Table 2. Dynamic optimization results for HEN synthesis

HEN Candidate	Control Strategy	HE Area (m ²)				Investment Cost (k\$)	Operating Cost (k\$/y)
		H1 – C1	H1 – C2	H2 – C1	H2 – C2		
1	PI	/	585.0	138.7	106.3	530.0	6911.4
	mp-MPC	/	604.4	125.6	99.9	528.4	7357.0
2	PI	210.5	518.6	/	167.1	553.8	8885.9
	mp-MPC	221.4	522.2	/	165.7	557.4	8593.9

3.6. Verifiable and Operable Intensified HEN Designs

Up to this point, several HEN candidates have been delivered as design alternatives with desired flexibility, increasing level of inherent safety, and different control strategies. In this context, this framework opens up the potential for comparison of various operable design alternatives. As the benefit, the final construction decision will enjoy a much larger freedom to investigate the trade-off between desired operability behavior and economic performance.

4. Conclusions

In this paper, we present an integrated framework, which embeds inherent safety, flexibility, and controllability analysis within a phenomenological Generalized Modular Representation Framework to derive intensified designs with guaranteed safety and operability performance. The framework is demonstrated by a heat exchanger network synthesis problem to achieve thermal intensification. Ongoing work focuses on further developing and demonstrating the framework to general process intensification problems, such as reactive separations and other hybrid processes (Tian et al., 2018).

Abstract

Isobutyl acrylate (*i*-BA) can be produced by direct esterification of acrylic acid with isobutanol using solid-based catalysts. The novelty of this work consists in developing a process for *i*-BA production, for which design, control and economic evaluation studies have not been reported in literature. The reaction is performed in a multitubular fixed-bed reactor, while the separation system employs conventional distillation equipment. The difficult separation between the acrylate and acid (close boiling and maximum temperature homogeneous azeotropy at 1.013 bar) is achieved by vacuum distillation, condition at which the relative volatility increases and the azeotrope disappears. The process is controllable, the control system showing robustness when production capacity and reactor temperature change. The economic evaluation shows attractive key economic indicators in terms of revenues, and capital and utility costs.

Keywords: acrylic acid, *i*-butanol, esterification, reaction-separation-recycle

1. Introduction

Isobutyl acrylate (*i*-BA) is used as precursor in the production of coatings, adhesives, and polyethylene plastics (Karakus et al., 2014). Being considered a higher-acrylate, *i*-BA is preferably produced batchwise by esterification of acrylic acid (AA) with isobutyl alcohol (*i*-BuOH) in presence of an organic solvent as entrainer and sulfuric acid as homogeneous catalyst (Ohara et al., 2003). To overcome corrosion, eliminate catalyst separation problems and prevent environmental issues with catalyst disposal, this esterification reaction was studied using solid-based catalysts (Karakus et al., 2014).

To the best of our knowledge, process development studies for *i*-BA production processes using solid catalysts have not been reported in literature. In this work, we present the design, control and economic evaluation of a reaction-separation-recycle process for production of 20.5 kt/y of *i*-BA at 99.6 %mass purity. Aspen Plus and Aspen Plus Dynamics are used as CAPE tools to support the analysis.

2. Thermodynamics and reaction kinetics

The pure component physical properties are available in the Aspen databanks. The UNIQUAC model is selected to model the phase equilibria, using two sets of binary interaction parameters. One set calculates the VLE, while the other calculates the LLE. The parameters for water/AA and water/*i*-BuOH are available in Aspen, for both VLE

and LLE applications; for water/*i*-BA, the parameters are estimated with UNIFAC-LL group contribution method, while for the remaining three pairs *i*-BuOH/*i*-BA, *i*-BuOH/AA and *i*-BA/AA, the UNIFAC method is used.

Equation (1) represents the liquid phase esterification reaction of AA and *i*-BuOH with formation of *i*-BA and water. The course of reaction under catalytic conditions (Amberlyst 131) can be described by the LHHW kinetic model given by equations (2)-(5), taken from recent literature (Karakus et al., 2014). The parameters for the adsorption constant equation are regressed using the data presented in the same reference. These are shown in Table 1.

$$r = \frac{k_f K_{acid} K_{alcohol} (a_{acid} a_{alcohol} - (1/K_{eq}) a_{ester} a_{water})}{(1 + K_{acid} a_{acid} + K_{alcohol} a_{alcohol} + K_{ester} a_{ester} + K_{water} a_{water})^2} \quad (2)$$

$$k_f / [\text{kmol}/(\text{kg}_{cat} \cdot \text{s})] = 2.526 \cdot 10^8 \exp\left(-\frac{76015.7}{8.314T}\right) \quad (3)$$

$$K_{eq} = \exp(1972.6/T - 1.5134) \quad (4)$$

$$\ln(K_i) = A_i + B_i/T, \quad i = \text{acid, alcohol, water, ester} \quad (5)$$

Table 1. Regression parameters *A* and *B* of the adsorption constant equation

Parameter	Acid	Alcohol	Water	Ester
<i>A</i>	-7.6835	-8.5882	-1.8902	-2.16
<i>B</i> / [K]	2753.6	2380.3	1215.6	738.67

Figure 1 shows the *x*-*y* diagrams for key binary systems; *i*-BuOH/*i*-BA diagram (left) suggests a good separation of the acrylate from a mixture with alcohol at atmospheric pressure, while the AA/*i*-BA diagram (right) shows that the acrylate separation from a mixture with acid is favoured at vacuum conditions. Figure 2 shows ternary diagrams of the four component system. For the three systems in which water is present, large immiscibility areas are observed. Water and acid are fully miscible; the ternary system of the organic components presents no immiscibility area. The binary systems water/*i*-BuOH and water/*i*-BH, and the ternary water/*i*-BuOH/*i*-BA present minimum boiling heterogeneous azeotropy.

Figure 1. Selected *x*-*y* diagrams: *i*-BuOH/*i*-BA (left) and AA/*i*-BA (right)

Figure 2. Ternary diagrams (mass based): liquid-liquid equilibrium at 30 °C and 1.013 bar and residue curve maps for the system water/*i*-BuOH/*i*-BA/AA; Boiling temperature of singular points (no./°C): (1/89.7), (2/90.3), (3/93.3), (4/107.7), (5/141.6), (6/100), (7/107.7), (8/137.0), (9/141.2)

3. Analysis of the reaction-separation-recycle system

The first analysis investigates the influence of conversion (X_{AA}) on the recycle flow rates of acid ($F_{AA,RCY}$) and alcohol ($F_{i-BuOH,RCY}$), and on the required mass of catalyst (m_{cat}) of the Reactor-Separation-Recycle process. The structure of the process, together with the results, is shown in Figure 3-left (top-right corner). The fresh ($F_{AA,0}$, $F_{i-BuOH,0}$) and recycled reactants are mixed and fed to a fixed-bed tubular reactor (PFR) operated adiabatically. The reactor is modeled using the kinetic model. The separation section (SEP) distributes the inlet components at given separation factors β_i . In this analysis perfect separation is assumed, the products being completely removed from the system ($\beta_{i-BA} = 1$, $\beta_{Water} = 1$) while the reactants completely recovered ($\beta_{i-BuOH} = 0$, $\beta_{AA} = 0$) and recycled to the reaction section as two separate streams. This structure with two recycles is possible since the boiling points are $T_{B,Water} < T_{B,i-BuOH} < T_{B,i-BA} < T_{B,AA}$. Low X_{AA} means large recycles (i.e. high separation costs), while high X_{AA} leads to a large amount of catalyst (i.e. high reaction cost). Thus, a preliminary X_{AA} interval of interest is 0.5-0.9.

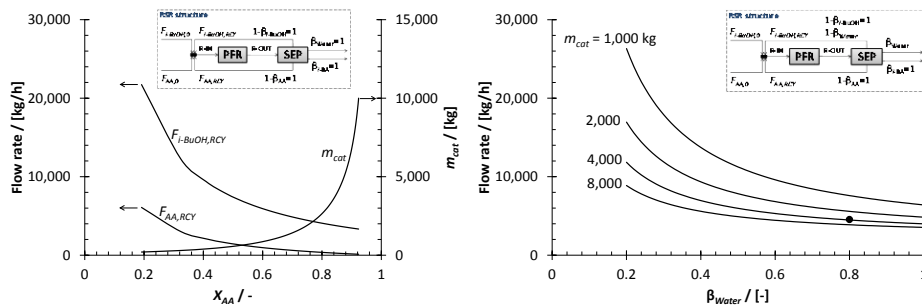

Figure 3. Effect of conversion (left) and water separation (right) on recycle and mass of catalyst

The second analysis investigates the influence of water separation (β_{water}) on the recycle flow rates, at various amounts of catalyst. The structure of the process (Figure 3-right (top-right corner)) is identical with the previous one, except that the water separation factor is not fixed (i.e. $\beta_{water} < 1$), water being allowed to return to the reactor. As more and more water is returned to the reaction, the (sum of the) recycle flow rates increase, and more catalyst is required to reduce this effect. For β_{water} in the interval 0.6-1, low catalyst amounts (1,000-2,000 kg) show high sensitivity to water recycle, while more than 4,000 kg do not give a significant reduction in the recycle flow rate.

4. Process design

Based on the previous analyses, a catalyst amount of 4,000 kg is selected. This operating point is shown in Figure 3-left (black dot). The structure of the separation system is developed starting with the composition of the reactor outlet, and making use of thermodynamic insights. The heterogeneous azeotropes containing large amounts of water can be obtained as vapour, condensed and phase split. *i*-BuOH/*i*-BA diagram suggests that the acrylate can be separated from a mixture with alcohol at atmospheric pressure, while the AA/*i*-BA diagram suggests the separation of acrylate from a mixture with acid at vacuum conditions due to increase in relative volatility at lower pressures.

The process flow diagram, together with a mass balance, is shown in Figure 4. The two-recycle structure previously proposed is preserved. Water is removed first; the heterogeneous azeotropes containing large amounts of water are obtained as vapour distillate (C-1, atmospheric), condensed (COND-1), and phase separated (V-3); the aqueous phase containing alcohol is flashed (V-4) to recover the reactant and to eliminate water from the system (99.1 %wt). The bottom stream of C-1 is distilled (C-2, atmospheric) obtaining the alcohol as distillate, which is recycled to the reaction section. The bottom stream of C-2 is further distilled (C-3, vacuum), obtaining the acrylate product as distillate, while the acid is recovered as bottoms and recycled.

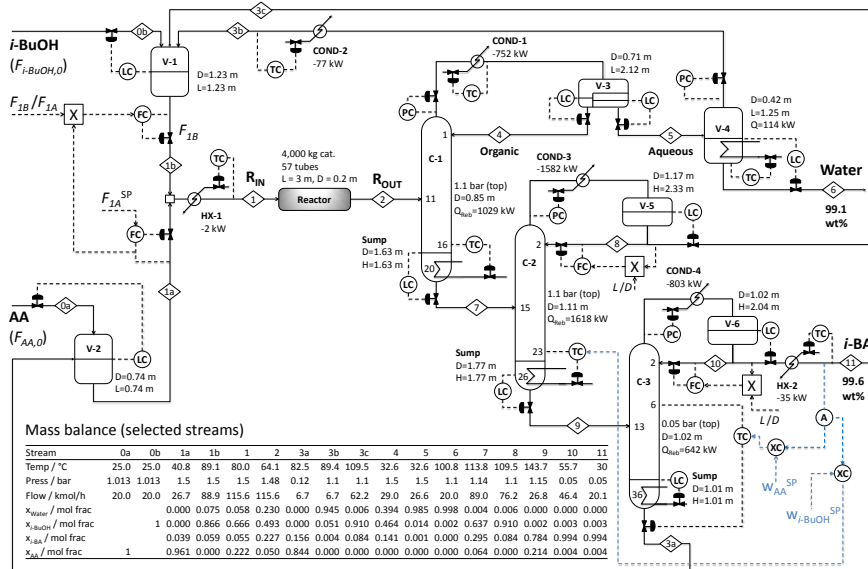

Figure 4. Process flow diagram, mass balance, main equipment sizes and plantwide control

5. Plantwide control

The plantwide control structure, shown in Figure 4, is typical to systems involving two reactants which are distinctly recycled (Bildea et al., 2004). It fixes the reactor-inlet flow rate of the limiting reactant (AA) and the ratio of reactants ($i\text{-BuOH}/\text{AA}$) at reactor inlet. The fresh reactants are fed on level control. In this way, the control structure ensures that the amounts of reactants brought in the process match the amounts of reactants consumed in the reactor. The distillation columns C-1 and C-2 are controlled using standard pressure, level and temperature control loops. The product column C-3 operates at high boilup ratio. Therefore, the reboiler duty is used to control the sump level, while the bottom flow rate controls one temperature in the column (LB configuration). PI controllers tuned by the direct synthesis method were used.

Figure 5 presents dynamic simulation results. The top diagrams show the flow rates of fresh reactants and products, and the products purity, when the reactor-inlet flow of the limiting reactant ($F_{I,A}$) is changed by $\pm 25\%$. The production rate changes by roughly $+10\%$ and -18% , respectively. The dynamics is rather slow, a new steady state being reached in several hours. The purity of the water product is practically constant. However, the purity of the $i\text{-BA}$ product drops significantly when control of the column C-3 uses only temperature control loop. Therefore, two concentration control loops are introduced (dashed lines in Figure 4), using the set-points of the temperature controllers of columns C-2 and C-3. In this way, the impurification of the product (continuous line in Figure 5) with alcohol or acid, respectively, is prevented (dashed line in Figure 5).

The bottom diagrams show the response of the plant for $\pm 10^\circ\text{C}$ changes of reactor-inlet temperature. The production rate changes by roughly $+14\%$ and -18% , respectively. The dynamics is comparable with the previous case. Again, concentration control is necessary in order to ensure product purity.

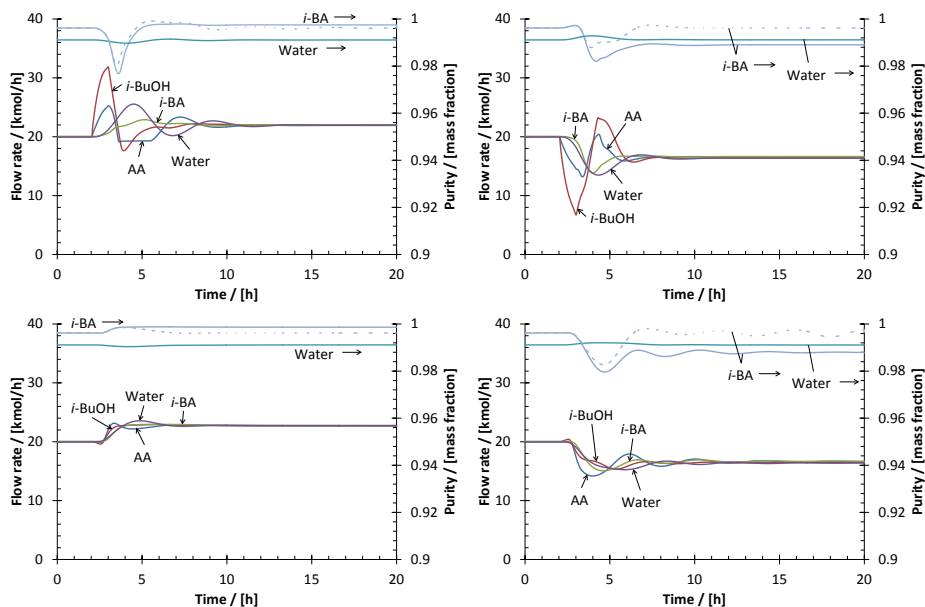

Figure 5. Dynamic simulation results (flow rates and products purity) at various process changes: $\pm 25\% F_{AA,I}$ (left/right top diagrams) and $\pm 10^\circ\text{C}$ reactor inlet (left/right bottom diagrams)

6. Economic evaluation

The economics of the process is evaluated using the annual economic potential (i.e. revenues), $EP = C_{\text{prod}} - (C_{\text{react}} + C_{\text{OpEx}} + C_{\text{CapEx}}/3)$. The cost of product and raw materials are taken from www.icis.com, a large source that shares chemical prices. The total investment costs (C_{CapEx}) include the reactor, heat exchangers, distillation columns and flashers, mixers and decanters. A payback period of 3 years is used, with 8000 hours/year operating time. For calculating the operating costs (C_{OpEx}), the heating, cooling and waste water treatment costs considered are standard: LP steam (6 bar, 160 °C, \$7.78/GJ), cooling water (25 °C, \$0.72/GJ), and bio-treatment of waste water (500 \$/t of organics and 27 \$/t of waste water).

The product sales bring 38,427,000 \$/y, while the overall production costs are 34,424,000 \$/y, thus annual revenues of 4,000,000 \$. The largest share of the production costs is attributed to the cost of reactants with 32,014,000 \$/y, followed by the cost of amortization with 1,531,000 \$/y, and the cost of utilities with 879,000 \$/y. A breakdown of the amortization cost shows that 38.3 % is taken by columns, 42.4 % by heat exchangers, 16.1 % by the reactor, and 3.2 % by other vessels. For utilities, 85.8 % is paid for steam, 10.4 % for waste water treatment, and 3.8 % for cooling water.

7. Conclusions

i-BA production at the industrial scale using Amberlyst 131 as solid catalyst is feasible. 20.5 kt/y are achieved in a RSR process using an adiabatic multitubular reactor and conventional distillation equipment. The required 4000 kg of catalyst is arranged in 55 tubes, each of 0.2 m diameter and 3 m length. The separation equipment has reasonable sizes and energy requirements (3400 kW heating, 2470 kW cooling). The difficult separation between *i*-BA and AA is achieved by vacuum distillation, condition at which the relative volatility increases and the binary azeotrope disappears. The process shows attractive economic indicators: annual revenues around 4,000,000 \$, for 34,424,000 \$/y production costs (raw materials, equipment amortization and utilities). The process is controllable, the plantwide control structures achieving a smooth transition to the new operating points for large throughput and reactor inlet temperature changes. To achieve tight control of the acrylate purity, two concentration control loops are required.

Abstract

This work proposes an optimization model for the design of an industrial cluster based on sugarcane bagasse in the Indian context. Three different products, namely, ethanol, electricity, and pellets, along with the possibility of selling raw bagasse and burning it in boiler are considered. An economic optimization model to maximize the net present value of the cluster is formulated. Simultaneously, a multi-objective optimization model to minimize the environmental impacts is formulated. The model was applied to a case of a sugar mill processing 181 Mg/h sugarcane. Economic optimization recommended electricity production as the optimal option at the current product prices. This was also desirable from the GHG emission reduction standpoint. However, electricity production led to highest water footprint. Ethanol price has to increase by 100% over the target price for economic feasibility. Pelletization was preferred only from a water footprint perspective.

Keywords: Bagasse, Industrial Ecology, Optimization, India, Ethanol

1. Introduction

Sugarcane bagasse is a highly promising source of biomass in the Indian context for the establishment of a bio-based economy. Bagasse can be used to produce a number of value added products such as pellets, electricity, ethanol, paper board, and specialty chemicals such as vanillin. Each of these products varies in terms of costs, technology readiness level, per unit revenue, and market capacity. Moreover, the environmental impacts of these alternatives also vary considerably. Utilization of sugarcane bagasse, therefore, poses a sustainability challenge with food, energy and water nexus. Region specific factors are critical and must be considered in the analysis. Such studies have been reported in literature for some sugar producing countries (Furlan et al, 2012, Ensinas et al, 2013). However, such an analysis has not been conducted in the Indian context. This work addresses this knowledge gap by proposing an industrial ecology approach and optimizing the design of an industrial cluster based on sugarcane bagasse. An existing sugar refinery providing a fixed quantity of bagasse is considered. Three different products of bagasse, namely, pellets, electricity, and ethanol, are considered. An economic optimization model is formulated to understand the profitable products and the sensitivity of those results to product market prices. Simultaneously, the global warming potential (GWP) and water footprint for the same products are calculated to understand the environmental trade-offs.

The article is arranged as follows. The optimization model formulation is given in Section 2. Section 3 discusses the key results from the simulation studies, and the important conclusions are summarized in Section 4.

2. Optimization model formulation

An existing sugar mill with a boiler to provide process heat in the form of steam is assumed. The procurement of sugarcane to the facility and the operations part of the conventional sugar mill are not considered since it is assumed that those are already set-up and operational. Similarly, transportation of products produced from bagasse (or bagasse as a product) is not the part of the system boundary. For a fixed capacity of the sugar mill, the bagasse availability is also known.

Bagasse generated can potentially be split into five streams, three of which include further processing to produce value added products, namely, ethanol, pellets, and electricity (Fig. 1). Of the remaining two streams, one stream goes to the boiler to meet the energy demand of the mill as well as various production processes within the industrial cluster. This ensures that the industrial cluster is energy self-sufficient. The second stream represents bagasse that is directly sold in the market without any processing. The energy production operations in the clusters (boiler and electricity) are further supported by trash collected from sugarcane farms as feedstock. It is assumed that only the trash on farms supplying sugarcane to the mill is available, which sets an upper bound on the total trash that can be utilized.

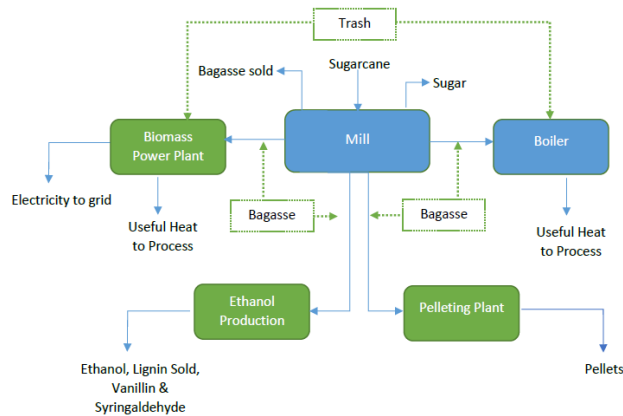

Figure 1: Alternatives for the utilization of bagasse and trash considered in the cluster. Blue boxes indicate existing facilities in the sugar mill while green boxes indicate new facilities

The ethanol production process uses the organosolvent pretreatment, which produces relatively pure lignin that can be used as feed to the boiler. The cellulose and hemicellulose separated after pretreatment are used for ethanol production. Pelletization involves three major steps: drying (up to 10% on wet basis), grinding (size reduction) and densification (Mani *et al.*, 2006). Individual pellet density ranges from 1000 to 1200 kg/m³ whereas the bulk density of pellets is 600 to 700 kg/m³. Pellets coming out of pellet mill (at about 70°C to 90°C) are cooled, packaged and sold. Biomass Integrated Gasification Combined Cycle (BIG-CC) configuration is considered for electricity production using bagasse and trash as the feedstock. Combustion gases drive the gas turbine to generate electricity through generator. The exhaust gases from gas turbine are used to generate steam in Heat Recovery Steam Generator. The steam drives

the steam turbine to generate more electricity and useful heat, which can be delivered to other processes of the facility (Ensinas *et al.*, 2007).

Two different optimization models have been formulated, capturing the economic and environmental impact associated with the proposed industrial cluster. These models are explained in the following sections.

2.1. Economic optimization model formulation

The model constraints include the mass and energy balances relevant to each unit process/operation described in the previous section. These constraints are formulated by considering the performance data from literature. Only selected constraints are reported here for brevity. A key mass balance constraint is the distribution of bagasse to five possible routes as shown in Fig. 1, which is modeled as follows:

$$total_{bagasse} = bgs_{eth} + bgs_{elec} + bgs_{pel} + bgs_{boiler} + bgs_{market} \quad (1)$$

where, $total_{bagasse}$ is the total available bagasse (Mg/h) obtained after sugarcane juice extraction, bgs_{eth} is the amount of bagasse (Mg/h) sent to ethanol production, bgs_{elec} is the amount of bagasse (Mg/h) sent to the electricity generation unit, bgs_{pel} is the amount of bagasse (Mg/h) sent to the pelleting plant, bgs_{boiler} is the amount of bagasse (Mg/h) sent to the boiler, and bgs_{market} is the amount of bagasse (Mg/h) that is directly sold in the market. Additional key constraint is the distribution of collected trash to electricity generation unit and the sugar mill boiler:

$$total_{trash} = trash_{elec} + trash_{boiler} \quad (2)$$

where, $total_{trash}$ is the total trash collected and transported (Mg/h) to the integrated facility, $trash_{elec}$ is the amount of trash (Mg/h) sent as a feed to electricity generation unit, and $trash_{boiler}$ is the amount of trash (Mg/h) sent to the boiler. Another important energy constraint is the overall heat demand of the facility:

$$C_{p,bagasse} * bgs_{boiler} + C_{p,lignin} * lignin_{boiler} + C_{p,trash} * trash_{boiler} + heat_{useful,elec} \geq heat_{mill} * Feed + bgs_{eth} * heat_{ethanol} \quad (3)$$

where, $C_{p,i}$ is the specific heat of combustion of material i (bagasse, trash, or lignin), $heat_{useful,elec}$ is the heat supplied by the power plant, $heat_{mill}$ is the heat demand of existing sugar mill, $heat_{ethanol}$ is the heat demand of ethanol generation facility, bgs_{boiler} is the amount of bagasse sent to boiler, $lignin_{boiler}$ is the amount of lignin sent to boiler, $trash_{boiler}$ is the amount of trash sent to boiler, and $Feed$ is the amount of sugarcane processed in the facility. The capital and operating costs for each of these processes are considered, and the corresponding cost functions constitute another important set of constraints. The key decision variables are the distribution of bagasse and trash to the various streams, as described the constraints in Eq. 1-3. The objective function is the maximization of Net Present Value (NPV) of the integrated facility where the NPV equation is linearized. This is a Mixed Integer Linear Programming (MILP) problem with 144 continuous variables, 4 binary variables

(selection of processing options), and 144 constraints. The model is formulated in GAMS[®] (General Algebraic Modelling System) solved using the CPLEX[®] solver.

2.2. Environmental optimization model formulation

The multi-objective optimization problem considering two environmental impact categories, namely, net greenhouse gas emissions (GHG) and water footprint, is formulated. Only the direct water footprint is considered. The model also considered the avoided GHG emission due to replacement effect, such as the replacement of petroleum based gasoline with ethanol from bagasse. Since the overall GHG emissions and water footprint numbers for all the processing options are directly used, a detailed mass balance for each step is not necessary. This model, therefore, is much simpler than the economic optimization model previously described. It is linear programming model with the decision variables as the amount of bagasse diverted to each of the five streams. ϵ constraint method is used to solve the problem and obtain the Pareto front. The model is not discussed here for brevity.

3. Results and discussion

The model was applied to a case of sugar refinery processing 181 Mg/h of sugarcane. 50% retention of trash on farm was assumed as base case. The selling prices for electricity (₹6/kWh) and pellets (₹10/kg) were as per the market values while the selling price of ethanol (₹39 /l) was as per the target price set by the government (₹ represents Indian Rupees). The pelletization rate was 4 Mg/h and a minimum size of 6.5 MW power plant was enforced. The prices of various chemicals and inputs were taken from literature. Table 1 shows the values of GHG emissions and water requirement for various products, including GHG offset due to replacement of an existing product.

Table 1: Life cycle input data for the different products produced from bagasse (adapted from different sources in literature)

Products	Bagasse requirement (kg)	GHG emissions; GHG offset (kg of CO ₂ /unit of Product)	Water requirement (lit /unit of Product)
Ethanol (lit)	6.046	0.562; 0.357	231
Electricity (kw)	2.394	0.0685; 0.81	224
Pellets (kg)	1.8	0.221; 0	65

3.1. Economic optimization

The model was first used to determine the Break Even Selling Price (BESP) for all the three commodities individually when integrated with the existing sugar mill. BESP of ethanol, pellets and electricity was ₹64/l, ₹9/kg, and ₹3/kWh, respectively. This indicated that ethanol production was not profitable. In contrast, electricity production was profitable; primarily due to the consideration that bagasse (feedstock) was free.

When the optimization model was solved considering all potential uses of bagasse, electricity generation was recommended as the optimal solution and no other processing route was chosen. With the feed rate of 181 Mg/h and 50% trash retention, all of the 22.17 Mg/h available bagasse and 12.62 Mg/h trash was sent to the power plant facility.

Boiler got no feed of bagasse and trash as the heat generated by the power plant was enough to meet the energy demands. The size of the plant was 37.84 MW and hence capable of providing around 281 million units (kWh) of electricity annually to the grid generating revenues of ₹169 crores at an initial investment of ₹712.6 crores with annual profit of ₹105.75 crores (1 crore is equal to 10 Million, and 1 ₹ is about 0.015 USD)

The sensitivity of the result to the market prices of various products was studied. Electricity market is well established and therefore the prices are relatively stable. Therefore the cost of electricity was fixed at the base value. The selling prices of ethanol and pellet were varied and the resulting optimal product portfolio was determined. The results (Fig. 2) indicated that ethanol production became profitable only if the selling price was more than ₹76/l. Similarly, pelletization became profitable if the selling price was more than ₹14/kg. Note that since there was an upper cap on the pellet market, electricity was still produced for a pellet price higher than ₹14/kg.

Trash retention is often recommended as a sustainable farming practice since it reduces the requirement of chemical fertilization and increases yield due to natural soil enrichment. Therefore, a scenario with 100% trash retention on farm was studied. This reduced the availability of trash. The results (Table 2) indicated that the optimal strategy in such a case was to use bagasse in the boiler to meet the energy demands of the mill and sell the remaining bagasse directly to the market. Production of any of the processed products was economically infeasible. This indicated the importance of trash collection and utilization for this system. Cases for various trash retention values between 0% and 100% were simulated and the results are not reported here.

Fig. 3 shows the results of the environmental impact optimization model. There was a strong trade-off between water footprint and net GHG emission. For minimum water footprint, pelletization was the only product produced. However, greater importance to GHG emission resulted in the production of ethanol and then electricity. This was primarily due to the avoided GHG emissions of conventional products (gasoline and coal based electricity). For minimum GHG emission, only electricity production was recommended

Table 2: Impact of trash retention on optimal industrial cluster design

Variable	Base Case	100% trash retention
Feed	181 Mg/h	181 Mg/h
Sugarcane yield	72.4 Mg/ha	82.9 Mg/ha
Bagasse processing route	Power Plant (37.84 MW)	Market & Boiler
Net Present Value (NPV)	₹366.06 crores	₹104.24 crores
Net annual profit	₹105.75 crores	₹10.22 crores

4. Conclusions

This work developed an optimization model to design an industrial cluster based on sugarcane bagasse in India. The economic optimization results indicated that electricity production was the most profitable option for a sugar mill processing 181 Mg/h sugarcane. Trash availability from sugarcane farms was important to achieve economic feasibility of the electricity production option. Ethanol and pellet market prices needed to increase significantly to achieve economic feasibility of those products from bagasse. The net GHG emission and water footprint had a trade-off and the desirable products

changed with varying weights given to each of these two objectives. The ongoing work is focusing on integrating the economic and environmental impact optimization problems. Although results presented here provide some insights into the trade-offs, the integrated problem will provide quantitative results.

Figure 2: Impact of product prices on optimal product portfolio of the industrial cluster. Points on orange line indicate electricity+pellets region and points on blue line indicate ethanol region

Figure 3: Net GHG emission and water footprint trade-off and the product portfolio. For the intermediate points (black), electricity and ethanol are produced in varying proportions

Abstract

Empty fruit bunch (EFB) is a kind of biomass formed during the production process of palm oil. EFB that used to be disposed of as waste has recently been used as fuel as quantities have increased. EFB commonly has a high moisture content, which lowers the combustion temperature and reduces energy efficiency. Therefore, a drying process should be incorporated when designing an EFB power plant. In this study, we simulated a process that includes the drying process for a 10-MW power plant and compared the optimized energy efficiency with an existing process. We found the optimum moisture content of EFB considering the temperature, time, flow rate, and critical moisture content of the drying process. At the optimum point, the moisture content of EFB was 7.79 %, and the efficiency was increased by 14.29 %.

Keywords: Biomass, Empty Fruit Bunch (EFB), EFB Power Plant, Moisture Content

1. Introduction

Empty fruit bunch (EFB) comprises 20 % of the byproducts produced during palm oil production. In Indonesia, the world's largest producer of palm oil, an enormous amount of EFB is produced every year, and the process of disposing of the EFB has led to significant costs and environmental pollution (Abdullah and Sulaiman, 2013). As the demand for electricity has increased due to rapid economic growth, Indonesia is planning to build biomass power plants for a smooth electricity supply (Differgroup, 2012). If EFB is used as fuel for a power plant, EFB would solve both environmental pollution and electric power supply problems. A drying process is essential to use EFB as fuel for a power plant.

Table 1. Properties of EFB.

**Figure 2. HHV vs Moisture content.**

was set as 400 °C, which is the optimum drying temperature for typical rotary dryers (Li et al., 2012). The residence time of the EFB was set so as not to exceed the average residence time of a typical rotary dryer of 17.5 min (Girovich, 1996).

2.2. Drying kinetics

The factors required for drying kinetics modeling in Aspen Plus are heat transfer coefficient (α_G) and mass transfer coefficients (β_G), critical moisture content (X_c) of the material, equilibrium moisture content, and the drying curve of a falling-rate drying period. Heat transfer and mass transfer coefficients were calculated from Eqs. (1) and (2) (Gunter Brenn and Helfried Steiner, 2014), (Sattler and Feindt, 2008). To calculate Le , Sc , and Re , vapor diffusion coefficient (δ_G), drying gas velocity (u_G), density (ρ_g), dynamic viscosity (η_g), specific heat ($C_{p,g}$), and thermal conductivity (λ_G) were obtained by using the stream analysis of Aspen Plus. The diameter, L , required to calculate the mass transfer coefficient and Reynolds number was replaced with the Sauter mean diameter (d_{32}) and median particle diameter (d_p) of EFB. As shown in Eqs. (1) ~ (6), the higher the velocity and temperature of the drying gas, the smaller the particle size, the higher the heat and mass transfer coefficients, and the better the drying process. The velocity of the drying gas for calculation of heat and mass transfer (typical range: 0.5 m/s to 2.5 m/s) was selected as the average value of 1.5 m/s (Saravacos and Kostaropoulos, 2002).

$$\beta_G = \frac{Sh * \delta_G}{d_{32}} \quad (1)$$

$$\alpha_G = \beta_G * \rho_G * C_{p,G} * Le^{1-n} \quad (2)$$

$$Sh = \sqrt{Sh_{laminar}^2 + Sh_{turbulent}^2} \quad (3)$$

$$Sh_{laminar} = 0.664 * \sqrt{Re} * \sqrt[3]{Sc} \quad (4)$$

$$Sh_{turbulent} = \frac{0.037 * Re^{0.8} * Sc}{1 + 2.443 * Re^{-0.1} * (Sc^{\frac{2}{3}} - 1)} \quad (5)$$

$$Re = \frac{u_G * d_p * \rho_G}{\eta_G}, Sc = \frac{\eta_G}{\delta_G * \rho_G}, Le = \frac{\lambda_G}{C_{p,G} * \rho_G * \delta_G} \quad (6)$$

The critical moisture content varies depending on the material, and it is further related to velocity and temperature. Because many factors affect the critical moisture content, we used the average value of the critical moisture content shown in Table 2 (Hasibuan and Wan Daud, 2007). The temperature and relative humidity of the drying gas significantly affect the equilibrium moisture content, which is different depending on the material. At a high drying temperature and low relative humidity, the equilibrium moisture content becomes close to zero. The drying rate starts to decrease after passing the critical moisture content, and the moisture is no longer evaporated when reaching the equilibrium moisture content. The drying curve of a falling-rate drying period given in Eq. (7) was used (Hasibuan and Wan Daud, 2007). $\frac{X}{X_c}$ refers to normalized moisture content, and $\frac{R}{R_c}$ refers to normalized drying rate.

$$\frac{R}{R_c} = [1 - (1 - \frac{X}{X_c})^{1.506}] \quad (7)$$

2.3. Boiler and steam cycle model

In the steam cycle shown in Figure 1, the pressure of the feed water increases to 2 atm by Pump 1. The feed water entering the deaerator is further preheated to 127 °C by the steam at 159 °C and 6 atm coming from the turbine extraction valve. The pressure of the preheated feed water rises to 67 atm by Pump 2. In the boiler, due to the heat obtained by burning the EFB, the water becomes steam at 433 °C and 60 atm. After heating the water, the temperature of flue gas is assumed to be 200 °C. High pressure steam generates 10-MW of electricity through the turbine, and the steam is discharged as low-pressure steam at 47 °C and 0.105 atm. The low-pressure steam entering the condenser is fully condensed and circulated by Pump 3.

2.4. Thermal efficiency of the boiler

The thermal efficiency of the boiler depends on the moisture content of EFB. Aspen Plus reflected the thermal efficiency of the boiler according to the moisture content of wood (Dzurenda and Banski, 2017).

$$y = -0.0025 x^2 + 0.0145 x + 84.612, R^2 = 0.9941 \quad (8)$$

2.5. Net power generation

The remainder after subtracting the work energy to generate from the power generation is called the net power generation.

$$W_{net} = W_{turbine} - (W_{boiler} + W_{pump 1} + W_{pump 2} + W_{pump 3}) \quad (9)$$

3. Results

3.1. Case study

A case study was conducted to examine the power generation efficiency by using the dried EFB. When the EFB was not dried, the base case was set to produce 10-MW of electric power by using EFB with a 60% moisture content. The amount of EFB required to produce the same power and the amount of fuel consumed in the drying process were calculated according to the flow rate of drying gas at 400 °C. The following constraints were applied to all cases to discover the optimum point while varying the flow rate. 1) The relative humidity of the drying gas exiting the dryer cannot exceed 95 %, as the

Table 2. Critical moisture content.

NO.	Xc	T(°C)	V(m/s)
T1	0.84	200	0.89
T2	0.62	220	0.89
T3	0.68	240	0.89
T4	0.7	260	0.89
T5	0.63	280	0.89
V1	0.7	200	0.79

Table 3. Simulation conditions.

Parameter	Value
Drying gas temperature	400 °C
Drying gas velocity	1.5 m/s
Mass transfer coefficient	0.1405 m/s
Heat transfer coefficient	0.068 kW/sqm-K
Outlet drying gas RH	≤ 95 %
Residence time	≤ 17.5 min
Particle size	5 mm
Excess air ratio	1.6

moisture can condense in the dryer. 2) The particle size of EFB is 5 mm. 3) The excess air ratio close to complete combustion was 1.6. 4) EFB with a moisture content of 60% was used as fuel in the burner for better comparison of the results with those obtained when kerosene, diesel, or natural gas are used. The simulation conditions are summarized in Table 3.

3.2. Case study result

The calculation results from the case study are shown in Table 4. Figure 3 shows the graph of the moisture content and total fuel consumption according to the flow rate. In the base case, there was no fuel used for the burner because EFB was not dried and 22,483 kg/h of wet EFB was required to generate 10-MW. Even without the energy for the drying process, the pump work required to operate the steam cycle basically was 101 kW. In Case 1, when the residence time of EFB is longer, the relative humidity of the drying gas exceeds 95 %. Thus, the residence time is extremely short compared with other cases. In Cases 2, 3, and 4, although the maximum residence time of the solids was reached, the relative humidity was much less than 95 % due to the high flow rate of the drying gas. Case 2 showed the maximum efficiency. The efficiency increased by 14.29 % compared with the base case, the moisture content was 7.79 %, and the drying gas flow rate was 58,477 kg/h. The efficiency gradually decreased from Case 3, which passed the optimum point, and the efficiency for Case 4 was -0.71 %, which was lower than that without drying.

Table 4. Result of case studies.

Parameter	Unit	Base	Case 1	Case 2	Case 3	Case 4

Relative efficiency	%	-	9.09	14.29	11.96	-0.71

Figure 3. Moisture content and Total fuel consumption vs Drying gas.

4. Conclusion

This study modeled and optimized a 10-MW power plant by using Aspen Plus. The drying process was modeled with a typical rotary dryer. As the heating value of EFB increases with drying, the amount of EFB required to produce 10-MW is reduced. However, the fuel consumption of burner also increases. We conducted the case study considering the EFB heating value and fuel consumption of burner to find optimum point. The results of the case study showed that less total fuel was required when some of the wet EFB was used for drying than when using the whole wet EFB as the fuel for a power plant. In Case 2, which is the optimum point, when EFB was dried to 7.79 %, the efficiency increased by 14.29 % compared with the base case without drying. When the drying was continued beyond the optimum point, the efficiency gradually decreased, and the efficiency of the drying gas was -0.71 % at the rate of 112,693 kg/h, and the drying became infeasible. Utilizing this process modeling, the optimum point can be easily and quickly obtained even under various conditions such as changing particle size or temperature of drying gas.

Abstract

In this paper, we aim to provide a feasible flowsheet of the process of dimethyl carbonate (DMC) production from urea and methanol. We use Aspen Plus for the simulation and we perform an economic and energetic study of the process. We also remark which process variables and units affect the design the most. The results prove the viability of this synthesis route, which for a production of 74 kt/y of DMC, grants a 21.1 MMS/y of profit, as long as a proper catalyst is employed in the synthesis.

Keywords: DMC, Aspen Plus, Techno-economic Analysis, Simulation.

1. Introduction

Dimethyl carbonate stands out as one of the key chemicals in the Green Chemistry approach thanks to its versatile uses as a safe, non-toxic, green reagent. Among its uses, its capability of replacing dimethyl sulfates and methyl halides in methylation reactions, as well as replacing phosgene in the production of polycarbonates, must be highlighted. It is also being considered as a component of reformulated fuels due to its high oxygen content, having as much oxygen as three times the amount in methyl-tert-butyl ether (MTBE), and good blending properties (Pacheco & Marshall, 1997). Its molecule is shown in Figure 1.

Figure 1. Dimethyl carbonate molecule.

Despite being able to be synthesized by numerous routes, DMC is only industrially produced by three different routes: liquid phase oxidative carbonylation of methanol, vapor phase oxidative carbonylation of methanol and transesterification of ethylene carbonate with methanol.

Traditionally, DMC was prepared by phosgenation of methanol, but that route is being gradually abandoned due to the environmental, safety and economic drawbacks that it entails. This, and a review of all the processes, can be found in Keller et al. (2010).

Focusing on the objective of the paper, the urea route allows the production of DMC using only urea and methanol as raw materials, which are comparatively abundant and

have a low price (Lin et al., 2004). It also avoids the use of phosgene, carbon monoxide, nitric oxide and ethylene oxide, which are present in the other routes. In addition, it also provides the perfect opportunity for the integration of both the fuel industry and the fertilizer industry, since urea production is comparable to the environmental gasoline oxygenates demand (Pacheco & Marshall, 1997).

As such, this route seems very attractive for the industry. It has however some drawbacks in which this paper dwells on.

2. Reaction mechanism

There are several studies of the synthesis of DMC from urea and methanol in literature. From these works, the following mechanism can be established:

In the first reaction, urea and methanol react to form methyl carbamate (MC), a reaction intermediate in this process, and ammonia. During the second reaction, MC reacts further with methanol to produce dimethyl carbonate (DMC) and more ammonia. This is the main reaction process, common in all the studies.

The third reaction is considered as the main side reaction. DMC and MC react between them to produce the by-product, N-methyl,methyl-carbonate (NMMC), methanol and carbon dioxide. Its extent is around 2 – 4 % of MC conversion.

The first reaction is thermodynamically favorable, while the second is not (Wang et al., 2007). In addition, the first reaction equilibrium is favored towards the products, thus favorable to the production of MC, while the second reaction is heavily favored towards the reactants, hindering the production of DMC, as shown in Table 1.

In the work by Wang et al. (2007), it is also noted that the first reaction is also remarkably fast, with urea reaching a high conversion to MC in a consistent residence time. Due to the equilibrium of the second reaction, that cannot be said for this step. As such, it is necessary to perform this second step, if not both at the same time, in a reactive distillation column adding a catalyst and removing the ammonia while it is being produced.

Table 1. Equilibrium data.

T(K)	Reaction 1		Reaction 2	
	$\Delta_r G(kJ \cdot mol^{-1})$	K	$\Delta_r G(kJ \cdot mol^{-1})$	K
300	-13.26	203.88	15.41	2.08×10^{-3}
350	-13.95	120.88	15.85	4.30×10^{-3}
400	-14.82	86.07	16.41	7.20×10^{-3}
450	-15.91	70.27	17.08	1.04×10^{-2}
500	-17.21	62.74	17.84	1.37×10^{-2}
550	-18.60	58.40	18.73	1.66×10^{-2}
600	-20.23	57.65	19.72	1.82×10^{-2}

Kinetic data for a heterogeneous catalyst of $ZnO - Al_2O_3$ are presented in the work of Zhao et al. (2012). The first and main problem of this route arises here, which is the kinetics. A representation of the amount of DMC and NMMC produced per amount of MC introduced at different temperatures in a plug flow reactor without taking into account the reverse reaction is shown in Figure 2. It can be seen that even at very high temperatures (~ 220 °C), the residence time for a significant yield of DMC is more than 5 h. This residence time is unobtainable in a continuous reactive distillation column. The process here is simulated considering the equilibrium is reached, and as such acts as an upper bound for the possible real process, once the catalysts reach satisfactory reaction rates.

In Figure 2 it can be also appreciated that when working at high temperatures, the amount of NMMC produced starts to overshadow the DMC, and thus working at extreme temperatures and pressures is not a solution. Additional research on the catalyst is required to obtain a viable conversion under a realistic operating time.

Therefore, we perform a curve fitting in order to use the kinetic parameters shown in Table 1. The equation has the form shown in Eq.(1) where the temperature (T) is in Kelvin. The results of the curve fitting can be seen in Table 2.

$$\ln K_{eq} = A + B / T + C \ln(T) + DT \quad (1)$$

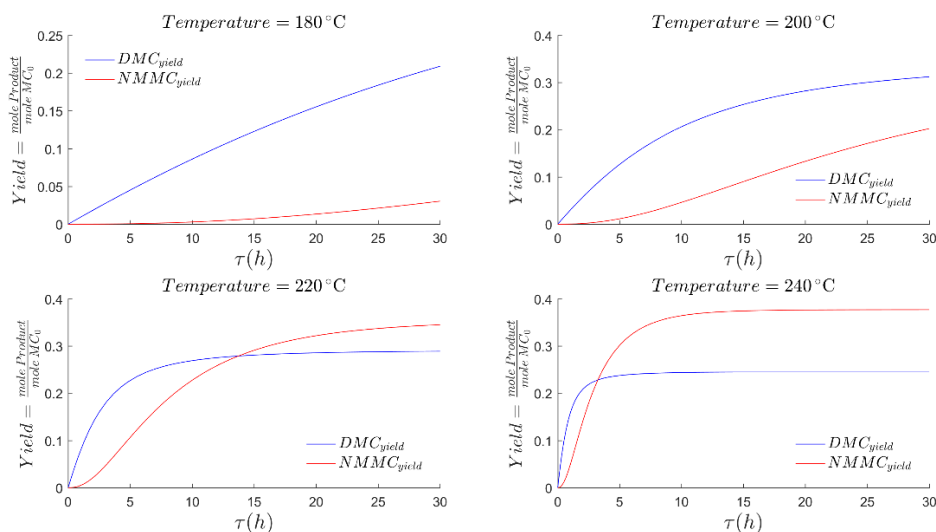

Figure 2. Kinetic of reactions 2 and 3 at different temperatures.

Table 2. Curve fitting for the equilibrium of reactions 1 and 2.

	A	B	C	D	R^2
Reaction 1	-14.48	2020	2.188	0.001952	0.9999
Reaction 2	-38.53	-521.3	6.543	-0.01077	0.9999

3. Simulation and results

The simulation is performed in a similar flowsheet to the one represented in the patent by Ryu and Gelbein (2002), with the following changes:

- In order to use the kinetic rate for the formation of NMMC, instead of the homogeneous catalyst Triglyme, we use a heterogeneous catalyst based on ZnO.
- While in the patent all the reactions are performed in a single reactive distillation column, in this simulation reaction 1 is carried out in a previous plug flow reactor, in order to remove the greatest possible amount of ammonia before entering the reactive distillation column where the second and third reaction occur.

The simulation, with a yearly production of 74 kt/y of DMC, is divided in the following three sections.

3.1. Section 1

In this first section (Figure 3), the stored urea and methanol are mixed, pumped and heated up to the conditions of the first reactor (R-101) which works at 155 °C and 9.3 bar. Here, the first reaction occurs, whose products are MC and ammonia. Ammonia is then removed in a flash separation unit (S-101) and the remaining MC, alongside the excess methanol, continues to Section 2.

Figure 3. First reaction step and separation of ammonia (Section 1)

3.2. Section 2

In the second section (Figure 4), the stream from the first section is mixed with a recycle stream from the end of the current section containing the heavy components, where MC is recycled. Then it is pumped and heated up to the entry conditions of the reactive distillation column (R-201). It is introduced in the fifteenth stage, while at the bottom of the column, in the reboiler, a stream of methanol make-up, mixed with a recycle from the third section, composed mostly by methanol, is introduced. The DMC is extracted from both the distillate and the bottoms of the column and thus it must be further separated. The distillate is introduced into another column (S-201), where the remains of ammonia are removed and DMC exits as the bottom product. The bottoms enter column S-202 where the heaviest components (mainly NMMC and MC) are recycled into the reactive distillation column. In addition, a purge avoids the NMMC build-up and helps with the convergence of the model in Aspen Plus. The DMC, alongside most of the methanol, continues to the third section.

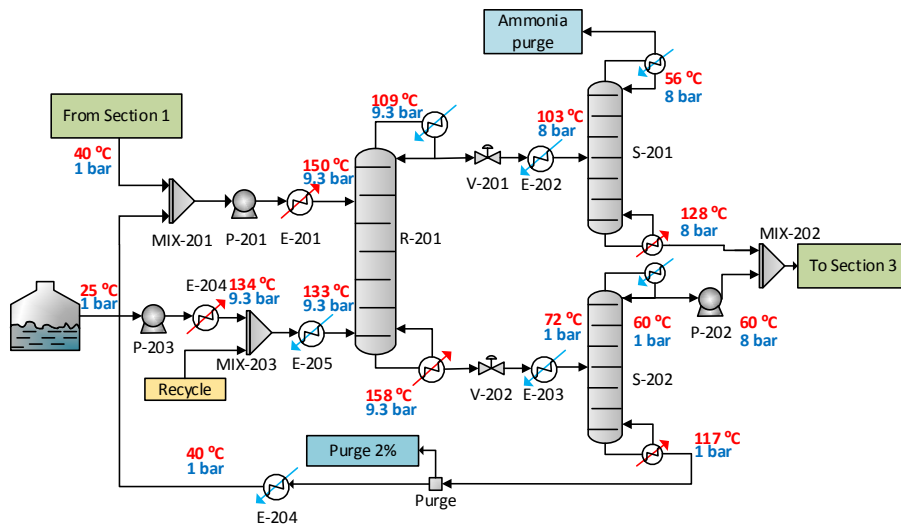

Figure 4. Reaction and initial separation of the product (Section 2)

3.3. Section 3

In the third section (Figure 5), the separation of the pair DMC / methanol is performed. This is a difficult step, since a binary azeotrope affects what otherwise would be an easy separation. Due to this, the stream from the second section is pressurized to 16 bar, where the azeotrope has a molar fraction of ~97 % of methanol, and heated up to its saturation temperature. The pair of columns S-301 and S-302 are utilized to separate this azeotrope. The distillate of these columns is composed of mostly methanol, with the molar fraction previously mentioned, while the bottom stream of S-302 has more than a 99 % of DMC molar fraction.

The distillate of this pair of columns is then mixed and sent back to section 2, where it is mixed with make-up methanol from storage and enters the reactive distillation column R-201. The DMC product is then prepared for storage and sale.

3.4. Results

The yearly results, considering 8000 h/y of operation, is shown in Table 3. Only the operation costs are taken into account for this study.

Table 3. Results of the simulation

MATERIALS	Price (\$/t)	Amount (t/y)	ENERGY	Price (\$/kWh)	Amount (kWh/y)
Urea	250	50,185	Cooling Water	0.0013	234,364,824

			High pressure steam	0.0637	3,372,372
			Electricity	0.0600	1,831,176
PROFIT (\$/y)					21,121,739

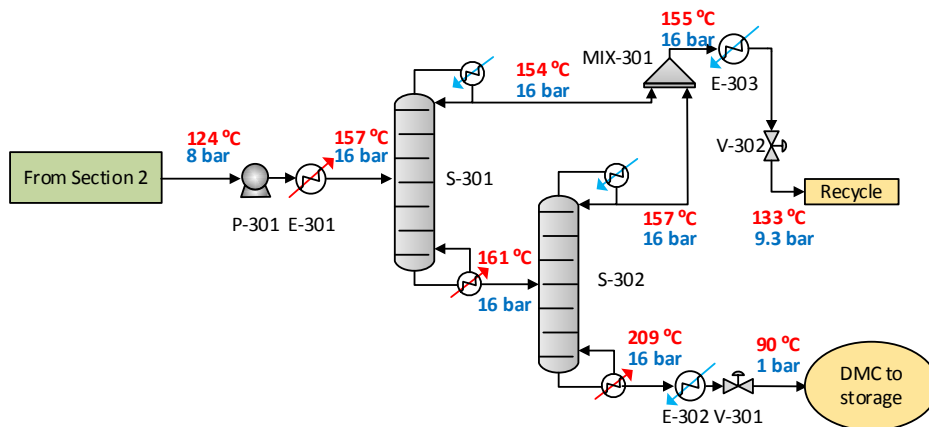

Figure 5. Separation of the azeotrope and the final product (Section 3)

4. Conclusions

The urea route for the synthesis of dimethyl carbonate (DMC) stands out as a promising alternative to the actual non-environmentally friendly processes. The results show that DMC could be synthesized with an annual production of 74 kt and profit of 21 M\$. Furthermore, the ammonia obtained as a byproduct could be integrated with a urea production plant to further increase the benefits, both economic and environmental.

However, overcoming the kinetic barrier with an adequate catalyst is the key to the rise of this technology. At this moment, with the studied catalysts, it is not possible to maintain a continuous production of DMC in a realistic time slot with this route. Hopefully, the progress in the development of the catalyst will reach a point where this route emerges as the most profitable and green method to synthesize DMC.

Abstract

Edible oil processing showed an increase interest in the last years as a result of new applications and improved product quality requirements. Recent developments in lipid pure compounds and mixtures property modelling allow the use of computer aided methods and tools for the edible oil industry. In this work, Shea oil solvent fractionation is designed and analysed using a systematic approach involving four steps: (1) process data collection, (2) process modelling, design and simulation, (3) process performance analysis (e.g.: energy, economic and environmental analysis), (4) process hot-spots identification and retrofit solutions. SPEED lipids database is used to provide pure compound and mixture property models, which includes the special lipids developed parameters for a wide range of UNIFAC models.

Keywords: lipids, process synthesis and design, solvent fractionation, Shea oil, UNIFAC model.

1. Introduction

Increasing consumer demands, lead to the expansion of many industries, one of them being the vegetable oils (lipids) industry, with both edible and non-edible applications, e.g.: food, pharma, bio-fuels, lubricants, paints, energy storage materials. For many years, the lipids related industries have been using empirical methods for developing their processes because of insufficient data and models to describe this type of compounds and their mixtures. However, improvements in lipids property modelling allowed the use of computer aided tools and methods for exploring, improving and developing lipids related processes.

The new systematic identification method for data analysis and phase equilibria applied for lipids systems (Perederic et al., 2018) provides a new set of parameters for group contribution type of models dedicated to lipids systems. The lipids parameters (Damaceno et al., 2018; Perederic et al., 2018) are available for following variants of the UNIFAC model: Original (Fredeslund et al., 1975), Linear (Hansen et al., 1992), Modified (Larsen et al., 1987) and Dortmund UNIFAC (Weidlich et al., 1987). The new sets of parameters improve phase equilibria description for lipids related systems, and

the predictive capacities of UNIFAC models allows a broader application, making feasible the synthesis, design and analysis of lipids related processes.

One such example is the fractionation of edible oils used in the food and pharmaceutical industries. Through dry or solvent fractionation (Kellens et al., 2007), added value products with specific characteristics (different melting curves and composition) can be obtained. The process is applied to cocoa butter equivalents (CBEs) production, which are used as replacements for cocoa butter within confectionary products. The need of CBEs has emerged as a result of increasing chocolate consumption and cocoa prices. Shea stearin and Palm mid fraction are used together as CBEs, and both can be obtained through fractionation of Shea and Palm oil, (V. K. S. Shukla., 2005). Shea oil is one of the most important natural sources for symmetrical stearic rich triacylglycerols (e.g.: Stearic-Oleic-Stearic triacylglycerol) which are exhibiting very closed properties (e.g.: melting point), making solvent fractionation the only feasible solution for separation. The solvent is used to lower the viscosity of the melted raw material, in order to have a faster crystallization process and a better selectivity (fractions with higher purity and sharper melting curves). The most commonly used solvents are hexane and acetone, and their selection depends on the composition of the Shea oil.

In this work, Shea oil fractionation using acetone is presented and analysed using a method consisting of four steps, as presented in following section. The work has been performed in collaboration with Alfa Laval, which has provided most of the process related data. For confidentiality reasons, a simplified PFD of the process is presented herein (Figure 1). The aim of the work was to analyse and improve the Shea oil fractionation process. Additionally, the performance of the SPEED Lipids Database, which includes lipids based parameters for Original UNIFAC model, can be validated within a process context.

2. Process and method description

The proposed process, acetone fractionation of Shea oil, consists of mixing the melted Shea oil with cooled solvent in the crystallizer. The crystals are separated by filtration and they are washed with fresh solvent. The solvent is recovered from the two products, Shea stearin and Shea olein, through a series of multiple effect evaporators followed by a steam stripping step for product finishing. Since both products are used in edible and/or cosmetics applications, the solvent has to be completely removed from the products. The solvent is recycled within the process directly, or after a purification step for water removal. The simplified process flow diagram (PFD) is presented in Figure 1.

The process of Shea oil solvent fractionation is modelled and analysed through a method consisting of four steps: (1) process data collection, (2) process modelling, design and simulation, (3) process performance analysis (e.g.: energy, economic and environmental analysis), (4) process hot-spots identification and retrofit solutions (Gani and Cameron, 2011). These steps are covering the design stage, stage two, within the three stage approach for synthesis and design (Bertran et al., 2017). The aim of this work is to improve the process performance, such as product quality, energy consumption, and environmental impact through a systematic approach.

2.1 Process data collection

Once the process is established by defining the problem to be solved, the required data is collected. The information for all process parameters is collected from the literature

and industrial data, and includes following type of information: feed composition, solvent-to-oil ratio, separation factors, and product specification. SPEED Lipids Database (Perederic et al., 2018) is used to provide all the necessary thermo-physical property data (e.g.: vapour pressures, melting points, phase equilibria behaviour) for all the compounds involved. The database provides also the lipids based group interaction parameters for the Original UNIFAC model (Perederic et al., 2018) for activity coefficient calculation.

2.2 Process modelling, design and simulation

The process model is developed in PRO/II by using the design data collected from Step 1. SPEED Lipids Database is linked to PRO/II, providing easy access to all the thermo-physical data necessary to perform the simulation. Simulation results are further used to perform equipment sizing (Biegler et al., 1999).

2.3 Process performance analysis

In this step, the process performance analysis is carried out. Energy requirements, economic analysis and life cycle assessment are used to determine economic, sustainability and environmental impact indicators. The computer-aided tools used to perform the evaluation are: ECON (Saengwirun, 2011) for economic analysis and LC Soft (Kalakul et al., 2013) for the life cycle (LC) assessment.

2.4 Process hot-spots identification and retrofit solutions

Using the results from the previous step, the process hot spots are identified and tackled for improvement through optimisation and process integration. After all the improvement solutions are implemented, the economic analysis and life cycle assessment are performed for the new case, and the results are compared with the ones from the base case (Step 2).

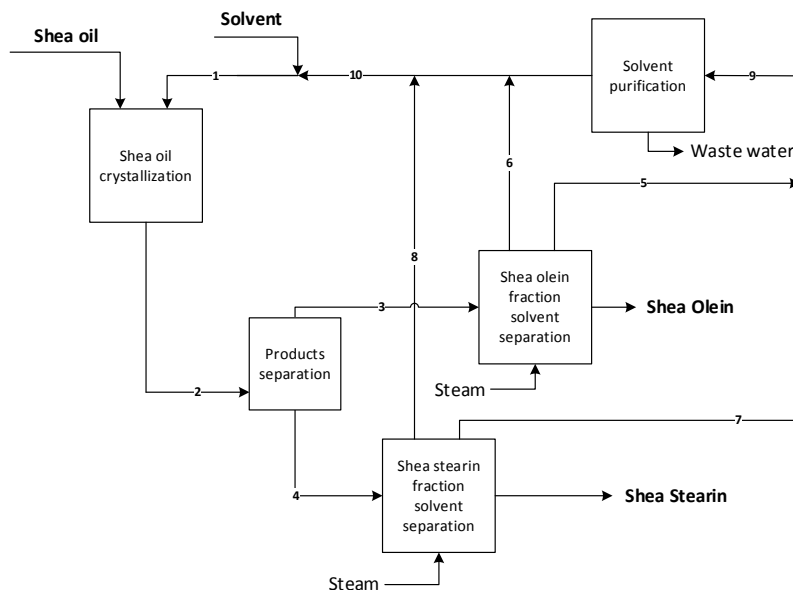

Figure 1. PFD of Shea oil solvent (acetone) fractionation.

3. Results

3.1. Process data collection

The aim is to design the process for a 2000 kg/h of Shea oil feed. The feed and products specifications (Shea olein and Shea stearin) are provided by Alfa Laval (see Table 1). The ratio between Shea oil and acetone is 1:4. High solvent purity is required, since water or other impurities can affect the crystallization process. It is assumed that the oil is dried before entering the process.

3.2. Process modelling, design and simulation

Short cut models are used for modelling of the crystallizer and the filter, while detailed models are employed for the solvent separation which consists of several evaporators modelled as flash units, stripping columns, a distillation column for acetone-water separation and several heat exchangers. The details for most important process streams for the base case as named in Figure 1 are given in Table 1. The products yield is 53% for Shea olein, and 47% for Shea stearin. Process utility requirements are 1.65 MW for cold utilities, and 1.68 MW for hot utilities. The results from the equipment sizing are used further to perform the economic analysis.

Table 1. Base case stream results.

