with maximal frequencies is selected as the optimal size of model M, then the parameter estimation of model M with size K can be solved by using the whole modeling data $S^{modeling}$.

Though accurate surrogate model M with small size K can be achieved by data-driven modelling methods, available realistic data for modelling are sparse. As the optimal surrogate model $\mathrm{M^K}$ based on simulating experiments is generated, an adaptive strategy based on limited realistic data is designed to decrease the true error of surrogate models. Key ideas of the strategy include (a) calculation of the similarity scores $Sim(s, \mathrm{S^{real}})$ between real data $\mathrm{S^{real}}$ and modelling data points $s \in S^{modeling}$, modeling data points with lowest similarity scores are defined as bad samples $\mathrm{S^{bad}}$; (b) renewal of the modeling data $S^{modeling}$ by adding real data points $\mathrm{S^{real}}$ and deleting bad samples $\mathrm{S^{bad}}$, then the surrogate model M is rebuilt by previous modelling methods. An independent real data set $\mathrm{S^{validate}}$ is used to estimate true model errors during the adaptive modelling.

Step 3: Multi-objective Optimization based on integrated FEW index. Since a family of unit models are developed to predict yields by proposed modeling methods, connections among them are quantified by using FEW flows. The land use problem is defined as a multi-objective MINLP problem by considering maximum profit (P), maximum food yield (F), minimum energy use (E), minimum water use (W) and minimum environmental penalty (En). These objectives are calculated based on resource use, cost and yield output from different pieces of land. $\mathrm{P_{sc}}$, $\mathrm{F_{sc}}$, $\mathrm{E_{sc}}$, $\mathrm{W_{sc}}$ and $\mathrm{En_{sc}}$ are indexes for these objectives, respectively. To comprehensively assess multiple solutions and achieve a balanced final solution, a FEW-Nexus index GA is developed to solve the multi-objective optimization problem by maximizing its value (Eq. (2)).

$$d = \frac{d-d_{\min}}{d_{\max}-d_{\min}}, d = \mathrm{P_{sc}},\ \mathrm{F_{sc}}\ ;\ d' = 1 - \frac{d'-d'_{\min}}{d'_{\max}-d'_{\min}},\ d' = \mathrm{E_{sc}}, \mathrm{W_{sc}},\ \mathrm{En_{sc}}$$
$$\mathrm{GA} = \frac{1}{2}(\mathrm{P_{sc}F_{sc}} + \mathrm{F_{sc}E_{sc}} + \mathrm{E_{sc}W_{sc}} + \mathrm{W_{sc}E_{sc}} + \mathrm{E_{sc}P_{sc}})\sin(72°) \quad (2)$$

3. Case Study: Land Allocation for A Crop-livestock System

The methodology for the framework is illustrated through a case study for a crop-livestock system in Yucheng Experimental Station belonging to Chinese Academy of Sciences, China. Figure 2 presents the superstructure for the system. The design supplies two-by-two land pieces for crops and livestock production units, respectively. The production units are two crops (wheat, corn) and two livestock (two kinds of layer chicken). It also includes multiple decision options for water supply, energy use, food production, and treatments of waste and byproducts. Previous modelling method is used to build the prediction models for crops, CPLEX solver is used to solve the MIP problem. Empirical models are used as prediction models for livestock. The resulting land use problem of this system is a MINLP problem, which is solved using solver ANTIGONE.

4. Results and Discussion

4.1. Component models and good-of-fit performance

Models for production components in the system are reported by Table 1. The good-of-fit performance for crop models by using proposed methods is illustrated in Figure 3. Strategy 1 is the common method by adding new realistic samples without adjusting bad samples, strategy 2 is the proposed strategy by considering bad samples. The results show strategy 2 has better and more robust performance especially when increasing adaptive times of realistic samples. The yield response functions of livestock include production ratio functions $Y_e(t)$ and growth curve models $Y_w(t)$, which are generated based on empirical functions (Savegnago et al., 2012).

Table 1. Models for production components in the crop-livestock system.

Component	Production Models
Crop 1	$\mathrm{F(x)} = -12150.4\log(0.001x_1) + 1197.3(1 - \frac{1}{0.01x_2+1}) - 2.03 \cdot 10^{-4}x_2x_3 + 13767.2\sqrt{0.001x_1}$
Crop 2	$\mathrm{F(x)} = -73497.3(0.01x_1)^2 + 0.01036x_2x_3 + 10235\sqrt{0.001x_1}$
Livestock 1	$Y_e(t) = 0.945(1 - e^{-0.968t+3.796})e^{-0.006t}$ $Y_w(t) = 1.771e^{-3.158e^{-0.132t}}$
Livestock 2	$Y_e(t) = 0.933(1 - e^{-0.469t+0.0005})e^{-0.017t}$ $Y_w(t) = 1.964e^{-3.777e^{-0.15t}}$

4.2. Optimal solutions for multiple objectives

The results of optimization for the five objectives and the integrated objective based on index GA are reported in Table 2. Optimal solutions for different objectives provide multiple decisions for land use, food yield, energy and water use, and choices of technique treatments in the system. The radar maps of proposed FEW indexes in Figure 4 show that, the solutions by maximizing index GA can give more balanced designs for decision making rather than the other five solutions based on single objectives.

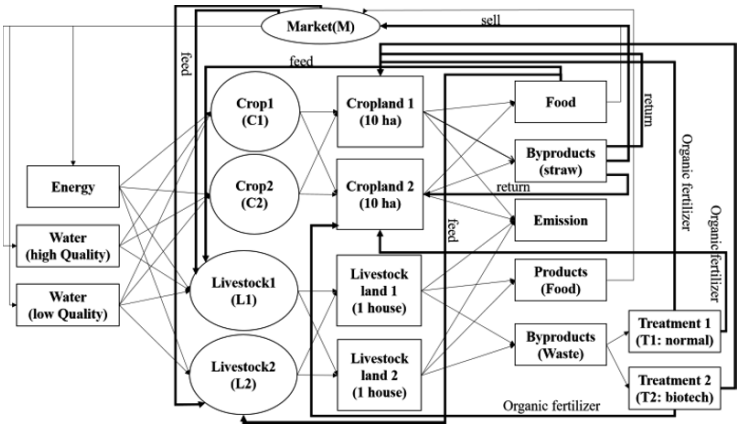

Figure 2. A superstructure design for the crop-livestock land use system.

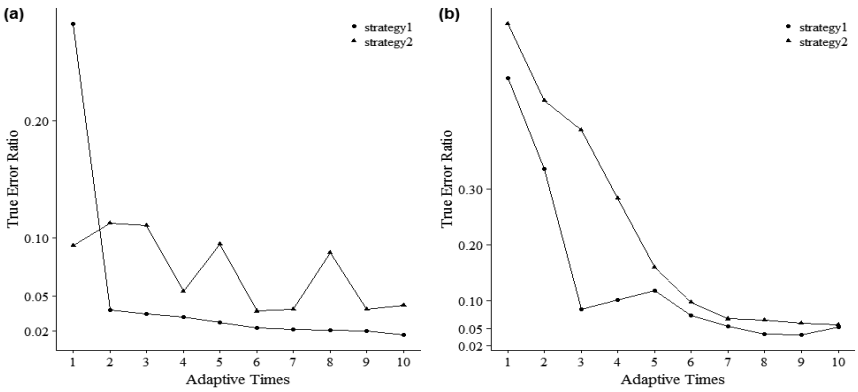

Figure 3. Good-of-fit performance of adaptive modelling methods.

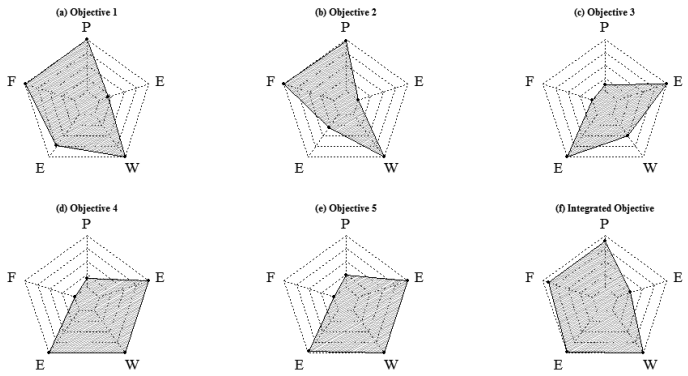

Figure 4. Evaluation of solutions for multi-objective problems based on FEW indexes.

Table 2. Optimal designs of land and resources for multiple objectives.

Optimal design	Max P	Max F	Min E	Min W	Min En	Max GA
Profit (yuan)	871,567	823,715	-220,218	-145,218	-83,423	743,005

Layer time (w)	63	63	4	4	4	56

5. Conclusions

Agricultural land use decision-making problems call for a systematic framework considering conflicted objectives, limited data and coupling components. This work takes a crop-livestock system as an instance, and illustrates a global optimization-based land allocation framework, including methods to achieve multi-objective land use solutions based on a FEW index, and develops an adaptive data-driven modelling method to predict yields for production components based on limited realistic data.

Abstract

The importance of developing micro-combustor with high efficient is apparent, due to the demand for miniature power source with high energy density. A two-dimension model of micro-combustor for a premixed methane/air mixtures combustion process, under the condition of stable burning, was constructed. The availability and the entropy generation of the combustion were analyzed. The minimum of entropy generation was set as the objective function, subject to a constraint of constant viscous dissipation. Through variation calculation, an optimal velocity field and associate body force field were obtained. Such a solution provided a thermodynamic limit to the enhancement of the combustion process. Inspired by the flow field obtained by the optimization, an improved internal structure of the micro-combustor that gave a higher efficiency was suggested and analyzed. The results obtained can provide a guideline for the design of micro-combustor with high burning efficiency.

Keywords: Micro-combustors; combustion efficiency; entropy generation minimization; optimal design

1. Introduction

Micro-combustors first suggested by Epstein and Senturia (1997) are kinds of miniature reactors, which have attracted considerable attentions. This is due to the increasing demand for portable power source of high energy density, such as miniaturized heat engines, gas turbines, air vehicle, thruster, thermo-photovoltaic etc. The importance of developing micro-combustors with higher efficiency is apparent facing to the growing concern of energy, economy and environment. The efficiency of the combustion process depends on the fluid flow pattern that is coupled with the heat and mass transfers and the reaction inside a micro-combustion chamber. Hüseyin Yapıcı et al. (2005) investigated the entropy generation rates of a methane-air burner for different equivalence ratios and swirl numbers. M. Bidi et al. (2010) optimized the burner by entropy generation minimization method, and improved the efficiency by changing the flame location. Uttam Rana et al. (2014) identified the major sources of exergy destruction and calculated the second law efficiency in different conditions. H. R. Arjmandi et al. (2015) investigated the effects of different parameters on the entropy generation and proposed the optimal value of each parameter based on EGM method. Most of these previous works on increasing the combustion efficiency, however, rely on the analysis-improvement scheme, in which the improvement of the structural or

operational parameters is based on the feedback from the performance tests by means of either experiment or numerical simulation.

For any operating condition, there should be an optimal fluid flow pattern that gives the highest combustion efficiency in terms of the reaction and heat or mass transfer inside a micro-combustion chamber. In the present work, basic ideas of Process Systems Engineering were used to develop a methodology for the optimal design of the flow pattern to give maximum combustion efficiency in a micro-combustion chamber. The combustion process was regarded as a system, and its behaviours can be manipulated by free variables so that a criterion that has relevance to the combustion efficiency can be minimized or maximized. In our work we took the entropy generation rate, which reflects the irreversibility of the combustion process as the objective function to be minimized and the mass and heat conservation equations as the constraints. We regard entropy generations due to burning reaction and heat transfer as the major sources of the irreversibility in the combustion system, and so the sum of these two entropy generations was taken as the criterion. The optimization problem was solved through variation calculation for a velocity field and associate body force field that give the combustion process the maximum thermodynamic efficiency. The proposed method was illustrated by an example, and optimal structure designs approaching to the thermodynamic limit of the highest efficient micro-combustor were discussed.

2. Optimization method

2.1. Numerical model

Figure 1: Schematic diagram of the micro-combustor

The schematic diagram of the problem is shown in figure.1. The width of the micro-combustor model was selected 2 mm, the length was 4 mm. For combustion stability (Norton and Vlachos, 2003, Norton and Vlachos, 2004), the boundary conditions are set as follows: the inlet velocity is 0.3 m/s; the temperature of the mixture at the inlet is 500 K, and the equivalence ratio, φ, is 0.9. The wall of the combustor is assumed adiabatic.

The governing equations include the continuity, momentum, energy conservation and mass conservation equations for a steady state gas flow.

The momentum equation is given by Eq. (1), where $\boldsymbol{F}$ is the body force which can be interpreted as the source of the enhancement of chemical reaction process.

$$(\rho\mathbf{U})\bullet\nabla\mathbf{U} = -\nabla P + \mu\nabla^2\mathbf{U} + \mathbf{F} \tag{1}$$

2.2. Availability analysis

The availability, or exergy, the maximum theoretical work obtained when the system interact with the environment, can be an evaluation criteria to measure the energy efficiency of a process.

The second law efficiency as the evaluation criteria of the process is defined as:

$$\eta = \frac{(\sum A)_{in} - I}{(\sum A)_{in}} \tag{2}$$

where I is the thermodynamic irreversibility, and is given by

$$I = T_{ref} \iiint \sigma \tag{3}$$

In the process of combustion of methane, the irreversibility is mainly due to the heat transfer and chemical reaction (Arjmandi and Amani, 2015, Bidi et al., 2010, Rana et al., 2014). The entropy generation rate can be approximately expressed as the sum of contributions of these two effects.

$$\sigma \approx \sigma_{cond} + \sigma_{ch} \tag{4}$$

$$\sigma_{cond} = \frac{\lambda}{T^2}(\nabla T)^2 \tag{5}$$

$$\sigma_{ch} = -\frac{1}{T}\omega_{ov}\Delta_r G_m \tag{6}$$

2.3. Optimal calculation

Based on the availability analysis in section 2.2, the second law efficiency can then be increased by minimizing the irreversibility of the process. So the integral of the total entropy generation is employed as the objective function in the optimization problem. And this objective function is given by

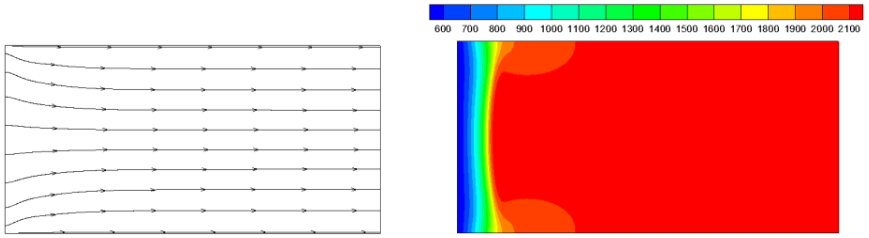
$$\min J^* = \iiint_{\Omega}\left[-\frac{1}{T}\omega_{ov}\Delta_r G_m + \frac{\lambda}{T^2}(\nabla T)^2\right] d\Omega \tag{7}$$

The combustion process must satisfy the continuity, the momentum, energy conservation and the mass conservation equations. By restricting the total viscous dissipation to a constant, the problem becomes the minimization of a functional with constraints. To solve the problem, a Lagrange function, which incorporates the constraints with the objective function via Lagrange multipliers, can be formulated. The minimum of the functional can then be calculated by using the Euler-Lagrange equations. Using the obtained velocity $\boldsymbol{U}$, the external body force $\boldsymbol{F}$ which can be known as the driving force to the flow field giving the minimum entropy generation rate, can be computed.

3. Results and discussion

To illustrate the proposed method above, a combustion process in the chamber shown in figure 1 was solved. The package FLUENT 14.5™ was used in the solution for the optimization problem. The UDS (user defined scalar) module was employed to solve the equation set calculated by variation method of the Lagrange function. The UDF (user defined function) module in the package was used to evaluate the body force $\boldsymbol{F}$ through the momentum Eq. (1).

For comparison, the combustion reaction process without optimization was firstly simulated under the condition of $\boldsymbol{F}$ = 0. The results of the streamline and the temperature distribution without optimization are shown in figure 2.



(a) Streamlines (b) Temperature distribution

Figure 2: Streamlines and Temperature distribution without optimization

And then, through solving the optimization problem of formulation (7) in section 2.3 under conditions of different values of viscose dissipation, entropy generations were obtained as shown in figure 3. Figure 3 shows that the minimum entropy generations due to the chemical reaction and heat transfer decreased with the increase of the viscous dissipation, and so did the total entropy generation.

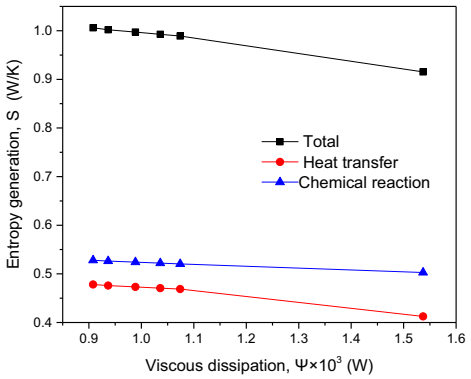


Figure 3: Variations of the entropy generation due to the chemical reaction and heat transfer, and the total entropy generation, with respect to the viscous dissipation

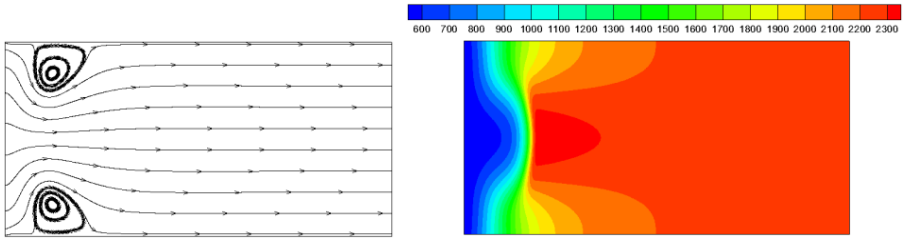


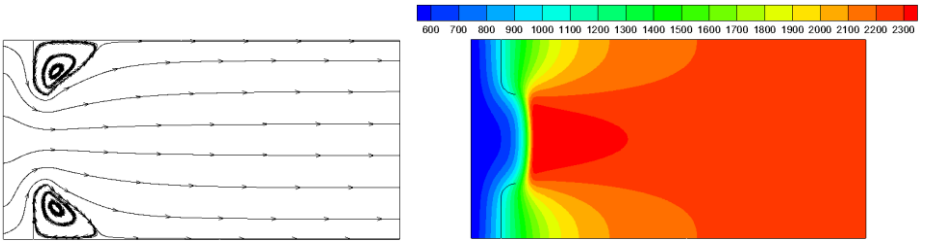
(a) Streamlines (b) Temperature distribution

Figure 4: Streamlines and Temperature distribution with optimization

The streamlines and the temperature distribution corresponding to the last point in figure 3 are shown in the figure 4. Compared with figure 2(a), it can be found that the optimization calculation led to the appearance of two axisymmetric eddies near the inlet of the combustor as shown in figure 4(a). The optimized flow field improved the mixing effects of the reactants and products and reduced the temperature gradient. As a result, the entropy generation of heat transfer decreases. Figure 4(b), compared with figure 2(b), shows the reaction (burning) region was extends towards the outlet of the chamber,

indicating that the reaction rate was more smoothed out with less availability losses of both the chemical reaction and the heat transfer. As a result, the outlet temperature of the combustion with the optimized flow field is higher than that in normal one, as shown in figure 5.

The total entropy generation reduced through optimization calculation and the second law efficiency calculated by Eq. (2) is increased from 71.87 % to 74.40 %, at a little more cost of viscous dissipation.



(a) Streamlines (b) Temperature distribution

Figure 5: Streamlines and temperature distribution in micro-combustor with baffles

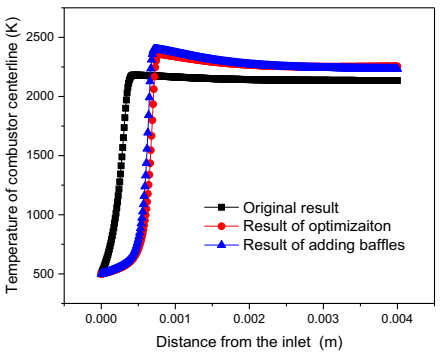


Figure 6: Centerline temperature profile comparison with the results of optimization, adding baffles and original results

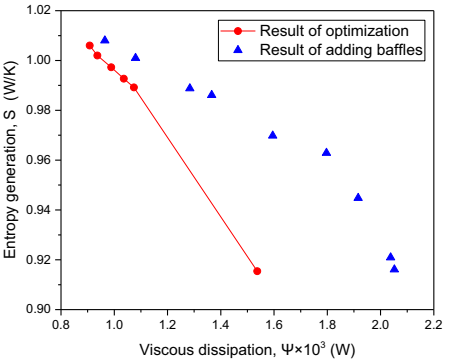

Figure 7: Entropy generation comparison after optimization and adding baffles

According to the Eq. (1), the optimized flow field can be known being generated by the body force **F**. In reality, however, it is difficult or even impossible to implement a force field to generate the optimized flow field as shown in figure 4(a). However, based on the optimization results in figure 4, we can design the internal structures of the micro-combustor so that the flow field can approach the optimal one. For example, inspired by figure 4, two axisymmetric baffles can be added into the micro-combustor near the inlet to generate similar eddies as shown in figure 4(a). The result close to the optimum one was obtained by changing the position, shapes and sizes of the baffles, as shown in figure 6. The streamlines and temperature distribution in figure 6 are shown similar to those in figure 4. Figure 5 shows that the combustion temperature for the improved combustor gives temperature lower than that for the optimal one, but much higher than the normal one.

Particularly, the value of the total entropy generations at the certain viscous dissipation in figure 3 can be regarded as the thermodynamic limit to the combustion enhancement by modifying the inner structure of the combustor. Figure 7 shows the comparison of total entropy generation after optimization and adding baffles. It can be seen that the availability destruction for adding baffles is never lower than that in the corresponding optimized one, which is the minimum of entropy generation of the process under the certain value of viscous dissipation.

4. Conclusions

Availability of the combustion process was used to define as the criterion for optimal design of a micro-combustor. The minimum of total entropy generation of the combustion process was set as the objective function, under fixed viscous dissipation. The calculus of variation was use to solve the optimization problem. The optimization results can be known as the thermodynamic limit for the enhancement of combustion process optimization. The thermodynamic limit can be used as the target of combustor structure design, although it is theoretical and difficult to reach in practice. Optimization design of the micro-combustor structures, according to the optimal flow field obtained, was obtained. The combustors with the modified structure had high second law efficiency, but lower than that by optimization at the same viscous dissipation.

In this paper, we proposed a method to the lowest entropy generation values at different values of viscous dissipation for the combustion process, which can provide a guideline for the micro-combustor design. The optimization design method of the micro-combustor can be extended to other types of combustor. Through the optimization method presented in this paper, one can retain more available energy in the combustion process, i.e., improve the grade of the energy, which is very meaningful in the age of resource and energy scarcity.

Abstract

The determination of water end use patterns by specific in-home equipment (appliance), the behaviour inherent to the users of the equipment, as well as the daily flow rate of water consumption, is important for the monitoring of water use, allowing the understanding of the system and the development of intelligent strategies for the management of this natural resource and its demand. Thus, the objective is to develop a model that identifies when an event is simple or combined (that is, simultaneous events, an event that includes several individual overlapping events), based on data obtained from low-income families in Brazil. An integrated approach was used combining water meters, home appliance audits and a self-reported household water use diary. Random Forest-based algorithms have been developed to aggregate flow tracking and to identify when an event is individual or combined. With the developed methods, it is easy to classify simple uses, but the combined uses still need more attention, being a future challenge the identification of its critical variables and improvement of classification.

Keywords: Water end-use event; Residential water flow trace disaggregation; Machine Learning. Pattern recognition; Random Forest.

1. Introduction

The world population has taken a major leap in numerical and industrial growth rates since the middle of the last century. In many cases, as in third world countries, socioeconomic development, as well as the supply chain, does not accompany population growth, with great disparity. Brazil, for example, is the 9th world economy (IPRI, 2017) and is home to about one fifth of the world's water reserves. However, although approximately 82.5% of the population has access to water, less than half of the population has access to sewage (48.6%), and the loss of about 37% in water supply (The World Bank, 2016). São Paulo, the largest and most well-developed city in the country, is experiencing a water crisis of the worst that has already been faced and there are no concrete plans to face the disaster that the crisis has caused (Carmo et al., 2016). Thus, the debate and the commitment to the development of strategies of water resources management are of great importance. Understanding how water use works in residential environments generates clear benefits for public water utilities, end users and for decision making regarding resource management strategies by allowing predictive

management of water supply during in periods of water scarcity or not, identification of water use peaks for water demand and cost management and identification of water use habits or water leaks at the facility, are some of these benefits (Carboni et al., 2016; Gurung et al., 2015.; McKenna et al., 2012; Morrison et al. 2014).

In order to provide the best knowledge of the residential consumption profile and help the understanding of the systems for the development of better public strategies, several approaches are used for the disaggregation of consumption and its subsequent characterization. The measurement can be based on different types of meters, such as those based on water flow, pressure evaluation, acoustic evaluation and multi-modal (article-sensors) and, as the measurement forms vary, the classifiers also do. For this work, we will focus on the approach of methods based on water flow, since they have a better adaptation to the residences in which the study was conducted. For this approach, the main commercial classifiers are *TraceWizard* (Aquacraft, 2016) and *Identflow* (WRc Plc, 2016), which have satisfactory identification of singular uses (based on Decision Trees algorithms), but still require great interaction with the user. In addition, they have low quality with respect to the analysis of multiple uses, which show the cases of greater difficulty. This problem has a good approach by Nguyen et al. (2013) which makes use of Hidden Markov Model (HMM) and Dynamic Time Warping to make the problem solvable. It is noteworthy that both HMM and DTW alone do not achieve such positive results, requiring a joint approach. Thus, we use this work to propose a new method based on Random Forest to identify the simple and multiple uses, which presents good quantitative and qualitative results.

2. Methodology

2.1. Obtaining Data

Data collection was conducted in the Plataforma and Chapada do Rio Vermelho neighbourhood, in the city of Salvador, state of Bahia, Brazil. This is the largest state of the Northeast Region of Brazil, with an estimated population of 15,344,447 inhabitants. Its population density is 24.82 inhab / km² and the average water consumption per capta is 110.57 L / inhab.day (IBGE, 2017). The state capital, Salvador, consumes comparatively most of the water, characterizing an uneven distribution. According to the Brazilian Institute of Geography and Statistics (IBGE), in the last census conducted (2010), the city of Salvador had a population density of 3,859.44 inhabitants / km² with an area of 692,818 km².

During the studies, ten families were monitored with the implanted system. This system was composed of a LAO®, DN 20 and metrological class B multi-jet water meter installed at the reservoir outlet, with a sensor to 0.1 L of water used. The system was then configured to collect data every 10 seconds, characterizing the period of each pulse. This gives us total of 2713 days of observations (plus users) between 2011 and 2014, which represents about 1.6 million pulses to be worked. The final data generated by the system were analyzed by *TraceWizard* software version 4.1 and after analyzed by trained technical analysts. Before starting the analysis using the software, it was necessary to define the flow chart corresponding to each device in the residence. Subsequently, they were entirely revised based on the usage log and, in the end, the

complete data was organized for each pulse, with the complete date (including hour, minute, second), the recorded flow, the utensil related to that use (including Toilet, Shower, Water Filter, Bathroom faucet, Washing Machine, Kitchen faucet, Clotheswasher faucet), family, ID of the house. It is worth mentioning that *TraceWizard* worked only as a process accelerator, with only 48.86% of the original data being preserved.

2.2. Data analysis and aggregation

All data were processed and aggregated, defined as single or multiple uses. The total duration of use was estimated as well as its volume and the appliances involved. It was organized as follows: contend fixture type, date of event, start time, stop time, duration, volume, peak flow rate, modal flow rate - as *TraceWizard* (DeOreo, 2011), mean flows, mode, number of repetitions of the mode, median, volume and the probability of the use to be simple (in each hour), besides the peak referring to the flows. All manipulations and analyzes were performed with the aid of the programming language R.

2.3. Random Forest

The Random Forest algorithm used was proposed by Breiman (2001). This algorithm is characterized with a supervised learning algorithm from a set of Decision Trees. These Decision Trees are trained by the bagging method, based on the idea that the combination of learning models improves the result. This differs from the standard trees because each node is divided using the best combination of all the variables. As the decision trees grow, an extra randomness is brought in for the random forest model and it searches for the best feature within a random subset of features. It does not make the algorithm more complicated to use since it requires only few hyperparameters and these generally produce a good classification results. Other important aspects to be considered are overfitting and the sensitive analysis of the variables. Because there are enough trees in the forest, the classifier is not expected to overfit the model. And by providing information of how much each feature is related to the model result (dependent variable), it is possible to select which features to use in the model, since features with low importance can end up, often, interfering negatively to the result.

For this research, the models were constructed using the R programming language and RandomForest package (Liaw and Wiener, 2002). A ratio of 80/20 was applied for the division of the training and test data set, the sets being sampled respecting the proportion of the categories contained in the database.

3. Discussion and Results

3.1. Model Accuracy

The Random Forest model was created with the variables: number of repetition of the mode, the mode, mean flow, peak flow rates, median, probability of the use in a given hour to be simple, volume of a use and the household, as with 500 trees. The obtained results show a precision, recall and F1 score of 0.935, 0.975 and 0.954 for the train set and 0.936, 0.975 and 0.955 for the test set. Precision indicates the number (or

percentage) of simple/combined uses that are actually simple/combined. Recall shows the number of accurate answer we labeled as simple/combined. The F1 score is the weighted average of Precision and Recall. Therefore, this score takes both false positives and false negatives into account. The results have good sensitivity, but the model is able to predict much better simple uses than combined ones.

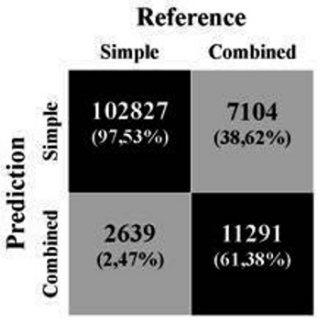

Figure 1. Confusion Matrix.

The major difficulty between differentiating single uses and combined uses is that the way in which the equipment works depends greatly on the behaviour of the user. There is no regular behaviour determined by mechanical parts, thus, the user can use the flow rate as desired. So often, a high flow from the shower can be confused with a high flow rate from the use of the sink and toilet, with similar durations, for e.g. In Figure 1, the confusion matrix can be evaluated.

3.2. Variable Importance

For the model created, for the prediction of simple uses, there are no outstanding variables. The most important variable is the median, but it does not have much difference in relation to the others. With respect to the combined uses, the most important variable is the mean flow, with great emphasis, as can be seen in Figure 2, where VM1 is the number of repetition of the mode; VM2 is the mode; VM3 is the mean flow; VM4 is the peak flow rate; VM5 is the median; VM6 is the probability of the use in a given hour to be simple; VM7 is the volume of a use and; VM8 is the household. The definition of the mean flow for the classification of combined uses as the most important variable comes along with the mode and the median, characteristics that say about the distribution of the flows in the time space of the use. Simple uses, in general, have more regular profiles, so the variables have similar amounts. The combined uses have distortions generated by the overlapping of the flows, which directly impact on the central tendency of the uses.

3.3. Model Threshold

As can be seen in Figure 3 and Figure 4, the model performs the correct prediction most of the time. The scale of the votes represents the degree of certainty that is in each vote, being 1.0 a vote of absolute certainty of the model. Thus, when the model has great certainty about the vote, it misses very little. The errors only surpass the hits when the vote is certain of 0.5, but for simple uses only.

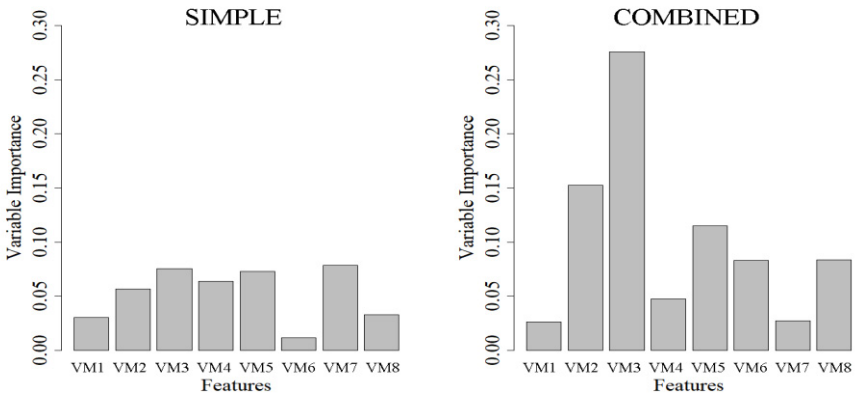

Figure 2. Variable Importance.

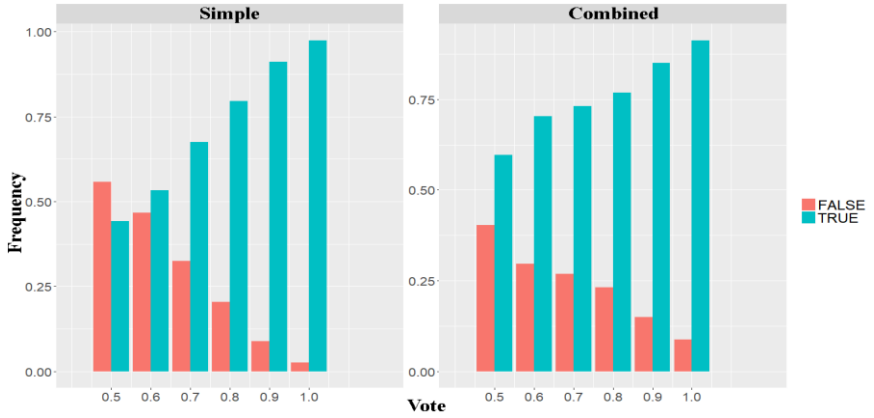

Figure 3. Model Threshold (Frequency vs. Vote).

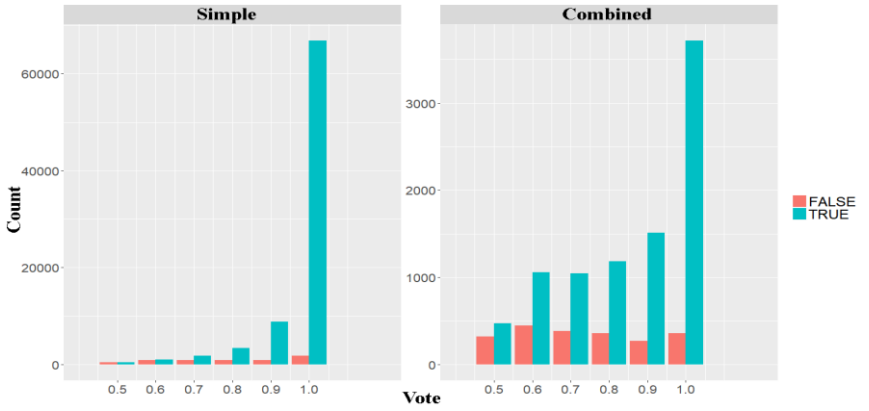

Figure 4. Model Threshold (Count vs. Vote).