Stream	Shea Oil	Solvent	3	4	Shea Olein	Shea Stearin	Waste Water
T, K	300	293	268	268	303	303	303
Flowrate, kg/h							
TAGs	1768.9	0.0	871.8	897.2	897.2	871.8	<10 ⁻⁴
DAGs	1.6	0.0	0.8	0.8	0.8	0.8	<10 ⁻⁴
MAGs	20.0	0.0	10.6	9.4	9.4	10.6	<10 ⁻⁴
FFAs	200.0	0.0	171.8	28.2	28.2	171.8	<10 ⁻⁴
Minor components	8.5	0.0	4.5	4.0	3.5	3.9	<10 ⁻⁴
Water	1.0	<10 ⁻⁴	0.5	0.5	0.7	1.0	12.1
Acetone	0.0	<0.1	7060.0	940.0	<10 ⁻⁴	<10 ⁻⁴	<10 ⁻⁴

TAGs – triacylglycerides, DAGs – monoacylglycerides, MAGs – monoacylglycerides, FFAs – free fatty acids, Minor components: sterols and tocopherols.

3.3. Process performance analysis

The economic analysis using ECON gives the following results: total capital investment is 2.8 M€, the operating cost is 24.5 M€/year, and the payback period is 3 years. Feasibility of the process is dependent by the product-raw material price balance, to which the process is highly sensitive. The biggest cost impact is given by the acetone-water separation column and the crystallizer, 30% of total capital investment. Regarding the utility consumption, the highest consumption belongs to the heat exchanger for heating up the Shea olein-solvent fraction resulted after the filtration step, and which consist of \approx 80% acetone.

For the LC analysis, all output streams were considered within the analysis (Shea stearin, Shea olein - products, waste water – waste stream) along with the utilities generation (natural gas is considered as fuel). The main impact indicators provided by the LC analysis are given in Table 2.

Table 2. Base Case main environmental impact indicators.

Indicator	HTPI	HTPE	ATP	GWP	PCOP	AP	HTC
Unit	1/LD ₅₀	1/TWA	1/LC ₅₀	kg CO ₂ eq	C ₂ H ₂ eq	H+ eq.	kg benzene eq
Value	6.1E-05	4.2E-04	3.2E-03	3.5E+02	3.0E-01	2.5E+01	1.4E+00

HTPI – human toxicity potential by ingestion, HTPE – human toxicity by exposure, ATP – aquatic toxicity potential, GWP – global warming potential, PCOP – photochemical oxidation potential, AP – acidification potential, HTC – human toxicity carcinogenic.

3.4. Process hot-spots identification and retrofit solutions

The hot-spots identified based on the results from Step 3 are presented in Table 3. The results indicate a necessity of heat integration to reduce the utility consumption. Moreover, an optimization of the flash units temperature in both stearin and olein fraction solvent separation sections could be performed in order to allow a higher energy recovery through heat integration. The improvements of process indicators after performing the heat integration are presented in Figure 2. Total capital investment increase with 0.13 M€, while the operation cost decrease with 0.23 M€ for the improved case. The LCA analysis show improvements in all environmental indicators as well. The global warming potential of the process drops from 350.9 CO₂ equivalent (eq.) to 61.9 CO₂ eq.

Table 3. Shea oil acetone fractionation process hot-spots.

Hot-Spots	Design targets	Improvement solution
High utility consumption in heat exchanger for olein fraction heating	Reduction of utility consumption	Optimization of flash temperature to allow energy recovery and better separation
High utility consumption for evaporators (flash units)		Heat integration

Figure 2. Process performance indicators variation reported to the base case.

4. Conclusions

A systematic analysis of Shea oil acetone fractionation process is presented. SPEED Lipids database using lipids based interaction parameters for Original UNIFAC model is used to provide all the thermo-chemical data necessary to perform the simulation. The process data is collected from literature and industrial data. The process modelling, design and simulation is performed in PRO/II. Economic and LCA analysis results are used to identify process hot-spots and to propose retrofit solutions. Process performance parameters of the base case were improved after heat integration was applied. In future work, the base case will be further improved by applying simultaneous process optimization and integration techniques.

Abstract

Assessing and enhancing the sustainability of chemical processes is a key challenge for chemical engineering. Sustainability is usually conjugated in three distinct but interconnected dimensions or *pillars*: economic, environmental, and social. In order to develop a sustainable process, the three pillars should be harmonized. In most cases, these pillars conflict with each other and a compromise may be found by solving a multi-objective optimization (MOO) problem. This paper proposes a solution strategy for the MOO of sustainability in the conceptual design of chemical plants. Two different approaches are analyzed and discussed, based on Pareto’s fronts analysis and scalarization technique.

Keywords: sustainability, process design, multi-objective optimization, Pareto front, scalarization

1. Introduction

The concept of sustainability embraces the economic, environmental, and social aspects of most human activities. In a nutshell, a sustainable process is the one that “*constrains resource consumption and waste generation to an acceptable level, makes a positive contribution to the satisfaction of human needs, and provides enduring economic value to the business enterprise*” (Bakshi and Fiksel, 2003). According to this definition, in order to be sustainable, an industrial process must be feasible and profitable from the economic point of view and, at the same time, must harmonize with both environmental and the societal matters.

This article embraces the detailed modelling and simulation of a chemical process, specifically the cumene production plant. Cumene is an important commodity derived from benzene, with a worldwide production of 16 million tons in 2016. It is produced through the Friedel-Crafts alkylation of benzene with propylene, followed by several undesired side-reactions of further alkylation to form p-diisopropylbenzene (PDIB) and heavier species (PIBs). For the sake of simplicity, our case study considers only the benzene alkylation and its main side reaction to PDIB. In conventional cumene plants, PDIB is converted back to cumene by a transalkylation reactor to recover valuable product. The present conceptual design is based on the flowsheet of Pathak et al. (2011). The second step consists in assigning the degrees of freedom of the optimization problem, *i.e.* the variables that mostly affect the process performance. Such dominant variables are the reactor inlet temperature and the reactor tube length. The Grid-Search algorithm was selected to optimize the plant because of its robustness and exhaustiveness. In fact, it evaluates all the possible plant configurations, which for the inlet temperature fall in the

300-350 °C range (with a discretization interval of 5 °C) and for the reactor length belong to the 4-12 m range (with a discretization interval of 0.5 m).

2. Formulation of the MOO problem: Sustainability criteria

As far as the economic sustainability is concerned, several economic assessment (EA) techniques have been developed in the literature. The most important milestone in this field is represented by “Conceptual Design” (Douglas, 1988), which entails a systematic methodology to assess the economic feasibility of a chemical process in the preliminary design stage. Starting from Douglas’ approach, Manca (2015) introduced a novel methodology that also accounts for the price fluctuations of raw materials, products, and utilities, christened “Predictive Conceptual Design” (PCD). The PCD concept has been applied successfully to different case studies (Barzaghi et al., 2016; Sepiacci et al., 2017; Scotti et al., 2017) and in this work the Dynamic Economic Potential of fourth level (Manca, 2015) is adopted as the economic sustainability objective function:

$$DEP_{4k} = \frac{\sum_{i=1}^{nMonths} (Revenues_{4i,k} * nHpM)}{nMonths/12} - \frac{\sum_{e=1}^{nEquip} (IC_e)}{nMonths/12} \quad (1)$$

With:

$$Revenues_{4i,k} = \max \left[0, \sum_{products} C_{i,k} F_p - \sum_{raw} C_{i,k} F_r - \sum_{utility} C_{i,k} F_u - \sum_{EE} C_{i,k} W_{EE} \right] \quad (2)$$

Where F_x [kmol/h] is the flowrate of products (p), raw materials (r), utilities (u), and W_{EE} is the electric energy (EE) consumption [MWh]. $C_{i,k}$ [€] is the price at month i and scenario k . The CAPEX terms are included in the installation costs (IC) of the equipment and $nHpM$ is the number of working hours of the plant per month.

Concerning the assessment of the environmental sustainability of a process, several methodologies are available in the literature. For the sake of plant optimization, a proper methodology should adopt a gate-to-gate approach, *i.e.* it should consider as boundaries of the system the battery limits of the plant and neglect the rest of the life cycle of the product and its corresponding physical and geographical spheres of influence. The Waste Reduction Algorithm (Young and Cabezas, 1999) is a valid candidate (see also Sepiacci et al. (2017) and Scotti et al. (2017) for further details). Thus, the Potential Environmental Impact (PEI) implements the following formulation:

$$PEI_{tot}^{out} = \sum_j^{st} M_j^{out} \sum_k^{cp} x_{kj} \sum_z^{ca} \alpha_z \psi_{kz} \quad (3)$$

where M_j^{out} is the mass flow rate of output stream j , x_{kj} is the mass fraction of species k in stream j . ψ_{zk} is the specific PEI for species k for the impact category z and α_z is the corresponding weighing factor for category z .

The objective function for the environmental sustainability is the normalized PEI, *i.e.* the PEI for unit of mass of product:

$$normalized\ PEI = \frac{PEI_{tot}^{out}}{F_{cumene}^{out}} \quad (4)$$

Where F_{cumene}^{out} is the cumene productivity in kg_{cumene}/h .

Eventually, social sustainability is the least defined, discussed, and understood dimension of sustainability. According to the context of this work, it can be stated in terms of “inherent safety” of the process, as proposed by Kletz (2013). Based on this philosophy, a proper methodology for the estimation of the inherent safety is required. For this purpose, the Hazard Identification and Ranking (HIRA) methodology (Khan and Abbasi, 1998) can be tailored for the optimization of the social sustainability of chemical plants (Scotti et al., 2017). Finally, the social sustainability objective function is the overall Hazard Potential (HP), calculated as follows:

$$\text{Overall HP} = \sum_{j=1}^{N \text{ units}} HP_j \quad (5)$$

Where HP_j is the Hazard Potential of the j-th unit.

3. Pareto's fronts analysis

The first solution approach is based on the analysis of the Pareto fronts and consists in identifying the trade-offs between each couple of objective functions. By doing so, the original MOO problem is decomposed into three two-objective optimization problems and the most relevant trade-offs are outlined. When pair-wise comparisons of the objective functions are involved, the problem can be dealt with by visualizing the Pareto front, which provides detailed information about objectives trade-off. This concept, introduced by the Italian economist Vilfredo Pareto (Pareto, 1897), defines as “Pareto optimal solutions” (also known as “dominant” or “non-dominated” solutions) those points within the decision space, whose corresponding objective functions cannot be all simultaneously improved. Starting from the whole set of possible combinations (named as Pareto curve, Fig. 1), the Pareto optimal solutions can be found numerically by means of some specific algorithm. The present work employs the algorithm reported in Mishra and Harit (2010). Three different Pareto fronts are reported in Figs 2-4, each accounting for a pair-wise comparison among the three objective functions (*i.e.* DEP4/PEI, DEP4/HP, and PEI/HP).

Figure 1: Pareto curve DEP4 vs PEI

Figure 2: Pareto front DEP4 vs PEI

Figure 3: Pareto front PEI vs PEI

Figure 4: Pareto front DEP4 vs HP

A closer look to Figs 1-2 allows identifying four dominant solutions, whose values are quite close. Indeed, the present case study does not exhibit any actual conflicts between the economic and environmental sustainability criteria. On the other hand, Figs 3-4 show evident trade-offs between those two and the social one.

4. Scalarization

As already outlined, Pareto fronts provide the final decision maker with some useful bits of information about the main trade-offs among the objective functions and identify a set of potential solutions of the overall MOO problem. However, when dealing with more than three objective functions, this approach can be confusing and sometimes misleading.

An interesting technique that can be applied for solving the Sustainability MOO problem is scalarization. This consists in transforming a MOO problem into a single-objective optimization problem by collecting all the conflicting criteria in a single objective function. The scalarization of an objective function essentially consists in normalizing it and make it comparable with other scalarized objective functions. Different scalarization methods can be adopted and the choice is usually arbitrary. In the present case, i.e. the MOO of sustainability criteria, each objective function is normalized in order to assume a value of 1 for the “most sustainable” solution and 0 for the unsustainable one(s).

As far as the economic sustainability of the process is concerned, a value of 1 is assigned to maximum DEP4, and a value of 0 to DEP4 equal to zero. This index, ranging from 0 to 1, is christened Economic Sustainability Index (EcSI), and is expressed as:

$$EcSI_i = \begin{cases} \frac{DEP4_i}{\max(DEP4)} & \text{if } DEP4_i > 0 \\ 0 & \text{if } DEP4_i \leq 0 \end{cases} \quad (6)$$

Where $DEP4_i$ is the value of DEP4 for configuration i , and $i = 1, \dots, NC$ with NC the number of process configurations (equal to 187). EcSI becomes equal to 0 when the process is unsustainable, i.e. when the DEP4 is zero or negative.

The same reasoning is followed for the expression of the Environmental Sustainability Index (EnSI), which assumes a value of 1 when PEI is minimum and 0 when PEI is greater than $0.15 \text{ PEI/kg}_{cumene}$. Indeed, this value can be considered as a threshold value above which the process becomes unsustainable from the environmental point of view. EnSI is formulated as:

$$EnSI_i = \begin{cases} \frac{(0.15 - PEI_i)}{(0.15 - \min(PEI))} & \text{if } PEI \leq 0.15 \\ 0 & \text{if } PEI > 0.15 \end{cases} \quad (7)$$

As far as the social sustainability is concerned, no threshold values are provided for the overall Hazard Potential in order to discriminate between sustainable and unsustainable processes. Hence, a possible way to normalize HP is to assign 1 to the lowest value, and 0 to the highest value. The Social Sustainability Index (SoSI) of the process is expressed as:

$$SoSI_i = \left\{ \frac{(\max(HP) - HP_i)}{(\max(HP) - \min(HP))} \right. \quad (8)$$

Finally, the objective function of the scalarized MOO problem is simply the weighted sum of the Economic, Environmental, and Social Sustainability indexes. Each of them is properly weighted, according to the relative importance of the three pillars of Sustainability. In the present work, the hierarchy of importance that is here proposed considers the economic aspect of sustainability as predominant, followed by environmental sustainability, and eventually by social sustainability. Therefore, a value of 0.5 is assigned to the economic pillar, and values of 0.3 and 0.2 to the environmental and social ones, respectively. The scalarized objective function is christened as Normalized Process Sustainability (NPS), and the scalarized MOO problem undertakes the following formulation:

$$\max_{T,L} NPS = \{w_{Ec} * EcSI + w_{En} * EnSI + w_{So} * SoSI\} \quad (9)$$

Where the degrees of freedom are T , the reactor inlet temperature, and L , the reactor tube length. w_{Ec} , w_{En} and w_{So} are the weighting factors for the economic, environmental, and social sustainability indexes, respectively.

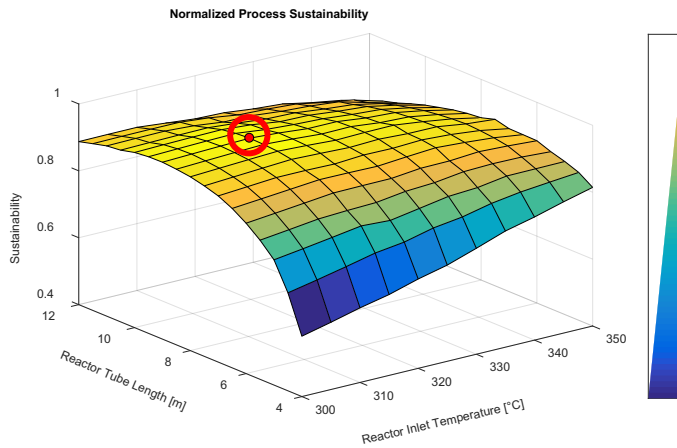

Figure 5: 3D plot of the Normalized Process Sustainability

Fig. 5 shows the 3D plot of the NPS function for the cumene case study. According to its definition, it ranges from 0 to 1, where 0 corresponds to completely unsustainable solutions and 1 to ideal sustainability, i.e. all the three indexes are maximized

simultaneously. The red circle identifies the optimal solution characterized by a NPS value of 0.938. This configuration corresponds to an inlet temperature of 315 °C and a reactor length of 9 m.

5. Conclusions

The cumene production process was adopted as a case study to perform a multi-objective optimization of economic, environmental, and social sustainability criteria. A proper objective function was formulated to assess each pillar of sustainability. The MOO problem was assigned and solved by means of two different approaches. The Pareto fronts analysis allowed identifying the relevant trade-offs among the three criteria and showed to be a valid support for the decision maker, even though it does not provide a univocal solution. The second approach to MOO involves scalarizing the problem and converting it to a single-objective optimization problem. The new objective function was defined as the weighted sum of the three criteria properly normalized. The values of the weighting factors were assigned to highlight a hierarchy among sustainability criteria. As far as the cumene case study is concerned, the optimal solution represents a good trade-off configuration, whose values of the objective functions are all close to their respective optimum values: its DEP4 is 67.58 MUSD (98.5% of the maximum), while its environmental (EnSI = 0.942) and social (SoSI = 0.813) indexes show that both PEI and HP approach their minimum (*i.e.* optimal) values.

Abstract

Considering chemical transformation, separation and/or reaction, is still a pending issue in the optimization of industrial symbiosis networks. This work aims to provide an optimization approach to determine the best network configuration by analysing the available separation and reaction alternatives. The model has been tested on an academic case study. Results show that the tool developed provides the best routes to convert waste into raw materials and gives rise to new possible synergies that could remain unnoticed without the use of a systematic tool. It is also highlighted that reaction plays a vital role in increasing the potential recycle of resources and closing material loops.

Keywords: Sustainability, Industrial Symbiosis, Material Exchange, Optimization, Superstructure.

1. Introduction

The first concerns on the problems generated by the degradation of the ecosystems date back to the last century (Hardin, 1968). This degradation is caused not only by the excessive consumption of resources but also due to the corresponding increase in waste accumulation. Industrial symbiosis offers a way to address both problems by providing an alternative to disposal of waste and reducing the amount of resources that are exploited. In this light, the focus of recent research has been on finding systematic methods to identify the best alternatives for establishing synergies.

Recent works are related to the building of superstructures that increase the opportunities of resources exchange (Boix et al., 2017). These benefits are increased if transformation opportunities are analysed as a way to convert waste into new profitable materials (Boix et al., 2015). There have been some attempts to solve the design of separation-reaction systems, but always applied to a single supply chain (Kong and Shah, 2016). Previous works address the development of superstructures for separation and the targeting of reaction systems (Somoza-Tornos et al., 2017; Giraldo-Carvajal et al., 2017). However, there is still the need of an integrated framework that considers separation and reaction opportunities in the decision-making process of industrial symbiosis systems.

The aim of this work is to extend the existing models to develop an optimization tool that integrates separation and reaction opportunities to increase the extent of material exchanges in industrial symbiosis. While common approaches focus on finding global solutions (i.e. a regulating administration), the novelty of this approach consists on addressing the problem from the point of view of a transformation company that seeks

maximizing its particular profit by closing the loop between waste producers (suppliers) and resource necessities (customers).

The system is modelled as a process superstructure in order to identify the best process configuration, selecting among the different available alternatives of separation and reaction steps.

2. Problem statement

The operation problem addressed can be posed as follows: Given are a set of waste streams i with known composition of products n coming from different industries, and a set j of resources needed by the same or other companies. Given are also a set of available treatment technologies k . They are modelled as separators ($k \in SE$) or reactors ($k \in RE$) with different operation modes m and associated cost parameters (γ_{km}). The different outlets of a transformation unit are represented in set l . Decisions include amounts of waste sent to disposal, reuse or recycling; the way to satisfy the demand of raw materials (with recycled or fresh inlets) and which transformation units are active. Thus, the optimal configuration of the system has to be determined.

The different alternatives are analyzed through the definition of a superstructure as the one shown in Figure 1. Waste streams are divided by the first set of splitters (S1) and may then by-pass the transformation units or enter in transformation stages. A first set of mixers (M1) concentrate all the flows entering the same treatment unit k of the set TU. After transformation, a second set of splitters (S2) divide the flow in the part that is recycled to other treatment units, the part that is valuable as raw material, and the part sent to disposal (D).

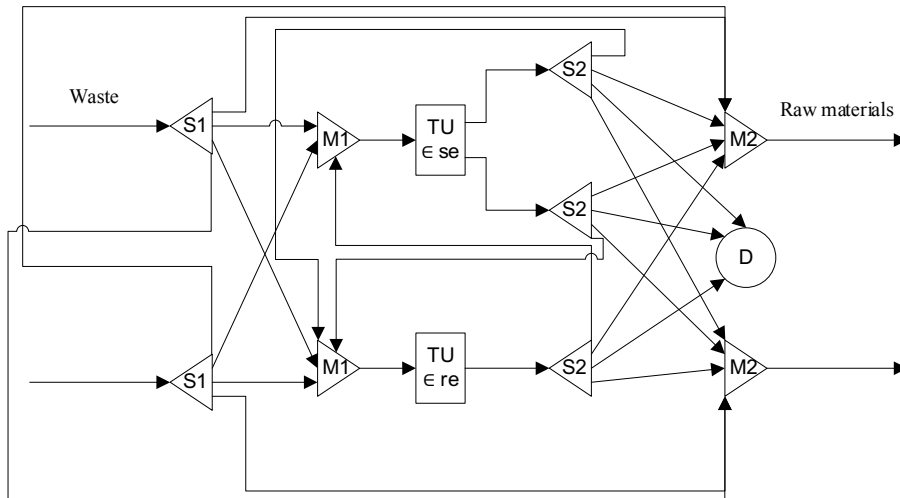

Figure 1. Superstructure for two waste streams, two treatment units (TU, a separator and a reactor) and two raw material streams.

3. Mathematical formulation

The proposed MINLP problem formulation associated to the problem statement extends a version in a previous work (Somoza-Tornos et al., 2017) to consider reaction and more general separation systems with l outlets instead of two.

3.1. Waste inlet

Eq. (1) defines the amount of waste from a supplier (W_{in}) that is acquired by the transformation company (a_{in}). It is calculated through fraction pa_i , which maintains composition constant. In Eqs. (2-4), this amount is divided in two parts, the one that is directly by-passed to the outlet streams (continuous variable p_{ijn} and 0-1 fraction $S1p_{ij}$) and the one sent to the transformation units (continuous variable f_{ikn} and 0-1 fraction $S1f_{ik}$). (Somoza-Tornos et al., 2017)

$$a_{in} = pa_i \cdot W_{in} \quad \forall in \quad (1)$$

$$p_{ijn} = a_{in} \cdot S1p_{ij} \quad \forall ijn \quad (2)$$

$$f_{ikn} = a_{in} \cdot S1f_{ik} \quad \forall ikn \quad (3)$$

$$\sum_j S1p_{ij} + \sum_k S1f_{ik} = 1 \quad \forall i \quad (4)$$

3.2. Treatment units

e_{kn} denotes the inlet of component n to treatment unit k and is calculated considering direct waste coming from inlet i and recycled streams from outlet l of treatment unit k' . Eqs. (6-7) express the constraints on the flow to be treated and its inlet concentration, which must be satisfied.

$$e_{kn} = \sum_i f_{ikn} + \sum_{k'l} g_{klkn} \quad \forall kn \quad (5)$$

$$\sum_m (tmin_{km} \cdot X_{km}) \leq \sum_n e_{kn} \leq \sum_m (tmax_{km} \cdot X_{km}) \quad \forall k \quad (6)$$

$$\sum_m (ctmin_{kmn} \cdot X_{km}) \leq \frac{e_{kn}}{\sum_n e_{kn}} \leq \sum_m (ctmax_{kmn} \cdot X_{km}) \quad \forall kn \quad (7)$$

In these equations, X_{km} represents the operation mode m that is active in treatment unit k . Separators can operate under a single mode at the same time (Eq. (8)), while reactors can have simultaneous modes, if several reactions occur at the same time (Eq. (9)).

$$\sum_m X_{km} \leq 1 \quad \forall k \in SE \quad (8)$$

$$\sum_m X_{km} \geq 0 \quad \forall k \in RE \quad (9)$$

The outlet flow l of component n after treatment unit k under operation mode m is stored in variable o_{kln} . It is then split into three streams: the one sent to outlet j (t_{jkl} denotes the amount and $S2t_{jkl}$ the fraction), the one recycled to treatment unit k' ($r_{klk'n}$ and $S2r_{klk'}$), and the disposed amount (d_{kln} and $S2d_{kl}$). The corresponding balances are given by Eqs. (10-13).

$$t_{jkl} = o_{kln} \cdot S2t_{jkl} \quad \forall jkln \quad (10)$$

$$g_{klk'n} = o_{kln} \cdot S2g_{klk'} \quad \forall klk'n \quad (11)$$

$$d_{kln} = o_{kln} \cdot S2d_{kl} \quad \forall kln \quad (12)$$

$$\sum_j S2t_{jkl} + \sum_{k'} S2g_{klk'} + S2d_{kl} = 1 \quad \forall kl \quad (13)$$

The next subsections present the specific equations for separation units and reactors.

3.2.1. Separation units

The outlet of each separation unit o_{kln} is given by Eq. (14), in which parameter xt_{kmln} denotes the recuperation of each component n in outlet l after treatment in unit k under separation mode m .

$$o_{kln} = e_{kn} \cdot \sum_m (xt_{kmln} \cdot X_{km}) \quad \forall l, n, k \in SE \quad (14)$$

3.2.2. Reaction units

The model for reaction units has been adapted from Kong and Shah (2016).

The reactor outlet Eq. (15) is a function of the inlet, the stoichiometric coefficient (sc_{kmn}) and the reaction extent (rx_{km}). The reactor outlet is constrained by Eqs. (16-17), so that the inlet of reactant cannot exceed the reactant required by the reaction and that it is bounded by a maximum value, respectively.

$$\sum_l o_{kln} = e_{kn} + \sum_m (sc_{kmn} \cdot rx_{km}) \quad \forall n, k \in RE \quad (15)$$

$$e_{kn} + \sum_m \frac{sc_{kmn} \cdot rx_{km}}{xc_{km}} \geq 0 \quad \forall n, k \in RE \quad (16)$$

$$0 \leq rx_{km} \leq X_{km} \cdot rx^{max} \quad \forall n, k \in RE \quad (17)$$

3.3. Demand constraints

c_{jn} denotes the amount of component n supplied as raw material j and can be calculated through bypassed and transformed streams as in Eq. (18). It cannot exceed the total demand of raw material R_j and should satisfy the range of concentration for each component (Eqs. (19,20)).

$$c_{jn} = \sum_i p_{ijn} + \sum_{kl} t_{jkl} \quad \forall jn \quad (18)$$

$$\sum_n c_{jn} \leq R_j \quad \forall j \quad (19)$$

$$Pmin_{jn} \geq \frac{c_{jn}}{\sum_n c_{jn}} \geq Pmax_{jn} \quad \forall jn \quad (20)$$

3.4. Objective function

Eq. (21) shows the objective function to be minimized. It consists of an economic balance taking into account the income from selling raw materials j (α_j), the economic value of using waste i from a producer company (β_i), the cost of transforming waste into raw materials (γ_k) the cost of disposal (δ_n). Note that α_j and β_i are aggregated parameters that include acquisition/selling and transportation costs.

$$OF = \sum_j (\alpha_j \cdot \sum_n c_{jn}) - \sum_i (\beta_i \cdot \sum_n a_{in}) - \sum_k (\gamma_k \cdot \sum_n e_{kn}) - \sum_n (\delta_n \cdot \sum_k d_{kn}) \quad (21)$$

3.5. MINLP model

The resulting model for the industrial symbiosis superstructure can be posed as follows:

$$\begin{aligned} \text{Sym} \quad & \min [\text{OF}] \\ \text{s.t.} \quad & \text{Eqs. (1)-(21)} \end{aligned}$$

4. Case study

An academic case study has been defined for the sake of comparison. It considers 4 available waste streams and 3 required resource streams composed by 3 components, which we may call A, B and C. The transformation company owns two distillation columns (one that separates A from B and the other that separates B from C) and a reactor where the reaction $A + B \rightarrow C$ can take place. Three different scenarios are analysed: 1) no transformation units are available, thus only direct synergies are feasible; 2) distillation columns are active but no reactors can be used; 3) all transformation units are available.

5. Results

Figure 2.a depicts the solution for the first scenario, in which the only possible connections are those between compatible waste and raw material streams. The higher purity of W1 leads to a higher acquisition cost than W2, but it is compensated by a lower transportation cost for its closeness to the transformation company. In the second scenario (represented in Figure 2.b), separation of waste streams can be considered, which results in an increase of the amount of waste that is recycled and the percentage of demand that is satisfied. This situation is even increased when reaction takes part.

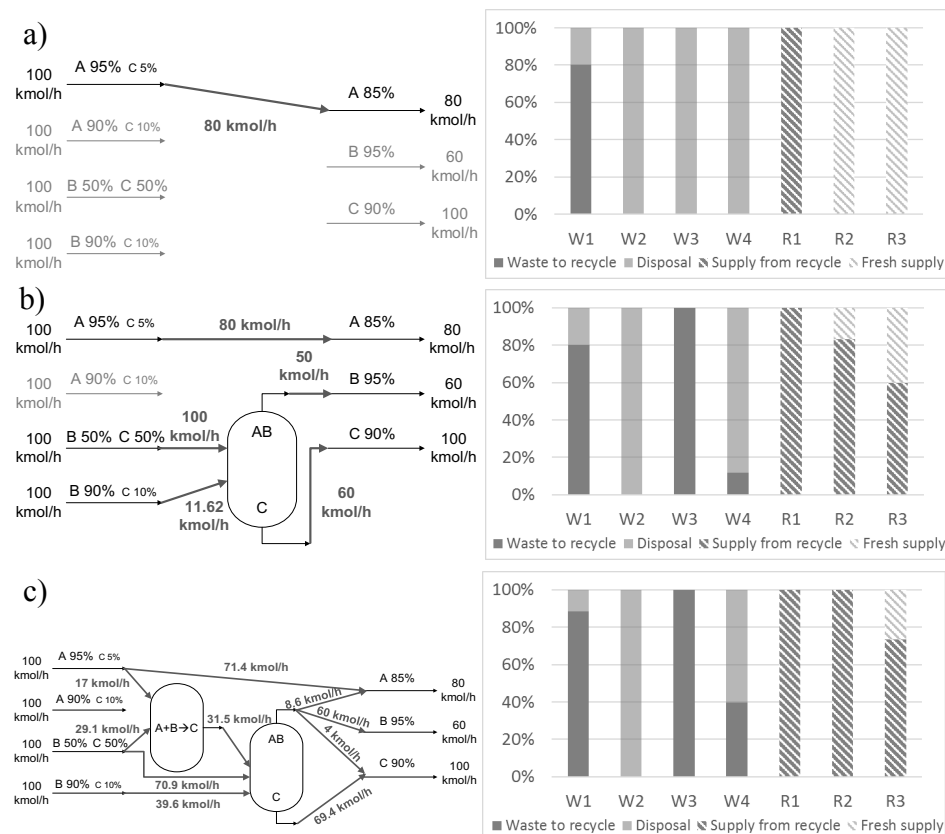

Figure 2. Network configuration and fraction of waste recycled and supply covered from it for a) scenario 1, b) scenario 2 and c) scenario 3.

(Figure 2.c). In this case, the amount of recycled material is 2.9 times higher than in the first scenario. It is achieved without the total coverage of the demand of R3, as it would lower the purity of B, resulting in an incompatibility with R2.

All the alternatives proposed are increasingly profitable for the transformation company, which by discovering these business opportunities contributes to integrating different supply chains and consolidating industrial symbiosis.

6. Conclusions

This study has focused on the development of an optimization model to detect new possible synergies in industrial symbiosis by considering separation and reaction. The approach is based on addressing the problem from the point of view of a transformation company that seeks maximizing its particular profit and contributes the consideration of specific transformation processes such as separations and reactions. Results show that the more transformation processes are involved the further extent of material reuse is achieved. Furthermore, the proposed model gives rise to new possible synergies that could remain unnoticed without the use of a systematic tool. Thus, it allows broadening the current limits of industrial symbiosis, moving towards a more sustainable use of resources, and expanding the lifespan of materials by identifying and assessing the business opportunities that transformation companies may take advantage of within the circular economy. Based on the promising findings, future work will address the multi-objective optimization of the system, taking into account sustainable criteria and considering the effect of negotiation between the different actors.

ricardo.morales@ugto.mx

Abstract

The design of optimal product, mixtures and processes must be performed relying on systematic steps. For example, the separation and purification of the acetone-butanol-ethanol (ABE) from a fermentation broth is still a challenge to overcome. A feasible process configuration that includes the use of liquid-liquid extraction (LLE) and distillation, requires the design/selection of the extracting agent/solvent and the equipment design in order to overcome the azeotropes in the ABE mixture. Therefore, this study proposes and implements a framework consisting of organized steps combining methods and tools, using as a case study the ABE separation from water and the purification of ABE compounds. The LLE unit included in the process allowed the solvent design, the formulation and evaluation of a mixture of extracting agents with the required characteristics for the extraction; followed by the process design of the equipment, and finally the optimisation step using a hybrid stochastic optimisation method, differential evolution with tabu list. The optimal design of the mixture of extracting agents converged in mass fraction values of 0.3799 for n-hexyl-acetate and 0.6201 for n-heptyl acetate, which allowed to reduce the total annual cost by 78 % and the environmental impact by 79 % relying on the eco-indicator, compared with base case scenario.

Keywords: molecular design, mixture design, heptyl acetate, hexyl acetate, ABE.

1. Introduction

The production of chemicals implies different tasks where the separation and purification processes (SPP) are important to obtain the desired product quality in terms of purity and quantity. There are some SPP that include the use of solvents or mixtures, for example, the crystallization process (Karunanithi and Achenie, 2007) and the liquid-liquid extraction (LLE) employ the use of extracting agents/solvents, where the selection of the compounds to perform the tasks is fundamental. Hence, the use of computer-aided molecular/mixture design (CAMD) becomes important since assisting to obtain tailor-made compounds and compositions for mixtures (Harper et al., 1999). According to the state of the art, there is still an opportunity to improve the design of processes (such as, LLE) that involve solvent and mixture design for SPP combining different computer-aided tools. Thus, the objective of this work is to present a systematic framework for the optimised design of solvent mixtures (to be used as

extracting agent) and SPP relying on sustainability metrics. The proposed framework is assessed employing the ABE fermentation broth composition for the SPP case study, where an important hurdle is the presences of two azeotropes in the ABE mixture. Thereby, it is necessary to include a LLE process that requires the design of the extracting agent that could be a sole solvent or a suitable mixture of solvents, its feasibility has been previously analysed in terms of cost and environmental impact (Errico et al., 2015)

2. A framework for optimised sustainable mixture and rigorous separation process design

The framework for optimized sustainable solvent-process design shown in Figure 1, may be summarized and explained as follow: 1) the data collection and state of art analysis related with LLE; 2) the product design task, aiming to find the potential extracting agents with tailor-made characteristics, employing a computer-aided molecular design software (CAMD) that is based on functional groups to build the molecules (Harper et al., 1999); 3) selection of the extracting agents based on the cost, market availability and toxicity, and the thermodynamic model suitable for the mixture to separate; 4) evaluation of extracting agents candidates in a simulation tool (Aspen plus, PRO II, etc); 5) comparison of the evaluated solvent with the base case (BC) in order to determine its performance and continue with the design of the subsequent equipment, whether the performance of the candidate is worse than the BC scenario in terms of selected criteria, it is possible to return to step number 3 to select another candidate, otherwise, just continue with the next step; 6) the potential candidates can be identified in order to formulate possible extracting agents mixtures, it is very important to perform a physicochemical properties analysis, since the selected compounds must have similar boiling points to facilitate their recovery, otherwise, the separation task could generate the introduction of an extra separation unit; 7) process design employing shortcut methods followed by a sensitivity analysis to refine the process specification, and finally, the selection of configurations with better performance based on product recovery, purity and operating cost, whether the mixture is not suitable it is possible to return to step 6 to formulate a new mixture of solvents or go back to step 3 for finding new potential individual extracting agents; 8) multi-objective optimization employing an stochastic hybrid method, differential evolution with tabu list (DETL), minimizing the total annual cost (TAC) and the environmental impact (EI) calculated with the Eco-indicator 99; and finally the selection of the best configuration based on a Pareto front. Please note that the solvent design includes only the first 6 steps, the process design steps 7-8 and the extracting agent's mixture design the steps from 3 to 8.

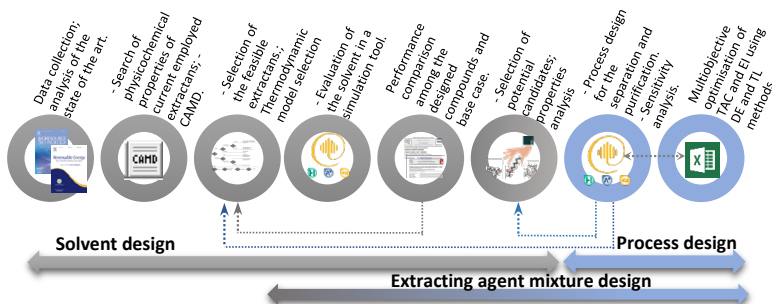

Figure 1. Framework for optimized sustainable mixture and rigorous separation process design.

3. How the framework for optimised sustainable mixture design works.

The framework used as case study the separation of a fermentation broth containing ABE, water, carbon dioxide and hydrogen, since the residual sugars such as glucose and xylose are separated in distillation column before entering to the LLE unit.

3.1. Data collection and state of the art analysis.

The implementation of LLE includes the selection of extracting agent. In a previous work Kraemer et al. (2010) employed 1,3,5-trimethylbenzene (mesitylene). Moreover, Morales-Espinosa et al. (2017) employed hexyl acetate (HEX) as extracting agent having better results than using mesitylene. In any case, it is still required to look for an environmentally friendlier and economic extracting agent substitute.

3.2. Solvent design by a computer-aided molecular design.

The potential molecules to be employed as extracting agents can be designed relying on CAMD principles (using molecular functional building blocks). Thereby, it is necessary to list the desired characteristics of the reference solvent (in this case mesitylene), such as, partition coefficient, water solubility, vapour pressure, not azeotrope creation with the present compounds, etc. That information is specified in the Pro-CAMD that is available in the ICAS software. The Pro-CAMD designed a number of candidates that were reduced by manipulating the lower and upper limit values of the desired characteristics. The software provided 846 compounds as potential extracting agents.

3.3. Selection of the potential candidate to be used as extracting agents and the thermodynamic model.

The discrimination to determine the final list of possible candidates was obtained checking the existence or availability of the compound in the market, and also the commercial prices compared with the reference compound. The heptyl acetate (HEP), HEX among others was found as the most promising substitutes for the mesitylene. HEX was already analysed as extracting agent in a previous study (Morales-Espinosa et al., 2017), while the implementation of the HEP is still in progress. In any case, both seem to be feasible for their implementation as extracting agents separately or together like a mixture. The thermodynamic model selected for the LLE unit was NRTL, while the liquid phase and vapour phase in the DC were the predicted using NRTL model and Hayden O'Connell equation of state, respectively.

3.4. Evaluation of the potential extracting agents/solvents candidates.

The HEX, HEP and mesitylene were tested in a LLE unit with the same number of stages (5), process conditions ($T = 35\text{ }^{\circ}\text{C}$ and $P = 1\text{ atm}$) and molar-based feeding ratio (1:0.84, ABE-water and extracting agents, respectively), just with the end of comparing and evaluating the performance of the extracting agents at the same circumstances.

3.5. Comparison of the potential candidates vs case base of extracting agent

The results employing HEX and HEP had similar ABE recovery. In addition, the commercial price of mesitylene compared with HEX and HEP prices were 1.62 and 2.62 times higher, respectively. Thereby, finding the HEX and HEP as feasible candidates in terms of economy.

3.6. Selection of potential candidates and property analysis.

The HEX and HEP are from the same organic family and differ by 1 and 2 carbon and hydrogen atoms, respectively. The boiling points of both compounds are higher for more than 50°C compared with butanol, which is the compound with higher boiling point present in the mixture to be separated.

3.7. Process design for separation and purification.

The process synthesis was done relying in heuristic rules, then the equipment design was done using shortcut methods for the DC and a sensitivity analysis to improve the LLE design and the DC. Once, the design is gotten a rigorous simulation is performed using EXTRACT unit for LLE and RADFRAC for DC in Aspen plus (AP). The process configuration is shown in Figure 2.

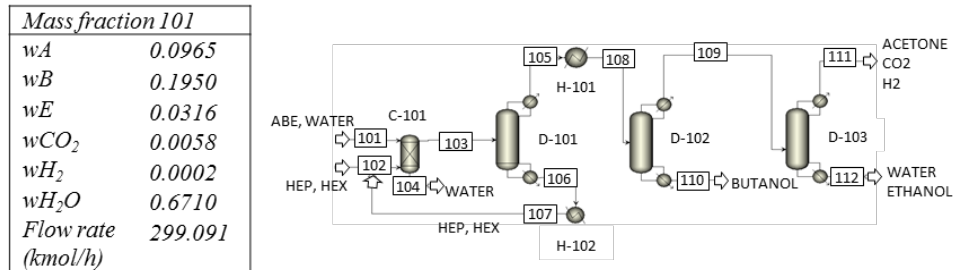

Figure 2. Configuration for the ABE separation using HEX-HEP mixture as extracting agent.

3.8. Multiobjective optimisation

The optimal mixture compositions of the extracting agent and the process design is performed simultaneously through the last step.

3.8.1. Objective Function

The objective function included the simultaneous minimization of the TAC and the eco indicator 99. The minimization of these objectives was subject to the required recoveries and purities in each product stream (see Equation 1).

$$\text{Min}(TAC, \text{Eco } 99) = f(N_m, M_{in}, N_{fn}, R_m, F_m, D_{cn}), \text{ subject to } y_m \geq x_m \quad (1)$$

where N_m are total column stages in LLE column and DCs, M_{in} is the mixture of the extracting agents feeding flowrate to the LLE, N_{fn} is the feed stage of all streams in columns, R_m is the reflux ratio, F_m is the distillate fluxes and D_{cn} is the column diameter, y_m and x_m are vectors of obtained and required mass purities (95%, 99.5% and 83% for ABE) with the mass recoveries (98%) for the m components, respectively. Moreover, note the variable M_{in} involves both the amount of mass in the feed stream and the mass fraction for the case of a mixture of the extracting agents. This minimization implied the manipulation of 18 continuous and discrete variables. The TAC calculation was performed as it is shown in Equation 2.

$$TAC = \frac{\text{Capital Cost}}{\text{Payback period}} + \text{Operative cost} \quad (2)$$

On the other hand, the environmental indicator was measured through the eco-indicator 99 based on the methodology of the life cycle analysis (Geodkoop and Spriensma, 2001). In the eco-indicator 99 methodology, 11 impact categories were considered, aggregated into three major damages categories: (1) human health, (2) ecosystem quality, and (3) resources depletion.

3.8.2. Global stochastic optimisation strategy

To optimize the process route for biobutanol production, a stochastic optimisation method, Differential Evolution with Tabu List (DETL) was used, which have shown being robust to optimize intensified separation systems. Srinivas and Rangaiah (2007) showed that the use of some concepts of the metaheuristic tabu can improve the performance of DE algorithm. The implementation of this optimisation approach was made using a hybrid platform where the DETL was coded using Microsoft Excel (ME) and the separation process was rigorously simulated using Aspen plus. For the optimisation of process routes analysed in this study, the following parameters for DETL method were used: 200 individuals, 300 generations, a tabu list of 50% of total individuals, a tabu radius of 0.0000025, 0.80 and 0.6 for crossover and mutation fractions, respectively.

4. Results

The results of the optimisation are illustrated in Figure 3. The possible optima are illustrated inside the oval. The point (a) which considers the use of a HEX-HEP mixture as extracting agent was determined as the optimal point, with a mass fraction in the feed stream of 0.3799 for n-hexyl-acetate and 0.6201 for n-heptyl. The TAC was equal to 2,956,262 US\$/year and eco indicator = 1,013,908 points/year. The comparison between the optimal scenarios for TAC and eco-points with the base case (BC) point scenarios for HEX (b), HEP (c), and the mixture HEX-HEP (d) indicated that the BC points were 2.3, 3 and 4.6 time higher for the TAC and 2.7, 3.1 and 4.8 times higher for the eco-indicator, respectively. The results showed an improvement in the terms of the economic and environmental because of reduction in the amount of extracting agent. In other words, the best points for each case were obtained using 22,938.57 kg/h in comparison with 39,040.8 and 77,646.9 kg/h for HEP and HEX respectively. Thus, the optimisation task undoubtedly achieved its objectives.

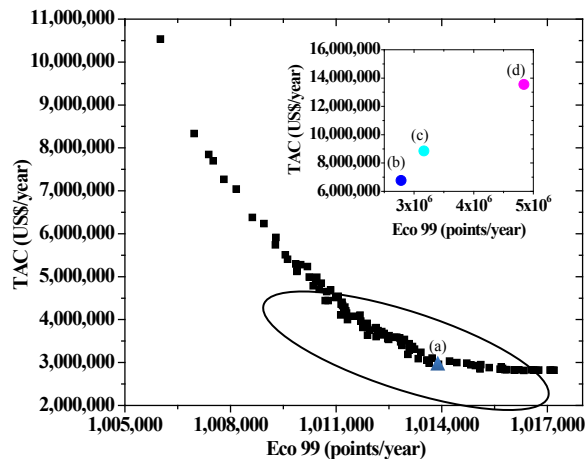

Figure 3. Pareto Chart for determining the optimal process design in terms of economic and environmental aspects.

Table 1 shows the optimal (Opt) specifications compared with the BC scenario. The results showed the D-101 and D-103 units are shorter, and the reflux ratio was highly decreased. The reflux ratio in D-103 was reduced several times that results on the reduction of the operation cost because of the heat duty decrease.

Table 1. Specifications of the unit operations included in the downstream section.

Unit	Base case	Optimal design
C-101	NS=5; P=1 atm; ABE-water/HEX-HEP =1.60; TT= 21.5°C; BT= 24°C	NS=7; P=1 atm; ABE-water/HEX-HEP =1.9; TT= 21.6°C; BT= 24.3°C

5. Conclusion

This study proposed a framework for the simultaneous design of the mixture of extracting agents employed in the LLE process, as well as the process design of the required equipment in the separation and purification process for ABE. The framework was possible due to the combination of different methods and computer-aided tools. The results showed an improved design by reducing the TAC and the eco-indicator 78% and 79%, respectively, because of the reduction in the amount of extracting agent. The enhancement was achieved due to the optimal and rigorous mixture and molecular design that provided the appropriate composition for the mixture of the extracting agents in the LLE unit, which had better performance as previous solvents used before.

Optimal Design and Operation of Hybrid Osmosis Processes for Simultaneous Production of Water and Power under Different Demand Conditions

jcjeng@ntut.edu.tw

Abstract

This study investigates the optimal design of hybrid osmosis process systems for simultaneous seawater desalination and power production under different demand conditions. Optimization of four serial configurations that connect the RO, PRO, and FO processes with different order (i.e., RO-PRO, PRO-RO, FO-RO-PRO and PRO-FO-RO) are conducted by minimizing the total annual cost (TAC). The results show that the configurations with FO process are not cost-effective. The PRO-RO system is more favorable when the water demand is relatively large compared to the power demand and when higher water quality is demanded. Furthermore, a general RO/PRO structure that involves more flexible connection of streams is developed and optimized. Compared with the serial configurations, the optimal general structures allow reductions of TAC up to 35%, depending on the demand scenarios. The results also reveal that there exists an optimal concentration of water permeate under a specific demand condition. The proposed model of process integration is effective for designing hybrid osmosis process systems to simultaneously produce water and power on demand.

Keywords: Process optimization, Reverse osmosis, Pressure retarded osmosis, Forward osmosis, Seawater desalination.

1. Introduction

It is recognized that potable water and energy are gradually insufficient for human needs. To exploit sustainable resources, technologies have been developed to desalinate seawater and produce power using salinity gradient. Reverse osmosis (RO) is one of the major technologies for desalinating seawater, while pressure retarded osmosis (PRO) is a promising technology for power production. Therefore, the hybridization of RO and PRO processes enables the build of dual-purpose desalination/power plants (Almansoori and Saif, 2014). Senthil et al. (2016) modelled six hybrid RO-PRO structures to minimize the net specific energy consumption (NSEC). The results showed that NSEC could be lowest when PRO draw solution entirely recycled to RO feed with an energy recovery device. However, there will be no power generation. Furthermore, forward osmosis (FO) can be used as a pre-treatment process of RO to reduce the extensive energy consumption required in RO process. Blandin et al. (2015) studied the energy consumption and economic evaluation of FO-RO hybrid. They reported that FO-RO hybrid can be beneficial for high energy costs and/or substantial operational cost savings. Altee et al. (2015) studied the impact of the draw and feed solutions' flow rate

and the impaired water TDS on the performance of three design configurations, PRO-RO, FO-RO, and RO-PRO.

In this study, we focus on the optimal design and operation of the hybrid osmosis systems that integrate the RO, PRO, and FO stages for power production and seawater desalination. The most efficient configuration of the hybrid likely depends on the demand conditions of water and power. Design configurations of four serial structures and a more flexible structure are proposed and the optimizations are carried out by minimizing the total annual cost (TAC). The effects of the demand conditions on the optimal structure and operation of the hybrid osmosis systems are investigated.

2. Configurations of hybrid osmosis process

Figure 1 shows four structures that connect the osmosis processes in series (i.e., RO-PRO, PRO-RO, FO-RO-PRO, and PRO-FO-RO). The seawater (TDS 35000 ppm) can be chosen entering any osmosis processes, serving as the RO feed or as the draw solution of FO and PRO. The leaving stream of a preceding osmosis process can be partly discharged before entering the next osmosis process. The feed solution of FO and PRO are municipality water (TDS 2000 ppm). The pressure exchanger (PX) is an energy recovery device that transfers pressure from a high-pressure stream to a low-pressure one. Hydro-turbine generates power when PRO draw solution partly passed it.

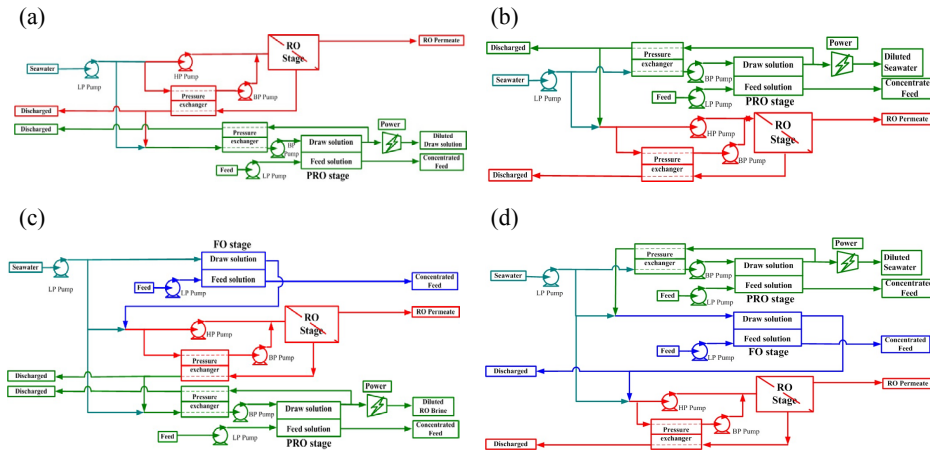

Figure 1. Four serial configurations of hybrid osmosis processes. (a) RO-PRO; (b) PRO-RO; (c) FO-RO-PRO; (d) PRO-FO-RO.

3. Optimization model

The MINLP optimization model describes the design and operation of the hybrid osmosis systems. The mathematical programming equations involve the mass balance for the mixing/splitting points and the model equations for the osmosis stages. Binary variables define the number of pressure vessels and number of membrane modules in a pressure vessel for each osmosis stage. Continuous variables define the flow rate, concentration, and pressure in the system. The model equations for RO, PRO, and FO stages have been given by Almansoori and Saif (2014) and Blandin et al. (2015). The characteristics of the membrane for RO, PRO, and FO are shown in Table 1.

Table 1. Characteristics of RO, PRO, and FO membrane (Almansoori and Saif, 2014; Blandin et al., 2015).

	RO	FO	PRO
active area (m ²)	37.2	37.6	37.6
length of the element (m)	0.88	2.25	2.25
feed channel equivalent diameter (m)	0.0008126	0.0025	0.0025
feed flow rate range (kg/s)	0.22-4.5	0.22-4	0.22-4
feed cross-section open area (m ²)	0.0147	0.0097	0.0097
void fraction of the spacer	0.9	0.8	0.8
maximum operating pressure (Mpa)	8.3	1	2
water permeability (kg/m ² · s · Mpa)	0.0035	0.013	0.012
TDS permeability (kg/m ² · s)	0.000032	0.00012	0.000457
structural parameter (m)	1000	0.00000346	0.00000034

The objective function for minimization is the total annual cost (TAC) which is defined as the sum the annualized total capital cost (ATCC) and annual operation cost (AOC). The TCC comprises the capital costs (CC) of pressure vessels and membranes, seawater and municipality water intake/pretreatment equipments, booster and high pressure pumps, pressure exchangers, and hydro-turbine:

$$ATCC = 0.071 \left(\sum_i CC_i^{PV} + \sum_i CC_i^{SWIP} + \sum_j CC_j^{MWIP} + \sum_k CC_k^{BP} + CC_{RO}^{HPP} + \sum_k CC_k^{PX} + CC_{PRO}^{HT} \right) \quad (1)$$

$$\begin{aligned} CC_i^{PV} &= C_i^{Mem} (NE_i \times NPV_i) + C_i^{PV} NPV_i; \quad CC_i^{SWIP} = C_i^{SWIP} (F_i^{SWIP})^{0.8}; \quad \forall i \in RO, PRO, FO \\ CC_j^{MWIP} &= C_j^{MWIP} (F_j^{MWIP})^{0.8}; \quad \forall j \in PRO, FO \\ CC_k^{BP} &= C_k^{BP} F_k^{BP} \Delta P_k^{BP}; \quad CC_k^{PX} = C_k^{PX} (F_k^{PX})^{0.58}; \quad \forall k \in RO, PRO \\ CC_{RO}^{HPP} &= C_{RO}^{HPP} F_{RO}^{HPP} \Delta P_{RO}^{HPP}; \quad CC_{PRO}^{HT} = C_{PRO}^{HT} F_{PRO}^{HT} \Delta P_{PRO}^{HT} \end{aligned} \quad (2)$$

where C_i^{Mem} is the capital cost of a membrane, NE_i is the number of membranes in a pressure vessel, NPV_i is the number of the pressure vessels, C is the capital cost coefficient, F is the mass flow rate, ΔP is the pressure difference, and 0.071 is the annualized factor. The AOC comprises the operation cost (OC) of pressure vessels, seawater and municipality water pretreatment, booster and high pressure pumps, equipment insurance, maintenance, chemical usage, and labor:

$$AOC = \sum_i OC_i^{PV} + \sum_i OC_i^{SWIP} + \sum_j OC_j^{MWIP} + \sum_k OC_k^{BP} + OC_{RO}^{HPP} + \sum_i OC_i^{ins} + \sum_i OC_i^{maint} + OC_{RO}^{chem} + OC_{RO}^{lab} \quad (3)$$

$$\begin{aligned} OC_i^{PV} &= O_i^{PV} CC_i^{PV}; \quad OC_i^{SWIP} = O_i^{SWIP} \frac{F_i^{SWIP} \Delta P_i^{SWIP}}{\eta^{SWIP} \eta_{MOTOR}}; \quad \forall i \in RO, PRO, FO \\ OC_j^{MWIP} &= O_j^{MWIP} \frac{F_j^{MWIP} \Delta P_j^{MWIP}}{\eta^{MWIP} \eta_{MOTOR}}; \quad \forall j \in PRO, FO \\ OC_{RO}^{HPP} &= O_{RO}^{HPP} \frac{F_{RO}^{HPP} \Delta P_{RO}^{HPP}}{\eta^{HPP} \eta_{MOTOR}}; \quad OC_k^{BP} = O_k^{BP} \frac{F_k^{BP} \Delta P_k^{BP}}{\eta_{BP} \eta_{MOTOR}}; \quad \forall k \in RO, PRO \\ OC_i^{ins} &= O_i^{ins} \times TCC_i; \quad OC_i^{maint} = O_i^{maint} \times TCC_i; \quad \forall i \in RO, PRO, FO \\ OC_{RO}^{chem} &= O_{RO}^{chem} F_{RO}^{FEED}; \quad OC_{RO}^{lab} = O_{RO}^{lab} F_{RO}^{PERM} \end{aligned} \quad (4)$$

where O is the operation cost coefficient and η is the efficiency factor. The parameters and cost coefficients for calculation are shown in Table 2.

Table 2. The parameters and cost coefficients for calculation (Almansoori and Saif, 2014).

$C_{RO}^{Mem} / C_{PRO}^{Mem} / C_{EO}^{Mem}$ (\$)	1200/1000/1500	O_i^{PV} (yr^{-1})	0.2
C_i^{PV} (\$)	1000	O_i^{SWIP} , O_i^{MWIP} ($\text{kW}\cdot\text{yr}^{-1}$)	946
C_i^{SWIP} , C_i^{MWIP} ($\text{\$ (kg/s)}^{-0.8}$)	35300	O_{RO}^{HPP} , O_{RO}^{HPP} ($\text{\$ (kW}\cdot\text{yr)}^{-1}$)	946
C_k^{PX} ($\text{\$ (kg/s)}^{-0.58}$)	6590	O_i^{ins} (yr^{-1})	0.005
C_{RO}^{HPP} , C_k^{BP} , C_{PRO}^{HT} ($\text{\$ (kg/s}\cdot\text{Mpa)}^{-1}$)	187	O_i^{main} (yr^{-1})	283.8
η^{HPP} , η^{BP} (%)	75	O_{RO}^{chem} ($\text{\$ (kg/s}\cdot\text{yr)}^{-1}$)	638.6
$\eta^{PX} / \eta^{HT} / \eta^{MOTOR}$ (%)	95/90/98	O_{RO}^{lab} ($\text{\$ (kg/s}\cdot\text{yr)}^{-1}$)	283.8

The water production in the RO stage and the power production in the PRO stage should meet the designer-specified water and power demands, respectively. In addition, the quality (concentration) of product water should meet the designer-specified specification.

4. Results and discussion

4.1. Results for the serial configurations

To investigate the effect of demand conditions on the optimized hybrid osmosis system, three water demands (50, 150, and 250 kg/s) and three power demands (50, 150, and 250 kW), with a total of nine cases, are considered for the optimization. Furthermore, two specifications of product water concentration, i.e., 250 and 500 ppm, are considered.

The MINLP problems were solved using the GAMS software. Table 3 shows the best configuration that has the lowest TAC among the four configurations for each of the demand scenarios. The results show that the configurations with FO stage are not cost-effective in all the cases. Compared the FO-RO-RPO with the RO-PRO system, the use of FO stage can be beneficial for RO stage, while it has a negative impact on the PRO stage for power production. Compared the PRO-FO-RO with the PRO-RO system, the advantage of using FO stage becomes minor because the seawater has been diluted by the PRO stage that results in a low salinity gradient for the FO stage.

For the systems without FO stage, the PRO-RO system is more favourable when the water demand is relatively large compared to the power demand because the seawater feeds to the RO stage has a lower salinity. On the contrary, the RO-PRO system is suitable for large power demand because a higher salinity gradient becomes available for the PRO stage. Furthermore, the PRO-RO system tends to be more effective when a higher water quality (lower water concentration) is demanded.

Table 3. The configuration that has the lowest TAC for each of the demand scenarios.

Demand	250 ppm			500 ppm		
	50 kg/s	150 kg/s	250 kg/s	50 kg/s	150 kg/s	250 kg/s
50 kW	PRO-RO	PRO-RO	PRO-RO	RO-PRO	PRO-RO	PRO-RO
150 kW	RO-PRO	PRO-RO	PRO-RO	RO-PRO	RO-PRO	PRO-RO
250 kW	RO-PRO	RO-PRO	PRO-RO	RO-PRO	RO-PRO	RO-PRO

4.2. A more general RO/PRO hybrid structure

In addition to the configurations that connect the osmosis process in series, we further develop a more flexible structure that involves the recirculation of the stream leaving

the last stage. The recirculation of stream has the advantage of reducing pre-treatment cost and environmental impact. Because systems with FO stage are not cost-effective, only the RO and PRO stages are considered in the general structure. Figure 2 shows the general structure where the leaving stream from one stage can be recycled as the feed of the other stage.

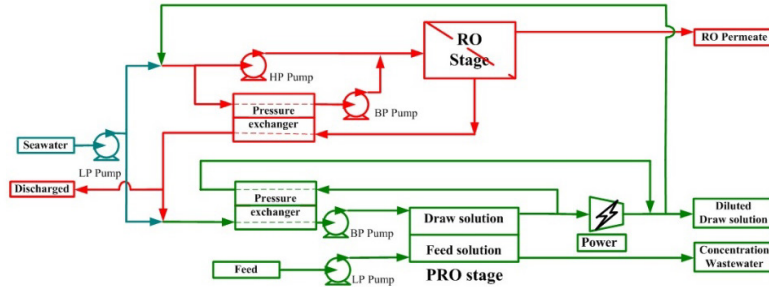

Figure 2. General structure of hybrid osmosis system of RO and PRO stages.

The minimum TAC for the general structure as well as those for the previous four serial structures under different demand conditions are presented in Figure 3. The general structure can be solved with the lowest TAC among the five structures for all the demand conditions. Compared with the optimal serial structure, the general structure allows a more than 25% improvement of TAC for most of the cases, with a maximum of 35% for the case of 250 kg/s (250 ppm) water and 50 kW power. In three cases (50 kg/s & 150 kW, 50 kg/s & 250 kW, and 150 kg/s & 250 kW), the TAC of the optimized general structure is close to that of the optimal serial structure. The optimization results indicate that the recirculation ratio of PRO draw solution is much lower in these three cases so that a large flow rate of seawater enters the system. This is because large draw solution recirculation would diminish the stream salinity in the system and, therefore, causes the PRO stage inefficient in the case of low water and high power demand.

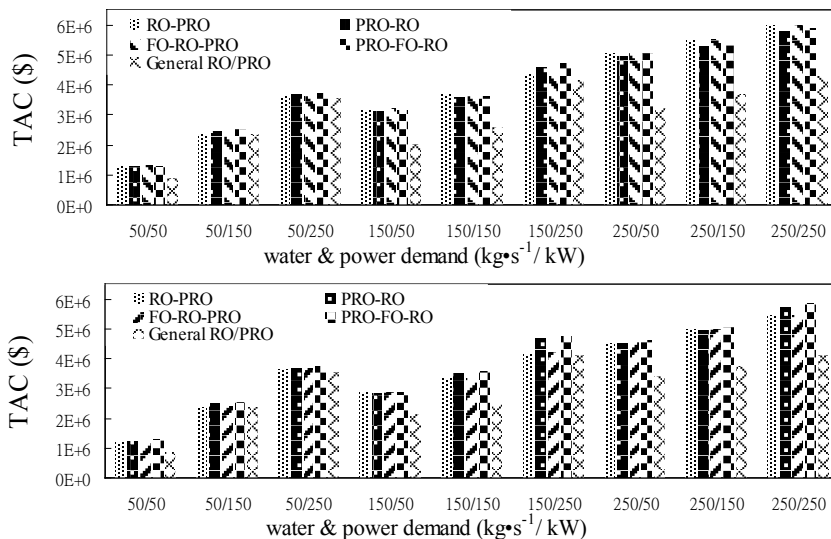

Figure 3. Minimum TAC for different demand conditions with product water TDS 250 ppm (up) and 500 ppm (down).

The effect of target product water concentration on the minimum TAC is also investigated. Figure 4 shows the minimum TAC of the general structure for the demand conditions of 150 kg/s & 50 kW with various target product water concentrations. The minimum TAC is identified at the product water concentration of 257 ppm. A higher product water concentration (lower RO brine TDS) may reduce the RO cost for water production but the PRO cost for power production is increased. On the other hand, the RO cost is increased for a lower product water concentration but the resulting higher RO brine TDS is advantageous for the PRO power production. Therefore, specifying a product water concentration greater than the optimal value should be avoided.

Figure 4. Minimum TAC of the general structure for the demand condition of 150 kg/s & 50 kW.

5. Conclusions

In this study, the optimizations of hybrid osmosis processes for simultaneous production of water and power under different demand conditions are presented and the results are analyzed. It is found that the use of FO as the pre-treatment unit for the RO stage is not cost-effective in the dual-purpose desalination/power plants. This is due to not only the extra capital cost of FO stage but also the insufficient salinity gradient in the PRO stage. For the systems with serial connection of RO and PRO stages, the favorable structure depends on the demand conditions and the target product water concentration. An efficient system is that the stage producing the major product follows the other stage. The proposed optimization model of the general structure can provide an effective RO/PRO integrated system for simultaneously producing water and power on demand.

Abstract

Although the methodologies of optimization-based process synthesis have evolved significantly during the last thirty years, the ability to robustly and accurately solve industrially-relevant global flowsheet problems remains limited. Engineering expertise and simulation-based sensitivity analysis still remain an essential guide for system alternatives generation and key devices selection.

The purpose of this study is to provide a superstructure mixed-integer nonlinear programming (MINLP) optimization within the commercial simulator ProSimPlus. The entire optimization loop is directly managed by the simulator and both continuous variables and discrete integer variables are optimized simultaneously by an external metaheuristic optimizer called MIDACO (Mixed Integer Distributed Ant Colony Optimization).

Keywords: Superstructure, Optimization, Process Simulator, MINLP, Ant Colony Optimization

1. Introduction

Thanks to the advances made in artificial intelligence and mathematical programming, the computer-aided approaches in process synthesis (e.g., superstructure optimization) have evolved significantly during last thirty years (Voll et al., 2013). Nevertheless, low disseminations of such optimization into the industrial community are noticed because that real-world industrial studies are complex non-linear and non-convex problems (Barnicki and Sirola, 2004; Quaglia et al., 2015).

One of the widely applied approach is the equation-based optimization, yet there is a known compromise on solution quality obtained (i.e., rigorousness) since linear approximation or surrogate models are frequently applied (Chen and Grossmann, 2017). On the other hand, simulator-based optimization approach has been received more attention recently since it can benefit directly from the reliability and rigor of process simulator. Regarding this topic, studies have been carried out in different applications such as distillation systems (Bravo-Bravo et al., 2010; Leboreiro and Acevedo, 2004; Caballero et al., 2005; Corbetta et al., 2016), chemical processes retrofit, (Diwekar et al., 1992; Gross and Roosen, 1998; Brunet et al., 2012; Chen et al., 2015) as well as

energy conversion system application (Wang et al., 2014). The MINLP optimizations carried out within process simulator (Flowtran, Aspen Plus, Aspen Hysys, PRO/II or Epsilon Professional) require an additional interface (i.e., GAMS, C++), requiring tedious supporting tool construction.

In this work, a superstructure MINLP optimization of SC-CO₂ Brayton cycle is brought out with ProSimPlus, a commercial simulator. Unlike researches cited above, our strategy is to use ProSimPlus as main (and the only) interface to both manage the graphical representation of the superstructure as well as the MINLP optimizer. An external solver MIDACO (Schluter et al., 2009), an Ant Colony Optimization (ACO) metaheuristic algorithm is applied for the MINLP problem discussed in this paper. The rigorous models for unit operations implemented in ProSimPlus are directly used during the MINLP optimization without approximation.

2. Methodology

2.1. Metaheuristic optimization with MIDACO

The motivation of using metaheuristic optimizer MIDACO in this study is its black-box and stochastic probabilistic nature. The first property allows to optimize non-convex MINLP problem without explicit expression of the objective and constraint functions. Secondly, the stochastic nature of ACO makes it possible to selectively search a much smaller fraction of the solution space thus reduces the computational time efforts.

2.2. Optimization unit in ProsimPlus

The link with an external optimizer is made possible in ProSimPlus thanks to predefined communication interfaces that are implemented in the ProSimPlus standard optimization unit.

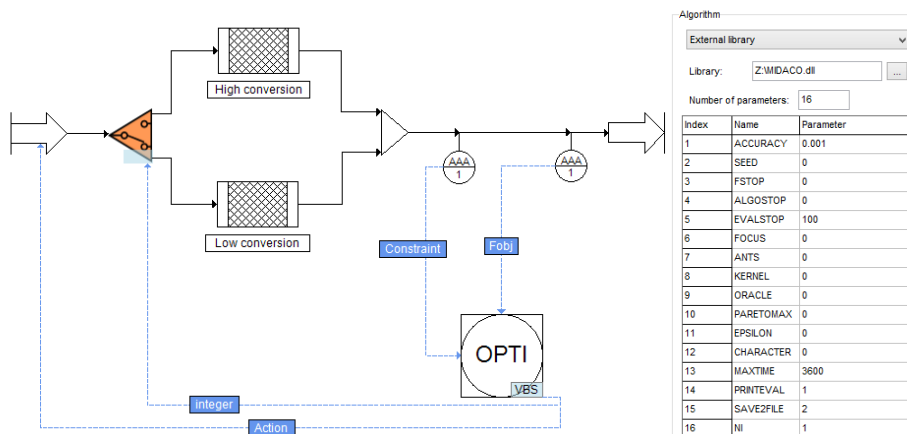

Figure 1 Illustration superstructure graphic representation (left) and optimization unit (right) in ProSimPlus, case of a Two Reactors Problem (blue dashed lines are information streams: 1 objective function, 1 constraint, 1 integer decision and 1 continuous variables)

If a user does not want to use the native stochastic optimization (genetic algorithm) or the default nonlinear programming optimization algorithm (based on a SQP method), it

is possible to select an external dynamic library which implements these communication interfaces and is statically or dynamically linked with the external algorithm.

When the external solver is provided as a dynamic link library, a wrapper dll is needed to perform the communication between ProSimPlus and the external algorithm.

The value of the objective function as well as the values of the equality and inequality constraints are automatically passed to the external dynamic library to make them available to the external algorithm, which calculates the new values of the optimization variables.

A customizable table of parameters, available in the graphical user interface of the optimization unit, allows to access to the parameters of the external algorithm, see the example in Figure 1 for a simple two reactors problems (such as in Diwekar et al., 1992).

2.3. Formulation strategy in process simulator

2.3.1. Superstructure connectivity

Defining the component connection in superstructure is to characterize the existence of component and to remove the redundant component when it is not used. For our superstructure formulation in this study, redundant component is only virtually removed by simply setting their flow rate to zero.

A multipath (2 or more) logical switch is coded in ProSimPlus. The switch level y_i is thus defined as the integer decision variable in the superstructure optimization and enables to select a specific path between all possible alternatives.

Figure 2 Logic switch defined in this study

2.3.2. Other rules in formulation stage

The result of a MINLP optimization is known to be strongly influenced by the formulation of the problem and the selection of variables. It is thus important to formulate the problem in the way that allows fast and easy convergences of the process simulator flowsheet with all the values in the range between lower and upper bounds (Corbetta et al., 2016). Several rules are set in this paper:

- a) Tear Stream. When the superstructure involves a closed loop or recycle loop, it is necessary to choose tear stream(s) in the simulator (both *feasible path* and *infeasible path* approaches can be used).
- b) Fictive unit. Components situated in the middle of a simulation sequence need to be combined with a fictive unit if the component is to be optimized with constraints along with dependency of other optimized variable. The fictive unit will only be activated if the evaluated scenario is infeasible. When it is active, the work (or heat) consumed by the entire fictive unit need to be considered in the objective function. Consider turbine outlet pressure optimization as an example: its fictive unit is composed of a fictive compressor and a fictive cooler in order to avoid infeasible engineering scenario (when the ratio is smaller than 1). It is preferred to have fictive units than additional inequality constraints (force the pressure ratio greater than 1) since the latter case introduces more non-convexity to the optimization problem.
- c) Counter-current exchangers' separation. The counter-current exchangers used in the superstructure optimization should be divided into two simple parts: a heater and a

cooler. This modification avoids additional simulation iterations inside the counter-current exchanger and reduces the possible divergent cases. The optimization itself benefits faster iteration from the relaxation of counter exchangers.

3. Application examples

3.1. Case study: SC-CO₂ Brayton cycle superstructure optimization

The fundamental aspects of supercritical CO₂ (SC-CO₂) Brayton cycle are under worldwide development, hence importance of optimization. Current optimizations of SC-CO₂ Brayton cycle have only been done to maximize the cycle efficiency with parametric optimization with fixed process topology (cycle configuration). However, an optimal-synthesis searching for the most energy efficient cycle layout can further reveal its real potential in its future deployment.

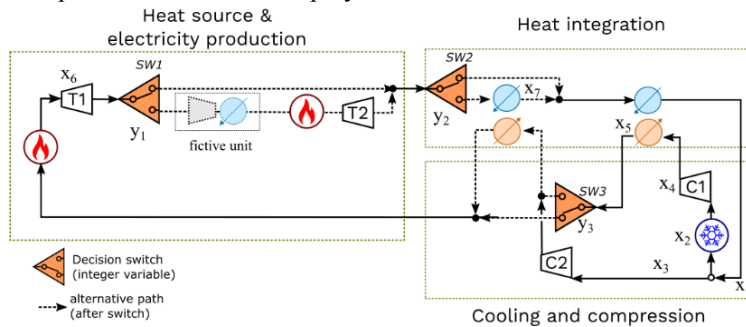

Figure 3 Superstructure of SC-CO₂ Brayton cycle with fictive unit ($2^3=8$ structural alternatives)

The superstructure in Figure 3 integrates some configurations based on previous experiences as well as some innovative design solutions created by the combination. Note that the rules described in section 2.3.2 are respected and a fictive unit is implemented after turbine T1.

The indicator of the energy performance, cycle efficiency, is seen as the objective function. 10 variables (3 integer variable y_1, y_2, y_3) are to be optimized in this MINLP problem.

3.2. Results and discussion

Figure 4 Optimization progress of four runs with different random seeds

Four different optimization runs are carried out with four different pseudo random number (seed) in MIDACO, Figure 4. Note that different random seed has indeed diverse progress of optimization, different corresponding populations are generated.

Moreover, at the end of 6 hours evaluation (up to 16,000 generations), the structural result of the best individual is identical (i.e., identical set of $\{x,y\}$), which also confirms that this layout is the best known solution to the defined optimization problem.

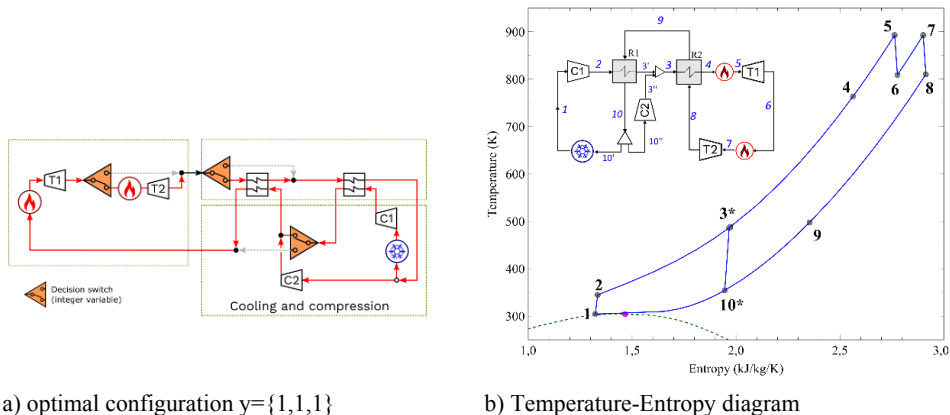

Figure 5 Process synthesis result: optimal flowsheet for the SC-CO₂ Brayton cycle

This optimal process layout with cycle net efficiency as high as 51.4 % is composed of two compressors, two recuperators, and one reheat (thus two turbines). Compared with the initial proposal of SC-CO₂ Brayton cycle by Feher, 1967 and Angelino, 1969, the optimal process configuration has an enforced heat integration. Figure 5 indicates all the exchangers have a minimal accepted thermal pinch (10 K). Furthermore, entropy loss is avoided at mixer since stream 3' and 3'' have the identical temperature and pressure (iso-entropy) before mixing.

4. Conclusion

In this work, we presented a simulator-based approach for superstructure optimization in process simulator ProSimPlus. Compared with other simulator-based optimization methods, the proposed superstructure optimization approach is more general on terms of component and optimizer. Any component available in the simulator can be used in the superstructure generation and external optimizers can be linked with ProSimPlus through its optimization unit.

Furthermore, this paper illustrated how the simulator enables to manage the entire optimization loop while both continuous variables and discrete integer variables are optimized simultaneously by MIDACO.

The case study carried out in this paper illustrate the above advantages of the presented optimization strategy. The obtained results are the best known optimal design for both application studies. In addition, the formulation rules provided in this paper guarantees the convergence of simulation which helps to reduce the infeasible region search while optimizing both continuous and integer variables.

Abstract

Taking into account the increase of business competitiveness and legislation compliance faced by industry's SC, environmental SC problems became a reality that companies have to deal with. This work is developed along this line and proposes a mixed integer linear programming model (MILP) that accounts for the economic and environmental pillars in the same objective function by monetizing environmental impacts. Economic and environmental performances are taking into account in the same unit allowing a single optimum solution. Conclusions can be drawn on how monetization can support decision maker's decision. To show model applicability a real-based SC is studied.

Keywords: supply chain, sustainability, monetization, design and planning

1. Introduction

Supply chain (SC) is an essential system in any organization, which has been studied for several years due to its importance in both research and industrial communities. Taking into account the increasing organizational competitiveness and governmental pressures, SC has expanded its main focus on economic profits to include environmental and social concerns as well (Barbosa-Póvoa et al., 2017). In addition, SC encompasses several complex decisions related to the number of products, entities, and variables involved. Thus, managing sustainable supply chains (SSC) towards efficient and sustainable objectives is a challenge, especially if this management encompasses the design and planning of the chain. Most SSC design and planning approaches have employed multi-objective methods to optimize the SC. In fact, the majority of real-world decision problems involve the optimization of more than one objective at the same time. As an example, considering the concern and awareness towards sustainability issues, stakeholders want to optimize companies' environmental performance, while accounting for economic issues. Therefore, multi-objective optimization methods are needed to analyze trade-offs between environmental and economic performances. However, the adequate weighting of such objectives is still a problem to be solved. In fact, these methods require a subjective weighting factors assignment for objectives by decision makers (Lim et al., 2013). In this context, the need to develop a mathematical optimization model with a single objective function for the economic and environmental pillars of sustainability becomes clear. One way to achieve this is by monetizing environmental impacts. According to Herendeen (1998), monetization is helpful to understand the cost of environmental impacts. For this reason, we intend to perform a monetization of environmental impacts of a real SC. Conclusions can be drawn on how these two pillars of sustainability can influence the SC design and planning decisions, and on how monetization can support decision maker's decision.

2. Environmental monetization methodologies

Diverse methods for assessing environmental impacts are available. Life cycle assessment (LCA) is one of the most used methodologies, which is composed by four main phases. The first one includes the goal and scope definition, where the context of the study is set out. This is a key phase that has to be clearly defined and consistent with the intended application as ISO standards require. The second phase is related to inventory analysis, which involves creating flows' inventory from and to nature for a system. These inventory flows can include inputs of water, energy, raw materials, releases to air, land, and water, and include the activities that are going to be assessed in the SC. The third step is the life cycle impact assessment (LCIA) phase that aims to evaluate the significance of potential environmental impacts based on the life cycle inventory flow results. This is a controversial phase because it encompasses the assignment of weighting factors by decision-makers and the difficult choice of the best methodology to use. The fourth phase is the life cycle interpretation that allows the identification, quantification, check and evaluation of the information from the LCA results. On the LCIA phase monetization is one methodology that can be used. Three monetization methods have been used to convert environmental impacts into monetary units (Chen and Holden, 2018), namely EPS, Eco-cost and Stepwise. According to the European Commission, EPS 2000 is a quite complete method and it has the uncertainties fully specified when compared to other LCIA methods. Thus, in this work, monetization is performed by using EPS. The environmental impacts are quantified in a monetary unit through EPS, which is mainly derived from the willingness-to-pay (WTP). The WTP values resulted from academic knowledge to proactively reduce environmental impacts (Steen, 1999).

3. Problem description and model characterization

The problem in study considers the SC design simultaneously with all the associated planning activities. The generic SC considered is represented in Figure 1, where raw materials flow from suppliers to factories and final products are obtained. Then, these final products flow to warehouses or directly to markets. End-of-life products can be recovered at the markets and sent to warehouses or directly to factories, where they are remanufactured. Transportation between SC entities can occur by unimodal or intermodal transportation. Thus, the problem under study can be defined as: given, the possible set of locations of SC entities, production and remanufacturing technologies, possible transportation modes between entities, and products within the SC; the goal is to obtain: the SC network structure, supply and purchase levels, entities' capacities, transportation network, production, remanufacturing and storage levels, supply flow amounts, and product recovery levels; in order to: maximize profit, and minimize environmental impacts.

Figure 1. Scheme of SC network

To solve the above problem a Mixed Integer Linear Programming (MILP) model is developed considering as basis the formulation from Mota et al. (2017). The economic

and environmental performances are considered independently and simultaneously in the objective function.

The economic objective function is obtained from the maximization of the Net Present Value (NPV), see Eq. (1). This is assessed through the sum of the discounted cash flows (CF) in each period at a given interest rate. These CF are obtained from the net earnings, which are given by the difference between incomes and costs. The costs include raw material costs, production/remanufacturing operating costs, product recovery costs, transportation costs, handling costs at the hub terminal, contracted costs with airline or freight, inventory costs, and labor costs. Also, for the last time period, it is considered the salvage values of the SC (FCI³). The environmental impact is obtained using EPS 2015, which is an updated version of EPS 2000. Considering the SC as a functional unit, LCA is performed on the transportation modes and on entities installed in the SC boundaries. The Life Cycle Inventory is retrieved from the Ecoinvent database (assessed through SimaPro 8.4.0 software). From these results, an inventory list is obtained, and knowing the corresponding quantities, it is determined the environmental impact of each activity (transport and installation of entities). The results are expressed in Environmental Load Units (ELU) and used as input data in Eq. (2), namely the environmental impact of transportation (first term) and environmental impact of entity (second term). Finally, Eq. (3) reflects the objective function that is obtained through maximization of the difference between NPV and environmental impact (EnvImpact).

$$\max \text{NPV} = \sum_{t \in T} \frac{CF_t}{(1 + ir)^t} - \sum_{\gamma} FCI_{\gamma} \quad (1)$$

$$\min \text{EnvImpact} = \sum_{\substack{t \in T \\ (a,m,i,j) \in \text{NetP}}} ei_{ac} pw_m d_{ij} X_{majt} + \sum_{i \in I_f \cup I_w} ei_{ic} YC_i \quad (2)$$

$$\max \text{NPV} - \text{EnvImpact} \quad (3)$$

4. Case study

To show the applicability of the proposed methodology a case-study of a real SC based in Italy, already addressed by Mota et al. (2017) is considered. The company's suppliers are located in Verona. Currently, the company owns a factory and a warehouse in Verona with sufficient capacity to meet the demand of their existing clients. These clients are located in three main markets: Spain, Italy, and Germany. Currently, the SC capacity cannot meet a demand increase and four new potential clients induce the company's decision-makers to study different SC possibilities of expansion. Given the locations of the clients, Leeds and Hannover are possible locations for installing new factories, which may lead to significant changes in the transportation modes, especially for clients that are located outside Europe. Also, other possible warehouse locations are to be considered namely in Hannover, Leeds, Zaragoza, Lisbon, São Paulo and Recife, being these close to the markets. In addition, Budapest and Sofia are also possible considerations, given the economic and social attractive features.

Regarding SC products, there are two types of products (fp1 and fp2) that are currently being produced in Verona through technologies gp1 and gp2, respectively. However, there are two new technologies (gp1alt and gp2alt) available to produce the referred products. Final product fp1 can be obtained either through technology gp1 or gp1alt. In

the same way, final products fp2 can be obtained through technologies gp2 and gp2alt. End-of-life products can be recovered, being referred as rp1 and rp2. These can be remanufactured into final products through remanufacturing technology gr1 and gr2.

Related to transportation, there are two available options, namely unimodal and intermodal that can be performed only by road or through a combination of road, air and sea transportation modes, respectively. In addition, transportation by road implies investment in trucks. There are two types available (Truck1 and Truck2) that vary in terms of capacity, investment costs, depreciation rate, variable costs, and vehicle consumption.

Based on the SC reality, three scenarios are designed to understand the different decisions that can be made, regarding design and planning of the SC. These are:

Scenario A: studies the solution with the optimum economic performance as main target;

Scenario B: studies the solution with the optimum environmental performance as main target, assessed using two different methods: EPS and ReCiPe;

Scenario C: studies the solution with the optimum balance between economic and environmental performances (the later assessed using EPS).

5. Results

Table 1 shows the total environmental impact and the NPV obtained in each scenario. Comparing all scenarios, it can be seen that scenario A has the highest NPV associated, resulting from the maximization in its objective function. On the other hand, scenario B, which minimizes the environmental impact has the lowest NPV value independently of the environmental method used. When using the ReCiPe methodology (as described in Mota et al., 2017) the environmental impact is translated into 389,238.00 points (Pts), while when using the EPS methodology the environmental impact corresponds to 508,676,145.00 €. Finally, scenario C represents the maximization of the difference between NPV and environmental impact costs, which can only be performed due to the monetization of environmental impact, performed through the EPS method.

Table 1. Results for the economic (NPV) and environmental (EPS and ReCiPe) performances.

	Scenario A	Scenario B		Scenario C
	-	EPS	ReCiPe	EPS
Objective function	Max. NPV	Min. EnvImpact		Max. (NPV-EnvImpact)
NPV	1,280,985,986.00 €	878,621,338.00 €	832,789,347.00 €	1,279,892,213.00 €
Environmental impact	110,483,902,918.00€	508,676,145.00 €	389,238.00 Pts	516,848,072.00 €

Thus, comparing scenario A with C, it is possible to say that the SC global profit is reduced in 1 million euros, but the environmental impact improved almost 110 billion euros, which is only possible to achieve with a single objective function. Moreover, between scenario B and C, we can note that global profit increased more than 400 million euros, while environmental impact is worst at almost 8 million euros.

Table 2 shows SC structure decisions considering the objectives explained in Table 1. It can be seen that there are some variations across the scenarios studied. In addition to the already existent Verona factory, all scenarios suggest that two other factories should be installed, namely Hannover and Leeds. On the warehouses, the results of all scenarios show that there is a need to increase global capacity by opening new warehouses. Scenario A and C have a warehouse located in Sofia, which is justified by the smaller

construction costs. On the other hand, scenario B has warehouses located in different places, which is a result of environmental impacts' balance between both entities installation and transportation.

Table 2. Summary of the SC decisions considering the different scenarios

	Scenario A		Scenario B		Scenario C
	-		EPS	ReCiPe	EPS
Factories			Verona, Hannover, and Leeds		
Warehouses	Verona and Sofia		Verona Lisbon	and Verona, Leeds and São Paulo	Verona and Sofia
Suppliers	Verona and Leeds		Verona, Hannover, and Leeds		
Suppliers allocation	Verona supplies factories in Verona and Hannover. Factory in Leeds is supplied by Verona and Leeds		Factories are supplied in totally by closest supplier		
Production	Most production of fp1 is in Verona				
	Most production of fp2 is divided between Hannover and Leeds				
Remanufacturing	Most remanufacturing of fp1 is performed in Leeds. Most remanufacturing of fp2 is performed in Hannover		Mostly performed in Leeds. The remaining is divided between Verona and Hannover		Mostly performed in Verona. The remaining is divided between Hannover and Leeds
Product recovery	Minimum possible				
Inventory	fp1 and fp2 divided between Verona and Sofia		fp1 divided between Verona and Lisbon; and most inventory of fp2 kept in Verona	Most fp1 kept in Leeds and São Paulo; and fp2 divided between Verona and São Paulo	fp1 divided between Verona and Sofia; and most inventory of fp2 kept in Verona
Transportation	Road	8 Truck1 and 15 Truck2	6 Truck1 and 22 Truck2	1 Truck1 and 24 Truck2	3 Truck1 and 18 Truck2
	Air	Not used	Used for some transportation	intracontinental	Not used
	Sea		Used in all cases		

Regarding suppliers' choice and suppliers' allocation it can be seen that in scenario B and C (where environmental impacts are considered), the results reveal that 100% of the needs of each factory are met to the closest supplier of the installed factories and the allocation follows the same principle. This can be explained by the minimization of environmental impact of transportation. On the other hand, in scenario A, the maximization of the NPV leads to a balance between lower costs of raw materials and fewer transportation costs. On the transportation, the truck with more capacity (Truck2) is preferred in scenarios where environmental impacts are accounted for since this has a lower environmental impact. However, in scenario A, the choice between truck types is more balanced due to both lower investment and lower transportation costs of Truck1. Regarding intermodal transportation, sea option is preferred in all scenarios. Finally, air transportation is preferred in scenario B since it has a higher capacity compared with trucks, which compensate in terms of environmental impact. On the other hand, in scenarios A and C, the higher cost of this transportation mode justifies the preference to alternative transportation modes.

Looking closer to all scenarios, it can be seen that the network structure of scenario C is similar to scenario A since both SC entities and transportation modes are the same, with only some differences in the capacities involved and in the flows between entities. This fact added to the values obtained for NPV and environmental impact of these two scenarios leads to the conclusion that there is a huge benefit to the environment with a

low variation of NPV when environmental performance and profit are considered in the same objective function (scenario C).

6. Conclusions

This work aimed to understand how monetization can improve decisions related to design and planning of SSC. Overall, we note that different optimization objectives result in different decisions. In the same way, according to the results, all decisions are interconnected with each other, because a given decision implies that the other SC levels have to adapt. Considering the monetization approach, we are able to quantify the environmental impacts in a monetary unit (€). This process of monetization allows a better comprehension of environmental impacts, particularly for decision-makers, who are accustomed to perceive financial impacts on their SC. Thus, this work intends to provide a financial value for something that is commonly described in the literature as a score helping the decision process. In this way, it is possible to provide a solution that contemplates both economic and environmental performances in the same objective function. When comparing to the most used multi-objective approaches such methodology allows a variety of options for decision makers by comparing the financial and environmental performances. However, decision-makers are often more sensible to analyze decisions evolving monetary units, which can only be achieved by this monetization approach. To conclude, regarding economic and environmental performances, instead of comparing euros with points they can compare euros with euros, respectively supporting as already said a more informed decision.

As future work, some aspects are important to mention. Further research should be done on this topic to evolve monetization approaches in order to be a reliable alternative for multi-objective optimization approaches, particularly in assessing weighting factors. Also, an extension of this work should account for the need of monetizing social impacts considering the three pillars of sustainability in the same unit of analysis.

Abstract

Biocatalytic production of many natural compounds is usually connected with strong inhibition effect of the product; therefore, an innovative process, where reaction and separation steps are integrated into one operational unit, has been developed. There are no general rules for optimal hybrid system design and final decision is made after the economic analysis of different production alternatives (Krishna, 2002). In this paper, the comparison of different process configurations for biotechnological production of 2-phenylethanol from L-phenylalanine by yeasts *Saccharomyces cerevisiae* with strong inhibitory effect on the production strain is presented. Classical fed-batch fermentation and two different hybrid systems were simulated using appropriate mathematical models and compared considering: overall production rate of target product, performance cost of proposed technology, investment cost, energy consumption, waste production. It has been shown that the hybrid system with in-situ product removal using an immersed extractive hollow fibre membrane module with continuous regeneration of organic solvent provides better results in 2-phenylethanol production compared to traditional batch technology.

Keywords: 2-phenylethanol, batch system, hybrid system, bioreactor, membrane extraction.

1. Introduction

In the recent years, the innovations in natural aromas and flavours produced by biotechnological route have been on the rise. One of those flavours is 2-phenylethanol (PEA), an aromatic alcohol with rose-like aroma, widely used in cosmetics, pharmaceuticals or food industry. Nowadays, natural PEA is produced via transformation of L-phenylalanine (PHE) in a bioreactor using yeasts *Saccharomyces cerevisiae*. Process is strongly aerobic and product formation is directly connected to yeast growth. PEA concentrations above 2 g/L severely inhibit yeasts' growth and concentrations above 4 g/L are fatal for the yeasts (Hua and Xu, 2011). Additionally, side product of the growth, ethanol, can produce synergistic inhibitory effect with PEA (Wang et al., 2011). Therefore the usual production time of conventional batch system is 24 h (Červeňanský et al., 2017). In order to prolong the production time and maximize product yield, systems, in which reaction and separation steps are integrated into one operation unit (so called hybrid systems) have been studied and developed (Krishna, 2002).

This work focuses on comparison by means of mathematical modelling of three PEA production alternatives – traditional batch production, and two hybrid systems for in situ PEA removal from fermentation broth. Mathematical models were developed, described and compared with experiments in our previous papers Mihal' et al., 2014, Červeňanský, 2017.

2. System design

2.1. Simulation constraints

For the sake of comparability, basic constraints were set for each of the systems. Based on these constraints, reaction and separation were simulated and the results were used to propose the equipment, design time schedule and calculate capital and operating costs. General constraints applying to all systems are: volume of the bioreactor is 10 m³, final product as 40 wt. % PEA in organic solvent (pentane), initial yeasts concentration in fermentation medium is 3.143 g/L. Furthermore, each system has its own subset of additional constraints, such as fermentation time, based on the characteristics of the system, (Červeňanský et al., 2017).

2.2. Batch system

Based on the results from the simulations, the batch system for PEA production and separation was proposed, as seen in Figure 1. The production starts with filling the bioreactor with glucose, PHE, yeasts and water and Glucose tank (GT) with glucose solution. When the fermentation is done, fermentation broth is transported to Fermentation broth tank (FBT) and subsequently should undergo separation: by microfiltration (MF) biomass is removed and PEA from permeate is extracted in hollow fibre membrane extractive module (E) into organic solvent. Solvent is regenerated in Rectification column (RC), distillate stream contains practically pure pentane and is recycled back to Pentane tank (PT). Product – 40 wt. % PEA solution leaves the column in the bottoms. Time schedule of each unit is shown in Figure 2, the results are summarized in Table 1.

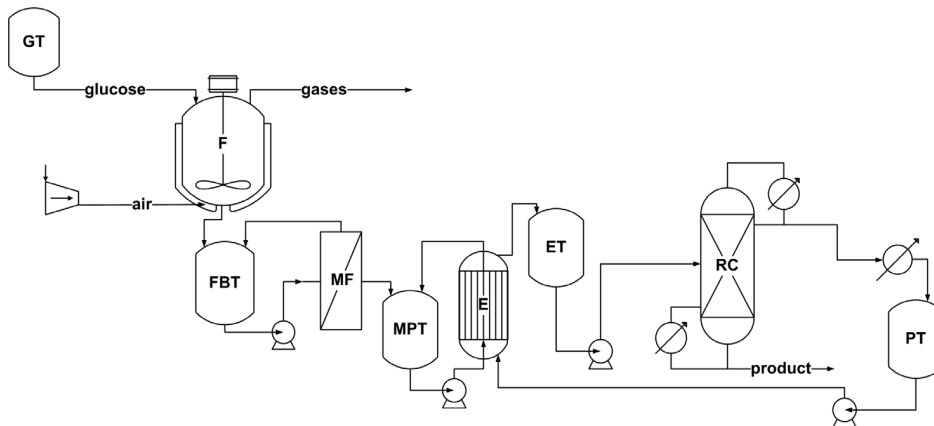

Figure 1 Scheme of proposed Batch system: bioreactor followed by separation steps.

Figure 2 Time schedule of each unit for Batch system.

2.3. Hybrid system I

Hybrid system I integrates bioreactor with separation part (MF with E and RC) resulting in elimination of PEA inhibitory effects, prolonging the fermentation time and keeping PEA concentration below 2 g/L. Figure 3 and Figure 4 show simple process scheme and time schedule of each unit, respectively. In-situ product removal is activated 5 h after the fermentation starts. Fermentation broth is circulated through MF. Retentate is led back into the reactor and permeate is led through Microfiltration permeate tank (MPT) into the E. There, PEA is extracted into pentane and the mixture then continues into Extraction tank (ET). The retentate from extraction is pumped back into the reactor. PEA-pentane mixture from ET is separated in RC, from which distillate is recycled into the PT and bottoms is the desired product.

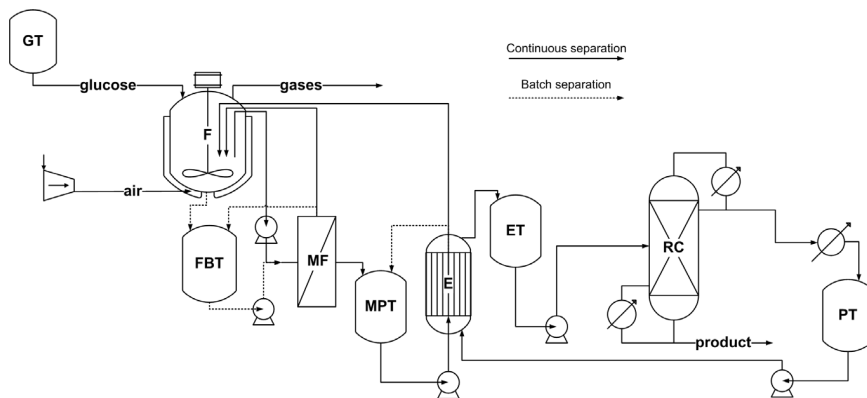

Figure 3 Scheme of proposed Hybrid system I.

Figure 4 Time schedule of each unit in Hybrid system I.

2.4. Hybrid system II

The weakest link in previous Hybrid system I is microfiltration because of membrane fouling at high biomass concentrations. The removal of microfiltration membrane and immersing hollow fibre extraction module into bioreactor (FIEM) leads to lengthening the fermentation time up to 70 h. After 6 h, the extraction starts, and PEA is continually removed directly from the reactor. Similar to Batch and Hybrid system I, PEA is extracted into pentane, then led through ET into the RC. Bottoms is the desired product and distillate is pure pentane, which is recycled into PT. Figure 5 and Figure 6 show overall process scheme and time schedule of equipment.

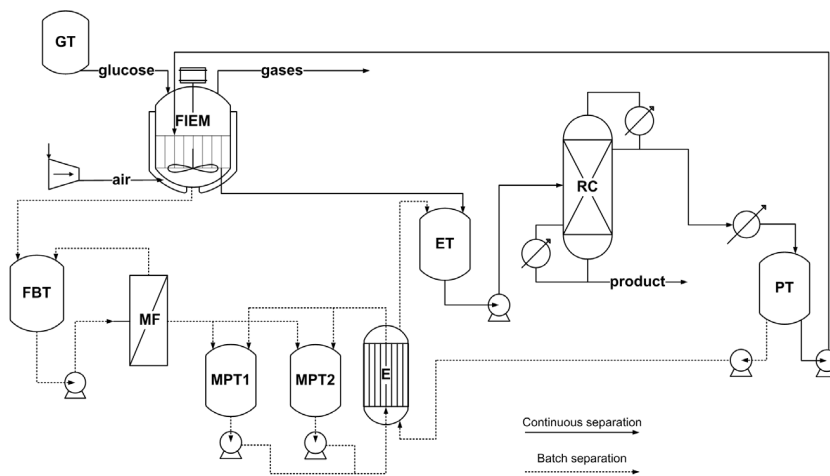

Figure 5 Scheme of proposed Hybrid system II.

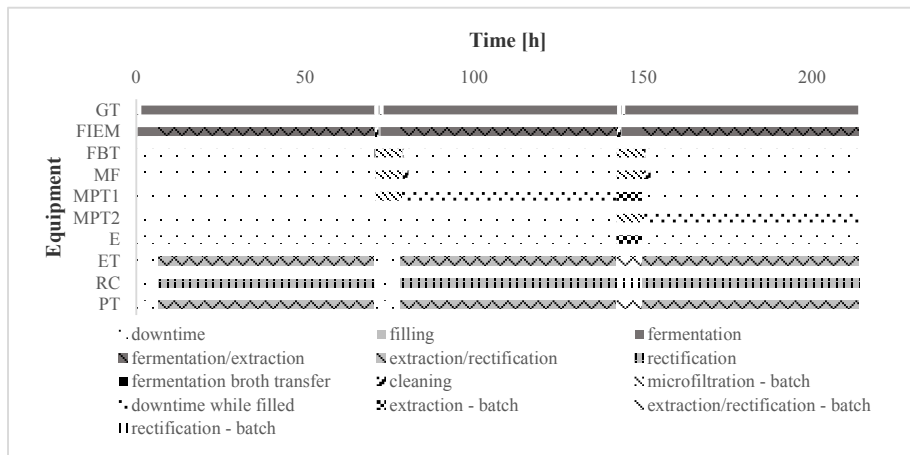

Figure 6 Time schedule of each unit in Hybrid system II.

3. Comparison of proposed systems

The summary of compared parameter for each system is shown in Table 1. The highest amount of acquired PEA is via Hybrid system II, even more than two times the amount of PEA acquired via Batch system. Naturally, the profit from product sales is the highest for this production alternative. The price used for this comparison was 830 \$ per 1 kg of PEA. Investment costs were calculated based on their size or power using simple increment method (Woods, 2007). Higher investment costs in hybrid systems are caused by the requirement of equipment with large effective surface (namely microfiltration membrane) in Hybrid system I and the custom-made, more expensive immersed extraction module in Hybrid system II. Operating costs consist of costs for electricity, water, heat and raw materials. The lowest operating costs are in Hybrid system II, which is related to the fact that in-situ product removal lengthens the fermentation time. This means that there is overall less downtime for the bioreactor and separation units and raw materials are being used more efficiently.

4. Conclusion

Three configurations of biocatalytic 2-phenylethanol production using *Saccharomyces cerevisiae* as a production strain were proposed – traditional batch production, hybrid system with microfiltration and organic solvent extraction, and hybrid system with immersed hollow fibre extraction module. Using appropriate mathematical models and simulations the three systems were designed and compared. The results show that via hybrid system, approximately two times more 2-phenylethanol can be acquired compared to batch system while operating costs of hybrid system are lower than operating costs of batch system.

Hybrid system II promises the best results out of the three compared alternatives. During fermentation, there is no microfiltration membrane used, which allows longer fermentation time and saving of raw materials, thus reducing operating costs. The main disadvantage of Hybrid system II is that the immersed extraction module has to be made

Table 1 Comparison of proposed systems.

	Batch system	Hybrid system I	Hybrid system II
Time of one cycle (h)	25.7	40.7	70
Cycles per year	308	190	110
PEA removed during fermentation (kg)	-	81.34	166.83
PEA removed from FB after fermentation (kg)	27.11	9.58	6.04
Total amount of PEA per year [kg]	8,350	17,275	19,016
Annual sales profit (after 20 % taxes) [mil. \$]	5.54	11.47	12.62
Investment costs [mil. \$]	3.72	5.79	5.21
Operating costs [mil. \$]	2.86	2.34	1.89
Investment return rate [y]	1.33	0.62	0.48

specifically for the given type of bioreactor. Moreover, for the final separation of the fermentation broth, separate microfiltration membrane and extraction module have to be used, which on the one had increases the amount of acquired 2-phenylethanol, but on the other hand it also increases overall investment costs. But in any case, comparing data from Table 1, Hybrid system II exhibits the best alternative for PEA production.

Abstract

In process system engineering, we often adopt a constructivist approach to answer the question “How can we go from parts to a whole system?” To answer to this question we need to propose approach that, based on the knowledge of phenomena at small-scale, allows going up the different scales in order to design process but also to innovate thanks to the creation of new knowledge. In this paper, a bio inspired design approach is presented. It is based on two main principles which intervene repetitively to understand and analyze the passage between scales for living organisms: the juxtaposition of foundational blocks that assemble, and then differentiation. The goal of this paper is to demonstrate that these principles can find a more widespread use and in particular they can be integrated into a process system engineering constructivist approach for innovative design. After defining the fundamental building blocks to initiate the process of juxtaposition and integration, an example on distillation and reactive distillation is used to illustrate the method capabilities in process synthesis.

Keywords: Process Innovation, Bio inspiration, Constructivist approach, Process synthesis.

1. Introduction

Process engineering is becoming more and more complex as our analyses become more efficient. Process engineering has evolved over time through instrumental and modelling developments that have made our capabilities for observations and analysis more efficient. But in his approach for problem solving, engineer tends to divide a problem into levels of understanding. For example the process engineering offers a broad set of methods and tools for efficient problem solving for different scales: molecular, phase and transport, unit operation, process, industrial parks... Similarly, in the manner of nested dolls, life is organised on scales of increasing complexity ranging from the cellular organelle to the eco-system, via the cell, the tissue, the organ, the organism, the population. Figure 1 illustrates this parallel between the decomposition and hierarchization of scales between living organisms and process engineering. But, it is important to keep in mind that any division or hierarchization is arbitrary and offers only an ease of analysis. Therefore, any fragmented analysis of a living or technological system does not make it possible to understand it in details. Indeed, in this approach we isolate the parts, as a consequence we do not consider exchanges between scales and thus we reduce the understanding of the problem.

Multi scale approaches try to restore this dialogue in order to have a better understanding of the system under study. Despite the important advances of these

approaches and therefore the improvement of processes, most of the time we reach only incremental innovation. The aim of this paper is to propose a new way to analyse, integrate and cross the scales with a bio inspired approach as the nature is constantly obliged to innovate. The goal is to demonstrate that the physical processes and the principles that appear in the evolution of the living organisms are relevant to be used in the design of new process, and could lead to solutions with a higher level of innovation.

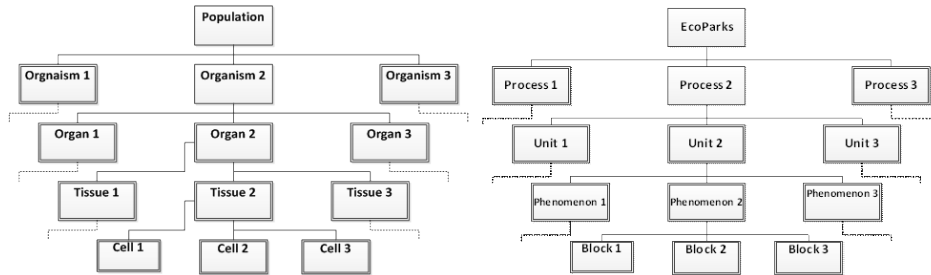

Figure 1 Comparison of scales hierarchization between living organism and process synthesis

2. Backgrounds

Most of the research works in process engineering are based on a reductionist approach, which consists of understanding the fundamental phenomenon. Analyzing a system by focusing on one element moves away from the overall understanding of this system. Thus, focusing on parts takes away from a global vision. Conversely in process system engineering, we often adopt a constructivist approach to answer the question “How can we go from parts to a whole system?” Thus it is easy to understand the difficulty encountered by the process designers: without multiscale integration and systemic approach, the vision of the whole makes the complexity and the relations between the parts invisible. A process (or even at the macroscopic a supply chain) can be seen as a set of nested structures, made up with distinct elements, which juxtapose but which cannot be simply explained by summing the elements. As a result, a process encompasses different scales, each as its own “world” and it is constituted with all those of lower ranks and with which it shares some properties. Thus the elements of a scale serve to constitute the next higher scale. All this leads to the emergence of the complexity, i.e. we cannot reduce the behavior of a scale to the simple addition of those of lower levels. As a result, the large-scale organization comes from a hierarchy of assembly from the smallest to the largest and the interdependence where large scales require smaller ones. The complexity is due to the fact that on the one hand the connections between elements are multiple and that everything is linked, and on the other hand to the passage from one scale to another sometimes accompanied by a paradigm shift. Addressing this complexity and offering systematic solution is the heart of process systems engineering. In conclusion, to have a whole vision of a system, it is necessary to understand what is happening at smaller scales. So, with a constructivist approach, the question that arises is how to do this upscaling.

To continue the parallel with the nature, a starting point for answering to this question was the analysis of complexity of living things made by (Chapoutier and Kaplan, 2011). In the emergence of the complexity for living organisms two main principles seem to intervene repetitively to understand and analyze the passage between scales: the

juxtaposition of foundational blocks that assemble, and then differentiation. The two fundamental principles are the juxtaposition of entities of the same order of complexity (and thus of the same scale) and then modification (mutation) of these entities in higher level structures. For example, cells juxtapose then mute to form a tissue, or at a different scale organisms to form a population. Figure 2 gives a schematic interpretation of these principles for two successive scales. Even if theoretically these steps can be repeated indefinitely, in nature they rarely exceed 5 to 6 levels of complexity: from the cell to the animal population.

Figure 2 juxtaposition and integration principles (Chapoutier, 2001).

In figure 2, the juxtaposition of element A gives B, where elements do not interact with each other. The integration leads to C where the interaction appears while elements preserve a certain autonomy. Then the process is repeated with the juxtaposition of C to create D and then E by mutation.

For process synthesis, as a first approximation, the juxtaposition can be done linearly and sequentially by appealing not only to elements of the same level of complexity but also to strictly identical elements. Then we find more integrated entities, sometimes more intensified in engineering processes, to form more complex structures. This step is important because in the design of a process, one seeks the maximum efficiency that leads to specialization, which implies to accentuate the integration and the interactions between elements. The purpose is to optimize the transfers, the weight, the form, to make it as compact as possible ... and most often to operate each part to its limits, i.e. to its maximum constraints.

It must be also emphasized that the evolution of living organisms is based on the integration of elements within higher-level elements. The main reasons for the diversification of life and its hierarchical organization are these mutations of individualities at all levels that we have mentioned. As a result, the application of this principle to process synthesis may lead to enhancement of the process performances but also to innovative solutions.

The next step is to identify the initial blocks, i.e. leafs of the tree of figure 1, for process synthesis, which will allow scaling up through the successive repetition of the principles of juxtaposition and integration (also named mutation).

3. Knowledge representation: building blocks

All living organisms are deduced from a four-letters alphabet that are the four nitrogen-containing nucleobases (cytosine [C], guanine [G], adenine [A] or thymine [T]) of the DNA molecule. In the same way as for DNA, it is necessary to determine the constitutive elements that have many degrees of freedom that will thus offer more efficient and sustainable alternatives, but also immense potentialities that can lead to innovations. For process synthesis, these elements must be based on the current process engineering knowledge. Furthermore the knowledge representation chosen must be compatible with the constructivist approach previously mentioned. The fundamental building blocks representation, recently proposed by (Demirel et al., 2017) and (Babi et al., 2015), seems to be a relevant way to represent knowledge. For the former, a bloc is an abstract module that represents a fundamental constituent of a unit operation, which can host single or multiple phenomena. For the latter, a block gathers only one phenomenon. This last definition is well suited for our approach and compatible with the two principles. Relying on the work of (Babi et al., 2015), as most of processes combine, mass, energy, and momentum phenomena, a first set of building blocks could be mixing (M), two phases mixing (2phM), cooling (C), heating (H), reaction (R), phase contact (PC), phase transition (PT), phase separation (PS). These building blocks can be associated with different levels of scale and complexity: process phenomena, tasks, unit operation, etc. In the previous studies, these building blocks are used to formulate a mixed integer nonlinear optimization model to identify process alternatives. Even if some innovative solutions could be reached with this approach, to go deeper in the innovation process, i.e. to find solutions with a higher level of inventiveness, we must propose new principles for the construction. Indeed, there are missing laws to explain consciousness and tacit knowledge.

Let's take the example of (Babi et al., 2015) to detail the proposed approach. The figure 3 depicts the juxtaposition and mutation principles to represent different phenomena and unit operations. First, different building blocks can be juxtaposed in order to generate a feasible phenomenon, e.g. figure 3 is the association of mixing, phase contact, and phase separation. From this point, a first option consists in designing a specific unit where this phenomenon can occur, for the previous example the phenomena can be interpreted as a flash if there is a liquid and a vapor phase. A second option consists in a juxtaposition of the same phenomena. In this configuration if the two phases are liquid then we would find a liquid-liquid extraction. On the other hand, if there is a liquid phase and a vapor phase, i.e. the succession of the same phenomena as the flash vessel, no known unit operation appears clearly. Then the mutation principle can be applied as for example with the addition of cooling and heating at both ends to represent a condenser and a reboiler in order to generate a distillation column. From this point, we can go further in the mutation by adding a reaction block as reaction and separation can occur simultaneously. The reaction block is not added to all the previous blocks but only to some of them, because the mutation does not necessarily apply to all blocks present. This second mutation (or deeper mutation) enables to find the reactive distillation unit operation.

In the same way, at the unit level (figure 1), juxtaposition and integration of unit operations lead to the design of a process alternatives. Indeed, for example the purification section of a process is often composed by successive separation units (juxtaposition). Sometimes this can be improved by the external integration if two

different types of separators to fulfil one purification also known as hybrid separation in process intensification (e.g. distillation and membrane, distillation and crystallization). As a result, another strength of the proposed approach is to make more systematic the best process intensification option at the different scales.

It can be also noticed that instead of relying on phenomenon, building blocks could be atoms to generate new groups and then molecules. As a result, the proposed approach is also relevant for computer aided design molecules.

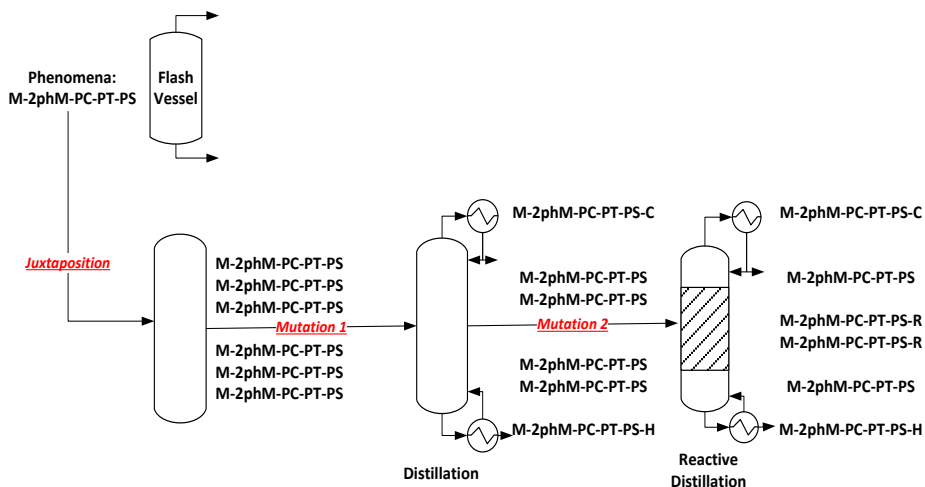

Figure 3: Example of juxtaposition and mutation based on the case study of (Babi et al., 2015)

4. Discussion

In most cases, living organisms are made up of many characteristic units, i.e. cells, so they are in their vast majority multicellular. The objective of the successive integrations of these different cells is also to create specialized structures with particular functions, e.g. heart, liver, nervous system ... for the organs. Likewise, at the same hierarchical level as the organs but on the process engineering side (figure 1), the unit operations also consist of several blocks in order to achieve at least one function. However, a current trend in process engineering is to design multifunctional devices, but this aspect is less present in living organisms. As demonstrated by the example of reactive distillation, more advanced mutations on the process engineering side make it possible to produce multifunctional devices (and more generally more intensified processes and for all scales). But in return, the direct consequence of a further mutation is an increase in the number of possibility of juxtaposition and mutation as the scales rise. As a result, the problem becomes highly combinatory.

Indeed, when dealing with innovation, the search for a solution requires exploring the space of solutions in its entirety, so we must test all possible combinations. For example, during juxtaposition, the number and the type of entity to be juxtaposed are not predefined. When an entity is repeated multiple times, it is difficult to establish when the completion is reached. Moreover, the juxtaposition can be operated with similar or different entities as we have seen in the previous examples. The combinatorial

aspect also comes from the principle of mutation. As we demonstrated in the example on reactive distillation, the mutation does not necessarily concern all entities on the one hand, we can also delete, add or replace one or several entities on the other hand. Therefore, all these mutations offer a lot of possibilities. Moreover, for each juxtaposition or mutation, we must verify if the proposed solution is feasible or not. In the previous example, we underline that the multiple repetitions of the phenomenon can lead to none feasible solution when we have a liquid and vapor phases. For living organisms, this question of feasibility does not arise because naturally the steps of juxtaposition and mutation do not allow the creation of non-viable entities. Another direct consequence of this natural selection is the decrease of the combinatorial aspect. For process synthesis, one way to proceed to avoid this drawback could be to define and to use predefined combination rules. Unfortunately, this strategy of adding predefined knowledge would have the detrimental effect of diminishing the innovation potential of the approach. A more relevant solution would be to refine the definition of blocks by adding functional, financial, regulatory etc. aspects. This strategy would also have the advantage of integrating these dimensions from the initial design of the process.

Another crucial point is that we propose only theoretical reflection, strongly supported by examples, but experimental studies should also be proposed to validate the future alternatives created.

5. Conclusions

In this paper, we propose bio-inspired design approach for process synthesis. Nature often evolves and innovates according to a mosaic organization, by using two fundamental principles *juxtaposition* of entities of the same order of complexity and then *modification* of these entities in higher level structures. These two principles permit to understand and to explain the passage between two successive spatial scales. As a result, this vision of mosaic complexity emerging from life, compatible with Darwinian evolution but proposing general principles of progress towards complexity and diversity. The goal of this paper is to demonstrate that these principles can find a more widespread use and in particular they can be integrated into a process system engineering constructivist approach for innovative design in process engineering. After defining the fundamental building blocks to initiate the process of juxtaposition and integration, an example on flash vessel, distillation and reactive distillation is used to illustrate the method capabilities in process synthesis. The main drawback on this approach is that it is highly combinatorial. As a result, it is impossible to explore all the possibilities offered. A future perspective of this work would be to incorporate design constraints to limit the space of solutions to feasible alternatives.

Abstract

Biobutanol is a renewable fuel produced nowadays from waste biomass feedstocks. It features low water miscibility, flammability, corrosiveness, with the additional advantage that it can replace gasoline in cars, without any engine modifications. The butanol obtained after the fermentation step has a low concentration (typically less than 3 %wt) that leads to high energy requirements for conventional downstream separation. To overcome this issue, we propose here a novel hybrid separation process based on a heat pump assisted azeotropic dividing-wall column (A-DWC). CAPE tools and Pinch analysis have been used for the process synthesis, design and optimization of the process. The plant capacity considered here is 40 ktpy butanol (99.4 %wt). Remarkably, the energy requirement for butanol separation using heat integration and vapour recompression assisted A-DWC is reduced by 58 % from 6.3 to 2.7 MJ/kg butanol.

Keywords: Azeotropic dividing-wall column, distillation, heat pump, energy efficiency

1. Introduction

In the fermentation process of acetone-butanol-ethanol (ABE), biobutanol is obtained in diluted form, typically less than 3 %wt concentration. The low concentration of butanol obtained by fermentation leads to high energy requirements for downstream processing, in the range of 14.7-79.05 MJ/kg butanol (Patrascu et al., 2017). A higher butanol yield is achieved in fermentation using anaerobic bacteria as *Clostridium acetobutylicum* and *Clostridium beijerinckii* (Tashiro et al., 2013). Moreover, the ABE concentration can be further increased by gas stripping technology to 4.5 %wt acetone, 18.6 %wt butanol and 0.9 %wt ethanol (Xue et al., 2013). On the other hand, the productivity, yield and concentration can be also improved by genetic engineering, which is a longer-term goal. This has an important impact on the cost of the separation, which needs to be significantly reduced. Numerous separation techniques are available for ABE separation, such as distillation, reverse osmosis, adsorption, liquid-liquid extraction and others (Abdehagh et al., 2014; Sanchez-Ramirez et al., 2017). This work develops a new hybrid separation sequence combining distillation and vapour recompression (Kiss et al., 2013). The azeotropic DWC combines three distillation columns into one unit and reduces the energy used for separation by employing a heat pump and heat integration.

2. Problem statement

The conventional separation sequence using three distillation columns along with one decanter (Figure 1, left) requires 6.3 MJ/kg butanol. By using heat integration and combining two columns into a dividing-wall column (Figure 1, right), a reduction of 29 % of the energy requirement was achieved (Patrascu et al, 2017). This is a significant reduction of the energy requirements, but can the energy savings be pushed any further?

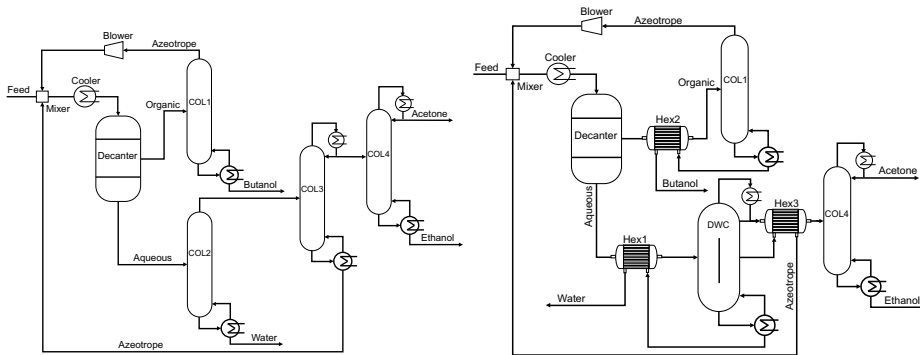

Figure 1. Process flowsheet of ABE downstream separation sequences (Patrascu et al., 2017)

To achieve more savings, a novel process is proposed in this work. The decanter is not used here as the first separation unit, as the organic phase (rich in butanol) has a high impact on reboiler duty for butanol purification and makes the heat pump extremely inefficient. Note that the temperature of the compressed vapour is limited to 150 °C, and the temperature in the reboiler is around 127 °C. High energy usage occurs under 120 °C for vapours condensation. By using a highly integrated azeotropic dividing-wall column (A-DWC) assisted by vapour recompression (VRC) technology the energy savings can be increased by another 39 % as described hereafter.

3. Modelling approach

The process is simulated in Aspen Plus, using the NRTL as suitable property model. In Figure 1 the fourth column (COL-4) separates only the light components (acetone and ethanol) hence it is not considered in the energy requirement for butanol separation. To account for a realistic composition of the ABE mixture, impurities are taken into account: 0.1 %wt. CO₂, as well as small amounts of acetic acid and butyric acid.

Several basic assumptions and design specifications are used for the optimization and heat integration: butanol purity is 99.4 %wt.; each side of the dividing wall has the same number of stages; feed streams are preheated to 97 °C; product streams are cooled to 25 °C; the (left) side reboiler is not considered in optimization process of A-DWC because will be replaced with a heat exchanger.

Pinch analysis provides understanding of the energy targets and subsequent design of the optimal heat exchange network. The investment and operation costs of the complete process are evaluated in order to show the advantages of this design (Dimian et al., 2014). The coefficient of performance (COP) is used for evaluating the feasibility of using a heat pump, while also accounting the additional costs and the payback time.

4. Results and discussion

4.1. Heat integration analysis

Figure 2 shows the composite curves that reveal the energy targets. The left side of Figure 2 shows that heat integration may lead to important reduction of heating and cooling requirements. However, the energy savings are rather small compared to previous separation sequences (Figure 1). In particular, the vapour stream from the top of the A-DWC cannot be used for heat integration due to its low temperature. But, by recompression to 5.8 bar, it can be heated to 150 °C, which is useful for heat integration. The suitability of using VRC is evaluated by using the COP as given by:

$$COP = Q/W = 1/\eta = T_c/(T_r - T_c) > 10 \quad (1)$$

where Q = reboiler duty, W = work provided, η = Carnot efficiency, T_r = reboiler temperature, and T_c = condenser temperature (Plesu et al., 2014). If the Q/W ratio is lower than 5, using a heat pump (HP) brings no benefits, but if it exceeds 10 then a HP should be considered. The maximum energy savings are given by (Blahusiak et al., 2018):

$$Max.savings(\%) = 100 \cdot (Q_{reb} - HR \cdot Q_{reb} / COP) / Q_{reb} \quad (2)$$

Figure 2 (right) shows that, for a Q/W ratio of 7.43, the heat pump helps to reduce the heating and cooling requirement by about 50 % (equivalent to 2.7 MJ/kg butanol).

Figure 2. Composite curve for simple heat integration (left) and heat pump assisted (right)

Figure 3 shows the dependence on pressure of the LMTD and compressor power. The compressor outlet temperature is max. 150 °C for safety reasons: at higher temperatures the system may fail from worn rings, acid formations, oil breakdown (Luo et al., 2015).

Figure 3. Dependence of compressor duty and the long-mean temperature difference (LMTD) on the pressure

4.2. Heat pump assisted azeotropic dividing-wall column design

Figure 4 presents the process flowsheet, including the key design parameters. The column has a total of 45 stages, 13 stages for the fractionation section and 32 stages for stripping sections. Butanol and water are the bottom products, while acetone and ethanol with some water (AEW) are obtained as distillate. The ABE feed and the aqueous phase recycled from the decanter are fed on 1st stage of the stripping section (14th stage of A-DWC), which separates water as bottom product. The top vapour stream is compressed to 5.8 bar (150 °C), provides heat to the (left) side reboiler (HEX1), preheats the diluted ABE feed (HEX2) and is finally condensed. The liquid flowing down the column is routed to the right stripping section. From the 13th stage, a mixture close to the azeotropic composition is withdrawn as side stream, cooled, and sent to liquid-liquid separation. The organic phase is recycled on 2nd stage of the right stripping section (15th stage of A-DWC), from which butanol is obtained as bottom product. The aqueous phase is recycled to the left stripping section. Additional heat is recovered by using the water product stream to preheat the aqueous and organic phases (HEX3, HEX4).