4. Conclusion

The classification of uses by Random Forest is promising, with satisfactory results when compared with others available in the literature. In previous work of the group, we have already been able to classify and predict the category of simple uses. This work serves as a complement to the identification of combined uses, which is a major challenge for most approaches to the problem. The model has good sensitivity, but the accuracy can still be better. Thus, it is necessary to evaluate what could be new variables that add more information to the model. For future work, it is expected to be able to describe the profile of the use and to use a more integrated approach, without the need of specific algorithms for each step (identification of simple or combined uses and later classification). Other approaches in addition to machine learning algorithms are also evaluated for future work.

Abstract

This work presents a mathematical model that simultaneously optimizes water and energy usage in hydraulic fracturing using continuous time formulation. This is achieved through purification of the highly contaminated water using membrane technology which is energy intensive. The membrane regenerator considered in this work is membrane distillation (MD). Detailed design model for this technology is developed and incorporated within the water network superstructure in order to allow for simultaneous optimisation of water, operation, capital cost as well as energy used. The study also looked at the feasibility of utilising the co–produced gas that is traditionally flared (in the case of oil producing shale) as energy source for the membrane regenerator. The resultant model is applied in a case study to demonstrate its applicability. The application of the model results in 22.4 % reduction in freshwater consumption and 23.2 % savings in the total cost of freshwater. The thermal energy consumption is in the order of 244×10^3 kJ/m^3 of water.

Keywords: Hydraulic fracturing, water and energy, membrane technology, MD, flaring

1. Introduction

The "shale revolution" has stimulated tremendous production of oil and natural gas globally. From 2007 to 2015, shale gas production in the US has grown from 2 to 15 trillion cubic feet per year with estimates of continued growth to support massive monetization projects (Zhang and El-Halwagi, 2017). However, the process by which it is carried out known as hydraulic fracturing is associated with several environmental challenges, i.e. excessive amount of water usage, generation of significant volume of wastewater and widespread flaring of co-produced gas.

Water management decisions within shale gas production fall into two primary categories, i.e. water utilization within hydraulic fracturing operations and disposal of wastewater from drilling and production (Gay et al., 2012). Shale gas production is a highly water-intensive process with a typical well requiring around 5 million gallons of water to drill and fracture. Water contamination is another aspect of shale gas production that has generated significant resistance to current shale production processes. Thus, water consumption in shale gas production has become a major concern making water resource management an important operational and environmental issue (Hasaneen and El-Halwagi, 2017). The efficient use of water resources involves the treatment of

wastewater for reuse or recycling which can be achieved using water purification units often classified as membrane and non-membrane processes. The use of membrane system for water treatment is an energy intensive process, therefore minimising energy within the water network is also of great importance.

A number of studies have been carried out on the optimisation model for water management in shale gas production. Yang et al. developed mixed integer linear programming (Yang et al., 2014a) and mixed integer nonlinear programming (Yang et al., 2015) investment and scheduling model for optimal water management in shale gas which dealt with short and longer term operation respectively. Gao and You (2015) addressed a similar problem but assumed a fixed schedule for the wellpad fracturing. Bartholomew and Mauter (2016), also developed a multiobjective mixed integer linear programming for assessing the trade-offs between financial cost and human health and environment costs. However, most of these studies have adopted the discrete time scheduling formulation for the wellpad fracturing which does not guarantee model accuracy and leads to suboptimal solution due to the discrete approximation of the time horizon. In addition, most of the research done in this area has represented the wastewater treatment unit as a "black box "which does not give the true cost representation of the project or uses "short cut" regenerator model (Yang et al., 2014b) due to the complexity of the regenerator design.

Furthermore, studies available in literature for the utilisation of the co-produced gas that is flared in the case of oil producing well is either focused on the onsite atmospheric water harvesting (Wikramanayake and Bahadur, 2016) using the captured gas or channelling the gas that would have been flared as a source of heat (Glazer et al., 2014) for heat based regenerators. The work by Glazer et al. (2014) is done based on analytical framework and not in the context of mathematical optimization.

This paper addresses the synthesis and optimisation of an integrated water and membrane network that simultaneously optimizes water and energy consumption in hydraulic fracturing using continuous time formulation. The membrane technology considered is membrane distillation. A detailed design of this regenerator is incorporated to determine the optimal operating conditions for efficient energy use.

2. Problem statement

The problem statement in this work can be stated as follows. Given are: (i) number of freshwater sources, (ii) set of wellpads S with known flow rates and known maximum allowable contaminant concentrations, (iii) total number of frac stages for each wellpad, (iv) earliest fracturing date for each wellpad, (v) set of wastewater injection wells, (vi) volume of water required per stage, (vii) the minimum and maximum number of stages that can be fractured per day (viii) time horizon of interest, (ix) regenerator with variable removal ratio and (xi) a gas storage facility.

Using the given data, it is required to determine (i) the fracturing schedule of the wellpads that optimizes water and energy usage, (ii) optimum design of MD regenerator such as number of membrane modules and energy consumption and (iii) the feasibility of using captured flared gas as energy source for the regenerator.

3. Model formulation

Based on the problem statement, the superstructure in Figure 1 is developed.

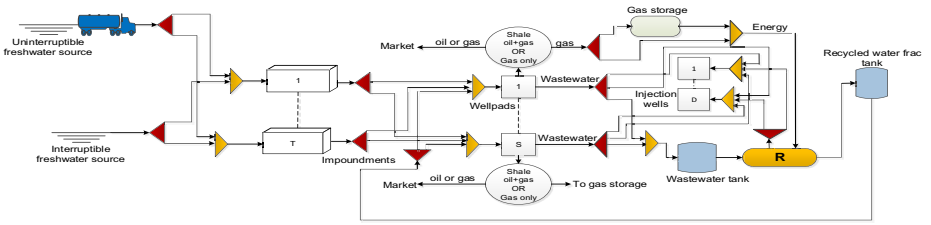

Figure 1. Superstructure representation of the water network.

The objective of the problem is defined in Eq. (1) as:

$$\max\ profit = R - \left(c^{fw} + c^{ww,trt} + c^{ww,st} + c^{dis}\right) \tag{1}$$

The objective function is subject to the following constraints:

Eq. (2) is the allocation constraint which specifies that each wellpad *s* has to be fractured exactly once at time point *n.* A time point is a precise moment within a given horizon when an event occurs.

$$\sum_{n} wx_{s,n} = 1 \qquad \forall s \in S \tag{2}$$

Eq. (3) states that the time at which time point *n* occurs must correspond with the availability time of wellpad *s.*

$$Tt_{n} \geq \sum_{s}\left(st_{s} wx_{s,n} - H\left(1 - wx_{s,n}\right)\right) \qquad \forall n \in N \tag{3}$$

Water requirement by each wellpad is supplied with freshwater and/or recycled water from the frac tank, which is obtained by Eq. (4).

$$tw_{s,n} = fw_{s,n} + rw_{s,n} \qquad \forall s \in S, n \in N \tag{4}$$

Eq. (5) states that the flowback water generated after wellpad fracturing can be sent to regenerator R for treatment or injection well.

$$f_{s,n}^{bw} = f_{s,n}^{trtb} + f_{s,n}^{dis} \qquad \forall s \in S, n \in N \tag{5}$$

The heat required by the feed into the regenerator R is given by Eq. (6)

$$Hrf = QfCp\left(Tbf - Tsf\right) \tag{6}$$

The regeneration network involves both capital and operational costs. These functions are included in the overall objective function of the water network as $c^{ww,trt}$, such that the energy consumption and subsequent cost of regeneration are optimized in conjunction with water consumption.

The annualized fixed and operating cost of the MD network excluding heating is given by Eq. (7)

$$AC = \left(58.5A_{m} + 1115Qf\right) + \left(1411 + 43\left(1 - LR\right) + 1613\left(1 + V\right)\right)Qf \tag{7}$$

The annual heating cost is given by Eq. (8)

$$AHC = AOT\left(khHrf\right) \tag{8}$$

Additional constraints include water and contaminant balance around the storage vessel and the regenerator, sequencing constraint for the water and regenerator network, and the design constraints for the regenerator.

4. Case study

To illustrate the application of the proposed model, an example taken from Yang et al. (2014) is considered as illustrated in Table 1. Three scenarios are considered to ensure the detailed analysis of the model. Scenario 1 is the base case which is the water integration without regeneration. Scenario 2 is the case where black box model is used; i.e. water minimisation only. Scenario 3 considers water integration involving detailed regenerator where water and energy are optimized simultaneously.

Table 1. Wellpad Data

Wellpads	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11	S12	S13	S14
Earliest frac day	1	1	1	1	1	39	1	273	273	273	396	379	379	1
# of stages	57	61	54	55	64	26	97	88	86	76	63	100	100	87

The solution comparison between the three scenarios is given in Table 2 and the fracturing schedule for each scenario is presented in Figures 2-4. The results show that the model proposed to make use of freshwater from interruptible sources thereby reducing the cost and environmental issues that is associated with trucking. Figures 3 and 4 show that the tightness in fracturing schedule of each group of wellpads improves the recycling efficiency of flowback water. Due to efficient reuse of flowback water, a saving of 183,534 m^3 of freshwater is achieved out of the total volume of 818,000 m^3 required for the 14 wellpads. The saving is found to be 21.2 % higher than the study in literature (Yang et al., 2014a) using discrete time formulation. In scenario 2, 96.7 % of the flowback water is sent to regenerator *(R)* and the remaining 3.3 % is sent to the injection well to be disposed while in scenario 3, 99.4 % of the flowback water is sent to regenerator (*R)* while the remaining 0.6 % is disposed.

In order to calculate the cost and energy associated with the wastewater regeneration, a cost analysis based on the black box model and detailed model was performed. The results obtained are given in Table 3. The results show that the deviation of the cost function from the actual cost of regeneration in scenario 2 is 12.7 %. The result obtained in scenario 3 show that the optimized cost of regeneration is 6.6 % higher than the cost of MD standalone model. This is due to the fact that optimizing the MD-feed temperature results in a decrease in the water flux thereby increasing the membrane area required which in turn leads to an increase in the fixed cost of the membrane. The simultaneous optimization of both energy and water within the water network results in 12.7 % reduction in the amount of energy required by the regenerator based on the throughput per day. The amount of energy required is reduced from 699×10^6 kJ to 610×10^6 kJ. The thermal energy consumption is in the order of 244×10^3 kJ/m^3 of water, which is found to be lesser than the range of thermal energy consumption values reported for membrane distillation in literature. The range of thermal energy required by membrane distillation is between

120 and 1700 kWh/m^3 equivalent to between 432×10^3 kJ/m^3 and 6.12×10^6 kJ/m^3 (Suarez and Urtubia, 2016). Using gas that would otherwise be flared as the source of heat for the regenerator rendered the heating cost in the objective function to become zero.

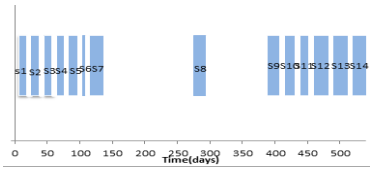

Figure 2. Fracturing schedule (base case)

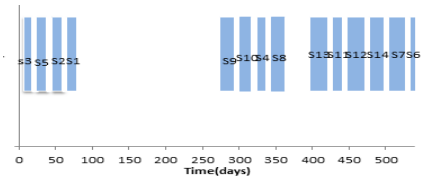

Figure 3. Fracturing schedule (scenario 2)

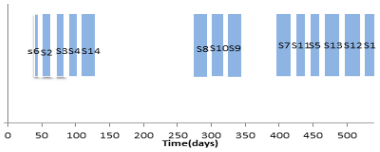

Figure 4. Fracturing schedule (scenario 3)

Table 2. Solution comparison

	Scenario 1	Scenario 2	Scenario 3
Freshwater pumped (1,000 m^3)	818.8	640.3	635.3
Freshwater trucked (1,000 m^3)	0	0	0

	Estimated cost (Scenario 2)	Standalone cost	Water and energy optimization (scenario 3)
MD	11,307	9,875	10,575

5. Conclusions

This work explores simultaneous water and energy optimization in shale play using continuous time formulation with the incorporation of detailed MD model within the water network. The goal is to balance the tradeoff between water acquisition from interruptible and uninterruptible water sources. The efficient recycling of wastewater leads to 22.4 % reduction in the amount freshwater required. The approach indicates that optimizing energy and water simultaneously results in significant reduction in the amount of thermal energy required for regeneration. Based on the data gathered from literature, the amount of gas that is flared in most of the shale play is sufficient to provide the energy needed for regeneration.

Nomenclatures

R revenue from gas production	c^{fw} freshwater cost
AC annual fixed and operating cost	AHC annual heating cost
$c^{ww,trt}$ wastewater treatment cost	A_m required membrane area
$c^{ww,st}$ cost of wastewater storage	kh cost of heating
c^{dis} cost of disposal	$f_{s,n}^{bw}$ flowback water at time point *n*
$tw_{s,n}$ total water needed for fracturing wellpad *s* at time point *n*	Qf flowrate into regenerator *R*
	Cp specific heat of the feed into *R*
$fw_{s,n}$ freshwater required at time point *n*	Tbf temperature of the feed in the bulk of *R*
Hrf heat required by the regenerator feed	Tsf supply temperature of the feed into *R*
LR Liquid recovery for the regenerator	Tt_n time corresponding to time point *n*
H time horizon of interest	
v ratio of recycled reject to raw feed	$f_{s,n}^{trtb}$ amount of water sent to regenerator *R* at time point *n*
$rw_{s,n}$ recycled water needed at time point *n*	
st_s Availability date of wellpad *s*	$f_{s,n}^{dis}$ amount of water sent to disposal at time point n
$wx_{s,n}$ binary variable for the assignment of task *s* at time point *n*

Abstract

In this paper, a mathematical model used to represent the thermal behavior of an air conditioning water-air system applied to a large commercial building is proposed to represent its operation. Thermodynamic properties of refrigerant are rigorously modelled as well as subcooling and superheating of refrigerant inside the chiller. A simplified first principle model is presented for the description of the several conditioned rooms. The proposed model is used to evaluate the dynamic behavior of the system when subjected to external ambient air and thermal load disturbances. System response to step changes in the main manipulated variables are also shown.

Keywords: Air conditioning, vapour compression system, chiller, air-water systems, process simulation.

1. Introduction

In commercial buildings, energy consumption by heating, ventilation, and air conditioning (HVAC) can achieve 50% of the total energy consumed and it is reported that air conditioning may be responsible for 10 to 20% of the national energy demand in developed countries (Vakiloroaya et al., 2014). Therefore, being able to better control or optimize the operation of air conditioning systems is an up-to-date challenge.

Air-water HVAC systems are widely used in large commercial applications because they can ensure good temperature and air quality control. Figure 1 shows one possible implementation of an air-water HVAC, which is considered in this paper. Cool air inflated in the conditioned zones is refrigerated by cold water in fan-coils. The water into the fan-coils comes from chillers. Each chiller mainly consists of a vapor compression system, possessing a compressor, a condenser, an evaporator and an expansion valve. In order to control the temperature in the conditioned zones, the flowrate of the air into the zones is maintained fixed and a water bypass is introduced in each fan-coil, as is shown in figure 1. The bypass fraction is manipulated in order to control the temperature in the zone. Although water condensers are preferably used in large applications, air condensers can also be used, as is the case here. As for the compressor and expansion valve, in this paper, a positive displacement compressor and an electronic expansion valve (EEV) are used.

In order to test new control or optimization strategies a suitable model of the process is needed. Afram and Janabi-Sharifi (2014) reviewed modelling methods for HVAC

systems. Models that are based on physics and system performance data have appropriate generalization capabilities and accuracy and are more largely used. However, several models used in the literature for testing more advanced control strategies make use of significant simplifications. For example, Ma et al. (2009) developed a model to test several control strategies. Instead of calculating the compressor work using a rigorous thermodynamic model, they evaluated the compressor work from the work obtained from a compression cycle where the vapour phase at the exit of the compressor is saturated. In this paper, we will see that this approach is not adequate for the HVAC considered here.

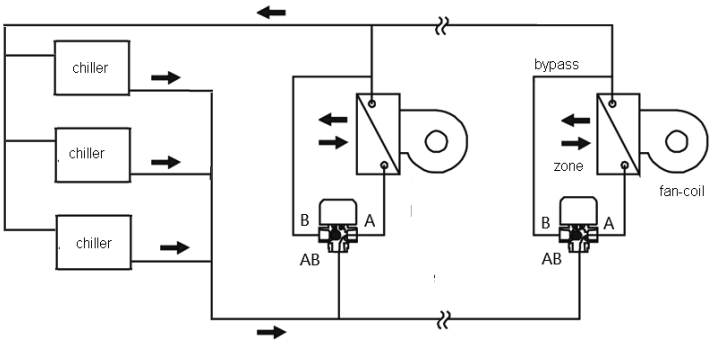

Figure 1: HVAC system considered in the present work.

2. Building description and mathematical modelling

Nomenclature					
A_{eev}	EEV opening	$\dot{V}$	volumetric flowrate	e	entry

ua	humidity ratio	cd	condenser	vw	vapour water
UR	relative humidity	cp	compressor	w	water
		da	dry air	z	zone

The building considered in this paper is situated in the city of Belo Horizonte in Brazil and has an area served by the HVAC system of 19,193.40 m^2, which is divided into 73 zones served by 73 fan-coils. The nominal capacity of each of the 3 chillers needed to refrigerate the building at operating point is 1064,4 kW. The refrigerant is R-410A. In the design, ambient dried and bulb air temperatures were considered to be, respectively, 32 ºC and 24 ºC. Ambient conditions of all zones are to be controlled at 24ºC and a relative humidity of 50%. Evaporator´s and condenser´s saturation temperatures are, respectively, -5ºC and 50ºC at nominal point. The design superheating is of 10ºC and subcooling (ΔT_{sub}) was designed to be 5ºC.

Air and liquid water properties are modelled as in ASHRAE (2017). Specific volume of R-410A is modelled by Martin-Hou equation of state (DuPont, 2004). Enthalpy, internal energy and entropy of superheated vapour at low pressure conditions were modelled considering an ideal gas behaviour. The heat capacity of the ideal gas was considered as in Dupont (2004). All other properties were obtained from the data presented in Çengel and Boles (2011).

The focus of the modelling presented here is on the thermal behaviour of the HVAC system. Friction losses in piping and heat exchangers are therefore neglected. The energy balances of each zone and of its corresponding fan-coil, as well as of each evaporator and condenser are modelled assuming a mixed chamber as usually done in HVAC modelling (Afram and Janabi-Sharifi, 2014). Eq.(1) to Eq.(4) exemplify the procedure. Note that although the equations simplify the physical reality, they can adequately predict subcooling and superheating of the refrigerant in the chillers. Also, the effect of external air state on system performance is explicitly taken into account. Water flowing through the evaporator of each chiller has constant flowrate. Heat rate for each heat exchange device is related to the logarithmic mean temperature. In this paper, every global heat exchange coefficient is assumed constant. The idea is that those values can be obtained on-line from data reconciliation (Özyurt and Pike, 2004). Thermal load to the zone may be varied accordingly to the design thermal profile or to simulate abnormal ambient conditions.

$$\frac{dT_{ret}}{dt} = \frac{\dot{m}_{air}\left(cp_{da} + ua \cdot cp_{vw}\right)\left(T_{in} - T_{ret}\right) + q_z}{m_z\left(cv_{da} + ua \cdot cp_{vw}\right)} \tag{1}$$

$$\frac{dT_{fan}}{dt} = \frac{\dot{m}_{fan} cp_{lw}\left(T_{fc} - T_{fan}\right) + q_{fan}}{m_{fan,w} cp_{lw}} \tag{2}$$

$$\frac{du_{cd,air}}{dt} = \frac{1}{m_{cd,air}}\left(\frac{\dot{V}_{ext}}{VU_{ext}}\left(h_{ext} - h_{cd,air}\right) + q_{cd}\right) \tag{3}$$

$$\frac{du_{cp,e}}{dt} = \frac{\dot{m}_{rf}\left(h_{cd,s} - h_{cp,e}\right) + q_{ev}}{m_{ev,rf}} \tag{4}$$

All water streams from all fan-coils are mixed into one stream that is divided into 3 streams, each entering one chiller. Similarly, all water streams from the 3 chillers are mixed and then split into the 73 streams that will feed the fan-coils. In this work, we use the model proposed by Li (2013) to simulate the EEV. Under chocked condition, Eq. (5) can be used to model the mass flowrate of R-410A. The parameters a_1 to a_4 can be retrieved from Li (2013), ΔT_{sub} is the subcooling at the condenser and the critical temperature T_c is 345.28K (Dupont, 2004).

$$\dot{m}_{rf} = 0.676123\left(-a_1 + a_2 \cdot A_{eev} - a_3 \cdot A_{eev}{}^2 + a_4 \cdot A_{eev} \cdot \Delta T_{sub} T_c^{-1}\right) \cdot A_g \sqrt{\rho_{cd,s} \cdot P_{cp,s}} \tag{5}$$

In this paper, the positive-displacement compressor is modelled at steady-state, assuming that its dynamic is very fast. The volumetric flowrate is modelled as usually done in the literature by Eq. (6) and the volumetric efficiency is modelled by Eq. (7). The shaft work is given by Eq. (8). Roskosch et al. (2017) suggest a dependency of the

isentropic efficiency on the pressure ratio of the compressor. This is the approach considered here in Eq. (9).

$$\dot{V} = V_{cp} \cdot \omega \cdot \eta_v \tag{6}$$

$$\eta_v = 0{,}91 - 0{,}011279\left(P_{cp,s} \cdot P_{cp,e}^{-1}\right)^{\gamma} - P_{cp,s} \cdot P_{cp,e}^{-1} \tag{7}$$

$$W_{cp} = \dot{m}_{rf}\left(h_{cp}^{*} - h_{cp,e}\right)\eta_i^{-1} \tag{8}$$

$$\eta_i = 0{,}0046362 P_{cp,2}^{3} \cdot P_{cp,e}^{-3} - 0.068534 P_{cp,2}^{2} \cdot P_{cp,e}^{-2} + 0.34692 P_{cp,s} \cdot P_{cp,e}^{-1} + 0.11229 \tag{9}$$

3. Results

The equations were solved with the aid of Matlab®. The differential equations were solved using Runge-Kutta 4th order method with a maximum integration step of 1s. The non-linear set of equations were solved through Matlab®´s SQP algorithm. For the lack of space, we will only present open-loop simulation results around the nominal operating point with constant chiller´s condenser pressure.

Figure 2 presents some system responses to step changes in the main manipulated variables. Both EEV opening and external air flowrate were perturbed by +/- 5% of their nominal point value. Bypass fraction was changed from 10% at normal operating point to 15% and 5% in all zones. Figure 2 includes simulations obtained by solving the model presented here and the model to evaluate compressor work by Ma et al. (2009). For the latter, the coefficients for the quadratic empirical model relating the real compressor shaft work with the compressor work obtained from what the authors called the fictitious vapour compressor cycle, were obtained by regression to six different operating points. We can see that some responses exhibit a higher order dynamic behaviour with a very fast response. Suction temperatures varied over 10% of their nominal value, somewhat affecting the compressor shaft work. Suction temperature must be controlled at least within a specified range so that no liquid enters the compressor and compressor blades be not damaged. From figure 2c we can see that bypass fraction does not significantly affect compressor shaft work, but as can be seen from figure 2d, external flowrate will somewhat affect it. When analyzing the results with the model of Ma et al. (2009), acceptable responses are obtained only for perturbation in EEV opening. Wrong directions are obtained by increasing bypass fraction or air flowrate. This probably occurred because their model does not take into account variations in the thermal load of the condenser. The difference in CPU time using the current model and the model by Ma et al. (2009) is very small (only 0,6 s for a time horizon of 600 s in an Intel T5500 Core 2 Duo 1.66GHz processor).

Figure 3a shows system response to simultaneous perturbations in the bypass ratio and in the thermal load (-5%) for all zones. It can be seen that the temperature of the zones exhibits a non-linear behaviour. The zone temperature can be controlled at the desired value. Noteworthy is also the large variation in time response of zone temperature dependent on the water bypass ratio value. In figure 3b the thermal load was perturbed in only four zones, respectively by -5%, + 3%, -10% and +3%. The temperatures of these zones were able to be controlled by manipulating the bypass ratio. The increase of 3% in the thermal load saturated the manipulated variable. We can also see that although the thermal load of the 5th zone was not varied, there was the need of manipulating the bypass ratio in order to control the temperature. All temperature were controlled within a range of +/- 0,1ºC.

Figure 4 shows how the external air state may affect both the temperatures of the zones and the compressor shaft work. Relative humidity was considered 50% and the air dry bulb temperature was varied to 31ºC and to 33ºC. Similar types of dynamic responses as in the previous cases are observed. It is noteworthy to say that the shaft work does not significantly vary. Variations were below 1% for the relatively small perturbations performed.

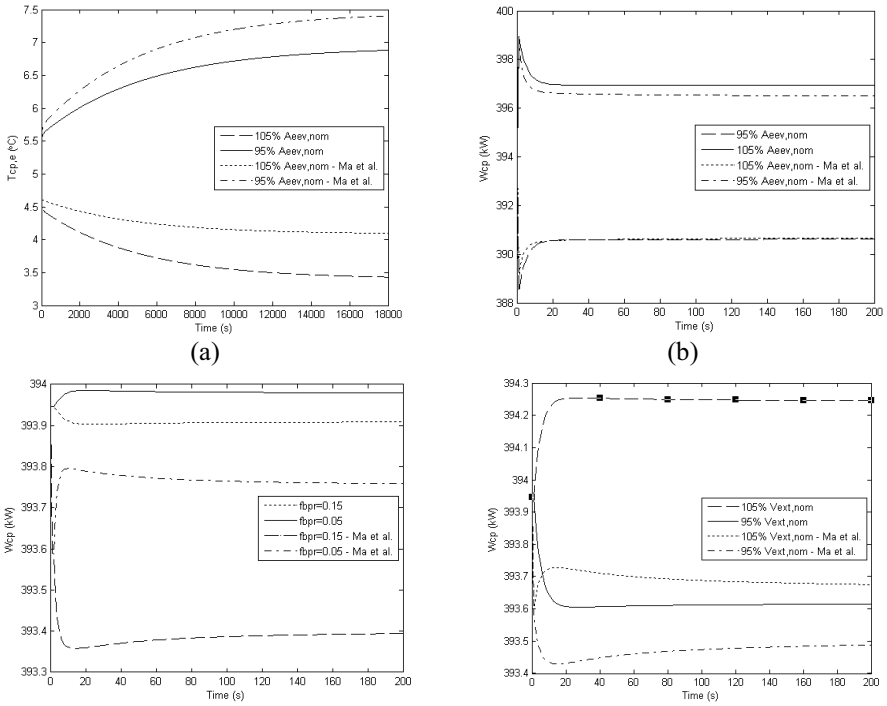

Figure 2: Responses to step changes in manipulated variables in open-loop: (a) EEV effect on compressor suction temperature (b) EEV effect on compressor shaft power (c) Changes in water bypass fraction effect (d) External air flowrate into condenser effect

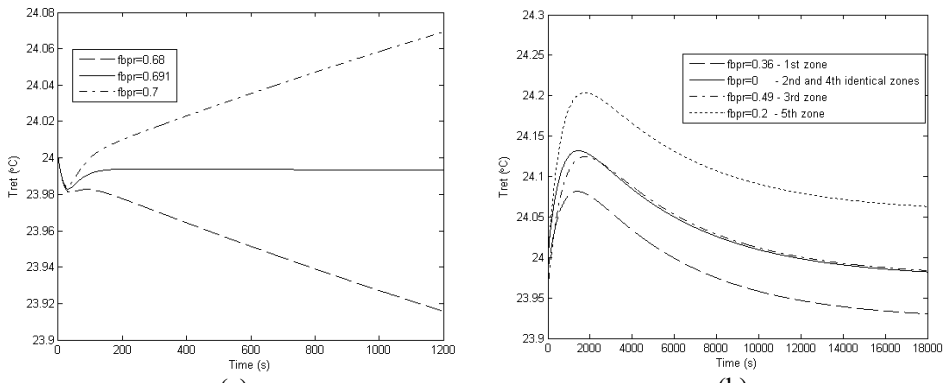

Figure 3: Response to perturbation in thermal load and bypass ratio

The responses show that the system exhibits some non-linear response and that there are different dynamic behaviours with too different time constants. There are also degrees of freedom to control zone temperatures and at the same time minimize compressor shaft work while maintaining important process variables within required ranges. So, it seems that system performance would benefit from advanced control strategies and that the model presented here can be used to test more advanced control strategies.

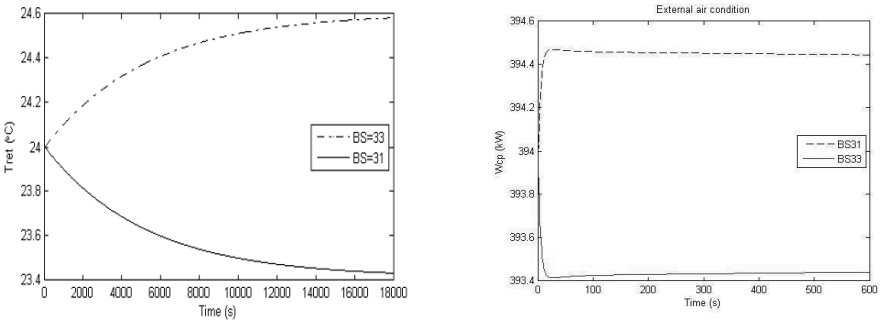

Figure 4: Effect of external air temperature

4. Conclusions

In this paper a model of an air-water HVAC system operating with an air condenser and using water bypass to control the temperature of the conditioned zones was presented. The modelling approach is based on rigorous thermodynamic modelling and explicitly relates the effect of disturbances like external ambient condition and thermal load to the conditioned zones. The thermal dynamic behaviour of the HVAC was presented and the dynamic response of the system could be analysed. The system exhibited a non-linear behaviour on some variables, large variations in time constants and different types of dynamic responses. The model seems adequate to test advanced control strategies.

Abstract

In order to hasten the implementation of optimal, cost-effective, and sustainable treatment trains for resource recovery, a nutrient recovery model (NRM) library has been developed and validated at steady state. The reported research aims to use the NRM library to establish the operational settings of a sustainable and cost-effective treatment scenario with maximal resource recovery and minimal energy and chemical requirements. Under the optimized conditions and assumptions made, potential financial benefits for a large-scale anaerobic digestion and nutrient recovery project were estimated at 2.8-6.5 USD m^{-3} manure based on net variable cost calculations, or an average of ± 2 USD m^{-3} y^{-1}, equivalent with 40 USD t^{-1} total solids y^{-1}, over 20 years in the best case when also taking into account capital costs. Hence, it is likely that in practice a full-scale ZeroCostWRRF (water resource recovery facility at zero cost) can be constructed.

Keywords: anaerobic digestion; circular economy; mathematical modelling; process optimization; resource recovery

1. Introduction

To hasten the implementation and integration of sustainable nutrient recovery strategies and to adequately put together an optimal treatment train of unit processes for resource recovery, a generic nutrient recovery model (NRM) library has recently been developed and validated at steady state (Vaneeckhaute et al., 2018). The proposed models are dynamic mathematical models, based on detailed solution speciation and reaction kinetics. Key unit process models were developed for anaerobic digestion (NRM-AD), phosphorus precipitation/crystallization (NRM-Prec), nitrogen stripping (NRM-Strip) and absorption using an acidic air scrubber (NRM-Scrub). In view of simulating

complete treatment trains for nutrient and energy recovery, also ancillary unit process models for solid-liquid separation (NRM-Settle), chemical dosing (NRM-Chem) and a heating unit (NRM-Heat) were built. To facilitate numerical solution, a highly efficient interface between the geochemical modelling software PHREEQC and the water quality modelling software WEST (DHI) was established and verified. Global sensitivity analyses (GSA) were performed in order to define the most important factors impacting a wide range of 25 performance indicators of a nutrient and energy recovery treatment train, such as methane and biogas production, digestate composition and pH, ammonium sulfate recovery, struvite production, product particle size and density, and air and chemical (acid, base) requirements (Vaneeckhaute et al., 2015).

Model simulation outputs were very sensitive to input waste stream characteristics through their direct effect on pH, which is adequately determined by means of the chemical speciation calculation integrated in the process models. Moreover, important generic insights in the interactions between process inputs and outputs were obtained through GSA (Vaneeckhaute et al., 2015). Based on the results, it was possible to define an optimal sequence of unit processes in a treatment train for energy and nutrient recovery aiming at the production of high-quality fertilizers at minimal cost (Figure 1).

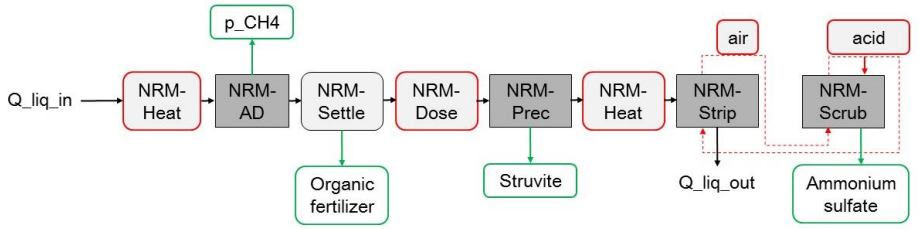

Figure 1 Optimal treatment train configuration targeting bio-based struvite and ammonium sulfate fertilizer production; Red = consumable (= cost); Green = recovered resource (= revenue); AD = anaerobic digestion; Dose = chemical dosing; Heat = heat exchanger; Prec = precipitation/crystallization; p = partial pressure in the biogas; Q_liq = liquid flow rate; Scrub = scrubber; Strip = stripper.

This paper aims to present the use of the NRM library to establish the operational settings of a sustainable and cost-effective treatment scenario with maximal resource recovery and minimal energy and chemical requirements. To this end, an economic analysis was programmed in the process model library, and the operational settings of the above treatment train (Figure 1) were optimized for pig manure as a case study.

2. Methodology

First, realistic design parameters for the unit processes in the nutrient recovery treatment train (Figure 1) were obtained by distributing a technical questionnaire to key technology suppliers in the field. A cost estimate for a design flow of 2,000 m^3 d^{-1} as input to the anaerobic digester was requested using input ranges for nitrogen (N), phosphorus (P), chemical oxygen demand (COD), volatile suspended solids (VSS), total solids (TS), and alkalinity from Cesur and Albertson (2005). The resulting digestate composition (Cesur and Albertson, 2005) was used as input to the nutrient recovery units. Based on the data obtained from the budget proposals, the operational envelope for optimization was compiled. It includes: i) the operational temperature, liquid flow rate, and amount of base/alkalinity dosing for the anaerobic digester, ii) the fraction of

non-settleable precipitates and particulate COD for the phase separation unit, iii) the amount of base dosing, the concentration of seed material in the input flow, and precipitate extraction rate for the precipitation unit, iv) the operational temperature and gas flow rate for the stripping unit, and v) the acid dose and liquid recycle flow rate for the scrubbing unit. The initial values for the optimization experiment were set at the design values provided by the technology providers. The lower and upper limits were set at the values for the unit process GSAs defined in Vaneeckhaute (2015).