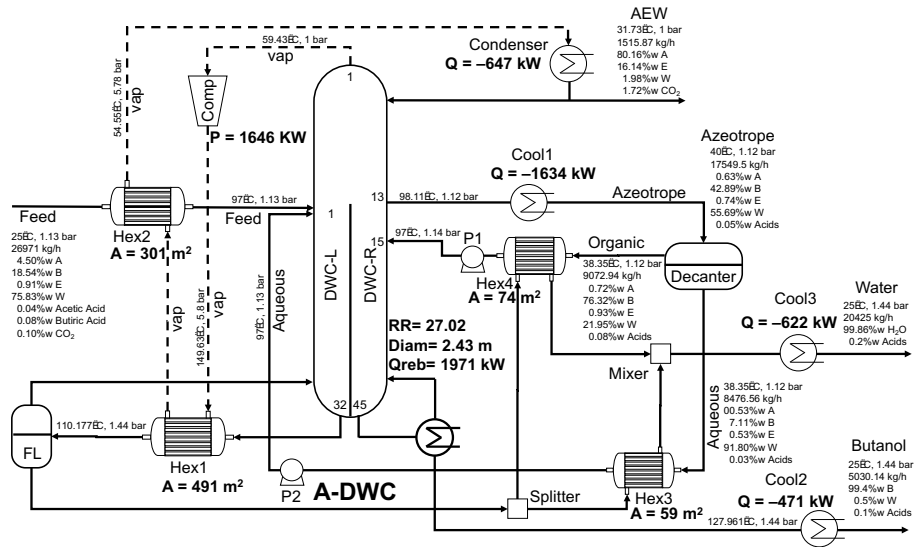

Figure 4. Process flowsheet of the new downstream separation process based on A-DWC

Figure 5. Temperature and mass composition profiles along the A-DWC unit

5. Process evaluation

The process is optimized using the total annual cost (TAC) as the objective function to be minimized: $TAC = OpEx + CapEx / 3$. The design parameters (e.g. number of trays, feed tray) are used as decision variables in the optimization (Patrascu et al., 2017).

The total investment costs (CapEX) include the heat exchangers, coolers, heat pump, flash unit, distillation column, and the decanter. The equipment cost is evaluated at 5,250 k\$/year. A payback period of 3 years is used, with 8000 hours/year operating time. The heating and cooling costs considered are standard: LP steam (6 bar, 160 °C, \$7.78/GJ), cooling water (25 °C, \$0.72/GJ) and chilled water (5 °C, \$4.43/GJ). The compressor power cost taken into account is 15.5 \$/GJ power. The minimized operating cost is 1,435 k\$/year, including also the cooling of the products.

Table 1. Economic evaluation of the heat pump assisted A-DWC for butanol recovery

Item description (unit)	DWC	Decanter	Coolers	Exchangers	Flash &Comp
Shell / [10^3 US\$]	718.1	71.6	-	-	1618.9
Trays / [10^3 US\$]	94.6	-	-	-	-
Condenser / [10^3 US\$]	266.7	-	1,179.5	-	-
Reboiler / [10^3 US\$]	497.8	-	-	803.4	-
Heating / [10^3 US\$/year]	441.8	-	-	-	737.3
Cooling / [10^3 US\$/year]	82.5	-	173.2	-	-
TAC / [10^3 US\$/year]	1,050.0	23.9	566.4	267.8	1,276.8

Figure 6 shows a comparison of the energy efficiency. Note that the energy required for heating without any heat integration and no heat pump assistance is 8.78 MJ/kg butanol, which exceeds 6.3 MJ/kg butanol for the conventional separation sequence. The heat pump assisted A-DWC design requires only 2.7 MJ/kg butanol (58 % less than in conventional separation sequence). But using a heat pump increases the capital cost due to the expensive compressor (1,581.5 k\$). Considering the energy savings (1.69 MJ/kg butanol) evaluated at 1,893 k\$/year, the payback time is about 10 months.

Figure 6. Energy efficiency for the new vs previous butanol downstream processes

6. Conclusions

The biobutanol recovery from the ABE mixture obtained by fermentation can be efficiently achieved in just a few separation units: three classic distillation columns are combined in one azeotropic dividing-wall column (A-DWC) and one decanter is used for the liquid-liquid split of the heterogeneous azeotrope. The novel process proposed was designed, optimized, and heat integrated. The economic evaluation proves that it is feasible. The energy requirement is drastically reduced by applying heat integration and vapour recompression technology. The investment cost of the process (40 ktpy capacity) is $5,250 \cdot 10^3$ US\$, and the operating cost is $1,434 \cdot 10^3$ US\$/year. Although, the cost of the heat pump is high ($1,581.5 \cdot 10^3$ US\$), the payback period is only 10 months. The highly integrated A-DWC system reduces the energy requirement for butanol separation to only 2.7 MJ/kg butanol, a reduction of 58 % as compared to a conventional design.

yshastri@che.iitb.ac.in

Abstract

An optimization model for the supply chain design of biomass to energy system considering potential biomass supply disruption scenarios has been proposed. The model includes farms/supply points, regional biomass processing depots (RBPD), and biorefinery. Disruption is modelled as loss of biomass availability at farms, with each farm assigned a specific disruption probability and level of disruption. Shortfall in fuel production as well as short-term feedstock procured during disruption is penalized. The objective function to minimize the total production cost considering disruption. The model was applied to a case of 452 farms distributed over a region of covering 202,500 km². For base case with shortfall penalty of \$ 335/Mg and short-term procurement penalty of 50% over the base value, the proposed model led to a 6.9% reduction in the total production cost as compared to a model ignoring the disruptions. The penalty on shortfall was varied from \$ 320-375/Mg to understand their impact on the design decisions as well as total cost.

Keywords: Optimization, supply chain, resiliency, biofuel, disruption

1. Introduction

Biomass-to-energy systems require an efficient supply chain of biomass feedstock due to the highly distributed availability of low density material. As a result, biomass supply chain optimization has emerged as a key research area. However, biomass based systems are highly susceptible to natural disruptions such as droughts, floods, and pest attacks, which significantly affect the availability of biomass. These disruptions must be considered at the supply chain design stage to improve the resiliency of the system. Maheshwari et al. (2017) developed an optimization model considering potential disruptions and illustrated that ignoring the effect of these disruptions led to sub-optimal designs. This work extends their formulation to make it more comprehensive and realistic. Firstly, the possibility of unmet biomass demand at the biorefinery is included (Poudel et al., 2016). Moreover, the possibility of replacement feedstock during disruption being available at a higher price is modelled. The model is then applied to a case study considering supply of corn stover from 452 farms randomly distributed over a given region. The results are compared with those obtained using a model that completely ignores the possibility of disruption.

The paper is arranged as follow. The next section discusses the components of the supply chain and summarizes the optimization model formulation. Section 3 describes

the case study, while section 4 presents the base case as well as sensitivity results. Section 5 provides the conclusions.

2. Optimization model formulation

The biomass to energy system considered in this paper includes three components: farms/supply points, regional biomass pre-processing depots (RBDs), and biorefineries. The farms are considered to provide low density chopped biomass which can be pelletized at the RBDs to improve storage and transport efficiencies. The biomass from farms can also be sent directly to the biorefineries. Storage facilities are available at both RBD and biorefinery since no storage is assumed at farms. The farm sizes are known, which decides the maximum availability of biomass from each farm. All the farm locations also serve as the potential RBD and biorefinery locations. The biorefinery has a fixed monthly demand of biomass and converts it into ethanol. The transportation is assumed to be via trucks. Maheshwari et al. (2017) explain the basic version of the optimization model in detail. The constraints of the model relate to the mass balance of biomass from farms to the biorefinery. This includes supply constraints at each farm, storage and capacity constraints at the RBD and biorefinery, and demand constraints at the biorefinery. In reality, the disruptions are stochastic in nature, and stochastic programming problem is necessary. However, stochastic programming problems are computationally highly challenging. Therefore, this work considers scenario based optimization, where the design is optimized over a selected number of scenarios. Multiple disruption scenarios model loss of biomass at the farms due to a natural event. The probability of disruption captures the likelihood of disruption affecting the farm in a given year (based on historical data), while the level of disruption decides the extent of losses incurred by the farm. Each farm is assumed to have a predefined probability and level of disruption. Moreover, those are uncorrelated with each other since farms may have varying capacities to handle disruptions. The design problem considers an ideal scenario without disruption as well as multiple scenarios with disruption. Disruption scenarios may require procurement of additional feedstock from farms not considered in the ideal scenario. Such feedstock is considered to be available at a premium price by considering a penalty. This is possible since such farms may not be contracted and hence may charge a higher price. The penalized feed quantity is calculated as shown in Eq. 1 and is weighted over by the probability of the disruption scenario.

$$B_{\text{penalized}}(i, es) = \max(0, B_{\text{Total}}(i, es) - B_{\text{Total}}(i, ei)), \quad \forall i, es \quad (1)$$

where, set i indicates a farm, and sets es and ei indicates disrupted and non-disrupted (ideal) scenarios, respectively, which are a subset of total scenarios represented by set e . However, production cost increases with an increase in the cost of biomass or for a very low availability of biomass during disruption. In such cases, biorefineries may prefer to not procure biomass and instead prefer to pay a penalty for not meeting contractual obligation regarding the supply of fuel. This is modelled by enabling the biorefineries to have an unmet demand ($B_{\text{Unmet}}(n, e)$), in addition to the biomass processed at the biorefinery ($C_{\text{OP}}^B(k, n, e)$), to meet the total demand ($D(n, e)$) as shown in Eq. 2.

$$D(\mathbf{n}, \mathbf{e}) = \sum_k C_{OP}^B(k, \mathbf{n}, \mathbf{e}) + B_{Unmet}(\mathbf{n}, \mathbf{e}), \quad \forall \mathbf{n}, \mathbf{e} \quad (2)$$

where, \mathbf{k} is the set of biorefineries and \mathbf{n} is the set of months. The cost functions of all the operations, including transportation, storage, pelletization, and processing are the additional set of model constraints. In addition, operational decisions such as flow of biomass along the various links are also optimized. The decision variables include design decisions such as locations of farms to be contracted, RBDs and biorefineries, as well as the capacities of RBDs and biorefineries. The objective function is to minimize the total cost (TC) for a specific target ethanol (fuel) production target, which is the weighted sum of the cost for ideal (\mathbf{ei}) as well as each disruption scenarios (\mathbf{es}).

$$\text{Min } TC = \sum_e P(\mathbf{e}) * (G_{SC}(\mathbf{e}) + G_U(\mathbf{e})) + \sum_{es} P(\mathbf{es}) * (G_{FP}(\mathbf{es})) \quad (3)$$

Here, $G_{SC}(\mathbf{e})$ and $G_U(\mathbf{e})$ are the total cost of production in the supply chain, and the penalty due to unmet demand, respectively. $G_{FP}(\mathbf{es})$ is the penalty on additional biomass procured during disruption scenario. This model is termed as the resiliency model in further discussion. A base model that ignores the disruption is also solved for comparison. This model is a subset of the resiliency model with only one scenario (\mathbf{ei}) without any disruption. The model simulation and decision making horizon is one year, and operational decisions are optimized on a monthly basis. The objective function considers the total annual operating costs as well as the capital costs that are annualized. The detailed mathematical formulation is not reported here for brevity. It is a mixed integer linear programming (MILP) model, which is programmed in GAMS and solved using the CPLEX[®] solver.

3. Case study details

The proposed model was applied to a case study considering 452 farms randomly distributed over a 450 km x 450 km grid (Fig. 1). For computational efficiency, the region was divided into 16 square sub grids, and one of the central farms in each grid was considered as the potential RBD locations (stars in Fig. 1, 16 potential locations). Similarly, five farms, roughly distributed in the central part of the region, were considered as potential biorefinery locations (red square in Fig. 1). The biomass feed considered was corn stover which was assumed to be available for three months in a time horizon of 12 months. The probability of disruption was assumed to be uniformly distributed between 0-30%. The disruption level was normally distributed with a mean of 50% and a standard deviation of 15.4% (minimum of 12% and maximum of 99%). The disruption scenarios included disruptions in each of the 16 grids independently, thereby generating 17 scenarios including the ideal scenario. Simultaneous disruption in multiple grids was not considered. The probability of disruption and the level of disruptions for each of these farms was fixed and randomly sampled from the mentioned range. Farm size was normally distributed with a mean of 58.66 ha. Corn stover yield was 6.9 Mg/ha (Maheshwari et al., 2017) and 70% of stover was available for use. The unit feed cost was \$ 40/Mg. The capital cost at RBD was scaled using CEPCI for 2016 using a base value of \$ 269,000/y for a capacity of 45,000 Mg/y (Mani et al., 2006). The operating cost at RBD was considered to be \$ 21.16/Mg (Mani et al., 2006). Biorefinery costs were also obtained using CEPCI considering capital cost of \$ 357,203,083/y for a capacity of 772,000 Mg/y and operation cost of \$ 49.49/Mg (Humbird et al., 2011). Variable component of transportation cost was \$ 0.13/Mg-km for chopped biomass and \$ 0.047/Mg-km for pelletized biomass. The fixed component

of transportation cost was \$ 12/Mg for chopped biomass and \$ 2.8/Mg for pelletized biomass. RBPDS and biorefineries were assumed to have a collection radius of 90 km and 75 km, respectively. A demand of 89,378 Mg/y of ethanol was assumed at the biorefinery, which account for 80% of feed available in an ideal (non-disruption) scenario. Shortfall penalty for unmet demand was \$ 335/Mg of biomass and penalty on additional feedstock was 50% of the base value. The model includes 1,982,711 variables (42 discrete variables) and 1,874,511 constraints.

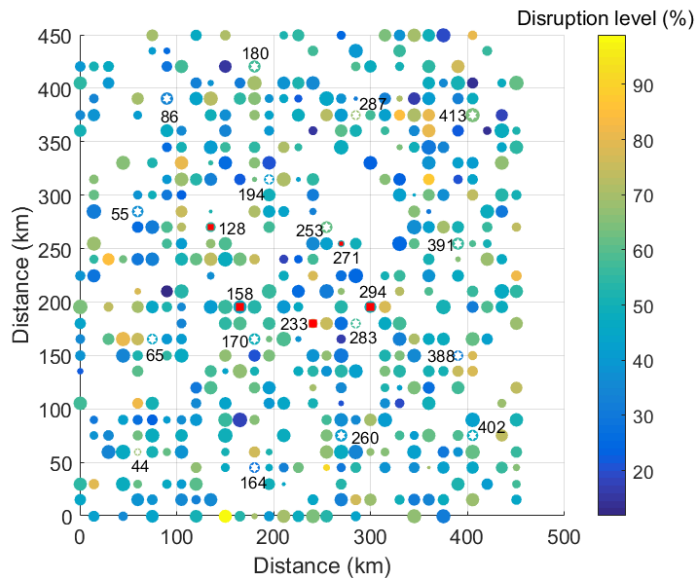

Figure 1: Farm location with disruption level. Size of the dot represents relative size of the farms and colour represents the level of disruption

4. Result and discussion

The base case results are first discussed, followed by the sensitivity analysis with respect to the two penalty factors.

4.1 Base case

For the base case, it was observed that the resiliency model recommended 11 RBPDS and a central biorefinery at the 294th location. The biorefinery had a design capacity of 89,378 Mg/y and a total of 36,707 Mg/y of demand was left unmet. This was due to the fact that procuring replacement feed was costlier than paying the penalty for unmet demand. In contrast, only 8 RBPDS were recommended for the base model (ideal scenario only). The biorefinery was proposed at the 294th location with a capacity of 88,825 Mg/y. In addition to the difference in the number of RBPDS, it was observed that the capacities of the RBPDS also differed significantly (Fig. 8). For example, instead a large RBPDS of 40,760 Mg/y capacity at location 55 for the base model, two smaller RBPDS were selected at locations 65 and 86 for the resiliency model (Fig. 2). It was also observed that grids with lower average probability of disruption were preferred for procurement. The benefit of the resiliency model was quantified by optimizing the resiliency model again but with the design decisions fixed to those proposed by the base model. It was observed that the resiliency model solution reduced the total cost by \$

242,782/y on a total annual cost of \$ 31,032,304/y for the base model solution. This emphasized the importance of considering disruptions in the design stage.

Figure 2: RBPDs selected in resilient and ideal design for a shortfall penalty= \$ 335/Mg and 50% penalty on additional feedstock

4.2 Variation in penalty on supply shortfall

For this case, the results of the base case simulation were compared with the results when shortfall penalty was equal to \$ 320/Mg and \$ 375/Mg. The penalty on short-term feedstock via penalty factor was fixed to 50% for both these simulations. It was observed that for a smaller shortfall penalty of \$ 320/Mg, the complete demand was left unmet by a resiliency model solution, thus resulting in 6.9 % lower total cost as compared to base model solution. However, with an increase in the shortfall penalty to \$ 375/Mg, where production at biorefinery is an economically beneficial option, a reduction in the unmet demand was observed. The unmet demand quantity reduced from 36,707 Mg/y to 33,581 Mg/y and an additional RBPD was set-up at the 388th location as per the resiliency model solution. The optimal biorefinery location also changed to 233 as compared to the base model solution which is indicated in black hexagon (Fig. 3a, 3b). While base model solution did not change the location and capacities of RBPDs for both penalty values, the resiliency model recommended an additional RBPD as well as reduction in long distance collection of biomass. A major change was observed for RBPDs at 44th and 65th location with new design capacities of 14,671 Mg/y and 50,095 Mg/y, respectively. The annual total cost also showed a 1.1 % reduction to \$ 31,097,077/Mg as compared to a base model solution. The change in penalty on additional feedstock would also effect the design decisions such as the facility location, and capacity, which would be discussed in subsequent studies.

5. Conclusions

A novel formulation to design optimal biomass to energy supply chains considering potential disruptions at the design stage was proposed. The possibility of demand being unmet as well as replacement biomass being available at a higher cost was incorporated. Farms/supply points were effected by disruption where the probability and extent of

loss due to drought were non-uniform. The supply chain was optimized to minimize the overall cost across all potential disruption scenarios in addition to the ideal scenario. The results indicated that for an increase in the shortfall penalty from \$335 to \$ 375/Mg a change in the biorefinery to 233rd location was observed for a 50% penalty factor. An additional RBPB established at 388th location to improve the transportation efficiency of the biomass. These results also showed notable benefits of the proposed resiliency model as compared to the base model without considering disruptions.

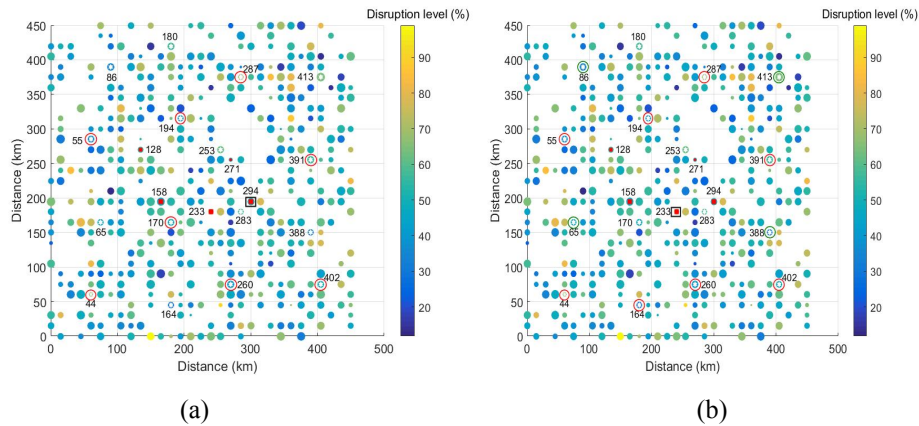

Figure 3: RBPB and biorefinery location for shortfall penalty = \$ 375/Mg and penalty factor = 50% for: (a) Ideal design; (b) Resilient design

Abstract

Nowadays, many Eco-Industrial Parks (EIP) are emerging all around the world. In these eco-industrial parks, industries gather to share several streams like energies, water, resources, and wastes in order to realise economic benefits while lowering their environmental impact. However, most of the time, these EIP are historically constituted and therefore sub-optimal. To really observe the sought gains, exchange networks need to be optimally designed. This article aims to develop a methodology for a grassroots design of hybrid power system (HPS) based on multi-objective optimization to supply an EIP. Overhang of this study is multi-objective (MO) approach which aims to minimize energy cost for project lifespan and to minimize environmental impact of energy production to supply EIP demand. This last criterion is evaluated by a life cycle assessment (LCA) on each sources. Another advantage is that geographical influence on HPS design is taken into account to evaluate climate effect on RE production and LCA impact depending on selected position for the EIP. A case study compares single objective and MO optimization and geographical influence on designed HPS for the same EIP, in two countries, Malaysia and in Germany. Results shows that a big reduction on environmental impact (above 70%) thanks to a little invest (cost increased about 10%) can be reached. Also, compared with different geographic positions, designed solution is really contrasted according to cost, environmental impact and selected RE sources.

Keywords: eco-industrial parks, renewable energies, multi-objective optimization, environmental assessment

1. Introduction

In recent years, at climate conference of the UNO (COP23 in 2017) important measures have been taken to fight against climate change and global warming, and to reduce human footprint on his environment. In this aim, to reduce extraction of raw materials and to limit amount of generated wastes, industrial ecology proposes to industries to gather within eco-industrial parks (EIP) to exchange energies and resources. Thereby, the main opportunity for companies is to reduce their environmental impact while increasing their competitiveness by making economic gains. In their review (Boix et al., 2015) have analysed methods applied to design and to optimize networks and streams in

EIP. Previous studies have been mainly focused on water and materials networks, while there is already a little number of publication dealing with energy networks for EIP. However to supply energy demand while reducing its environmental impact an EIP could produce its own local energy by using a renewable energy hybrid power system (HPS). An HPS is an energy network where several renewable energy sources are available also called RE-HPS. Lee et al. (2014) developed an LP optimization model to minimize energy loss of a RE-HPS. More recently, Theo et al. (2016) have completed this study by introducing an MILP model to minimize operating and investment costs and to select storage technologies.

The aim of this paper is to develop an on-grid HPS model to optimize energy planning to supply an EIP. MO optimization method is driven by both antagonist criteria: economic and environmental. To measure geographical impact of the location, the same HPS is optimized in different countries (Malaysia, Germany) using the same EIP demand, regardless of HPS technologies. Moreover, this model for the grassroots design of an EIP allows to optimize energy storage size, and renewable energy power rating (for wind Turbines, photovoltaic panels and biomass combustion) in order to provide known energy demand of EIP's processes.

2. Methodology and model formulation

The first step of this methodology is to define a model representing HPS. To this end, a superstructure has been developed, in which are represented links between sources and power demand (each company owns a number of process units representing sinks). Scheme of this superstructure is illustrated in figure 1.

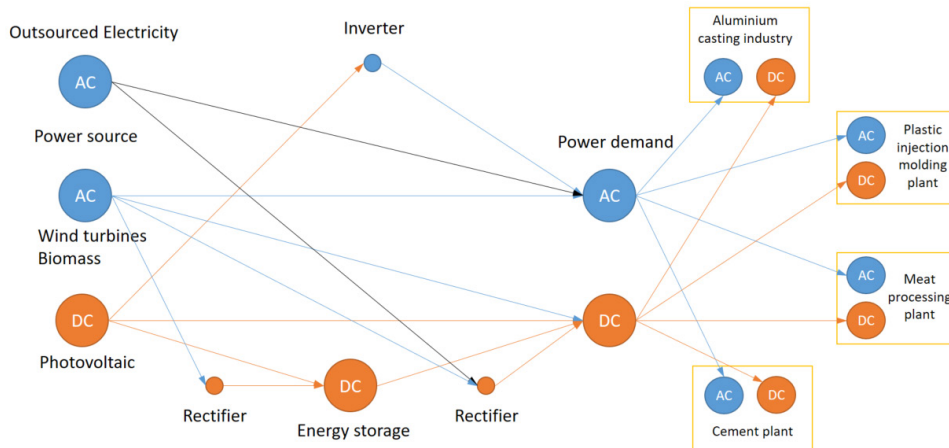

Figure 1: Superstructure of the HPS model

In this HPS, the renewable energy Alternative Current (AC) power sources are Wind Turbines, Biomass and Direct Current (DC) one is Photovoltaics panels. It is also possible to buy AC outsourced electricity (OE) from grid. To convert AC or DC electric current, rectifier and inverter are available. Due to the intermittency of renewable energy production, it is a dynamic model, in which time is discretized by hour, at any hour of the horizon time.

The EIP consists in 4 industries composed of AC or DC process to supply. While it is a theoretical EIP, energy demands are those of real process industries, in order to represent a complex demand, with many variations over time. Indeed in the aluminium casting industry works as a batch production (most of energy demand is between 7AM and 6PM) while the other industries works continuously. The cement plant is the biggest consumer (above 75% of the consumption) due to processes like raw-mill driver, cement mill driver and conveyor system. Moreover, renewable energy production can be stored in DC energies storage which is lead-acid batteries technology due to their best price capacity ratio to make profitable storage use.

The main mathematical constraints are energy balances at power source which is supplied directly to the power demand or charged into storage. This constraint is available for each power source and for each type of electrical current. Concerning the demands, the power demand must be satisfied by equivalent power of sources or batteries multiplied by potential energy loss if it has to be converted or discharged. Any loss corresponds to charging efficiency (90%) and converter efficiency (95%).

Energy balance for the storage system is also considered, i.e. the total amount of energy stored at the end of a time slice is the sum of the initial amount of energy stored and the net difference of charging and discharging. Additional constraints are added in order to limit converter and batteries capacities to maximal values observed throughout the duration time of the simulation. Furthermore, the geographical influence is considered through input model parameters. These parameters are outsourced electricity (OE) price, wind and solar power, and environmental impact of each renewable energy sources. The parameters related to geographical position are external electricity price, impact of sources, wind speed and solar irradiation.

The variables are the power rate of each renewable energy source, power capacity of converter (inverter and rectifier), the storage capacity and the amount of OE purchased.

A multi-objective optimization model is solved with an economic and an environmental criteria. The economic criteria to minimize is defined as the total Net Present Value of HPS over its lifetime, including capital investment, maintenance cost, operational expenditure for designed decision variable which are renewable energy sources, lead-acid batteries, and convertors. Finally cost of purchased OE from external network is taken into account. The environmental objective is based on a LCA approach (cradle-to-grave), for each source (renewable energy and outsourced electricity) producing 1 kWh, the impact is quantified through SIMAPRO® software. This value depends on the country where energy is produced. The function to minimize is calculated by adding total impact produced by each source.

The resulting optimization model is an LP model able to find a global optimal solution and it has been solved with IBM ILOG CPLEX Optimizer.

3. Case study

In this case study, Malaysian data are taken from a previous work so that the model can be validated (Theo et al., 2016). The second location, i.e. Germany, is chosen to be very different from the first one because they have adopted a policy to promote renewable energy sources, favourable to renewable energy HPS implantation. Germany is a windy country with an important potential for wind turbines and low solar potential while

Malaysia is sunnier. Furthermore, in Germany, impact of RE sources is globally really lower than in Malaysia (Figure 2).

To get reliable data, horizon time of this simulation is set at 4 days, one per season, which allows to consider annual climate changing. Indeed, while Malaysia is near from equator with low seasonal impact, in Germany huge variations can be noted between seasons.

Solar information, are obtained with PVGIS® tool from the European commission. On the other hand wind speed for Malaysia comes from Theo et al. (2016) and for Germany from Fraunhofer ISE European research institute (2014). Outsourced electricity price used in this model is the average for industries in Malaysia: 0.078 USD/kWh (Theo et al., 2016) and in Germany: 0.103 USD/kWh according to Clean Energy Wire (2015).

The different sources taken into account in this model and their impact are shown in figure 2, for Malaysia and Germany. Values come from SIMAPRO® software, using Ecoinvent® database and Impact 2002+ method. It allows to propose an aggregated indicator, gathering 4 damage categories: Human health, Ecosystem quality, Climate change and Resources. The unity of this unique indicator is the mean environmental impact of a European during a year.

Figure 2 Environmental impact data collected for each country

4. Results and discussion

This section highlights the differences between mono and multi-objective optimization and also investigates the influence of geographical position. Figure 3 shows the Pareto front solutions obtained for Malaysia (MY) and Germany (GE). In addition, detailed results for designed HPS are presented in Table 1 where the geographic influence between Malaysia and Germany can be clearly highlighted.

According to these results, it can be noticed that these criteria are antagonist (when cost increases, environmental impact (ENV) decreases) what justifies the choice to use a MO

analysis. As a result, the MO approach epsilon-constraint is retained to obtain the Pareto front illustrated in figure 3. Multi-criteria decision analysis (MCDA) tool TOPSIS gives a solution among optimal ones, this solution is the nearest from the best value for each criteria and the farthest from worst ones.

Figure 3 Pareto fronts and optimal points for Malaysian and German HPS implantation

Compared to the minimal cost point (Min COST), the TOPSIS multi-criteria solution observes a project cost 7% higher but a decrease of 72% on environmental impact for Malaysia. In Germany, it is also significant with a cost 14% higher and an ecological effect 78% lower. These results emphasize the importance of using a MO optimization because it shows that a little invest can have a big effect on environmental impact. One can also observe that when cost is minimized (min COST), compared to Malaysia, the German project is more expensive (+20%) and environmental impact also (+12%). This is mostly due to the higher price of OE which favours biomass. The latter gets a bigger impact than wind turbines used in Malaysian case.

Then, when environmental impact is minimized (min ENV), the German case observes a lower impact than Malaysia (-56%) that can be attributed to lower LCA impact of German RE sources (Figure 3). Lastly, with comparison of TOPSIS, the values obtained show a higher cost and a lower environmental impact. In both cases, wind turbines are essentially used. To conclude about geographic influence, this comparison between countries implantation shows some important differences on the respective solutions. This can be explained by (i) price for OE, (ii) impact for renewable energy sources, and (iii) by weather conditions, like seasonal influence (Germany is far from equator while Malaysia has a more regular climate). Regarding the types of renewable energy sources used, no solution proposes the solar one, it can be explained by an important investment cost and its high environmental impact (mainly due to the step of production of

photovoltaic panels) (cf. figure 2). Simulating in a more sunny country and including government helps should promote this technology. Biomass can be chosen, depending on countries, indeed, in Germany its impact is really low. At last, due to its low impact on environment, wind turbines appear to be the most used solution in this design.

		Cost (M USD)	ENV (Pts/day)	Cost storage (M USD)	Cost OE (M USD)	Wind Power rated (kW)	Biomass Power rated (kW)	Solar Power rated (kW)
Min COST	Malaysia (MY)	72,6	61,2	2,7	18,4	8764	2262	0
	Germany (GE)	86,9	68,4	6,6	8,6	0	13497	0
	Comparison GE/MY (%)	20%	12%	142%	-53%	-100%	497%	-
Min ENV	Malaysia (MY)	124,1	9,9	35,1	0	14717	0	0
	Germany (GE)	149,4	4,3	42,8	0	16578	0	0
	Comparison GE/MY (%)	20%	-56%	22%	-	13%	-	-
TOPSIS	Malaysia (MY)	78	17,0	8,0	9,1	12545	0	0
	Germany (GE)	99	14,8	10,4	33,3	9027	0	0
	Comparison GE/MY (%)	27%	-13%	30%	267%	-28%	-	-

Table 1 Detailed results for each designed solution

5. Conclusion

In support of a framework for energy supply of an eco-industrial park, we have presented a generic methodology to optimize the renewable energy sources with a MO optimization approach. Using this methodology, we can determine, economic cost and environmental impact of such a solution but also the corresponding size for storage batteries. It also allows to determine the most profitable RE sources for a given geographic position. An interesting perspective, after this design of the EIP depending on its geographic implantation is to achieve a sensibility analysis. To go further future improvements for this model can be to allow it to select between several technological alternatives for RE sources or storage, due to its genericity it can be done easily by transforming it into an MILP. Finally because an EIP is constantly evolving, by using a multi-period approach, future research may make possible to modify network over time to adapt it to its moving context.

andreia.d.santos@tecnico.ulisboa.pt

Abstract

Life Cycle Assessment (LCA) is the most used methodology to assess the environmental impacts of supply chains. Despite being the most used methodology, LCAs studies regarding forest wood supply chains considering an exhaustive Life Cycle Impact Assessment (LCIA) approach are still lacking with the majority choosing a small subset of impact categories and indicators. This work aims to develop a comprehensive Life Cycle Assessment considering two different LCIA methodologies (IMPACT 2002+ and ReCiPe 2008) to the pulp and paper supply chain to identify possible alternatives that would allow a better environmental impact based on the identification of the most critical impact categories through the Pareto principle. A Portuguese company from the pulp and paper industry is used as an illustrative case study.

Keywords: Life cycle assessment, ReCiPe 2008, IMPACT 2002+, Paper industry, SimaPro

1. Introduction

The forest sector is responsible for the transformation of a very important renewable resources into various products vital to human well-being such as furniture, lumber, energy in all its forms (heat, electricity, and fuels), newsprint and hygienic papers (World Wildlife Fund, 2000). Portugal in the European and even international context is a country specialized in this industry which is responsible for 2% of the gross domestic product, 10% of exports and for the creation of 92,000 (Instituto da Conservação da Natureza e das Florestas, 2017). It was on the forest sector that the concept of sustainability was first introduced at the beginning of the 18th century (Carlowitz, 1713). Since then, the sustainability concept has evolved with the economic, environmental and social areas being identified as equally important pillars (Department of Economic and Social Affairs, 1992). In relation to the environmental pillar, Life Cycle Assessment (LCA) has been the most used methodology to estimate the environmental impacts of different products and processes and was also identified by the European Commission as the best framework to do so (Mimoso, et al., 2015). There are several Life Cycle Impact Assessment (LCIA) methods that can be used when conducting an LCA and these methods consider different impact categories to assess the environmental impacts which can have distinct names and can be express using different units. This diversity of methods makes the decision on the best method to use harder. By using an illustrative case study of a Portuguese company from the forest sector, particularly the pulp and paper industry, and the SimaPro software, this study compares two LCIA methods, namely IMPACT 2002+ and ReCiPe 2008, in terms of the single score obtained and the critical impact categories considered by each method.

These critical categories were identified by conducting a Pareto's analysis. In Section 2 the methodology followed in this study is explained and in the following section the case study is presented. Section 4 presents the results' analysis. In the last section the main conclusions and limitations of the study are given along with suggestions for future lines of research.

2. Methodology

The LCA methodology consists of four main steps including Goal and Scope Definition, Inventory Analysis, Impact Assessment, and Results Interpretation (ISO, 2006). These steps are presented in Figure 1.

Figure 1 - Methodology followed in this study.

A brief explanation of each step is given below (ISO, 2006):

Goal and Scope Definition – where the main objectives of the study, functional units and boundaries of the system are defined. The functional unit is a representative element of the system being study and is the basis from which all inputs and outputs are calculated. The inputs and outputs to be considered depend on the boundary defined.

Inventory Analysis or Life Cycle Inventory (LCI) – consists in the calculation/collection of all the flows of materials/energy and processes needed for the functional unit. The materials and processes to be considered depend on the goals and system boundaries defined in the previous step. This step is also known as.

Impact Assessment or Life Cycle Impact Assessment (LCIA) – where the environmental impact of the inventory listed in the preceding step is measured. The inventory values are converted into impact category indicators at the midpoint level using characterisation factors. Depending on the LCIA method used, these midpoint categories can be aggregate into fewer categories of damage (endpoint categories). Different LCIA methods will consider different midpoint and endpoint categories. The endpoint categories can then be normalised using a normalisation factor. The normalised results can be multiplied by a weighting factor (assigned to each impact category based on their relative importance) and the weighted results can be added up to calculate one single score (SS).

Results Interpretation – consists in analysing and interpreting the results of the three previous steps to identify the hotspots of the system being studied and suggest possible improvements. Pareto analysis can be used to identify the critical impact categories.

In the next section the case study and the results of applying the LCA methodology to this case study are presented in terms of the first three steps. The last step is presented in Section 4.

3. Case Study

The Portuguese company from the pulp and paper industry used as a case study is integrated in a supply chain illustrated in Figure 2. This company produces and sells to the domestic and European markets three products: pulp, UWF (uncoated wood free) printing and writing paper, and tissue paper.

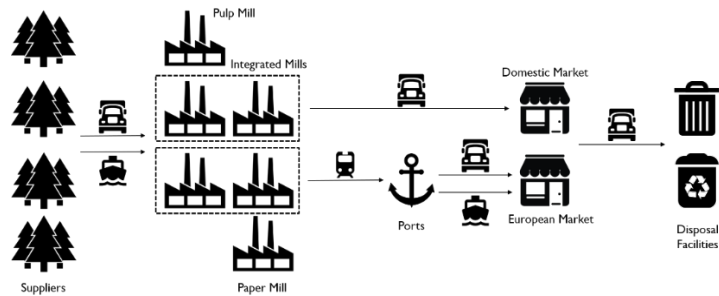

Figure 2 - Case study's supply chain.

Following the methodology presented in the previous section:

Goal and Scope Definition – the main objective of this study is to assess the environmental impacts of a forest wood supply chain, particularly a paper supply chain, to identify the critical processes (hotspots) and give improvement suggestions. A Cradle-to-Grave boundary was considered which includes all stages of the products' life cycle starting with growing and harvesting trees and finishing with products' disposal. The functional unit selected was 1 hectare of trees harvest which allows the production of approximately 25 t of pulp, 27 t of UWF printing and writing paper, and 716 kg of tissue paper.

Inventory Analysis or Life Cycle Inventory (LCI) – Table 1 presents the results of the LCI step considering the functional unit and system boundary defined, the flow between different entities of the supply chain and a paper recycling rate of 72 %.

Table 1 – Life cycle inventory and selected SimaPro references.

Life Cycle Stage	SimaPro Process	Quantity	Unit
Pulp Production	Sulfate pulp {GLO} market for	25076.4379	kg
UWF Paper Production	Paper, woodfree, uncoated {RoW} paper production, woodfree, uncoated, at integrated mill	27072.3177	kg
Tissue Paper Production	Tissue paper {GLO} production, virgin Conseq, U	716.4697	kg
Road Transportation	Transport, freight, lorry, unspecified {RER} transport, freight, lorry, all sizes, EURO5 to generic market for	24160.1270	tkm
Rail Transportation	Transport, freight train {Europe without Switzerland} market for	5420.0682	tkm
Maritime Transportation	Transport, freight, sea, transoceanic ship {GLO} processing	67898.5670	tkm
Products' Disposal	Paper (waste treatment) {GLO} recycling of paper Conseq, U	72	%
	Waste graphical paper {Europe without Switzerland} treatment of waste graphical paper, sanitary landfill Conseq, U	28	%
	Waste paper, sorted {RER} tissue paper production Conseq, U	100	%

Impact Assessment or Life Cycle Impact Assessment (LCIA) – The IMPACT 2002+ and ReCiPe 2008 methods were selected. SimaPro was the chosen software to help assess the environmental impact of the supply chain studied. Table 1 also shows the references used to create a model in this software that best represents the case study. When using SimaPro, the hierarchist perspective was selected for the ReCiPe 2008 method. After implementing the case study in the SimaPro software, the results can be analysed.

4. Results and Discussion

An overall environmental impact of 28.7 Pt and 8.83 kPt was obtained using the IMPACT 2002+ and ReCiPe 2008 methods, respectively. Looking at these results, it was possible to conclude that in both LCIA methods the production and usage phase of the products (Market for All Products) contribute the most to the overall environmental impact as can be seen in Figure 3. Furthermore, it is the production and usage of UWF Paper (Market for UWF Paper) that most contributes to this result as represented in Figure 4. The impact of the Market for UWF Paper is higher when using the IMPACT 2002+ method while the impact of the Market for Pulp is higher when using the ReCiPe 2008 method.

Figure 3 - Life Cycle

Figure 4 - Market for All Products

The process that most contributes to the impact of the Market for UWF Paper is UWF Paper Production in both LCIA methods considered as represented in Figure 5.

Figure 5 - Market for UWF Paper

A Pareto analysis was performed to identify the most critical impact categories regarding the UWF Paper Production process. The results are illustrated in Figure 6 for the IMPACT 2002+ and ReCiPe 2008 methods. From Figure 6 it is possible to conclude that four midpoint categories (respiratory inorganics, terrestrial ecotoxicity, global

warming, and non-renewable energy) are responsible for 84 % of the environmental impact related to UWF Paper Production when considering the IMPACT 2002+ method. It is also possible to conclude that three midpoint categories (agricultural land occupation, climate change and fossil depletion) are responsible for 85 % of the environmental impact related to UWF Paper Production when considering the ReCiPe 2008 method.

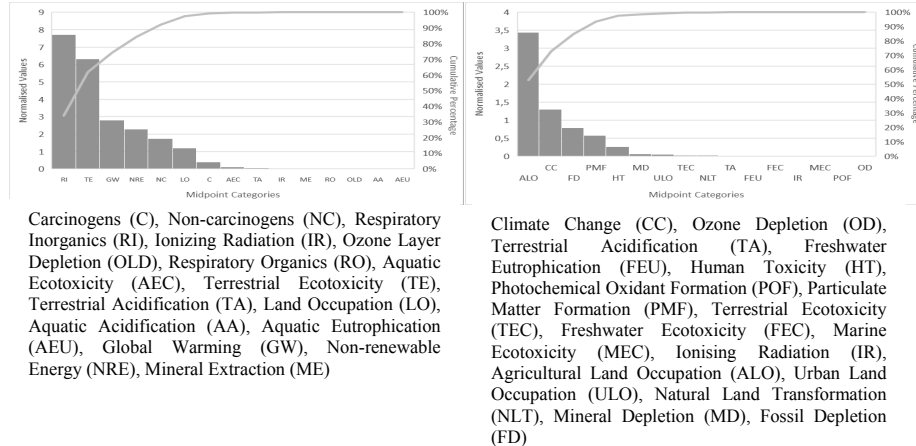

Figure 6 - Pareto Analysis (IMPACT 2002+ on the left and ReCiPe 2008 on the right)

The inputs of the UWF Paper Production process that most contribute to the critical impact categories identified previously are illustrated in Figure 7 for both LCIA methods. From the analysis of Figure 7 it is possible to conclude that electricity is the input that most contributes to three of the four critical impact categories identified with IMPACT 2002+ with the exception being the terrestrial ecotoxicity where the input that most contributes is wood ash mixture. Similarly, electricity is the input that most contributes to two of the three critical impact categories identified with ReCiPe 2008 with the exception being agricultural land occupation where the input that most contributes is pulpwood. For these reasons and to minimize the environmental impacts of the supply chain studied, a switch in the sources of electricity could be made by switching from non-renewable sources to renewable sources of energy such as biomass.

Figure 7 - Main Inputs of the UWF Paper Production (IMPACT 2002+ on the left and ReCiPe 2008 on the right)

The comparison of the two methods allows the following conclusions to be drawn:

- 1- Both methods pointed out the same process as the bottleneck of the life cycle and therefore the confidence in this conclusion is high.

2- In terms of the most relevant impact categories the results are not the same. This reinforces the problem of standardization in LCA, where the same bottleneck influences different impact categories.

3- It is not possible to recommend the best method to apply, but it is possible to recommend that bottlenecks' identification in terms of processes and environmental impacts, should be done through the application of several methods, in order to strength the robustness of the conclusions.

4 – When making comparison amongst systems, in our case supply chain, the same method should always be used so as to avoiding unfair comparisons, but as mentioned in point 3 the usage of different methods reinforce the bottlenecks' identification.

5. Conclusions

A comparative analysis of two LCIA methods, IMPACT 2002+ and ReCiPe 2008, was proposed. These methods were applied to a case study, a Portuguese company from the pulp and paper industry, which was implemented in the SimaPro software. The LCA methodology revealed to be useful for identifying the most impactful processes from an environmental point of view. With this information, improvement suggestions could be made. The study presented in this paper should be extended to include more LCIA methods to make the conclusions more robust. Furthermore, other case studies could be analysed to identify similarities between different industries in the forest sector.

Abstract

Globalization has increased the exposure of Supply Chains (SC) to higher uncertainties that call for adequate strategies, thus supporting the creation of SC Resilience. There is, however, no absolute strategy that decision makers can follow to guarantee such resilience and the knowledge on how to characterise SC resilience (SCR) is still an open issue. This work focuses on a strategic level of decision and analyses the relationship between SCR and SC complexity, aiming to conclude how SC flow complexity reflects SCR. The design and planning of a multi-product, multi-period SC are addressed through a Mixed Integer Linear Programming (MILP) model where demand uncertainty is considered. A set of disruptions is studied for different SC structures and as main conclusions, it can be stated that SC flow complexity leads to an increase in SC resilient performance and appears as a good indicator of SCR.

Keywords: Supply Chain Resilience, Quantitative models, Flow Complexity; Design and Planning

1. Introduction

The concept of Supply Chain Management was for the first time introduced in the XX century by Oliver et al. (1982) and since then has evolved. The need to guarantee competitiveness in a global market has lead SC to expand geographically and consequently, SC structures have been facing an increased exposure to risks due to a larger set of uncertainties that they have to deal with. This has created the necessity of deeply analysing the concept of SC resilience as a way to deal with such uncertain context. This is critical in the case of process supply chain as this type of systems are frequently global chains, whose business spreads around the globe, and whose products with great importance to society have to be continuously available, as is the case of pharmaceuticals, food, chemicals, energy, amongst others (Barbosa-Póvoa, 2014).

SCR is one of the newer concepts in SC and it comes as a need to better prepare SC for challenges brought by global SC operations. As stated by Ribeiro and Barbosa-Povoia (2018) in a recent review on the topic, “A resilient supply chain should be able to prepare, respond and recover from disturbances and afterwards maintain a positive steady state operation in an acceptable cost and time”.

In such setting, the interest in a sound understanding of SCR has led academics and companies to pursuit efforts regarding such objective (Tang, 2006; Kamalahmadi and Parast, 2016). It is on the best interest of real SC the increase in knowledge in SCR as it is fundamental to better understand not only the resilience concept but also how this can help SC to deal with disruptive events that can endanger their steady-state operation (Cardoso et al., 2015). Several authors have been recently

studying SCR but there is still a lack of understanding on how to quantify SCR (Ribeiro and Barbosa-Póvoa, 2018). Cardoso et al. (2015) studied SCR and proposed a set of SC indicators that could be used to analyse SCR. SC flow complexity was identified as one of the most promising indicators and further studies on this should be performed to confirm such result.

Based on these results, the present work focus on the design and planning of SC where decisions taken on the SC network structure are analysed. A design and planning multi-product, multi-period MILP model is developed where demand uncertainty is considered. Five different supply chain structures are analysed and the associated complexity optimized. The resulted SC structures are subject to a set of disruptive events and their resilience is analysed.

2. Problem and Model Description

In order to be able to discuss how different SC networks behave towards resilience, a five echelons supply chain was considered, where reverse flows are also possible to occur. Such SC involves: Raw Material Suppliers; Plants that can also function as Disassembling Centres with end of life products; Warehouses with added value activities as reconditioning non-conforming products; Outsourcing contractors as an alternative to plants production and finally Markets. In the plants and warehouses, technologies can be installed, which influence production, assembly and disassembly processes. These technologies can be fitted to the entities, or upgraded, to provide better performance.

Based on this generic SC structure five different SC cases are studied where different SC structures are considered and allow to compare and construe results on SC resilience: Case A - a forward supply chain; Case B - similar to A, but now integrating also reverse flows between consecutive echelons; Case C - similar to B, but plants and markets can directly exchange products, thus bypassing the warehouses; Case D - similar to B, but with the possibility of transshipment at plants, disassembling centres and warehouses; Case E - the most general case, encompassing all the previous ones, forming a closed-loop supply chain where plants send directly products to markets and can also receive directly from markets the end-of-life products. Transshipment is allowed at plants, warehouses and disassembling centres.

The MILP model developed by Cardoso et al. (2015) is taken as a base and was adapted to this work goals, providing a new objective function and a set of constraints to study SC flow complexity. Uncertainty was considered in the SC demand and on Disruptions. A scenario tree is constructed combining the two sources of uncertainty. Demand variability is introduced by generating a scenario on each period from a set of three possibilities (Pessimistic, Realistic or Optimistic). The result probabilistic nodes are then combined with the variability from the disruption that can only assume two options, or it occurs or it does not occur on a specific time period to consider. With this, each scenario probability is given by the probabilities of the path, with all stages, between the root node and each final leaf node.

2.1. Objective Function

Two objective functions are studied, Equations 1 and 2. A first one considers the maximization of the network flow complexity (Equation 1), as this would return a network configuration with maximum flow complexity (FC) under the feasibility space generated by problem constraints, being FC_t the summation of all positive flows present in the SC for each time period.

$$\text{Max} \sum_t FC_t \quad (1)$$

This model formulation, although returning a SC with the maximum amount of feasible possible flows does not take into consideration economic concerns, leading to solutions that may have a

low performance in financial terms. This issue can, however, be tackled by setting additional constraints in the model, as is the case of establishing a minimum profit that must be obeyed. However, this method was not followed due to two reasons. First, restrictions had to apply to all cases and scenarios, which involve setting up conditions that cannot interfere with the feasibility of the model. Second, by setting up new conditions there is the possibility of endangering the established relationship and compatibility with the original model.

Therefore, a two-step approach is followed. Primarily the model is run based on Equation 1 to retrieve the SC with maximum flow complexity within the model feasibility. The second step is used to retrieve the obtained network configuration and then study how much such network configuration maximizes the economic return. The economic return is based on the Expected Net Present Value, Equation 2 (where CF stands for the Cash flow for each scenario and time period, and ir for a defined interest rate). Through this method it is ensured a network with maximum flow complexity and with the most advantageous economic performance to the company.

$$MaxENPV = \sum_s pb_s \times NPV_s \quad pb_s = \text{Probability scenarios} \quad NPV_s = \sum_t \frac{CF_{st}}{(1+ir)^t} \quad (2)$$

By fixing the network configuration there is no capability for the SC network to change, however, it can adapt to the variability introduced in each situation by investing in new technologies, or upgrades to the existing facilities as well as optimize the supply chain flows.

3. Case Study

The presented model is tested in a Case Study of an European Chemical Process SC. The values associated are scaled down, due to confidentiality reasons. The initial SC configuration comprises a set of European locations, with one plant in Hamburg, one warehouse in Munich, four raw materials suppliers, 3 suppliers of final products and 18 European cities as markets. In broad terms, the company is studying the existent SC in order to assess the investment necessary in technologies for current entities, or the implementation of new facilities, to improve the SC's resilient capability. Four operational conditions are studied; one reference case with perfect operational conditions and three examples of disruptions. The disruptions were chosen following failure modes defined by Rice and Caniato (2003). **Disruption 1** (Production Facilities)- "100% decrease in the production capacity of the most important plant (plant P13), in time period 2, caused, for example, by a major natural catastrophe". **Disruption 2** (Supply)- "The most important raw materials suppliers (s3, s5, s8, s9 and s10) have their supply suspended in time period 2, due to an assumed industrial action". **Disruption 3** (Transportation)- "The 3PL hired to operate those transportation links, between plants and warehouses, that carry the highest quantity of products (links between P13 and warehouses W1, W2 and W4), goes out of business in time period 2". The scenario tree responsible for the uncertainty in the demand is built based on the assumption that the demand in the beginning is known and that there are three possible branches for time period 2 and 3, with the same probability in both periods; Optimistic 0.25, Realistic 0.5 and Pessimistic 0.25. (Time period 2: Optimistic with an increase of 10%; Realistic with an increase of 3%; Pessimistic with a decrease of 2%. Time period 3: Optimistic with an increase of 5%; Realistic with an increase of 2%; Pessimistic with a decrease of 2%)

For each SC case, two configurations are established based on the SC network provided by the two objective functions: maximization of ENPV and maximization of flow complexity, when there is no disruption. These network designs are then subject to the disruptions and the results are analysed and discussed. The MILP model is developed using the GAMS software. The results when applying a network configuration for ENPV maximization can be seen in Table 1, whereas the results for a SC with its flow complexity maximized are presented in Table 2.

3.1. Case A

Case A represents a simple SC structure allowing only forward flows. One relevant analysis can be made regarding the delta of ENPV value between the two options, maximizing ENPV versus maximizing complexity. Comparing the results from both configurations, respectively in Tables 1 and 2 it can be seen an increase in service quality (ECSL) and that the loss in ENPV by incrementing complexity (-0.01E7€) is easily compensated by the gains in disruption 1 and 2 (0.15E7€ and 0.1E7€), representing gains of 9% and 5% respectively. During Disruption 3 the leaner SC network is able to provide the same economic return than the network with increased complexity, however, it does so with a decreased service quality.

3.2. Case B

Case B represents a SC structure where reverse flows are allowed between consecutive echelons adding complexity to the operation. It is expected an increase in flow complexity in order to cope with such requirement. The SC configuration with ENPV maximization has an increased impact from disruptions causing a decrease in ENPV of 14%, 7% and 6% for disruptions 1, 2 and 3 respectively. When no disruption is present a variation of -0.03E7€ in ENPV is expected, when the SC shifts to a more complex network the ENPV variation are positive, with a gain more than the double of the cost if no disruption is present. The service quality is also impacted by a more complex configuration with improvements of 21%, 15% and 7% for disruptions 1, 2 and 3 respectively.

3.3. Case C

Case C introduces a different kind of flexibility to the network, it allows the same flows as Case B and also allows for plants and markets to exchange products without any warehouse intervention. There is an increased susceptibility to Disruption 2 in Case C and this is much related with the non-existence of transshipment between entities in the same echelon. The leaner SC has a decrease in ENPV of 19%, 30% and 10% for disruptions 1, 2 and 3 respectively, while the more complex

Disruption 1	516	1.89E+07	1.23E+06	9.51E+05	916.495	365270	52210000	95.2%
Disruption 2	520	1.92E+07	1.25E+06	9.80E+05	975.706	354997.874	51803000	92.8%
Disruption 3	523	1.94E+07	1.10E+06	8.26E+05	915.648	377860	52886000	99.0%

SC shows improvements of 14%, 27% and 5% for disruptions 1, 2 and 3 respectively. In terms of service quality it is perceptible an increase in ECSL for the more complex structure, maintaining levels of above 90% even during disruptions.

3.4. Case D

Case D allows forward and reverse flows between consecutive echelons and adds a new set of possibilities by allowing transshipment at plants, disassembling centres and warehouses. Applying the leaner configuration, disruptions cause an ENPV decrease of 19%, 7% and 6% for disruptions 1, 2 and 3 respectively. These results can be improved by 13% and 3% for disruptions 1 and 2 respectively, if a more complex network is deployed. In terms of ECSL the leaner configuration leads to a decrease of 24%, 16% and 10% for disruptions 1, 2 and 3 respectively, the more complex network allows for a steady service level of around 80%, improving the alternative configuration by 22%, 13% and 7% for disruptions 1, 2 and 3 respectively.

3.5. Case E

Case E represents a network that includes all the possibilities from previous cases. This closed loop SC can perform transshipment at all levels, except for markets, and flows bypassing intermediate entities are also allowed. ENPV variations between steady-state operation and disruptive scenarios are visible, resulting in a decrease of 20%, 20% and 10% for disruptions 1, 2 and 3 respectively on the network provided by the ENPV maximization. On the other hand, applying the more complex network the results of ENPV during the disruptive events are improved by 15%, 16% and 5% for disruptions 1, 2 and 3 respectively. With the maximization of complexity, the SC can return ECSL higher than 90% in all scenarios, even when a disruption does occur. When a leaner network is implemented disruptive scenarios cause a decrease in service level of 13% and 19% for disruptions 1 and 2 respectively. Applying the network with a higher amount of permitted flows leads to an improvement of 14%, 19% and 1% for disruptions 1, 2 and 3 respectively.

4. Conclusions and Discussion

From the above study, it can be concluded that the obtained results vary not only with the SC complexity but also with the SC structure (e.g. forward or closed-loop) as well with the different types of disruptions. Different disruptions cause different results and so decision makers should have enough information to make the most acceptable decision considering model results and available information. It is in this line that, studying SC Resilience factors gain importance, as it allows the development of better models to aid decision making.

Considering the behaviour on ENPV caused by the increased complexity, when no disruption occurs, is observed an increment on costs, due to the obligations that come from opening and maintaining more facilities and flows. However, if disruptions occur, there is an evident benefit of operating a more complex SC. The difference in ENPV in disruptive scenarios between the more complex and a leaner SC is always positive, in comparison with not investing in preventive strategies.

There is a more evident benefit from deploying a more complex SC in terms of ECSL. The notable shift is made possible by the increased flexibility and redundancy allowed by the higher amount of entities and flows involved resulting in an increased SC responsiveness. The investment made in increasing complexity is completely overcome by the resilience created in the supply chain structures as they are able to better react to disruptions guaranteeing higher service levels and higher profit values. However, this characteristic should be always met by a specific analysis of each SC and to its, perceptible, vulnerabilities.

As a final analysis, it is relevant to compare the results of this paper with those from the original publication of Cardoso et al. (2015), aimed at maximizing ENPV for each SC structure and scenario. As expected, our results produce a network with lower ENPV but with a trade-off for better ECSL.

As main conclusions, it can be said that investing in proactive resilient Supply Chain Design can reduce losses, generate value to companies and reduce the need for reactive strategies, in case of facing a disruptive event. With this work, we are also capable of attesting the positive correlation between the increased SC complexity with a positive outcome in case of some disruptions, as suggested by Cardoso et al. (2015) in their study.

Abstract

Fractals are the evolutionary answer that Nature has developed to provide highly packed structures for mass and heat transfer. In this work, a computational fluid dynamics model will be presented to gain insight on the multiphase flow characteristics within fractal geometries. A substantial increment of the gas-liquid interface area with the fractal dimension of the particular geometry being tested is expected. This will allow the implementation of more compact designs, i.e. with greater specific area, than the conventional structured packings currently used for gas separation. More compact designs also mean less solvent used for the same gas absorption rate, reducing the heat duty of solvent regeneration. The next steps of this research will include the use of 3D printing techniques to reproduce fractal geometries to be tested in an experimental set-up, and the study of the interaction between nature-inspired gas absorbers and the rest of the carbon emitting facility through process simulations.

Keywords: CFD, fractals, biomimetics, structured packing, gas separation.

1. Biomimetics and the need for a new generation of structured packings

Nature has provided some of the most ingenious and elegant solutions to complex engineering challenges over millions of years of evolution. On different scales and in various scenarios, many living creatures have encountered similar design problems than humans, such as drag reduction or the need for efficient heat and mass transfer. Biomimetics consists on the replication of systems found in Nature to solve complex engineering situations. The design of Japan's bullet trains is an example. At high speeds, the blunt nose of the train would create a sonic boom upon exiting tunnels far exceeding environmental noise standards. By mimicking the geometry of the kingfisher beak, engineers were able to develop a more silent high speed train, which was also 10% faster and used 15% less electricity. Replication of the microscale patterns of shark skin to be applied to marine vessels and planes is another example of biomimetics. Shark scales possess a geometry that prevents the formation of microorganisms, and also reduces the overall hydrodynamic drag making swimming less energy consuming. It has since been applied to airplanes, marine vessels, and high-performance swimsuits. The application of biomimetics to improve chemical engineering equipment has not been however, so extensively explored to date. This work aims to investigate the

application of nature-inspired fractal geometries to improve structured packings (SPs) for gas separation. The purpose of SPs is to increase gas separation efficiency by providing high specific area. They consist of a sequence of parallel corrugated sheets with a purpose-built embossed surface texture to allow maximum spreading of a given solvent, hence maximizing the gas-liquid contact area. SPs are ubiquitous in industry, being distillation, air separation, and the production of chemicals some of their applications. Carbon capture and storage (CCS) is another remarkable field of recent development where SPs have been utilized. Proof of the importance of SPs in industry is the estimation from the CCS Association, which foresees that CCS could create 100,000 jobs across the UK by 2030, contributing £6.5 billion to the UK's economy (IME), and that the CCS industry could be as big as the North Sea oil industry, taking a significant share of a £5 trillion global CCS business by 2050 (AEA). The UK, with the plus of having an adequate storage capacity, will have a unique opportunity to benefit from this emerging sector. Given their widespread use, an improvement in the design of SPs would result in an enormous impact in the UK's chemical sector. One of the drawbacks of gas separation processes is the regeneration of the effluent solvent from the absorption column, which constitutes the greatest energy penalty of the process. To tackle this issue, the underlying hypothesis of this work lies in that a significant reduction of the regeneration cost could be achieved by reducing the volume of solvent circulated within the CCS facility, the key to achieve that goal being a dramatic increase in the process intensification. The results of the literature research conducted suggest that the application of microfluidics and fractal geometries increase the specific gas-liquid contact area, resulting in a significant reduction in the amount of solvent and the subsequent heat duty, and opening the gates towards economically attractive CCS. The results are transferrable to other chemical engineering sectors such as petrochemical, pharmaceutical, etc., which are fundamental to the UK's economy. The design of the novel breed of SPs is supported by recently developed fields such as microfluidics, fractal geometries, the application of externally generated turbulence, and rapid prototyping, the relation between them and the objectives of the project being depicted in Figure 1.

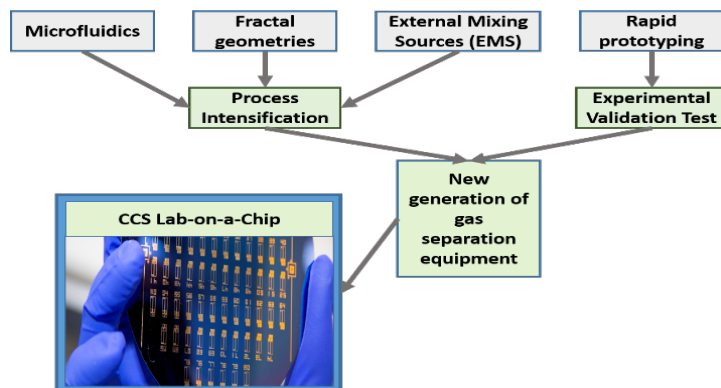

Figure 1 Relation between the novel concepts introduced in the design process and the objectives of this research

A substantial gain in intensification, determined by the use of fractal shapes and the scaling of the geometry down to the microscale, is thus envisaged. As laminar flows are encountered in microfluidic devices owing to the low Reynolds numbers, mixing is to be improved with the use of external sources of turbulence, namely electrophoresis, ultrasonic fields, etc. The partial objectives of this research are thus to determine the intensification capabilities of the application of the three above mentioned technologies, and the use of rapid prototyping, i.e. 3D printing techniques, to overcome past difficulties encountered in the manufacturing process of such complex geometries. Rapid prototyping will allow reducing any delay between the CFD-based analysis and the experimental confirmation of the resulting models. The whole design process is framed in a modelling approach that consists in multi-scale CFD analysis of the multiphase flow within fractal geometries to accelerate the validation of shapes tested numerically and the analysis of the performance of the new shapes in a process modeling environment.

2. Microfluidics, the concept of fractals and their application to the design of gas separation systems

Fractal shapes appear regularly in Nature in a variety of places and for many purposes. Snowflakes, blood vessels, plant root systems and DNA are just some of the numerous examples. Fractal shapes consistently appear in situations which require mass or heat transfer throughout a large space, such as blood vessels transporting blood to extremities of the body. The reason they are so common is how effectively they can use a given space to its maximum potential by spreading in a repetitive and consistent pattern. Tatsumi et al. (1989) demonstrated that a number of trees and plants used fractal root systems to gather nutrients. Rather than just growing in one long bending root, the roots split and spread to be able to gain more nutrients from the same volume of soil. This characteristic of optimal spreading and transfer throughout a space is of particular interest for heat and mass transfer devices. A fractal-shaped gas separation device would be potentially more compact than current SP designs and as a result, less solvent would be needed for the same gas absorption rate, reducing the heat duty for regeneration.

Repetitive patterns were first investigated in the 17th century, but little was understood until two centuries later when mathematician Karl Weierstrass demonstrated the first function that later would be defined as a fractal. A number of mathematicians followed on from Weierstrass' work and studied the geometry of fractals, being Sherman's functional relationship between the diameter of the branches and a number of flow characteristics including pressure gradient, wall shear stress, velocity gradient, Reynold's number, volumetric flow and average linear velocity of the flow (Sherman, 1981) one of the key achievements. Fractals had been recognized as appearing frequently in nature, but a holistic theory was not developed until 1982 by Mandelbrot, who investigated the fractal structures of coastlines, snowflakes, clouds, galaxy clusters, and other various naturally-occurring shapes, and defined the concept of fractal dimension as a measure of their space-filling capacity. The application of fractals to

improve fluid dynamic designs started when West derived a general model for minimising the work flow for bulk fluid transport through a network of branching tubes (West et al., 1997). To date, evidence has been reported in the literature as to the underlying phenomena which explains the available space exploitation provided by fractal shapes, as well as better pressure drop characteristics with respect to regular cylindrical geometries. Alharbi et al. (2004) demonstrated that the pressure drop through a fractal-like network is 50% less than that through a straight channel network. This difference is attributed to a local pressure recovery at each bifurcation. Fractal shapes provide thus a means to maximise the exploitation of the space available with more favourable pressure drop conditions than that found in geometries used in current SP designs.

3. Objectives

The general objective of this research is the design of a novel CCS technology in which the amount of solvent is drastically reduced compared to current SP designs, giving as a result a smaller heat duty at the solvent-recovery stage of the facility. A step-change in the performance of PCC facilities is therefore needed to accomplish the above-mentioned goal, which will eventually lead to a significant reduction of the volume of solvent used and a lower heat duty in the regeneration column. The general objective of this research is thus to take advantage of the high specific area of fractal geometries so as to investigate its application to gas absorption processes in order to reach high intensification. Further process intensification will be achieved through the scale of those geometries down to the characteristic size of microfluidic devices by imitation of natural structures, such as ramifications in blood vessels and other fractal structures, both at the level of the channel network and the wall roughness inside the channel. A new generation of small-scale PCC facilities with low heat duty and pressure loss will be obtained as a result. Since laminar flow characterises is encountered in microfluidic channels owing to their small diameter, external mixing sources (EMS) such as the application of electrophoresis, magnetic and ultrasonic fields, are to be investigated to improve mixing by inducing turbulence to obtain high performance designs in terms of separation efficiency.

Figure 2 Illustration of the application of electrophoresis for mixing enhancing in microchannels.

Figure 2 shows a schematic of the mixing enhancement based on electrophoresis. The direction of the flow is from the left (where laminar flow is encountered owed to the small Reynolds number) to the right-hand side. The momentum exchange between the particles, which owe their movement to the external electric field, and the fluid result in enhanced mixing, thus opening the door towards even smaller structured packing geometries. Several parameters might affect the final degree of mixing, namely the particle size and the shape of both the particle and its trajectory within the microchannel.

Finally, experimental testing of the resulting prototypes will be possible by using rapid prototyping, i.e. 3D printing. The study is firstly focused on CCS applications, and therefore the main two columns which form such a facility (the absorption column and the stripper) are the primary object of this research. The regeneration of the solvent accounts for as much as 70% of the total opex cost for carbon capture and is the main target, although it should be noted that the findings can be extrapolated to the absorption column, and to any unit operation in a chemical plant involving gas separation. The specific key objectives of the project are summarised as follows:

- To tackle the problem of the high cost of solvent regeneration by achieving a critical reduction in the volume of solvent used within the post-combustion CCS facility. The latter implies the reduction of the heat duty in the stripping process, which is the main energy penalty.
- To characterise the hydrodynamics of multiphase flows within a ramified network of vessels in terms of reactor volume and pressure drop.
- To reach an unprecedented reduction in the size of the equipment needed for CCS, owing to the combination of the use of microfluidics with specifically built shapes, and EMSs.
- To explore the capabilities of rapid prototyping to create fast experimental fractal-like samples to be validated.
- To find the trade-off between the increase in specific surface resulting from the use of fractal shapes and the extra pressure drop expected from the scale-down to microfluidic characteristic lengths.
- To investigate the effect of the EMSs in the increase of mixing and, ultimately, their capability to provide extra intensification.

The design of the final unit capable of treating the entire amount of exhaust gases produced in a large carbon dioxide source, i.e. a power plant, is envisaged with the application of experimental validation and process simulations to check the interaction with the rest of the plant. The final unit will be formed of smaller lab-on-a-chip (LOC) modules in either cascade or parallel disposition, or a combination of both. Modularity is expected to help with adapting the size of the final unit to the amount of exhaust gas to be treated, which can vary with the source power output. The intensification potential resulting from the application of the fractal vessel network will determine the volume of exhaust gas that can potentially be treated with each LOC module and its nominal size. The basic configuration of the final LOC module design will therefore consist in the fractal vessel network, the external turbulence source equipment and the auxiliary control and instrumentation equipment. Replication of the basic LOC module will result in the final design being adaptable to the gas separation requirements at hand.

4. Conclusions

Although being a long-standing and mature technology, with not much evolution in the last decades, there is still room for improvement in the field of structured packings. Its matureness has actually resulted in a widespread use in almost any field of the chemical industry in which gas separation is needed, yet their efficiency has proved insufficient in the field of carbon capture and storage, owing to the high heat duty of the solvent recovery unit. This leads to the need for seeking a new paradigm in the design of structured packing geometries.

An improvement of the overall efficiency of the carbon capture process is envisaged in this work by implementing a radical change in the design of mass transfer equipment. This paradigm shift is based on the imitation of naturally occurring fractal-like geometries, and the use of micro fluidics to boost the specific area and thus reduce the amount of solvent to be regenerated for a given carbon removal rate.

Computational fluid dynamics are to be used to explore the intricacies of the multiphase flow within such complex geometries, saving the hurdles posed by experimental work in this aspect. The experimental work is reserved for the final testing of 3D printed prototypes resulting from the numerical investigation. The link between absorption columns filled with the new breed of packings and the carbon producing facility will be explored by using process simulations.

Abstract

Evaluating the applicability of reactive distillation (RD) is an important stage in the conceptual design phase, when RD is considered as a promising process intensification option. However, performing that task may be both time consuming and difficult due to the complexity of the models and the detailed data required. To solve this problem, this study presents a quick approach to perform a preliminary economic ranking of RD using a navigation method. This method works like a global positioning system (GPS) in which pre-defined maps (i.e. the plot of reflux ratio vs number of stages) are used to charting the applicability of RD. Together with the pre-defined maps, the data of RD configurations (i.e. number of rectifying, reactive, stripping stages) are generated. By using the navigation method, this study checks the applicability of RD for quaternary reversible reaction systems ($A+B=C+D$) with different boiling point orders. The result of a preliminary economic assessment is given as RD cost ranking which can be used as a valuable pre-screening prior to performing any detailed economic analysis. Therefore a full assessment requiring a long time can be avoided. With a fair comparison in terms of relative volatilities, the system with mid-boiling reactants generates the lowest cost, whereas the system with mid-boiling products requires the most expensive RD setup.

Keywords: reactive distillation, navigation method, conceptual design.

1. Introduction

Multifunctional reactors are essential components of process intensification, which integrate reaction and at least another function into a single unit operation (Stankiewicz, 2003). These technologies offer major benefits in reducing costs and saving energy (Castillo-Landero et al., 2017). Among the available multifunctional reactors, reactive distillation (RD) has become one of the most recognized and attractive units in chemical processing. The RD operation is promising for various types of reactions, e.g. (trans)esterification, hydrolysis and isomerization. In the RD application, optimum conversion and selectivity are attainable (Kiss 2003a), the separation limitation due to azeotropes can be prevented (Kaymak, 2017), a better plant environment (in terms of emission reduction and safety improvement) can be obtained (Shah et al., 2012). Considering the encouraging pathway of RD utilization, the primary evaluation of the RD applicability in the phase of conceptual design is important. However, performing that assessment may be both time consuming and difficult due to the detailed data,

complexity of the models and the lengthy algorithms required for optimal design (Segovia-Hernandez et al., 2015). Moreover, in many cases the result of the evaluation of RD application is unfortunately economically infeasible. In other words, the amount of time allocated to investigate the RD application and the results of the RD evaluation are unbalanced. To overcome this problem, this study presents a quick approach to perform an early economic ranking of RD using a navigation method. Using the proposed approach, the outcome is expected to be the first consideration of selecting chemical systems which might benefit from using RD as an intensified process.

2. Modelling approach

The navigation method used in this study has been introduced in our previous work (Muthia et al., 2018). The main objective of the method is to predict the RD applicability to real (non-ideal) chemical systems based on generic (ideal) cases. In this work, the only focus is applying the method to perform preliminary economic ranking for the RD application. For the sake of clarity in this study, the generic cases of quaternary systems ($A+B=C+D$) with different boiling point orders were assessed. Using pre-defined maps (i.e. the plot of reflux ratio (RR) vs number of stages (NTS), see Figure 1), this GPS-like method navigates the applicability of RD. Next to the pre-defined maps, the data of RD configurations (i.e. number of rectifying, reactive, stripping stages) are presented. To generate the pre-defined maps, ideal generic cases were used and few basic (constant) parameters were required, i.e. relative volatility values (α) and chemical equilibrium constants (K_{eq}).

For consistency, the groups naming of the quaternary systems used in this study follows the rules proposed by Luyben and Yu (2008). A fair comparison of the relative volatilities was determined in which the α_{AB} and α_{CD} values were specified (Table 1). Only the specified variables in the group I_r are different from those in the other groups since the boiling points order gives no opportunity to obtain the specified α_{AB} and α_{CD} at 2 and 6, respectively. The groups with either the heaviest reactants (group II_p , i.e. $T_{b,C} < T_{b,D} < T_{b,A} < T_{b,B}$) or the lightest reactants (group II_r , i.e. $T_{b,A} < T_{b,B} < T_{b,C} < T_{b,D}$) are excluded because, from a thermodynamic viewpoint, collecting either the lightest or the heaviest products from equimolar reactants would be almost impossible.

Using the proposed method, a preliminary cost ranking was obtained for these quaternary systems. The cost relation can be obtained because NTS directly represents the height of column and gives an estimation of the investment cost. RR is proportional to the column diameter and is associated with the energy requirements (Kiss, 2013b). Using NTS and RR as indirect cost parameters for equipment and energy, in this study there was no explicit cost formula. The outcome of the preliminary cost ranking was then compared with the results reported by Luyben and Yu (2008) who generated the economic estimation data by performing detailed simulations with only a fixed K_{eq} .

Table 1. Groups of quaternary systems based on boiling points orders

Group	A + B \rightleftharpoons C + D, T_b orders	Specified variables		Set variables	
		α_{AB}	α_{CD}	α_{CA}	α_{BD}
I_p	C < A < B < D	2	6	2	1.5
I_r	A < C < D < B	6	2	0.6	0.6
III_p	C < A < D < B	2.1	6	4	0.7
III_r	A < C < B < D	2.1	6	0.7	4

All the simulations were performed using the Aspen Plus (v8.6) process simulator. The feed streams of pure A and B (saturated liquid) in a stoichiometric ratio were fed to a RD column operating at an atmospheric pressure. The light reactant was introduced into the column at the bottom part of the reactive section and the heavy reactant was fed at the top part of the reactive section, therefore resulting in a counter current flow along the reactive part of the RD column. There were two important design criteria specified: a) 99 mol% bottom product purity, and b) 0.5 mol/mol bottom-to-feed ratio. Having set these two criteria, the minimum overall conversion was always 99 mol%.

3. RD applicability space

Figure 1 (left) presents an illustrative applicability space of RD for a certain chemical system. The dotted line indicates the boundary of the RD applicability space which separates the “applicable” and “not-applicable” areas. Exactly on the boundary line and inside the “applicable” area, the product purity is equal to or larger than the minimum criterion. For the sake of presenting clear results in this study, the applicability space is shown with the maximum scale of 100. The NTS_{min} is specified as NTS with $RR=100$ and the RR_{min} is defined as the lowest RR in case $NTS=100$. From the bottom-left to the top-right inside the “applicable” area, the colour shifts from white to light grey to darker grey, which indicates that the lighter colour is the preferred region for the RD operation.

The vertical orange line shows an example of a NTS with multiple RD configurations which have different RR values. Point 1 highlights the lowest RR and point 2 gives a higher RR with another RD configuration. Selecting point 1 with the lowest RR may be preferred in terms of the energy use. However, it is essential to also consider other points, such as point 2, since some configurations could be more beneficial and gives less capital investment (e.g. less number of reactive stages).

Figure 1 (right) presents an example of a plot of RR vs number of reactive stages for the illustrative applicability space in Figure 1 (left) at $NTS=40$, which indicates multiple RD configurations available with the RR values slightly higher than the lowest RR at point 1. In practice, the very marginal difference of RR values (e.g. in two decimal places) is negligible. Therefore, in this study it seems logic to consider the RD configurations with the RR values within the 3% range of the lowest RR, e.g. 20 reactive stages for the lowest RR value as shown in Figure 1 (right).

Figure 1. An illustrative applicability space of RD (left) and multiple RD configurations available inside the applicability space at $NTS = 40$ (right) (Muthia et al., 2018)

4. Preliminary economic ranking of RD

For the preliminary economic ranking of RD configurations, the applicability spaces and the configurations of RD are presented. Figure 2, Figure 3 and Figure 4 on the left show the RD applicability spaces for groups I_p, III_p, III_r, respectively. In the cases of groups I_p and III_p, the boundary lines of $K_{eq}=0.01-10$ are obtained for $NTS \leq 100$ and $RR \leq 100$. For group III_r, the boundary line of $K_{eq}=0.01$ is outside the applicability space and might still be obtained if $NTS \geq 100$ and $RR \geq 100$. All the groups (I_p, III_p, III_r) show the same trend of the RD applicability spaces in response to the increasing K_{eq} . For a higher K_{eq} , the applicability space is always larger since a higher K_{eq} gives a better conversion, which implies a lower RR required for a certain NTS.

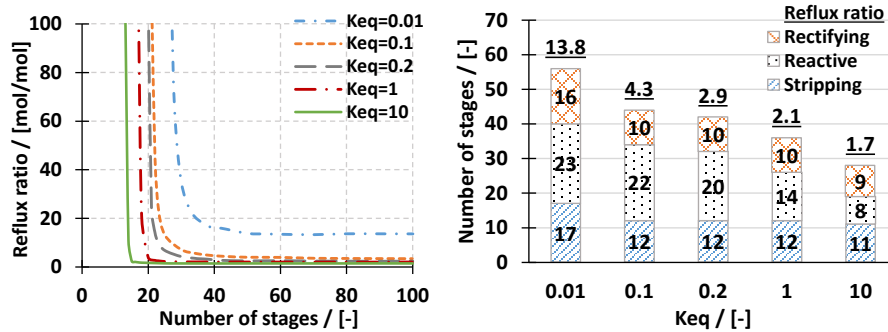

Figure 2. RD applicability spaces (left) and configurations (right) at $NTS=2 \cdot NTS_{min}$ for group I_p

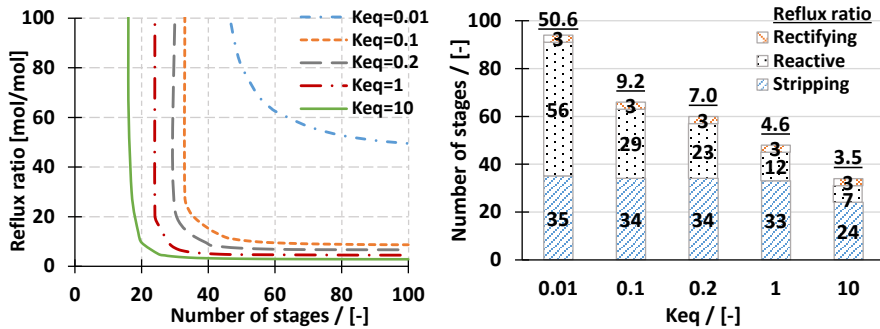

Figure 3. RD applicability spaces (left) and configurations (right) at $NTS=2 \cdot NTS_{min}$ for group III_p

Figure 4. RD applicability spaces (left) and configurations (right) at $NTS=2 \cdot NTS_{min}$ for group III_r

For group I_r , a single RD column is not applicable since the simulations of the generic cases with $K_{eq}=0.01-10$ did not meet the required product purity and the bottom-to-feed ratio. Obtaining mid-boiling products from the lightest and the heaviest reactants might need an RD set-up with side-draw product stream(s). In that case, at least one additional normal distillation is required to purify the desired products (Luyben and Yu, 2008). As another option, a reactive dividing wall column can be considered. Due to its complexity, group I_r results in the most expensive RD set-up of all the categories.

Figure 2, Figure 3 and Figure 4 on the right show the RD configurations for groups I_p , III_p , III_r , respectively, in response to varying K_{eq} . The underlined numbers in the plots show reflux ratios. The presented plots are based on the lowest RR at $NTS=2 \cdot NTS_{min}$ in the RD applicability spaces. Selecting this NTS is only based on design rules for conventional distillation columns. Alternatively, other NTS values, such as the NTS at $1.2 \cdot RR_{min}$, can also be selected. For a higher K_{eq} , the number of reactive stages and RR are always smaller due to the better reaction performance. The number of rectifying and stripping stages stays more or less the same but the separation can be done with less reflux ratio RR since the reactants are converted to a larger extent in the reactive section, therefore making the separation easier.

The RD configurations of the various groups presented in Figure 2, Figure 3 and Figure 4 (all plots on right) are then analyzed for a uniform K_{eq} . The NTS and RR values increase from group I_p , III_p , to III_r which are also in an agreement with the increase in the number of reactive stages. The increase of NTS and RR clearly indicate the cost ranking of these three groups – I_p , III_p , III_r – from the lowest to the highest cost respectively. The comparison of the RD configurations at the same K_{eq} also suggests the RD column design as shown in Figure 5. This suggestion is in accordance with the results obtained by Luyben and Yu (2008).

If group III_p is compared to group I_p , a larger reactive section is needed to convert reactant B and to avoid B reaching the stripping section. Besides, the number of stripping stages of the group III_p is bigger than the stripping section of the group I_p because the separation between reactant A and product D is more difficult to achieve ($\alpha_{AD}=3$ for group I_p and $\alpha_{AD}=1.5$ for group III_p). The number of rectifying stages of the group III_p is smaller because the separation, mainly between reactant B and product C, is easier than the group I_p ($\alpha_{CB}=4$ for group I_p and $\alpha_{CB}=8.4$ for group III_p).

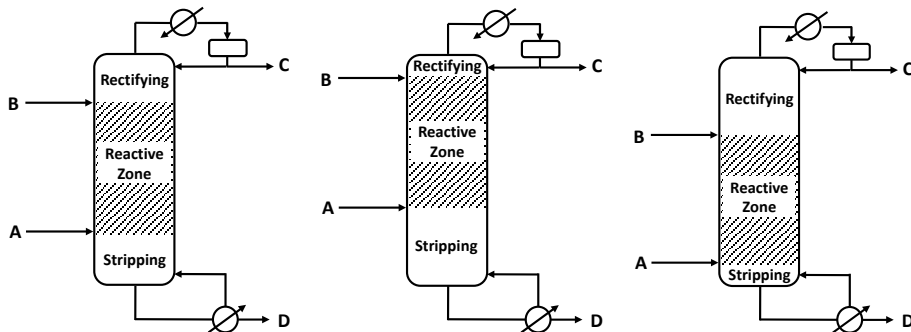

Figure 5. Proposed RD configurations for groups I_p (left), III_p (center), and III_r (right)

Considering the relative volatilities listed in Table 1, the RD configurations of group III_r were expected to be the mirror of the RD column set-up of group III_p. However, the results show that a larger reactive section and a larger RR are required for group III_r in comparison to group III_p. A larger reactive section is required to convert reactant A and avoid it reaching the rectifying section. This reaction task is more challenging than the one in group III_p since the reactant A is easily vaporized, therefore interfering with the desired purity of product C. Correspondingly, a higher reflux ratio is needed to condense it back to the liquid phase.

5. Conclusions

The investigation of the quaternary systems with various boiling point orders and a fair comparison of the relative volatilities (based only on the outcome of RD configurations for the generic cases) gives a first overview of the cost ranking – group I_p, III_p, III_r – from the lowest to the highest cost. A single RD column is not applicable for group I_r in which a RD followed by a conventional distillation or a reactive dividing wall column can be considered. In this respect, group I_r leads to the most expensive RD set-up. The GPS-like navigation method was successfully applied to perform preliminary economic ranking of RD for different generic cases of the quaternary systems, and this quick approach holds the promise to be used in a real system. Prior to implementing that task, the RD applicability for a real system can be quickly evaluated by the navigation method, as provided in our previous work (Muthia, et al. 2018).

Multi-scale system modelling under circular bioeconomy

Miao Guo*

Department of Chemical Engineering, Imperial College London, SW7 2AZ, UK

miao.guo@imperial.ac.uk

Abstract

Waste sector is expected to play significant roles in the evolving circular bioeconomy in the coming decades. Considerable amount of carbon-containing and nutrient-rich wastewater and organic solid waste resources are generated every year globally. In the UK, wastewater is estimated as 16 billion litre per day, which together with annual production of over 100 million tonnes of carbon-containing solid biowaste (e.g. biodegradable fraction municipal solid waste (BFMSW)), above 14 million tonnes of forestry and agricultural residues and large amount of other waste provide significant opportunities (BIS 2015). They could be converted via various routes to bioenergy or other value-added products such as bioenergy, biofuels, bio-plastics and fertilisers, which shift us to a resource-circular bioeconomy. In this study, a multi-scale system modelling approach is presented to investigate the holistic economic and environmental profiles of alternative resource recovery methods integrated into wastewater and organic waste treatment systems, and bring such sustainability criteria into the process synthesis and value chain optimisation. By introducing game theory into the multi-objective optimisation model and formulating the interactions between multi-level nodes involved in the supply chain, our modelling toolkit offers the functionality to account for both macro-level economy performances and micro-level individual stakeholder benefits. The modelling methodology has been applied to two case studies - wastewater and lignocellulosic waste resource recovery. Our results suggest that ion exchange is a promising technology showing high nitrogen and phosphorus removal and recovery efficiency from municipal wastewater and delivering competitive sustainability scores; whereas the integrated thermochemical and biochemical routes are favourable options for lignocellulosic resources. Current study also demonstrates such multi-scale modelling toolkit can support decision-making on optimal or equilibrium solutions for the waste bioconversion process design and waste recovery supply chain strategy at temporal-spatial scales, which are the key elements in building a sustainable circular economy.

Keywords: Waste resource recovery, process design, sustainability, optimisation.

1. Introduction

Bioeconomy has made substantial contribution to the global socio-economic growth; in the UK, it injected over £200 billion gross value into British economy and supported 5 million jobs by 2014 (Bauen et al. 2016). The predominant role of waste market has been highlighted in the UK and beyond. Considerable amount of carbon-containing and nutrient-rich wastewater and organic solid waste resources are generated every year globally. As estimated by Green Investment Bank, UK waste capacity by 2020 could

bring £5 billion investment opportunity. UK wastewater estimated as 16 billion litre per day, together with annual production of over 100 million tonnes of carbon-containing solid biowaste (e.g. BFMSW) above 14 million tonnes of forestry and agricultural residues and large amount of other waste provide significant opportunities (BIS 2015). They could be converted via various routes to bioenergy or other value-added products shifting us to a resource-circular bioeconomy. By far the most widespread recovery technology in the wastewater treatment and bio-based solid sectors is anaerobic digestion (AD). The generated biogas i.e. carbon recovery is often used for onsite combined-heat-and-power generation, but may as well be upgraded and injected into the natural gas grid or compressed as transport fuels, or used for methanol and biodegradable plastic production (such as PHA) (Science and Technology Committee 2014; Karthikeyan et al. 2015) or reformed to hydrogen for microbial single cell protein production (Matassa et al. 2015). In the UK, AD has been promoted as an environmentally favourable option for waste carbon recovery, undergoing significant development since 2011 when Anaerobic Digestion Strategy and Action Plan was launched (DEFRA 2011, 2015). By end of 2016, there were 540 operational AD facilities in the UK with a total capacity of 708 MW (equivalent to powering 850,000 households); over 90 AD plants injected bio-methane into the natural gas grid, accounting for 2.2% UK gas consumption (Anaerobic Digestion & Bioresources Association 2016). Despite of the fact that nutrient-rich waste recovery (e.g. struvite recovery) is in particular of interests due to the dominancy of fossil fuel in nutrient production (e.g. energy-intensive Haber-Bosch process for nitrogen fertiliser production), and depleting non-renewable mineral deposit (e.g. phosphorus), the value and cycling of nutrients resulted from AD (e.g. nitrogen and phosphorus) are often overlooked. Much concerns have been also raised regarding the over capacity issues and the fact that the energy-focused incentive strategies could hinder the penetration of other, potentially more environmentally favourable, resource recovery options. Such risks could be mitigated via AD-based bioconversion systems integrating advanced C conversion with other technology options for N/P and wider resource recovery e.g. AD integration with nature-based remediation solutions (Lee et al. 2018). However, such paradigm shift requires an understanding of the process configuration and whole resource-waste system design, but also the stakeholders (e.g. technology developers and operators, feedstock suppliers, finance systems, policy-makers) involved to achieve optimal or equilibrium solutions for the entire value chains, considering the environmentally sustainable and economically viable development of waste bioresource sectors. Despite of the advances in mathematical modelling, waste-treatment process synthesis e.g. (Puchongkawarin et al. 2015; Puchongkawarin et al. 2016), and sustainability evaluation and optimisation, research gaps emerge in the integrative system modelling approach that links the inherently waste recovery sub-systems with value chains complexity and wider ecosystem and natural capital variables (e.g. land, water). This study aims to contribute to the modelling advancement by proposing a multiple-scale modelling tool, which combines biogeochemical and process simulation, sustainability evaluation and multi-objective optimisation to bring environmental and economic criteria into optimal and equilibrium solutions and bridge process synthesis and whole-system level design. In particular, under the modelling framework, the interconnection of bio-waste with wider resources and ecosystem drivers has been addressed; multi-scale decision spaces involved in the waste resource management have been considered.

2. Methods

As presented in Fig 1, the modelling framework is underpinned by a closed-loop concept for resource-waste-land-water nexus under circular bioeconomy. The proposed modelling framework is presented in Fig 2, where the resource-waste-land-water nexus are captured by the integrative approach incorporating biogeochemical simulation, process-based waste recovery into optimization tools. Multi-scale (i.e. operational and tactical and strategic decision) and multi-echelon (resource supply, technology, distribution) complexity involved in the nexus are reflected in the model; ecosystem drivers and various conversion technologies (centralized vs. decentralized) and sustainability matrix and multi-stakeholders involved in the decision making are formulated. Under the framework, the combined reaction kinetic and equilibrium modelling approaches are employed to configure the process and operation and simulate the technical performances of diverse waste resource recovery to derive process flowsheet. This has been achieved by combining Aspen Plus and a state-of-the-art wastewater treatment simulator (GPS-X). The input-output flowsheet predicted was used to represent process performance; by applying CapdetWorks in conjunction with GPS-X and Economic Analyser embedded in AspenTech, the costing flows were obtained. As formulated in Eq. (1), a life cycle sustainability assessment (LCSA) approach was adopted as a systematic and rigorous evaluation tool to account for holistic sustainability (economic and environmental perspectives). The cradle-to-grave LCSA was performed on Simapro[®] platform.

$$EI_{kpi} = \sum_r \sum_s EI_{r,kpi}^{in} F_{r,s}^{in} X_{r,s}^{in} + \sum_c \sum_s EI_{c,kpi}^{out} F_{c,s}^{out} X_{c,s}^{out} \quad (1)$$

Where the variable EI_{kpi} denotes the total impacts of a given process (per functional unit) expressed as key sustainability performance indicator kpi . EI_{kpi} is determined by the characterisation impact factors for input resource r ($EI_{r,kpi}^{in}$) or emitted compound c ($EI_{c,kpi}^{out}$) input-output flows ($F_{r,s}^{in}$ or $F_{c,s}^{out}$) and concentration ($X_{r,s}^{in}$ or $X_{c,s}^{out}$) at stage s .

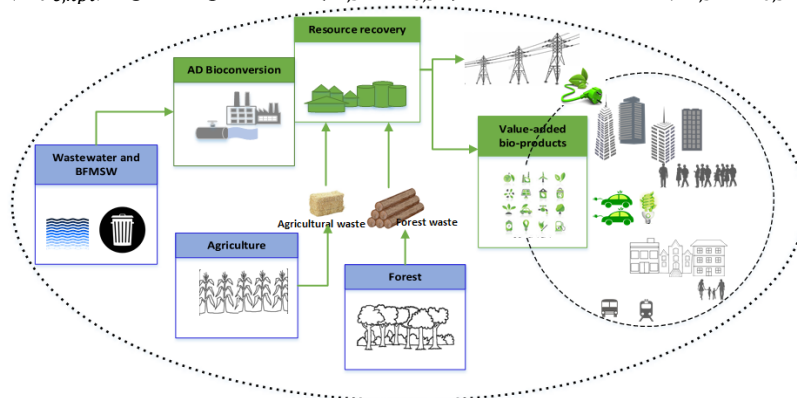

Figure 1 Waste resource recovery under circular bioeconomy

A mixed integer linear programming (MILP) optimisation model was developed to explore the temporal-spatial solutions for waste recovery system design (e.g. AD-based bioconversion) under circular bio-economy, where nonzero-sum, non-cooperative games were modelled to explore equilibrium solutions. As the modelling concept demonstrated in the Fig 1, different stakeholders involved across supply chain echelons were captured in the equilibrium model, including the feedstock suppliers, existing technology (e.g. AD) operators, new bioconversion technology developers and operators, distribution centres, investors and finance systems, policy-makers and regulators. The government is modelled as system regulator defining the marco-economy boundary conditions and implementing

policies, where the deployment policies were grouped into seven schemes and formulated in the model. A flexible echelon structure was simulated; whereas the model was further configured to consider the natural capital resource competition issues e.g. land-competition between the agricultural waste as feedstock and the bioenergy crops (e.g. miscanthus) exclusively grown for waste resource recovery processes.

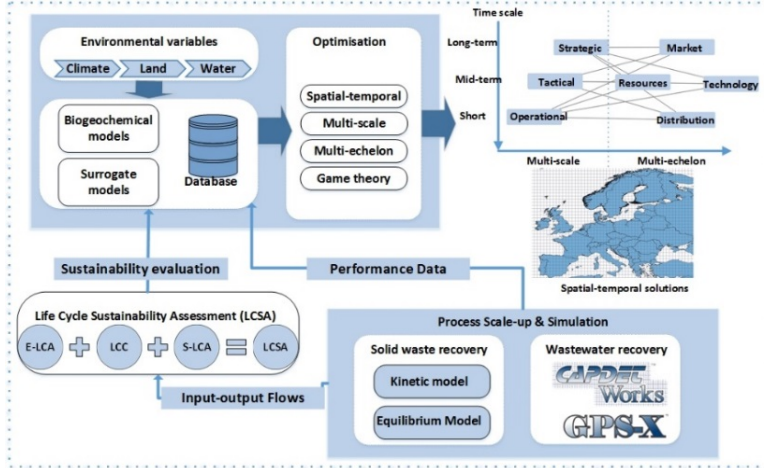

Figure 2 Multi-scale modelling framework for circular bioeconomy

Under decentralised optimisation mode, objective function (Eq. (2)) is to achieve Nash equilibrium solution for the multi-echelon waste-recovery value chains where the stakeholders involved in are expressed as nodes n_1, n_2, \dots . Each node n has a status quo point (\widehat{TI}_n), which reflects the acceptable profitability threshold of the investment on node n . The Nash solution is TI_n , where $TI_n \geq \widehat{TI}_n$ and future economic impacts are discounted back to the present values. ε_n represents the negation power of the node n . The higher negotiation power indicator is, the more advantage the node n has in profit allocation. The variable TI_n (Eq.(3)) is determined by the income of node n from trading in market and with other nodes n' over time period t ($SALEI_{n,t}$), government subsidy during time period t ($SUBSIDY_{n,t}$), tax paid by node n ($TAX_{n,t}$), loan interest over time period t ($Interest_{n,t}$), capital investment with bank loan decision (binary parameter $Equity_n$), Insurance cost for n ($Insure_{n,t}$), and impacts caused by process operation ($OPEX_{n,kpi,t}$), transport ($TRI_{n,kpi,t}$), capital inputs ($CAPEX_{kpi,n}$) as well as the discount rate over time t (Dis_t). Two key performance indicators (kpi) were accounted for i.e. economic and greenhouse gas (GHG). The impacts of GHGs have been monetarised by introducing a weighting factor $WeightF_{kpi,t}$, where the market price for traded C emissions is applied (£/kg CO₂ equivalence). A user defined parameter $\theta_{kpi,t}$ scopes whether policy instrument for emission trading is included (1=inclusion; 0=exclusion).

$$\max Obj = \prod_n (TI_n - \widehat{TI}_n)^{\varepsilon_n} \quad (2)$$

$$TI_n = \sum_t ((SALEI_{n,t} + SUBSIDY_{n,t} - TAX_{n,t} - Interest_{n,t} Equity_n - Insure_{n,t} - \sum_{kpi} (OPEX_{n,kpi,t} + TRI_{n,kpi,t} - Cap_{kpi \in EPI,n,t}) WeightF_{kpi,t} \theta_{kpi,t}) \times \frac{1}{(1+Dis_t)^t} - \sum_{kpi} CAPEX_{kpi,n} \quad (3)$$

Based on the IRN, IPCC, IE renewable deployment policy reports (IEA 2011), key renewable deployment policies have been classified and generalised into seven schemes

(Eq.(4)). By incorporating such schemes, model could address a range of questions e.g. how the system performs in response to the different government incentive strategies.

$$SUBSIDY_{n,t} = \sum_{sub} (In_{sub,n,t} + ProPay_{sub,n,t} + TaxRed_{sub,n,t} + LoanSUB_{sub,n,t} + TarrifSUB_{sub,n,t} + BuySUB_{sub,n,t} + CertiTrade_{sub,n,t}) \tau_{sub,n,t} \pi_{sub,t} \quad (4)$$

Where $\pi_{sub,t}$ is a user-defined parameter (1= policy *sub* is implemented; 0= exclusion of policy *sub*) and binary variable $\tau_{sub,n,t}$ represents the choice of node *n* in terms of their participation in government subsidy scheme *sub*. The following seven schemes have been taken into account -

Scheme 1 lump-sum direct subsidy $In_{sub,n,t}$ e.g. grant, premium payment, rebate;

Scheme 2 revenue support for bio-products *r* produced (e.g. energy production payment), where variable $ProPay_{sub,n,t}$ is determined by Eq. (5);

Scheme 3 government tax reduction variable $TaxRed_{sub,n,t}$ (Eq.(6)) depending on the revenues e.g. tax credit, tax reduction, accelerated depreciation schemes

Scheme 4 continuous variable $LoanSUB_{sub,n,t}$ (Eq. (7)) representing the government financing provided to nodes in return for a loan as investment;

Scheme 5 deployment policies to guarantee node with priority access and dispatch by setting a fixed tariff per unit bio-product *r* delivered ($TarrifSUB_{sub,n,t}$, Eq. (8))

Scheme 6 as formulated in Eq.(9), government green product purchasing schemes regulate the supply of green product purchase beyond obligations (e.g. green energy purchasing); the variable $BuySUB_{sub,n,t}$ depends on the regulated rate $BuySUBR_{sub,r,t}$ and bio-product purchase and consumption.

Scheme 7 certificate trading gain under quota mandate scheme. Variable $CertiTrade_{sub,n,t}$ Eq.(10) is determined by the purchased or consumed bioproducts, obligation threshold for bioproducts and price under certificate trading scheme.

$$ProPay_{sub,n,t} = \sum_{mr} \sum_c \sum_m \sum_p ReS_{sub,mr,t} Con_{mr,p,m} Pro_{p,m,c,n,t} \quad \text{if } Con_{r,p,m,n} > 0 \quad (5)$$

$$TaxRed_{sub,n,t} = NRev_{n,t} TaxRRate_{sub,t} \quad (6)$$

$$LoanSUB_{sub,n,t} = SubIntR_{sub,t} Loan_n \quad (7)$$

$$TarrifSUB_{sub,n,t} = \begin{cases} 0 & \text{if } FixedTarrif_{sub,r,t} \leq P_{r,t} \\ \sum_{mr} (FixedTarrif_{sub,mr,t} - P_{mr,t}) Sale_{mr,n,t} & \text{if } FixedTarrif_{sub,r,t} > P_{r,t} \end{cases} \quad (8)$$

$$BuySUB_{sub,n,t} = \sum_{mr} BuySUBR_{sub,mr,t} (Purchase_{n,mr,t} - Mandate_{mr,t}) \quad (9)$$

$$CertiTrade_{sub,n,t} = \sum_{mr} Certificate_{sub,mr,t} (- \sum_c \sum_m \sum_p Con_{mr,p,m} Pro_{p,m,c,n,t} - Mandate_{mr,t}) \epsilon_{sub,t} \quad \text{if } Con_{r,p,m,n} < 0 \quad (10)$$

The non-linear equations in the model (e.g. Eq.(4)) were converted to linear formulations. Objective function (Eq. (2)) is non-linear and non-convex, which was transformed into a logarithmic formulation Eq. (11). The derived mixed integer non-linear programming can be converted to MILP using the algorithm proposed by You and Grossmann (2011).

$$\max Obj' = \sum_n \epsilon_n \ln(TI_n - \widehat{T}I_n) \quad (11)$$

3. Results

The modelling methodology has been applied to two case studies - wastewater and lignocellulosic waste resource recovery. In case study 1, the chemical and biological

pathways and ion exchange pathways for phosphorus (P) and nitrogen (N) removal and recovery were simulated using ManTIS 3 built in GPS-X. These include three N removal and recovery routes (i.e. conventional nitrification/denitrification, Anammox, and an anaerobic route with ion exchange), three P removal and alternative recovery routes (struvite, ferric & phosphate recovery and hydroxyapatite recovery). Overall the ion exchange route performs best for N removal, with a superior costing profile, and environmental advantages on most impact categories except for its high eutrophication burdens. Under multiple sustainability criteria, chemical pathway outperformed biological routes and ion exchange for P removal whereas the struvite is shown as a promising P recovery route in terms of environmental footprint. In case study 2 the integrated thermochemical and biochemical routes were indicated as favourable options for lignocellulosic waste resource recovery. The process design and sustainability performance results were fed into MILP model and solved in AIMMS 4.0 using CPLEX 12.6 solver on a 3.4 GHz (2 processor) 96GB RAM computer (results not shown here). Via two case studies, this research highlights the insights the proposed framework could generate for multi-scale value chain design for waste recovery at spatial and temporal scales and to explore trade-offs between economic targets and environmental issues involved in the waste resource recovery systems in the coming decades. The model can be extended to include other technologies for generating other high-value products from bio-waste and used to address a range of research questions e.g. how the circular bioeconomy system and individual stakeholder would perform in response to the different government incentive schemes and what would be the most effective approach (e.g. incentives) to achieve innovative waste recovery technology deployment.

Abstract

An integrated reactive separation process for the production of jet diesel from vegetable oils and gasoil mixture has been developed. The integrated reactive separation process consider three interconnected sections: 1) a triglyceride hydrolysis section consisting of a catalytic heterogeneous reactor which is used to transform the triglycerides of the vegetable oils or animal fats to the corresponding fatty acids and a coupled decanter-distillation column to separate the fatty acids from glycerol and water; 2) a co-hydrotreating section where a reactive distillation column is proposed to perform the deep hydrodesulfurization (HDS) of gasoil and the hydrodeoxygenation (HDO) and the decarbonilation of the fatty acids simultaneously and 3) a isomerization section where a catalytic reactor is used to produce the jet diesel with the appropriate fuel properties. Through intensive simulations the effect of the different operating variables of the three sections were studied. Results show that for the first section the water excess and the operating pressure are key variables for the transformation of the triglycerides. For the reactive distillation column for the HDS of gasoil and HDO of the fatty acids, it is very important to maintain the hydrogen excess in the feed with a low reflux ratio to allow the release of the light gases produced and, to guarantee the deep HDS of gasoil and the complete transformation of the vegetable oils. Finally, the isomerization reactor must be carefully operated with respect to the amount of light hydrocarbons compounds allowed in the mixture to be cracked and isomerized.

Keywords: Jet diesel, co-hydrotreating, reactive distillation.

1. Introduction

The emergence of new economies where energy demand is increasing exponentially is forcing the petroleum-based fuels consumer countries to redefine their energy strategies.

Such concerns have promoted much research on reliable alternatives to conventional fuels. In this way, a renewable diesel or Jet diesel has emerged as a substitute for mineral diesel fuels. Its production is not limited to seed oils, but it is flexible in that it can use a number of different feedstocks. Renewable or Jet diesel can be produced by hydrotreating (HDT) of vegetable oils, whereby the oxygenates in bio-feedstocks are hydrogenated into hydrocarbons. HDT may take place in existing diesel hydrotreaters reactors in a co-processing scheme, where the bio-feed component is deoxygenated and the fossil diesel component is simultaneously desulphurised, or it can take place in a standalone unit processing 100% bio-feed. In both cases, conversion occurs over HDT catalysts and in conditions similar to those used in hydrotreaters. Recently, Pérez-Cisneros et al (2017) proposed a reactive distillation process for the co-hydrotreating of sulfured diesel and triglycerides and fatty acids. They conclude that the hydrodesulfurization reactions are mainly affected by introducing larger amounts of triglycerides while these are not affected when only fatty acids are considered. Therefore, in this work, a novel integrated technological approach for producing Jet diesel considering a previous step of triglycerides conversion to fatty acids is included. Thus, the integrated process considers: 1) a triglyceride hydrolysis section consisting of a catalytic heterogeneous reactor which is used to transform the triglycerides of the vegetable oils or animal fats to the corresponding fatty acids and a coupled decanter-distillation column to separate the fatty acids from glycerol and water; 2) a co-hydrotreating section where a reactive distillation column is proposed to perform the deep hydrodesulfurization (HDS) of gasoil and the hydrodeoxygenation (HDO) and decarbonilation of the fatty acids simultaneously and 3) an isomerization section where a catalytic reactor is used to produce the jet diesel with the appropriate fuel properties required by the international standards.

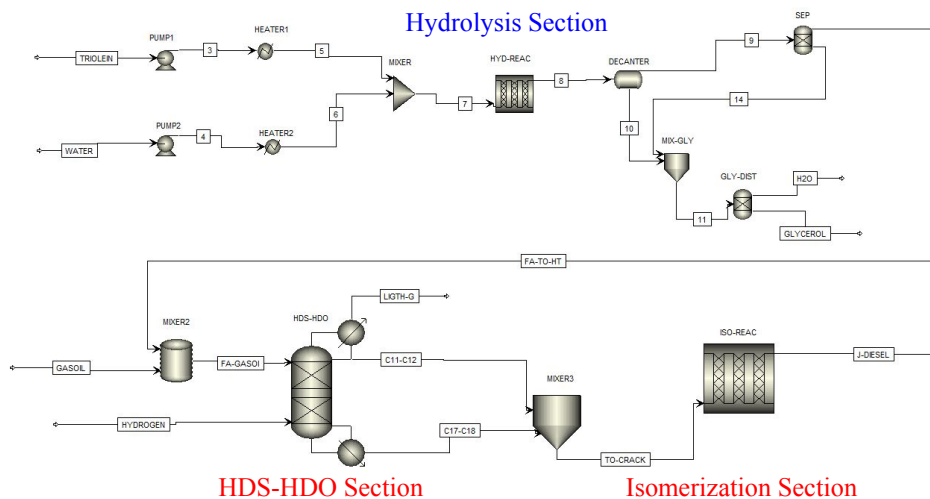

Figure 1. Simplified integrated co-hydrotreating reactive separation process for jet diesel production from vegetable oils and sulphured gasoil

2. The integrated reactive separation process

Figure 1 shows the integrated reactive separation process flowsheet. The first section (hydrolysis) considers two pumps where the pressure of the exit streams is 30 atm and two heaters where the temperature of the streams entering to the mixer is 180 C. The fixed bed hydrolysis reactor operates at moderated pressure (30 atm) and it consists of 2 tubes with 0.5 m of diameter and 25 m length. Next, a decanter tank is used to separate the glycerol water mixture followed by two distillation columns where the pure fatty acid is separated from a low concentration glycerol-water mixture and a second distillation column where pure glycerol is produced. The second section (HDS-HDO) considers a reactive distillation column (RDC) where a mixture of sulphured gasoil and fatty acid is fed at the top of the RD column and hydrogen is fed in excess at the bottom. The light gases leave the RDC from the vapour-liquid condenser and a liquid mixture of C₁₁-C₁₂ linear hydrocarbon chains are mixed with the hydrodesulphurized gasoil compounds and the C₁₇-C₁₈ hydrocarbons produced by the HDO reactions. The third section considers a fixed bed hydrocracking-isomerization reactor where the C₁₁-C₁₂ hydrocarbons and the C₁₁-C₁₈ hydrocarbons mixture is cracked and isomerized to obtain the jet diesel.

2.1 The triglycerides hydrolysis section

Fatty acids are major components and presursors for a great variety of products such as soaps, detergents, pharmaceuticals, etc. In general, at moderate temperatures, the hydrolysis of vegetable oils reactions can be described as follows:

Currently, fatty acids are obtained commercially from the reaction of vegetable oils and/or animal fats with superheated steam. Conventionally, the reaction is carried out at 100-260 °C and 100-7000 kPa using a 0.4-1.5 wt % water-to-oil ratio. Different variations of this technology have been used by industry (e.g., the Twitchell process, the Colgate-Emery synthesis, and the Eisenlohr process). These processes are normally referred to as fat splitting. In the present work the reaction kinetics reported by Ngaosuwan et al (2009) are used for the fixed-bed reactor simulation considering a tungstated zirconia (WZ) and the solid composite SAC-13 as catalyst.

2.2 The HDS-HDO section

Hydrotreating (HDT) of vegetable oils has previously been used to produce straight chain alkanes ranging from *n*-C₁₅-*n*-C₁₈, from a fatty acid fraction of tall oil, and other vegetable oils. The aim of the hydrodeoxygenation (HDO) process is to upgrade vegetable oils by removing the oxygen content as water. The process includes treatment of vegetable oils at high pressures and moderate temperatures over heterogeneous catalysts. The use of vegetable oils, mainly non-edible vegetable oils, as feedstock for the HDO process is highly favorable because their hydrocarbon content is in the same range as that of fossil fuels, such as kerosene and diesel. The fatty acids in vegetable oils are composed of straight chains of carbon atoms, and HDO produces *n*-alkanes as the primary products. Thus, fatty acids in the vegetable oils are transformed into alkanes with water as by-product. Carbon dioxide or carbon monoxide is also obtained as by-products when the reaction follows decarboxylation and decarbonylation under HDO

conditions. The reactions considered for the HDS of the sulphured gasoil can be written in a simplified form as:

It should be noted that Eq. 6 only considers the hydrogenolysis reaction pathway. For the HDO of fatty acids the simplified reactions are:

Kinetic expressions for the HDS reactions are taken from Perez-cisneros et al (2017) and, due to the lack of information about the kinetics of the complex HDO reactions, a conversion of 99% of fatty acids was considered for the numerical simulations.

2.3 The hydrocracking-isomerization section

The hydrocracking reactions of the larger normal hydrocarbons produced in the HDS-HDO section can be written in simplified form as:

and the isomerization reactions as:

It should be noted that the cracking reactions produce n-butane, which it is further separated in the gas phase. The yield of cracking and isomerization was taken from Yeob-Kim et al (2017) where a Pt supported on nanocrystalline large-pore BEA zeolite is used as catalyst.

3. Simulation of the integrated reactive-separation process

3.1. Hydrolysis section

Several amounts of triglycerides were used for intensive simulation of the integrated process. Due to space reasons only the results for the production of 70 kmol/h of fatty acid are reported here. Table 1 shows the simulation results for the hydrolysis section considering the production of 70 kmol/h of oleic acid (fatty acid) using ASPEN-PLUS. It can be observed that a complete conversion of triolein is achieved at 453 K and water in excess (150 kmol/h). The decanter and the distillation column for glycerol separation operate at 1 atm and 278 K. Also, it must be considered that a reliable thermodynamic model to treat the polar reactive mixture. In this work the RK-ASPEN has been applied for the hydrolysis section.

Table 1. Simulation results of the Triglycerides hydrolysis section

Stream	TRIOLEIN	WATER	7	8	11	GLYCEROL	FA-TO-HT

	1	1	30	30	1	1	30

3.2. HDS-HDO section

Table 2 shows the simulation results for the HDS-HDO section considering a mixture of oleic acid and gasoil of 70 and 100 kmol/h, respectively. The hydrogen feed was set to 400 kmol/h in order to achieve complete conversion of the fatty acid. The Reactive distillation column consists of 14 stages with two reactive stages sections (5-7, 9-11) operating at 30 atm. It can be noted in Figure 2a that the composition of the C11-C12 stream contains mainly *n*-undecane and *n*-dodecane hydrocarbons and stream C17-C18 carried the heavier hydrocarbons (C_{16} - C_{18}). On the other side, Figure 2b shows that the LIGTH-G stream is rich in the light gases produced by the HDS and HDO reactions (i.e., CO , CO_2 , H_2 , H_2S , H_2O , etc). It should be noted that the temperature of the C11- C12 stream (185 C) is different from the C17-C18 stream (473 C), thus a extra heater must be considered to heat the C11-C12 stream before mix it with the heavier hydrocarbons. PC-SAFT EoS was used for the simulation of this section. The gasoil feed composition and temperature condition was taken from Pérez-Cisneros et al (2017).

3.3. Isomerization section

Finally, Table 3 shows the final composition of the jet diesel obtained in the hydro cracking and isomerization reactor. It should be clear that the exit stream from this reactor should be flashed in order to eliminate the hydrogen and butane present in the final mixture. The specific kinetics and reactor configuration were established considering the information given by Yeob-Kim et al (2017).

Figure 2a. Liquid profile in the HDS-HDO RD column

Figure 2b. Vapor profile in the HDS-HDO RD Column

Table 3. Simulation results of the cracking-isomerization section

Stream	TO-CRACK	J-DIESEL
Mass Flow (kg/h)	3,0294E+04	4,3419E+03
Mass Frac		
<i>n</i> -C11	2,1024E-01	5,9269E-02
<i>n</i> -C12	1,7289E-01	6,9593E-02
<i>n</i> -C13	5,3954E-03	2,5800E-02
<i>n</i> -C14	9,8195E-04	1,7533E-02
<i>n</i> -C16	4,4027E-02	2,2512E-02
<i>n</i> -C17	3,7044E-01	2,4435E-01
<i>n</i> -C18	1,9602E-01	1,6085E-01
<i>n</i> -BUTANE	0,0000E+00	5,1456E-04
<i>iso</i> -HEXA	0,0000E+00	2,0084E-02
<i>iso</i> -HEPTA	0,0000E+00	2,1498E-01
<i>iso</i> -OCTA	0,0000E+00	1,6400E-01
H ₂	0,0000E+00	5,1374E-04
Temperature K	7,4415E+02	5,4815E+02

It can be observed in Table 3 that the jet-diesel produced contains mainly *n*-C₁₇ and *n*-C₁₈ linear hydrocarbons with their corresponding isomers *i*-C₁₇ and *i*-C₁₈. Also, the presence of the light linear hydrocarbons *n*-C₁₁ and *n*-C₁₂ gives the appropriate final jet fuel properties.

4. Conclusions

An integrated co-hydrotreating reactive separation process for the production of jet diesel from mixtures of fatty acids and sulphured gasoil, is proposed. From the simulation results it can be concluded that the key operating parameters for the production of the jet diesel are the water excess and the total pressure for the hydrolysis reactor and the non presence of light compounds (H₂S, CO₂, CO) in the feed stream for the cracking-isomerization reactor. Finally, it is mandatory to have more reactive stages at the HDS-HDO RD column in order to achieve an ultra-clean (no-sulphur) diesel at the bottom of the column. Work considering the controllability of the integrated process and its economic evaluation is currently done.

Abstract

Semicontinuous, ternary distillation was first envisioned using a single distillation column and a middle vessel (MV) in the seminal work by Phimister and Seider. In the “sequential design methodology” introduced by Pascall and Adams for semicontinuous distillation, firstly, a steady state side-stream column that only meets the distillate and bottoms product purity specification is designed. Then by recycling the side-stream to the MV, the system is forced to move away from the steady state (initial state). Through repetitive input actions the system becomes periodic.

The objective of the current study is to understand the effect of changing the above initial state on the nature of the periodic orbit; specifically, its period. The initial state is changed by varying the values of the internal column recycle rates and also the external recycle rate. The periods of the converged periodic orbits are remarkably lower (almost 18 %) when compared to the base case design. Results revealed that the sequential design methodology is inherently sub-optimal. In conclusion, a rigorous design procedure that searches the space of initial states to reach an economically optimal periodic orbit is essential.

Keywords: Dynamic system analysis, design procedure, periodic orbits, semicontinuous process.

1. Introduction

Distillation systems are ubiquitous to chemical process industries. A significant portion of the total process industry’s energy demand and therefore, a major portion of the operational costs of the plant can be attributed to these systems (Halvorsen and Skogestad, 2011). Semicontinuous distillation is aimed to be the best design for industries that are slowly transitioning from low to high production rates, which are currently being operated within intermediate production ranges (Adams and Pascall, 2012). It is an intensified process that has a forced cyclic operating policy to separate multicomponent mixtures using a single distillation column and a number of tightly integrated middle vessels (MVs). The number of MVs required are decided based on the number of intermediate boiling components in the mixture to be separated. For example, to separate an imaginary ternary mixture A, B, and C, where ‘B’ is the intermediate boiling component, one middle vessel and one distillation column is required. In this study, the focus is on separation of ternary mixtures. A single semicontinuous cycle is demarcated based on the concentration of intermediate boiling component ($x_{MV,B}(t)$) and the height of liquid in the MV ($h_{MV}(t)$) into three modes of operation: the separating mode, the discharging mode, and the charging mode. Discrete input actions on the flow control valves on streams associated with the MV, trigger these mode changes when the algebraic states of the system: $h_{MV}(t)$, $x_{MV,B}(t)$, reach pre-specified values.

1.1. Ternary semicontinuous distillation: Process Description

In a typical semicontinuous ternary distillation process, the feed flow to the column from the MV ($F(t)$), the distillate flow rate ($D(t)$), the bottoms flow rate ($Bo(t)$) and the side stream recycled to the MV ($S(t)$) are all continuous functions of the independent variable, time (t). The MV has two inlet streams and two outlet streams. Based on the mode of operation, the number of functional inlet streams that supply liquid material and the number of outlet streams that draw from the MV varies. In the “separating mode”, the MV has only one functioning liquid inlet ($S(t)$) and one liquid outlet ($F(t)$) stream. The side stream is drawn from a location in the column that has high intermediate boiling component mole fraction when compared with the contents in the MV and therefore, the liquid in the MV gets gradually concentrated in component ‘B’. Once the desired purity of component ‘B’ in the MV is reached, the contents of the middle vessel are discharged through a middle vessel discharge stream ($F_{dis}(t)$) by fully opening the discharge valve. This discrete input action marks the end of the separating mode and the beginning of the “discharging mode”. During this mode, liquid is drawn from the middle vessel through two outlet streams: $F(t)$, $F_{dis}(t)$ and enters the MV through one inlet stream ($S(t)$). The discharge valve is fully closed when $h_{MV}(t)$ reaches a pre-specified lower limit while the charging valve is opened fully immediately, which controls the supply of liquid feed to be separated to the system ($F_{char}(t)$). Through these discrete input actions, a mode transition to the “charging mode” is signified. In this mode, the MV has two inlet streams ($S(t)$, $F_{char}(t)$) feeding liquid and one outlet stream ($F(t)$) drawing liquid from the MV. Liquid feed is fed to the MV until the liquid height in the MV reaches a pre-specified upper limit, delineating the end of the charging mode. The end of this mode also simultaneously demarcates the end of the cycle and a new cycle begins. During a cycle, because of the input actions the system is forced to move away from any steady states.

1.2. Ternary semicontinuous distillation: Control structure

Because of the concentration dynamics in the feed to the column, the process is not self-regulating, and therefore controllers are used for maintaining the distillate and bottoms purities at the desired values. The Distillate-Bottoms (DB) control configuration is used for this purpose (Figure 1). This control configuration was shown to be capable of handling off-spec products, because, in a total reflux condition, the MV prevents the preservation of liquid inventory within the column (Phimister and Seider, 2000). The control topology suggested by Pascall and Adams (2013) is typically used to regulate the reflux drum level, the sump level, and the column pressure along with the low and high volatile component concentrations in the distillate and bottoms streams. The semicontinuous ternary distillation

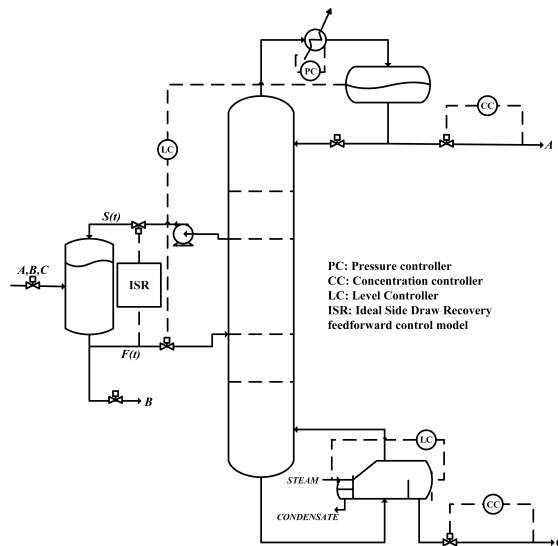

Figure 1: Semicontinuous Ternary Distillation Process

process has seven degrees of freedom out of which five are used as control inputs in the suggested multi-loop control structure. They also recommended the use of a model-based control of the side stream flow rate to address the issue reducing the loss of intermediate boiling component

through the distillate and the bottoms streams. The model used was first derived by Adams and Seider (2008) by assuming that the column is operated at pseudo steady state and that the side stream is a 100 % pure in component ‘B’. The model:

$$S(t) := F(t)x_{MV,B}(t) \quad (1)$$

was nomenclated as the “ideal side draw recovery” control law (ISR). The remaining degree of freedom, which is the reflux rate ($L(t)$) is fixed at the initial steady state value (\bar{L}) throughout the process.

1.3. Ternary semicontinuous distillation: The initial state

In simulation studies that ensued the seminal work on semicontinuous ternary distillation, the initial state was chosen to be a “hypothetical” steady state of a continuous side stream column, where the distillate and bottoms products are separated to the desired purity continuously. The steady state reflux rate (\bar{L}) and the steady state reboil rate (\bar{V}) are varied for a chosen steady state side stream flow rate (\bar{S}) to achieve the desired degree of low and high volatile product separation (Pascall and Adams, 2013). Therefore, different steady states can be generated by choosing a different value of ‘ \bar{S} ’. This design procedure will be henceforth referred to as the “sequential design methodology”. The semicontinuous system evolves from the chosen initial steady state (or initial condition) after recycling the side stream flow rate, and through repetitive state dependent input actions it converges to a periodic orbit in the n-dimensional phase space; the operating locus of the semicontinuous distillation process described in section 1.1.

Pascall and Adams (2013) briefly mentioned the effect that ‘ \bar{S} ’ has on the cycle time (or period of the converged periodic orbit) (T) of the semicontinuous distillation operation when using the sequential design methodology. However, there is no reason stated in the literature for choosing the initial condition of the dynamical system as a steady state where the distillate and bottoms products are separated at the desired purity. From an economic point of view, a steady state must be chosen from the space of initial conditions such that the converged periodic orbit has the minimum possible separation cost (defined as the total annualized cost per kmol of feed/product processed) subject to system constraints. The focus of this study is not to solve this general optimization problem, but to analyze the effect that the initial condition has on the system dynamics and to motivate research on proposing better algorithms to find the optimal designs of semicontinuous distillation of zeotropic mixtures.

2. Methodology

The cycle time (T) is a composition of the time taken to complete each of the three operating modes. The separating mode is completed when the concentration of intermediate boiling component in the middle vessel reaches the desired purity. Therefore, to reduce the separating time, the rate at which this component is concentrated in the MV has to be increased. From the dynamic component mass balance and the total mass balance of the MV during the separating mode:

$$\frac{dx_{MV,B}(t)}{dt} = \frac{S(t)}{M(t)}(x_{S,B}(t) - x_{MV,B}(t)) \quad (2)$$

where, $M(t)$ is the total molar holdup of liquid in the middle vessel, and $x_{s,B}(t)$ is the mole fraction of component B in the side stream recycled to the MV; in the time period close to the initial time ($t = 0$), it can be inferred that for the left hand side of Eq.(2). to be large for a given non-zero value of $M(t) \approx \bar{M}$ and $x_{MV,B}(t) \approx \bar{x}_{MV,B}$, both the values of $S(t)$ and $(x_{S,B}(t) - \bar{x}_{MV,B})$ have to be large. However, $S(t)$ is controlled using the ISR control law, and because $F(t)$ is the manipulated variable for controlling the reflux drum level, the reflux rate ($L(t) \equiv \bar{L}$) should also have an effect on the

rate at which the intermediate boiling component is concentrated in the middle vessel although they are spatially separate. Thus, the chosen steady state value of reflux rate has an effect on cycle time. However, since the mathematical analysis of the differential equation (Eq.(2).) for all time is not straightforward, numerical simulation experiments were conducted in this study. Similar dynamical equations can be written for the discharging and charging modes of a cycle.

The high purity (99 mol%) semicontinuous separation of a near-equimolar mixture (33-33-34 mol%) of benzene, toluene, and o-xylene (B-T-X) was chosen as the simulation example since it is an industrially significant and an almost ideal ternary mixture (Ling and Luyben, 2009). The design data required to simulate the steady state initial point were taken from Ling and Luyben (2009), and Meidanshahi and Adams (2015). The column was designed to have 40 stages with the feed stream location “above stage 25” and the side stream location “on stage 14”. The column diameter was chosen to be 1.3716 m so that flooding within the column can be avoided at all points during the cycle. In the present study, the sequential design methodology was adopted for simulating the BTX semicontinuous separation system. The thermodynamic properties are computed using the Non-random Two-Liquid (NRTL) activity coefficient model (Ling and Luyben, 2009), which was shown to match well with experimental data for the isobaric state of 101.325 kPa (R^2 value of approximately 0.99 for each binary interaction); experimental data was obtained from Gupta and Lee (2012, 2013).