The key performance indicators evaluated in the optimization experiment were:

i. **Net costs = chemical costs + energy costs – revenues** (objective = minimize), where:
   a. energy cost items are related to raising the liquid temperature for anaerobic digestion and stripping (with potential for heat exchange, see below), as well as to air pumping for stripping;
   b. chemical cost items refer to the addition of alkalinity or base to the digester, of acid for N absorption in the scrubber, and of base for pH-increase prior to precipitation and stripping;
   c. revenues are related to CH_4 production (energy recovery was assumed, see below), the marketing of mineral fertilizer N, P, and potassium (K), and the potential marketing of organic fertilizer.

ii. **Resource recovery** (objective = maximize), which includes:
   a. methane recovery in NRM-AD;
   b. mineral N, P, and K recovery in NRM-Prec;
   c. mineral N and sulfur (S) recovery in NRM-Strip/NRM-Scrub;
   d. organic (+ N/P/K) fertilizer recovery (settled solids) in NRM-Settle.

iii. **Use of consumables** (objective = minimize), involving:
   a. net thermal energy use = heat required for stripping + heat required for digestion – heat recovered from CH_4 production – potential heat recovered in heat exchangers (see below);
   b. net electricity use = blower energy (air) – electricity recovered from CH_4 production;
   c. chemical use = acid use + base/alkalinity use.

Biogas CH_4 was assumed to be valorized as energy in a combined heat and power generation (CHP) unit, with a conversion efficiency of 40 % as heat, 38 % as electricity, and assuming 22 % heat losses. In terms of heat requirements, both a worst and best-case scenario was considered. In the best case, 10 % heat losses in the digester and 50 % internal heat recovery in the stripping system were assumed as indicated by technology providers. In the worst case, the heat requirements in the digester were 1.9 times higher than the theoretical heat required to heat the input flow. In that case, no internal heat recovery in the stripping system was considered.

To perform the calculations, the GN_Direct algorithm, i.e. DIviding RECTangles algorithm for global optimization (Gablonsky and Kelley, 2001), available from the NLOpt solver package in WEST, was used with a tolerance of 10^{-8} and a maximum of 10,000 evaluations. The latter was identified as the most convenient optimization algorithm/strategy for this type of complex problems following virtual testing and evaluation of various global optimization methods. As compared to other methods included in WEST, it allowed to reduce computation times significantly while ensuring

convergence to the global optimum. The operational envelope of the treatment train was optimized, after which a detailed economic analysis for the treatment train with optimized operational settings was performed, including all operational costs, labor, material and maintenance costs, revenues from CO_2-emission reduction credits, and capital costs.

3. Results and Discussion

The optimized values of the operational factors considered in the optimization experiment are compiled in Table 1. Key performance indicators that were calculated using the optimized factors are also provided. An overview of the annual treatment train operational costs and revenues under the optimized conditions, as well as the capital costs for each unit process in the treatment train is presented in Table 2. The estimation is based on an operational basis of 8,000 hours per year. All costs are expressed in USD.

As depreciation costs and loan service costs vary depending on when and where the money is borrowed, stakeholders are interested in the **yearly net cash flows** determined by the variable costs and revenues. Based on the optimized values obtained and all assumptions made in this case study, the yearly net variable cost balance can be positive. Financial benefits could even be obtained, estimated at about 2.8-6.5 \$ m^{-3} manure y^{-1} (55-130 \$ t^{-1} TS^{-1} y^{-1}) for the large-scale project and associated assumptions in this case. Hence, in terms of net variable cash flows, it is likely that in practice a ZeroCostWRRF (water resource recovery facility at zero cost) could be achieved. As one could be critical on the optimized (low) digester temperature and hydraulic residence time (HRT) obtained in this study (Table 1), the economic analysis was also performed for a digester operated at a temperature of 50 °C with a HRT of 15 d. The financial benefits in this scenario amounted to 2-6 \$ m^{-3} manure y^{-1}, which is competitive with the above optimal scenario. Hence, if a high-temperature treatment is required for end-product pasteurisation, the latter scenario may be targeted, though it is less sustainable in terms of consumables (heat and chemical use). At a HRT of 30 days, the financial benefits amounted to about 3 \$ m^{-3} y^{-1} in the best case, but a loss of 1.5 \$ m^{-3} y^{-1} was obtained in the worst case. The most important factor impacting the operational cost balance, next to the HRT, is the potential for heat recovery. Hence, process and design engineers should focus on the optimization of heat balances in the configuration of future integrated nutrient and energy recovery facilities.

Furthermore, when considering capital costs, stakeholders may be interested in the **net present value** (NPV), which is the sum of the present values of incoming and outgoing cash flows over a period of time, including the investment cost at time 0. Assuming an average discount rate of 6 % and a depreciation period of 20 years for all unit processes, except for the stripping unit, for which a depreciation period of eight years was assumed as advised by technology providers, the nutrient recovery project presented above would have a positive NPV in year 7 of operation in the best case. This value is at the lower end of the range of payback times for existing anaerobic digestion plants without a nutrient recovery treatment train in the US, i.e. 6.9-8.9 years based on a survey of 24 plants (Vik, 2003). The NPV after 20 years amounted to about 3.5 M \$, resulting in average net financial benefits of ± 2 \$ m^{-3} manure y^{-1} (40 \$ t^{-1} TS y^{-1}) over 20 years.

Table 1 Value of the optimized factors in the treatment train optimization experiment and of the resulting performance indicators; Underlined values impact costs, while italicized values impact revenues; COD = chemical oxygen demand; f_ns_P = fraction of non-settleable precipitates; f_ns_X = fraction of non-settleable biological particulate solids.

Unit process	OPTIMIZATION Optimized factor	Value	PERFORMANCE Indicator	Value
Anaerobic digester	Temperature (°C)	28	Heat input (best/worst case; MWh_{th} d^{-1})	24-41
	Flow rate (m^3 d^{-1})	2,700	HRT (d)	15
	Ca-dose (kg d^{-1})	0	*COD degradation (%)*	55
			VSS degradation (%)	45
			CH_4 production (m^3 m^{-3} manure)	5.8-7.4
			Heat recovery (MWh_{th} d^{-1})	72
			Electricity recovery (MWh_{el} d^{-1})	68
Phase separation	f_ns_P	0.25	*Organic fertilizer production (ton X_COD d^{-1})*	15
	f_ns_X	0.05		
Precipitation unit	$Mg(OH)_2$ dose (ton d^{-1})	1.5	*Mineral fertilizer production (ton P d^{-1})*	1.5
	Seeding Kstruvite (g m^{-3})	3.1	*P recovery (%)*	99
	Seeding Struvite (g m^{-3})	3.1		
	Precipitate flow rate (m^3 d^{-1})	150		
Stripper	Temperature (°C)	55	Heat input (best/worst case; MWh_{th} d^{-1})	42-85
	Gas flow rate (Mm^3 d^{-1})	1.5	Electricity input (MWh_{el} d^{-1})	2.9
	Gas pressure (atm)	4		
Scrubber	Acid flow rate (m^3 d^{-1})	17.5	*Mineral fertilizer production (ton N d^{-1})*	5.0
	Liquid recycle rate (m^3 d^{-1})	2.5	*NH_4-N recovery (%)*	84

Table 2 Costs and revenues (k$ y^{-1}) for the optimized nutrient recovery treatment train; $ = USD; AD = anaerobic digester; CHP = conventional heat and power; CAPEX = capital expenditures; OPEX = operational expenditures.

COSTS (k$ y^{-1})	FIXED COSTS	VARIABLE COSTS					REVENUES RESOURCE RECOVERY		
		OPEX							
	CAPEX	Heat (best)	Heat (worst)	Electricity	Chemicals	Maintenance, material & labor	Biogas + fertilizer best	Biogas + fertilizer worst	CO_2 credits
AD + CHP	22,500	694	1,198	621	-	977	3,547	3,547	1,334
Phase separation	1,250	-	-	2.5	to be evaluated	226	1,741	0	-
Precipitation	4,750	-	-	6.3	102	48	1,468	1,468	-
Strip/Scrub	680	1,034	2,069	74	913	6.8	2,365	2,365	-
Other	2,000	-	-	-	-	-	-	-	-
Rounded total	**31,000**	**1,750**	**3,250**	**700**	**1,000**	**1,250**	**9,100**	**7,400**	**1,350**

The **internal rate of return** (IRR), i.e. the discount rate that makes the NPV equal to zero, after 20 years in this case was 18 %, which approximates the estimated best-case IRR (including subsidies) after 20 years for an operational full-scale WRRF in the Netherlands, i.e. 19-21 % (Gebrezgabher et al., 2010). In the worst-case scenario, the IRR after 20 years was only 5 %. Hence, based on the analysis (worst vs. best case), it can be stated that the feasibility of implementing a resource recovery project will highly depend on the heat recovery potential, the marketing potential of the fertilizers, as well as the subsidies obtained. For instance, when accounting for an income of 40 $ t^{-1} net saved CO_2-equivalents (= current global market price of carbon; LLC, 2012) instead of the conservative US carbon prices (15 $ t^{-1} CO_2-equivalents), the IRR would be around 26 % and 14 % in the best and worst case, respectively, resulting in a revenue of 1.3-3.4 $ m^{-3} manure y^{-1} (25-70 $ t^{-1} TS y^{-1}) averaged over 20 years.

4. Conclusions

The potential of the NRM library for optimization of the operational settings of a selected nutrient and energy recovery treatment train was presented by means of a case study for pig manure. An economic analysis indicated that in the best-case scenario a ZeroCostWRRF can be constructed. The NPV after 20 years amounted to about 3.5 M

USD, resulting in average net financial benefits of ± 2 USD m^{-3} manure y^{-1} or 40 USD t^{-1} total solids y^{-1} over 20 years. The IRR after 20 years was 18 %. Results indicate that subsidies, fertilizer marketing potential and heat balances are key factors determining the feasibility of resource recovery projects. Hence, process and design engineers should focus on the optimization of heat balances in the configuration of future integrated nutrient and energy recovery facilities. Fertilizer regulations and subsidies should be adjusted accordingly.

Abstract

With the demand for water increasing rapidly, optimal operation of Water Distribution Networks (WDNs) is necessary to provide consumers with the maximum amount of water possible in an equitable manner. This paper presents the outcomes of an experimental investigation of supply policies implementable on rural WDNs. Tests conducted on a fully automated lab scale network, configured to represent rural WDNs, shows significant variations in supply time with the operational policy followed. Further, a systematic set of experiments are carried out to determine the flow rates in different network configurations and this data is later used to formulate a linear programming problem that identifies an optimal operational policy for the system.

Keywords: Water distribution networks, intermittent water supply, scheduling, linear programming.

1. Introduction

The global demand for water is increasing rapidly and many Water Distribution Networks (WDNs) are unable to cope with increased demands (Vairavamoorthy et al., 2008). Network operators in developing countries, often resort to demand management through intermittent supply as a temporary solution (Vairavamoorthy et al., 2008). In such intermittent systems, it is common for the supply to be deficient as well as inequitable (Bhave and Gupta, 2006). Even in other networks that normally provide adequate supply, infrastructure becomes a bottleneck for a short time while the system recovers from failures (Chandapillai et al., 2012). These scenarios necessitate an optimal operation of WDNs so that the available water is distributed equitably, in the minimum time possible.

Operation of WDNs has been actively studied in the past few decades and in most of these studies, the objective has been the reduction of operational expenditure (Sankar et al., 2015; Mulholland et al., 2013; Shi and You, 2016). Maintaining the quality of water has also been the objective for few studies (Nichita and Oprea, 2007). As the techniques proposed in the above-mentioned works were mostly intended for urban water networks, availability of sufficient water has been an assumption that is common to all of them. Even though millions of people still receive water for only few hours in a day, the available literature on the operation of WDNs in water deficient scenarios is limited. The method for quantifying the fairness in distributing available water put forth by Solgi et al. (2014) and the model predictive control for water deficient networks proposed by Sankar et al. (2015) are noteworthy efforts in this regard.

In this work, we propose a technique for operating a class of networks with intermittent supply, commonly referred to as Regional Rural Water Supply Systems (RRWSSs). In these systems, one or two sources provide the water required for a group of beneficiary villages with the help of pumps or by gravity. The supply is intermittent and during the supply hours and the objective for the operational policy is to deliver as much water as possible during the day equitably. The control elements available for this are the valves and pumps in the system. Though there have been few recent works that deals with similar networks (Amrutur et al., 2016), the authors have assumed the system to be equipped with continuous control valves. As a feedback loop with flow measurements is necessary for using control valves, they are difficult to implement for rural WDNs and therefore, in this work we limit our scope to networks with only ON/OFF valves. The other important aspect that distinguishes this paper is that it presents the results of an experimental study where experimental data is used instead of a calibrated model. The configuration of the network, experiments carried out on it and results obtained are given in the following sections.

2. Problem description

A typical rural water supply scheme serves several communities or villages in a region. Here, water is stored in a main balancing reservoir and supplied under gravity to village or local tanks using a piped network. The inlet to each tank is fitted with a valve that is either fully open or fully closed and hence behaves like an ON/OFF valve. The basic operation problem of such a WDN is to supply the desired amount of water to each community or village. There are several reasons for poor performance of the network which can be attributed to issues related to design and operation, e.g., mismatch between actual and forecast demand, poor design practices, aged pipes. Even in well designed, relatively new networks, villages at higher elevations or located far away from the source receive lower supplies than those situated near the source or in low-lying areas. The end result is poor performance as defined in terms of limited availability of water, reduced hours of operation, uncertainty and inequity in supply.

The problem we address is the maximal distribution of water to the beneficiary villages maintaining equity. A simple policy is to fill each tank one at a time. An alternative policy is to open all valves simultaneously and close the valves leading to a particular tank when the demand is met. However, these heuristics may not be feasible or guarantee equitable supply. We propose to solve this problem by formulating an optimization problem (P) where the objective is to meet the cumulative demands while minimizing the time required by manipulating the ON/OFF valves in the inlet of the respective tanks. The decision variables are the time span between event points in the day (τ) and the state of the ON/OFF valves (x) during this time. Additionally, the variables Q and h indicate the flow and head in pipes and junctions respectively. Sets E_{pipe}, E_{valve} N_T, N_S and N_I represent the pipes, valves, beneficiary villages (demand points), source nodes and intermediate nodes in the network. I_{max} denotes the number of intervals the available time is divided into. Other parameters used here are the length of pipes (z), diameters (d), Hazen William's coefficients (ϕ) and demand for water at the villages (D). In this Mixed Integer Non-linear Program (MINLP), constraint equations (2) & (3) model the flow across pipes and valves respectively, (4) specifies the head at the source and villages, (5) represents mass balance at intermediate nodes and (6) ensures the demand satisfied at all downstream villages.

$$(\mathrm{P}) \min_{\tau,x,Q,h} \sum_i \tau_i \tag{1}$$

$$\text{s.t.} \quad h_{i,l} - h_{i,m} = sgn(Q_{i,(l,m)}) \frac{10.67\ |Q_{\{i,(l,m)\}}|^{1.85} z_{(l,m)}}{\phi_{(l,m)}^{1.85} d_{(l,m)}^{4.87}} \qquad (l,m) \in E_{pipe},\ 1 \le i \le I_{max} \tag{2}$$

$$\left(h_{i,l} - h_{i,m}\right) x_{i,(l,m)} = 0 \qquad (l,m) \in E_{valve}, 1 \le i \le I_{max} \tag{3}$$

$$h_{i,j} = h_{i,j0} \qquad j \in N_T \cup N_S, 1 \le i \le I_{max} \tag{4}$$

$$\sum_{(l,m)\in E} Q_{i,(l,m)} = 0 \qquad m \in N_I, 1 \le i \le I_{max}, E \in E_{pipe} \cup E_{valve} \tag{5}$$

$$\sum_i Q_{i,(l,m)} \tau_i = D_m \qquad j \in N_T \tag{6}$$

Upon solving the problem P, if the minimum time is less than the maximum time of operation (e.g., 24 hours if daily demand is specified), the solution is feasible. However, if the minimum required time is greater than the available time, the solution is infeasible. In such a case, we reduce the supply time for every community by the same factor and such a policy would distribute the maximum amount of water equitably.

The above problem is a computationally challenging MINLP and requires a well calibrated hydraulic model to be solved. We address both these issues and present an efficient technique for solving the same. To this end, we propose to decouple the optimization from the hydraulic modeling completely. Each of the valve configurations results in a unique set of flow rates in the network. Given n tanks in the network, each inlet valve can be either in the ON or OFF state and hence the number of states is $N=2^n$. Hence, the network state space is finite and the flow rates in the pipes and the tank inlets are uniquely determined by the state of the valves. The problem would determine the time for which the system had to be operated in each of the above-mentioned valve configurations to meet the demand requirements. The objective is to minimize the time required for supplying the water. The decision variables t_p are the time intervals for which valve configuration p had to be active. $q_{j,p}$ denotes the flow rate into tank j in valve configuration p.

$$(P1) \min_{t\ge 0} \sum_{p=1}^{N} t_p \qquad s.t \quad \sum_{p=1}^{N} q_{j,p}\, t_p = D_j\ , 1 \le j \le N_T \tag{7}$$

The flow rates q_{jp} can be determined using a hydraulic solver. However, if the number of tanks is small, the flow rates can be determined experimentally by recording flow rates into the tank in all the N valve configurations. Thus, the decomposition approach allows us to solve a Linear Program ($P1$) to be solved instead of a challenging MINLP and obviating the need for a well calibrated hydraulic model.

3. Experimental setup

This study was conducted on a lab scale WDN indicating a RRWSS with a single source supplying water to five downstream villages. A schematic of the setup is given in Fig.1. It consisted of one Over Head Tank (OHT) representing the source and five Small Tanks (STs - numbered T1 to T5) representing the storage at the villages. The OHT was made of PVC with 75 cm height and 45 cm diameter and had a capacity of 100 litres. It

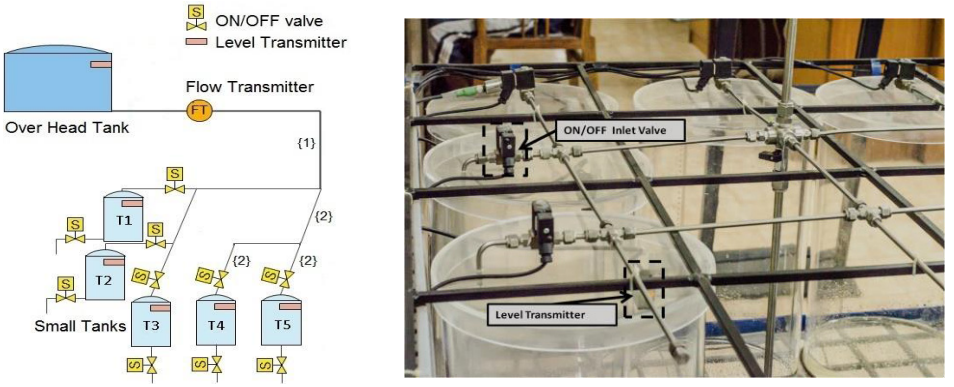

Figure 1 a) Schematic of network b) Lab scale water distribution network

was placed at an elevation of 4 m from the ground. The STs were made of acrylic glass with 50 cm height, 30 cm diameter and 25 litres capacity. The main pipe denoted as 1 in Fig.1(a) had 300 cm length and 1.27 cm diameter and smaller pipes denoted as 2 were of 30 cm length and 0.32 cm diameter. All pipes were made of stainless steel and the complete setup was supported on a 4 × 2.5 × 2 m steel structure.

The out flow of the OHT was controlled by a flow control valve connected to its outlet. The flow into the STs were controlled by ON/OFF valves (Burkert 6011, solenoid valve) placed at their inlet and out flow from them were controlled by ON/OFF valves connected to their outlet. All tanks were equipped with ultrasonic level transmitter (Baumer U500) to measure the water level online. Additionally, there was an ultrasonic flow transmitter (Burkert 8081) connected downstream of the control valve to measure the flow inline. All the instruments were interfaced to a computer through National Instruments DAQ card and LabVIEW was used to program and control the devices. The water level in the OHT was maintained at a constant level of 42.5±2.5 cm.

Here, the problem of supplying water to beneficiary villages translates into the problem of supplying water to the STs from the OHT. For this, the water requirements at the STs were decided as given in Table 1. The problem at hand was to satisfy the water requirement of the STs in the minimum time possible. As in the RRWSS discussed by Bhave and Gupta (2006), the control elements available for our experiments were the ON/OFF valves at the inlet of the STs. The outlet of these tanks was kept closed and therefore, the amount of water supplied could easily be inferred from the level measurements. Levels were measured at a rate of 5 Hz and filtered within LabVIEW. The control valve immediate downstream of the OHT was always kept fully open.

4. Operational policies

Two heuristic supply policies were tested for the case. In the first case (HEURISTIC-I), the inlet valves to all the five STs were opened simultaneously. The supply to each tank was stopped as when its respective demand was satisfied. This mode of operation required 2284 s to meet the requirements as shown in Figure 2. A colored cell indicates that the valve is open and white cell indicates that the valve is closed. In the next policy tested (HEURISTIC-II), the inlet to only one tank was opened initially. Once the

requirement for the tank was satisfied, it was closed and the next was opened. Continuing likewise for all tanks, it took 3712 s to provide the water. The actual amount of water supplied following each of the above-mentioned control policies is given in Table 1.

The optimal operation here is the one which meets the requirements of the STs in the minimum time. The setup involved five tanks with ON/OFF valves connected at their inlet, there were a total of 2^5 valve configurations possible. Therefore, 32 different experiments were conducted to determine the flow rates into each tank at different valve configurations. The optimal supply scheme (OPT) obtained by solving $P1$ required 2197 s to supply the water. The Gantt chart depicting this is shown in Fig. 3. The actual amounts of water supplied (last column of Table 1) are almost equal to the demands. The slight deviations between them is due to flow measurement errors and marginal variation in the head within operating range set for OHT. While the heuristic supply schemes have only one downstream tank receiving supply for all or some of its operational time, the optimal scheme provides supply to at least two tanks always. In this way, it makes a better use of the pipes in the network and delivers water in the minimum time.

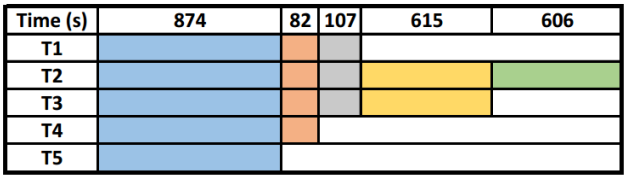

Figure 2: The heuristic supply policy beginning with all tanks open (HEURISTIC-I)

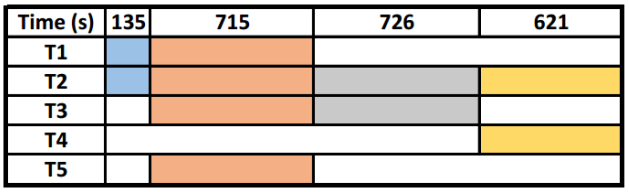

Figure 3: Gantt chart showing optimal supply policy (OPT)

Now if in the real scenario, we have only 1750 s to complete the supply, even the optimal supply policy would not meet the requirement in the given time. In such a case, the active time of every network configuration in the optimal operational policy has to be brought down by a factor of 1750/2197. Such a scheme of operation would reduce the supply to every ST by the same factor i.e.~ 0.8 and ensure equitable operation.

Table 1: Water supplied to the STs

Tank Number	**Demand (l)**	**Supplied (l)**		
		HEURISTIC-I	HEURISTIC-II	OPT
T1	6.40	6.44	6.27	6.37
T2	18.70	18.81	18.58	18.82
T3	11.35	11.39	11.41	11.33
T4	7.48	7.53	7.43	7.50
T5	7.48	7.45	7.41	7.51

5. Conclusions

The paper presented the determination of supply time in WDNs with operational policies with the help of experiments conducted on a lab scale network. The optimal supply scheme required 4 - 69 % less time in comparison to heuristic supply strategies. Also, on implementing the operational policies developed from measured flow rates, the actual water supplied met the demands for all consumers. The results are encouraging for implementing the operational scheme on intermittent WDNs retrofitted with automated ON/OFF valves.

Sustainable Industrial Water and Energy Nexus Integration for an Industrial Park

Jamileh Fouladi, Patrick Linke

Texas A&M University at Qatar, Education City, Doha, Qatar
jamileh.fouladi@qatar.tamu.edu

The water-energy nexus and integration has been recently proposed to minimize water-energy footprint of an industrial park. Their sustainable design requires careful consideration of energy and water management aspects. This work represents an integrated management across the water and energy nexus. We propose an optimization-based methodology, which considers main decision across the water-energy nexus for industrial clusters. Building on our previous work in industrial water networks, a representation is generated that accounts for the links between water and energy. In this work, the Tool for the Reduction and Assessment of Chemical and other environmental Impacts (TRACI) metrics have been used in order to quantify some of the environmental emissions. Global warming and eco-toxicity impacts are the ones, which are calculated for the optimized design. Pareto front curves are generated for a case study in order to capture the trade-offs between the minimum total annual cost and environmental sustainability metrics.

Keywords: Water-Energy Nexus, Sustainability Metrics, Optimization.

1. Introduction

Global population is expected to reach 8.5 billion by 2030. As a consequence, the water and energy demands are increasing steadily. Industrial clusters have high energy and water footprints especially in the Gulf Cooperation Council (GCC) region. Therefore, solutions need to be developed for high performance with respect to sustainability dimensions, especially regarding economic and environmental impacts. In this work, waste heat utilization has been added to the previous published superstructure (Alnouri et al, 2014). Waste heat utilization means the use of waste heat that can be converted to power based on the design electricity demand, while the non-reusable heat is discarded to the cooling systems. There are different sustainability metrics and methods available nowadays which can cover these dimensions. Sustainability metrics mainly are divided into three different categories; economical, environmental, and social impacts. Concerns that are addressed by these metrics include economics, environmental, and safety concerns. Process design for sustainability involves complicated decision-making scenarios and this makes it difficult to explore the trade-offs using existing methods. Over the years, researchers have suggested many metrics and indicators but most of the metrics cover only one of the aspects. Accordingly, in this work the objective is to design a systematic approach to explore efficient strategies and design for integrated water and energy management. Moreover, to introduce a methodology for designing sustainable chemical and petroleum processes during early stages of design in order to capture the trade-offs between economic and environmental concerns.
Research contributions mainly focused on reducing the water and energy footprints of existing industrial park with process water-energy integration interactions especially

considering process cooling requirements and cooling systems, desalination systems, and treatment units. The method consider an optimization model to systematize the search for the representation.

2. Problem Statement

In this work an existing water network problem has been expanded from Alnouri et al (2014, 2015) by considering process cooling requirements (Air Coolers (AC), Cooling Towers (CT), Cooling Seawater (CS)), and desalination plants. Moreover, each plan has a surplus waste heat which can be converted to power and used in any energy sinks (Figure 1).

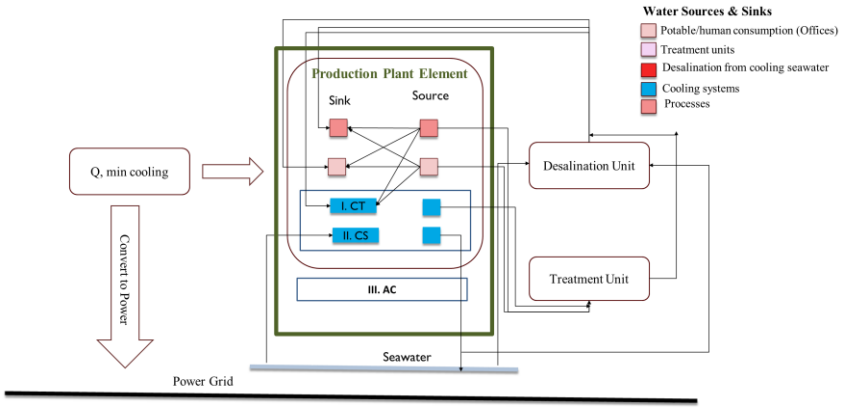

Figure 1. Water-Energy Integration

The main optimization objective is the total annual cost (TAC) minimization (which covers by economic metrics), subjected to some environmental emissions and metrics. In this work, the TRACI approach is used to calculate the environmental emissions and impacts. TRACI is one of the environmental impact assessment software available with different characterization factors to assess life cycle assessment and sustainability metrics. Characterization factors measure the potential impacts. The impact categories include the followings: Ozone Depletion, Global Warming, Acidification, Eutrophication, Smog Formation, Human Health (Particulate, Cancer, and Non-cancer), Eco-toxicity, Fossil Fuel Use, Land Use, and Water Use. The water-energy integration and optimization problems will not change the industrial city design and layout. Therefore, safety and health metrics are not affected by these types of simulations and can their change can be negligible.

3. Implementing Methodology

Figure 2 shows the methodology in order to calculate the sustainability metrics for the proposed water-energy networks. As it is shown in Figure (2), the main objective of the optimization problem is minimizing the total annual cost of the design.

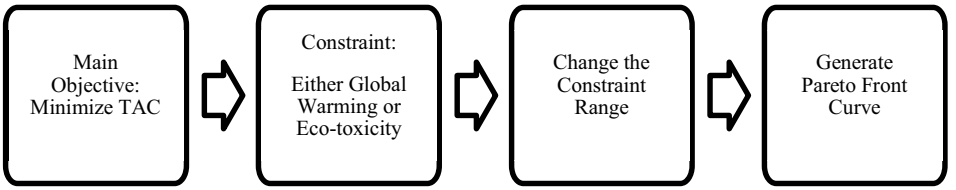

Figure 2. Implemented methodology

Meanwhile, an emission cap is subjected to the objective as a constraint. Once the optimum design with the minimum total annual cost is obtained, the next trial the optimum design for the minimum selected emission will be found. Therefore, the boundaries and range of constraint can be determined by getting the maximum and minimum values for the corresponding emission.

In this work, the environmental waste and emissions for the proposed problem were analyzed as shown in Figure 3. The environmental emissions in this problem based on the components can be divided as solid waste, atmospheric impact, and aquatic impact. However, solid waste do not change significantly since the treatment options are not the main differences in different trials. So, only two categories have been quantified; global warming and eco-toxicity impacts.

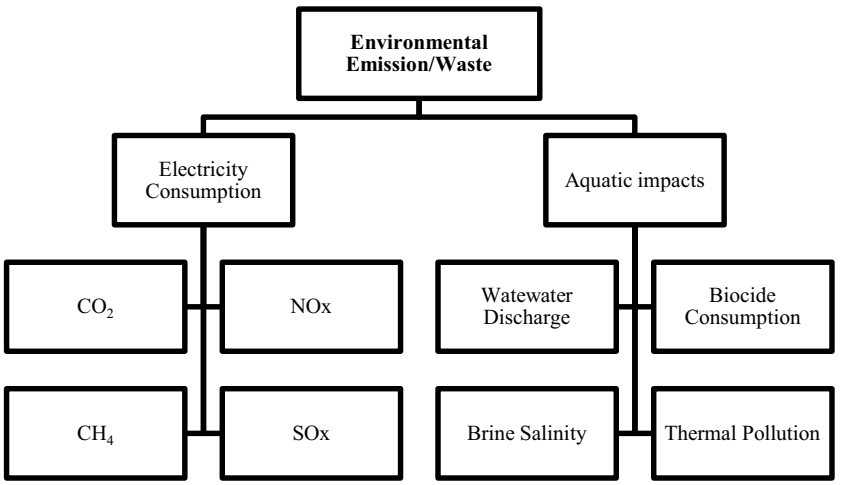

Figure 3. TRAICI environmental emissions corresponding to the defined problem

In order to quantify emission impacts the following equation has been used (EPA, 2012):

$$I^i = \sum_{xm} CF^i_{xm} * M_{xm} \quad (1)$$

Where:

I^i= The potential impact of all chemicals (x) for a specific impact category of concern (i)

CF^i_{xm}= The characterization factor of chemical (x) emitted for impact category (i)

M_{xm}= The mass of chemical (x) emitted

4. Case Study

The proposed method is illustrated with a case study of three plants; Ammonia, Methanol, and Gas-to-liquid (GTL). Water sources and sinks data with selected for four contaminants (TDS, Organics, Sulphate, Oil and Grease) have been collected (Martinez, 2014). It was assumed that there is a single central and decentral treatment as well as central desalination units. The technology used in the problem is Nano-Filtration since it satisfies all the sink contaminants composition.

5. Results and Discussion

Different scenarios were solved to compare the differences between applying energy concept with and without waste heat to power utilization and see the trade-off between economic and sustainability metrics.

5.1. Without Waste Heat Utilization

Different scenarios have been optimized without the waste heat utilization (cooling requirements) in order to get the trades-off between the total annual cost and different categories in sustainability metrics. The total annual cost of the design increases as the environmental emissions (Global Warming (GW)) decreases. Obtained trends show the more sustainable the solution is, the more expensive the design gets. The cooling system design changes from air coolers to cooling seawater from point F to A. The global warming impact reduces in case of cooling seawater as the power consumption is the minimum. Moreover, the water network design changes by changing the cooling systems, which means the amount of reused water, discharged water and other flow rates change. In general the trends show, the total annual cost increases by decreasing the global warming impact, since more treatment is required and therefore more water reuse.

Table 1: Total annual cost versus global warming impact before waste heat utilization

	Scenarios					
	A	**B**	**C**	**D**	**E**	**F**
Cooling System	Both AC	Both AC	AC+CT	AC+CT	CT+CS	CS

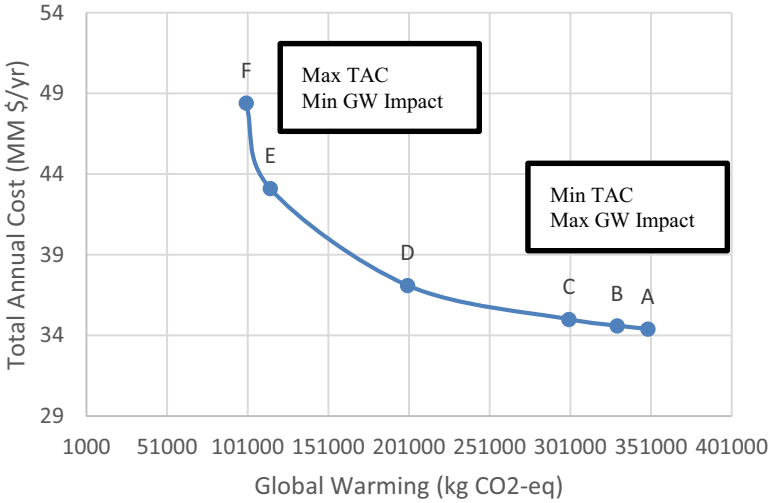

Figure 4. TAC versus GW impact (without waste heat utilization)

For the eco-toxicity influence (Aquatic impact), in case of the optimal solution, which is selecting Air Coolers there is no difference in the impact by doing different trials since the contaminants included in the case study are not in the Aquatic eco-toxicity categories in TRACI metrics and in the Air Cooler design there is no flow for water. If we force the design to select other cooling options, it can be noticed that as the cooling system option changes from the Air Coolers to Once-Through Cooling Seawater the eco-toxicity increases with total annual cost. Once-Through Cooling Seawater has the maximum impact because of the Biocide components (Seawater Chlorination).