A condenser pressure of 0.37 atm with a stage pressure drop of 0.0068 atm was chosen by Ling and Luyben (2009) such that cooling water and low pressure steam can be used as condenser and reboiler utilities respectively. Since a very similar configuration was adopted by Meidanshahi and Adams (2015) to simulate a steady state continuous side stream column, and because a rigorous procedure was applied to obtain the location of the feed stream, side stream and the number of stages, the design data from this study was used. The MV, which is an essential part of semicontinuous separation was sized using the heuristics that were used in the case studies from Pascall and Adams (2013), to have total molar hold-up of 200 kmol of liquid feed, by using a length to diameter ratio of three and 90 % of its volume filled with liquid at the end of each charging mode.

All valves were sized to accommodate a 3 atm pressure drop except the distillate and the bottoms flow control valve, which were sized to have a 0.1 atm pressure drop keeping the operating pressure of the column in mind. The reflux drum and the sump were sized according to the design heuristics of Luyben (2013). The control configuration using the ISR feedforward control model for side stream molar flow control was used. A proportional controller (P) was used for reflux drum level, sump level, and side stream flow rate control and a proportional-integral (PI) controller was used to control the remaining outputs similar to the study by Meidanshahi and Adams (2015).

3. Results and Discussion

The base case was chosen as the case where \bar{L} , \bar{V} were found such that the desired degree of benzene and o-xylene separation was achieved. The value of \bar{S} for the base case can be chosen to be $\bar{F}\bar{x}_{MV,B}$ according to the ISR control law. However, at this value of the side stream flow rate, the steady state column used as initial state was found to operate beyond the flooding limit. Therefore, a slightly higher value was chosen to avoid flooding in the column. Two sets of experiments were performed: constant internal column recycle rates (\bar{L} , \bar{V}), and constant external recycle rate (\bar{S}).

In the first set of experiments, the ratio of side stream molar flowrate to the feed molar flow rate to the column was varied from the base case value in increments of 0.05 until a value of 0.65 in one set of numerical simulation experiments. Beyond the value of 0.65, the magnitude of bottoms flow rate was found to be small enough that it is impractical to control the bottoms product concentration by manipulating it using a controller. The reflux rate and the boilup rate were not changed from the base case value, and therefore the distillate and bottoms product purities were not maintained at the desired values. The results are presented in Table 1:

Table 1: Results of constant reflux and reboil rates experiments ($\bar{F} = 100$ kmol/h)

	Base Case	Case 1	Case 2	Case 3	Case 4	Case 5
Steady State: Specified						
$\frac{\bar{L}}{\bar{F}}$	0.106	0.106	0.106	0.106	0.106	0.106
$\frac{\bar{V}}{\bar{F}}$	0.117	0.117	0.117	0.117	0.117	0.117
$\frac{\bar{S}}{\bar{F}}$	0.396	0.45	0.5	0.55	0.6	0.65
Steady State: Calculated						
$\bar{x}_{D,B}$	0.99	0.976	0.954	0.932	0.911	0.892
$\bar{x}_{Bo,B}$	0.99	0.999	0.999	0.999	0.999	0.999
$\bar{x}_{S,B}$	0.82	0.72	0.634	0.565	0.507	0.459
Column flooding	No	No	No	No	No	No
Periodic Orbit: Calculated						
T (h)	16.60	14.96	13.64	12.65	12.03	12.40
Column flooding	No	No	No	No	No	No

Consider for example “Case 2”, the $\frac{\bar{S}}{\bar{F}}$ ratio of the steady state point used as the initial state was changed from the base case value by 25 %. At this steady state, the distillate mole fraction is less than the desired purity by 3.6 %. When the base case was used to simulate the dynamic behaviour, the cycle time was observed to be around 16.6 h. By choosing the $\frac{\bar{S}}{\bar{F}}$ ratio to be 0.5 and using the sequential design methodology ($\bar{x}_{D,B} = 0.99$ and $\bar{x}_{Bo,B} = 0.99$ are specified at steady state) resulted in a periodic orbit of cycle time of approximately 16.47 h (result not presented in the table). However, when the steady state presented in the table was used as the initial condition for dynamic simulation, the cycle time dropped to 13.64 h; an approximate 18 % drop. Furthermore, from the table we can infer that “Case 4” has the lowest possible cycle time when compared to the rest of the cases in the first set of experiments. The reason for the observed differences in cycle time can be attributed to the contrasts in the behaviour of the individual controllers after the side stream is recycled to the MV because of the differences in initial state. Similar results were observed (although not of the same magnitude) when one of the internal column recycle rates - reflux rate (\bar{L}) is maintained constant and the $\frac{\bar{S}}{\bar{F}}$ ratio is varied. For the sake of brevity these results are not presented in this article.

Since reflux rate is a degree of freedom that is maintained at a constant value \bar{L} during the semicontinuous distillation operation, its effect on cycle time was also studied. This investigation resulted in the next set of experiments using a constant external recycle rate (\bar{S}); results are presented in Table 2. The reflux rate was increased from the base case value of 106.34 kmol/h to 140 kmol/h. Increasing this value further resulted in column flooding at steady state. In these set of experiments, the bottoms concentration was not changed from the desired value at steady state. Although reflux rate has an influence on cycle time, its effect is not as significant when compared to the previous set of experiments. In practice, ideally the optimal values of \bar{L} , \bar{V} , and \bar{S} (or the optimal initial condition) has to be found, which results in the optimum separating cost.

4. Conclusion

The sequential design methodology that was historically used to converge to a periodic orbit can result in sub-optimal periodic orbits as demonstrated using the simulation experiments. The space of initial conditions from which the system can reach a stable periodic orbit has expanded to include more steady states than previously imagined. From the numerical simulation experiments, for the equimolar separation of BTX, a case was found where an approximate 18 % decrease

Table 2: Results of constant side draw flow rate experiments ($\bar{F} = 100$ kmol/h)

	Base Case	Case 1	Case 2	Case 3
Steady State: Specified				
$\bar{x}_{Bo,B}$	0.99	0.99	0.99	0.99
$\frac{\bar{L}}{\bar{F}}$	0.106	0.12	0.13	0.14
$\frac{\bar{S}}{\bar{F}}$	0.396	0.396	0.396	0.396
Steady State: Calculated				
$\bar{x}_{D,B}$	0.99	0.994	0.995	0.996
$\frac{\bar{V}}{\bar{F}}$	0.117	0.129	0.137	0.146
$\bar{x}_{S,B}$	0.82	0.821	0.821	0.822
Column flooding	No	No	No	Close
Periodic Orbit: Calculated				
T (h)	16.60	16.35	16.18	16.03
Column flooding	No	No	No	Yes

in cycle time was observed while operating without violating the column hydraulic constraints. Although this initial state is “hypothetical”, a start-up procedure for semicontinuous zeotropic separation can be devised where this steady state is first reached before allowing the system to converge to a periodic orbit. An alternate optimization based design methodology is thus required to search through the space of steady states and choose the optimal steady state. This methodology should also incorporate the other decision variables, like for example, the controller tuning parameters, to ensure that the control inputs are optimal. A dynamic optimization based procedure that considers all the above requirements would be ideal. Research in this area is currently in progress.

Abstract

Hybrid process schemes, which combine processing units operating at their highest efficiencies to perform one or more process tasks, are increasingly being considered as promising innovative and sustainable processing options. The objective of this paper is to present an integrated design method for solvent-membrane screening with energy efficient and/or high product yield hybrid processing schemes. Application of the method is illustrated through two case studies. Case-1 involves a highly energy intensive distillation operation that is replaced by a combination of distillation and membrane or solvent based extraction. Case-2 involves simultaneous reaction-separation to increase the product yield through a hybrid scheme.

Keywords: Hybrid reaction-separation schemes, Ionic liquids, Membrane, Computer-aided molecular design (CAMD), Energy intensive processes.

1. Introduction

Solvents and membranes are widely used in many applications in chemical and related industries. For example, solvents have a multipurpose role in chemical and pharmaceutical processes since different solvents can be used in different processing steps, such as chemical reaction and separation. In these processes, a reaction step often takes place in one solvent and the separation step for product recovery requires another solvent or membrane. In bio-processes, downstream separations are usually very difficult (Woodley et al., 2017), while in petrochemical and chemical processes, most vapor-liquid separations are energy intensive (Tula et al., 2017). For all these processes, hybrid schemes are able to significantly reduce the complexity (for biochemical processes) and/or reduce energy consumption.

Together with organic chemicals, Ionic liquids (ILs) are receiving attention as solvents for use in hybrid schemes replacing energy intensive processes. Unlike volatile organic chemicals (VOCs) that easily escape into the atmosphere because of their high volatility, ILs possess attractive features like almost negligible vapor pressure, low-melting point, and high thermal and chemical stability (Rogers et al., 2003). IL based extraction is an alternative to energy intensive volatile organic solvent based extractive distillation (Lei et al., 2014) and Fang et al., (2016) proposed a molecular designed method based on COSMO-SAC for using IL as solvent in some extractive distillation

processes. For the same reason, membrane-based separations are also promising processing options (Drioli et al., 2011). However, both IL based extraction as well as membrane based separation are limited to low flux operations due to operational and economic constraints. Therefore, combinations of processing units operating at their highest efficiencies in hybrid schemes are promising options.

The objective of this paper is to introduce hybrid schemes that have potential to satisfy the demands of lower energy consumption, reduced waste as well as satisfying process specifications. As successful application of the hybrid schemes depends on the appropriate choice of the solvents and/or membranes for the schemes considered in this work, a screening method is integrated with the design of the hybrid scheme. As proof of concept, results from two case studies are presented.

2. Generation of Hybrid Scheme

2.1. Flow-sheet of hybrid processing schemes

The generation of hybrid schemes is based on the method developed by Babi et al., (2015). Based on identified “hot-spots” of a process, design targets for improvement that overcomes the “hot-spots” are set. Different hybrid schemes are generated to test if any match the targets while also satisfying the process specifications. In addition to the six hybrid schemes proposed by Babi et al., (2015), two new schemes are proposed in this paper. In scheme-1 (see Figure 1), a conventional energy intensive distillation operation is replaced by a combination of not energy intensive distillation operation with a membrane or IL-based extraction. The result is same separation obtained at much lower cost, better environmental impact and reduced waste. In scheme-2 (see Figure 2), a typical bioreactor operation is combined with solvent-based product removal giving a higher yield and avoiding catalyst (enzyme) inhibition.

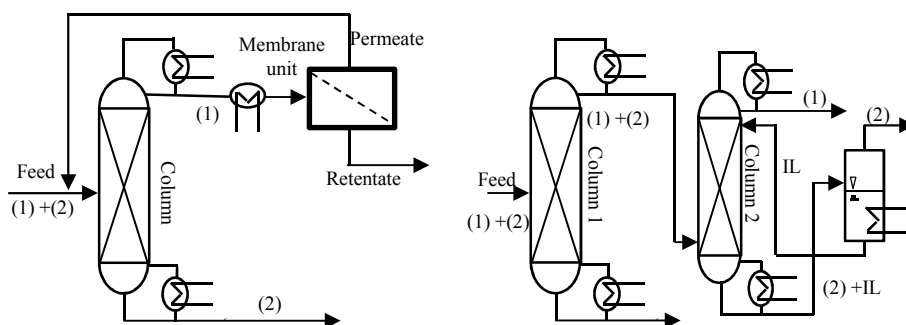

Figure 1a: Hybrid distillation with membrane Figure 1b: Hybrid distillation with IL

2.2. Solvent (IL) and membrane screening method

A large collection of organic solvents (Kalakul et al., 2017) and ILs (Chen et al., 2017) is available. Also, a database of known membranes used for specific separation tasks is under development. These databases have a search-retrieve engine where given the target properties for the solvents and or membranes, the sets of feasible solvents or membranes are generated. The most appropriate solvent or membrane is then selected

by ordering the results according to a performance indicator, such as solubility versus selectivity (for solvents) or permeability versus selectivity. The organic solvents database has around 2000 organic chemicals; the IL database has 4960 ILs, out of which around 300 have been reported to exist.

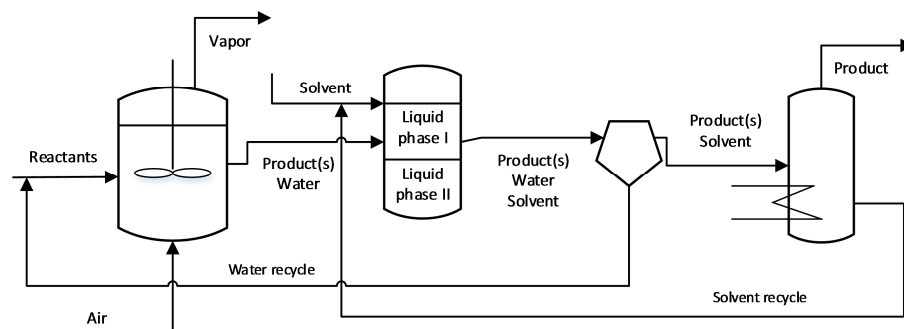

Figure 2: Reaction-separation scheme

3. Case studies

In this paper two proof of concept case studies are presented. Case-1: Methanol dehydration; and Case-2: Bio-oxidation of alcohols

3.1. Methanol dehydration

Separation of aqueous solutions is widely encountered in industries, such as in methanol dehydration process, the energy input increases rapidly with respect to the recovery of methanol from 0.98 to 0.995 (shown in Figure 3). Therefore, a sustainable hybrid design for methanol dehydration is a promising alternative for this separation process.

Figure 3: Energy consumption distribution Figure 4: Ternary plot

In this hybrid schemes, IL-based extractive distillation is considered to perform the separation work with the recovery from 0.98 to 0.995. 1-dodecyl-3-methylimidazolium tetrafluoroborate ($[C_{12}MIm][BF_4]$) is selected as the entrainer based on the CAMD method (Gani, 2004; Chen et al., 2017). This hybrid scheme is verified through simulation with AspenPlus and the results are given in Table 1. Compared with the traditional distillation process that required heat duty of 6027 KW, clearly the hybrid

process design proposed in this work has a better energy performance. The hybrid scheme-1 with membranes (see Fig 1a) has also been verified and the energy consumption (recovery from 0.98 to 0.995) by around 50% can be reduced.

Table 1: Fixed parameters and optimization results of the methanol dehydration process

Fixed parameters	Value	
Column operating pressure	1 atm	
Feed rate and composition	500 kmol/h, (0.5 CH ₃ OH, 0.5 H ₂ O)	
Purification of product	0.995 CH ₃ OH	
Optimal variables	Hybrid design	Traditional distillation
Solvent (IL)	[C ₁₂ MIm] [BF ₄]	
Solvent flow rate	10 kmol/h	
Heat duty (recovery from 0.5-0.98)	3103 KW	3103 KW
Heat duty (recovery from 0.98-0.995)	1108 KW	2924 KW
Heat duty (IL recycle)	15 KW	
Total heat duty	4226 KW	6027 KW

3.2. Bio-oxidation of alcohols

Dehydrogenation of alcohols is a widely used method for the synthesis of aldehydes in industries. In this work, the proposed hybrid reaction-separation scheme (see Figure 2) is applied to bio-oxidation of alcohols (see Table 2). Six primary alcohols (1-propanol, 1-butanol, 1-pentanol, 1-hexanol, 1-heptanol and benzyl alcohol) are considered as reactants to produce six corresponding aldehydes in this application.

Table 2: Information of the studied bio-oxidation of alcohols

Reaction scheme	$A + B \longrightarrow C + D$
Reaction class	Oxidation
Reactants	Primary alcohol, oxygen
Products	Aldehyde, water
Reaction class form	$R-OH + O_2 \longrightarrow R-CHO + H_2O$
Catalyst	Galactose oxidase

Table 3 summarizes the process conditions and the kinetic data (adopted from Toftgaard et al., 2015) needed to perform the calculations. The operating conditions for the reactor are the same for all the six reactions.

For steady state, the objective is the separation of the diluted aldehyde from water. The design methodology includes also a methodology for solvent selection, since the separation technique is liquid-liquid extraction. Following the method for solvent screening and by using the tool Pro-CAMD, heavy organic solvents were identified. The evaluation of the separation feasibility with the identified solvent is performed by the ternary plots for system of water + aldehyde + solvent. Simulations of the reactor for all the case studies are run in PRO/II and the NRTL is employed for the liquid-liquid equilibrium calculations. Results of the hybrid scheme simulation (Bio-oxidation of 1-propanol) are given in Table 4. The product is to be recovered from the liquid outlet.

The solvent used for this process is n-octane and the ternary plot for water+1-propanal+n-octane is presented in Figure 4, from which the feasibility of the 1-propanal separation from water is validated, since the phase split occurs.

Table 3: Important data used in the present work

Kinetic parameters			
Parameters	Value	Parameters	value
K_{cat} (kmol/kg CFE)	0.066	C_E (kg/m ³)	0.0011
K_{mS} (kmol/m ³)	0.051	C_O (kg/m ³)	0.5
K_{IP} (kmol/m ³)	0.0017	C_S (kg/m ³)	0.265
Reactor conditions			
T (°C)	25	$C_{alcohol}$ (kmol/m ³)	0.05
P (atm)	1	Aeration (vvm)	0.5

Table 4: Mass balance in the reactor – Bio-oxidation of 1-propanol

Component	Inlet (kmol/h)	Vapor outlet (kmol/h)	Liquid outlet (kmol/h)	% vapor loss
1-propanol	0.05	0	0	-
1-propanal	0	4.0190E-03	0.046	8.04
Water	55.4537	0.0403	55.4634	0.073
Oxygen	0.2659	0.2407	2.4054E-04	
Nitrogen	1.0004	0.9999	5.0907E-04	

For the dynamic state, the objective is to increase the reaction yield. The simulation is performed in MOT (Fedorova et al. 2015) and the molar composition in the reactor with respect to time is calculated based on the kinetic parameters presented in Table 3.

The results of the batch simulation are compared with the results of simulations for continuous product removal. Figure 5 illustrate the product yield, Y and reaction rate, R between batch operation and continuous product removal. Clearly the hybrid scheme of continuous product removal has a better reaction and yield performance than the batch operation.

In addition, for the cases of heavy aldehydes, heavier and non-volatile compounds would be required. A solution to that might be the use of hydrophobic ionic liquids. The difficulty of finding the appropriate solvent is due to the similarities between alcohol and aldehydes, which make them miscible to the same substances

Figure 5: Comparison between batch operation and continuous product removal

4. Conclusions

Hybrid schemes that have potential to satisfy the demands of lower energy consumption, reduced waste as well as satisfying process specifications have been proposed in this work. Case studies involving methanol dehydration and bio-oxidation of alcohols have been presented to highlight the hybrid schemes in this work. Future work is to expand the method into a generalized one covering a wide range of applications, integrated with a collection of tools consisting of, for example, databases, models and design strategies for hybrid schemes.

Abstract

The utilization of biomasses has advantages with respect to energy conservation, emission reduction and resource utilization. In this paper, the concept of functional exergy efficiency is extended as a unified approach for evaluating the effective utilization of energy in three utilization pathways of biomasses; pyrolysis, gasification and anaerobic digestion. Based on our prediction model for higher heat value (*HHV*) of biomass, it has been shown that the Gibbs energy minimization method can be used to simulate the pyrolysis and gasification processes of biomasses. Biogas data of anaerobic digestion process is obtained through the practical biochemical methane potential (PBMP) model. Based on our chemical exergy prediction model of biomass, functional exergy efficiencies of utilization processes of biomasses (three kinds of straws and three kinds of manures) are evaluated. It is found that the functional exergy efficiencies of gasification process of manures and straws are all greater than those of the pyrolysis process at different temperatures, and compare with pyrolysis and gasification processes after 850 °C, the functional exergy efficiencies of anaerobic digestion are the lowest.

Keywords: Biomass utilization, Process simulation, Process evaluation, Exergy efficiency

1. Introduction

The chemical conversion technologies for utilizing biomass can be separated into three basic categories: direct combustion processes, thermochemical processes (pyrolysis process, gasification process and direct liquefaction), biochemical processes (anaerobic digestion and alcoholic fermentation). Biomass resources include wood and wood wastes, agricultural crops and their waste by-products, municipal solid wastes, animal wastes, wastes from food processing and aquatic plants and algae (Demirbaş, 2001). From the proximate analysis or ultimate analysis of biomass, the composition and moisture of biomasses are varied depending on the kind of biomasses considered and even for the same kind of biomass it may vary at different regions and reasons. Different utilization pathways and various types of biomasses lead to issues such as the lack of unified approach to evaluate the biomass utilization. In this study, we focus on how to evaluate utilization pathways of biomasses with respect to energy utilization. The purpose is, thus, to simulate different utilization pathways and then to evaluate the effective utilization of energy based on the simulation results.

At present, there is no general method in the literature to analyse and compare the efficient utilization of energy for the utilization pathways of biomasses. For thermochemical processes, the main criteria of the effective use of energy efficiency are the loss of exergy (Ex_{loss}) and exergy efficiency. Therefore, current energy use in thermochemical conversion processes for biomass are analysed via exergy analysis (Peters et al., 2015). However, for the biochemical utilization of biomasses in order to obtain biogas, any exergy analysis is basically not considered because of the difficulty to determine the exergy of broth, biogas slurry and biogas residue. Therefore, output to input ratio of energy efficiency is selected as an effective indicator of energy use (Havukainen et al., 2014). Since the energy efficiency is based on the first law of thermodynamics, so it cannot truly reflect the utilization of energy. In the field of power plants, exergy efficiency can be divided into two different approaches (A brute-force or functional exergy efficiency), compare with brute-force exergy efficiency, a functional exergy efficiency for any system is defined as the ratio of the exergy associated with the desired energy output to the exergy associated with the energy expended to achieve the desired output (DiPippo, 2004).

The main objective of this study is to compare utilization pathways of biomasses. It should be mentioned that both process simulation and energy evaluation are based on experimental thermodynamic data of biomass in the literature. As the type and composition of biomasses vary, it is necessary to predict their thermodynamic data in order to compare utilization pathways of biomasses via the composition of biomasses. The innovative aspects of this study are related to the following two points: (1) The functional exergy efficiency concept was extended to evaluate utilization pathways of biomasses; (2) Process simulation and energy evaluation are based on the prediction model of HHV (Qian et al., 2016) and chemical exergy (Qian et al., 2017) of biomass from our previous studies. Thus, with the help of ultimate analysis and proximate analysis of biomasses, utilization pathways of biomasses can be simulated and evaluated.

2. Material and methods

2.1 System boundary and definition of functional exergy efficiency

Forming system boundaries around a system is a method to examine the input and outputs from this system. In this study, system boundaries (the dashed box) of pyrolysis, gasification and anaerobic digestion processes were shown in Figures 1-3, respectively. It should be mentioned that the mass of wet biomass was taken as 100 g in different utilization pathways to compare the energy utilization better.

Figure 1 Schematic diagram of the pyrolysis process of biomass

Figure 2 Schematic diagram of the oxygen gasification process of biomass
System III

Figure 3 Schematic diagram of the anaerobic digestion process of biomass

Based on the system boundaries, the functional exergy efficiencies of pyrolysis, gasification and anaerobic digestion processes were defined, respectively, as follows:

$$\eta_I = \frac{Ex_{\text{syngas,total}}}{Ex_{\text{wb,total}} + Ex_{\text{heat1,total}} + Ex_{\text{heat2,total}}} \quad (1)$$

$$\eta_{II} = \frac{Ex_{\text{syngas,total}}}{Ex_{\text{wb,total}} + Ex_{\text{O}_2,\text{total}} + Ex_{\text{heat3,total}} + Ex_{\text{heat4,total}}} \quad (2)$$

$$\eta_{III} = \frac{Ex_{\text{biogas,total}}}{Ex_{\text{wb,total}} + Ex_{\text{heat5,total}}} \quad (3)$$

2.2 Thermodynamic data prediction

The value of energy change of combustion reaction in oxygen bomb calorimeter is *HHV*:

$$-0.001M \times HHV = x\Delta_f H_{m,\text{CO}_2} + \frac{y}{2}\Delta_f H_{m,\text{H}_2\text{O}(l)} + \frac{a}{2}\Delta_f H_{m,\text{N}_2} + b\Delta_f H_{m,\text{SO}_2} - \Delta_f H_{m,\text{C}_x\text{H}_y\text{O}_z\text{N}_a\text{S}_b} - (x + \frac{y}{4} - \frac{z}{2} + b)\Delta_f H_{m,\text{O}_2} \quad (4)$$

where M is molecular weight of **dry biomass**, $100\text{g}\cdot\text{mol}^{-1}$. With the help of a prediction model of *HHV* proposed in our previous study (Eq. (5)) (Qian et al., 2016), the final calculation equation of standard molar enthalpy of formation of dry biomass was obtained (Eq.(6)).

$$HHV = 874.08\left(\frac{1}{3}C + H\right) \text{ kJ}\cdot\text{kg}^{-1} \quad (5)$$

$$\Delta_f H_{m,\text{C}_x\text{H}_y\text{O}_z\text{N}_a\text{S}_b}^\circ = -32.762C - 141.781H - 9.258S + 0.874M\left(\frac{1}{3}C + H\right) \text{ kJ}\cdot\text{mol}^{-1} \quad (6)$$

Standard molar entropy S_m° (Song et al., 2011) and heat capacity C_p (Rath et al., 2003) of dry biomass were predicted via Eq. (7) and Eq.(8), respectively.

$$S_m^\circ = M \times (0.0055C + 0.0954H + 0.0096O + 0.0098N + 0.0138S) \text{ J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1} \quad (7)$$

$$C_p = 0.001Mc_p = 0.001M(-212.928 + 4.8567T) \text{ J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1} \quad (8)$$

2.3 Process simulation

Thermochemical processes were simulated via Gibbs energy minimization (Shabbar & Janajreh, 2013) and the final equation was shown as follows:

$$\Delta_f H_{m,i}^o + \int_{298.15}^T C_{p,i} dT + T \left(S_{m,i}^o + \int_{298.15}^T \frac{C_{p,i}}{T} dT \right) + RT \ln \left(\frac{n_i}{n_{total}} \right) + \sum_k \lambda_k a_{ik} = 0 \quad (9)$$

According to Eq. (9), with $\Delta_f H_m^o$, S_m^o and C_p of biomass, the equilibrium composition (n_i) of the system at given temperature and pressure is received.

Anaerobic digestion processes of biomass were simulated via the PBMP model (Liu et al., 2016) in order to obtain the volume of biogas.

$$V_{CH_4} = 100 \times \text{PBMP} (\text{mL CH}_4 / \text{g wb}) \\ = (80.4 - 2.70 \text{Lignin}) \% \times 22400 \text{TS} \% \times (C/24 + H/8 - O/64 - 3N/112) \text{ mL} \quad (10)$$

2.4 Calculation of exergy

In order to obtain the functional exergy efficiencies, exergies of wet biomass, syngas, biogas, drying process, and reactor were calculated based on process simulation and thermodynamic data prediction and the results are listed in Table 1.

Table 1 Exergy calculated in the utilization pathways of biomasses

	Pyrolysis	Gasification	Anaerobic digestion
Wet biomass (wb)	$Ex_{db} = 92.072 (\frac{1}{3}C + H) \text{ kJ} \cdot \text{mol}^{-1}$ (Qian et al., 2017) $Ex_{wb, total} = n_{wb} Ex_{db} + n_{water} Ex_{H_2O}$ $= (TS/100) Ex_{db} + ((100 - TS)/18) Ex_{H_2O}$ $= 92.072 (\frac{1}{3}C + H) \times TS \% + 5.278 \times (1 - TS \%)$		
Dryer	$Ex_{heat1, total} = n_{water} Ex_{heat1}$ $= 5.556(1 - TS \%)(1 - \frac{T_0}{T_{Dry}}) \left(\int_{T_0}^{373.15} 0.001 C_{p, H_2O} dT + 40.668 \right)$ $Ex_{heat3, total} = Ex_{heat1, total}$		
Reactor	$Ex_{heat2, total}$ $= TS \% \times (1 - \frac{T_0}{T_I}) \times \int_{T_0}^{T_I} 0.001 C_{p, db} dT$	$Ex_{heat4, total} = Ex_{heat4, O_2, total} + Ex_{heat4, db, total}$ $= TS \% \times (1 - \frac{T_0}{T_{II}}) \int_{T_0}^{T_{II}} 0.001 C_{p, db} dT$ $+ TS \% \times (1 - \frac{T_0}{T_{II}}) \int_{T_0}^{T_{II}} 0.001 C_{p, db} dT$	$Ex_{heat5, total} = m_{ad} e_{heat5}$ $= 0.027S \times (1 - \frac{T_0}{T_{III}}) \times 4.2 \times (T_{III} - T_0)$
Gas product	$Ex_{syngas, total} = Ex_{total}^{ph} + Ex_{total}^{ch} = (n_{H_2} Ex_{H_2}^{ph} + n_{CO} Ex_{CO}^{ph})$ $+ (n_{H_2} (e_{H_2}^{ch} + RT_0 \ln x_{H_2}) + n_{CO} (e_{CO}^{ch} + RT_0 \ln x_{CO}))$		$Ex_{biogas, total} = n_{total} Ex^{ch}$ $= n_{CH_4} e_{CH_4}^{ch}$

2.5 Biomass scenarios

We selected straws (3 types) and manures (3 types) to compare utilization pathways of biomasses. The physical and ultimate analysis results are listed in Table 2.

Table 2 Physical and ultimate analysis of biomass (Li et al., 2013)

Wet biomass	TS%	VS%	VS/TS%	Lignin	Ash	C	H	O	N
Chicken manure	25.9	19.5	75.3	1.6	24.7	35.9	5.1	30.5	3.4
Dairy manure	38.5	28.8	74.8	17.4	25.2	37.6	5.1	28.9	2.8
Swine manure	30.4	22.0	72.4	4.3	27.6	34.8	4.7	30.3	2.2
Corn stover	84.9	76.9	90.6	10.3	9.4	43.2	5.9	40.2	0.8
Wheat straw	90.5	77.9	86.1	7.6	13.9	39.9	5.7	39.6	0.4

Rice straw	92.9	81.6	84.6	10.8	15.4	39.7	5.4	38.2	0.9
------------	------	------	------	------	------	------	-----	------	-----

3. Results and discussion

The exergy efficiencies of pyrolysis of six wet biomasses at different temperatures are shown in Figure 4. For the same type of biomasses, the exergy efficiencies increase with increasing pyrolysis temperature. In general, the exergy efficiencies of straws are higher than that of manures at different pyrolysis temperatures. At 950 °C, the exergy efficiencies of manures can reach about 0.6, while that of straws can reach about 0.7.

Figure 4 Exergy efficiencies of pyrolysis of six wet biomasses at different temperatures

Figure 5 Exergy efficiencies of oxygen gasification of six wet biomasses at different temperatures

Figure 6 Exergy efficiencies of anaerobic digestion of six wet biomasses

The exergy efficiencies of oxygen gasification for six wet biomasses at different temperatures are shown in Figure 5. The higher the gasification temperature is, the greater are the exergy efficiencies for the same type of biomasses. However, the picture changes little after 850 °C, and the exergy efficiency slightly decreases at 950 °C, which is different to the pyrolysis process. This is mainly due to the increase of the available energy required for heating the oxygen added at 950 °C. Unlike what was the case with the pyrolysis process, the exergy efficiencies of dairy manure at 850 and 950 °C are the lowest in the pyrolysis process but the highest in the gasification process, this is due to the relative high carbon content in dairy manure, which leads to increase of CO generated. Exceeding 850 °C, compared with the pyrolysis process, the exergy efficiencies of the manures have increased, close to those of straws.

The exergy efficiencies of anaerobic digestion processes of six wet biomasses are shown in Figure 6. Compared with thermochemical processes, the exergy efficiencies of the anaerobic digestion process of most manures, except for the dairy manure (due to its high lignin content (no degradable)), are higher than that of straws. The highest exergy efficiency is chicken manure (0.6). The exergy efficiencies of anaerobic digestion are

lower than that of thermochemical processes while the temperature exceeds 850 °C for the organic matter (includes lignin) entering the biogas residue.

4. Conclusions

(1) Pyrolysis process: the functional exergy efficiencies of manures are about 0.6 and generally lower than that of straws (0.7), and the higher the temperature (<950 °C), the greater are the exergy efficiencies;

(2) Gasification processes: the functional exergy efficiencies of manures (>0.7) and straws (maximum 0.77) are all higher than that of pyrolysis process. Below 850 °C, the higher the temperature, the greater the exergy efficiencies, after 850 °C, a slight downward trend is observed;

(3) Anaerobic digestion process: the functional exergy efficiencies of straws are generally lower than that of manures.

Compared with the pyrolysis and gasification processes, although the functional exergy efficiencies of the gas products of anaerobic digestion are low (< 0.6), anaerobic digestion has received increasing attention due to its economic, agronomic, and environmental advantages. Therefore, an important task of the anaerobic digestion process is to improve its biogas production rate such as via pre-treatment to reduce the lignin content.

Abstract

This contribution presents a methodological tool for synthesis and design of sustainable processes and supply chains under uncertainty. The methodology decomposes the problem into two main parts where firstly the first-stage variables are derived, and in the next step, the second-stage variables are determined followed by the generation of the probability functions of decision criterion. Main advantage of the proposed approach is that the exponential growth of the optimization models while increasing the numbers of uncertain parameters is avoided by using “as low as practically reasonable” number of scenarios, thus providing useful information at sufficient level of confidence. Sustainability of processes and supply chains is accounted for by using composite sustainability objective functions that combine the economic, environmental and social objectives. Proposed methodology is demonstrated on two case studies, i) synthesis of flexible heat exchanger network, and ii) complex biogas supply network, that demonstrate the potential of the methodology for solving more challenging problems.

Keywords: sustainable processes and supply chains, flexibility, uncertainty, mathematical programming, synthesis and design

1. Introduction

Optimization under uncertainty has been an active area of research in different fields over the last decades (Grossmann et al., 2015). Over the years several barriers have been identified, such as availability of data in terms of uncertainty, the nature of uncertainties, selection of strategy for solving uncertain systems, large computational expense and difficulties regarding interpreting the results (Grossmann et al., 2015). On the other hand, there are several typical uncertain parameters relating to synthesis and design of flexible processes and supply chains, such as product demands, prices, product yields, sizes of equipment, technical parameters (Grossmann et al., 2016), parameters related to political and cultural context (Martín and Martínez, 2015) and other.

Despite the importance of uncertainty in synthesis and design of processes and supply chains, the uncertainty analyses are still uncommon (Moret et al., 2016). Even less research is performed relating to uncertainty of systems including different sustainability objectives, despite growing awareness relating to more sustainable systems (Tsao et al., 2018). This contribution presents a methodology for decision-making regarding sustainable design of processes and supply chains with larger numbers of uncertain data.

Methodology is based on several steps in order to produce flexible process/supply chain designs with a manageable number of scenarios which enables solving problems of any complexity. Sustainability is incorporated into decision-making process by using objective functions that combine economic, environmental and social criteria on a monetary basis within a single-objective optimization (Zore et al., 2017).

2. Methodology

The proposed methodology is intended to handle large-scale problems with great numbers of uncertain input data. It consists of several steps described below.

2.1. Nominal process flowsheet

The main goal of this step is to obtain a process structure at the nominal values of uncertain parameters, which would serve as a good starting point for generation of flexible process flowsheet in the second step. Initial process structure is generated by solving one-scenario Mixed Integer Linear or Nonlinear Programming problem (MILP or MINLP, Eq. (1)).

$$\begin{aligned}
 Z^N &= \min(c^T y^N + f(d^N, x^N, z^N, \theta^N)) \\
 \text{s.t.} \\
 h(d^N, x^N, z^N, \theta^N) &= 0 \\
 g(d^N, x^N, z^N, \theta^N) + B y^N &\leq 0 \\
 d^N &= g_d(x^N, z^N, \theta^N) \\
 A y^N &\leq a \\
 d^N, x^N, z^N &\geq 0, y^N \in \{0, 1\}
 \end{aligned} \tag{1}$$

where Z is a scalar objective variable, c fixed costs of alternatives, f variable cost function, y binary variables, d design variables, x operating variables, z control variables, h equality constraints, g inequality constraints, g_d design expressions, θ uncertain parameters, and A , B and a are the matrices and vectors of constants. Superscript N denotes the nominal values. The result of this step is an optimal nominal process flowsheet which is most likely inflexible for deviations of uncertain parameters from their nominal values.

2.2. Flexible process flowsheet

The main goal of this step is to determine first-stage variables, i.e. the topology binary variables (y) and the sizes of process units (d) for feasible operation within specified deviations of uncertain parameters. This step starts with the initial nominal process flowsheet and is performed by solving sequentially two-scenario MINLP problems, see Eq. (2). The first scenario corresponds to the nominal point (θ^N) while the second one stands for a randomly selected extreme point (θ_s). Those binary variables that obtained unity values at previous iterations are fixed to 1, while the remaining binary variables are optimized either to 1 or 0. Design variables are limited downwards by the optimal values obtained at previous iterations (d_{s-1}). In this way, already selected topology options (e.g. process units) are forced to increase their design variables (sizes) as much as possible, while the new alternatives are included into the flowsheet only if required for feasibility.

$$\begin{aligned}
Z_s &= \min \left(c^T (y_s \setminus y_{s-1}^1) + f(d_s, x^N, z^N, \theta^N) \right) \\
\text{s. t. } & h(d_s, x^N, z^N, \theta^N) = 0 & h(d_s, x_s, z_s, \theta_s) = 0 \\
& g(d_s, x^N, z^N, \theta^N) + B y_s \leq 0 & g(d_s, x_s, z_s, \theta_s) + B y_s \leq 0 & \forall s \in S_{\text{RSV}} \\
& d_s \geq g_d(x^N, z^N, \theta^N) & d_s \geq g_d(x_s, z_s, \theta_s) \\
& d_s \geq d_{s-1}, \quad A y_s \leq a & y_s = \begin{cases} 1 & \text{if } y_s \in y_{s-1}^1 \\ \{0,1\} & \text{otherwise} \end{cases} \\
& d_s, x_s, z_s, x^N, z^N \geq 0
\end{aligned} \tag{2}$$

where s is an index of random vertex scenarios within the set S_{RSV} , and y_{s-1}^1 is a vector of binary variables that obtained unity values at previous iterations.

The model shown in Eq. (2) is solved by successively adding the new vertex points to the nominal point until the new topology options are added into the flowsheet and/or the design variables increase. It is assumed that flexible structure is achieved when the flowsheet structure and the values of design variables stop changing. The results of this step are the values of the first-stage variables that are most likely flexible for prescribed variations of uncertain parameters.

2.3. Flexibility index and stochastic Monte Carlo optimization

The flexibility index of process flowsheet structure and design variables obtained in previous step is determined by maximizing scaled deviations of uncertain parameters from their nominal values towards the extreme values in positive and negative directions (Swaney and Grossmann, 1985). Nonlinear programming (NLP) one-scenario problems are solved over a randomly selected set of vertex directions. Flexibility of the first-stage variables is confirmed if the minimum scaled deviation is greater than or equal to one.

In the next step stochastic Monte Carlo optimizations are performed in order to determine the values of the second-stage, i.e. the operating and control variables (x and z). Single-scenario problem shown in Eq. (3) is solved within a loop for a set of randomly selected points from the intervals of uncertain parameters at the fixed values of binary and design variables (y_{opt} and d_{opt}).

$$\begin{aligned}
Z_s &= \min \left(c^T y_{\text{opt}} + f(d_{\text{opt}}, x_s, z_s, \theta_s) \right) \\
\text{s. t. } & h(d_{\text{opt}}, x_s, z_s, \theta_s) = 0 \\
& g(d_{\text{opt}}, x_s, z_s, \theta_s) + B y_{\text{opt}} \leq 0 & \forall s \in S_{\text{MC}} \\
& d_{\text{opt}} \geq g_d(x_s, z_s, \theta_s) \\
& A y_{\text{opt}} \leq a, \quad x_s, z_s \geq 0
\end{aligned} \tag{3}$$

where S_{MC} is a set of randomly-selected points from the intervals of uncertain parameters. If the sample size is large enough, it could be assumed that the objective variable is normally distributed, and the expected value could be expressed as the mean value of the objective values Z_s obtained at the selected scenarios.

2.4. Derivation of probability functions

Finally, based on the results of the stochastic Monte Carlo optimizations the interval of the objective values obtained is divided into a specified number of subintervals, following by the generation of frequency and cumulative distribution functions for

optimal flexible process flowsheet or supply chain. These curves provide the insights into the distribution of the decision criteria, and represent the tools for the efficient decision-making process.

2.5. Sustainability objective function for multi-objective decision-making

Sustainability objective functions incorporate economic, environmental and social aspects, and are defined as single-objective optimization criteria to avoid generation of multiple Pareto solutions. Sustainability profit (SP) from the macro-economic perspective is used as optimization criterion (Zore et al., 2017). SP is a composite measure of sustainability expressed in monetary terms and is defined as the sum of the economic profit (P^{Economic}), eco-profit (P^{Eco}), and social profit (P^{Social}), see Eq. (4).

$$SP = P^{\text{Economic}} + P^{\text{Eco}} + P^{\text{Social}} = \left(R - E - \frac{I^{\text{Economic}}}{t_d} \right) + (EB - EC) + (SS + SU - SC) \quad (4)$$

where R represents the revenue (€/y), E the expenditure (€/y), t_d depreciation period (y), I^{Economic} capital investment (€), EB eco benefit (€/y) arising e.g. from using waste as raw material or by replacing the existing products with ‘greener’ ones, EC is the eco-cost (€/y) representing the pollution prevention cost, SS the social security payments (€/y), SU unburdening of social funds due to new jobs (€/y), and SC the social cost (€/y). For more details relating to SP the readers are referred to the literature (Zore et al., 2017).

3. Examples

3.1. Synthesis of flexible Heat Exchanger Network

Heat Exchanger Network (HEN) consisted of 6 hot and 3 cold streams, see Figure 1. Supply temperatures of all streams were assumed to deviate for ± 10 K from the nominal values. The flowsheet obtained at the nominal point is shown in Figure 1, and included 6 process-to-process matches (No. 1-6), two coolers (No. 7 and 8) and two heaters (No. 9 and 10).

In the second step, a set of random vertices was generated, and the MINLP problems were solved while sequentially adding vertices to the nominal point. At each iteration the sizes of the existing heat exchange units were allowed to increase and/or the additional heat transfer units can be added into the network.

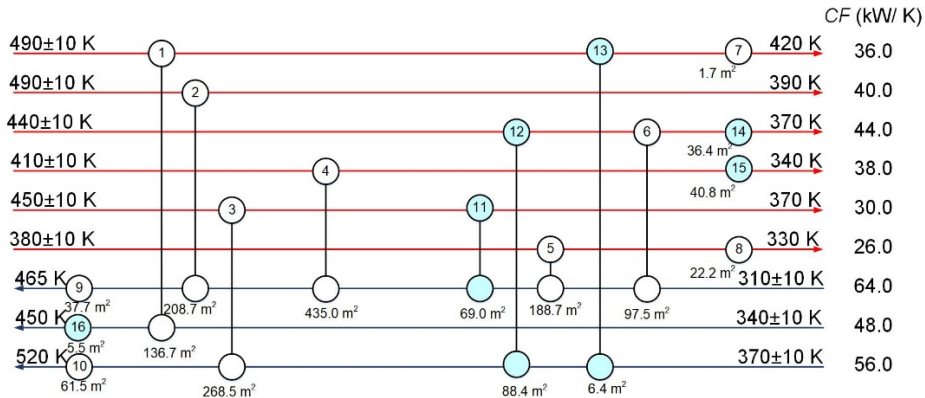

Figure 1: Nominal HEN structure (units 1 to 10) and flexible structure (units 1 to 16)

After 240 iterations, HEN structure and the areas of heat exchangers stopped to change, and the final HEN consisted of nominal units (No. 1-10) plus three additional heat exchangers, two coolers and one heater (No. 11-16).

The flexibility of determined HEN structure was confirmed over 12,000 randomly selected vertices. Stochastic Monte Carlo optimization over 12,000 randomly selected points provided the expected Total Annual Cost (TAC) of 1.308 M\$/y. Cumulative probability and frequency functions (Figure 2) were derived in the final step yielding the information about distribution of decision criterion.

Figure 2: Frequency and cumulative distribution functions of TAC in flexible HEN

3.2. Synthesis of a biogas supply network

The second example was a synthesis of supply network for electricity production from biogas (modified from Egieya et al., 2018 and simplified from Egieya et al., 2017). A multi-period (monthly-based) mixed integer linear programming (MILP) model could choose up to 6 locations for biogas facilities, 15 input substrates, and 2 transportation modes for delivering substrates to biogas plants (road transport or pipeline). Substrates could be selected within the radius of up to 9 km from biogas facilities in 5 locations, and digestate could be used in 5 locations. 18 uncertain parameters were defined that varied $\pm 10\%$ from their nominal values: availability of poultry manure and grass silage in 5 locations, dry matter content of poultry bedding and grass silage, methane content of poultry manure and poultry bedding, and prices of digestate, electricity, grass silage and wheat silage. Objective function was defined as the sum of the economic and eco-profit. The latter included the unburdening effects of the manures, slurries and bedding, the substitution of electricity mix from the grid with the biogas-based one, and inorganic fertilizers with the organic one. Burdening effects originated from cultivation of silages, straws and grains, production of electricity, utilization of fertilizers, use of water, and from transportation.

Optimal solution under nominal conditions included four biogas plant locations with the total capacity of 3.3 MW, 16.2 M\$ of capital investment, and 1.51 M\$/y of annual composed profit. Selected raw materials were poultry and cattle manures, poultry bedding, poultry slurry, and various types of silages transported by road trucks and tanks. After including the deviations of uncertain parameters, the total capacity increased to 3.8 MW at the total capital cost of 17.6 M\$, while the expected profit decreased to 1.37 M\$/y. The same substrates were selected as in nominal solution while additionally a small quantity of glycerol was chosen using the same transportation mode. Flexibility of supply chain was confirmed over 1000 randomly selected vertices.

4. Conclusions

This work presented a new general methodology for the synthesis of flexible process flowsheets and supply chains having larger numbers of uncertain parameters. The methodology consists of several steps that gradually lead from generally inflexible flowsheet obtained at the nominal conditions to the generation of flexible process structure, and to the final optimization of the second-stage variables and generation of decision criteria distribution functions.

The main advantage of the proposed approach is that the model size does not increase with the number of uncertain parameters, but instead the single- or two-scenario problems are solved in the loops yielding the optimal flexible solutions at the specific level of confidence which is suitable for quality decision-making in practice.

Abstract

Reliability is one of the most important properties of processing systems, still there is no general method that is able to simultaneously considering the reliability during the design procedure. The proposed method is capable of synthesizing processing networks simultaneously taking into account reliability constraints or generating all Pareto optimal solutions for cost vs. reliability. The method is based on structural examinations and P-graph algorithms

Keywords: Reliability, P-graph, Process synthesis

1. Introduction

Process systems design and reliability engineering are based on different types of mathematical modeling tools that makes their simultaneous consideration difficult. While process systems design is traditionally solved as mixed-integer optimization, reliability engineering is primarily based on probability theory and combinatorial mathematics.

There are only few major contributions in this area. In designing a batch plant, Pistikopoulos et al. (1996) optimized the redundancy of the equipment units. Terrazas-Moreno et al. (2010) considered both reliability and flexibility in optimizing the production capacities, the intermediate storages, and the redundancy on the production units. Goel et al. (2002) retrofitted a HDA process with additional structural options.

For the simultaneous consideration of reliability in process design, a general modeling technique is required that can conveniently represent the two areas.

In the present work, it has been shown that the formerly developed axioms based combinatorial approach to process network synthesis (PNS), the so-called P-graph framework (Friedler et al. 1992b), can conveniently cover and integrate these two areas. The interface between the synthesis and the reliability analysis of process systems design is established on the basis of the axioms of structurally feasible processing networks. Since the structural feasibility of the synthesis procedure and the structural operability of the reliability engineering are closely related terms, they can simultaneously be considered in an integrated procedure.

P-graph framework is based on the fundamental combinatorial properties of feasible process networks. Since these properties are general and independent of the types of mathematical models of the operating units, the framework is also general and independent of these mathematical models. For this reason, the current work will be

shown for the simplest type of mathematical models of the operating units, it can simply be extended to other types of models. The key point of the development of the integrated procedure is the combinatorial interface between the two areas, this is the focus of the paper. It is supposed that the failures of operating units in a system are independent and time invariant. An operating unit is either functional or non-functional, the probability of the functionality of an operation is given as its reliability.

2. Main components of the P-graph framework

The P-graph framework represents a processing network by a directed bipartite graph of the operating units and the materials. A PNS problem is given by the sets of operating units, raw materials, and products. The optimal solution of the problem is to be given as a subset of the set of operating units that represents the related P-graph as the network of the process. Naturally, the set of operating units of a feasible process, including the optimal process, must satisfy certain structural (combinatorial) properties. For example, each product must be produced by at least one operating unit from this set of operating units. Also, if a material is consumed by at least one operating unit and not produced by any of them from this set, this material must be a raw material. In the P-graph framework, these types of combinatorial properties of the feasible process networks are collected and formally identified as set of five axioms. Networks of operating units satisfying the five axioms are called combinatorially feasible networks. Therefore, the network of each feasible process must be combinatorially feasible. Consequently, the search for the optimal network can be reduced to the set of combinatorially feasible networks. In practice, the set of combinatorially feasible networks is a small subset of all sets of networks. There are algorithms exploiting this property of networks resulting in a big acceleration in the search for the optimal network.

Algorithm MSG (Friedler et al. 1992a) is for generating the so-called maximal network (super-structure) that is the minimal among networks that include all combinatorially feasible networks. Algorithm SSG (Friedler et al. 1992a) is capable of generating the whole set of combinatorially feasible networks, while algorithm ABB (Friedler et al. 1996) is an accelerated branch-and-bound algorithm for generating the optimal network. These algorithms are the building blocks of process network synthesis simultaneously considering reliability constraints.

3. Reliability formula for processing systems

Though it is easy to determine the reliability of specific systems, e.g., for series or parallel systems (Biroliini 2007), no formula is known for general, highly interconnected processing systems that may include several loops.

Suppose that there are n operating units on the maximal network numbered from 1 to n . Each operating unit has a binary state, which determines if it is functional or not. Binary vector $X=(x_1, x_2, \dots, x_n)$, describe the functionality of the operating units where x_i is 1 if unit i ($i= 1, 2, \dots, n$) is functional, otherwise it is 0. The functional operating units represented in X describe a network of units that is a subnetwork of the maximal network. The operability of the network of functional operating units is to be determined next. Since the structural properties of the networks are considered here and no mathematical models of the units are given, structural operability will be defined. A network is considered to be structurally operational if it has a combinatorially feasible subnetwork. Naturally, any operational network is also structurally operational. This property can easily be tested by algorithm MSG. Therefore, set U of operational

networks can be determined by selecting the operational networks from all binary n -vectors.

Unit failures are supposed to be independent. The reliability of unit i is given by p_i , ($i=1, 2, \dots, n$). The probability of the occurrence of subnetwork given by binary vector (b_1, b_2, \dots, b_n) is determined by Formula (1), where P denotes the probability of an event.

$$P((x_1, x_2, \dots, x_n) = (b_1, b_2, \dots, b_n)) = \prod_{i=1}^n p_i^{b_i} (1-p_i)^{(1-b_i)} \quad (1)$$

The reliability of the network of operating units is the sum of the probabilities of the structurally operational networks in set U as determined by Formula (2).

$$P(U) = \sum_{(x_1, x_2, \dots, x_n) \in U} \prod_{i=1}^n p_i^{x_i} (1-p_i)^{(1-x_i)} \quad (2)$$

Once set U is determined for a process network, the reliability formula gives the reliability of the process for any values of p_i , ($i=1, 2, \dots, n$). Naturally, this general formula is also valid for specific process networks e.g., for parallel and sequential networks.

4. Synthesis with Reliability Consideration

The previous section summarized the method to determine the reliability of any system represented by P-graph. We can integrate this procedure into algorithm SSG of the framework to create a method capable of solving process network synthesis problems with reliability considerations.

The network of the operating units given in the input is represented as a P-graph, then, algorithm MSG generates the maximal network by eliminating those units that cannot be involved in any feasible process. It is followed by algorithm SSG for generating all combinatorially feasible networks. Naturally, the optimal solution of the PNS problem with required level of reliability is one of the elements of this set of networks (if it exists). For the determination of the optimal solution, each combinatorially feasible network must be evaluated for its costs and reliability. Then, the optimal solution or solutions can simply be selected.

The cost of a combinatorially feasible network is to be determined by an available process systems analysis technique or simulation program. The reliability of a network is given as far as it is shown at the reliability formula.

Note that the procedure for determining the optimal solution of a PNS problem that satisfies reliability requirements is general, e.g., no limitations applied for the number of nodes, the level of interconnections, the number of loops or any other structural property.

5. Case study

The structure of the case study is given by the maximal network shown in Figure 1, it was generated by algorithm MSG. The simplest model is considered here for each operating unit, therefore, it is assumed that the cost of a unit is constant, and the cost of a process is the sum of the costs of its units. It is also assumed that the reliability of a unit is constant and time-independent. The reliabilities and costs of the operating units of the case study are given in Table 1. Operating units O1A and O1B are considered as alternatives. Unit O1B has higher reliability with higher cost than that of unit O1A.

Similarly, for units O2A and O2B. Material flows, and material costs are not considered in this example.

Figure 1: Maximal network of the case study

Figure 2: Network #12 as one of the 58 combinatorially feasible networks of the case study.

Table 1: Reliabilities and costs of the operating units

Unit	Reliability	Cost
O1A	0.99900	10
O1B	0.99995	16
O2A	0.99900	12
O2B	0.99995	20
O3	0.99990	5
O4	0.99990	6
O5	0.99950	4
O6	0.99950	3
O7	0.99950	5

There are 58 combinatorially feasible networks for the case study. For each of these networks, the cost and reliability are determined. This is illustrated by analyzing network #12 (from the 58 networks), it is shown on Fig. 2. This network has 4 operating units, thus, $2^4=16$ networks are tested by algorithm MSG. Six of the 16 networks are structurally operational, these networks are shown in Fig. 3.

The probability of the occurrence of each subnetwork is determined next. The sum of these probabilities gives the reliability of the network, it is 0.99994999. The cost of network #12 is the sum of the costs of its operating units, i.e., it is 30.

For illustration, the costs vs probabilities of failures for all 58 combinatorially feasible networks are shown on Fig. 4 on logarithmic scale, where the probability of failure of a network is 1 minus its reliability. There are 8 Pareto-solutions; these solutions are listed in Table 2. Each solution is given with its reliability, cost, probability of failure, and the number of structurally operational subnetworks.

Figure 3: Structurally operational subnetworks of network #12.

Figure 4: Combinatorially feasible networks shown as cost vs. probability of failure.

6. Note on nonlinear models of the operating units

In the present work, the integration of PNS and reliability analysis is primarily based on combinatorial properties of process networks. The proposed procedure is independent of the types of the mathematical models of the operating units. In chapters 4 and 5, the simplest model has been shown. In practice, more realistic models are to be used for the selection of the best network in terms of cost and reliability.

Suppose that the operating units are described by simulation program modules. Then, the procedure given in this paper is to be extended as follows. Algorithm SSG generates the combinatorially feasible networks as given in chapter 4. Each of these networks must be tested for feasibility by the simulation program. For each feasible network, the

structurally operational subnetworks must be tested for feasibility by the simulation program. Then, the reliabilities of only the feasible networks are determined as far as it has been given in formula (2).

Table 2: Costs and reliabilities for the Pareto-solutions

Network	Operating units in the network	Reliability	Cost	Probability of failure	Number of structurally operational subnetworks
#1	O1A, O3	0.9989001000	15	0.0010999000	1

7. Concluding remarks

A general procedure has been introduced to perform process network synthesis simultaneously taking into account reliability. The procedure is general and capable of effectively designing complex, highly interconnected processing networks. A by-product of the present work is the launch of the formerly unavailable reliability formula of processing networks. It has been shown that the P-graph framework is capable of effectively integrating structurally related design problems for their simultaneous solution.

Abstract

Ensuring sustainability during production of chemicals and related products has become an ever-growing challenge due to rising demand for sustainability. Thus, there is a need to look for innovative solutions that are not only economic and efficient but also sustainable. Process intensification as an integrated part of process synthesis & design has the potential to determine more sustainable and innovative solutions. In this paper, a multi-stage and multi-level computer aided framework to perform sustainable process synthesis, design and intensification is presented. The framework employs a phenomena-based technique, which is capable of generating innovative, more sustainable and non-trade off solutions for any existing process flowsheet or a totally new process. In this paper, the framework is further extended in terms of application range validated through a case study for production of bio (enzyme-based conversion) succinic acid from multiple feed options. The case study highlights the generation of a novel superstructure of alternatives, from which an optimal processing route under different scenarios is determined. This optimal processing route is further improved through phenomena-based technique to generate innovative, more sustainable and intensified alternatives for the production of bio succinic acid.

Keywords: process intensification, computer-aided framework, sustainable solutions.

1. Introduction

Sustainable solutions refer to those design alternatives that correspond to improved values of a set of targeted performance parameters related to economic, social and environmental factors. Process Intensification (PI) is defined as improvements of a process at unit operational, functional and/or phenomena levels that can be obtained by integration of unit operations, integration of functions and phenomena's or targeted enhancement of the phenomena for a set of target operations (Lutze et al., 2013). The conventional approach for process synthesis design operating at unit operation (Jakslund et al., 1995) and functional level (Jakslund et al., 1995, Siirola, 1996) has been further extended by incorporating a lower scale phenomena level (Babi et al., 2015). At the phenomena level, one can investigate underlying driving forces associated with unit operations (unit-ops) to generate new unit-ops that lead to innovative flowsheet alternatives. At the highest level of aggregation, process flowsheets options in terms of unit-ops are synthesized and/or evaluated. These flowsheet options correspond to acceptable designs matching the process specifications and represent the "base case" design. However, at this level, only known unit-ops are considered and thus the search space is limited. This search space can be

further increased by operating at a lowest scale of aggregation, i.e. phenomena level (Papalexandri et al., 1996, Lutze et al., 2013). At this level, the phenomena involved in performing specific tasks are identified and are recombined using a systematic and generic approach such that they perform the same tasks, while not only matching the original process specifications but also satisfying a set of design targets. This leads to the generation of more sustainable and non-trade-off alternatives compared to the base case and measured in terms of a set of performance criteria.

In this work, the phenomena based synthesis approach is extended by expanding the database and algorithms to identify phenomena building blocks (PBB's) and generation of new basic structures translating to unit-ops. In its application, the superstructure-based optimization is performed for various scenarios to consider the influence of different parameters on the optimization, for example by varying the objective function, varying the prices of material and utilities according to different locations etc., to obtain corresponding optimal processing routes, which are further developed in the design and innovation stages of the framework.

2. Multi-stage framework for sustainable process synthesis-intensification

An overview of the multi-stage and multi-level computer aided framework for sustainable process synthesis-intensification is shown in figure 1. This framework is based upon a generic 3-stage approach for sustainable process design (Babi et al., 2015). The computer-aided tools used at different stages of the framework are also highlighted. Note that entry to a problem can be at any stage, depending on the available input information, for example, if a process flowsheet already exists, entry is at stage 2.

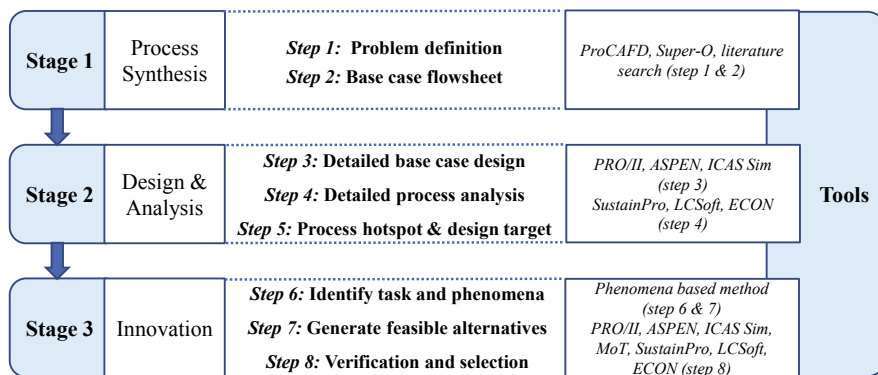

Figure 1: Overview of multi-stage framework for sustainable process synthesis-intensification

The objective of stage 1 is to identify the optimal process flowsheet. In stage 2, the detailed design and analysis for the selected flowsheet is performed to identify the process “hot-spots” and set design targets for improvement. In stage 3, these targets are achieved by applying phenomena based intensification. The detailed steps of the framework are not explained here, as they are available in Garg et al. (2018).

3. Case study

The case study involves the application of the framework for production of bio succinic acid. Succinic acid is a potential precursor to produce a wide range of chemicals, which

have great industrial significance in the food, pharma and chemical sectors (Song et al., 2006). Thus, the main objective of this case study is to identify more sustainable and intensified alternatives for the production of bio succinic acid under different scenarios not reported earlier.

3.1. Stage 1: Synthesis

The main objective of the synthesis problem is to find the optimal processing route for the production of bio succinic acid with a purity of at least 99.9%. Glucose, glycerol, maltose and sucrose along with CO₂ have been considered as the raw materials. On basis of selected raw materials, reaction paths with different bacterial and yeast strains are identified from literature along with required reaction data (step 1). To solve the synthesis problem, the superstructure-based optimization is employed (step 2). The superstructure describing the network of configurations for different processing routes has 8 processing steps and 33 processing intervals excluding raw material and product steps (see figure 2). Then the superstructure-based optimization problem is set up in Super-O (Bertran et al., 2017), where it is solved to determine the optimal processing route. The optimization problem is solved for different scenarios, which are described below.