5.2. With Waste Heat Utilization

In the next section, the sustainability metrics were quantified and compared for the scenario with waste heat utilization. In this scenario, the global warming effect decreased by almost 90 percent while the total annual cost is reduced by 10 percent. The remaining 10 percent of global warming impact is emission related to the external utility which will not be affected by the problem design. As it is shown in Figure 5 different Pareto front curve is generated after waste heat utilization. As it is clear by waste heat utilization the annual cost decreases a little. However, the change in the emissions impact is significant (around 90%), which means the result is lower cost, lower emission. Figure 4 indicates that the obtained trend shows that in the case of air coolers the maximum benefits is obtained for the global warming impact. It can be justified since the air coolers have the maximum power consumption compared to other cooling system options. The change in the total annual cost is not significant since the power-generated cost from the waste heat is almost the same as the external power cost. By waste heat utilization, the cooling load reduces which reduces the cooling systems cost.

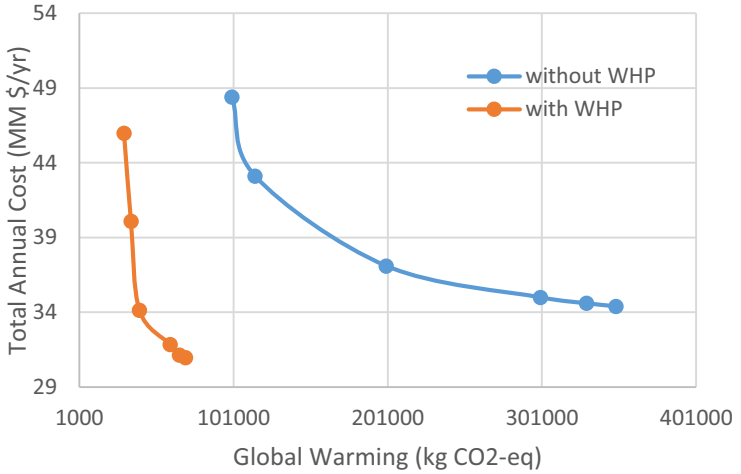

Figure 5. Global warming impact comparison before and after waste heat utilization

6. Conclusions

This work represents a systematic approach for integration of industrial parks across the water-energy nexus. The objective of this paper is to develop a framework for optimizing energy and water resources from processes that have a surplus of energy at various qualities by accounting for different sustainability metrics. Furthermore, a case study was used to illustrate the approach and compare different scenarios for developing sustainable water-energy strategies.

Abstract

This aim of this work is to provide a framework for application of Simulated Annealing (SA) Algorithm for solving Water - Heat Nexus problems for Industrial Cities. The combined water-heat network synthesis problem has been formulated into a Mixed Integer Non-Linear Programming (MINLP) and this work describes the various components of the framework needed to handle it. The SA algorithm converges asymptotically across several runs. Apart from the best solution, this tool stores multiple solutions with varying degree of performance. The application of this algorithm has been illustrated with a case study and the benefits of metaheuristics search techniques have been highlighted.

Keywords: Simulated Annealing, Meta- Heuristics, Water - Energy Networks, MINLP.

1. Introduction

Synthesis of efficient water or heat networks in industries is an important aspect of planning for a sustainable and cost effective enterprise, as they are important constituent of all industry. These networks can be more efficient if the nexus between water and energy resources are studied and benefits exploited. Often these problems are presented as MINLP and solved using deterministic solvers, which reportedly struggle with complexities, involved (Gao and You, 2015).The aim of the paper is to apply SA for solving these network problems and highlight their benefits. Though it has been used to solve problems like molecular design [2] and reactor networks [3], it has not been used in solving water-energy network problems and this work will be the first attempt to solve these problems using SA. It would provide a basic framework for executing SA and can later be utilized for solving similar optimization problems with more resources involved.

2. Simulated Annealing

SA is a probability based metaheuristic method that is used for finding optimum values for large solution space problems. It mimics the actual annealing process for determining the optimal solution. For water-energy network problem, an initial solution is provided and then transitions are made on this solution to generate multiple solutions around its neighbourhood for given artificial temperature. This process mimics the part where the system is allowed to attain the maximum number of states and equilibrates the system at each temperature stage. If the performance of the solution is better than the previous solution, it is accepted. If it is worse, it is not rejected straightaway but

rejected with a probability and gives the system a chance to go towards going towards adverse performing regions. Compared to deterministic algorithms that are gradient based and process the full MINLP model simultaneously, the approach utilized to develop the stochastic algorithm implementation handles the equations, inequalities, objective function with different modules. The advantage being its ability to able to handle non-linearities in the problem effectively and since the search mechanism is independent from other components, the tool has the freedom to explore the solution space thoroughly without being stuck.

3. Water – Energy Nexus Problem

The water-heat network problem illustrated in this work includes water network formulation adapted from Alnouri et al [4] with addition of cooling systems for waste heat. Figure 1 shows the combined network and the synergy between them. The problem consists of an industrial infrastructure with sources, sinks, on-site decentral treatment units and a centralized treatment units for water networks. To discharge the waste heat, options of cooling tower, air cooler and once through seawater system have been incorporated. Cooling Tower and once through seawater system require water for their operation. Usage of cooling water incorporates a new sink and source in the water network when they are utilized and hence the nexus. The sinks can be supplied with external supply of freshwater, treatment units and water from sources. Water from sources can be discharged to environment, sent to treatment units or can be recycled back to sinks. There are concentration constraint on sinks and environment. Together with all the information about these facilities and spatial information about the industrial city, a MINLP problem is formulated with an objective of minimizing total cost and finding the optimal configuration of the combined network.

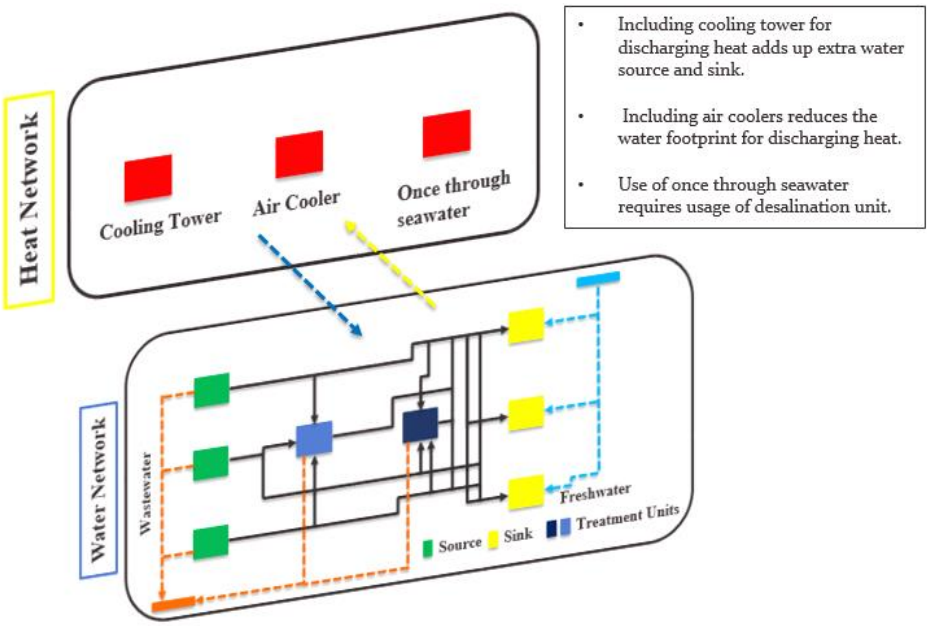

Figure 1: Water – Energy Nexus

4. Implementation

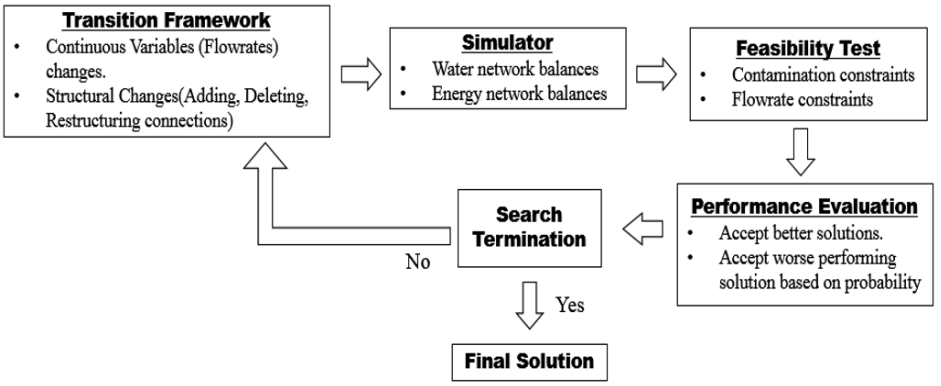

Fig 2: S.A Implementation: Modular Approach

The implementation begins with an initial solution, which in this case is a linear structure in which the requirement of sinks are met by freshwater and heat being disposed from cooling tower. Random changes are made on the given structure using the transition framework to generate new solutions which involves assigning values to different connections across various facilities. As the superstructure of this network has a large number of possible connections, the search becomes complicated exponentially with the problem size. Due to constraint of space, this transition framework will be described in detail in the complete manuscript. This solution is then simulated to calculate the freshwater and wastewater discharges. The simulator consists of mass balance equations at sources, sinks, treatment units and wastewater discharges and heat balances for the three cooling options. These equations are transformed into set of linear equations as many of the variables are varied by the solver in one module. The new solution is simulated to find the freshwater and wastewater discharges and feasibility checks are performed. The solution is accepted if it better than the previous one. If it has lower performance, then it is not rejected outright but has a probability assigned to it according to which it may be accepted or rejected. Traditional MINLP optimization packages often struggle to handle larger size case studies just for single resource problem [5], the tool presented in this paper is able to handle multiple resources in single problem and stores multiple optimal solutions which are similar in performance but different in structure. This gives the user insight into the other solutions and options to implement any of them. In case of traditional package, the user gets only one structure as final answer and no insight into other solution.

5. Case Study

The case study consists of three plants of Ammonia, Methanol and GTL, which discharge four major contaminant, namely TDS, Organics, Ammonia and Nitrogen. Tables 1 & 2 present the source and sink data used for the case study and Table 3 presents the waste heat data from the three different plant.

Table 1: Source Data

	Flowrate(tons/d)	TDS(ppm)	Organics(ppm)	Ammonia(ppm)	Nitrogen(ppm)
P1S1	45	50	4	1	50
P1S2	154	2500	20	2.5	25
P1S3	400	550	15	25	40
P2S1	281	500	100	0.5	5
P2S2	115	2500	20	2.5	25
P2S3	500	550	15	25	40
P3S1	16648	500	46	0.5	5
P3S2	147	550	15	25	40

Table 2: Sink Data

	Flowrate(tons/d)	TDS(ppm)	Organics(ppm)	Ammonia(ppm)	Nitrogen(ppm)
P1D1	2571	500	4	0.5	21
P1D4	840	200	4	0.5	5
P2D1	1912	500	4	0.5	21
P2D4	500	200	4	0.5	5
P3D1	7115	500	4	0.5	21
P3D3	163	200	4	0.5	5

Table 3: Waste Heat Data (MW)

Plant	Cooling Tower
Ammonia	237
Methanol	104.8
GTL	982.67

The objective function of optimization problem is minimization of cost that includes the freshwater cost, capital and operating cost of treatment unit and the piping cost for water network. For the heat network, the cost includes capital and operating cost of cooling tower, air cooler and once through seawater cooling option.

6. Results

SA algorithm has been implemented using MATLAB using a desktop PC with Intel® Core ™ i7-2620M, 2.7 GHz, 16.00 GB RAM, and a 64-bit Operating System. The optimal solution has been obtained after running several runs with different markov chain length with sizes varying from 50 -100 and it takes around 4-6 hours for a run to converge. The lowest cost solution has an objective function value of \$33.1 x 10^6 per year. Apart from the best solution, the program stores all the solutions are better than initial configuration. The result for the least cost structure has been listed in tables 4-6. All the flowrates are in tons/hr.

TR(GTL)	0	0	0	0	0	0
TR(Central)	107.125	35	79.67	20.833	296.45	6.792

Requirement of water at all the sinks is met by treated water from sources. The treatment unit utilized is reverse osmosis. The best solution doesn't require extra fresh water from an external source and there are no connections from sources and sinks.

The waste heat generated from the three plants is directed to Air Coolers to be discharged into the environment. The reason being the other two options required a lot more water for removal of heat which in turn added to the cost.

The problem was solved using various initial points and varying markov chain to test the robustness of the platform. Figure 3 shows various runs converging asymptotically to solutions with similar objective function value thereby establishing the robustness of the solver.

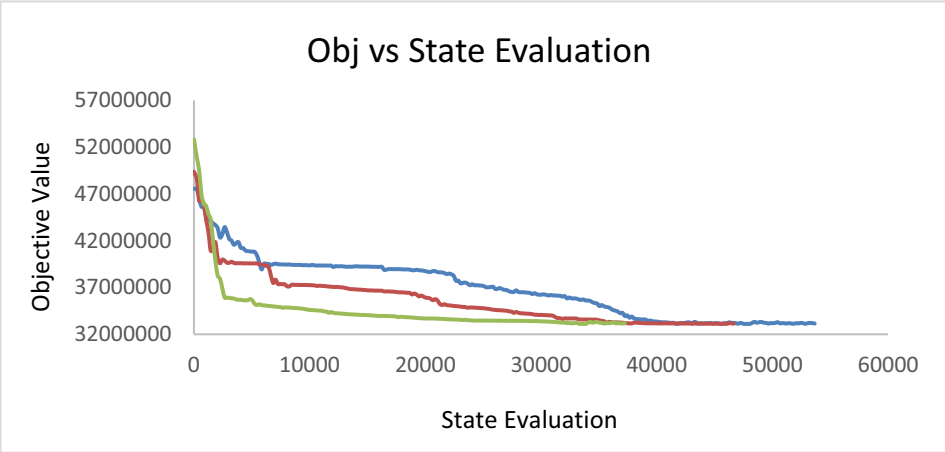

Fig 3: Objective Function vs State Evaluation

7. Conclusions

The solution procedure proposed in this work provides an alternative approach for solving Water Network problem. Various aspect of an optimization problem (equality constraint, inequality constraints and the objective function) has been dealt with separately compared to deterministic methods where they are considered together while solving the problem. The method converges asymptotically to a solution and provides multiple solution options apart from the best solution obtained. The work provides a framework for applying SA to solve multi - resource optimization problems. Future works will target problems like Water-Heat- Carbon Dioxide network optimization.

Abstract

This work proposes an optimization model for the design of an industrial cluster based on sugarcane bagasse in the Indian context. Three different products, namely, ethanol, electricity, and pellets, along with the possibility of selling raw bagasse and burning it in boiler are considered. An economic optimization model to maximize the net present value of the cluster is formulated. Simultaneously, a multi-objective optimization model to minimize the environmental impacts is formulated. The model was applied to a case of a sugar mill processing 181 Mg/h sugarcane. Economic optimization recommended electricity production as the optimal option at the current product prices. This was also desirable from the GHG emission reduction standpoint. However, electricity production led to highest water footprint. Ethanol price has to increase by 100% over the target price for economic feasibility. Pelletization was preferred only from a water footprint perspective.

Keywords: Bagasse, Industrial Ecology, Optimization, India, Ethanol

1. Introduction

Sugarcane bagasse is a highly promising source of biomass in the Indian context for the establishment of a bio-based economy. Bagasse can be used to produce a number of value added products such as pellets, electricity, ethanol, paper board, and specialty chemicals such as vanillin. Each of these products varies in terms of costs, technology readiness level, per unit revenue, and market capacity. Moreover, the environmental impacts of these alternatives also vary considerably. Utilization of sugarcane bagasse, therefore, poses a sustainability challenge with food, energy and water nexus. Region specific factors are critical and must be considered in the analysis. Such studies have been reported in literature for some sugar producing countries (Furlan et al, 2012, Ensinas et al, 2013). However, such an analysis has not been conducted in the Indian context. This work addresses this knowledge gap by proposing an industrial ecology approach and optimizing the design of an industrial cluster based on sugarcane bagasse. An existing sugar refinery providing a fixed quantity of bagasse is considered. Three different products of bagasse, namely, pellets, electricity, and ethanol, are considered. An economic optimization model is formulated to understand the profitable products and the sensitivity of those results to product market prices. Simultaneously, the global warming potential (GWP) and water footprint for the same products are calculated to understand the environmental trade-offs.

The article is arranged as follows. The optimization model formulation is given in Section 2. Section 3 discusses the key results from the simulation studies, and the important conclusions are summarized in Section 4.

2. Optimization model formulation

An existing sugar mill with a boiler to provide process heat in the form of steam is assumed. The procurement of sugarcane to the facility and the operations part of the conventional sugar mill are not considered since it is assumed that those are already set-up and operational. Similarly, transportation of products produced from bagasse (or bagasse as a product) is not the part of the system boundary. For a fixed capacity of the sugar mill, the bagasse availability is also known.

Bagasse generated can potentially be split into five streams, three of which include further processing to produce value added products, namely, ethanol, pellets, and electricity (Fig. 1). Of the remaining two streams, one stream goes to the boiler to meet the energy demand of the mill as well as various production processes within the industrial cluster. This ensures that the industrial cluster is energy self-sufficient. The second stream represents bagasse that is directly sold in the market without any processing. The energy production operations in the clusters (boiler and electricity) are further supported by trash collected from sugarcane farms as feedstock. It is assumed that only the trash on farms supplying sugarcane to the mill is available, which sets an upper bound on the total trash that can be utilized.

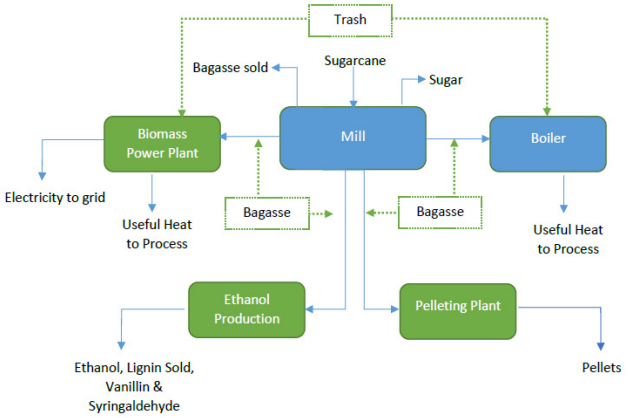

Figure 1: Alternatives for the utilization of bagasse and trash considered in the cluster. Blue boxes indicate existing facilities in the sugar mill while green boxes indicate new facilities

The ethanol production process uses the organosolvent pretreatment, which produces relatively pure lignin that can be used as feed to the boiler. The cellulose and hemicellulose separated after pretreatment are used for ethanol production. Pelletization involves three major steps: drying (up to 10% on wet basis), grinding (size reduction) and densification (Mani *et al*., 2006). Individual pellet density ranges from 1000 to 1200 kg/m^3 whereas the bulk density of pellets is 600 to 700 kg/m^3. Pellets coming out of pellet mill (at about 70°C to 90°C) are cooled, packaged and sold. Biomass Integrated Gasification Combined Cycle (BIG-CC) configuration is considered for electricity production using bagasse and trash as the feedstock. Combustion gases drive the gas turbine to generate electricity through generator. The exhaust gases from gas turbine are used to generate steam in Heat Recovery Steam Generator. The steam drives

the steam turbine to generate more electricity and useful heat, which can be delivered to other processes of the facility (Ensinas *et al*., 2007).

Two different optimization models have been formulated, capturing the economic and environmental impact associated with the proposed industrial cluster. These models are explained in the following sections.

2.1. Economic optimization model formulation

The model constraints include the mass and energy balances relevant to each unit process/operation described in the previous section. These constraints are formulated by considering the performance data from literature. Only selected constraints are reported here for brevity. A key mass balance constraint is the distribution of bagasse to five possible routes as shown in Fig. 1, which is modeled as follows:

$$total_{bagasse} = bgs_{eth} + bgs_{elec} + bgs_{pel} + bgs_{boiler} + bgs_{market} \quad (1)$$

where, $total_{bagasse}$ is the total available bagasse (Mg/h) obtained after sugarcane juice extraction, bgs_{eth} is the amount of bagasse (Mg/h) sent to ethanol production, bgs_{elec} is the amount of bagasse (Mg/h) sent to the electricity generation unit, bgs_{pel} is the amount of bagasse (Mg/h) sent to the pelleting plant, bgs_{boiler} is the amount of bagasse (Mg/h) sent to the boiler, and bgs_{market} is the amount of bagasse (Mg/h) that is directly sold in the market. Additional key constraint is the distribution of collected trash to electricity generation unit and the sugar mill boiler:

$$total_{trash} = trash_{elec} + trash_{boiler} \quad (2)$$

where, $total_{trash}$ is the total trash collected and transported (Mg/h) to the integrated facility, $trash_{elec}$ is the amount of trash (Mg/h) sent as a feed to electricity generation unit, and $trash_{boiler}$ is the amount of trash (Mg/h) sent to the boiler. Another important energy constraint is the overall heat demand of the facility:

$$C_{p,bagasse} * bgs_{boiler} + C_{p,lignin} * lignin_{boiler} + C_{p,trash} * trash_{boiler} + heat_{useful,elec} \geq heat_{mill} * Feed + bgs_{eth} * heat_{ethanol} \quad (3)$$

where, $C_{p,i}$ is the specific heat of combustion of material i (bagasse, trash, or lignin), $heat_{useful,elec}$ is the heat supplied by the power plant, $heat_{mill}$ is the heat demand of existing sugar mill, $heat_{ethanol}$ is the heat demand of ethanol generation facility, bgs_{boiler} is the amount of bagasse sent to boiler, $lignin_{boiler}$ is the amount of lignin sent to boiler, $trash_{boiler}$ is the amount of trash sent to boiler, and $Feed$ is the amount of sugarcane processed in the facility. The capital and operating costs for each of these processes are considered, and the corresponding cost functions constitute another important set of constraints. The key decision variables are the distribution of bagasse and trash to the various streams, as described the constraints in Eq. 1-3. The objective function is the maximization of Net Present Value (NPV) of the integrated facility where the NPV equation is linearized. This is a Mixed Integer Linear Programming (MILP) problem with 144 continuous variables, 4 binary variables

(selection of processing options), and 144 constraints. The model is formulated in GAMS® (General Algebraic Modelling System) solved using the CPLEX® solver.

2.2. Environmental optimization model formulation

The multi-objective optimization problem considering two environmental impact categories, namely, net greenhouse gas emissions (GHG) and water footprint, is formulated. Only the direct water footprint is considered. The model also considered the avoided GHG emission due to replacement effect, such as the replacement of petroleum based gasoline with ethonol from bagasse. Since the overall GHG emissions and water footprint numbers for all the processing options are directly used, a detailed mass balance for each step is not necessary. This model, therefore, is much simpler than the economic optimization model previously described. It is linear programming model with the decision variables as the amount of bagasse diverted to each of the five streams. ε constraint method is used to solve the problem and obtain the Pareto front. The model is not discussed here for brevity.

3. Results and discussion

The model was applied to a case of sugar refinery processing 181 Mg/h of sugarcane. 50% retention of trash on farm was assumed as base case. The selling prices for electricity (₹6/kWh) and pellets (₹10/kg) were as per the market values while the selling price of ethanol (₹39 /l) was as per the target price set by the government (₹ represents Indian Rupees). The pelletization rate was 4 Mg/h and a minimum size of 6.5 MW power plant was enforced. The prices of various chemicals and inputs were taken from literature. Table 1 shows the values of GHG emissions and water requirement for various products, including GHG offset due to replacement of an existing product.

Table 1: life cycle Input data for the different products produced from bagasse

Products	Bagasse requirement (kg)	GHG emissions; GHG offset (kg of CO_2/unit of Product)	Water requirement (lit /unit of Product)
Ethanol (lit)	6.636	0.31; 0.357	247
Electricity (kw)	5.14	0.051; 0.81	224
Pellets (kg)	2	0.27; 0	73

3.1. Economic optimization

The model was first used to determine the Break Even Selling Price (BESP) for all the three commodities individually when integrated with the existing sugar mill. BESP of ethanol, pellets and electricity was ₹64/l, ₹9/kg, and ₹3/kWh, respectively. This indicated that ethanol production was not profitable. In contrast, electricity production was profitable; primarily due to the consideration that bagasse (feedstock) was free.

When the optimization model was solved considering all potential uses of bagasse, electricity generation was recommended as the optimal solution and no other processing route was chosen. With the feed rate of 181 Mg/h and 50% trash retention, all of the 22.17 Mg/h available bagasse and 12.62 Mg/h trash was sent to the power plant facility. Boiler got no feed of bagasse and trash as the heat generated by the power plant was enough to meet the energy demands. The size of the plant was 37.84 MW and hence

capable of providing around 281 million units (kWh) of electricity annually to the grid generating revenues of ₹169 crores at an initial investment of ₹712.6 crores with annual profit of ₹105.75 crores (1 crore is equal to 10 Million, and 1 ₹ is about 0.015 USD).

The sensitivity of the result to the market prices of various products was studied. Electricity market is well established and therefore the prices are relatively stable. Therefore the cost of electricity was fixed at the base value. The selling prices of ethanol and pellet were varied and the resulting optimal product portfolio was determined. The results (Fig. 2) indicated that ethanol production became profitable only if the selling price was more than ₹76/l. Similarly, pelletization became profitable if the selling price was more than ₹14/kg. Note that since there was an upper cap on the pellet market, electricity was still produced for a pellet price higher than ₹14/kg.

Trash retention is often recommended as a sustainable farming practice since it reduces the requirement of chemical fertilization and increases yield due to natural soil enrichment. Therefore, a scenario with 100% trash retention on farm was studied. This reduced the availability of trash. The results (Table 2) indicated that the optimal strategy in such a case was to use bagasse in the boiler to meet the energy demands of the mill and sell the remaining bagasse directly to the market. Production of any of the processed products was economically infeasible. This indicated the importance of trash collection and utilization for this system. Cases for various trash retention values between 0% and 100% were simulated and the results are not reported here.

Fig. 3 shows the results of the environmental impact optimization model. There was a strong trade-off between water footprint and net GHG emission. For mimium water footprint, pelletization was the only product produced. However, greater importance to GHG emission resulted in the production of ethanol and then electricity. This was primarily due to the avoided GHG emissions of conventional products (gasoline and coal based electricity). For minimam GHG emission, only electricity production was recommended.

Table 2: Impact of trash retention on optimal industrial cluster design

Variable	Base Case	100% trash retention
Feed	181 Mg/h	181 Mg/h
Sugarcane yield	72.4 Mg/ha	82.9 Mg/ha
Bagasse processing route	Power Plant (37.84 MW)	Market & Boiler
Net Present Value (NPV)	₹366.06 crores	₹104.24 crores

4. Conclusions

This work developed an optimization model to design an industrial cluster based on sugarcane bagasse in India. The economic optimization results indicated that electricity production was the most profitable option for a sugar mill processing 181 Mg/h sugarcane. Trash availability from sugarcane farms was shown to be important to achieve economic feasibility of the electricity production option. Ethanol and pellet market prices needed to increase significantly to achieve economic feasibility of those products from bagasse. The net GHG emission and water footprint had a trade-off and the desirable products changed with varying weights given to each of these two

objectives. The ongoing work is focusing on integrating the economic and environmental impact optimization problems. Although results presented here provide some insights into the trade-offs, the integrated problem will provide quantitative results.

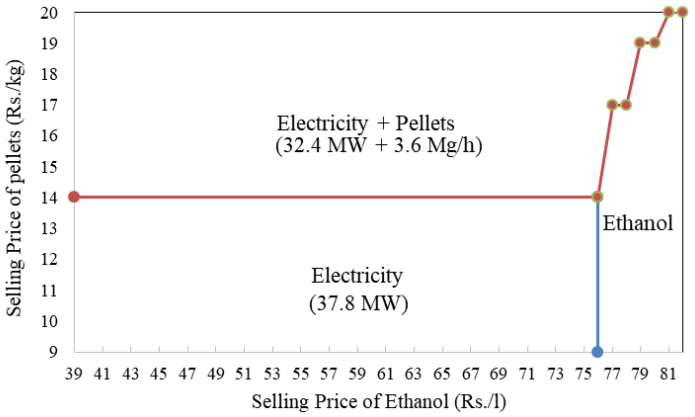

Figure 2: Impact of product prices on optimal product portfolio of the industrial cluster. Points on orange line indicate electricity+pellets region and points on blue line indicate ethanol region

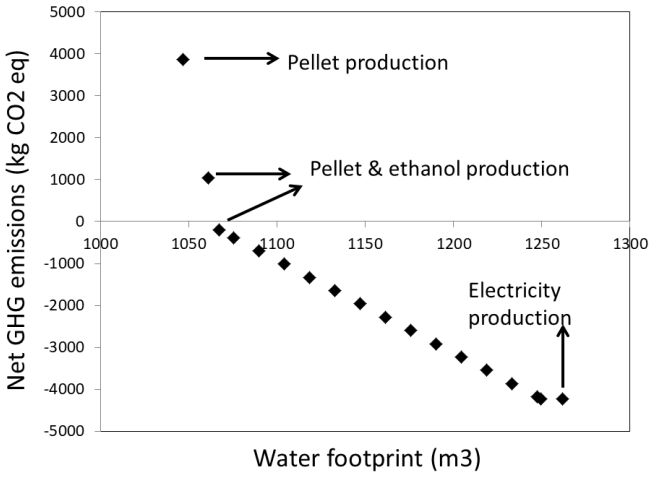

Figure 3: Net GHG emission and water footprint trade-off and the product portfolio for Pareto solutions. For the intermediate points, electricity and ethanol are produced in varying proportions

Abstract

Recently, there have been various studies how to incinerate explosive waste safely due to environmental problems and safety problems. Explosive waste requires a new incineration mechanism, because of the pollution gas generated during the conventional treatment process, such as rotary kiln or outdoor exploration. This study focuses on the fluidized bed incinerator technology which can burn the target material using only a small amount of air at a relatively low temperature condition. In this study, we simulated the process of burning Double Based Propellant (DBP) mixed with water in the incinerator safely. The fluidized bed incinerator was modeled as a cylinder with a diameter of 0.5 m and a height of 2.0 m, and a case study was carried out by changing the mixing ratio of the injected slurry. As a result, we confirmed the optimal mixing ratio with water for burning DBP without explosion, and confirmed that DBP combustion and decomposition reaction occurring inside the incinerator can be safely simulated. Based on this, it is considered that the design of the actual incinerator will provide a new direction for research on the explosive waste treatment process in Korea in the future.

Keywords: Fluidized bed, Double based propellant, water composition, simulation.

1. Introduction

Methods of disposing of explosive wastes, such as ammunition and propellants, have been used for incineration or for exploitation in the open air. However, it has various problems such as environmental problems caused by combustion gases and safety problems of processing facilities. In Korea, about 3,000 tons of explosive waste are generated annually, and 9,700 tons of waste propellant is being loaded untreated due to lack of proper treatment facilities. In the past, research on the incineration process using a rotary kiln has been carried out, but the safety problem has not been solved and the incineration process using a fluidized bed incinerator has been proposed. The treatment process using the fluidized bed incinerator has a higher rate of complete combustion than the conventional method and the combustion gas emission is remarkably low, and the efficiency of operation is also high due to the characteristics of the fluidized bed. Also, by utilizing the effect of mixing with the charged particles in the reactor, the heat energy generated during combustion is efficiently dispersed, thereby reducing the possibility of high temperature or overpressure. In this study, the optimum conditions of

the flow phenomenon and mixing effect in the incinerator were determined through the previous study of the cold model of the fluidized bed reactor. Based on this, the process of burning the waste propellant in the incinerator was designed, and the computational fluid dynamics program was used to simulate and analyze the particle behavior, the internal temperature change, and the gas component change.

2. Simulation scheme and condition

2.1 Design of fluidized bed

The fluidized bed incinerator simulated in this study was selected based on previous studies to determine optimal fluidization conditions. [1] The fluidized-bed incinerator shown in Figure 1 is designed as a cylinder with a height of 2.0 m and a diameter of 0.5 m and a fluidization of 440 K is introduced at a speed of 0.5 m / s under the incinerator. Inside, sand particles with a diameter of 260 μm were charged to 30% of the height of the incinerator. After fluidization reaches a steady state, slurry particles are injected at the side of 1.1 m in height and burned. The slurry is a mixture of water and Double based propellant (DBP) at a ratio of 1: 1 for the stability of process and reaction, and its size is 3 mm in diameter. DBP is a mixture of Nitrocellulose 52% and Nitroglycerin 48%. [8]

2.2 Double based propellant combustion reaction

DBP has a total of seven reaction mechanisms until complete decomposition. When water evaporates as heat is applied, conditions are set for DBP to ignite, and degradation occurs from the surface, resulting in gas generation and combustion in a chain. The two reactions occurring in the condensed phase are the degradation and gasification reactions of DBP, respectively [9] In the gas phase, there are two secondary reactions to NO2, a reaction to NO-carbon, and three secondary reactions to aldehyde and NO.

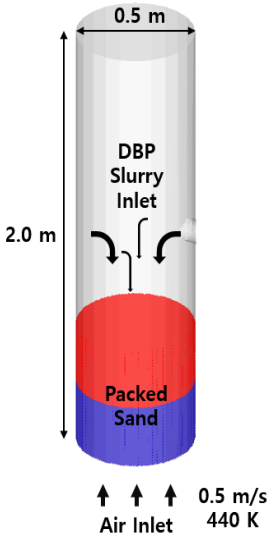

Figure 1: Schemes of fluidized bed incinerator

Table 1: Thermochemical parameters of double based propellant

Parameter	Value
E_c	167.4, kJ/mole
E_{NO_2}	20.9, kJ/mole
E_{CH_2O}	104.7, kJ/mole
$E_{(CHO)_2}$	83.7, kJ/mole
E_{NO}	209.3, kJ/mole
B_c	1.0×10^{17}, 1/s
B_{NO_2}	1.3×10^{6}, 1/s
A_{NO_2}	1.0×10^{5}, $m^3/kg{\cdot}s$
A_{CH_2O}	5.0×10^{8}, $m^3/kg{\cdot}s$
$A_{(CHO)_2}$	5.0×10^{8}, $m^3/kg{\cdot}s$
A_{NO}	5.0×10^{9}, 1/s
Q_c	-135, kcal/kg
Q_{NO_2}	1040, kcal/kg
Q_{CH_2O}	389, kcal/kg
$Q_{(CHO)_2}$	-539, kcal/kg
Q_{NO}	1900, kcal/kg
ρ_c	1620, kg/m^3
C_p	0.35, kcal/kg·K
C_c	0.40, kcal/kg·K

$$Double\ based\ Propellant \rightarrow 2.49NO_2 + 2.36CH_2O + 1.26(CHO)_2 + 0.17CO + minor\ residue \quad (1)$$

$$NO_2 + 0.56CH_2O + 0.16(CHO)_2 \rightarrow NO + 0.38CO + 0.5CO_2 + 0.5H_2O + 0.22H_2 \quad (2)$$

$$NO_2 + 0.56CH_2O + 0.16(CHO)_2 \rightarrow NO + 0.38CO + 0.5CO_2 + 0.5H_2O + 0.22H_2 \quad (3)$$

$$CH_2O + CH_2O \rightarrow CO + 0.5C_2H_4 + H_2O \quad (4)$$

$$(CHO)_2 + (CHO)_2 \rightarrow 4CO + 2H_2 \quad (5)$$

$$NO + 0.16CO + 0.12C_2H_4 + 0.12H_2 \rightarrow 0.5N_2 + 0.4CO_2 + 0.36H_2O \quad (6)$$

$$C + NO \rightarrow CO + NO_2 \quad (7)$$

Eq.(2) and Eq.(3) are the same reaction but different reactions occurring in the condensed phase and gas phase, respectively. The reaction heat of the DBP decomposition reaction in the condensed phase is about 1,100 cal/g [2, 3, 4, 5, 6, 7, 8]. The units are the same in kg/m^3·s. The thermochemical parameters of the reactions are shown in Table 1. All values were calculated in previous studies or calculated using the measured values. [8]

2.3 Fluidization condition

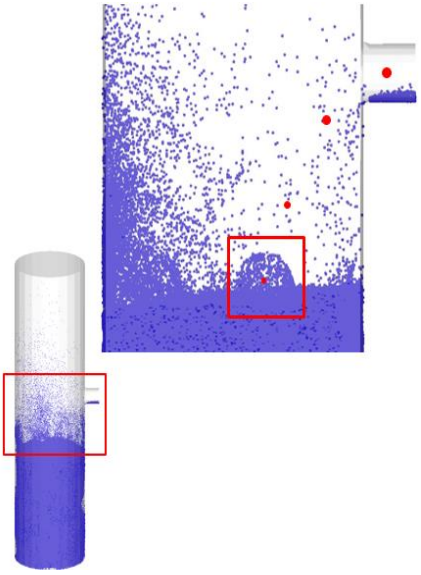

Figure 2: Sequence of slurry injection

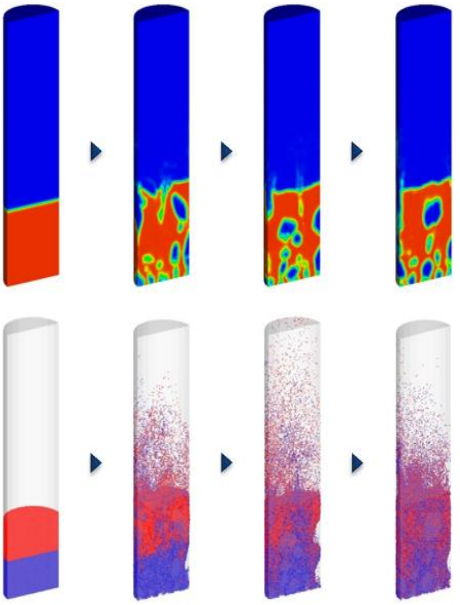

Figure 3: Fludization and mixing effect of fluidized bed incinerator

Before injecting DBP to make safe combustion conditions, the inside of the reactor must reach a steady state where flow phenomenon occurs. Figure 2 shows that all the sand particles are mixed and flow phenomenon occurs actively after 15 seconds. [1]

3. Simulation result and analysis

3.1. Particle movement analysis

Figure 3 simulates the inside of the reactor when the slurry is injected. After the slurry is injected, the water evaporates as it drops, and its size gradually decreases. Thereafter, the reaction occurs instantaneously between the sand particles. This can be confirmed by the fact that the sand particles are spread around the slurry. Thus, it was confirmed that the sand particles absorb the gas generation impact caused by combustion and protect the inner wall of the reactor. And the disappearance time of the particles is 0.28 seconds after the first injection, which is a very short time. Therefore, DBP decomposition reaction is very fast reaction.

3.2. Temperature profile

In Figure 4, temperature changes were observed in the reactor from 15.28 seconds when the slurry particles disappeared, and temperature changes were irregular spherical hot spots. In each case, the temperature of the hot spot was 901, 964, 1003K for each case, and then the gas exited over the incinerator as heat energy was dispersed. It takes about 0.7 seconds for gas to escape to the incinerator. As the water ratio increased, the temperature of the hot spot decreased.

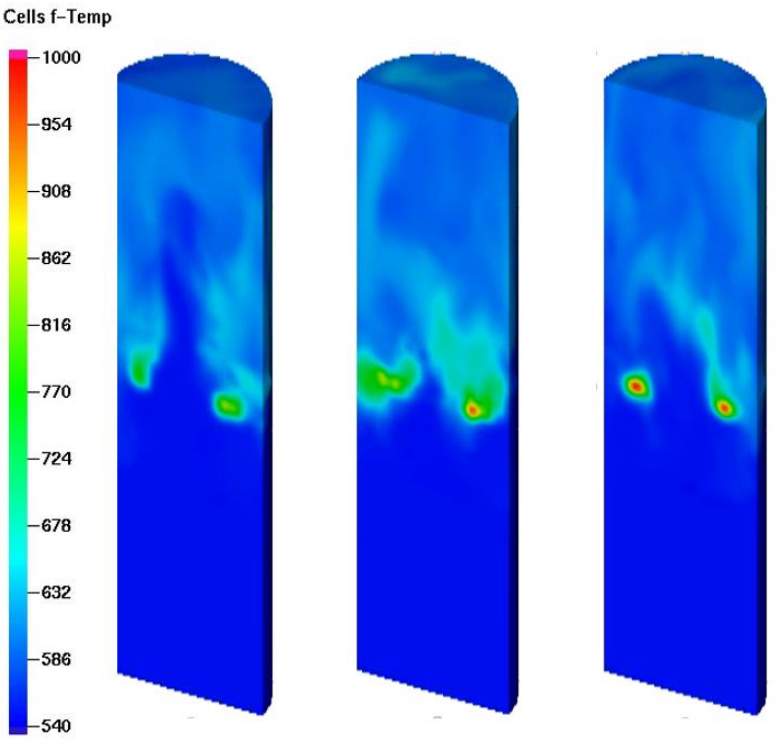

Figure 4: Hot spot profile, (a)5:5, (b)6:4, (c)7:3 (DBP:Water)

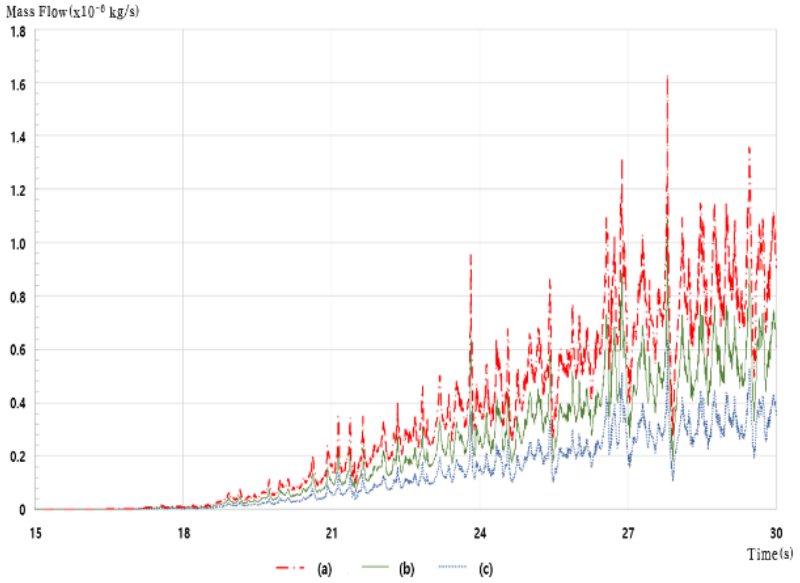

Figure 5 Flow rates of NO by time. (a)5:5, (b)6:4, (c)7:3

3.3 Flue gas analysis

Figure 5 shows the fluctuation of air flow at the time of reaction. This is because the reaction occurs rapidly and a large amount of gas is generated in a short time and the air is pushed up irregularly to the top. As a result of the analysis of the components, the chemical species generated at the time of disappearance of the hot spot starts to escape to the upper part of the reactor. Only N_2, O_2, H_2O and CO_2 should be observed at the upper part of the incinerator if complete combustion actually occurs. However, since incomplete combustion products such as NOx and aldehyde are observed, it can be seen that the gas is pushed up before complete combustion occurs. Also, as the water ratio decreases, the incomplete combustion products decrease, because the rate at which the reactants burn is faster.

4. Conclustion

In this study, CFD is used to explain the mechanism of the combustion of pulsed propellant without explosion in a fluidized bed incinerator. The maximum temperature of the generated hot spot was about 1000 K. As the water ratio increased, the temperature of the hot spot was lowered and the reaction rate was slowed down. The results of all cases are within the range that does not affect the physical properties of the reactor or packed particles. It was found that the feed ratio (water: DBP), the superficial velocity, and the size of the sand particles were found to have a great influence on the design of the operation condition, and energy optimization for this need to be further performed. As a result of the simulation, some of the gas produced after the reaction escapes to the top of the incinerator without being completely combusted, which can be treated by designing an additional downstream separation purification process.

If the simulated fluidized bed incinerator model is designed according to the actual process size, it can process 2,100 tons of waste propellant per year. These studies are

expected to contribute greatly to the disposal of accumulated pulmonary propellants in Korea.

A high-performance molecular reconstruction method with parameter initialization based on PCA

Kexin Bi, Tong Qiu*

Abstract

Molecular reconstruction of naphtha is the first step of naphtha cracking, and a detailed and accurate feedstock composition is required for molecular management in ethylene preparation. PCA method extracts key variables from naphtha properties, and then parameter initialization and range limitation can be regressed based on industrial data. Relatively accurate result is obtained in simulated annealing model during naphtha composition's optimization process due to the precise distribution graph of carbon number. A smaller optimization limitation range is indispensable for the high-performance simulation because the local optimal solution is avoided.

Keywords: Molecular reconstruction, Gamma distribution, Parameter initialization, PCA

1. Introduction

As the first step of molecular management[1], molecular reconstruction means molecular composition modeling and properties prediction of crude oil. For naphtha cracking process, the accurate molecular reconstruction result of naphtha expedites high-quality products and brings economic interests for refineries[2]. Analytical techniques to obtain detailed composition of crude oil, such as GC, GC×GC, GC-MS,[3] is improving rapidly nowadays, but these operations are time-consuming and the output is excessively specific. So a high-performance molecular reconstruction model need to be developed.

During the past decade, a wide variety of molecular reconstruction methods of naphtha have been proposed. Lumped components modeling methods are adopted by simulation software such as SPYRO[4] and CRACKER[5], but the flexibility and extendibility of these methods are rather limited, and accuracy of the result can't be ensured. Recent proposed stochastic methods solve these problems, and stochastic Monte Carlo modeling approach is adopted extensively in studies. Van Geem (2006) applied Shannon's entropy criterion in molecular reconstruction model with linear constraints.[6] Steven P (2011) imposed probability density function(PDF) on both the carbon number distribution in each homologous series of components and on the structural attribute distributions to reduce the number of parameters.[7] Zhang (2012) combined the model mentioned above and demonstrated the feasibility to obtain missing information for models.[8]

For some optimization algorithms, the initial values and ranges of variables are vital to get global optimal solution in small amount of calculation time. In some studies, a series of carbon number distribution probabilities are randomly generated to describe the detailed molecular composition information, and simulated annealing algorithm is applied in optimization process to meets all the property conditions. Nevertheless, using the variables with strong randomicity may result in a wrong solution because of the uncertainty of fraction characterization. These deficiencies make stochastic methods error-prone, time-consuming, and hard to apply into simulation software.

Based on analyses of naphtha fractions, parameter initialization and limitations of optimization can be determined by principal component analysis (PCA) regression model. In this paper, naphtha properties and composition information of western part of China is collected to characterize the carbon number distribution of homologues. PCA method extracts a few uncorrelated variables from Multi-collinear property variables. The extracted principle components are applied to regress the mathematical expectations and variances of the distribution. Assisted with simulated annealing algorithm, the distribution graph can be portrayed accurately and then molecular composition which satisfy the measured properties can be obtained.

2. Parameter initialization using PCA regression method

Stochastic molecular reconstruction process uses PDF to character the carbon number distribution. Some mixture properties obtained from industry analysis are applied to optimize the model, including the PIONA (P for paraffins, I for isoparaffins, O for olefins, N for naphthenes, A for aromatics), the Engler distillation curve (T for ASTM D86 distillation curve), the mixture's molecular weight (Mw) and the H/C ratio (HC).

To fit the carbon number distribution, a reasonable PDF should be picked up for main homologous series (PIONA) in naphtha. Gamma distribution is a rather flexible PDF with two parameters (shape parameter k and scale parameter θ). It is widely used to regress the boiling point curve and carbon number curve of crude oil: [9]

$$f(x;k,\theta) = \frac{x^{k-1} e^{-\frac{x}{\theta}}}{\Gamma(k)\theta^{k}} \tag{1}$$

With $\mathrm{E}(\mathrm{x}) = k\theta$ and $\mathrm{Var}(\mathrm{x}) = k\theta^2$, and x is the carbon number of homologues series.

The origin distribution function need truncation and normalization before application.

Optimization parameters in simulated annealing algorithm can be set as P,I,N weight percentages (olefins is approximately equal to 0) and Gamma distribution parameters. Before optimization, initial value and range of parameters need to be assigned. A novel method of parameter initialization is proposed through PCA on the basis of already given properties of feedstock. Figure 1 explains the process of PCA regression.

3. Optimization model of naphtha molecular reconstruction

During the optimization process with simulated annealing algorithm, Shannon's entropy[10] is applied as a criterion. Shannon's entropy, proposed by Claude Shannon in 1948, can be introduced into naphtha molecular reconstruction to maximize the amount of "information":[11]

$$S(x_i) = -\sum_{i=1}^{N} x_i \ln x_i \quad \text{with} \sum_{i=1}^{N} x_i = 1 \tag{2}$$

Before optimization, weight percentage of specific component need to be calculated. For example, weight percentage of N-Pentane can be described as:

$$P(series = P, Cnum = 5) = P(series = P) \times P(Cnum = 5 \mid series = P) \tag{3}$$

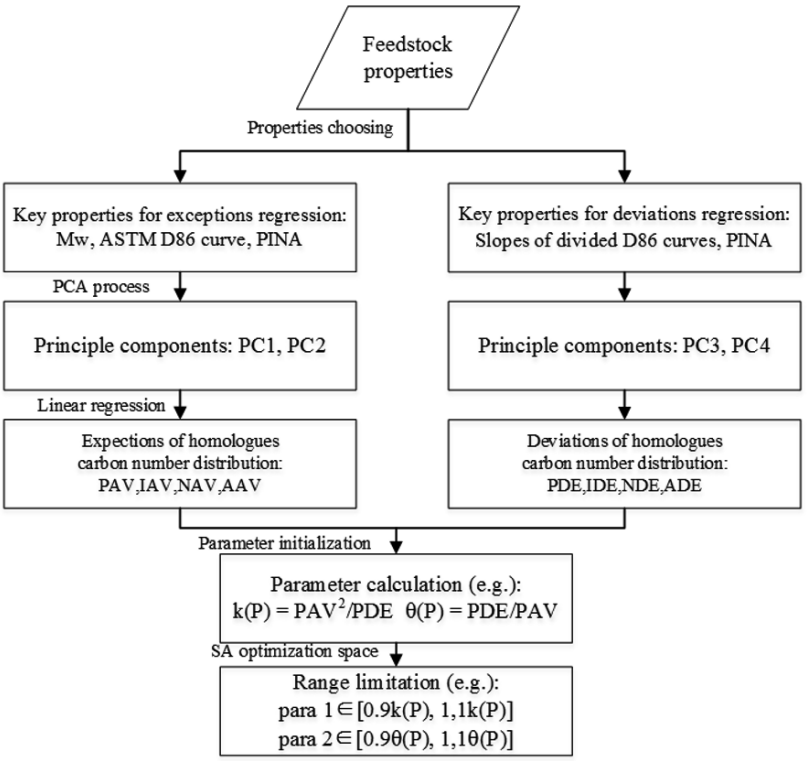

Figure 1. Parameter initialization method using PCA regression for simulated annealing algorithm

To summarize, the simulated annealing optimization model uses a combined function including Shannon's entropy and mixture properties. Properties and related objective functions are listed in Table 1.

Table 1. Properties and corresponding objective functions in simulated annealing algorithm

Properties	Objective functions
Molecular Weight (Mw)	$\exp(k_1 \times \frac{Mw^0 - Mw}{Mw^0})$
H/C ratio (HC)	$\exp(k_2 \times \frac{HC^0 - HC}{HC^0})$
PIONA	e. g. $\exp(k_3 \times \frac{P^0 - P}{P^0})$, $\exp(k_3 \times \frac{I^0 - I}{I^0})$
Boiling Point	e. g. $\exp(k_4 \times \frac{T^0 - T}{T^0})$

The overall objective function in simulated annealing algorithm can be concluded as:

$$f = \sum_{i=1}^{N} x_i \ln x_i + \sum \exp(k_j \times \frac{property^0 - property}{property^0}) \quad (4)$$

with $property \in \{PIONA, ASTM, Mw, HC\}$.

The weighting factors, $k_{j,}$ is assigned as 50 to balance the effects of different factors in objective function above.

4. Result and discussion

Once naphtha properties are entered, expectations and variances of carbon number distribution of homologues PINA can be calculated. Table 2 lists the key properties of naphtha for calculation. Initialization and range limitation for parameters related to PDF in simulated annealing algorithm are presented in Table 3, and the calculation method can be found in Figure 1. As a comparison, parameters obtained from average statistics are listed and the reconstruction result is also calculated by simulated annealing algorithm.

Table 2. Naphtha properties used for calculation

Property	Mw	HC	P (wt%)	I (wt%)	O (wt%)	N (wt%)	A (wt%)
Value	94.31	2.1	32.46	30.75	0	29.19	7.6
Property	IBP (°C)	10% (°C)	30% (°C)	50% (°C)	70% (°C)	90% (°C)	FBP (°C)
Value	35.4	60.3	82.7	100.8	119	145.9	163.5

Table 3. Parameter initialization for carbon number distribution (paraffin as an example)

parameter	k (P)	θ (P)	k (I)	θ (I)	k (N)	θ (N)	k (A)	θ (A)
				Average statistics				
initial value	10.03	0.57	7.87	0.66	9.18	0.42	9.30	0.39
lb	5.22	0.31	4.29	0.43	6.34	0.31	5.49	0.21
ub	14.84	0.83	11.46	0.88	12.01	0.54	13.12	0.56
				PCA regression				
initial value	7.38	0.70	5.82	0.78	9.47	0.39	10.75	0.30
lb	6.65	0.63	5.24	0.70	8.53	0.35	9.67	0.27
ub	8.12	0.77	6.40	0.86	10.42	0.43	11.82	0.33

The calculation process is executed by Matlab R2017a, and the simulation time is counted by Matlab on an Inter Core i7 processor of 2.80 GHz. Figure 2 demonstrates the calculation results of two methods compared to analysis data, and Table 4 concludes the calculation error and time-consumption of two methods

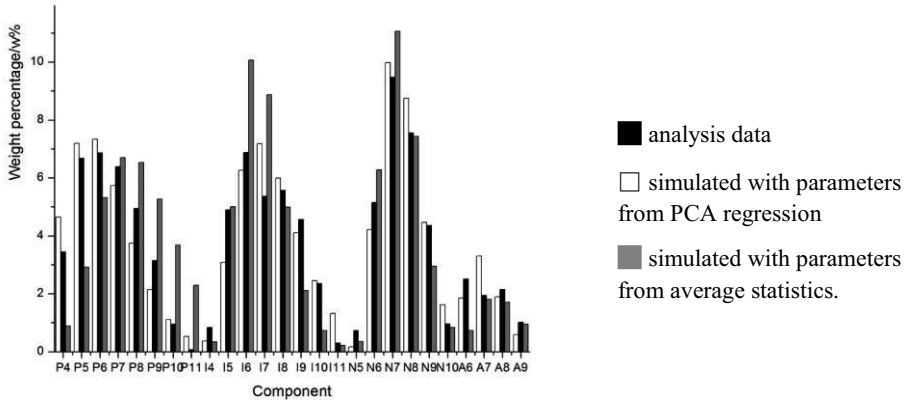

Figure 2. Comparison of analysed and calculated naphtha components' weight percentage.

Table 4. Comparison of calculation quality between two simulation process

	Manhattan Distance (wt%)	Average deviation (wt%)	Time-consumption(s)
simulated with PCA regression	19.42	0.7469	13.04
simulated without PCA regression	36.71	1.4119	186.59

Obviously, the calculation process with parameter initialization and range limitation provided by PCA regression demonstrates a lower deviation and simulation time. The reason can be traced back to Table 3. The fluctuation of the carbon number distribution in paraffin homologue of different calculation process is represented in Figure 3 after inverse transformation of data pretreatment.

Without PCA regression, the carbon number distribution may change from monotonically decreasing to monotonically increasing, as shown in curve (1) and curve (7) in Figure 3. In consequence, the large parameter space could make simulated annealing algorithm fall into local optimal solution. As a comparison, parameters initialization and range limitation using PCA regression cause the zenith and nadir of the carbon number distribution graph relatively fixed and the fluctuation range of the function shape narrow, as shown curve (3), (4), and (5) in Figure 3. With the shrinking of optimization searching area and the precise initialized parameters, the iteration process in simulated annealing algorithm displays faster rate of convergence. What's more, most of unrealistic local optimal solutions are excluded due to the minimal fluctuation range of distribution graph. Compared with the imprecise method using average statistics, the absolute deviation of molecular reconstruction result is reduced by 47.1% and the calculation time is shortened by 93.0% after using these ranges of parameters obtained by principal component regression.

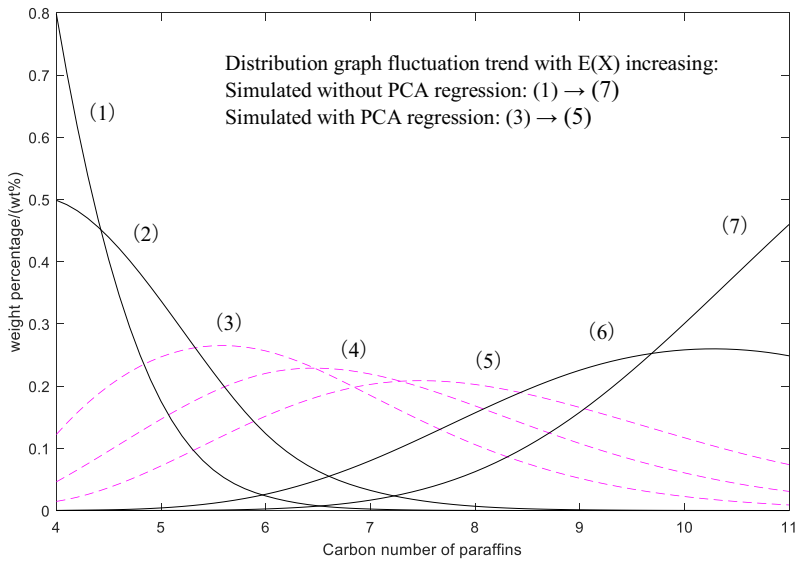

Figure 3. The fluctuation of carbon number distribution shape for paraffin. Optimization space shrinks from (1) → (7) to (3) → (5) with PCA regression of parameters

5. Conclusion

Parameter initialization and range limitation based on PCA regression is applied for optimization process of molecular reconstruction of naphtha. Calculation accuracy is promoted and simulation time is shortened for simulated annealing algorithm with Shannon's entropy and mixture properties as objective function. Lesser fluctuation of carbon number distribution is the main reason, causing the optimization algorithm convergence faster and the local optimal solution hard to appear. The molecular reconstruction model is extendable for naphtha due to multi-regional naphtha calibration data application for the regression process.

Accurate and fast molecular reconstruction method is essential to molecular management in the refining process, such as ethylene thermal cracking process. This high-performance simulation process has potential to be applied for component analysis of feedstock and product in smart manufacturing, which may create higher timely profit in molecular management strategy. [12] Data set and molecular reconstruction model of specific area can be constructed for accuracy promotion and process acceleration.

Abstract

In this paper, the methyl isocyanate (MIC) hydrolysis reaction in a CSTR is used as an example to demonstrate the performance of a Lyapunov-based model predictive control (LMPC) system integrated with the activation of a safety system. Initially, in the presence of small disturbances, it is demonstrated that the closed-loop system state under LMPC is able to stay close to the operating steady-state and within the stability region. However, in the presence of a significant disturbance in the feed, the control system cannot maintain the closed-loop state inside the stability region, and thus, it has to be integrated with the reactor safety system to avoid thermal runaway.

Keywords: Predictive control; Process control; Process safety; Reaction runaway

1. Introduction

Process operational safety is a critical element of chemical plant operation due to the severe consequences for both lives and property when safe process operation is not maintained. Despite the very significant efforts to develop safe process/plant design and operation procedures, accidents continue to occur. Innovative operating strategies such as integrating directly the actions of process control and safety systems are required to prevent unsafe process operation which may lead to catastrophic events. In particular, coordinating the control system actions with the ones of the safety systems, while maintaining their independence for redundancy purposes, would represent a significant paradigm shift in both control and safety system design that has the potential to impact process operational safety.

Motivated by the above considerations, in the present work, we investigate how the activation of the safety system should be accounted for in conjunction with model predictive control (MPC) design because the actions of the safety system change the process dynamics, and thus, they should be accounted for in the MPC implementation. To demonstrate for the first time the integration of MPC with a safety system, we focus on the methyl isocyanate (MIC) hydrolysis reaction in a CSTR; MIC is the principal chemical involved in the Bhopal disaster (Toro et al., 2016).

2. Process description

The exothermic hydrolysis reaction of methyl isocyanate to the corresponding amine and carbon dioxide is given as follows:

$$CH_3NCO_{(l)} + H_2O_{(l)} \longrightarrow CH_3NH_{2(aq)} + CO_{2(aq)}$$

The MIC hydrolysis reaction in a CSTR is considered (Ball, 2011). By applying mass and energy balances, the dynamic model of the process can be described as follows:

$$\begin{aligned} m\frac{dC_A}{dt} &= -mk_0 e^{\frac{-Ea}{RT}} C_A + F(C_{A0} - C_A) \\ mC_P\frac{dT}{dt} &= (-\Delta H)mk_0 e^{\frac{-Ea}{RT}} C_A + FC_P(T_0 - T) - L(T - T_j) \end{aligned} \tag{1}$$

where C_A is the concentration of MIC in the reactor, m is the total mass of the mixture in the reactor, and T is the temperature of the reactor. The concentration of reactant MIC, the temperature and the mass flow rate of the feed are denoted as C_{A0}, T_0 and F, respectively. The reacting liquid has a constant heat capacity of C_P. k_0, E_a and ΔH are the reaction pre-exponential factor, activation energy and the enthalpy of the reaction, respectively. The CSTR is equipped with a cooling jacket where L is the heat transfer coefficient and T_j is the cooling jacket temperature. The reactor is simulated at the conditions reported for the Bhopal catastrophe (Toro et al., 2016). Process parameter values are listed in Table 1.

Table 1: Parameter values of the CSTR.

$T_0 = 293\ K$	$F = 57.5\ kg/s$
$m = 4.1 \times 10^4\ kg$	$E_a = 6.54 \times 10^4\ J/mol$
$k_0 = 4.13 \times 10^8\ /s$	$\Delta H = -8.04 \times 10^4\ J/mol$
$C_P = 3 \times 10^3\ J/(kg\ K)$	$R = 8.314\ J/(mol\ K)$
$L = 7.1 \times 10^6\ J/(s\ K)$	$C_{A0} = 29.35\ mol/kg$
$T_{js} = 293\ K$	$C_{As} = 10.1767\ mol/kg$
$T_s = 305.1881\ K$	

3. LMPC design and thermal runaway

3.1. LMPC control design

The control objective is to stabilize the reactor at its steady-state by adjusting the manipulated input (denoted by u) which is the cooling jacket temperature T_j. The LMPC scheme is formulated as the following optimization problem:

$$\min_{u \in S(\Delta)} \int_{t_k}^{t_{k+N}} (\|\tilde{x}(\tau)\|_{Q_c}^2 + \|u(\tau)\|_{R_c}^2) d\tau$$

$$\text{s.t.} \quad \dot{\tilde{x}}(t) = f(\tilde{x}(t), u(t)) \tag{2b}$$

$$\tilde{x}(t_k) = x(t_k)$$

$$u(t) \in U, \forall t \epsilon [t_k, t_{k+N})$$

$$\frac{\partial V(x(t_k))}{\partial x} f(x(t_k), u(t_k)) \leq \frac{\partial V(x(t_k))}{\partial x} f(x(t_k), h(t_k)) \tag{2e}$$

where $\tilde{x}$ is the predicted state trajectory, $S(\Delta)$ is the set of piecewise constant functions with period Δ, and N is the number of sampling periods in the prediction horizon. The

optimal input trajectory of the LMPC optimization problem is $u^*(t)$, which is calculated over the entire prediction horizon $t\epsilon[t_k, t_{k+N})$. The control action computed for the first sampling period in the prediction horizon $u^*(t)$ is applied over the first sampling period, and the LMPC problem is resolved at the next sampling period. The objective function Eq.(2a) is minimizing the integral of $\|\tilde{x}(\tau)\|_{Q_c}^2 + \|u(\tau)\|_{R_c}^2$ over the prediction horizon. The constraint of Eq.(2b) is the deviation form of Eq.(1) that is used to predict the states of the closed-loop system. Eq.(2c) defines the initial condition $\tilde{x}(t_k)$ of the optimization problem which is the state measurement $x(t_k)$ at $t = t_k$. Eq.(2d) defines the input constraints applied over the entire prediction horizon. The constraint of Eq.(2e) is to decrease $V(x)$ such that $x(t)$ will move towards the origin at least at the worst-case rate achieved by the Lyapunov-based controller $h(x)$, which will be defined later. The explicit Euler method with an integration time step of $h_c = 10^{-2}\ s$ was applied to numerically simulate the dynamic model of Eq.(1) under the LMPC. The nonlinear optimization problem of the LMPC of Eq.(2) was solved using the IPOPT software package with the following parameters: sampling period $\Delta = 1\ s$; prediction horizon $N = 10$. $Q_c = [30; 05]$ and $R_c = 1$ are chosen such that the term related to the states and the term related to the input are on the same order of magnitude in $\|\tilde{x}(\tau)\|_{Q_c}^2 + \|u(\tau)\|_{R_c}^2$. The manipulated input is the cooling jacket temperature T_j, which is bounded as follows: $280\ K \le T_j \le 300\ K$. The CSTR is initially operated at the steady-state $[C_{As} T_s] = [10.18\ mol/kg\ \ 305.19\ K]$, with steady-state $T_{js} = 293\ K$. Therefore, the states and the input of the closed-loop system are represented in deviation form as $x^T = [C_A - C_{As}\ \ T - T_s]$ and $u = T_j - T_{js}$, such that the equilibrium point of the system is at the origin of the state-space. The Lyapunov function is designed using the standard quadratic form $V(x) = x^T P x$, where the positive definite matrix P is as follows: $[200\ 33; 33\ 40]$. The stability region Ω_ρ is characterized as $\Omega_\rho = \{x \in R^2 | V(x) \le \rho\}$. For the system of Eq.(1), the stability region Ω_ρ with $\rho = 8000$ is found based on the above Lyapunov function V and the following controller $h(x)$ (Lin and Sontag, 1991) for the system of form $\dot{x} = f(x,u) = f(x) + g(x)u$:

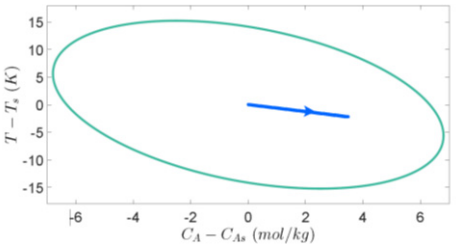
$$h(x) = \begin{cases} -\dfrac{L_f V + \sqrt{L_f V^2 + L_g V^4}}{L_g V^2} L_g V & \text{if} \quad L_g V \neq 0 \\ 0 & \text{if} \quad L_g V = 0 \end{cases} \tag{3}$$

3.2. Simulation results

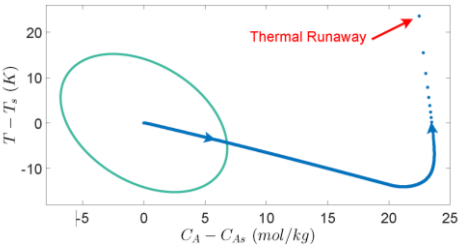
A small feed disturbance (i.e., change of feed concentration from $29.35\ mol/kg$ to $35\ mol/kg$) is initially considered and Figs. 1a and 1b demonstrate that the closed-loop system under the LMPC is robust to the small disturbance by stabilizing the system state at another steady-state within the stability region.

However, when there exists a large disturbance (i.e., the change of feed concentration is from $29.35\ mol/kg$ to $70\ mol/kg$) due to, for example, device failure, it is shown in Fig. 1c that the state goes out of the stability region and the manipulated input hits its lower bound to cool down the reactor as much as possible. However, after 150 seconds of implementation of maximum cooling, the reactor temperature starts to increase significantly. The reason for this increasing value of the temperature is that when the reactor temperature rises, the exothermic reaction rate also increases, causing further increase in temperature, which is a dangerous phenomenon called thermal runaway. Therefore, it can be concluded that in the presence of large disturbances, the reactor

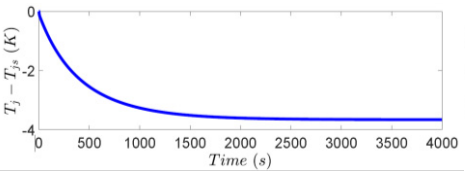
may operate in an unsafe region due to the restriction of the control actuator, which motivates the development of a safety system to maintain reactor safety.



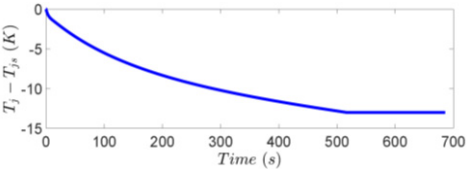
(a) State-space profile under small disturbance



(c) State-space profile under large disturbance



(b) Input trajectory under small disturbance



(d) Input trajectory under large disturbance

Figure 1: (a) and (b) demonstrate that the LMPC can stabilize the closed-loop state at another steady-state when there is a small disturbance. (c) and (d) demonstrate that the LMPC fails to keep the closed-loop state inside the stability region when there is a large disturbance.

4. Integration of MPC with safety system

In this section, the safety system is first designed using two different safety mechanisms: (a) safety relief valve; (b) cool water injection. Then, the entire process control/safety system which integrates the safety system with the LMPC is developed to guarantee closed-loop safety and stability. Finally, the MIC reaction example is used to demonstrate the application of the proposed control/safety scheme.