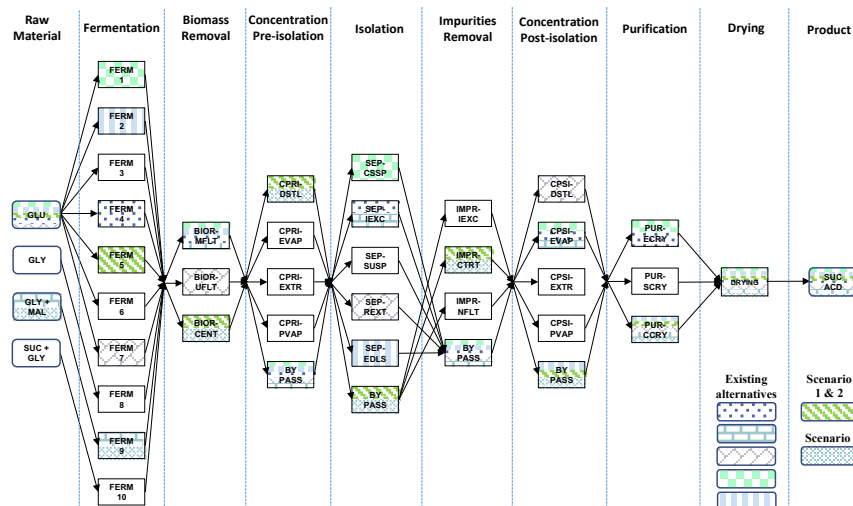

Figure 2: Superstructure of alternatives for the bio succinic acid case study

Optimization scenarios: The first scenario involves optimization to find the processing route corresponding to maximizing sales profit of the product considering raw material cost, chemical cost and product cost in USA. The optimal route for this scenario is shown in figure 2. In the second scenario, the objective is again to maximize the sales profit of the product, but in this case, the operational costs are also considered with same location as scenario 1. Considering the operational cost, the optimal solution remains the same with the same fermentation model and downstream separation route. In the third scenario, the optimization is performed considering scenario 2 but by changing the raw material, chemical and utility prices to another country, for example, Thailand. Owing to lower raw material prices, the optimal processing route changes as compared to scenario 1 and 2. Here the optimal route goes through the interval with fermentation model 9 while downstream separation intervals are the same as scenario 1 and 2. The problem type for all the scenarios is MILP and the solver used is CPLEX. Other model statistics for the three scenarios are listed in table 1.

The optimal process flowsheet alternatives obtained from the three scenarios are novel processing routes while five other existing routes reported in the literature, for example, by Glassner et al. (1992) are also identified (see figure 2). Thus, potentially from this superstructure 2604 novel and existing feasible process flowsheets alternatives can be generated for the production of bio succinic acid.

Table 1: Superstructure-based optimization statistics for different scenarios

Superstructure parameter	Scenario 1	Scenario 2	Scenario 3
Location	USA	USA	Thailand
Objective function	Sales	Sales-OPEX	Sales-OPEX
Number of equations	989,003	989,003	989,003
Number of variables	973,451	973,451	973,451
Number of discrete variables	164	164	164
Execution time (seconds)	2.50	2.52	2.56
Objective function (MM USD/y)	42.56	30.91	40.72

3.2 Stage 2: Design and analysis

The optimal processing route, which is same for the first and second scenario, is considered for stage 2. Here, the basic design information, like reaction conversion, operating conditions, distillation column stages and reflux ratios, feed and product material information, is obtained from literature, databases or design calculations. Using this basic information, the base case process is designed and simulated (PRO/II) to get the base case design (step 3). Then from the simulation results, the detailed mass and energy balance data is extracted to perform process analysis (step 4) in terms of sustainability, life cycle analysis and economics using the in-house tools SustainPro (Carvalho et al., 2013), LCSOFT and ECON (Kalakul et al., 2014). The sustainability analysis indicates loss of product and raw material in open path (in-out streams) containing crystallizer. The economic analysis shows high utility costs related to distillation operation in one open-path. Further, the LCA analysis confirms the high carbon footprint for the reboiler of the same distillation column. Based on the above analysis, process hot-spots (inefficient operations) are identified that are translated into design targets for improvement (step 5). The identified process hotspots are high energy consumption and/or demand for succinic acid recovery and loss of product in the above mentioned open paths. Their translations to design targets are reduction of energy demand, increase in product recovery, reduction in number of unit operations and improvement in sustainability and LCA factors.

3.3 Stage 3: Innovation (Phenomena based intensification)

The base case flowsheet based on unit-ops is first represented in terms of separation and reaction tasks. These tasks are further represented in terms of phenomena constituting the initial search space. The identified PBB's are R (reaction), M (mixing), 2pM (two phase mixing), PC(VL), PT(VL), PS(VL), PC(LS), PT(LS), PS(LS), H (heating) and C (cooling) where, PC is phase contact; PT is phase transfer and PS is phase separation; while V, L and S represent vapor, liquid and solid phases. Here, the tool library to identify the PBB's has been extended in order to incorporate wider search space. The pure component and mixture property analysis is performed using ICAS (Gani et al., 1997), which identified one azeotrope between water and ethanol. As in this case study, the main objective is to get pure succinic acid, the separation of water and ethanol is not considered in further

steps. Thus, using process hot-spots, additional list of PBB's are identified and added to the existing list leading to an increase of search space. The new list consists of 20 PBB's where PT(PVL), PT(VV), PS(VV), PC(LL) and PS(LL) are additional PBB's. The total number of possible combinations of these PBB's to form simultaneous phenomena building blocks (SPB's) are 519,252. However, not all combinations are feasible. Thus, using connectivity rules, 244 SPB's are found to be feasible.

The identified feasible SPB's are combined to form basic structures. These basic structures are formed in a way that they satisfy the identified reaction and/or separation tasks. These combinations of basic structures are then translated to unit-ops and thus three intensified flowsheet alternatives are generated, as shown in figure 3.

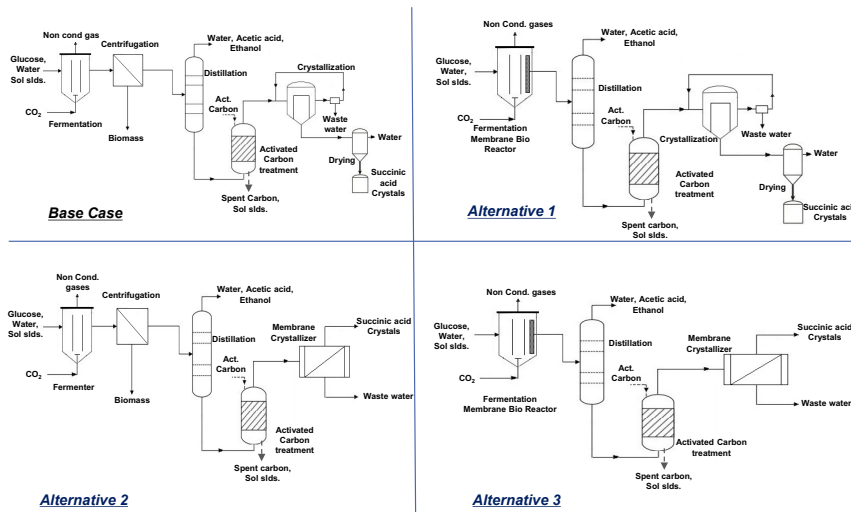

Figure 3: Base case and intensified flowsheet alternatives for bio succinic acid

In alternative 1, starting with the first task of reaction, the second task, which is biomass separation could be combined to obtain a new basic structure of phenomena's consisting of reaction (R) and separation PS(LS) phenomena. This combination of basic structure is then translated into a membrane bioreactor. In this unit operation, the fermentation broth is clarified, i.e., the reaction product is removed continuously and the cell culture remains in the bioreactor leading to increase in cell concentration and high product yield, also observed by Wang et al. (2014). In alternative 2, the integration of basic structures for the last two separation tasks is considered. This is possible as both separation tasks involve SPB involving separation of crystalline product from the liquid phase. Thus, a basic structure having phenomena PT(LS) and PS(LL) is selected. Additional PBB's like cooling, heating and mixing can also be added to the selected SPB's. Thus, in flowsheet alternative 2 the combined basic structure is translated to membrane crystallizer to obtain higher recovery and desired purity of succinic acid. Alternative 3 is a combination of alternative 1 and 2 including both membrane bioreactor and membrane crystallizer.

The radar plot (see figure 4) confirm that the intensified alternatives are more sustainable and non-trade-off, in terms of the selected performance criteria. Here, the outer boundary of the plot represents the base case design while all the more sustainable intensified alternatives should be within the boundary. The values are calculated by taking percentage ratios of different factors with respect to the base case (except profit

where inverse ratio has been taken). Note that the base case and all alternatives also satisfy the process objectives.

Figure 4: Comparison of intensified alternatives relative to the base case design (HTPI: Human toxicity potential by ingestion, GWP: Global warming potential)

4. Conclusions

An overview of multi-stage and multi-level framework for process synthesis–design and intensification has been presented. The application of the extended framework is illustrated through the bio succinic acid case study where, different scenarios have been analysed using the superstructure-based optimization approach, generating more than 2600 alternatives at the synthesis stage. However, by applying the phenomena based method, three intensified and more sustainable alternatives, compared to the base case, have been determined. Current and future work is extending the phenomena based approach and its implementation in the ProCAFD tool (Tula et al., 2017).

Abstract

A thermodynamic network flow approach (TNFA) is proposed for the purpose of process synthesis. Firstly, the feasible region of the thermodynamic state space (T, p, x) is analyzed wherein the optimal process route should be identified. Within this region, we define elementary directions into which the matter elements can be moved by manipulation of mass and energy fluxes. Secondly, we discretize the feasible region along the elementary directions such that a grid of thermodynamic state points is obtained. The grid points form the nodes of a directed 'thermodynamic graph'. To each graph edge, a cost contribution is attributed. Thirdly, a network flow problem is formulated based on the graph representation in order to determine the optimal flow distribution at minimal cost. By defining a linear cost function in terms of the network flows, due to the fact that the nodes of the graph have fixed thermodynamic coordinates, the flow problem results in a purely linear programming (LP) problem. The TNFA methodology is demonstrated with two case studies: i) the feed compression section and ii) the reactor section of the methanol synthesis process. With these examples, a proof of concept of the TNFA is given highlighting the versatility of the proposed methodology.

Keywords: Process Design, Process Optimization, Network Flow Problem, Methanol Synthesis

1. Introduction

The synthesis of highly efficient chemical production processes remains one of the most important tasks in Process Systems Engineering. In a previous work, we have sketched a novel approach to process design, named 'Elementary Process Functions (EPF) methodology' (Freund and Sundmacher, 2008). The key idea of this EPF approach is to track matter elements over time and to identify an optimal route in the thermodynamic state space as a basis for the subsequent technical realization by use of modular functional devices. So far, the EPF approach was successfully demonstrated for the design of catalytic gas phase reactors (Peschel et al., 2010) and multiphase reactors (Kaiser et al., 2017). The motivation for the present work is to extend the EPF approach for designing complete chemical production systems consisting of multiple processing steps, including the feed pretreatment, reactor section, separation of the product from non-converted reactants, and the final product purification. In order to account for different process unit types, the EPF methodology is modified: the step-wise approach starting from an ideal thermodynamic pathway towards real process units is replaced by a directed graph representing the discretized thermodynamic state space where edges denote elementary process functions. The subsequent process design task is then formulated as a flow optimization problem.

2. Method

Chemical processes are inherently nonlinear due to a strong temperature, pressure and composition dependence of the underlying elementary operations. Therefore, the optimization of such processes leads to nonlinear programming (NLP) formulations. Despite of the availability of very efficient NLP-solvers, a large number of decision variables increases the computational effort significantly, requires good initializations and may attain only local optima (Biegler and Grossmann, 2004).

In this contribution, we propose a novel optimization approach that decouples the nonlinear build-up of the solution space and the linear mass- and energy flux optimization. By discretizing the thermodynamic state space (Figure 1), the chemical process is divided into elementary steps, such as conversion, heating or cooling. Suitable nonlinear models are used to simulate each discrete elementary step. In this way, a graph of nodes and edges is created. The nodes represent discrete state points which are connected by a single elementary step, representing an edge.

The derived graph of discrete state points serves as a superstructure of numerous possible pathways from an initial state towards a final state. In order to identify the optimal pathway, a linear programming problem (LP) is formulated. The previously identified key information are used to relate each elementary edge with a certain cost level. In this way, each edge shows a different impact on the objective function.

$$\begin{aligned} \min_{\mathbf{x}} \quad & f(\mathbf{x}) = \mathbf{c}^\top \mathbf{x} \\ \text{s.t.} \quad & \mathbf{A}\mathbf{x} \leq \mathbf{b} \\ & \mathbf{lb} \leq \mathbf{x} \leq \mathbf{ub} \end{aligned} \quad (1)$$

Eq. (1) shows the general form of a LP. Herein, f is the objective function and $\mathbf{x} = (\dot{\mathbf{N}}, \dot{\mathbf{\Gamma}}, \dot{\mathbf{Q}}, \dot{\mathbf{W}})^\top$ denotes the vector of all decision variables, namely the mass fluxes $\dot{\mathbf{N}}$, the heat $\dot{\mathbf{Q}}$ and work fluxes $\dot{\mathbf{W}}$ and the unit scaling factors $\dot{\mathbf{\Gamma}}$. The influence of the decision variables on the objective function is determined by the cost vector $\mathbf{c} = (\mathbf{c}_N, \mathbf{c}_\Gamma, \mathbf{c}_Q, \mathbf{c}_W)$. The cost vector \mathbf{c} , the coefficient matrix \mathbf{A} and the solution vector \mathbf{b} as well as the lower \mathbf{lb} and upper bounds \mathbf{ub} vary depending on the chosen application.

In this contribution, the validity and versatility of the TNFA are illustrated using two examples: a compressor cascade and the methanol synthesis reaction. In the following sections, both case studies are introduced with their respective balance equations as well as possible objective functions. Afterwards, optimal pathways for different objective functions are presented and discussed for both example processes.

2.1. Case Study 1: Compressor Cascade

In the first case study, the TNFA is illustrated for the pretreatment compression cascade of Lurgi's methanol synthesis where the directed graph is best illustrated using a p - T grid (Ott et al., 2012). Three possible edges result from this node formulation for the compressor cascade: heating, cooling and isentropic compression. Pressures are linked by either single stage compression – i.e. compression to the adjacent grid point – or multiple compression stages – i.e.

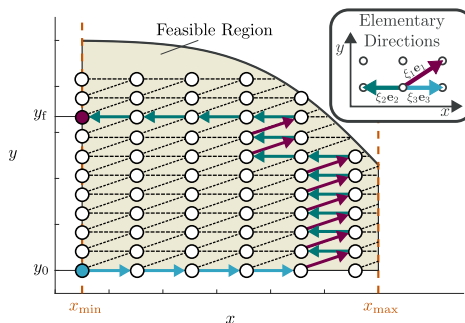

Figure 1: Illustration of the optimal path in state-space for an arbitrary process based on fixed thermodynamic state points (nodes). The elementary directions define feasible transitions between nodes.

connection of non-neighbouring grid points.

Heating and cooling duties $q^{\text{hcu,ext}}$ are derived from the energy balance of the heating/cooling unit (hcu). Enthalpies are obtained from the Shomate equation (Burgess, n. d.)

$$0 = (h_{\text{in}}^{\text{hcu}} - h_{\text{out}}^{\text{hcu}}) + q^{\text{hcu,ext}}. \quad (2)$$

In order to generate the isentropic compression edges, outlet temperatures of the compression $T_{\text{out}}^{\text{comp}}$ and the necessary technical work w_t^{comp} are calculated for the predefined pressure grid:

$$T_{\text{out}}^{\text{comp}} = T_{\text{in}}^{\text{comp}} \left(\frac{P_{\text{in}}^{\text{comp}}}{P_{\text{out}}^{\text{comp}}} \right)^{\frac{1-\kappa}{\kappa}}, \quad w_t^{\text{comp}} = (h_{\text{out}}^{\text{comp}} - h_{\text{in}}^{\text{comp}}). \quad (3)$$

Optimizations are performed using two different objective functions: the first optimization (I) serves as an identification of the compression route which requires minimal technical work (Eq. 4a). In contrast to the first objective function, the second optimization (II) identifies the minimum capital cost via an estimation of the relative equipment cost (Eq. 4b) (Peters et al., 2004).

$$C^{\text{I}} = \sum_{i=1}^{N_{\text{comp}}} W_i = \mathbf{c}_W^{\top} \mathbf{W} \quad \text{with} \quad \mathbf{c}_W := \mathbf{1}, \quad \mathbf{c}_N, \mathbf{c}_T, \mathbf{c}_Q := \mathbf{0}, \quad (4a)$$

$$C^{\text{II}} = \sum_{i=1}^{N_{\text{comp}}} C_{\text{scale},i} = \mathbf{c}_T^{\top} \mathbf{T} \quad \text{with} \quad c_{T,i} := \left(\frac{\Delta p_i}{\Delta p_0} \right)^{0.69}, \quad \mathbf{c}_N, \mathbf{c}_Q, \mathbf{c}_W := \mathbf{0}. \quad (4b)$$

2.2. Case Study 2: Reactor Design

The second case study is a methanol synthesis reactor design study illustrating the versatility of the proposed concept. Instead of pressure in the compressor example, the product mole fraction of methanol is considered on the ordinate. Therefore, adiabatic reactor edges are defined instead of compressors in order to move from lower to higher product mole fractions in the thermodynamic state space. The adiabatic reactor edge is defined as a discrete step in the product mole fraction which is reformulated as a conversion of the reactant CO and a single reaction equation:

By introducing the conversion $X_{\text{CO}} = 1 - \frac{\dot{N}_{\text{CO,out}}}{\dot{N}_{\text{CO,in}}}$, the adiabatic temperature difference is obtained from

$$\Delta T_{\text{ad}} = \frac{-\Delta_R H(T_{\text{in}})}{-v_{\text{CO}}} \cdot \frac{\dot{N}_{\text{CO,in}}}{\sum_i \bar{N}_i c_{p,i}(T_{\text{in}})} \cdot X_{\text{CO}}, \quad (5)$$

where \bar{N}_i is the arithmetic average molar flux of component i along an adiabatic reactor edge. Acquiring an energy optimal solution is not relevant since the major part of the enthalpy change originates from the reaction enthalpy. Instead, an exergetically optimal pathway (III) is derived by minimizing exergy losses due to cooling. In a second optimization, the reactor volume is minimized which is achieved via maximization of the reaction rates. For this purpose, the adiabatic reactor edges are priced with kinetic rate expressions obtained from the kinetic model 2 for CH_3OH synthesis by Villa et al. (1987)

$$C^{\text{III}} = \sum_{i=1}^{N_{\text{hcu}}} E_{L,i} = \mathbf{c}_Q^{\top} \mathbf{Q} \quad \text{with} \quad c_{Q,i} := \left(1 - \frac{T_{\text{env}}}{T_i} \right), \quad \mathbf{c}_W, \mathbf{c}_T, \mathbf{c}_N := \mathbf{0}, \quad (6a)$$

$$C^{\text{IV}} = - \sum_{i=1}^{N_{\text{reac}}} R_i = -\mathbf{c}_T^{\top} \mathbf{R} \quad \text{with} \quad c_{T,i} := r_i, \quad \mathbf{c}_Q, \mathbf{c}_W, \mathbf{c}_N := \mathbf{0}. \quad (6b)$$

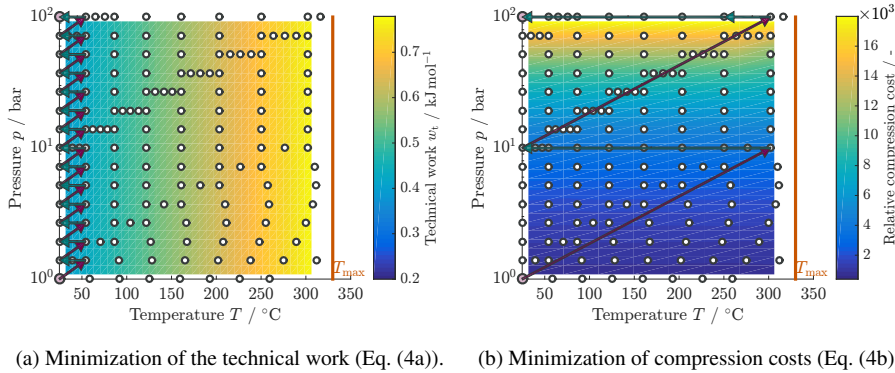

Figure 2: Thermodynamically attainable region and optimization result of the TNFA applied to a compressor cascade of Lurgi's methanol synthesis.

3. Results & Discussion

3.1. Optimal Compression Cascade

Results of the compressor cascade optimization are illustrated in Figure 2 in a semilogarithmic plot. The case study is a synthesis gas compression from 1 to 100 bar with in- and outlet flows at ambient temperature. A logarithmically equidistant pressure grid is applied and a maximum temperature of 330 °C is assumed as the upper temperature limit at the outlet of the compressor. Figure 2a shows the minimization of technical work as formulated in Eq. (4a). A colormap in the background illustrates the technical work required for compression at each compressor edge mean temperature. The energy minimal pathway climbs up to the required pressure in as many single steps as possible because compression work increases with temperature and this pathway is closest to the ideal case of a reversible isothermal compression. The second optimization scenario that takes only relative compressor costs into account (Eq. (4b)) results in the minimum number of compressor units and a maximum compression duty – i.e. combination of single edges to multiple edges – in each unit while fulfilling the temperature constraint.

The results of both optimizations are summarized in Table 1 representing the extreme cases: purely variable and purely fixed cost minimization. However, the real compressor cost are strongly loca-

Table 1: Compressor cascade optimization results.

Scenario	Technical work / kW	Relative capital cost / -
Energy minimization (Eq. (4a))	11.9	$1.3 \cdot 10^5$
Investment cost minimization (Eq. (4b))	16.2	$7.6 \cdot 10^4$

tion dependent due to a regional variability in capital and operational cost. As a consequence, a worldwide optimum is thus not sensible. The generic formulation proposed here allows to identify the best technical approximation and forms the foundation for decision making in specific cost scenarios.

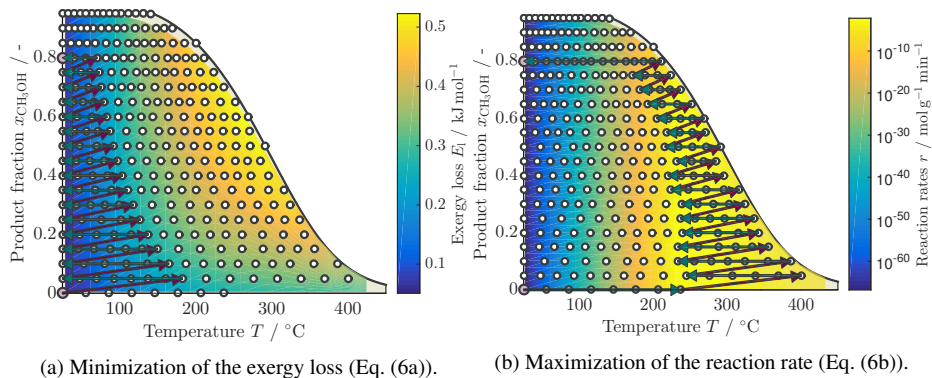

Figure 3: Thermodynamically attainable region and optimization result of the TNFA applied to the methanol synthesis reaction.

3.2. Optimal Reaction Pathway

The results of the reactor optimization for both objective functions (Eqs. (6a) and (6b)) are illustrated in Figure 3. In both cases, the reactor feed is a stoichiometric mixture of CO and H₂ at a temperature of 25 °C under isobaric conditions at 150 bar. At the reactor outlet, the molar flux is desired to contain 80 % of CH₃OH. The feasible region is bounded by the chemical equilibrium line which is obtained by Gibbs energy minimization and the thermodynamic state points are computed by means of Eq. (5). First, the results of the exergetic optimization (Eq. (6a)) are shown in Figure 3a. There, the background colormap denotes the exergy loss due to cooling to ambient temperature at each state point which increases with higher temperatures. The exothermic reaction is favored at low temperatures according to Le Chatelier's principle and requires therefore intermediate cooling. Consequently, the exergy optimal reaction pathway is found at low temperatures even though low reaction rates are present in this regime.

Figure 3b illustrates the optimization results for the kinetic rate maximization (Eq. (6b)). In contrast to the exergetic optimization, the reactants are preheated first. Due to the heat production during the reaction, the reactor still has to be cooled in order to stay within the feasible region. Considering the technical realization, the obtained pathway leads to a compact construction of the reactor since a pathway along maximum reaction rates is directly linked to a minimum reactor volume. The optimization results of both cases are summarized in Table 2. The kinetic optimization

Table 2: Methanol reactor optimization results.

Scenario	Exergy loss / kW	Reaction rate / mol g ⁻¹ min ⁻¹
Exergetic optimization (Eq. (6a))	$10.3 \cdot 10^3$	$9.9 \cdot 10^{-43}$
Kinetic optimization (Eq. (6b))	$47.8 \cdot 10^3$	$5.4 \cdot 10^{-3}$

leads to 4-5 times higher exergy losses due to cooling while increasing the reaction rates significantly. Therefore, the methanol synthesis process is typically carried out at temperatures between 250 °C to 300 °C (Ott et al., 2012) in industrial plants. Once more, both examined scenarios have to be regarded as extreme cases which were selected in order to demonstrate the applicability of our proposed method for reactor design purposes.

4. Conclusion

In this contribution, a novel thermodynamic network flow approach for the optimization of chemical processes is proposed. In this method a generalized matter element in the thermodynamic state space under the action of mass and energy fluxes is considered. By evaluating the thermodynamic potential of every discretized state point and evaluating the elementary steps in terms of heat, work and mass fluxes required for the node-to-node transition, the nonlinearities are decoupled effectively from the optimal network flow problem, which is purely linear if linear cost functions are chosen. The methodology is successfully validated and illustrated with two processes, a compressor cascade and the methanol synthesis reaction.

Since the decoupled linear optimization is solvable efficiently for a high number of decision variables – while preserving uniqueness and global optimality – and the required nonlinear computations can be carried out a priori, the proposed method is well suited for application to complex processes. Furthermore, the number and complexity of elementary process steps is easily adjustable due to the decoupling and modular build-up of the state point grid. Especially for industrial applications, it seems to be favorable that the formulation of the objective functions is highly versatile and enables numerous optimization scenarios depending on the application priorities as shown with the two case studies.

However, it should be mentioned that the accuracy of the optimization results depends strongly on the grid spacing in the state space. Finer grids require higher computational cost for the formulation of the constraint matrix. Finally, the novel proposed methodology should be benchmarked in terms of efficiency with well established nonlinear mixed integer approaches.

Abstract

The paper presents a general methodology for model-based chemical substitution, which considers different problem definitions depending on the objective for substitution. The developed methodology makes use of validated property models and modeling tools, thus avoiding the resource intensive and time-consuming experimental procedures during the initial stages. First, data and the property models are used to identify the chemicals present in a product that do not satisfy the regulatory property (EH&S: environmental, health and safety) bounds. Next, candidate molecules are generated and evaluated in order to identify those that can serve as safe substitutes and which are compatible with the original product or process function. Practical examples on substitution of chemicals used in processes and products in various sectors like automobiles, coatings and solvents, and polymers have been solved (Jhamb et al., 2017). In this paper we illustrate the methodology with an example concerning the substitution of a solvent, which is toxic to the aquatic environment (Eurochlor.org, 2015) but commonly used for dissolution of ultrahigh molecular weight - polyethylene (UHMW-PE), in its gel spinning process.

Keywords: property models, chemical substitution, general methodology.

1. Introduction

The regulatory authority on the safety of chemicals, the European Chemical Agency (Echa.europa.eu, 2007), has a goal to advance the safe use of chemicals for the benefit of the environment and human-health in the European Union (EU). One of the ways in which they strive to achieve this mission is by implementing the REACH regulation, which compels companies operating in the EU to stop the use of hazardous substances and replace them with environmentally benign and safe chemicals without disturbing the product function. However, in order to perform this task in a versatile manner, a systematic, model-based methodology can help to find the substitutes, as a first estimate, in a fast and reliable way, before focused experiments to validate the results are carried out.

Consumer-oriented chemical-based products are generally structured product formulations and they are composed of a set of chemicals, which due to their useful properties have brought substantial benefits to human lives and health. Besides these, single molecule products used in processes as working fluids, like solvents and refrigerants are also essential and have significantly contributed to the needs of our society. However, some chemicals constituting these products can be damaging to

human health and destructive for the environment due to their hazardous EH&S properties. Also, there are many more chemicals, which have not been evaluated due to lack of sufficient resources for experiments and paucity of reliable estimation methods (Hukkerikar *et al.*, 2012). Hence, there is an urgent need to efficiently identify substitute chemicals that will not be dangerous to the environment and/or toxic to human health while allowing the smooth functioning of the eco-system.

The objective of this paper is to present a chemical substitution methodology that can quickly and reliably identify promising candidates for substitution through model-based techniques that can later be verified through experiments. In this way, the experimental resources are used for verification rather than the time-consuming, trial-and-error search for alternatives. The very large search space, depending on the problem and the range of chemicals to-be considered, is reduced by employing a reverse design approach (Gani, 2004). That is, predictive property models are used to find alternative chemicals by matching the desired properties of the original product and avoiding the undesired EH&S properties of the 'compound to-be substituted'. The developed methodology can be used to systematically identify safe and environmentally compatible alternatives to the chemicals of concern. Note also that safe chemical product formulations with the same or better product performance as well as processes that make use of less hazardous chemicals, can be designed through this methodology.

2. A Generic Framework for Model-based Chemical Substitution

A systematic and generic framework, which incorporates model-based methods and tools that is able to solve a wide range of chemical substitution problems, is presented here. The framework contains a comprehensive property model library, EH&S property database, and a chemical properties database. A workflow diagram for the methodology for substitution of hazardous chemicals available through the framework is shown in Figure 1 (adopted from Jhamb *et al.*, 2017).

It should be noted that while solving any chemical substitution problem, if after the problem formulation step, it is recognized that the necessary property models or data are not available, then they will need to be added to the framework first. GC models for the required properties can then be quickly developed through the property modeling toolbox in ProCAPD (Kalakul *et al.*, 2017) by regressing the group contribution parameters.

3. Application of the Methodology

Case-study 1: The application of the methodology is highlighted through a case study involving the substitution of a single molecule solvent used in a UHMW-PE polymer spinning process (Fang *et al.*, 2016). UHMW-PE can yield fibers with high mechanical strength after extrusion in a gel-spinning process. However, due to its high melt viscosity it cannot be directly extruded. Therefore, it needs to be dissolved in a solvent before it passes through the extruder and is spun into fibers. Typically, 1,2,4-trichlorobenzene is used as a solvent for the dissolution of this polymer. In a post-extrusion step, an extraction solvent, n-hexane is used to remove the solvent from the polymer gel fibers. However, 1,2,4-trichlorobenzene appears on the REACH restricted substance list and it therefore needs to be replaced by another acceptable solvent.

3.1. Task 1: Identification of Problem Type

Firstly, the problem type, that is, the objective for substitution and function of the 'compound to-be substituted' in the original product or process, is identified. In this case, 1,2,4-trichlorobenzene is the solvent currently being used for UHMW-PE. The -

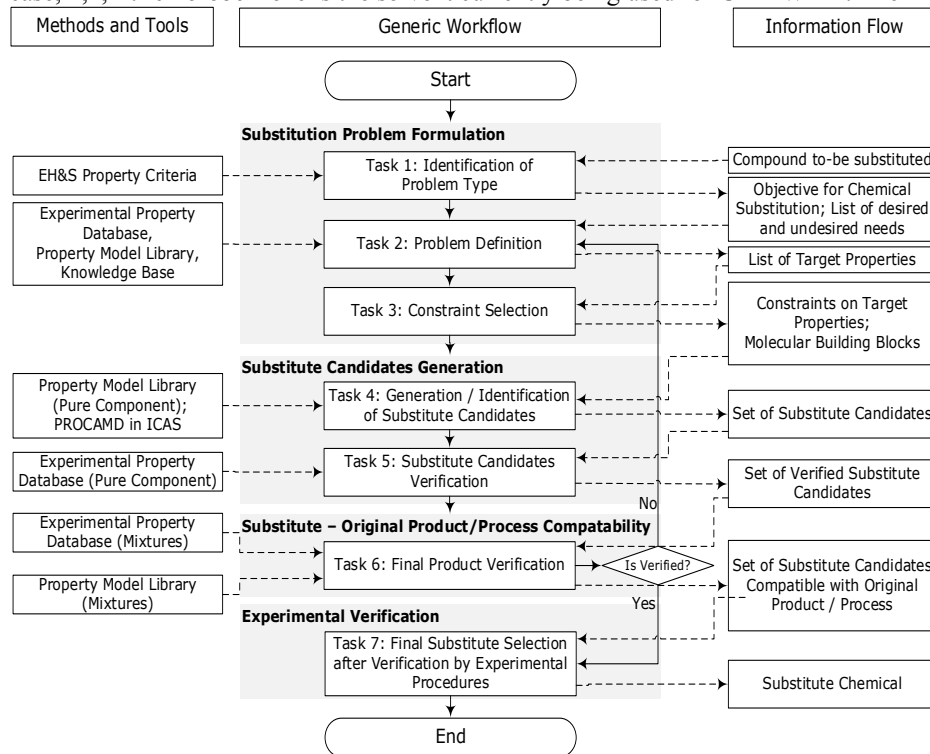

Figure 1: Workflow diagram for the methodology for chemical substitution

$\log(\text{LC}_{50})$ measured for fathead minnow (FM) – a freshwater fish, is 4.7 for this solvent (Eurochlor.org, 2015). For compliance with REACH regulations, solvents with values of $-\log(\text{LC}_{50})$ less than 3.5 and molecular weights in the range of 100 to 300 g/mol (Fisk, 2004) need to be used.

3.2. Task 2: Problem Definition

With the desired and undesired needs identified, they are converted to target pure component and mixture properties as given in Table 1 using a special knowledge base developed for the methodology.

3.3. Task 3: Constraint Selection

The constraints on the desired properties like normal melting point, normal boiling point, vapour pressure, viscosity, etc., associated with the function and performance of the solvent, are selected as close as possible to those of 1,2,4-trichlorobenzene, while the $-\log(\text{LC}_{50, \text{FM}})$ should be at least lower than the regulatory limit.

3.4. Task 4: Generation of Substitute Candidates

Since Group Contribution (GC) based models for the prediction of the pure component properties (Marrero and Gani, 2001) are available in the property model library for this problem, Computer Aided Molecular Design (CAMD) is used to generate substitute candidates with the tool, ProCAMD in ICAS (Gani et al., 1997). For this case-study, the

molecular building blocks of carbocyclic compounds are chosen because these are similar to the repeating unit of the polymer to be dissolved. The building blocks of aromatic compounds are not used to avoid hazardous properties associated with these structures. Four compounds are found to satisfy the pure component physicochemical

Table 1: Needs, Target Properties and Constraints for Example

Need	Target Property	Target Property Constraints
Ability to dissolve UHMW-PE at operating temperature	Solubility Parameter (δ_{Hild})	$16 \text{ MPa}^{1/2} < \delta_{Hild} < 18 \text{ MPa}^{1/2}$
Total Miscibility with the extraction solvent (n-hexane)	Gibbs Energy of Mixing (ΔG^{mix})	$\Delta G_{mix}/RT < 0$
Low volatility	Vapor Pressure (VP)	$0.0003 \text{ bar} < VP < 0.0012 \text{ bar}$
Not too viscous to allow flowability	Viscosity (η), Density (ρ)	$\eta < 1.65 \text{ cP}, \rho < 1.5 \text{ g.cm}^{-3}$
Liquid phase at operating temperature	Normal Melting Point (NMP), Normal Boiling point (NBP)	$NMP < 293.2 \text{ K}$ $475.2 \text{ K} < NBP < 600 \text{ K}$
Non-toxic to aquatic environment	Lethal Concentration ($LC_{50,FM}$)	$-\log LC_{50,FM} < 3.5 \log(\text{mol.L}^{-1})$

target properties. Out of these only one with building groups: CH_3 (1), CH_2 (10), CH (1) that is, methyl cycloundecane (CAS: 13151-44-5), satisfies the EH&S property constraint.

3.5. Task 5: Substitute Compound Verification

Since, the average absolute error in the $-\log(\text{LC}_{50, FM})$ property prediction model is 0.48 (Hukkerikar et al., 2012), this property needs to be verified experimentally for the identified substitute solvent. At this stage, the properties of methyl cycloundecane are also compared with other similar solvent candidates reported in the literature. Decalin, which is a carbocyclic compound with two rings, has satisfactory functional properties for the process considered here (Schaller et al., 2015). However, it is toxic to the aquatic environment ($-\log(\text{LC}_{50, FM})$ is 4.8) and highly volatile.

3.6. Task 6: Final Product Verification

Lastly, it is required that the generated candidate is compatible with the other chemicals used in the original process. This is done using appropriate mixture property models. Since, the extraction solvent used to remove the solvent from the extruded polymer is n-hexane, the miscibility of the recognized substitute solvent with n-hexane is checked by calculating the Gibbs energy of mixing using Eq. (1). Here, the activity coefficient (γ_i) is estimated using the original UNIFAC model. The Gibbs energy of mixing (ΔG_{mix}) at 298.2 K is found to be negative for all molar compositions of the methyl cycloundecane and n-hexane mixture (Figure 2), suggesting total miscibility.

$$\frac{\Delta G_{mix}}{RT} = \sum_i^{NC} x_i \ln(x_i) + \sum_i^{NC} x_i \ln(\gamma_i) < 0 \quad (1)$$

Besides this, the trend in the activity of methyl cycloundecane with increasing molar fraction in its mixture with UHMW-PE is checked, by using the UNIFAC-FV activity coefficient model (Oishi and Prausnitz, 1978). It is seen that the activity monotonically

increases (Figure 3), hence ensuring the solubility of the polymer in methyl cycloundecane.

3.7. Task 7: Final Substitute Selection after Verification by Experimental Procedures

Here, all the target properties of the methyl cycloundecane are verified through appropriate experiments before it is finally selected as the replacement solvent. This

Figure 2: Gibbs energy of mixing for methyl cycloundecane-n-hexane mixture

Figure 3: Methyl cycloundecane activity in methyl cycloundecane-polymer mixture using UNIFAC-FV model

step, however, is not performed in this case study.

Other case studies: The methodology has been successfully applied to substitution of hazardous and/or unsafe compounds from single-phase liquid formulated products. The classes of product (Gani and Ng, 2015) for which these substitution problems have been solved along with the function of the ‘compound to-be substituted’ are shown in Figure 4 and a summary of the results obtained is given in Table 2.

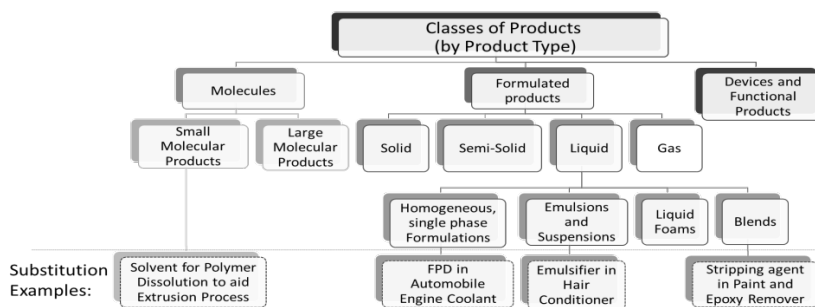

Figure 4: Class of products for which substitution problems are solved using the developed methodology

Table 2: Summary of results for solved substitution problems from chemical-based products

Compound to-be Substituted	Function of the Compound	Reason for Substitution	No. of properties compared	Substitute candidates recognized
Ethylene glycol	Freezing point depressant (FPD) in automobile engine coolant	Toxicity to mammals	1 EH&S + 8 physico-chemical properties	Propylene glycol

Methylene chloride	Stripping agent in paint and epoxy remover	Moderate aquatic toxicity	1 EH&S + 8 physico-chemical properties	2-propanone
Cetrimonium bromide	Surfactant in hair conditioner	High aquatic toxicity, Low biodegradability	2 EH&S + 4 physico-chemical properties	CAM (N _α -acyl-arginine methyl ester, n=8)

Specifically, for the case of cetrimonium bromide substitution, the amino acid based surfactant, CAM (Pérez et al., 2002) is identified as a substitute by means of a database search due to lack of GC-based models for EH&S and surface-active properties for amino acids and their derivatives.

4. Conclusion and Future Work

A systematic model-based methodology for chemical substitution has been developed and its application is illustrated via an example to substitute an environmentally hazardous single molecule solvent from a polymer spinning process. The methodology has also been used to find substitutes to environmentally unfriendly and/or unsafe chemicals used in single-phase liquid product formulations from various industrial sectors. The challenges and opportunities for chemical substitution in other classes of products like devices, solid-state products, polymers and plastics still need to be evaluated. While some of the missing property models have been developed and validated, for instance, the GC models for predicting normal melting point, water solubility and octanol water partition coefficient for the amino acid class of compounds (Jhamb et al., 2018), the development of many more property models is necessary for expanding the scope, significance and range of applicability of model based methodologies like these.

Abstract

This paper gives a brief review of the available energy sources for consumption, their effects in terms of CO₂-emission and its management, and sustainable chemical processing where energy-consumption, CO₂-emission, as well as economics and environmental impacts are considered. Analysis of the data indicate that not all available energy sources are being utilized efficiently, while, the energy sources causing the largest emissions of CO₂ are being used in the largest amount. Sustainable alternatives are defined as those where the energy consumption – CO₂ emission are addressed such that the net CO₂ emission is significantly reduced while still satisfying the energy demand. Different schemes for generating these sustainable alternatives are highlighted in this paper. These examples highlight issues of energy related to CO₂ neutral design; sustainable conversion; retrofit design, and process intensification.

Keywords: energy sources, energy consumption, CO₂ emission & management, sustainable alternatives

1. Introduction

Among the challenges we are facing today, one of the most important concerns is energy as it effects directly and/or indirectly most of the other challenges related to water, food and environment. Energy is needed in some form for almost all our activities within sectors such as transportation, commercial, industrial and residential. The energy needs (demands) for the different sectors are met through different sources of energy that is dependent on geographical location, availability, cost of harnessing it as well as environmental effects. Availability of the energy sources is not uniform through-out the earth, neither are costs or needs. The sources of energy can be broadly classified as conventional and unconventional. Conventional sources of energy are the natural energy resources (coal, oil, natural gas, wood, etc.), which are generally accepted as fuel to produce heat, light, food and electricity. Unconventional energy sources are classified as solar, wind, biological wastes, hot springs, tides, etc., that may be used also to generate heat and power. Unlike the conventional energy sources, which are non-renewable, limited in terms of availability and cause pollution (for example, emits CO₂ to the atmosphere), the unconventional energy sources are renewable, are present in abundance in nature and also generally pollution free.

Energy consumption per capita is an important parameter to assess the quality of life of the population of a country. Thus, sustainable harnessing of the available energy resources with a view to meet the necessities of increasing world population, to ensure a

safe and healthy living of the present as well as the future generations on earth, is an essential ingredient of all governmental planning (Brundtland Commission, 1987). With the rapid industrialization and growth in population, the demand for energy is increasing continuously. However, because of the cost and availability, the most used source of energy is non-renewable, which also has the largest effect on the environment because of the emission of CO₂.

Depending on the specific application, these sources of energy are converted into potential energy (any type of stored energy, for example, chemical, nuclear, gravitational, or mechanical) and/or kinetic energy, which is related to movement (for example, electricity is the kinetic energy of flowing electrons between atoms (does not release CO₂). Note that the kinetic energy that help the wheels to turn in a car is the transformed potential energy trapped in gasoline, for example and results in CO₂ emission. Another common example of transformation of energy from one form to another is a power plant. However, power plants using non-renewable energy sources (coal, natural gas, oil, wood) transform the chemical potential energy trapped in the fossil fuels to electricity (releasing, thereby, CO₂); while nuclear power plants change the nuclear potential energy of uranium or plutonium also into electricity, wind turbines change the kinetic energy of air molecules in wind into electricity, hydroelectric power plants transform the gravitational potential energy of water as it falls from the top of a dam to the bottom into electricity. Initiatives to capture the released CO₂ is therefore similar to trying to “cure” the pollution problem. As the amount and source of energy used effects our environment and thereby, our sustainability, to meet demand for energy, the conventional resources need to be supplemented with the unconventional resources such that CO₂ emission could be managed together with energy utilization.

The objective of this paper is to present a brief analysis of the available energy resources for consumption and their effects in terms of sustainable development. Recently, Vooradi, et al. (2017) provided a detailed overview of the different types of energy resources and their current consumption. In this paper, we further extend the analysis of Vooradi, et al. (2017) with additional data, new analysis together with new developments related to generation of more sustainable alternatives, that aims to prevent the pollution problem rather than curing it after it has occurred. That is, “prevent” the pollution problem through alternatives that are sustainable.

2. Energy resources, their consumption and CO₂ emission – current status

The distribution of energy consumption in the OECD and non-OECD countries is shown in Fig 1a, while the distribution of the total energy in different regions of non-OECD countries is shown in Fig 1b and distribution of total energy in terms of sectors is shown in Fig 1c. It can be noted that the biggest increase in 2040, compared to 2015, will be in non-OECD countries (in Asia) and in terms of sectors, in the industrial sector (see Fig 1c). The question, however, is which energy resources should be used to meet this increased energy demand? Figure 2 shows the distribution of energy sources to generate electricity (Fig 2a), while Figs 2b-2e show the energy resources consumed by different sectors. If we combine this data with the data from Table 1, where the three most used conventional fuels are analyzed, we can see that we will have a major ‘curing’ the pollution problem. Clearly, this is not sustainable! Figures 3a-3c, however, show a positive trend. Some countries have managed to reduce their overall CO₂ emission, China has managed to stabilize its CO₂ emission by reducing the consumption of coal and a few countries have increased their CO₂ emission, but their contribution

compared to the total is quite small. This indicates that re-allocation of energy resources to tackle the energy consumption – CO₂ emission is already going on and needs to be further advanced.

Figure 1: Energy consumption a) Total energy b) Total energy in Non-OECD c) Sector wise (Data Source: The International Energy Outlook, 2017).

Figure 2: Different forms of energy (a) Net electricity generation by fuel; Energy consumptions (b) in Residential sector, (c) in Commercial sector (d) in Industrial sector (e) in Transportation Sector. Data Source: The International Energy Outlook, 2017.

Table 1: Fossil energy information for the year 2016 (Statistical review of world energy, 2016; GES Yearbook, 2017)

Energy	Reserves	Consumption	CO ₂ Emission	Remarks
Oil	1706.7 Bb	35.40 Mb/year	10.7 Bt	Accounts for nearly 1/3 of global energy consumption.
Natural Gas	186.6x10 ³ Bcm	3550 Bcm	6.93 Bt	World consumption increased by 63 Bcm (1.5%).
Coal	1139.3 Bt	3.75 Btoe	13.84 Bt	World consumption is showing a decreasing trend, which is 0.053 Btoe (1.7%).

Units: Bb-Billion barrels, Bt-Billion Tons, Bcm- Billion cubic meter, Btoe-Billion Tons of Oil Equivalent

2.1 Perspectives

The above analysis points to the need for re-allocation of energy resources to meet the energy demands. While the trend is an increased energy demand, significant effort is needed to meet these demands through unconventional energy resources, such as biomass, solar, wind, etc., especially in the transportation and residential sectors. At the

same time, the design and operation of energy intensive processes need to be revised so that new, more sustainable and innovative designs can be found (see section 3 on sustainable alternatives).

Figure 3: CO₂ emissions a) Countries with decreasing trend b) China c) Countries with increasing trend. World CO₂ emissions: 2016 – 33432 MtCO₂; 2015 – 33304 MtCO₂; 2014 – 33342 MtCO₂; * Percent of total world emission (GES Yearbook, 2017).

3. Sustainable alternatives

Examples of energy consumption -CO₂ emission management are highlighted below for selected cases involving the industrial sector (chemical and related processes).

3.1 Energy-CO₂ neutral process design

This option is not really preventing the pollution problem but it nevertheless promises the potential to significantly reduce the CO₂ emission as well as points to issues that need to be resolved if the energy consumption - CO₂ emission management should find a sustainable solution. Roh, et al. (2015) and more recently Bertran, et al. (2017) have shown that the CO₂ released from power plants can be captured with the currently available technologies and converted to chemicals such as methanol, dimethyl ether, dimethyl carbonate, succinic acid and many more with a net CO₂ emission of zero or negative (CO₂ released – CO₂ utilized). The problem, however, is that the demands for the chemicals produced are currently so low that the CO₂ captured from a few power plants of standard size is enough to cover these demands. Note that this is a pollution “curing” problem after it has occurred, making it more difficult to solve. To make a significant impact, the demands for the chemicals need to increase or the power plants need to switch from fossil to unconventional resources, thereby, preventing the pollution problem.

3.2 Energy-process intensification (use of solar energy as source)

The development and implementation of alternative energy conversion techniques using solar energy, prominent due to its abundance, has been reported by Gencer and Agrawal (2017). More specifically, they introduced a process design concept to synthesize Solar Electricity, Water, Food and Chemical (SEWFAC) processes by optimally utilizing solar energy. The objective is the development of coproduction processes around the clock on an as-needed basis. Application of this interesting concept is illustrated through the design of efficient solar thermal hydrogen production. The underlying principle is to maximize solar energy conversion via coproduction of hydrogen and electricity and an efficient way to supply the required electricity demand is by cogenerating from incident solar energy. Much more work, however, is needed to establish this interesting concept, especially related to sizing of the plant, material of

construction, high temperature of operation and heat integration issues. The scope and significance of final integrated process will be able to significantly reduce the size of the power generation unit of the plant for the same overall output. Other intensification options to generate more sustainable energy efficient alternatives have been reported by Babi, et al. (2015).

3.3 Energy – sustainable conversion of biomass

Biomass chemical conversion processes allow the production of solid, liquid and gaseous biofuels, which can substitute almost any kind of fossil fuel and reduce the associated greenhouse gas emissions. Three interesting recent works are highlighted here. Bertran. et al. (2017) recently reported the development of a systematic method for conversion of biomass into useful chemicals, including biofuels, taking into account the biomass location, amount available, chemical (product) demand, and transportation costs. Through the developed method and associated computer aided tools, it is possible to identify more sustainable alternatives to convert a given biomass at a specific geographical location to a set of desired products at other locations, according to their demand. Note that production of chemicals reduces the use of non-renewable resources for their production, thereby making the bio-conversion route more sustainable. Girones, et al. (2017) proposed a biomass gasifier to convert lignocellulosic biomass such as wood into syngas, which can be used in Solid Oxide Fuel Cell (SOFC) to produce heat and electricity. Also, Sharma, et al. (2017) compared many biomass conversion options taking into account the complete energy conversion pathway, from the resource to the supply of energy services. The comparison (includes 56 scenarios) is performed by evaluating the CO₂ abatement potential of integrating these different pathways into a national energy system. Results show that biofuels can allow for an overall better performance in terms of avoided CO₂ emissions compared to direct combustion of biomass. To exploit this potential, however, it is necessary to link the production of biofuels to a wider deployment of the corresponding efficient end-use technologies. Biomass is an attractive renewable and stored energy that can be converted to transportation fuels, chemicals and electricity using bio-chemical and 5hermos-chemical conversion routes. Notably, biofuels have relatively lower greenhouse gas emissions compared to the fossil fuels. A biomass gasifier can convert lignocellulosic biomass such as wood into syngas, which can be used in Solid Oxide Fuel Cell (SOFC) to produce heat and electricity. SOFC has very good thermodynamic conversion efficiency for converting methane or hydrogen into electricity, and integration of SOFC with gasifier gives heat integration opportunities that allow one to design systems with electricity production efficiencies as high as 70%. Generally, process design and operational optimization problems have conflicting performance objectives, and Multi-Objective Optimization (MOO) methods are applied to quantify the trade-offs among the objectives and to obtain the optimal values of design and operating parameters. This study optimizes biomass gasifier and SOFC plant for annual profit and annualized capitalBiomass is an attractive renewable and stored energy that can be converted to transportation fuels, chemicals and electricity using bio-chemical and 5hermos-chemical conversion routes. 3.4 Energy-retrofit design

Application of the energy efficient hybrid separation scheme proposed by Tula, et al. (2017) is highlighted here for the energy intensive separation of two azeotropic mixtures, namely benzene-cyclohexane and acetonitrile-water. In the separation scheme for benzene-cyclohexane mixture, membrane unit is used to enrich the cyclohexane product purity. In the second example, the mixture at the azeotropic composition is separated by using membrane. The proposed schemes are associated with the additional capital cost due to the inclusion of the membrane module. However, the hybrid schemes result in significant operational (energy) savings. The economics of the proposed designs are investigated by calculating the payback period for the additional capital investment using the operational savings (selected results are given in Table 2).

Table 2: Economics of the hybrid schemes

Calculation details	Benzene-cyclohexane	Acetonitrile-water
Membrane considered	carboxymethyl cellulose (Kuila and Ray, 2014)	SiO _x modified Al ₂ O ₃ ceramic membrane (Kolsch, et al. 2002)
Base case utility need	43.5 Gcal/h	0.045335 Gcal/h
Base case (Opex)	1456.032 €/h	1.517472 €/h
Hybrid case utility need	17.042 Gcal/h	0.037978 Gcal/h
Hybrid case (Opex)	905.14 €/h	1.272 €/h
Membrane area	19942 m ²	40.9411 m ²
Membrane Capex	10649028 €	3302.31 €
Operational savings	550.9 €/h	0.2461 €/h
Payback period	193330.24 h (2.2 years)	13418.5 h (1.53 years)

4. Conclusion and Future Work

The grand challenges of energy, water, food and health facing current and future societies can be addressed through sustainable development (Negro, et al. 2017). For the next 25 years, renewables as well as unconventional (solar, wind, and nuclear) are projected to be the world's fastest-growing energy sources. Current research on energy storage technologies is in tune with the recent developments in renewable energy harvesting technologies, so as to ensure an uninterrupted power supply. For the next few decades, fossil fuels are still projected to be the main energy source for the base load power supply. Hence these processes need to be integrated with CCS and CCU for sustainable development with the objective of net CO₂ emission reduction. Also, re-allocation of energy sources needs to be made so that unconventional sources not emitting CO₂ is consumed in a bigger amount together with better design of energy intensive processes. Superstructure based optimization techniques successfully being applied in process synthesis can be adopted for optimal energy source allocation matching various forms of energy demands at reduced CO₂ emission. That is, given a set of energy sources, a set of energy demands, select a set of appropriate energy efficient technologies to match the sources-demands such that the CO₂ emission is

significantly lower and sustainable. Uncertainties in data and location dependence of energy sources and/or demands may also be included in the problem formulation. Collection of data and development of appropriate models is a good starting point.

Process synthesis and optimization of membrane systems with superstructure approach for the mitigation of CO₂ emissions from a coal-fired power plant

Sunghoon Lee^a, Jin-Kuk Kim^a

^a*Hanyang University, Dpt. of Chemical Engineering, 222 Wangsimni-ro, Seongdong-gu, Seoul 04763, KR*

jinkukkim@hanyang.ac.kr

Abstract

Greenhouse gases emissions to the atmosphere has become a crucial cause to the climate change. As, CO₂ accounts for about 90% of emissions in volume, various separation technologies, such as absorption, adsorption, and membrane etc. have been studied for CO₂ removal. In particular, the membrane for CO₂ capture is regarded as a promising solution, due to clear advantages i.e. small foot print, easy installation, fast membrane development and flexibility in hybrid process. Furthermore, coal-fired plant contributes almost 46 % of global CO₂ emission (IEA, 2016), and its dominance is expected to be remained for the near future. Hence, the introduction of CO₂ capture systems to the coal-fired power plant has been considered to achieve cost-effectiveness of CO₂ capture process.

Here, we first developed in-house mathematical model for single-stage membrane in MATLAB® of which accuracy has been validated with literature. It is accepted that only single membrane process is limited to achieve both high purity and recovery for CO₂ product simultaneously from low CO₂ concentration of the feed flue gas. The multi-stage membrane is widely adopted in separation fields. The modeling framework for membrane is expanded to consider multi-stage networks, and a superstructure approach is applied for the process-synthesis of membrane systems which can evaluate all the possible configurations with various combinations of the pressure controllers, in a systematic manner. Furthermore, the optimization framework is developed, such that rigorous economic trade-off is systematically evaluated with capital expenditure (compressor, membrane etc.) and main operating expenditure of factors (power usage). Genetic Algorithm (GA) is adopted as an optimization solver to identify optimal operating conditions and membrane configurations.

With the developed automated tool for membrane system, design complexity in multi-stage configurations can be readily dealt with, while system-wide design interactions can be fully exploited in confidence. Sensitivity analysis of key design variables was carried out, with which conceptual understanding and design guidelines for membrane-based CO₂ capture systems are obtained. In particular, techno-economic impacts on the systems are investigated when membrane performance (permeance and selectivity) are varied. This provides practical guidelines for future membrane development in the CO₂ capture process. Case study is presented to demonstrate the applicability of

superstructure-based optimization method and illustrate the effectiveness in identifying the most appropriate membrane network, subject to process constraints and other practical limitations.

Semantically-enabled CAPE platform: Towards a generic and dynamic formulation for the synthesis and optimisation of value chains

Eirini Siouγκrou^a, Foteini Barla^a, Antonis Kokossis^a

^a *National Technical University of Athens, Chemical Engineering, 9 Heroon Polytechniou Street, 157 80 Athens, GR*

esiouγκrou@mail.ntua.gr

Abstract

In an attempt to link, manage and put in new-use the large amount of dispersed and heterogeneous CAPE data and models, a dynamic platform is developed able to offer high-throughput discovery and analysis of information for a wide range of users based on ontology engineering. Ontological modelling capabilities have recently attracted a lot of attention in process systems community for managing, querying and enriching knowledge. The services that have been designed for the platform consider a range of user roles, including three main categories of services. (a) Basic services, such as search and upload of conversion pathways and models, (b) integration with external tools and databases, and (c) custom-made services that include synthesis and optimisation of value chains. The basic services include models, which are of varied scale and describing diverse systems. The scale of a technology model could range from a detailed equation-based model or a conceptual flowsheet to a black box with some composition data, and all these developed in different design tools. A corresponding range can also be found for physical property, cost and LCA models.

The developed platform supports the integration of models, such as property or data models (e.g. LCA models, cost models). Not only will the user be able to get information about these models but also apply them to data from the database or personal data. Furthermore, a data mining approach has been used to implement the link to external databases service.

For the custom-made services, the technology models could be interlinked, according to their input and outputs, establishing value chains. The service enables the automatic design of value chains by semantic querying and retrieval algorithms. Further, the value chains could be assessed for economic and environmental feasibility through means of mathematical optimisation. Building on previous works (Barla et al., 2016; Siouγκrou & Kokossis, 2016), the platform is further developed to enable a customised formulation for the optimisation of the value chains. A general formulation of the model equations is introduced, where each process unit is considered to be a black box described by inlets, outlets and generic functions that define the relationship between inlets and outlets, e.g. mass balances, energy requirements, cost functions, etc.. The user can define the form of the model equations in the ontology and then the model equations are transferred from the ontology to a mathematical form through a disjunctive programming formulation. Design constraints, such as product requirements

and feedstock availability, can also be added to the optimisation formulation in a similar manner. Piecewise interpolation is applied to any non-linear model equations, to produce a final Mixed Integer Linear Programming formulation which is then solved with the GAMS software. The generic optimisation formulation and the ontological representation of the model equations render the formulation dynamic and completely flexible to the user's needs.

Representative services of the semantic platform are illustrated as alternative cases of possible users, demonstrating platform's ability to integrate information of varied origin and type using synthesis analysis, produce and assess metadata via reasoning and optimisation, and enabling to reach a wider audience, thus achieving to develop an expandable open CAPE platform.

espc@xanum.uam.mx

Abstract

A simple Gibbs-Driving force method for designing non-reactive and reactive distillation columns (non-RDC and RDC respectively) has been developed. Based on the binary driving force diagrams (Gani and Bek-Pedersen, 2000)(Pérez-Cisneros and Sales-Cruz) coupled with the equilibrium Gibbs energy plots a systematic graphical method for the design of non-RDC and RDC is proposed. The design method exploits the connection between the driving force values and the equilibrium Gibbs energy to determine the number of stages, the optimal feed location, the heat required at the reboiler and condenser and the minimum reflux ratio. The final design guarantee an optimal operation since the global minimum of the equilibrium Gibbs energy is achieved. The above optimal criteria is equivalent to the maximum entropy condition required for a stable operation of the distillation columns. The method has been applied for the design of two non-reactive systems: a) Benzene-Toluene ideal system and b) propanol-water non-ideal system as well as, two reactive systems: a) isomerization of n-butane and b) the MTBE production. The final designs of the non-RDC and RDC were validated through intensive simulation, showing that the designs obtained correspond to the minimal energy requirements for the separation.

Abstract

There are many challenges facing the widespread industrial deployment of scheduling solutions. These include to find a generic scheduling model that can be applied to a broad variety of scenarios, and to design algorithms that can provide good quality solutions in industrially relevant time frames. The discrete-time Resource-Task Network (RTN) is a generic scheduling framework that has been successfully applied to many different problems. However, RTN models can quickly become intractable as problem size increases. In this work, an iterative neighbourhood-search based algorithm is developed in order to speed-up the solution of RTN scheduling models. The speed-up is achieved by limiting the binary variables of a subproblem to a specific neighbourhood in a way that allows the algorithm to iteratively move towards better solutions. Results show that this approach is able to tackle problems that are intractable for a full-space model while still finding near optimal solutions.

Keywords: Resource-task network (RTN), Heuristic, Neighbourhood search, Iterative scheduling algorithm

1. Introduction

Some of the challenges facing the use of scheduling in industry are: to find a generic scheduling framework and efficient solution algorithms, which can provide good quality solutions that can be used in practice (Harjunkski et al. (2014)). The discrete-time Resource-Task Network (RTN) formulation has been shown to be applicable to various industrial applications with small application-specific configuration effort required. Such applications include, stainless steel-making (Castro et al. (2013)), thermo-mechanical pulping (Hadera et al. (2015)), and petrochemical production (Wassick and Ferrio (2011)). In the direction of deploying industrial scheduling solutions, Harjunkski and Bauer (2014) suggested the use of the ISA-95 standard as a way to efficiently communicate between the layers of the so-called automation pyramid.

The advantages of the RTN formulation and of mixed-integer linear programming (MILP) scheduling solutions in general are that they provide optimal solutions to problems with complex objective functions. The downside of MILPs is that solution time often increases dramatically with problem size, to the point where even a feasible solution cannot be guaranteed. Conversely, constructive

scheduling heuristic algorithms have fast execution times and scale very well with problems size; however, they give no indication of optimality and cannot handle competing objectives.

It is therefore desirable to combine the speed and scalability of heuristics with the mathematical rigor of MILPs. Works in this area include the sequential updating procedures proposed by Roslöf et al. (2001) which updates an initial heuristic-based solution by iteratively releasing a set of jobs and optimally inserting them into the existing job sequence. Other options include the use of pre-ordering rules to eliminate sequencing variables (Méndez and Cerdá (2002)) or to use heuristics to limit the search space of a problem and to use that solution to initialize a full-space model as in Panek et al. (2005). Alternatively, Castro et al. (2011) proposed a greedy algorithm to insert orders into a schedule a few jobs at a time, while allowing for partial rescheduling at each iteration.