4.1. Components of safety system

4.1.1. Safety relief valve

The valve is activated to reduce the temperature and pressure of the reactor by discharging material when the temperature or pressure is extremely high in the reactor. In industry, reaction runaway may occur due to different failures, such as mis-charging reactant, loss of cooling temperature and so on. Since the above unsafe operating conditions are unpredictable and uncontrollable, a suitable and correctly sized relief system is crucially important as a backup method to prevent fatal accidents (Hace, 2013). The size of the relief valve is carefully chosen. Specifically, if the relief valve is under-sized, high pressure and equipment failure may occur; if the relief device is over-sized, the relief system may become unstable during the operation and too much material may be wasted (Crowl and Tipler, 2013).

4.1.2. Cool water injection

A direct cool solvent injection can cool down the reaction mixture temperature. It has been demonstrated in both simulation and experiment (Vernières-Hassimi and Leveneur, 2015) that cool water injection can lower the reactor temperature very fast.

4.1.3. Safety system for simulation

In our simulation, high temperature is the trigger of the opening of the relief valve. Specifically, the valve opens once the temperature is higher than $320\ K$. To simplify the development, we assume that the relief recharge flow is in liquid phase. The relief valve size is $0.004\ m^2$ and the relief flow is determined by the equation in (Hace, 2013):

$$G_{relief} = 0.9 \times 144 \times \frac{dP}{dT} \times \left(\frac{32.2}{778.16} \times \frac{T}{C_P}\right) \tag{4}$$

Cool water is injected at 280 K, and the flow rate is the same as the relief valve flow rate, thus the total mass in the reactor remains unchanged.

4.2. Logic integrating control and safety systems

LMPC integrated with the activation of the safety system is developed to help the closed-loop system state to avoid thermal runaway when the LMPC fails to maintain the state inside the stability region in the presence of large disturbances. A schematic of different regions and an example closed-loop trajectory is shown in Fig. 2, where different control schemes will be activated in the following three regions.

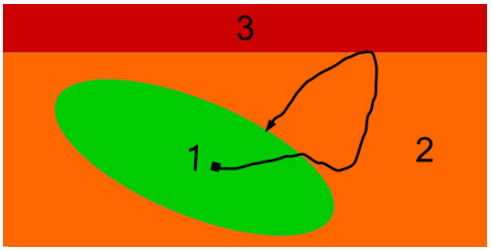


Figure 2: A schematic showing the stability region (green), unsafe operating region (orange), and the thermal runaway region (red), together with an example trajectory starting from the origin.

Region 1: When the closed-loop state is inside the stability region, the LMPC is implemented to stabilize the system at the origin or at another steady-state if there continuously exist small disturbances. At this stage, the safety system is not activated.

Region 2: If large disturbances are introduced into the reactor, the state comes out of the stability region. In order to ensure process operational safety, the manipulated input (i.e., T_j) is set to its lower bound, namely the lowest cooling jacket temperature, since the control system fails to work outside of the stability region.

Region 3: If large disturbances keep affecting the reactor and the maximum cooling is not able to lower the temperature, then the reactor temperature reaches a high value (i.e., the lower boundary of Region 3). Safety actions are taken in Region 3. Specifically, the relief valve opens immediately after the state enters Region 3 and stays open until the state goes back to Region 1. Meanwhile, cold water is injected into the reactor, cooling down the reactor. Injection stops once the relief valve is closed (state goes back into Region 1). At the same time, the jacket temperature stays at its lower bound to apply maximum cooling.

4.3. Simulation results

In Fig. 3, it is demonstrated that in the presence of a large disturbance, LMPC integrated with the safety system via the above logic succeeds to avoid thermal runaway and to drive the state back to the origin. At the beginning of the simulation, a large disturbance

is introduced into the reactor, resulting in the failure of LMPC to keep the system state within the stability region. After about 600 seconds, since the heat generated by the reaction is much more than the heat that the cooling system can remove, the concentration of the reactant is accumulated to such a great extent that the temperature starts to increase rapidly and reaches the safety limit of 320 K. Once the temperature exceeds the safety limit, the relief valve opens to discharge hot fluid from the reactor and an additional stream is employed to feed fresh water into the reactor. Liquid relief flow rapidly decreases the total internal energy and the reactant concentration in the reactor. Cool water promptly cools down the reactor temperature and it dilutes the reactant concentration. The safety system is activated for about 10 seconds to drive the closed-loop state back to Region 1. Once the closed-loop state goes back to Region 1, the LMPC replaces the safety system to stabilize the system state to the origin. Inside Region 1, a well-designed LMPC is guaranteed to stabilize the system state to the origin when there is no disturbance. It should be noted that if the large disturbance still exists after the closed-loop system state goes back into Region 1, then the overall process control system with the safety system is implemented again to avoid thermal runaway as discussed above.

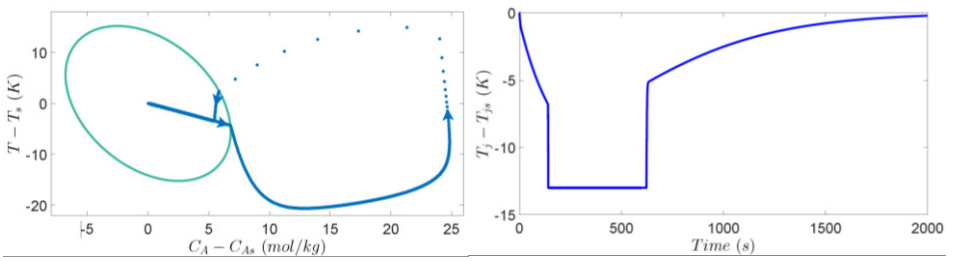

Figure 3: State-space plot and input plot of LMPC integrated with the safety system.

5. Conclusion

In this work, an LMPC system integrated with the activation of a safety system was developed for the MIC reaction in a CSTR to avoid thermal runaway. Specifically, in the presence of large disturbances, it was demonstrated that the closed-loop system under LMPC integrated with a safety system achieved process safety by avoiding thermal runaway and driving the state back into the stability region.

Abstract

In this work, we propose a parallelized Bayesian model identification approach to derive a data-driven model for the outer reforming tube wall temperature (ORTWT) distribution in a steam methane reforming furnace as a function of the fuel distribution and total fuel flow rate. The parallelization ensures that the data-driven models for all ORTWT can be derived simultaneously from the reformer data and independently from one another. The identification of the models is based on Bayesian variable selection, Bayesian model averaging, sparse nonlinear regression, reformer geometry, and theories of thermal radiation so that the model building process for each ORTWT can systematically identify predictors and simultaneously collect a corresponding library of sub-models. A collection of data-driven models for all ORTWT is defined as a data-driven model for the ORTWT distribution. The Bayesian model identification is executed on the Hoffman2 cluster at UCLA to construct the data-driven model for the ORTWT distribution from the training data set, and the results from the resubstitution and forecast tests of the data-driven model are used to demonstrate the effectiveness of the proposed approach.

Keywords: Steam methane reforming; Bayesian Statistics; Sparse nonlinear regression.

1. Introduction

Hydrogen gas is used in a wide range of applications. Among the commercial processes for the production of hydrogen gas, steam methane reforming (SMR) is the most common process (Darvishi et al., 2017). SMR is a catalytic endothermic process in which methane reacts with superheated steam to produce hydrogen, carbon dioxides, and carbon monoxide in the presence of nickel-based catalyst pellets at high temperature, e.g., 1023-1223 K, and high pressure, e.g., 20-40 bar, conditions to ensure that the process is economically viable and a desired methane conversion is achieved (Darvishi et al., 2017).

SMR is carried out inside furnaces. A typical steam methane reforming furnace, i.e., a reformer, has two closed, thermally coupled domains, i.e., the tube side and furnace side. In the tube side, there are hundreds of tubular packed-bed reforming reactors, which are designed to sustain the severe operating condition required for a profitable hydrogen production, and in the furnace side, fuel is burned in excess air to create the high temperature environment to facilitate the production of hydrogen in the tube side. The reformer considered in this work belongs to a hydrogen plant with a designed daily production of 2.8×10^6 Nm^3 of hydrogen (Tran et al., 2017b). The reformer is the most energy intensive unit at the hydrogen plant, and approximately 60% of the production cost is attributed to the procurement of feedstock; therefore, improving the thermal

efficiency of the reformer is expected to result in a significant financial benefit for the hydrogen plant.

The thermal efficiency of the reformer can be qualitatively measured by the hydrogen composition of the synthesis gas stream exiting the reformer, controlled by the total fuel mass flow rate and constrained by the design temperature of the reforming tube wall (Tran et al., 2017a). Therefore, the ORTWT distribution is frequently used as a control variable for the real-time reformer optimizer whose objectives are to retain the expected service life of the reforming tubes and to maintain the reformer safe operation to avoid unplanned plant shutdowns and capital/production losses. In practice, the task of finding the reformer input to deliver the maximum fuel flow rate without the risk of rupturing the reforming tubes is challenging and is an issue of interest in the hydrogen manufacturing industry. Therefore, an accurate and computationally efficient model for the relationship between the ORTWT distribution and the reformer inputs is required to design a real-time reformer optimizer.

Although this relationship can be modeled by using first principles modeling and computational fluid dynamic (CFD) modeling, first principles models and CFD models for the ORTWT distribution are often unsuitable for designing a real-time optimizer. First principles models overlook the influence of flow field on transport variables, which often yield solutions with poor accuracy, and CFD models are computationally expensive. Therefore, data-driven modeling is an alternative solution because data-driven models can be computationally inexpensive and can have reasonable accuracy. Motivated by this, we propose a model identification approach based on Bayesian statistics, sparse nonlinear regression, principles of thermal radiative heat transfer and the reformer geometry to derive a data-driven model for the ORTWT distribution.

2. Bayesian model general structure

This section aims to elaborate on the motivation for implementing Bayesian statistics in the model building process for the ORTWT distribution; to simplify our discussion, we consider a model building process for an arbitrary *ith* ORTWT.

We have found that in the reformer the dominant mode of heat transfer is thermal radiation, and more than 95% of the energy absorbed by the tube side is transferred to outer wall of reforming tubes by thermal radiation (Tran et al., 2017b). In addition, the first principle model for thermal radiative heat transfer indicates that the intensity of thermal radiation decreases drastically with increasing distance between the heat source and the heat sink. This analysis allows us to deduce that the *ith* ORTWT depends only on the fuel flow rates of the nearby burners. Nevertheless, the size of the neighborhood of the *ith* reforming tube is an ambiguous hyperparameter because there is no evidence suggesting that a data-driven model that uses a larger neighborhood has higher forecast accuracy compared to a data-driven model that uses a smaller neighborhood.The Bayesian model identification is designed to search for all data-driven models for the *ith* ORTWT with a high goodness of fit (which are denoted $\tilde{T}_{i,k}$ and referred to as sub-models in this manuscript) and to combine them to create the prediction model for the *ith* ORTWT (denoted $\hat{T}_i$) as follows,

$$\hat{T}_i = \sum_{k=1}^{K_i} \omega_{i,k} \tilde{T}_{i,k} \quad \text{where} \quad \sum_{k=1}^{K_i} \omega_{i,k} = 1. \tag{1}$$

where $\omega_{i,k}$ is the weighting factor of $\tilde{T}_{i,k}$. The prediction model for the *ith* ORTWT is expected to have a higher forecast accuracy than any individual sub-model (Hoeting et al., 1999).

3. Sparse nonlinear regression

We use sparse nonlinear regression to derive the sub-models for the *ith* ORTWT so that the sub-models can capture any nonlinearity in the relationship between the *ith* ORTWT and the reformer input. In this effort, we propose a library of transformations based on the expected response of the *ith* ORTWT to changes in the reformer input. For instance, if the *jth* burner is in the neighborhood of the *ith* reforming tube, increasing the fuel flow rate of the burner is expected to cause the *ith* ORTWT to increase. In addition, a non-zero fuel flow rate of the burner is expected to cause the *ith* ORTWT to raise above the ambient air temperature. Thus, we propose eight non-negative, monotonically increasing transformations as follows $f_1\left(\vec{F}^n\right)=\left[F_1^n,\ldots,F_{96}^n\right]^T$, $f_2\left(\vec{F}^n\right)=\left[(F_1^n)^2,\ldots,(F_{96}^n)^2\right]^T$, $f_3\left(\vec{F}^n\right)=\left[(F_1^n)^3,\ldots,(F_{96}^n)^3\right]^T$, $f_4\left(\vec{F}^n\right)=\left[\sqrt[2]{F_1^n},\ldots,\sqrt[2]{F_{96}^n}\right]^T$, $f_5\left(\vec{F}^n\right)=\left[\sqrt[3]{F_1^n},\ldots,\sqrt[3]{F_{96}^n}\right]^T$, $f_6\left(\vec{F}^n\right)=\left[\sqrt[4]{F_1^n},\ldots,\sqrt[4]{F_{96}^n}\right]^T$, $f_7\left(\vec{F}^n\right)=\left[\sqrt[5]{F_1^n},\ldots,\sqrt[5]{F_{96}^n}\right]^T$, $f_8\left(\vec{F}^n\right)=\left[\exp(F_1^n),\ \ldots,\exp(F_{96}^n)\right]^T$, where $\vec{F}^n$ is the *nth* fuel distribution. Next, we use the library of transformations to formulate the generalized form of $\tilde{T}_{i,k}$ as follows,

$$\tilde{T}_{i,k}=\sum_{g=1}^{8}\left(\vec{\alpha}_i^{kg}\right)^T\cdot f_g\left(\vec{F}\right)+\alpha_i^k \tag{2}$$

where $\vec{\alpha}_i^{kg}$ is the parameter vector associated with the *gth* transformation function of $\tilde{T}_{i,k}$ and α_i^k represents ambient air temperature of $\tilde{T}_{i,k}$. Then, we use a maximum likelihood estimator (MLE) formulated as a constrained L_1 minimization to estimate the parameters of $\tilde{T}_{i,k}$ as follows,

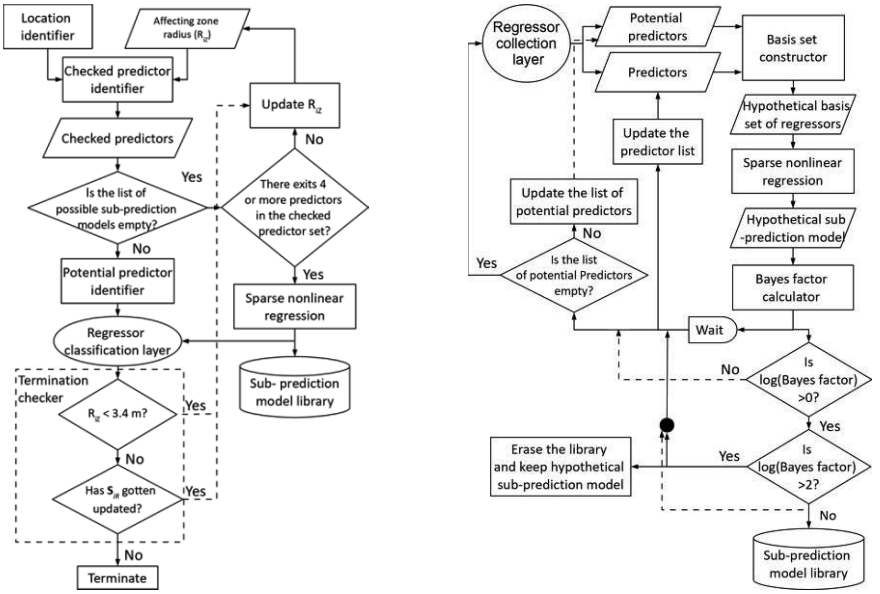
$$\min_{\substack{\alpha_i^k\in[298.15,348.15]\\ \alpha_{ij}^{kg}\in[0,\infty)}}\sum_{n=1}^{N}\frac{\left(T_i^n-\tilde{T}_{i,k}^n\right)^2}{2(\sigma^n)^2}+\lambda_i\sum_{g=1}^{8}\left\|\vec{\alpha}_i^{kg}\right\|_1 \tag{3a}$$

$$\text{subject to:}\qquad \bar{F}^0=\frac{F_{tot}^{typ}}{96} \tag{3b}$$

$$\sum_{g=1}^{8}\alpha_{il}^{kg}f\left(\bar{F}^0\right)=\sum_{g=1}^{8}\alpha_{ij}^{kg}f\left(\bar{F}^0\right)\qquad \text{if } d_{il}=d_{ij} \tag{3c}$$

$$\left(\frac{d_{ij}}{d_{il}}\right)^{\beta_u}\sum_{g=1}^{8}\alpha_{ij}^{kg}f\left(\bar{F}^0\right)\geq\sum_{g=1}^{8}\alpha_{il}^{kg}f\left(\bar{F}^0\right)\geq\left(\frac{d_{ij}}{d_{il}}\right)^{\beta_l}\sum_{g=1}^{8}\alpha_{ij}^{kg}f\left(\bar{F}^0\right)\qquad \text{if } d_{il}<d_{ij} \tag{3d}$$

where N is the total number of training data sets, T_i^n is the *ith* ORTWT in the *nth* training data, d_{ij} and d_{il} are the distances from the *ith* reforming tube to the *jth* and *lth* burners, respectively, σ^n is the standard deviation of the measurement noise in the *nth* training data, λ_i is the LASSO parameter of the model building process for the *ith* ORTWT, β_u = 6.0 and β_l = 1.0 are hyperparameters of the constraints and are chosen by trial and error, respectively, and F_{tot}^{typ} is the total fuel flow rate typically reported in the SMR literature. In the formulation tot of the MLE, Eqs.(3c) and (3d) are proposed in an effort to integrate the inverse square law of thermal radiative heat transfer into the sub-



(a) Regressor collection layer (b) Regressor classification layer

Figure 1: Framework for the Bayesian model identification

models. Specifically, Eq.(3c) allows the sub-models to realize that when two burners are in the neighborhood of the *ith* reforming tube, are separated from the *ith* reforming tube by the same distance and have the same fuel flow rate, the two burners should have the same impact on the *ith* ORTWT. Using this logic, Eq.(3d) allows the sub-models to realize that a closer burner to the *ith* reforming tube is expected to have a higher, but finite, impact on the *ith* ORTWT compared to that of the farther burner. The proposed sparse nonlinear regression method is integrated into the Bayesian model identification so that the impact of incorporating a burner into the predictor set for the *ith* ORTWT on the model goodness of fit can be quantified, which allows it to judge if this burner is an important predictor.

4. Framework for the Bayesian model identification

In this section, the framework for the Bayesian model identification is presented. Specifically, it is structured to have two layers, namely, the regressor collection layer and the regressor classification layer as shown in Figs. 1a and 1b, respectively. The regressor collection layer makes use of the knowledge that thermal radiative heat transfer is the dominant mode, and it functions under an impression that the *ith* ORTWT is controlled by the fuel flow rates of the nearby burners, which it identifies by creating a cylindrical neighborhood with the radius of the affecting zone around the *ith* reforming tube. This allows the Bayesian model identification to reduce the predictor space and to define an optimized path to search for the important predictors for the *ith* ORTWT. In addition, we assume that the 4 nearest burners of the *ith* reforming tube are the default predictors for the *ith* ORTWT, and together they form the default predictor set, which is denoted by $\mathbf{S}_{iR}$ and is used as the input to the sparse nonlinear regression to create the default sub-model.

After $\mathbf{S}_{iR}$ has been identified, and the default sub-model, which is also considered to be the "current best" sub-model, has been created, the regressor collection layer considers

all new nearby burners to be potential predictors which are used as inputs to the regression classification layer. Then, the regression classification layer uses the potential predictor set to identify additional important predictors, additional sub-models and new "current best" sub-model for the *ith* ORTWT in a step-wise fashion by means of Bayes factors, Bayesian information criterion (BIC) and the modified Jeffery's interpretation of Bayes factor (Kass and Raftery, 1995). Next, the updated $\mathbf{S}_{iR}$ is returned to the regressor collection layer.

In the regressor collection layer, the termination checker uses the radius of the affecting zone and $\mathbf{S}_{iR}$ to decide to terminate the model building process of the *ith* ORTWT. Specifically, when the radius of the affecting zone is less than the critical value of 3.4 m, the model building process for the *ith* ORTWT is always continued to ensure that the Bayesian model identification thoroughly explores the minimum predictor space. However, when the radius of the affecting zone is greater than the critical value, the model building process is continued if at least one new potential predictor has been added to $\mathbf{S}_{iR}$ to prevent the Bayesian model identification from exploring unnecessary regions in the predictor space. In a case that the model building process of the *ith* ORTWT is continued, the radius of the affecting zone is expanded by a step increment of 1.5 m. Then, the process of constructing $\mathbf{S}_{iR}$ is repeated until all important predictors judged based on the training data set (denoted $\mathbf{T}_i$) are identified.

We continue this discussion by assuming that the model building process has identified K_i distinct sub-model for the *ith* ORTWT. Using Bayesian model averaging, the expected value of the *ith* ORTWT based on $\mathbf{T}_i$, $\vec{F}^n$ and F_{tot}^n is denoted $E\left(T_i^n|\mathbf{T}_i,\vec{F}^n,F_{tot}^n\right)$ and is computed as follows,

$$E\left(T_i^n\,|\,\mathbf{T}_i,\vec{F}^n,F_{tot}^n\right)=\sum_{k=1}^{K_i} pr\left(\tilde{T}_{i,k}\,|\,\mathbf{T}_i\right)E\left(T_i^n\,|\,\mathbf{T}_i,\vec{F}^n,F_{tot}^n,\tilde{T}_{i,k}\right) \tag{4}$$

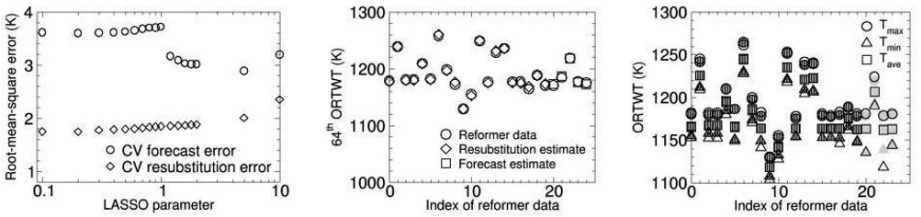
where $pr\left(\tilde{T}_{i,k}|\mathbf{T}_i\right)$ is the posterior probability of $\tilde{T}_{i,k}$ and $E\left(T_i^n|\mathbf{T}_i,\vec{F}^n,F_{tot}^n,\tilde{T}_{i,k}\right)$ is the expected value of the *ith* ORTWT based on $\mathbf{T}_i$, $\vec{F}^n$, F_{tot}^n and $\tilde{T}_{i,k}$. We compare Eq.(1) to Eq.(4) and deduce that $\omega_{i,k}$ is equivalent to $pr\left(\tilde{T}_{i,k}|\mathbf{T}_i\right)$, which can be expressed in terms of Bayes factors and approximated using the BIC. As a result, we can form an explicit algebraic model for the *ith* ORTWT as a function of the total fuel flow rate and fuel distribution.

5. Results

In this work, we partition our reformer database, which consists of 24 reformer CFD solutions generated by subjecting the reformer CFD model with varying fuel flow rates and fuel distributions, into two groups, i.e., the training data set and testing data set (Tran et al., 2017a,b). The training data set is randomly assigned 80% of the reformer database, and the testing data is assigned the remaining 20%. We propose 18 LASSO parameters, i.e., $\mathbf{S}_{\boldsymbol{\lambda}}$ = {0, 0.1, ⋯, 1, 1.2, ⋯, 2, 5, 10}, and we use leave-out-one (LOO) cross validation (CV) to select the optimal parameter of each model building process. In the remainder of this section, we present the result of the model building process for the 64*th* ORTWT as an illustrative example.

The results of LOO cross validation used to determine the optimal LASSO parameter of the model building process for the 64*th* ORTWT are shown in Fig. 2a. We note that the

magnitude of LASSO parameters controls the goodness of fit and complexity of the prediction model for the 64*th* ORTWT. Specifically, the model building processes that use small LASSO parameters yield high goodness-of-fit prediction models which might



(a) (b) (c)

Figure 2: Fig. 2a displays the results of the LOO cross validation for selecting λ_{64}^{op}. Fig. 2b displays the results of the resubstitution and forecast tests of $\hat{T}_{64}$. Fig. 2c. displays the results of the resubstitution (denoted by stripe symbols) and forecast (denoted by gray-filled symbols) tests of the prediction model for the ORTWT distribution.

be overfitting the CV training data sets, and the model building processes that use large LASSO parameters yield CV prediction models with low level of complexity which might be underfitting the CV training data sets. Fig. 2a reveals that the optimal LASSO parameter (denoted λ_{64}^{op}) is 5 which yields CV prediction models with the smallest forecasting error. Then, we use λ_{64}^{op} and $\mathbf{T}_i$ to derive $\hat{T}_{64}$. Fig. 2b shows that $\hat{T}_{64}$ yields estimates with small resubstitution error and small forecast error, specifically, the maximum and average forecasting errors are 4.62 K and 1.85 K, respectively. Finally, we combine the prediction models for all ORTWTs to create the prediction model for the ORTWT distribution. Fig. 2c demonstrates the high fidelity of the prediction model by showing that the resubstitution estimates and forecasting estimates of the ORTWT distribution are consistent with the reformer data.

6. Conclusions

In the present work, we used Bayesian statistics, BIC, sparse nonlinear regression, theories of thermal radiation and reformer geometry to develop a Bayesian model identification for the ORTWT distribution as a function of the fuel distribution and total fuel mass flow rate. We demonstrated the effectiveness of the proposed method by showing that the prediction model for the ORTWT distribution generates resubstitution estimates and forecasting estimates with small errors.

Study and Application of the Computing Architecture of Petrochemical Cyber-Physical System (PCPS)

Defang Li*

China Petrochemical Corporation, Beijing, 100728, China
hansheng.suo@pcitc.com

Abstract

Cyber-Physical System has become the key infrastructure supporting the development of smart manufacturing. In this paper, the computing architecture of Petrochemical Cyber-Physical System (PCPS) is defined in combination with the features of petrochemical industry. This paper divides PCPS into unit PCPS, system PCPS and System of Systems PCPS, and describes the work pattern of PCPS achieving multiscale Smart Factory business and optimization from the perspectives of system architecture and computing architecture. Finally, it introduces the application scenarios of PCPS computing architecture in the construction of Sinopec Smart Factory.

Keywords: Petrochemical Cyber-Physical System (PCPS); computing architecture; Smart Factory.

1. Background

Smart manufacturing, characterized by accelerating integration of new-generation information communication technology and manufacturing industry, has become the major trend of global manufacturing industry development (Yuan et al., 2017), and is gradually permeating into the whole process of manufacturing industry, hence promoting a great transformation in production process. Not only researchers around the world devote to smart manufacturing and have made progress both in theory and applications, governments also have given strong support. For instance, Jim Davis et al. think smart manufacturing uses the integration of next generation operations technology and information technology to realize significant untapped market opportunities, and they utilize the concept of smart manufacturing into furnace temperature balancing in steam methane reforming process (Davis, 2017; Korambath et al., 2016). Moreover, US Dept of Energy also leveraging high performance computing to drive advanced manufacturing R&D (Johnson, 2017).The core of achieving integration refers to the Cyber-Physical Systems (CPS) capable of connecting real physical world and virtual network world (Rho et al., 2016; Branicky, 2008).

China Petrochemical Corporation (Sinopec for short) took a lead in carrying out the construction of Smart Factory in 2013(Li, 2015), and put forward industry-oriented Petrochemical Cyber-Physical System (PCPS for short), taking PCPS as the infrastructure of petrochemical Smart Factory, and carrying out pilot construction in four enterprises.

By combining the construction of Sinopec Smart Factory, the system architecture and computing architecture of PCPS of petrochemical Smart Factory are further discussed in this paper, and the application practices of unit PCPS, system PCPS and System of Systems (SoS) PCPS in the construction of Sinopec Smart Factory are summarized.

2. System Architecture of PCPS

2.1. Definition of PCPS

Petrochemical Smart Factory, as the entire industry chain link oriented towards petrochemical production, deeply integrates new-generation information technology, process and equipment operation technology of existing petrochemical production process as well as people, achieves high horizontal, longitudinal and end-to-end integration of factory, improves four key capabilities of comprehensive perception, predictive warning, collaborative optimization and scientific decision-making, enhances the operation and management level of factory in a more delicate and dynamic manner, and promotes the innovation of new manufacturing and business model(Li, 2016).

PCPS as the infrastructure of petrochemical Smart Factory, aims to construct a new-generation petrochemical production environment featuring ubiquitous perception and ubiquitous smart service, and connects the ubiquitous sensor, smart hardware, control system, computing facility and information terminal into a smart network via PCPS to enable interconnectivity among enterprises, people, equipment and service, so as to develop, integrate and make use of various information resources, knowledge and wisdom to the largest extent (Wang, 2017).

2.2. PCPS system architecture

Unlike traditional pyramid layered information hierarchical architecture, PCPS adopts an architecture based on distribution. High-level PCPS, formed by interconnected integration and flexible networking of low-level PCPS, has high openness, interconnectivity and flexibility, achieving flexible expansion and ubiquitous perception of system. On each level, embedded intelligence, responsive control and predictive analysis as well as distributed computing measurement and control and predictive analysis can be deployed, and distributed computing measurement and control system and distributed edge computing system also can be deployed. Unlike strict layered structure of traditional industrial control system, the system architecture of PCPS is as shown in Figure 1.

(1) Unit PCPS

Unit PCPS, facing process production unit, process node or logistics node, can finish specific tasks through physical hardware, own embedded software system and communication module, and coordinate with other PCPSs to complete complex production and operation.

(2) System PCPS

System PCPS, facing factory, finishes the production process in the factory through the introduction of network and coordination with unit PCPS.

(3) SoS PCPS

SoS PCPS, facing the whole value chain of petrochemical industry, finishes the collaboration of multiple production lines or factories, and achieves optimal collaboration of total process and whole value chain of product lifecycle.

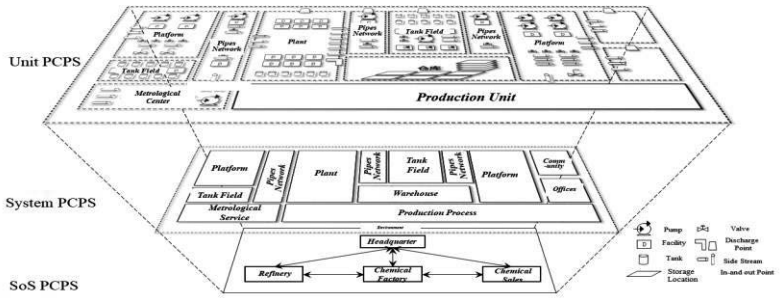

Figure 1. PCPS system architecture

2.3. PCPS unit structure

PCPS completes target, strategy, perception, computing, decision-making and execution through its basic model unit, achieves mutual collaboration, timely adjusts operational process, production process and management status, and achieves the interconnectivity, global optimization and overall coordination of devices, factories and enterprises. The model structure of basic unit of PCPS is given in this section.

The basic model structure of PCPS can be divided into two parts, namely domain layer and collaborative control layer. The domain layer is used for solving problems in professional fields, while the collaborative control layer aims to control the domain layer, enabling the domain layer to coordinate with domain layers of other PCPSs. PCPS model consists of communication network, planning goal, goal decomposition, strategy control and computing unit (perception, simulation calculation, decision-making and execution), knowledge library, database, and other modules.

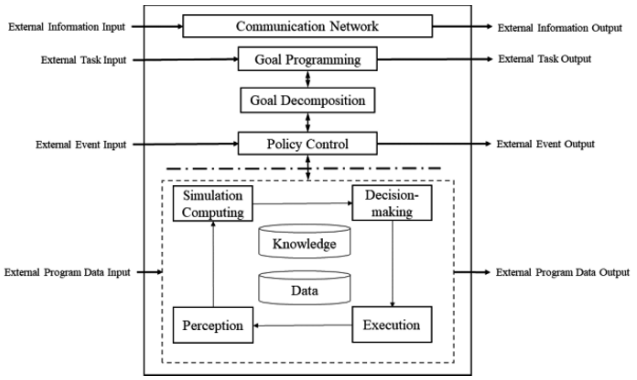

Figure 2. PCPS unit structure

PCPS system adjusts task planning through monitoring and protection, each PCPS is responsible for one specific task, and the knowledge library of each PCPS can be built more specifically, obtaining higher search efficiency. In the PCPS system, each PCPS improves its own performance through information interaction and mutual learning, thus improving the problem solving ability of entire self-adaption coordinative protection system. The coupling relationship between PCPSs is loose, so the entire system has more flexible structure and better real-time response to the changes of environment, as shown in Figure 2.

3. Computing Architecture of PCPS

3.1. Logical structure of PCPS

The logical structure of PCPS is divided into five levels, namely perception level: which perceives the data and information of physical system through control system, IoT equipment, new sensor and intelligent instrument; communication network level: which provides communication paths with service quality guarantee for devices through sensing network, industrial wireless network, wired network and other transmission forms; computing processing level: which provides centralized integration, intelligent analysis, visualization, real-time computing and other computing power, processes the data of perception level, and provides the obtained knowledge to the strategy control level; strategy control level: which serves the optimization of corporate production and operating activities, and makes strategies to control the physical system, including energy optimization, equipment operation optimization, and production coordination optimization; application level: which provides applications facing Smart Factory, smart oil and gas field, smart supply chain, and so on, and meets different production and operation demands of enterprises.

3.2. PCPS computing architecture

PCPS computing architecture includes the edge side and the cloud with each part having its own independence and the ability to achieve local autonomy. And the overall function of PCPS is realized through their mutual collaboration.

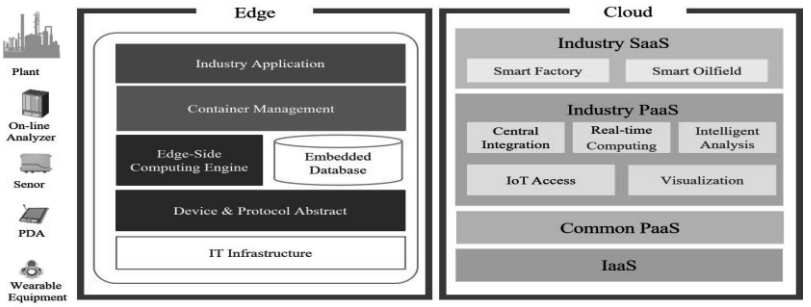

Figure 3. PCPS computing architecture

(1) PCPS computing architecture – the edge side

In a bid to decrease pressure on cloud computing, cut down storage overhead, speed up the response of enterprise field applications, and reduce the usage of network bandwidth, PCPS expands the edge layer, which boasts storage, computing, and container management capabilities, between the cloud and terminal devices, thereby deploying the timeliness-demanding computing services and related data on the edge side in form of containers. The software stack on the PCPS edge side can be embedded into industrial equipment (such as gateways, control systems, and sensors) to provide such capabilities as distributed intelligence, homogeneous software architecture, open development architecture, authentication and secure communications, and edge application stores based on container technology.

(2) PCPS computing architecture – the cloud

As a driving engine, the PCPS cloud drives deep integration of technical services such as artificial intelligence, big data, and Internet of Things, and industrial services in the

process industry to build an innovative industrial ecosystem; provides industry SaaS applications which cover smart factories and smart oil and gas fields; industrial PaaS has five core competencies, namely, centralized integration, real-time computing, intelligent analysis, Internet of Things (IoT) access, and visualization; PaaS layer provides effective support for the operation, development and maintenance of the upper level intelligent applications and services; and IaaS layer provides resources such as computing, storage and network.

4. PCPS Application Practices

According to the development characteristics of the industry and itself, Sinopec started the construction of Smart Factory in four enterprises, namely, Sinopec Beijing Yanshan Company, Sinopec Maoming Petrochemical Company, Sinopec Zhenhai Refining & Chemical Company and Sinopec Jiujiang Company in 2013, enabling the PCPS to be deeply applied to the existing petrochemical production process. The specific architecture is as shown in Figure 4 in which the PCPS is divided into three levels, namely, SoS PCPS, system PCPS, and unit PCPS. SoS PCPS is mainly responsible for decision-making and procurement optimization, the results of which are transmitted to enterprises to conduct planning and scheduling optimization. Then the planning and scheduling optimization results are broken down to each device of the enterprises (atmospheric and vacuum, catalytic cracking, continuous catalytic reforming, hydrogen cracking, etc.), so that the real-time optimization system in the unit PCPS is utilized to achieve optimization objectives. The application practices and challenges of PCPS stated in this paper are based on the actual application of four enterprises.

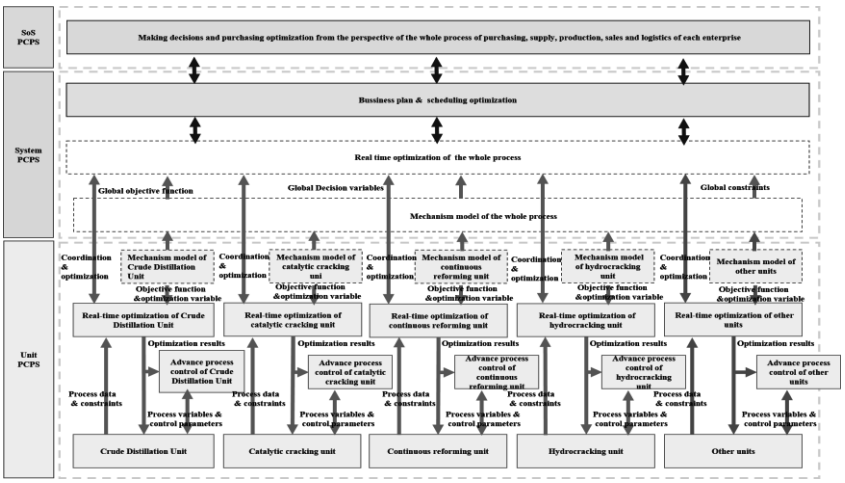

Figure 4. PCPS application architecture of smart factory which has 3 levels

The PCPS application in Smart Factory realizes the overall connection of SoS PCPS, system PCPS and unit PCPS. Sinopec Zhenhai Refining &Chemical Company is taken for instance. When market price fluctuates, SoS PCPS optimizes procurement and sales plans based on market price changes. System PCPS develops a factory-wide plan and scheduling program, which is broken down to each device. Finally, the real-time optimization system of unit PCPS calculates the optimal operating parameters of each device (atmospheric and vacuum, catalytic cracking, continuous catalytic reforming,

hydrogen cracking, etc.) according to the scheduling program and feeds back the calculation results to SoS PCPS. Where the calculation results are consistent with the procurement and sales objectives set by SoS PCPS, the advanced control system performs the optimization results of the real-time optimization system, enabling the device to operate under optimal operating parameters.

Thanks to PCPS, the ethylene unit of Sinopec Zhenhai Refining & Chemical Company achieves integrated application of Real Time Optimization and Advanced Process Control, and realizes the overall connection of SoS PCPS, system PCPS and unit PCPS based on the whole-process mechanism model. With maximum economic benefits as the objective, data reconciliation, model regression and other technologies are utilized to ensure the accuracy of the basic data; the sequence control, steady-state test and other technologies are adopted to improve the feasibility of computing results; and the price system model of chemical products is employed to ensure the timely update of raw material and product value. Without increasing the investment in major equipment, the real-time optimization system fully exerts the operation potential of the existing production facilities and effectively achieves the objectives of output increase, energy conservation and consumption reduction, thus creating new benefits for Sinopec Zhenhai Refining & Chemical Company. After the system is put into operation, the system is stable and reliable in operation. The ethylene benefit increases by RMB 26.34 per ton with the annual benefit increasing RMB 30.91 million.

5. Conclusions and Prospects

This paper presents the system architecture and computing architecture of PCPS. The application practices are conducted in four pilot enterprises of Sinopec Smart Factory with great application effects obtained. Along with the development of petrochemical industry and in-depth application research of PCPS in future, the PCPS will be applied and popularized in many pilot enterprises, and PCPS theory, application research results and experience will be extended to other industrial sectors, enabling CPS to realize more favorable development.

Abstract

Scheduling is not only a key component of petrochemical factory production management, but also the core of the implementation of production plan, the coordination of production activities and the maintenance of on-site safety. Based on the characteristics of petrochemical industry scheduling and the design conception of Cyber-Physical System (CPS), a new method of comprehensive application of industrial big data algorithm, expert rules engine and abnormal operation condition identification model is proposed, the architecture of the Intelligent Scheduling System, which has four major capabilities: comprehensive perception, real-time analysis, early forecasting and warning and collaborative execution, is constructed. Intelligent Scheduling System has achieved successful application in the construction of Sinopec Smart Factory. Also, good practice effect and satisfied economic benefit have been obtained.

Keywords: Petrochemical industry; intelligent scheduling system; smart factory.

1. Introduction

As the control centre of refining enterprises, production scheduling plays an important role in realizing safe, stable and efficient production of petrochemical factory. Starting with the research work of Conway, Maxwell and Miller's (1967), the theory of production scheduling has been developing for more than half a century and the satisfied achievements have been gained (Cecchini et al., 2012). The national strategy such as Made in China 2025 and Industry 4.0 has promoted further transformation and upgrading of traditional industries. Also, intelligent scheduling system in petrochemical industry has gradually realized informatization and intelligence (Huang et al., 2006), a series of base layer intelligent software such as HOLLIAS is formed.

In recent years, due to the changes of social demand, production scale, raw material composition and product structure, the existing production scheduling system in petrochemical factory cannot meet the requirements of work. The abnormal events are disposed by human experience and the emergency disposal scheme cannot be generated and pushed automatically. The lack of effective early warning mechanism makes the emergency events cannot be detected and prevented in advance. The yield cannot be predicted, and the optimal production plan cannot be chosen.

Aiming at the weaknesses of the existing system, especially the above three problems, Intelligent Scheduling System is carried out to find a solution. Based on the characteristics of petrochemical industry scheduling and the design conception of Cyber-Physical System (CPS), a new method of comprehensive application of industrial big data algorithm, expert rules engine and abnormal operation condition identification model is

proposed, the architecture of the Intelligent Scheduling System, which has four major capabilities: comprehensive perception, real-time analysis, early forecasting and warning and collaborative execution, is constructed. Intelligent Scheduling System has achieved successful application in the construction of Sinopec Smart Factory. Also, good practice effect and satisfied economic benefit have been obtained.

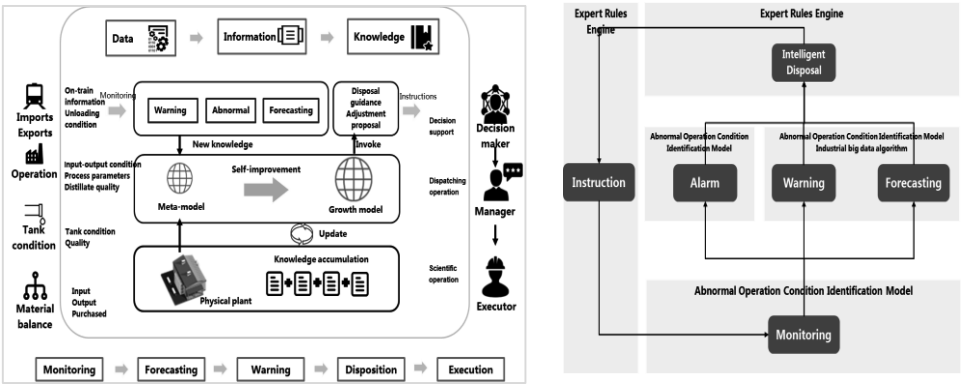
2. Design concept

Studies are conducted on intelligent scheduling system based on CPS design concept. Proposed by U.S. NSF (National Science Foundation) in 2006, the design concept of CPS system is the core technology of the fourth industrial revolution, performing in-depth symmetric management on contents of physical activities through data analysis, modelling and control at virtual terminals of the network.

Proceeding with system-level CPS, this study constructs a set of closed-loop enabling system (Intelligent Scheduling System) based on automatic flows of data between information space and physical space with 4 abilities: status awareness, real-time analysis, scientific decision-making, and precise execution (Li and Qiu, 2015; Sun et al., 2016), so as to improve the scientific decision-making level and enhance the proactive problem-solving ability (Cui et al., 2012). Specifically, the identification rules base, prediction algorithm base, and early warning algorithm base are set up for petrochemical factories' management of material incoming and product delivery, tank farm management, equipment operation management, and material balance, so as to implement monitoring, early warning and prediction on the whole production process of the factory. Operation rules are refined and operation logic is solidified, with disposal rules base for abnormalities being created, so as to automatically push suggestions and assist production directors in making scientific decisions. A closed-loop management system integrating production instructions simultaneously is established, and the closed-loop management of the process from plans to instructions, execution, and feedback is initially

implemented, with the efficiency of coordinated command being enhanced. The design schematic of intelligent scheduling system is shown in figure 1.



(a)The overall design scheme (b) The application of key technology

Figure 1. The design schematic of intelligent scheduling system

3. Key technology

3.1. Industrial big data

With the process data of production equipment as the basis, the intelligent scheduling system optimizes operation process and improves quality and efficiency by exploiting the potential of equipment through utilization of big data technology plus mechanism model and algorithm analysis, and it is mainly applied in the yield prediction models which solves the problem that product yield cannot be predicted in advance (Ouyang and Jiang, 2008; Papadopoulos et al.,2012).

In this study, the industrial big data analysis technology is employed to build a prediction model for the yield of ethylene and propylene. Meanwhile, in the current production conditions, with the increase of the yield of ethylene and propylene as the target, the adjustable parameters that can be optimized are calculated so as to ensure that the yield of ethylene and propylene is the highest in current working conditions. The idea of yield prediction is shown in figure 2.

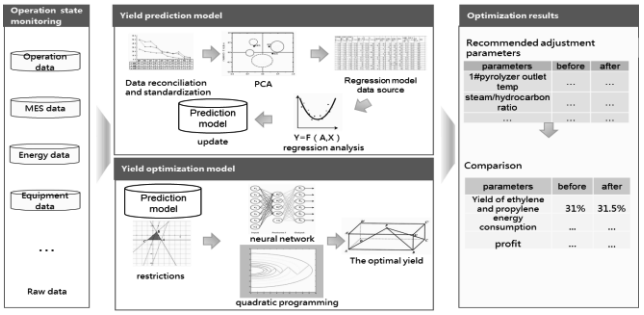


Figure 2. Yield prediction

3.2. Enterprise expert rules engine

The intelligent scheduling system constructs an intelligent disposal experience base by drawing on the experience of dispatching experts, refines business control rules, solidifies business experience logic, sets up an intelligent disposal suggestion model, supports the disposal and analysis of production alarming, early warning, and prediction, pushes scientific guidance and suggestive plans automatically, and assists dispatchers in making scientific decisions. It solves the problem that the solution cannot be automatically generated and pushed. The schematic of enterprise expert rules engine is shown in figure 3.

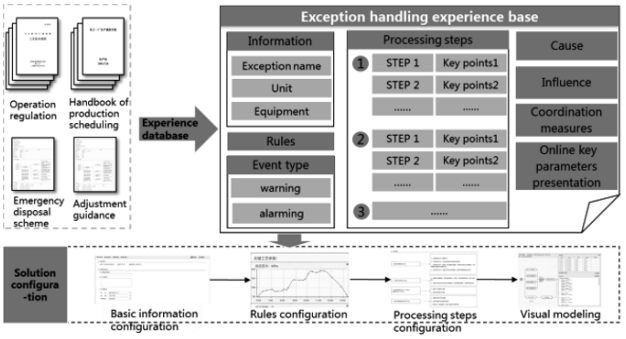

Figure 3. Enterprise expert rules engine

3.3. Abnormal condition identification model

Intelligent Scheduling System establishes abnormal working condition identification models and turns the passive monitoring mode into proactive perception of abnormal information in the factory's operation by comparing it with defined normal working conditions, identifying anomalies, and focusing on anomalies, so as to solve the problem of that emergency events cannot be detected and prevented in advance.

Alarms of operation parameters are the most common abnormal conditions in equipment operation and management (Laird et al., 2011; Hada et al.,2013), and the equipment cannot work normally when such parameters as temperature, pressure, liquid level, and flow exceed the range specified on the technique card. Through real-time monitoring over parameters, the system sets up abnormal working condition identification models to identify potential anomalies in advance, with countermeasures being pushed automatically. In the following, early warnings for rapid changes in parameters of the equipment, which is shown in figure 4, are taken as an example to introduce the abnormal working condition identification model.

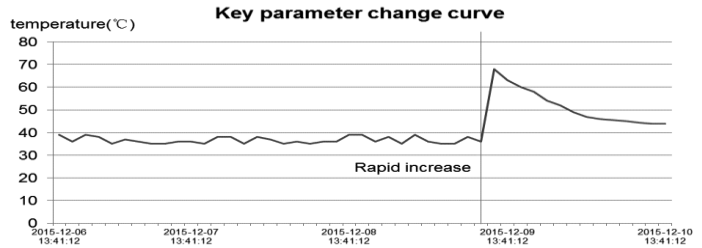

Figure 4. Early warnings for rapid changes

Model rule: When M> K, it means that the real-time value rises rapidly; and when M<Q, it means that the real-time value declines rapidly.

$$y = m_1T_1 + m_2T_2 + \cdots + m_nT_n + b \quad (1)$$

$$Y = MT + B \quad (2)$$

$$H = n \times f \times M \quad (3)$$

Intelligent countermeasures: When the system detects a rapid change in the real-time value, it will push: "XX technique parameter rises/falls rapidly by H within n * f seconds. Please check it timely."

4. Case study

Taking Sinopec Zhenhai Refining & Chemical Company as an example, the previous scheduling system failed to realize the automatic generation and push of pre-warning and disposal plan. After the successful application of Intelligent Scheduling System, real-time state perception monitoring is achieved by collecting data, data models of every factories and units as well as the abnormal operation condition identification model are set up for real-time analysis. Industrial big data analysis is used for early warning and forecasting. Also, scientific decision-making and precision execution are realized by the use of expert rules engine. The company, based on the intelligent scheduling system, has established an online instruction circulation system fully covering the production work of the entire company, and changed the management of planning, dispatching and operation from a segmented mode to a whole-process on-line and closed-loop mode, and its production management efficiency has been improved significantly, with labour time being reduced by 20 people/day and the working efficiency being increased by 15 %. The tank management pages are shown as below:

(a) Tank condition monitoring

(b) Tank abnormal disposal

Figure 5. Tank management page

5. Conclusions

Intelligent Scheduling System has been applied to 4 subsidiaries of Sinopec as demonstration pilots. There were remarkable results including the level-improving of automation, visualization and digitization in production operations management as well as the improvement of reforming promotion, quality and efficiency.

The establishment of the Intelligent Scheduling Control Centre has achieved production management delayering so that dispatching instructions can be given directly. It is also realized the cooperation of internal and external operation has been achieved. As a result,

the operation pass rate has increased to 100 % from 90.7 % and the team number in demonstration pilots has decreased by 13 % with significantly improved productivity.

Because of the application of industrial big data analysis in catalytic cracking process, through analysis of the root cause for major warnings, the warning time could be 1 minute to 2 minutes earlier before failure emerging and the operators would get enough valuable time for taking steps to avoid risks. Moreover, the application of industrial big data analysis in continuous catalytic reforming process has increased the yield of high-value-added product, with annual economic benefit being increased by more than ¥7,000,000.

Intelligent Scheduling System is the successful application of CPS design concept. It has realized information and data sharing among various levels. Moreover, material flow, cash flow and information flow have been unified as well as intelligent scheduling has been achieved within the whole plant. By building data models for factory and plant, productive process can be automated and forecasted. With these models, the optimum operation pattern that fits in current status can be obtained for production process, which lay a good foundation for effective explosion of “Prospective Unmanned Factory”.

Abstract

Ethylene and propylene are the most important basic resources for chemical industry, and the demand of them dramatically increases worldwide. However, the pyrolysis process is too complex to build a precise mechanism model. Traditional mechanism models based on molecular reactions are also very complex and one single simulation of them is generally time-consuming. In addition, the off-line lab test of yields of the components of outputs has great time delay. So it is very difficult to achieve a precise closed-loop control for pyrolysis process because the yields of ethylene and propylene cannot be tested online or predicted precisely with traditional mechanism models. To handle this problem, this paper tries to establish some data-driven models for the pyrolysis process based on ensemble learning methods, such as AdaBoost.R2 and AdaBoost.RT, and process data. The parameters used in the ensemble learning models are determined by the evolutionary algorithm instead of traditional method based on experience. Their performances are evaluated based on practical process data.

Keywords: pyrolysis process, yield prediction, ensemble learning method, evolutionary algorithm

1. Introduction

1.1. Naphtha pyrolysis process

As one of the most important monomers in the petrochemical industry, ethylene is the base for organic material productions. The key equipment for the naphtha pyrolysis in the ethylene plant is the cracking furnace, whose schematic production process is illustrated in Fig. 1. First, the naphtha feed is put into the convection section and preheated, and then the dilution steam gets in and mixes with the heated naphtha feed. After completely vaporized in the convection section, their mixture enters the U-type cracking coil of the radiant heating section and the pyrolysis reaction occurs immediately. Finally, the products mainly consisting of ethylene and propylene flow out to the subsequent sections to be separated. In the operation of the cracking furnace, the key control parameters (or variables) are the coil outlet temperature (COT), the steam-to-naphtha ratio, and the outlet pressure, because they are closely related to the reaction depth that determines the yielding rate of ethylene and propylene. The main task of an operator is to determine the real-time values of these key control variables so as to maximize the yields of ethylene and propylene. However, in most pyrolysis processes there is no online testing equipment for the yields of ethylene and propylene. The output products need to be sent to the lab for precise test of the yield of each component. That is, the off-line lab test of yields of the components of final outputs has great time delay.

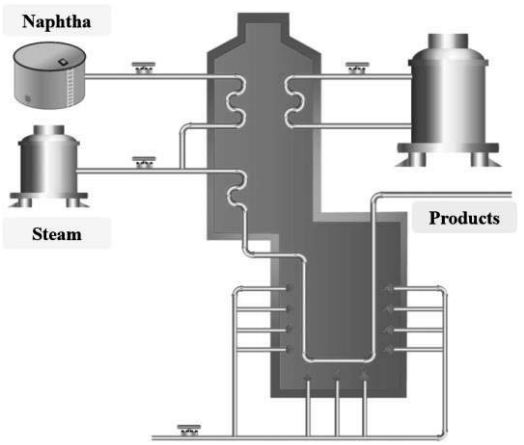

Figure 1. Schematic production process of the steam cracking furnace

Although there have been many kinds of reduced mechanism model based on molecular reactions for the pyrolysis process, there is no reaction kinetics model that can precisely describe the pyrolysis process because once activated thousands of reactions will occur concurrently in the cracking coil at a very short time. Moreover, one single simulation of the traditional mechanism models based on molecular reactions is also very time-consuming. So it is very difficult to achieve a precise closed-loop control for pyrolysis process because the yields of ethylene and propylene cannot be tested online or predicted precisely with traditional mechanism models.

1.2. Literature review

Though there have been many literatures on the modeling of the naphtha pyrolysis, few papers focused on the yield prediction of the naphtha pyrolysis process.

With respect to the mechanism modelling methods, they can be classified into three categories according to the review of Gao *et al*. (2008), namely the free-radical reaction kinetics model, the molecular reaction kinetics and the experiential models. Although the free-radical reaction kinetics model, e.g., Joo and Park (2001), had the most precise yield prediction, it was too time-consuming to be used in practical real-time control. The experiential models such as Hao *et al*. (1999) were less complex, but they were based on experience, especially for specific kinds of naphtha feed and cracking furnaces. The molecular kinetics models, e.g., Kumar and Kunzru (1985), were often adopted in practical production, however, one single run of such models was still very time-consuming.

1.3. Contribution of this paper

To handle the problem that traditional mechanism models cannot be used to establish real-time optimization or closed-loop control for the pyrolysis process, this paper tries to establish the data-driven models for the pyrolysis process based on ensemble learning methods, such as AdaBoost.R2 and AdaBoost.RT. Since the parameters used in these modeling methods have great impact on the prediction precision, we prefer to use evolutionary algorithm, instead of traditional method based on experience, to obtain the appropriate parameter settings. Finally, the performances of the two kinds of ensemble learning methods are evaluated based on practical process data.

2. Sub-learning machine based on LSSVM

For the sub-learning machine in the ensemble learning modelling, we prefer to adopt the least square support vector machine (LSSVM) because it has good balance of simplicity and precision. In the LSSVM, the key parameters are the regularization parameter γ and the kernel width parameter σ. Since the two key parameters have significant impact on the performance of the LSSVM model, in this paper we adopt an improved particle swarm optimization (IPSO) to determine their values. Different from the standard PSO, the main feature of the IPSO is that it incorporates an elite set consisting of the best solutions found in search history to guide the search direction of particles and replace non-promising particles in the population to improve the search diversity of PSO.

In the IPSO, a solution is represented as $X_i=(\gamma_i, \sigma_i)$ and the fitness of each particle is calculated as $fitness(X_i)=\sqrt{\sum_{k=1}^{l}(\hat{y}_k-y_k)^2/l}$, where $\hat{y}_k$ is the prediction value of the output (yield of ethylene or propylene) according to sample data k consisting of the input (the steam-to-naphtha ratio, the coil outlet temperature, and the outlet pressure).

As mentioned above, the elite set has two functions: (1) guiding the search direction of particles and (2) replacing nonpromising particles in the population. The first function is implemented by revising the update equations of particles as follows.

$$v_{ij}^{t+1}=w\cdot v_{ij}^{t}+c_1r_1\cdot(p_{ij}^{t}-x_{ij}^{t})+c_2r_2\cdot(g_j^{t}-x_{ij}^{t})+c_3r_3(e_j^{t}-x_{ij}^{t}) \tag{1}$$

$$x_{ij}^{t+1}=x_{ij}^{t}+v_{ij}^{t+1} \tag{2}$$

where w is the inertia parameter, c_1, c_2 and c_3 are respectively the cognitive, social and elite learning parameters, r_1, r_2 and r_3 are random numbers uniformly distributed in (0,1), p_{ij}^{t} is the jth position value of the personal best, g_j^{t} is the jth position value of the global best, and e_j^{t} is the jth position value of a solution randomly selected from the elite set. Since the elite solutions are the best 20 solutions found in the search history and they are randomly selected in implementation, the incorporation of the elite set can help to improve the search diversity of PSO while keeping good solution quality.

3. Experimental results of AdaBoost based on LSSVM

Ensemble learning is one of the hottest research areas in machine learning because it can enforce the prediction precision or classification precision of several learning machines, even if they are weak learning machines. Besides, the experimental results showed that the ensemble of several sub-learning machines could significantly improve the robustness of the prediction or classification model.

In this section, we combined the LSSVM in the two famous versions of AdaBoost, i.e., AdaBoost.R2 and AdaBoost.RT, and tested their performance for the modelling of the pyrolysis process to predict the yields of ethylene and propylene. In the two ensemble learning methods, a set of 5 sub-learning machines (i.e., LSSVMs) were used.

In the experiment, we collected a total of 108 data samples, among which 88 samples randomly selected from the 108 samples were used as training data while the left 20 samples were used as the testing data to verify the performance of the two ensemble learning methods.

3.1. AdaBoost.R2 based on LSSVM for yields prediction

The yield prediction of ethylene for the training and testing data were given in Figure 2 and Figure 3, respectively. And the yield prediction of propylene for the training and testing data were given in Figure 4 and Figure 5, respectively.

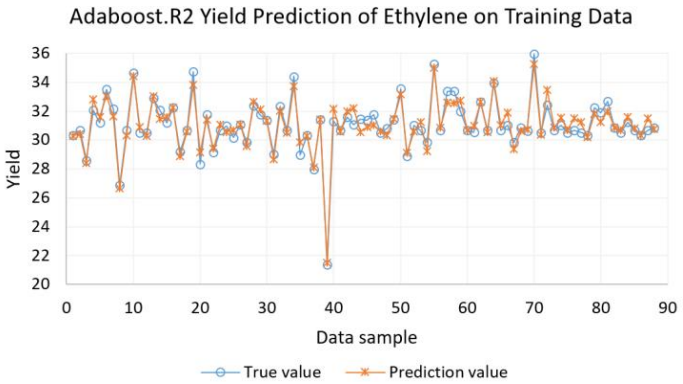

Figure 2. Yield prediction of ethylene with AdaBoost.R2 on training data

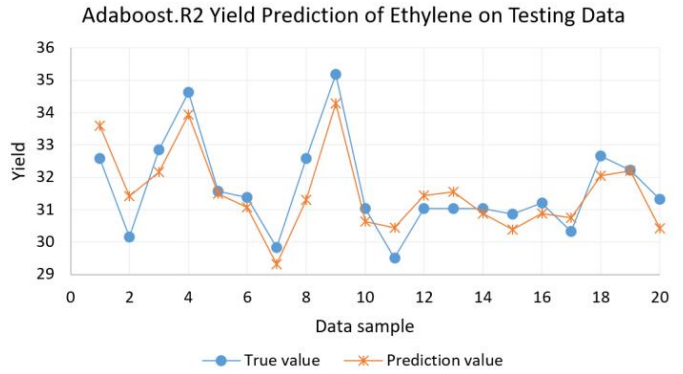

Figure 3. Yield prediction of ethylene with AdaBoost.R2 on testing data

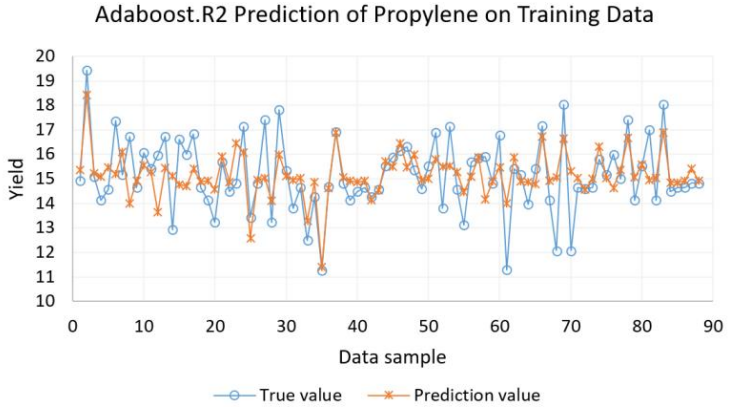

Figure 4. Yield prediction of propylene with AdaBoost.R2 on training data

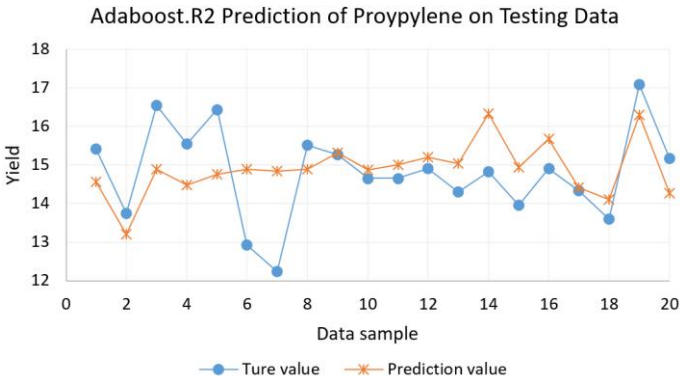

Figure 5. Yield prediction of propylene with AdaBoost.R2 on testing data

3.2. AdaBoost.RT based on LSSVM for yields prediction

The yield prediction of ethylene for the training and testing data were given in Figure 6 and Figure 7, respectively. And the yield prediction of propylene for the training and testing data were given in Figure 8.

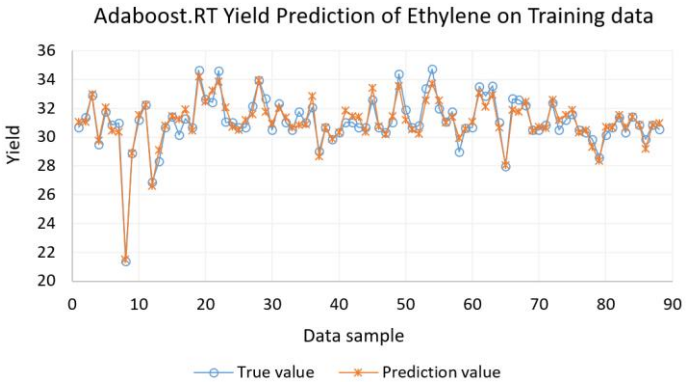

Figure 6. Yield prediction of ethylene with AdaBoost.RT on training data

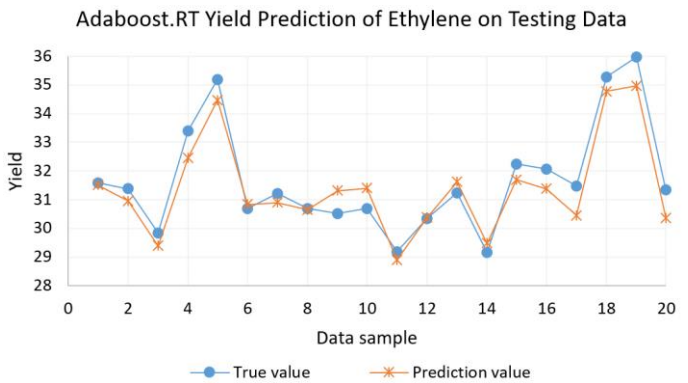

Figure 7. Yield prediction of ethylene with AdaBoost.RT on testing data

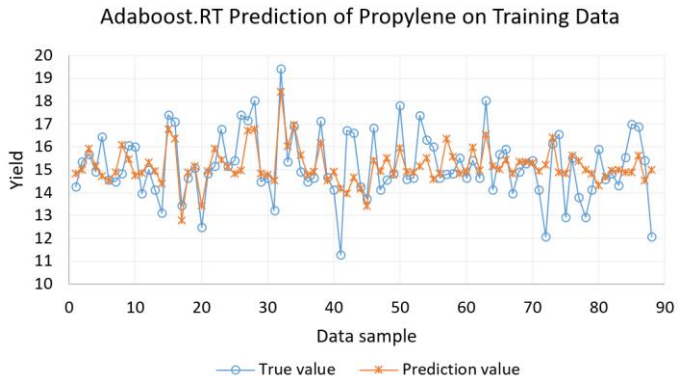

Figure 8. Yield prediction of propylene with AdaBoost.RT on training data

4. Conclusions

In this paper, two kinds of ensemble learning methods based on LSSVM were tested for the yield prediction of pyrolysis. The results show that the two models can both predict the yields precisely and the AdaBoost.R2 is a little better. These models can be used in the online prediction and real-time optimization of the pyrolysis process.

Abstract

In recent years, the development of AI has been accelerated so that the semiconductor manufacturing process has also been regarded as a very important issue. Many research results related to the plasma etch process which is one of the most important processes in the semiconductor manufacturing process have been presented in various forms. Recently, our research group has also presented a case of successful real-time multivariable control of plasma parameters based on optical emission spectroscopy.

Although the above results are expected to bring about positive effects in various fields, they do not consider the variability of the system. Plasma related systems are so sensitive that online system identification is inevitable. In this paper, we performed the online system identification of the system composed of the plasma parameter through recursive parameter estimation method. Through the recursive algorithm using forgetting factor and input and output information which was gathered in real-time, we detected that the system was changing in real-time and updated the model parameters. We expect the results introduced in this paper contributes not only to the semiconductor manufacturing process but also to all the processes using plasma.

Keywords: Online System Identification, Recursive Parameter Estimation, Real-time Control, Plasma Parameter Control

1. Introduction

Due to the ever smaller feature size according to Moore's law, the semiconductor industry is demanding higher quality control. In addition, the development of AI has been accelerated so that the semiconductor manufacturing process has also been regarded as a very important issue. Many research results related to the plasma etch process which is one of the most important processes in the semiconductor manufacturing process have been presented in various forms. Recently, our research group has also presented a case of successful real-time multivariable control of plasma parameters based on optical emission spectroscopy (OES).

Even though those studies show excellent results, it is difficult to directly apply them to the semiconductor manufacturing environment for a variety of reasons. One of the reasons is that real-time detection of system changes is essential in systems dealing with sensitive materials such as plasma, but some studies have been carried out without consideration of them. Especially, in the previous studies conducting the plasma control through model predictive control (MPC), which is widely used in recent years, the importance of the

online system identification should not have been excluded because MPC has a high model dependency.

In this paper, we performed the online system identification of the system composed of the plasma parameter through recursive parameter estimation method. We utilized an OES based single input single output (SISO) plasma parameter controller. OES is a default plasma monitoring sensor for every plasma reactor so that there is no concern about installation. In addition, OES, a non-invasive tool, has the advantage of less impact on the system than other invasive sensors such as hairpin probe. This study is of great value as the first attempt to control the plasma parameter with non-invasive sensor and online system identification.

This paper is organized as follows. In Section 2, the experiment environment and the system definition of our electron density control system are explained briefly where the monitoring sensor is OES. In Section 3, the theoretical backgrounds which contain a recursive parameter estimation algorithm and the Box-Jenkins model structure used in our system model are explained. In Section 4, the results of the online system identification are illustrated, along with the MPC control results with the unchanged model applied.

2. Estimation of the plasma parameters from OES: System definition

In plasma etch, it is important to control plasma parameters such as electron density, electron temperature and so on. There have been many studies and literature dealing with the control of plasma parameters. Our research group have also published a paper about the control of plasma parameters monitored by optical emission microscopy (OES) which is a non-invasive diagnostic tool. Optical fiber attached on the viewport of the chambers measures the emission in plasmas. An emission intensity from a particular p^{th} state to k^{th} state is described as

$$\Phi_{pk} = n_0 n_e \int_{E_{thr}}^{\infty} \sigma_{pk}(E) \left(\frac{2E}{m_e}\right)^{\frac{1}{2}} f(E) dE \tag{1}$$

where n_0 is the number density of ground state atoms, n_e is the electron density, $\sigma_{pk}(E)$ is the excitation cross section from level p into level k as a function of electron energy E, $f(E)$ is the electron energy distribution function (EEDF), m_e is the electron mass.

In order to measure plasma parameters with OES, it would be useful to have a separate line-ratio techniques that is only a function of the electron density (J. B. Boffard et al., 2004). In a similar way, we utilized several emission lines to measure electron density.

In our experiment, we used a capacitively coupled plasma reactor that can carry 300 mm wafers. It is powered by three radio frequency (RF) generators and the gap betwen top and bottom electrodes is 25 mm. The reference plasma condition is 20 mT of pressure, 400 sccm of Ar flow rate and 16 sccm of SF_6 flow rate. The input variable defined in our system is 60 MHz RF power and the output variable is electron density. With OES and Eq. (1), the electron density is measured in real-time.

3. Recursive parameter estimation for Box-Jenkins model

The estimated model parameter that minimizes the weighted error criterion is as follows:

$$\widehat{\theta_t} = \underset{\theta}{argmin} \sum_{k=1}^{t} \beta(t,k)[y(k) - \varphi^T(k)\theta] \tag{2}$$

where $\widehat{\theta_t}$ is the estimated model parameter at time *t*, $y(k)$ is the measured output, $\varphi(k)$ is the regression vector, θ is the present model parameter and $\beta(t,k)$ is the weighting sequence which has the following property:

$$\beta(t,k) = \lambda(t)\beta(t-1,k), \qquad 0 \leq k \leq t-1$$

$$\beta(t,t) = 1 \tag{3}$$

where $\lambda(t)$ is the forgetting factor the value range of which is recommended to be between 0.98 and 0.995. When solving Eq.(2), we have

$$\widehat{\theta_t} = \hat{\theta}_{t-1} + \bar{R}^{-1}(t)\varphi(t)[y(t) - \varphi^T(t)\hat{\theta}_{t-1}] \tag{4.a}$$

$$\bar{R}(t) = \lambda(t)\bar{R}(t-1) + \varphi(t)\varphi^T(t) \tag{4.b}$$

which is a recursive algorithm where

$$\bar{R}(t) = \sum_{k=1}^{t} \beta(t,k)\,\varphi(k)\varphi^T(k) \tag{5}$$

The model structure we estimated in real-time is a linear, time-varying, discrete-time Box-Jenkins (BJ) polynomial model which can be generally described by

$$y(k) = \frac{B(k,z)}{F(k,z)}u(k) + \frac{C(k,z)}{D(k,z)}e(k) \tag{6}$$

where $u(k)$ is the input variable, $e(k)$ is a zero-mean, white noise with variance σ^2 and $B(k,q), C(k,q), F(k,q)$ and $D(k,q)$ are model parameters. The model parameters are calculated in real-time based on Eq. (2) ~ (5). Specifically in our system, $u(k)$ represents 60 MHz RF power and $y(k)$ represents the electron density. The recursive parameter estimation is supported in the MATLAB's commands and SIMULINK.

4. Results and Discussion

In order to evaluate the performance of the recursive parameter estimation algorithm, it is reasonable to compare the situation where the output variable is controlled. The setpoint tracking test of electron density was performed. The setpoint was calculated through the wall fluorination which is one of the most popular performance variable in the semiconductor etch process. The controller for the electron density was designed in MPC method which has been widely used as an advanced process controller recently.

First of all, the setpoint value of the electron density was calculated, then the MPC was activated to track the setpoint with manipulating the 60 MHz RF power. While this control operation was being operated, the model parameters were not changed. The unchanged

model (discrete-time output error (OE) model structure) was obtained by referring to previous research results (J. Koo et al., 2017). As shown in figure 1, the electron density setpoint tracking results were biased by distinct errors.

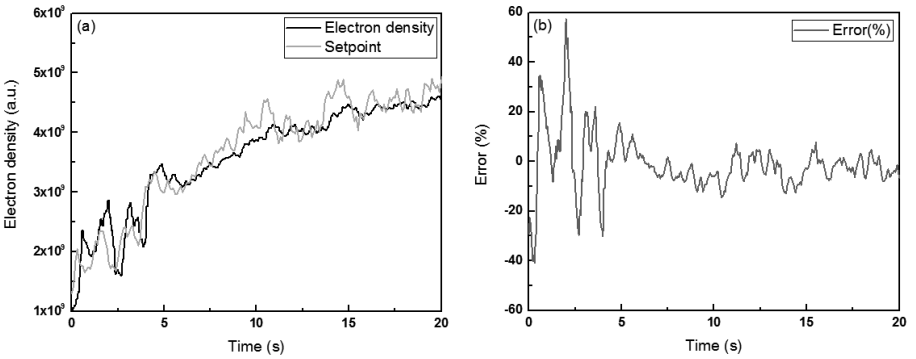

Figure 1. The setpoint tracking results with MPC controller applying constant model parameters (a) and the error percentage of the control results.

The bias can occur for a variety of reasons such as drift of the system caused by fluorine spread from the etcher wall, OES measurement drift error, system linearity issue and so on. The results clearly show that online parameter estimation of the system is inevitable.

The recursive parameter estimation algorithm, Eq. (2) ~ (5), was then applied to the same dataset. The dataset, electron density and 60 MHz RF power for $y(k)$ and $u(k)$ respectively, was used to the model parameter estimation simulation. The initial value of the each parameter was set from the unchanged model. That is, B_0 and F_0 had specific value from the unchanged model and C_0 and D_0 were 1 at time 0s. The forgetting factor, $\lambda(t)$, was set to be 0.995. The recursive parameter estimation simulation results are shown in figure 2.

The subscript number after the parameter in figure 2 refers to the degree of the parameter plus 1, that is, B_8 means $B(z) = b_8 z^{-7}$ and other parameters have the structure like $C(z) = c_1 + c_2 z^{-1}$, $F(z) = f_1 + f_2 z^{-1}$ and $D(z) = d_1 + d_2 z^{-1}$. All of the parameters b_1 to b_7 are 0 because of the time delay issue of the system.

The comparison of the measured electron density and the estimated electron density from the recursive parameter estimation algorithm are shown in figure 3.

It is clear that the electron density estimates in figure 3-(a) are fitting the actual measurements perfectly. The error percentage of that is shown in figure 3-(b) which shows nearly 0 % (within +/- 2 %) after 5 s. Within 5 s, there is an inaccuracy because the number of data for parameter estimation is small.

Based on these results, the plasma parameter control can be expected to be much more effective and accurate when an adaptive MPC controller with online system identification is implemented.

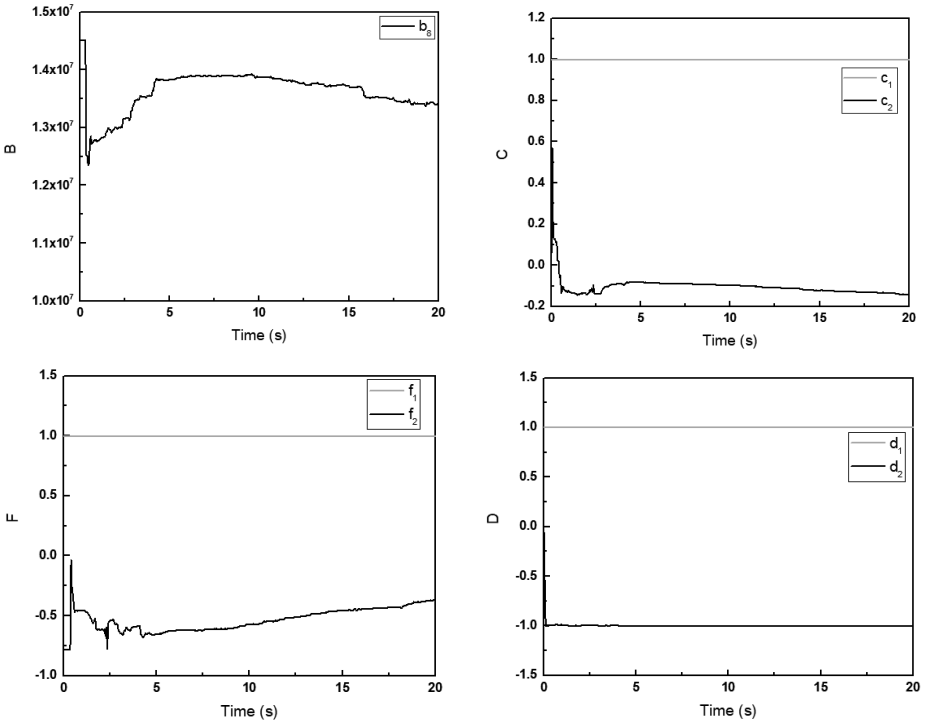

Figure 2. The model parameters estimated from the recursive parameter estimation algorithm.

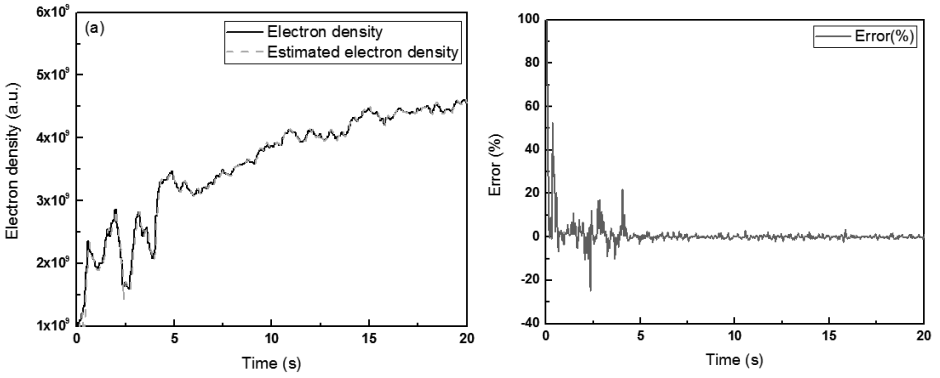

Figure 3. (a) The comparison of the measured electron density and the estimated electron density calculated by the recursive parameter estimation algorithm and (b) error percentage of that.

5. Conclusions

Through this research, we performed the online system identification to improve the efficiency of real-time control of the plasma parameters. The control objective was tracking the setpoint of the electron density in Ar and SF_6 plasma condition by manipulating 60 MHz RF power which was calculated by MPC controller. In the control results without online system identification, there was bias caused by several reasons such

as system drift, measurement drift and so on. The results justified the necessity of online system identification. The online system identification simulation of Box-Jenkins polynomial model was then performed using the dataset used in the control with the constant model parameters. As a result, it was confirmed that the estimation of the electron density follows the actual values well. Its error percentage was just only 2% which means the control performance will be maximized when applied to the adaptive MPC controller. These results are of great value as the first attempt to perform online system identification of the plasma parameter system using OES and recursive parameter estimation in the semiconductor manufacturing process. We hope that these successful results of applying established methodologies to the plasma related systems will contribute to maximize the sophistication and the efficiency of all processes using plasma as well as semiconductor manufacturing processes.

Abstract
This paper provides insight into the methodology employed for the development of a smart system called the J-Park simulator (JPS). JPS provides a virtual representation of an Eco-Industrial Park (EIP) and contains information pertaining to various aspects of an EIP. An ontology based approach is used to store this information in a structured and machine-readable form. Ontology represents data in a structured form and can be used for the creation of knowledge bases. These knowledge bases can then be utilised to conduct case studies on JPS. In one such case study the most suitable locations for modular nuclear plants in an EIP is identified. The architecture for the case study and how it can be implemented in JPS is demonstrated in the paper.

Keywords: ontology, knowledge base, modular nuclear power

1. Introduction

The ever-increasing price, demand and environmental cost for energy have driven mankind invest into developing more efficient and economical ways for utilizing energy. This line of thinking has led to the formation of industrial clusters called Eco Industrial Parks which achieves higher economic and environmental performance through collaboration over a wide range of sectors like energy, water, material etc. This concept maximizes the collective benefit of the cluster rather than focus on the profits of individual entities.

The functioning and efficiency of an EIP could be significantly improved by applying the concepts of Industry 4.0. J-Park simulator (JPS) (Zhou et al., 2017) is envisaged as a smart system which provides a virtual representation of an Eco Industrial Park (EIP) and contains information pertaining to its various aspects. The current version of JPS is inspired from the industrial park in Jurong island, Singapore. JPS studies the interactions between various domains that exist in an EIP through a variety of models. The sheer quantity of data and the complex nature of interactions make this a daunting task. We have used an ontology-based knowledge base for overcoming this difficulty. Ontology is a formal and explicit representation of knowledge in a domain expressed in a machine-readable form. It behaves as a road map with several interconnected nodes which makes data access efficient. Data pertaining to each physical object in the EIP could be represented by a virtual 'avatar' which is capable of communicating with each other. This paper focuses on the power generation aspect of an EIP and provides a case study which demonstrates the capabilities of JPS.

Power generation facilities are an integral part of an EIP. Conventional power generation technologies contribute significantly to global carbon emissions, so it stands against the design principles of an EIP. These emissions could be reduced drastically by employing greener alternate technologies like nuclear power. In the case study, we have considered a scenario in which the entire power demand for the EIP is supplied from modular nuclear power plants which are located strategically. The locations of the plants should be near the consumer locations so that transmission losses can be reduced. The major concern about nuclear power is nuclear fallout in case of an accident. This concern is quantified by conducting a risk analysis that takes into consideration a variety of factors like population density, cooling water availability etc. Based on these parameters a multi-objective MINLP model was formulated in GAMS. The model is then implemented in JPS where it conducts a risk benefit analysis on all available land sites and returns the locations of the most suitable ones. The data required for the model were taken from the knowledge bases through the usage of SPARQL queries. Once the model is executed the results are updated in the knowledge base and the locations are displayed in a Google map. The entire process is automated through the use of a series of agents capable of performing specific tasks.

2. Knowledge base development for power plants

2.1. OntoEIP

OntoCAPE is an existing ontology for the computer aided process engineering domain (Morbach et al.,2007). OntoCAPE is capable of representing knowledge in the chemical engineering domain. However, an EIP contains many other critical aspects, such as electrical engineering, transport system, civil engineering etc. Consequently, it is necessary to extend OntoCAPE to represent other domain knowledge, further to indicate cross-domain interdependencies. This extension of OntoCAPE ontology is called OntoEIP.

OntoEIP uses the concept of abstraction layering to represent concepts wherein the ontology is divided into different layers. Each level contains information required for its representation and all other information are passed to lower levels. The large-scale EIP system is decomposed into subsystems by applying a bottom up approach where the lower levels reflect information of more specific nature. In our case, an EIP is modelled by a five-layered system model with Industrial network, Plant network, Process, Unit and molecular levels arranged top-down. The industrial network level has a broad information about the electrical, energy, material and road network of an EIP while the plant level will have information specific to a plant. As we go down the layers the information becomes more detail-oriented and more specific to the application. For example, the molecular level will have information regarding the chemical structure and interactions between molecules.

2.2. Extension of OntoEIP for power plants

The upper levels of the OntoEIP ontology provides a framework for describing most of the objects and properties in an EIP. More specific details relevant to a sector have to be added to the lower layers separately. In the case of a power plant, it is defined as a sub-class of the technical system in the existing ontology. This power plant technical system has different aspect systems. Each of the aspect system limits the information in it to a particular view point. The realization aspect takes into consideration the physical and

design properties of a power plant. The function aspect considers the processes and the unit operations happening inside the plant. Finally, the performance aspect has different performance evaluators like carbon emissions, cost comparisons etc. to analyse the performance of a plant. It is important to ensure that the new classes and properties are consistent with the existing ontology. Also, the classes and properties should be unique and should not be presented elsewhere in the ontology. This ontology was developed in Protege which uses the Ontology Web language (OWL) and it's an extension of the OntoEIP ontology.

2.3. Creation of knowledge base

The ontology described above is capable of holding information about power plants. An instance of the power plant ontology provides information about a particular plant that is under consideration. An ontology with a set of instances can be called as a ontological knowledge base as it represents knowledge in a structured manner with classes, properties and instances (Zhang et al., 2017).In this study, the information used for the knowledge base creation was taken from the global energy observatory website (http://globalenergyobservatory.org/). A python script was used to mine the data from the website and the apache Jena library of java was used to add it into the ontology. A set of OWL files were created using the java code and each file has information regarding one power generation facility. These ontologies were then published online to keep the information decentralized.

The power plant knowledge base is then visualised using the google map java script API. The final visualization of the website is available at www.theworldavatar:82/ppalt and is shown in the figure below. It is a google map with location markers for all the power plants in the world. A single click on any power plant will reveal design information of that power plant while a double click will open a new tab with the ontological knowledge base of the power plant displayed in the xml schema format. Similar to this, the JPS has knowledge bases for chemical plants, road network etc.

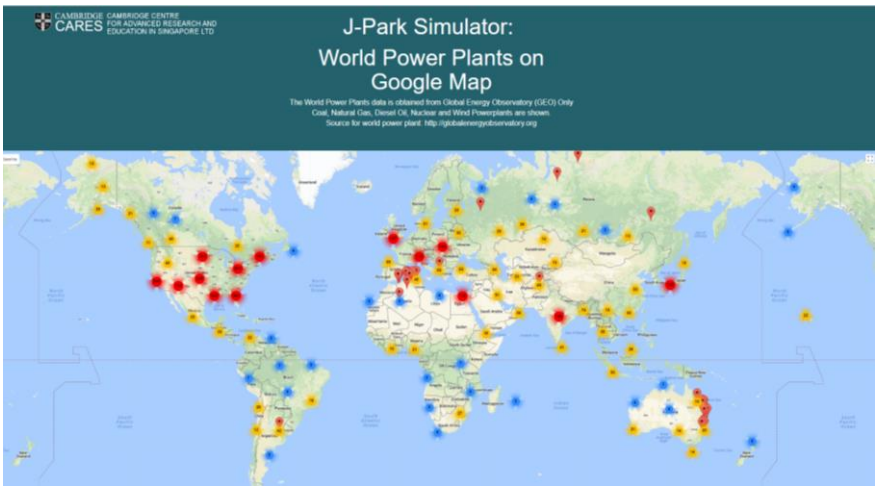

Figure 1 World power plants knowledge base

2.4. Architecture for case study in JPS

The knowledge bases created for representing the information in an EIP can be utilised for several purposes. One possible application is conducting case studies to analyse the

outputs from various scenarios that might occur in an EIP. These case studies should comply with the design principles of the JPS (Kleinelanghorst et al., 2016) so that it can be implemented easily. The architecture consists of agents capable of acquiring and changing the data presented in the knowledge base. Figure 2 shows how the case study can be implemented in the JPS.

Any case study or scenario analysis will have a model which can predict the output of that scenario. This model requires information that has to be acquired from the knowledge bases. An Input/output agent has the capability to search through the knowledge bases and acquire relevant information for the model. This I/O agent can be a SPARQL query, which is a query language developed for RDF framework. Once the information is fed to the model, it will be executed, and the output will be generated. This output has to be updated in the ontological knowledge bases. This is done by another agent which is a JavaScript that utilises the apache Jena library. Finally, the output will be visualized on the website using various tools.

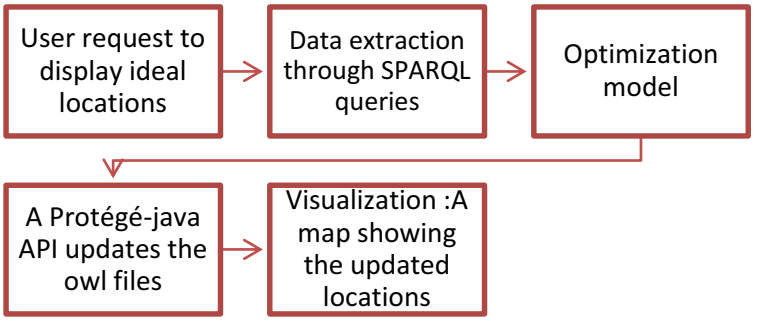

Figure 2 Architecture for case studies

3. Case study

3.1. Problem statement

The objective of the problem is to design a standalone power system for an EIP. An EIP consists of several industries and it is spread over a large area. Most of these EIPs are located in remote areas away from residential sites. A standalone power system can deliver power to the EIP with better efficiency and lower losses than from connecting it to an external grid. The entire area of an EIP can be divided into two categories. The first category includes all the areas which consume power like industries, storage facilities etc. These are defined as load points in this study. The second category includes the empty areas like unused spaces, roads, gardens etc. These are available sites for new power plants and are called potential sites. As a result, the entire area of the EIP can be divided into grids and each lot in the grid represents either a load point or a potential site. The suitability of a potential sites depends on a lot of factors like the population density, cooling water availability etc.

The objective function evaluates each potential site and selects the sites with least cost and risk associated with them. The objective function for the problem is defined below.

$$z = \min w_1 \left[\sum_{j=1}^{n} \sum_{i=1}^{m} \alpha d_{ij} x_{ij} + \sum_{j=1}^{n} f_j y_j\right] + w_2 \sum_{j=1}^{n} \beta_j y_j \quad (1)$$

where n represents the number of areas available for power plants and m the number of load points to which the power has to be delivered. d_{ij} represents the distance between the

potential plant location to the load point and x_{ij} represents the fraction of power delivered by the j^{th} plant to the i^{th} load point. y_j is a binary variable which shows whether the potential area is selected or not, f_j is the capital cost associated with the plant and β_j is the normalized risk factor . w_1 and w_2 are weighing parameters to balance the risk cost ratio while α is the power loss to cost conversion factor.

Subject to the constraints,

$$\sum_{i=1}^{m} x_{ij} = 1 \tag{2}$$

$$y_j = [0,1] \tag{3}$$

$$s_j y_j \geq \sum_{i=1}^{m} (1+\gamma) D_i x_{ij} \tag{4}$$

$$\sum_{j=1}^{n} s_j y_j \geq \sum_{i=1}^{m} (1+\gamma) D_i \tag{5}$$

Where D_i and s_j represents the demand and power supply from the load point and plant respectively. γ represents the excess power factor.

The risk factor can be written as,

$$R_j = \sum_{i=1}^{m} \left[\frac{A_i \rho_j}{d_{ij}} + \mu d_j^f \right] \forall\, d_{ij} \leq r \tag{6}$$

$$\beta_j = \frac{R_j}{\max(R_j)} \tag{7}$$

$$n_{jmax} = \frac{A_j}{A_u} \; where \; 0 \leq n_j \leq 12 \tag{8}$$

$$f_j = u_j n_j C \tag{9}$$

Where A_i represents the area of the land lot, ρ_j the population density, d_j^f distance to nearest cooling water source. A_u represents the minimum area required for a unit of the modular power plant and n_j the number of units that can be placed in a potential site. C is the fixed cost associated with a single unit. The capital cost of a modular plant decreases with the increase in capacity and the cost factor u_j takes that into consideration.

The information regarding the modular nuclear reactor is taken from the website of a company called NuScale Power. The other necessary information like the land lot properties and load point data is taken from the knowledge base using SPARQL queries.

3.2. Results and Discussion

The architecture proposed in the paper is utilized to implement the case study in the JPS. Three parameters in the model are user defined. They are the excess power factor, risk factor and cost factor. The user inputs the values of these models in the JPS website and clicks on the run button. This acts as the stimulus and initiates the following events. A

series of SPARQL queries will be executed and they will through the relevant knowledge bases to collect information. Information regarding the land, its area, location, ownership etc is stored in the Landlots.owl file. But not all the land-lots will be a suitable site for a modular nuclear power plant. The SPARQL query acts as a preliminary filter and removes impossible options based on the area and present purpose of the land-lot. The possible choices of the sites are then fed to the model. The model also requires information regarding the consumer power consumptions and their location. This is obtained from the electrical network owl file. Once the model is executed the results are written to an excel file. The Java agent then creates a series of owl files each of them representing a single power plant. The information in these owl files are then visualized using the Google map JavaScript API. The visualization of the power plants is available in JPS website and a snapshot is given in the figure below.

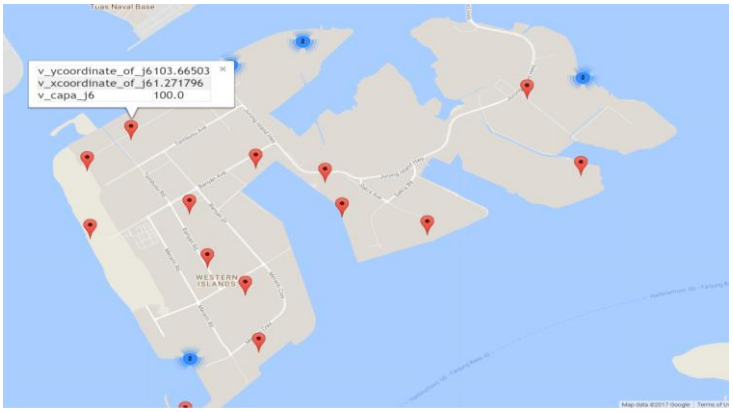

Figure 3 Visualization of the optimization model

4. Conclusion

An ontology based approach for building knowledge bases were discussed in the paper. It can be established that an ontology based knowledge management system can provide more efficient and hassle-free communication between different entities in an EIP. In the future real-time information from sensors could be fed into the knowledge bases and more complex case studies could be conducted in JPS.

Abstract

We present an approach to online scheduling of chemical plant operations that incorporates precise knowledge of the dynamics enforced by the automation system. The scheduling problem is solved using a discrete-time state-space resource task network formulation. Rescheduling is triggered when the schedule currently being executed conflicts with the dynamical behavior allowed by the automation system. We present a case study to show that better operation is achieved using our approach compared to iterative rescheduling alone.

Keywords: Automation, Online Scheduling, Formal Methods

1. Introduction

Scheduling of operations in a chemical plant is the activity of deciding when, and in which order, to perform various tasks, often by solving an optimization problem. Chemical production scheduling problems occur in a wide variety of applications, from batch production of fine chemicals to continuous production of bulk chemicals. Before a scheduling problem can be solved, an abstract framework is needed to represent the different elements of the problem, such as the production facility and the associated production recipe. The resource task network (RTN) enables this representation. The RTN representation has two components: resources and tasks. Resources include equipment, materials, utilities, etc., and a task is an operation that consumes and generates resources through the period of its execution. Many scheduling models employ a discrete time grid, where the time horizon is discretized into periods of uniform length, and tasks start and end at the grid points.

In a dynamic environment, disturbances or new information may lead to suboptimality or infeasibility of the computed schedule, necessitating rescheduling (Gupta and Maravelias, 2016). The revision of an existing schedule in response to such disturbances or new information is called online scheduling.

This work is sponsored in part by the Department of the Army through the Digital Manufacturing and Design Innovation Institute. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the Department of the Army.

One source of new information that may necessitate rescheduling is the plant's automation system, which makes the low-level discrete decisions that drive the plant's behavior. The key issue that we seek to address in this work is the mismatch between the model of the plant used in the scheduling problem and the actual behavior of the plant, enforced by the automation system. For example, for a batch reaction which is modeled as a single task with a fixed duration in the scheduling model, the automation system may include a sequence of 10 or more distinct steps, with transitions between those steps dependent upon the state of other pieces of equipment in the plant (which, in turn, have their own sequences of steps). Thus, a schedule computed using the coarser model may not actually be feasible when executed in the plant, even in the absence of disturbances. A similar issue arises when integrating scheduling and control (Engell and Harjunkoski, 2012; Baldea and Harjunkoski, 2014).

To address this problem, we develop a methodology that incorporates knowledge about the dynamics of the automation system to guide rescheduling. In the past, researchers have focused on extensions of the RTN model and advances in the state-space scheduling model. Wassick and Ferrio (2011) have proposed a number of extensions to the conventional RTN model. Nie et al. (2014) proposed a discrete-time RTN formulation for rescheduling. Subramanian et al. (2012) showed a general procedure to transform the mixed-integer programming (MIP) scheduling model into a state-space model, as is used in model predictive control. Gupta and Maravelias (2017) presented an extended state-space state task network (STN) model suitable for implementation in an online scheduling setting. Building upon these previous works, we develop a generalized discrete-time state-space RTN model that accounts for disturbances detected by analyzing the automation logic online. In the state-space RTN model, the status of the process is indicated by the state variables, and information obtained by analyzing the automation logic is represented by additional constraints involving those state variables. To monitor the execution of a schedule, we construct a finite transition system that models the plant's automation logic as in Rawlings et al. (2017), and augment that model with historic data on the amount of time the system spends in each step. With this detailed model of the plant's dynamics, we treat the current schedule as a specification of the desired system behavior, and apply model checking to determine whether that specification is violated (not to compute the schedule itself, as in Kim et al. (2009)). When it is, we extract relevant information to explain the infeasibility, and reschedule.

We illustrate the applicability of our methods through a case study that involves a batch reactor and postprocessing units, multiple final products, maintenance requirements, and operator availability restrictions. We show that the integration of scheduling and automation leads to better quality closed-loop solutions, with higher throughput than in solutions obtained through iterative rescheduling.

2. Accounting for Automation Logic when Scheduling

We now present our approach to accounting for decisions made by the automation system when scheduling (and rescheduling) chemical plant operations. An outline of the approach is shown in Figure 1.

2.1. Checking the Feasibility of a Schedule Subject to the Automation Logic

The scenario that we consider is periodic rescheduling at a fixed interval using a relatively coarse model, along with event-triggered rescheduling based on a more

detailed model of the automation logic. A rescheduling event is triggered whenever the more detailed model detects that the current schedule is no longer feasible (for example, because it does not account for some constraint imposed on the plant's behavior by the automation system).

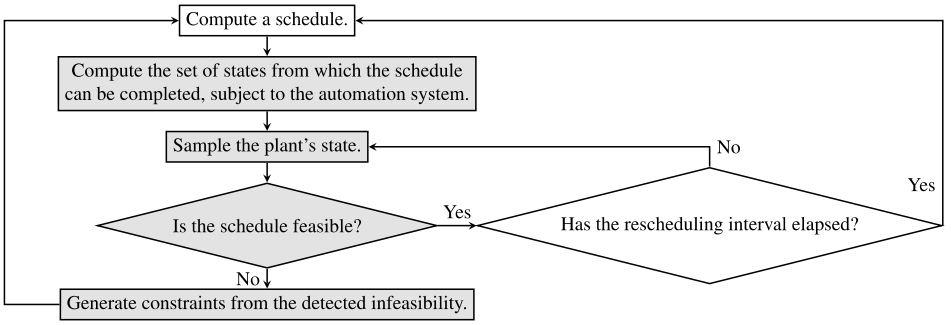

Figure 1. Rescheduling in response to a conflict with the automation logic (in addition to periodic rescheduling with a fixed interval). The new steps developed in this paper are highlighted in gray.

Because the automation system deals primarily with making discrete decisions like transitions between operating steps (whereas the control system generally makes the continuous decisions like flow rates, etc.), it is naturally modeled as a finite transition system. To this model, we add additional details related to scheduling, such as the minimum amount of time spent in each step historically and counters to keep track of batch number, with the result still being a finite transition system. Given the more detailed model, formal falsification can be applied as in Rawlings et al. (2017) to determine whether the schedule is feasible from the current state of the plant. In this case, the specification, written in computation tree logic, has the form

$$\mathrm{AG}(\textit{allotted time not exceeded} \wedge \mathrm{EF}(\textit{schedule completed}) \tag{1}$$

which requires that every task always (AG) stay within its allotted time, and that it remain possible to reach (EF) the state in which the schedule has been completed. For a finite transition system, any specification that has the form of Eq. (1) corresponds to a unique, maximal set of states in which the specification is satisfied (Rawlings and Ydstie, 2017). This leads to the strategy shown in Figure 1, where, every time a new schedule is computed, the set of states in which the schedule is feasible is computed, and then, if the plant ever enters a state not included in that set, the schedule is known to be infeasible.

2.2. Revising an Infeasible Schedule

When the current schedule is proven to be infeasible, it is necessary to guide the rescheduling problem so that it produces a schedule which avoids the infeasibility. Without additional constraints derived from the detailed model of the automation logic, the scheduling formulation might produce the same infeasible schedule. To produce these additional constraints, we modify the specification in Eq. (1) by relaxing the requirements until it becomes feasible. From the relaxation required to make the specification feasible, we can determine which part of the schedule has been violated, and apply the corresponding constraint to the rescheduling problem to avoid that infeasibility.

3. Case Study

To demonstrate our approach, we now apply it to a small example. The process is shown in Figure 2. The process consists of a reactor, which can produce two different products ("premium" or "regular"), a solvent recovery unit, and a check tank.

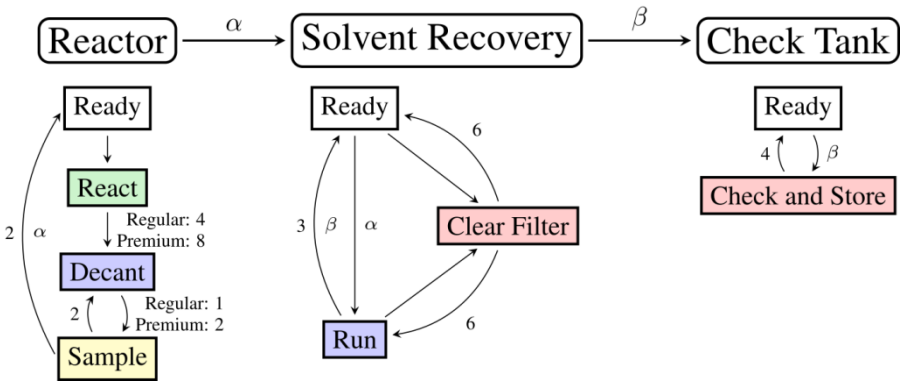

Figure 2. The example process. At the top, the flow sheet. Below each unit on the flow sheet, the sequence of steps that the automation logic implements (color coded to match Figure 3). Transitions between processing steps that require a certain amount of time are labeled with the time. Transitions that occur simultaneously (as enforced by the automation system) are labeled with the same Greek letter. The steps shown in red occupy the operator's attention, and cannot occur at the same time.

For both products, the reactor executes three steps: reaction, decanting, and sampling. Depending on the result of the sampling step, the decanting and sampling may need to be repeated. The amount of time required to complete some of the steps depends on which recipe (premium or regular) is being executed, as shown in Figure 2.

The solvent recovery unit processes each batch produced by the reactor. Over time, the filter in the solvent recovery unit becomes fouled, and requires routine cleaning, which is performed by the operator. Processing the regular product fouls the filter faster than processing the premium product.

The check tank receives the final product from the solvent recovery unit so that it can be checked for quality and sent to the appropriate storage area. The analysis is more involved than the sampling in the reactor, and requires the operator's attention.

We consider the problem of scheduling batches to maximize profit with a fixed deadline, i.e., a batch must be completed (including passing through solvent recovery and the check tank) before the deadline to count toward the profit. The parameters for the problem are shown in Table 1. Note that the scheduling formulation does not account for the individual steps in the reactor, and instead treats a batch as a single task, so that each product is assumed to require the amount of time to complete the reaction, decanting, and sampling steps. This also assumes that the decanting and sampling will not have to be repeated, which is the most likely scenario.

The automation logic in Figure 2 was implemented in the PLC programming language Structured Text and converted to a model using st2smv, as in Rawlings et al. (2017). This model was augmented to track the number of batches produced, the elapsed time, and to account for the operator only being able to perform one task at a time.

Table 1. Parameters for the scheduling problem.

Task	Time	Profit	Other details
React, decant, sample (premium)	12	100	
React, decant, sample (regular)	7	20	
Solvent recovery (premium)	3	-	Consumes 1 “unit” of filter