In this work, an algorithm is proposed that takes advantage of heuristics to assist RTN-based scheduling solutions to find good solutions with comparatively small computational effort. This is accomplished by combining the two approaches of MILP and heuristic solutions in a novel iterative neighbourhood-based approach. In this algorithm, a heuristic is used to provide an initial feasible solution which is then used to constrain the binary variables of RTN scheduling models in a way that greatly reduces the computation time of the MILP, while still allowing it to move towards better solutions.

2. RTN Formulation

The proposed approach is based on the discrete-time RTN framework to make it generic and easy to adapt to various applications. This section will briefly present the RTN-scheduling model as well as specific modeling constraints and scenarios that are necessary to make the model even more flexible, at the expense of computational efficiency.

The RTN formulation is generic as it represents the entire scheduling model as a set of resources (R) and tasks (I). In this formulation, tasks consume and produce sets of resources. Examples of resources include raw materials, final products, and processing units. In the discrete-time RTN formulation, the scheduling horizon H is divided into a set of δ sized intervals T . Tasks ($i \in I$) are characterized by two sets of variables, the binary variable $N_{i,t}$ and the continuous variable $\xi_{i,t}$. The binary variable identifies that task i starts at time point $t \in T$ while the continuous variable indicates the amount of a resource handled by the task. The parameter τ_i is the duration of task i and $\mu_{i,r,\theta}$ and $\nu_{i,r,\theta}$ represent the interaction of task i on resource r based on the occurrence (defined by $N_{i,t}$) and continuous (defined by $\xi_{i,t}$) extent of the task respectively. The resource consumption over the time horizon is tracked by the excess resource balance given in Equation (1).

$$R_{r,t} = R_{r,t-1} + \sum_i \sum_{\theta=0}^{\tau_i} (\mu_{i,r,\theta} N_{i,t-\theta} + \nu_{i,r,\theta} \xi_{i,t-\theta}) + \pi_{r,t} \quad \forall r \in R, t \in T \quad (1)$$

Equations (2) and (3) limit the excess resources and the continuous extent of a task respectively.

$$R_{r,t}^{\min} \leq R_{r,t} \leq R_{r,t}^{\max} \quad \forall r \in T, t \in T \quad (2)$$

$$V_{i,r}^{\min} N_{i,t} \leq \xi_{i,t} \leq V_{i,r}^{\max} N_{i,t} \quad \forall r \in T, r \in R^{eq}, i \in I \quad (3)$$

2.1. Problem Specific Considerations

In order to meet typical requirements the base RTN model needs to be modified. The first modification is related to product-specific batch-tracking. This means that a specific batch or order can be tracked at each stage of production with a unique batch identifier. In the base RTN model, tasks belonging to the same family are aggregated to reduce model size. To meet the batch-tracking requirement, these variables need to be disaggregated. This means that a unique task and resource needs to be associated with each stage of production for a product. This requirement aligns the

RTN formulation with the ISA-95 standard (as each order corresponds to a specific OperationsRequest) and is a scenario often found in industry. An example of this can be found in stainless steel making, where a specific batch needs to be tracked to ensure that sequencing constraints are met throughout the production process. This leads to the assumption of a fixed-batch size; since each batch needs to be specifically tracked it is assumed that the size of the batch is determined elsewhere. Thus, the continuous extent variable $\xi_{i,t}$ and Eq (3) are not considered in this RTN formulation.

Other simplifications that are often made when using RTN models are to aggregate parallel equipment, and to use simplified transfer times between the stages. In this work, a separate resource is defined for each parallel equipment at each stage of production (corresponding to a specific ISA-95 Equipment definition). This enables the consideration of machine-specific transfer tasks. This greatly expands the size of the model as a new $N_{i,t}$ variable is required for each pair of equipment between two subsequent stages as well as resources to distinguish between an intermediate product that is ready for transport or that already has been transported.

Another important feature to consider is sequence dependent changeovers. To model these, a new task is needed which ‘consumes’ a piece of equipment in a specific operation mode and ‘produces’ the same piece of equipment but in a different mode. A sample RTN containing all of the aforementioned features is shown in Figure 1.

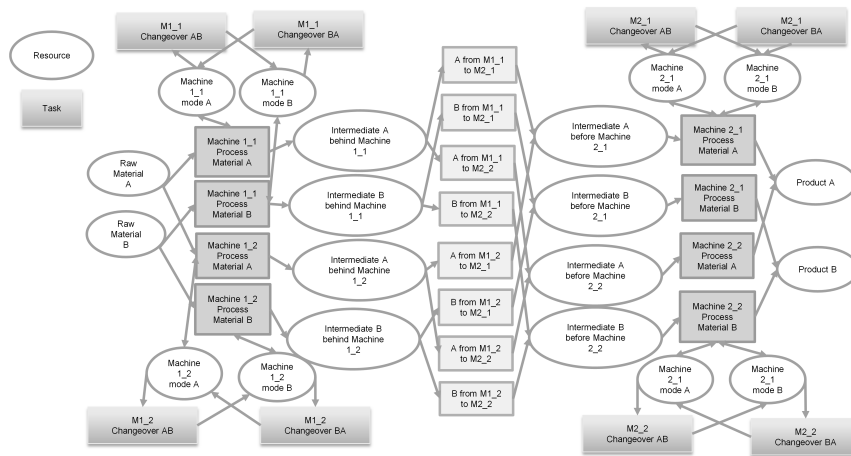

Figure 1: Example RTN of a two-stage batch process considering all the problem features.

While these specific features add flexibility to the RTN model, and conform to the ISA-95 standard proposed for scheduling, they add considerable complexity to the formulation. This provided the motivation to investigate new solution algorithms for such problems.

3. Proposed Algorithm

The proposed iterative algorithm uses a constructive heuristic to provide an initial feasible solution. Pseudocode for the constructive heuristic can be viewed below in Figure 2. The algorithm is initialized with the set of all jobs that needs to be scheduled. For example, job A needs to be processed on Stages 1,2, and 3, and a job is created for the processing of A at each stage. The next job to be scheduled is selected according to some sequencing rule. In this work an As Soon As Possible (ASAP) rule was used, but the algorithm can be applied to any sequencing heuristic. The last step of the algorithm is to greedily schedule that job to a machine based on its required

resource availability. This is performed until all jobs have been scheduled and a complete feasible solution is obtained.

```

I ← set of jobs to be scheduled
while I ≠ ∅ do
  | Select i ∈ I according to some sequencing rule (e.g. As Soon As Possible)
  | Greedily schedule i as soon as possible based on its resource availability
end

```

Figure 2: Pseudocode for the constructive scheduling heuristic

The next step of the algorithm is to match the continuous-time starting times of each of the jobs to the discrete-time grid used by the RTN. This can be done using Eq.(4) where $ST_{m,i}$ is the start time of job i on machine m as given by the heuristic and t_i is the corresponding start time interval in the discrete time RTN formulation.

$$t_i = \left\lceil \frac{ST_{m,i}}{\delta} \right\rceil \quad (4)$$

3.1. Neighbourhood Definition

The heuristic solution is then saved as the best solution which then can then be used to define a subset of the original domain where a better, or even optimal, solution could be located. This neighbourhood is defined based on the start times of adjacent jobs relative to the current task. A job is constrained to start between the start times of the W jobs preceding it (the W^{th} neighbour) on the current machine and the start time of the W^{th} neighbour following it. The neighbourhood of times when a job can start is then given by Equations (5) and (6), where $ST_{m,i}^{early}$ is the earliest time a task can start and $ST_{m,i}^{late}$ is the latest a task can start.

$$ST_{m,i}^{early} = ST_{m,i-W} \quad (5)$$

$$ST_{m,i}^{late} = ST_{m,i+W} \quad (6)$$

If the W^{th} neighbour of a job does not exist, the corresponding bound is not constrained. The earliest and latest possible start times can then be mapped to the discrete time intervals. A similar approach to define the window can be followed if the job start times are already in a form matching the RTN intervals. The binary start variable $N_{i,t}$ can then be constrained to this interval which greatly reduces the number of binary variables (and thus the computation time) of the RTN model while still allowing the jobs the flexibility to switch sequencing positions with their W adjacent neighbours. Note that this applies to the binary variables related to all parallel machines, so a job may be shifted to a different parallel machine. A diagram of the neighbourhood definition can be viewed in Figure 3. In this diagram, job A1 is constrained to start in the neighbourhood defined by the start time of jobs B1 and C2. The binary variables for the processing of job A1 outside of this interval on all machines are set to zero. Once the binary variables of the RTN model have been constrained to their respective neighbourhoods, the optimization problem can be run with the current best solution providing an initial feasible point. The solution from the optimization problem can be saved as the best solution, which then can be used to initialize the next iteration. This process can be performed iteratively until one of three stopping criteria are met. The stopping criteria are: maximum computation time, maximum number of iterations, or a convergence criterion. The convergence criterion checks if the optimal value from the previous iteration and the current iteration are the same. If they are, no further improvement can be made within this given neighbourhood meaning that further iterations would yield no improvement. The downside of the heuristic nature of the algorithm is that it is unable to guarantee global optimality. The complete algorithm flowchart can be seen in Figure 4.

Figure 3: An example neighbourhood for job A1 where $W = 1$.

4. Results and Discussion

The proposed algorithm was tested on a four stage batch process with two parallel machines at each stage. The problem considers six product types with four orders per type. The algorithm was tested against a full-space RTN, however for all cases the full-space model was unable to return a solution within the allotted time of 10,000 seconds. To provide an optimal reference point, an RTN which aggregates the products by type (by considering only one binary per product type which executes multiple times) provides an exact optimal value. This is an exact aggregation, however it violates the specific batch tracking requirements of the problem. The optimization problems were solved using GAMS 24.7.4/CPLEX 12.6.3.0. The algorithm was tested for three objective functions: makespan (min), electricity cost (€, with hourly prices), and inventory minimization. For the inventory objective, the goal is to minimize the waiting times of products between stages. Note that the objective function only applies to the MILP in the algorithm, as only an ASAP heuristic was considered in this work. All problems were run with neighbourhood sizes of one, two, and three jobs (denoted $W1$, $W2$, and $W3$ respectively). The results are presented in Table 1.

The results indicate that the iterative algorithm is able to find near optimal, or optimal solutions, in orders of magnitude less time than the full-space model would require. For the makespan objective, both the $W2$ and $W3$ configurations were able to find the optimum solution in less than half the time it took to solve the aggregate problem. For the electricity cost objective, none of the scenarios were able to find the optimum, however, they all got to within 0.5% of it. For this case the $W2$ and $W3$ scenarios both took longer to solve than the aggregated model, due to the fact that they had more binary variables per iteration. For the inventory objective the algorithm was able to find the optimal value of zero for all cases. It is interesting to observe that for all objectives the $W2$ scenario took longer than the $W3$ scenario as it was difficult for this configuration to close the optimality gap. For all objectives the $W1$ case took less than four minutes but was able to get to within 2.2% of the true optimum.

5. Conclusion

In this work a novel iterative neighbourhood search-based algorithm was proposed for the solution of RTN scheduling models. The algorithm reduces the search space of the original RTN problem by limiting the task start times to a neighbourhood in a way that greatly reduces the number of

Figure 4: Algorithmic flowchart of the proposed iterative neighbourhood search algorithm

binary variables while still allowing the schedule to move towards better solutions. This procedure is repeated iteratively until the stopping criteria are met. Results show that the novel approach is able to tackle problems that are intractable for the full-space RTN in industrially relevant time frames while sacrificing optimality. Future work includes combining this approach with a rolling horizon scheme in order to deal with very large problems.

Robust Process Scheduling under Uncertainty with Regret

Chao Ning, Fengqi You

Cornell University, Ithaca, New York, 14853, USA

Abstract

In this paper, we address multipurpose batch process scheduling under uncertainty problems. A novel adaptive robust process scheduling model is proposed that effectively incorporates the minimax regret criterion. In batch process scheduling, regret is defined as the deviation of profit obtained over the scheduling horizon from the perfect-information schedule. The regret arises due to the limited knowledge on realized uncertainty, and serves as an important evaluation metric for decision making on process scheduling. In addition to the conventional robustness criterion, the proposed multi-objective scheduling model also simultaneously optimizes the worst-case regret to push the performance of the schedule towards the utopia one under perfect information. Two case studies on multipurpose batch process scheduling under product demand uncertainty are presented.

Keywords: batch process scheduling, uncertainty, robust optimization, regret

1. Introduction

Multipurpose batch plants play a critical role in producing high-value-added products, such as food, semiconductors and pharmaceuticals (Wassick et al., 2012). Batch process scheduling allocates limited resources to different tasks over the scheduling horizon for a higher production efficiency and more profit. Therefore, scheduling of multipurpose batch process has attracted tremendous attention from both academia and industry (Chu and You, 2015). A large amount of literature is devoted to deterministic scheduling models which assume all the involved parameters are known for certainty (Méndez et al., 2006). However, in real practice, operators in batch plants need to make a schedule in the face of various uncertainties. As an inherent characteristic of batch processes, uncertainty could render the deterministic schedule suboptimal or even non-implementable. To this end, extensive research efforts have been made towards the development of systematic methodologies for handling uncertainty in batch process scheduling. Balasubramanian and Grossmann (2004) proposed a multistage stochastic optimization approach to address batch scheduling problems. To hedge against uncertainty, a proactive scheduling strategy was developed based on robust optimization and multiparametric programming (Wittmann-Hohlbein and Pistikopoulos, 2013). Adaptive robust optimization (ARO) was applied for process scheduling such that some decisions can be made in a “wait-and-see” mode based upon uncertainty realizations through a data-driven robust optimization framework (Ning and You, 2017a). Although conventional ARO based scheduling model has a number of attractive features, it does not account for an important evaluation metric, known as regret (Dunning, 2016), in decision-making theory (Bell, 1982). In this work, we propose a novel adaptive robust batch process scheduling model explicitly accounting for regret.

2. Bi-Criterion Adaptive Robust Scheduling Model

In this section, we propose a bi-objective adaptive robust scheduling model with regret based on a deterministic scheduling model (Méndez et al., 2006; Yue and You, 2013):

$$\begin{aligned}
\max \quad & \text{Profit of selling products minus the production cost} & (1) \\
\min \quad & \text{Regret over the scheduling horizon} & (2) \\
\text{s.t.} \quad & \text{Mass balance constraints} & (3) \\
& \text{Batch size constraints} & (4) \\
& \text{Inventory constraints} & (5) \\
& \text{Demand satisfaction constraints} & (6) \\
& \text{Timing constraints} & (7)
\end{aligned}$$

The resulting batch process scheduling model is formulated as a bi-objective adaptive robust mixed-integer program. The task assignment decision is made “here-and-now”, while other decisions, including continuous decisions on batch sizes, inventory levels, and timings of tasks, are made in a “wait-and-see” manner (Shi and You, 2016). The compact form of the scheduling model, denoted as (BCARO), is presented in (8).

$$\begin{aligned}
\min_{\mathbf{x}} \quad & \text{Worst-case cost} = C^w(\mathbf{x}) \\
\min_{\mathbf{x}} \quad & \text{Worst-case regret} = R^w(\mathbf{x}) \\
\text{s.t.} \quad & \mathbf{Ax} \geq \mathbf{d}, \quad \mathbf{x} \in R_+^{n_1} \times Z^{n_2} \\
& C^w(\mathbf{x}) = \max_{\mathbf{u} \in U} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{u})} [\mathbf{c}^T \mathbf{x} + \mathbf{b}^T \mathbf{y}] \\
& R^w(\mathbf{x}) = \max_{\mathbf{u} \in U} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{u})} [\mathbf{c}^T \mathbf{x} + \mathbf{b}^T \mathbf{y} - \Pi(\mathbf{u})] \\
& \Omega(\mathbf{x}, \mathbf{u}) = \{\mathbf{y} \in R_+^{n_3} : \mathbf{Wy} \geq \mathbf{h} - \mathbf{T}\mathbf{x} - \mathbf{Mu}\} \\
& \Pi(\mathbf{u}) = \min_{\hat{\mathbf{x}}, \hat{\mathbf{y}}} \mathbf{c}^T \hat{\mathbf{x}} + \mathbf{b}^T \hat{\mathbf{y}} \\
& \text{s.t.} \quad \mathbf{A}\hat{\mathbf{x}} \geq \mathbf{d}, \quad \hat{\mathbf{x}} \in R_+^{n_1} \times Z^{n_2} \\
& \quad \quad \mathbf{W}\hat{\mathbf{y}} + \mathbf{T}\hat{\mathbf{x}} \geq \mathbf{h} - \mathbf{Mu}, \quad \hat{\mathbf{y}} \in R_+^{n_3}
\end{aligned} \tag{8}$$

where \mathbf{x} represents the task assignment decision, and \mathbf{y} includes other decisions, such as timing and batch size decisions. Notice that \mathbf{x} is made “here-and-now”, whereas \mathbf{y} is made in a “wait-and-see” manner. $\Pi(\mathbf{u})$ is the best objective value that could be achieved by assuming that all the decisions are made in a “wait-and-see” mode.

We could further reformulate the worst-case regret to reduce the number of levels, shown in Eq. (9).

$$\begin{aligned}
R^w(\mathbf{x}) &= \max_{\mathbf{u} \in U} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{u})} [(\mathbf{c}^T \mathbf{x} + \mathbf{b}^T \mathbf{y}) - \Pi(\mathbf{u})] \\
&= \max_{\mathbf{u} \in U} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{u})} \left[(\mathbf{c}^T \mathbf{x} + \mathbf{b}^T \mathbf{y}) - \min_{\hat{\mathbf{x}}, \hat{\mathbf{y}} \in \Xi(\mathbf{u})} (\mathbf{c}^T \hat{\mathbf{x}} + \mathbf{b}^T \hat{\mathbf{y}}) \right] \\
&= \mathbf{c}^T \mathbf{x} + \max_{\hat{\mathbf{x}}, \hat{\mathbf{y}} \in \Xi(\mathbf{u}), \mathbf{u} \in U} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{u})} [\mathbf{b}^T \mathbf{y} - (\mathbf{c}^T \hat{\mathbf{x}} + \mathbf{b}^T \hat{\mathbf{y}})]
\end{aligned} \tag{9}$$

where $\Xi(\mathbf{u}) = \{\hat{\mathbf{x}} \in R_+^{n_1} \times Z^{n_2}, \mathbf{y} \in R_+^{n_3} : \mathbf{A}\hat{\mathbf{x}} \geq \mathbf{d}, \mathbf{W}\hat{\mathbf{y}} + \mathbf{T}\hat{\mathbf{x}} \geq \mathbf{h} - \mathbf{Mu}\}$.

By explicitly incorporating the minimax regret criterion, it pushes the performance of the resulting solution towards the utopia schedule under perfect information. We further propose a unified optimization model (BCARO- λ) shown in (10).

$$\begin{aligned}
& \min_{\mathbf{x}} \left[(1-\lambda) \cdot C^w(\mathbf{x}) + \lambda \cdot R^w(\mathbf{x}) \right] \\
& \text{s.t. } \mathbf{Ax} \geq \mathbf{d}, \quad \mathbf{x} \in R_+^{n_1} \times Z^{n_2} \\
& \quad C^w(\mathbf{x}) = \max_{\mathbf{u} \in U} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{u})} \left[\mathbf{c}^T \mathbf{x} + \mathbf{b}^T \mathbf{y} \right] \\
& \quad R^w(\mathbf{x}) = \mathbf{c}^T \mathbf{x} + \max_{\hat{\mathbf{x}}, \hat{\mathbf{y}} \in \Xi(\mathbf{u}), \mathbf{u} \in U} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{u})} \left[\mathbf{b}^T \mathbf{y} - (\mathbf{c}^T \hat{\mathbf{x}} + \mathbf{b}^T \hat{\mathbf{y}}) \right] \\
& \quad \Omega(\mathbf{x}, \mathbf{u}) = \left\{ \mathbf{y} \in R_+^{n_3} : \mathbf{Wy} \geq \mathbf{h} - \mathbf{T}\mathbf{x} - \mathbf{Mu} \right\}
\end{aligned} \tag{10}$$

where λ is a parameter ranging from 0 to 1. (BCARO- λ) could provide a wide spectrum of solutions by changing the value of λ from 0 to 1. Specifically, it reduces to the conventional ARO model when λ equals to 0, and it becomes the ARO with minimax regret criterion when λ equals to 1. If the value of λ is chosen between 0 and 1, the proposed model makes a trade-off between the conventional robustness and minimax regret criteria.

We develop (BCARO- ε) in (11) by transforming the objective on the worst-case regret into an extra constraint that specifies the upper bound of $R_w(\mathbf{x})$. Similarly, (BCARO- ε) can reveal the trade-offs between the conventional robustness and minimax regret criteria in the scheduling problem.

$$\begin{aligned}
& \min_{\mathbf{x}} C^w(\mathbf{x}) \\
& \text{s.t. } R^w(\mathbf{x}) \leq \varepsilon \\
& \quad \mathbf{Ax} \geq \mathbf{d}, \quad \mathbf{x} \in R_+^{n_1} \times Z^{n_2} \\
& \quad C^w(\mathbf{x}) = \max_{\mathbf{u} \in U} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{u})} \left[\mathbf{c}^T \mathbf{x} + \mathbf{b}^T \mathbf{y} \right] \\
& \quad R^w(\mathbf{x}) = \mathbf{c}^T \mathbf{x} + \max_{\hat{\mathbf{x}}, \hat{\mathbf{y}} \in \Xi(\mathbf{u}), \mathbf{u} \in U} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{u})} \left[\mathbf{b}^T \mathbf{y} - (\mathbf{c}^T \hat{\mathbf{x}} + \mathbf{b}^T \hat{\mathbf{y}}) \right] \\
& \quad \Omega(\mathbf{x}, \mathbf{u}) = \left\{ \mathbf{y} \in R_+^{n_3} : \mathbf{Wy} \geq \mathbf{h} - \mathbf{T}\mathbf{x} - \mathbf{Mu} \right\}
\end{aligned} \tag{11}$$

where ε is a parameter which bounds the worst-case regret from above.

3. Applications

We consider two batch scheduling problems in section to illustrate the proposed methodology. The state-task-network of the first batch process is shown in Figure 1. This batch process involves one heating task, three reaction tasks, and one separation task (Kondili et al., 1993). This network involves three raw materials (A-C), four intermediates (Hot A, Impure E, and I1-I2) and two products (P1-P2). There are four equipment units: one heater, two reactors, and one separator.

The scheduling results are shown in Figure 2. By comparing the two Gantt charts, we can observe that the assignment decisions determined by the two approaches are different. Specifically, Reaction 3 starts at a unique time point in the scheduling solution determined by the conventional robustness criterion, while Reaction 3 shares the same starting time point with Reaction 1 in the scheduling solution determined by the minimax regret criterion.

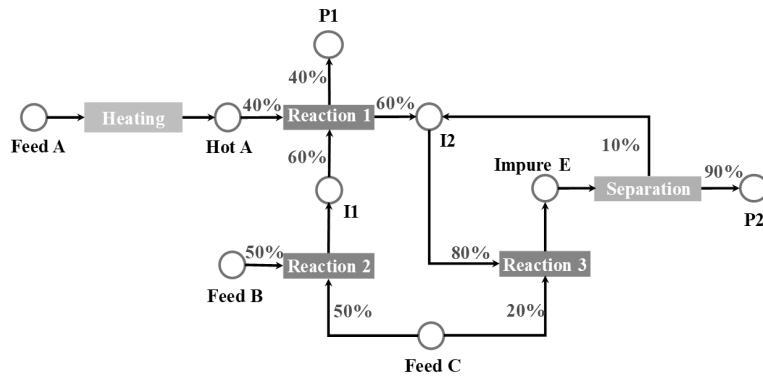

Figure 1. State-task network of the multipurpose batch process in case study 1.

The values of worst-case profit and regret are listed in Figure 2. The scheduling solution determined by the minimax regret criterion has the lowest worst-case regret of \$13.6, and only decreases the worst-case profit by 0.3% compared with solution under the conventional robustness criterion.

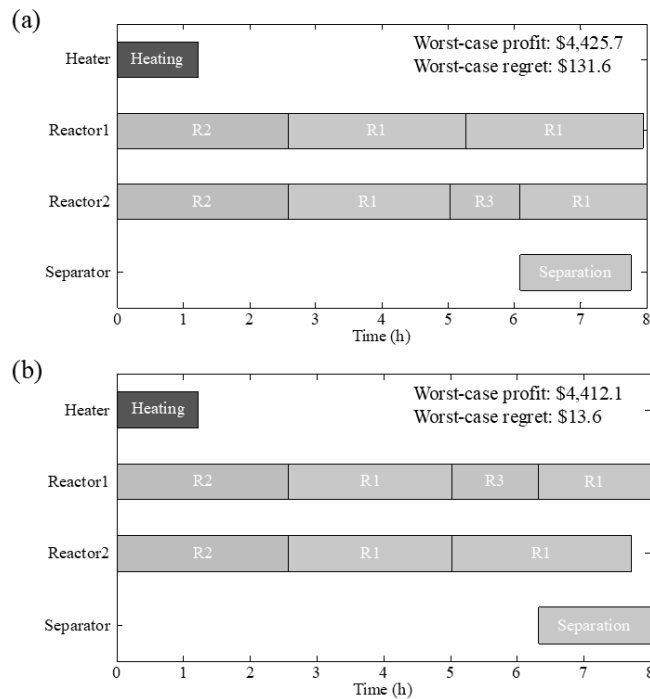

Figure 2. Gantt charts determined by (a) the conventional robustness criterion, and (b) the minimax regret criterion in case study 1.

We then apply the proposed scheduling approach to another process scheduling problem (Ning and You, 2017b). This case study is originated from an industrial multipurpose

batch process in The Dow Chemical Company (Chu et al., 2013), and the network is shown in Figure 3. This multipurpose batch process has one preparation task, three reaction tasks, two packing tasks and two drumming tasks. The equipment units include one mixer, two reactors, one finishing system and one drumming line (Chu et al., 2013). The scheduling horizon is one week, i.e. 168 hours, and there are 11 time points.

Figure 3. The state-task network of the multipurpose batch process in case study 2.

We solve the resulting scheduling problems with different values of parameter λ . The Gantt charts of the ARO solutions under the conventional robustness criterion and the minimax regret criterion are shown in Figure 4 (a) and (b), respectively. From the Gantt chart, we can observe that the assignment decisions are different, but the worst-case profit and regret remain unchanged for the two solutions. This is because of a different problem setup from Case study 1.

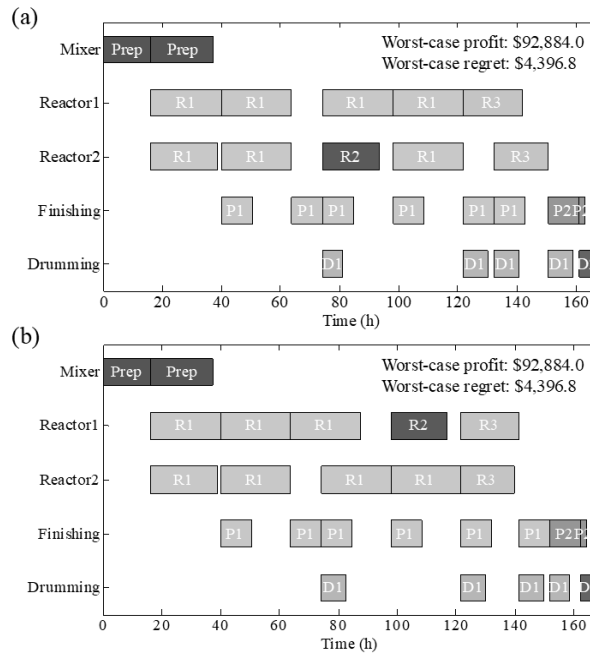

Figure 4. Gantt charts determined by (a) the conventional robustness criterion, and (b) the minimax regret criterion in case study 2.

4. Conclusions

In this paper, a novel multi-objective robust batch process scheduling model was proposed to account for the minimax regret criterion. Apart from the conventional robustness criterion, the worst-case regret was introduced as another objective to minimize the deviation of profit from the perfect-information schedule. A set of Pareto-optimal schedules was generated to reveal the systematic trade-offs between the conventional robustness and minimax regret criteria. The results of two case studies showed that the proposed scheduling decision could make a systematic trade-off between the conventional robustness criterion and minimax regret criterion.

Process Scheduling under Ambiguity Uncertainty Probability Distribution

Chao Shang, Fengqi You

Cornell University, Ithaca, New York, 14853, USA

Abstract

Distributionally robust optimization (DRO) has been gaining increasing popularity in decision-making under uncertainties due to its capability in handling ambiguity of distributions. However, it is a nontrivial task to approach the scheduling problem within the DRO framework. In this paper, we propose a novel DRO scheduling model under uncertain demand. We adopt max-out moment functions to characterize the ambiguity set, which includes a variety of distributions. In addition, we take into account recourse decisions made after random demands become known. In this way, a two-stage distributionally robust scheduling model can be developed, which can be approximately solved by linear decision rules. Applications in industrial-scale batch process scheduling show that, the proposed approach can leverage empirical data information with effect, better hedge against the inexactness of uncertainty distributions, and bring more profits.

Keywords: Distributionally robust optimization, decision-making under uncertainty, process planning, big data

1. Introduction

Process scheduling is an important control problem that has already been extensively investigated in process system engineering in the past two decades (Grossmann et al., 2016; Chu and You, 2015). The general purpose of a scheduling problem is to manufacture a series of products by optimally assigning limited resources at hand. Typical production objectives include maximizing the profit, minimizing the makespan, etc., which induces deterministic mixed-integer linear program (MILP) models.

However, deterministic scheduling models cannot handle uncertainties that are ubiquitous in real world. Therefore, stochastic programming (SP) and robust optimization (RO) have been extensively adopted in process planning and scheduling for better immunization against uncertainties (Balasubramanian and Grossmann, 2004; Shi and You, 2016). As an intermediate approach between SP and RO, distributionally robust optimization (DRO) is paving a new way for addressing uncertainties in optimization problems, and has received immense attentions in operations research community (Delage and Ye, 2010; Goh and Sim, 2010). DRO can be considered as optimizing the worst-case expected performance on a set constituted by a variety of distributions, which is termed as the ambiguity set and can be developed based on data. In this way, DRO could hedge against the ambiguity of probability distribution.

Nevertheless, process scheduling has not been benefited from recent advances in DRO. The orientation of this work is hence to fill in this gap by developing a novel DRO method for process scheduling applications. By considering uncertainties revealed sequentially and some adjustable wait-and-see decisions to be implemented after uncertainties are unfolded, we develop a two-stage DRO model. The linear decision rule

(LDR) approximation is adopted to provide a tractable, albeit conservative solution towards two-stage DRO problems. which enjoys considerable computational convenience in practice. An application in multi-purpose batch process scheduling demonstrates that the two-stage DRO model bears clear statistical interpretations and the conservatism of solutions can be significantly ameliorated. This highlights massive data as an asset for advancing decision-making in process scheduling.

2. Distributionally Robust Scheduling Model

Here we adopt the global event-based, continuous-time process scheduling model developed by Castro et al. (2004) as the deterministic model:

$$\begin{aligned}
 \max \quad & \text{Profit of selling products minus the purchasing cost and running cost} & (1) \\
 \text{s.t.} \quad & \text{Mass balance constraints} & (2) \\
 & \text{Batch size constraints} & (3) \\
 & \text{Inventory constraints} & (4) \\
 & \text{Demand satisfaction constraints} & (5) \\
 & \text{Processing time constraints} & (6)
 \end{aligned}$$

which is typically cast as an MILP. Let us further suppose that the product demands are random, whose exact distribution is unknown but belongs to an ambiguity set. We fix all binary sequencing variables and initial purchasing amount as first-stage decisions, while regarding continuous variables pertaining to batch sizes, inventory levels, and timings of all periods as second-stage decisions made after the demands are known. Therefore, the problem is cast in a two-stage setting. Therefore, based on the deterministic model (1)-(6), we can arrive at a succinct expression of the two-stage distributionally robust scheduling model:

$$\begin{aligned}
 \min_x \quad & \mathbf{c}^T \mathbf{x} + \sup_{\mathbb{P} \in \mathcal{D}} \mathbb{E}_{\mathbb{P}} \{L(\mathbf{x}, \boldsymbol{\xi})\} & (7) \\
 \text{s.t.} \quad & \mathbf{A}\mathbf{x} \leq \mathbf{b}
 \end{aligned}$$

Here \mathbf{x} includes both continuous and binary variables. The second-stage cost is given by:

$$L(\mathbf{x}, \boldsymbol{\xi}) = \begin{cases} \min_y \mathbf{d}^T \mathbf{y} \\ \text{s.t. } \mathbf{T}(\boldsymbol{\xi})\mathbf{x} + \mathbf{W}\mathbf{y} \leq \mathbf{h}(\boldsymbol{\xi}) \end{cases} \quad (8)$$

In this work, we adopt the following formulation of ambiguity sets:

$$\mathcal{D} = \left\{ \mathbb{P}_{\boldsymbol{\xi}} \in \mathcal{M}_+^M \mid \mathbb{P} \{ \boldsymbol{\xi} \in \Xi \} = 1, \mathbb{E}_{\mathbb{P}} \{ g_i(\boldsymbol{\xi}) \} \leq \gamma_i, i = 1, \dots, I \right\} \quad (9)$$

Here we use upper and lower bounds to specify the support of uncertainties $\Xi = \{ \boldsymbol{\xi} \mid \boldsymbol{\xi}_{\min} \leq \boldsymbol{\xi} \leq \boldsymbol{\xi}_{\max} \}$. The second constraint in (9) characterizes moment information of uncertainties via I functions $\{g_i(\cdot)\}$, and enforces the generalized moment $\mathbb{E}_{\mathbb{P}} \{ g_i(\boldsymbol{\xi}) \}$ cannot exceed a given threshold γ_i . In this work, we use the max-out function as moment functions:

$$g_i(\boldsymbol{\xi}) = \max \{ \mathbf{f}_i^T \boldsymbol{\xi} - q_i, 0 \}, i = 1, \dots, I \quad (10)$$

which can be conceived as the tail expectation along a certain direction f_i truncated at q_i . In fact, D can be rewritten as the projection of a lifted ambiguity set \bar{D} by introducing auxiliary random variables φ :

$$\bar{D} = \left\{ \mathbb{Q}_{\xi, \varphi} \mid \mathbb{P}\{(\xi, \varphi) \in \bar{\Xi}\} = 1, \mathbb{E}_{\mathbb{Q}}\{\varphi\} \leq \gamma \right\}, \quad (11)$$

and the lifted support is given by

$$\bar{\Xi} = \left\{ (\xi, \varphi) \mid \xi \in \Xi, g_i(\xi) \leq \varphi_i \right\}. \quad (12)$$

It turns out that the introduction of φ is particularly beneficial for deriving a desirable reformulation of the DRO problem. Note that the ambiguity sets could be derived from historical data using data-driven methods such as kernel learning (Shang et al., 2017).

3. Approximated Solution Algorithm with Linear Decision Rules

In a two-stage setting, deriving an explicit expression of optimal recourse policy and calculating the worst-case expectation are intractable (Bertsimas et al., 2010). A practical strategy is to adopt the well-known LDR, which assumes the recourse decision y to be affinely varying with the uncertainties (Ben-Tal et al., 2004; Chen et al., 2008; Ning and You, 2017a):

$$y(\xi, \varphi) = y^0 + Y^\xi \xi + Y^\varphi \varphi \quad (13)$$

By substituting the LDR approximation for the decision policy, a conservative approximation to the two-stage DRO problem can be derived:

$$\begin{aligned} \min_x \min_{y(\xi, \varphi)} c^T x + \sup_{\mathbb{P} \in \mathcal{D}} \mathbb{E}_{\mathbb{P}} \{d^T y(\xi, \varphi)\} \\ \text{s.t. } Ax \leq b \\ T(\xi)x + Wy(\xi, \varphi) \leq h(\xi), \forall (\xi, \varphi) \in \bar{\Xi} \end{aligned} \quad (14)$$

Here, coefficients of LDR can be regarded as first-stage variables, thereby resulting in a single-stage optimization problem. Then we concentrate on the inner problem, which can be explicitly expressed as:

$$\begin{aligned} \sup_{\mathbb{Q}} \int_{\bar{\Xi}} p(\xi, \varphi) d^T y(\xi, \varphi) d\xi d\varphi \\ \text{s.t. } \int_{\bar{\Xi}} p(\xi, \varphi) d\xi d\varphi = 1, \int_{\bar{\Xi}} p(\xi, \varphi) \varphi d\xi d\varphi \leq \gamma \end{aligned} \quad (15)$$

By adopting the conic duality, (15) can be translated into the following RO problem by introducing Lagrange multipliers (Shapiro, 2001):

$$\begin{aligned} \min_{\eta, \beta} \eta + \gamma^T \beta \\ \text{s.t. } \beta \geq 0 \\ \eta + \varphi^T \beta \geq d^T y(\xi, \varphi), \forall (\xi, \varphi) \in \bar{\Xi} \end{aligned} \quad (16)$$

Therefore, (14) could be also cast as a trivial RO problem. We can then leverage duality to translate infinite-dimensional constraints into their robust counterparts. Specifically, if we use classic uncertainty sets in RO such as the box and polyhedral sets to describe

the uncertainty support, a tractable MILP reformulation of the two-stage distributionally robust scheduling problem can be attained, which can be easily handled using CPLEX.

4. An Industrial-Scale Application

4.1. Problem Setup

The proposed DRO model is applied to an industrial multi-purpose pharmaceutical batch production process in The Dow Chemical Company (Chu et al., 2013). It includes one mixer, two reactors, one finishing system and one drumming line to accomplish one preparation task, six reaction tasks, two packing tasks and two drumming tasks (Chu et al., 2014). The actual demand fluctuations are supposed to follow a truncated Gaussian distribution around their nominal values. Accordingly, 500 data samples are collected in total. We developed the deterministic model, the two-stage DRO, and two-stage ARO models taken from Ning and You (2017b), all of which can be transformed into MILPs. In two-stage ARO, the box uncertainty set is adopted with its size estimated with 500 available samples. In two-stage DRO, we adopt principal component analysis to estimate projection directions f_i in moment functions from 500 data samples, and then set several truncation points q_i evenly on each principal axis.

We plot Gantt charts of scheduling decisions under nominal values of demands in Figure 1. Under the nominal case the deterministic model yields the highest profits, while the ARO model gives the lowest profits. This is due to the different optimization criteria adopted. In addition, it can be observed that DRO schedules more tasks than the other two methods, which allow for more flexibility to adjust batch sizes for a high profit under demand uncertainties, since more tasks can afford heavier manufacturing workload. The sequencing decisions attained by the deterministic approach may become infeasible when demands exhibit randomness, thereby lacking robustness.

Next we further examine performances of different approaches by resorting to Monte Carlo simulations. There are 1,000 random samples collected in total, and we first solve the problems of two-stage DRO and ARO and derive first-stage decisions. Then for each sample, we solve the second-stage problem by fixing first-stage decisions, and calculate the second-stage cost. By summarizing results over all random samples, we can empirically compute the mean value of total profits. In this way, we can arrive at a fair comparison between DRO and ARO. By varying the value of G , we obtain results under different magnitudes of uncertainties, as reported in Table 1.

Table 1. Expected Profits (\$) Based on Monte Carlo Simulations

G	5		10		20	
Profit	DRO	ARO	DRO	ARO	DRO	ARO
Total	2,416	2,416	2,222	2,131	1,959	1,470
1 st -Stage	-10,241	-10,240	-10,434	-10,386	-10,633	-10,247
2 nd -Stage	12,657	12,656	12,656	12,517	12,592	11,717

We can see that in the case of large magnitude of uncertainties ($G = 20$), DRO has significant advantages over ARO. In the case of small magnitude ($G = 5$), DRO and ARO yield nearly identical expected profits. This bears rationality since the worst-case realization that ARO hedges against is not sufficiently extreme.

Figure 1. Gantt charts of scheduling results of deterministic scheduling (top), two-stage DRO (middle) and two-stage ARO (bottom)

Notice that decisions made by DRO invest more in the first-stage. This is also implied by Gantt charts and the purchase amounts in Table 2, which shows that more initial materials, especially M1, are bought by DRO. Such a high investment finally turns out to be beneficial in obtaining higher second-stage profits as well more total profits on average. By contrast, the ARO-based approach tends to take conservative first-stage decisions, which finally exert significant influences on the overall profits. In this sense, by extracting useful statistical information from data, the two-stage DRO approach leads to less conservative solutions and achieves better expected performance in comparison with classic ARO-based approach.

Table 2. Purchase Amounts (kg) of Initial Materials as First-Stage Decisions

G	5		10		20	
	DRO	ARO	DRO	ARO	DRO	ARO
M1	608.00	608.00	608.00	601.60	608.00	571.18
M2	198.76	198.74	203.73	203.70	211.98	211.40
M3	198.76	198.74	203.73	203.70	211.98	211.40
M4	177.80	177.76	186.16	186.10	202.90	202.77

5. Conclusions

In this paper, a novel DRO-based strategy is proposed to solve process scheduling problems under uncertainties. The worst-case expected performance on the ambiguity set is optimized, thereby providing protection against the inexactness of probability distributions. We develop two-stage DRO models by including second-stage decisions made after uncertainty realizations, and adopt LDR approximations to derive tractable solutions. An industrial-scale application demonstrates that the proposed approach can effectively hedge against distributional ambiguity, and bring more profits under stochastic demands in comparison with classic RO-based approaches.

Mixed Integer Linear Programming Formulation for Sensible Thermal Energy Storages

Martin Koller^a and René Hofmann^{a,*}

^a*TU Wien, Institute for Energy Systems and Thermodynamics, Getreidemarkt 9, Vienna 1060, Austria*
rene.hofmann@tuwien.ac.at

Abstract

In order to model the charging and discharging power of sensible thermal energy storages for the unit commitment problem with mixed integer linear programming more precisely, two extended formulations are proposed in this work. To this end, simulation data of a detailed simulation model, derived from measurement data of a fixed bed regenerator test rig, were investigated in order to determine the actual charging and discharging power of the storage in highly dynamic operation. The two formulations were derived from an original MILP storage model with fixed maximum charging and discharging power. The first proposed formulation adds linear constraints for charging and discharging power depending on the fill level. The second proposed formulation introduces auxiliary variables, taking into account the fill level at the end of the previous charging or discharging phase. The predicted operation for a test case of the original and the two proposed mixed integer linear formulations are compared with the achieved operation of the detailed simulation model. While the original formulation allows infeasible predictions for the storage operation, the two proposed formulations are able to describe the real operating behavior more detailed, therefore decreasing the infeasible predictions for operation as well as increasing the overall system performance.

Keywords: Unit Commitment, Mixed Integer Linear Programming, Sensible Thermal Energy Storage, Industrial Processes, Smart Energy Systems

1. Nomenclature

ABBREVIATIONS			INDICES AND SETS	
CHP	Combined Heat and Power		<i>ch</i>	Charging
HTF	Heat Transfer Fluid		<i>chp</i>	CHP unit
MILP	Mixed Integer Linear Programming		<i>dis</i>	Discharging
SM	Storage Medium		<i>htf</i>	Heat transfer fluid
STES	Sensible Thermal Energy Storage		<i>k</i>	1D-element, from 1 to <i>K</i>
UC	Unit Commitment		<i>sm</i>	Storage medium
PARAMETERS			<i>t</i>	Time step, from 1 to <i>T</i>
c_p	[kJ/kg]	Specific heat capacity	<i>w</i>	Wall
m	[kg]	Mass	VARIABLES	
q	[MWh]	Heat demand	<i>S</i>	[MWh] Storage fill level
$\hat{\delta}_t$	[MWh]	Storage fill level	<i>H</i>	[MWh] Auxiliary variable
Δt	[s]	Time step size	<i>B</i>	[-] Commitment variable
ϑ	[°C]	Temperature	\dot{Q}	[MW] Power (heat flow)

2. Introduction

In Europe's changing energy system, industrial processes play a future key role with a share of the total energy consumption of 25.3 % according to eurostat (2017). By interconnection of electricity, heat and gas networks to a smart grid and by flexibilization of energy supply systems of industrial processes in such smart grids, the increasing share of volatile wind and solar energy can be supported and the occurring surpluses and shortages can be counteracted. To this end, important topics are the integration of energy storages and optimal control concepts to exploit the gained flexibility. The result is a smart energy system with a high share of renewable energy sources, as proposed in Lund et al. (2016).

The optimal control of energy supply systems is obtained by solving the corresponding unit commitment (UC) problem. There are several approaches to solve the UC problem in the literature, as listed in Padhy (2004). To this end, mixed integer linear programming (MILP), as proposed in Carrion and Arroyo (2006), is well suited. Some examples are studies on tighter and more compact MILP formulations (Morales-Espana et al. (2013)), minimal uptime and downtime formulations (Rajan and Takriti (2005)), intraperiod load gradient changes (Correa-Posada et al. (2017)) or different approaches for the modeling of start-up costs (Silbernagl et al. (2016)). Hardly any studies consider more detailed formulations of thermal energy storages. To the authors knowledge, MILP formulations for thermal energy storages are implemented mostly by storage energy balances with fixed maximum charging and discharging power, which is appropriate to model e.g. warm water storages in district heating networks. In Baeten et al. (2015) several more detailed formulations for model predictive control were compared, including slow accurate non-convex, fast suboptimal linear and iterative linear formulations for stratified hot water tank. In Steen et al. (2015) a storage model for improved tracking of losses is presented. Zachar and Daoutidis (2016) present a formulation for an electric battery storage that has a similar methodology as model B presented in this paper with maximum charging/discharging power depending on the fill level.

In reality, thermal energy storages often have more complex characteristics, like sensible thermal energy storages (STES). An example is that the charging and discharging power of these storages is dependent on the temperature spread of the in- and out-flowing heat transfer fluid (HTF). The temperature spread for STES typically decreases during a charging or discharging phase, which does not match the often assumed fixed maximum charging and discharging power in common MILP models. To address this problem, two formulations for more detailed modeling of a STES for MILP-UC are presented in this paper.

3. Methodology

The presented MILP models were developed based on simulation data of a 1D-model of a fixed bed regenerator that was validated by measurement data of a test rig. In the following the test rig, simulation model and data are briefly discussed, followed by the MILP formulation and comparison of the developed STES models. For both, MILP and simulation models, MATLAB[®] was used as modeling framework. Gurobi[™] was used as MILP solver.

3.1. STES Test Rig, Simulation Model and Data

The fixed bed regenerator presented in Mayrhuber et al. (2017) is a STES with gravel as storage medium (SM) and air as HTF with a steel casing (wall). These three components are considered for the developed first principle 1D-model for detailed simulations. This model was validated by measurement data of a test rig in the laboratories of TU Wien, see Figure 1. In Figure 2 a scheme of the 1D-model is depicted. The three components wall, SM and HTF each were modeled as discrete 1D-elements with heat transfer between the components for each discrete 1D-element and heat conduction for all components and convective transport of the HTF along the 1D-axis.

Figure 1: Fixed bed regenerator test rig without insulation

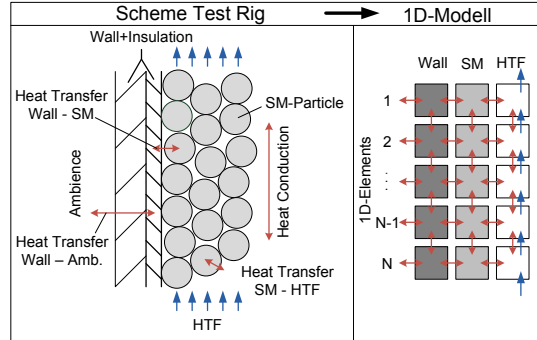

Figure 2: Realistic scheme and 1D-model of the regenerator

To facilitate the analysis of the storage characteristics, the model was slightly adjusted by choosing a cylindrical instead of the actual conic shape and neglecting thermal losses, so that the charging and discharging behavior is identical. With this simulation model, highly dynamic operation with non-complete charging and discharging cycles was simulated. Charging and discharging temperatures and mass flow of the HTF are fixed values, but the duration of charging and discharging phases was randomly chosen during the simulation to cover all possible operating states. The total simulated time is 5,000 hours with a time step size of 30 seconds. The model consists of $K = 48$ discrete elements along the 1D-axis for each component (SM, HTF and Wall).

In Figure 3 and Figure 4 simulation data of complete cycle operation and highly dynamic operation are shown. The plots show the parameters storage fill level, charging and discharging power (actually temperature spread of the in- and out-flowing HTF, but since the mass flow is fixed, this corresponds directly to the storage power, which is of interest in this paper) and an auxiliary parameter, representing the reached storage fill level of the previous charging or discharging phase. The arrows represent the trajectories for charging and discharging phases. The storage fill level is calculated according to Eq.(1) and represents the sensible heat.

$$\hat{s}_t = \sum_{k=1}^K m_{sm,k} \cdot c_{p,sm,k} \cdot \vartheta_{sm,k,t} + m_{htf,k} \cdot c_{p,htf,k} \cdot \vartheta_{htf,k,t} + m_{w,k} \cdot c_{p,w,k} \cdot \vartheta_{w,k,t} \quad (1)$$

For complete cycle operation the charging and discharging power depends on the storage fill level. For highly dynamic non-complete cycle operation, the charging and discharging power is also depending on the reached fill level at the end of the previous charging or discharging phase. If the STES is almost full or empty, a short discharging or charging phase leads again to a high charging or discharging power for the following charging or discharging phase respectively, despite the correlation of power and fill level of complete cycle operation.

Figure 6: View from below of Figure 5 (charging part) with feasible areas of model A and B

3.2. MILP Model Formulation

In order to integrate a STES model with the shown system behavior in a MILP-UC, two extended formulations (models B and C) for the original MILP model (model A) were developed. The shown bounds of the actual feasible operation space in Figure 4 have a non-convex hyperbolic shape, yet this is approximated by two convex solution spaces for charging and discharging (model C) or one convex area (model B). A visualization of model C is shown in Figure 5 and Figure 6.

Typical models include energy balances for the system and the storage with given heat demand:

$$(\dot{Q}_{chp,t} + \dot{Q}_{dis,t} - \dot{Q}_{ch,t}) \cdot \Delta t = q_t \quad (2) \quad S_{t+1} = S_t + (\dot{Q}_{ch,t} - \dot{Q}_{dis,t}) \cdot \Delta t \quad (3) \quad 0 \leq S_t \leq S_{max} \quad (4)$$

$$\dot{Q}_{ch,t} \leq \dot{Q}_{ch,max} \quad (5) \quad \dot{Q}_{dis,t} \leq \dot{Q}_{dis,max} \quad (6)$$

Model A: The above balance Eq.(2) and Eq.(3) and the constraints for maximum charging and discharging power Eq.(5) and Eq.(6) describe the original energy storage formulation. Note that storage losses can be modeled by adding coefficients to the terms in Eq.(3) for losses relative to the fill level, conversion losses or fixed losses. Model A has a fixed normalized maximum charging and discharging power ($\dot{Q}_{ch,max}$ and $\dot{Q}_{dis,max}$) of 1 in comparison to the varying maximum values for model B and C, see Figure 6.

$$\dot{Q}_{ch,t} \leq a + b \cdot S_t \quad (7) \quad \dot{Q}_{dis,t} \leq a + b \cdot (S_{max} - S_t) \quad (8)$$

Model B: Model A is extended by one or multiple instances of Eq.(7) and Eq.(8). These equations decrease the maximum charging power with increasing fill level and the maximum discharging power with decreasing fill level. The equations are a linear approximation of the real bounds, see Figure 3. Therefore the feasible area is enclosed smoother with an increasing number of constraints. This formulation ensures feasible charging and discharging power. Although the possible higher power output according to the investigation of simulation data is neglected as well. This model extension preserves the convexity of model A and therefore only slightly increases the computational effort, since there are just additional linear constraints, but no additional variables needed. The feasible solution space of model B equals model C with $H_{ch} = 0$ and $H_{dis} = 0$ in Figure 5 and Figure 6.

$$\dot{Q}_{dis,t} \leq a + b \cdot (S_{max} - S_t) + c \cdot H_{dis,t} \quad (9) \quad \dot{Q}_{ch,t} \leq a + b \cdot S_t + c \cdot H_{ch,t} \quad (10)$$

$$0 \leq H_{ch} \leq S_t \leq S_{max} \quad (11) \quad 0 \leq H_{dis} \leq S_{max} - S_t \leq S_{max} \quad (12)$$

$$H_{ch,t+1} \leq H_{ch,t} + B_{dis,t} \cdot S_{max} \quad (13) \quad H_{dis,t+1} \leq H_{dis,t} + B_{ch,t} \cdot S_{max} \quad (14)$$

$$H_{ch,t+1} \leq H_{ch,t} + e \cdot \dot{Q}_{dis,t} \quad (15) \quad H_{dis,t+1} \leq H_{dis,t} + f \cdot \dot{Q}_{ch,t} \quad (16)$$

$$0 \leq \dot{Q}_{ch,t} \leq \dot{Q}_{ch,max} \cdot B_{ch,t} \quad (17) \quad 0 \leq \dot{Q}_{dis,t} \leq \dot{Q}_{dis,max} \cdot B_{dis,t} \quad (18) \quad B_{ch,t} + B_{dis,t} \leq 1 \quad (19)$$

Model C: Model B is extended by two continuous auxiliary variables H_{ch} and H_{dis} as well as two binary variables B_{ch} and B_{dis} . The auxiliary variables are necessary to model the higher power due to non-complete cycles according to Figure 4. The auxiliary variables are represented in Figure 5 by the positive Z-axis for H_{ch} and the negative Z-axis for H_{dis} and determine the feasible operating area during the current charging or discharging phase. Eq.(9) and Eq.(10) describe inequality constraints representing the bounding planes. The binary variables define the current phase: Charging ($B_{ch} = 1$), discharging ($B_{dis} = 1$) or neither of both ($B_{ch} = 0$ and $B_{dis} = 0$). Only one of the two binary variables is allowed to be 1 in each time step according to Eq.(19). In Figure 5 several operating areas for different values of H_{ch} and H_{dis} are shown. To model the non-convexity of the simulation data even more detailed, additional binary variables can be introduced to split up the feasible space into multiple convex subspaces, although this increases the needed computational effort further. In this work, the operating range was approximated with just one convex subspace for both charging and discharging, still violating the convex model formulation of the original model A and the proposed model B. Since model C introduces two additional continuous and two binary variables for each time step, the needed computational effort increases. Coefficients a , b , c , d and e in the above equations emerge from the chosen bounding planes and will not be further discussed in this work.

4. Comparison and Discussion

The three models were tested by simulation of a test case over a duration of 30 days with a time step size of 15 minutes with receding horizon and a prediction horizon of 24 hours to simulate online scheduling. The case consists of a combined heat and power (CHP) unit and a STES, represented by the models A, B and C with given heat load that has to be satisfied. The fuel price for the CHP is assumed to be constant, electricity prices are taken from historic spot market prices and are given as well.

In each optimization step of the receding horizon the solutions of the optimization models A, B and C provide a prediction. Then the STES simulation model tries to operate according to the predicted STES operation from the optimization models. The fill level of the optimization models at the beginning of the prediction horizon is set to the real fill level achieved by the simulation model for each step of the receding horizon. If there is an infeasible prediction, the simulation model is not able to exactly match the predicted operation. In order to investigate the impact of this prediction error, the cost function values with the corrected storage operation are calculated. The resulting corrected cost function value is worse than the original and the difference of the two values indicates the impact of the prediction error. In Table 1 the original and corrected cost function values (normalized to the corrected value of model A), the relative infeasibility ($\frac{\sum |Predicted Power - Achieved Power|}{\sum Predicted Power}$) and the average computation time (Intel Xeon E5-1650 @3.5 GHz, 16 GB RAM) of each optimization step are shown for each model. The values depend on the chosen case and may differ for other cases.

The maximum power of model A is the least constrained, therefore the original cost function value is the lowest. Due to the assumed fixed maximum power, infeasible operation occurs, leading to high prediction errors. The maximum power of model B is the most constrained, therefore having the worst original cost function value, but the relative infeasibility is low. The original cost

Table 1: Comparison between models A, B and C of the relative infeasibility, the original and corrected cost function values and the average computation time

	Rel. Infeasibility	Cost Func. Value	Corr. Cost Func. Value	Av. Comp. Time
Model A	21.05 %	92.05 %	100.00 %	0.44s
Model B	3.91 %	96.57 %	96.69 %	1.59s
Model C	5.96 %	94.92 %	96.48 %	3.68s

function value and infeasibility of model C lies between the values of model A and B. Despite having the best original cost function value, model A has the worst corrected value, due to the high prediction error, resulting in the worst system performance. The corrected cost function value of model B is almost the same as the original, due to the low prediction error. Model C has the best corrected value, due to the compromise of feasibility and constraining, resulting in the best system performance. The average computation time for model A is lower than for model B. Due to the additional binary variables in model C the average computation time is clearly higher.

These models are still energy balance models, but the presented modeling approach can be used e.g. to satisfy temperature requirements.

5. Conclusion

A detailed simulation model validated by measurement data of a fixed bed regenerator was used to develop two extended MILP-UC models B and C based on an original model A. The optimization models A, B and C were tested with a test case and the predicted operation was checked by the STES simulation model to quantify the prediction error due to simplifications of the MILP optimization models. Models B and C both perform better than model A, regarding feasibility and corrected cost function value, whereas model B has less computational effort and less infeasible operation than model C, but model C reaches a better overall system performance than model B.

6. Acknowledgment

This work was initiated by the endowment professorship of the Technical University of Vienna (TUW), Institute for Energy Systems and Thermodynamics - Industrial Energy Systems, and the Austrian Institute of Technology (AIT) - Center for Energy - Energy in Industries. The authors want to thank the institute's department Thermodynamics and Thermal Engineering (TUW) for providing the measurement data of the fixed bed regenerator test rig (GSG, FFG-Project 836636).

Abstract

In the oil supply chain, products transportation by pipelines is the most used distribution modal, justified by its high volume capacity, reliability, and safety compared to the other transportation modes. The scheduling of pumping and delivery operations in pipelines is a complex problem. Thus, a better usage of the involved resources calls for the existence of tools that can help the associated decision-making process. This work explores this need and proposes a decomposition approach that integrates Mixed Integer Linear Programming models and heuristics to solve the scheduling of a single-source and multiple distribution centers (DCs) pipeline network, where a repumping DC operation, not yet considered in the literature in the area, is often used in practice. This operation corresponds to a situation where the repumping DC acts as the final DC of the network, receiving all batches arriving and, at the same time, operates as a source node. The DC repumps products previously received in tanks to attend the demand of downstream DCs. In this case, the storage profile has to be carefully controlled in order to perfectly manage the involved operations. A real-world Brazilian network, where such operation can be executed for the transport into the last segment, is used to validate the proposed approach. The approach solves the case where the repumping DC attends a single downstream destination. Scheduling results with and without the repumping operation active are presented. The obtained results translate valid operational solutions in a reasonable CPU time for both executions.

1. Introduction

Transportation of crude oil and its derivatives is one of the main problems faced by oil companies. Different transportation modes exist involving different stages of the oil supply chain: from oil terminals to refineries, from refineries to distribution centers (DCs), and among other segments until the client. The operation is carried out mainly by trucks, trains, vessels, and pipelines. However, for many countries, pipelines are the most used mode due to their high volume capacity, reliability, economy, and safety compared to the other modals (Sasikumar et al., 1997). The high cost associated in building a new pipeline network motivates oil companies to develop strategies and tools to aid the scheduling of pumping and delivery activities in the installed network with the purpose to optimize and improve the decision-making process of the system.

Often these networks involve multiproduct pipelines that allow the transportation of more than one product through the same pipeline and connect a single or multiples sources to one or more destinations. The disposition of the network sources, destinations and pipelines define the topology of the system and may consist of a straight pipeline or form complex structures, such as tree-structures, and mesh-structures. This work focuses on straight multiproduct pipeline networks connecting a single-source (a refinery) to multiples DCs. A typical transport operation in this network consists in allocating and sequencing batches of products to be pumped from the refineries, and scheduling delivery activities to attend the local demand of each DC. The problem involves many operational constraints, such as inventory management, demand attendance, flow rate limits, batch restrictions, tank and pipeline maintenance periods. Several approaches have been studied to solve this topology based on mathematical programming using mixed integer linear programming (MILP) (Zaghian and Mostafaei, 2016), mixed integer non-linear programming (MINLP) (Cafaro et al., 2015) and based on heuristics (Sasikumar et al., 1997). Research in such approaches has been exploring the introduction of new characteristics or more detailed operations in order to approximate the proposed approaches to the real-world pipeline networks where the complexity of the problem becomes a challenge. To overcome this problem, decomposition strategies have been also proposed by the academic community. For instance, Cafaro et al. (2012) developed a two-level hierarchical decomposition: aggregate planning with rolling horizon (sequence of the batches and aggregate deliveries) and detailed scheduling (temporization, when the deliveries should occur). Meira et al. (2018) also proposed a decomposition framework using heuristics and MILP models to solve the scheduling of a real-world multiproduct pipeline network with a refinery and multiples DCs. In this work, an extension of this framework is studied to consider a particular real type of operation, the so-called “repumping”.

The remainder of this work is organized as follows. Section 2 describes the problem and the repumping operation. Section 3 explains the decomposition approach. In section 4, we discuss the results of a case study of a real-world pipeline network. Section 5 presents the conclusions and future work.

2. Problem Definition

The problem considers a real-world straight multiproduct pipeline that connects a single-source (refinery) and multiple destinations (DCs), where the repumping operation is possible for the upstream DC of the last segment. Repumping operations are justified as they add some flexibility to the network and may avoid costs involved with shortage or surplus of inventory. In a repumping DC, the inventory capacity is usually higher in order to store more products and attend the downstream DCs whenever necessary. As this DC has no production, its operation requires a proper inventory management since its stock depends on having products received previously from the refinery. Additionally, it may happen that, simultaneously, the repumping DC may be receiving from the refinery and repumping to the downstream destination. The repumping option is decided by the operations managers when scheduling the pipeline operation, as this may be required to avoid extra costs of not supplying the necessary products to the destinations.

In this context, the objective is then to schedule the sequence of batches (product, start-end times, volume, flow rate) to be pumped by the refinery and the delivery operations in each DC during the established time horizon, while minimizing surplus or shortage of inventory for each product in each DC, flow rate variations in each segment, and the number of product interfaces. The solution has also to respect operational constraints, such as flow rate limits (pumping, repumping if active, delivery, and pipeline segment); inventory limits; batch size constraints; forbidden sequences of batches; pipeline and tank maintenance periods.

The developed approach relies on the following assumptions: (1) batches flow unidirectionally from the refinery to the downstream DCs; (2) the pipeline is always full of incompressible prod-

ucts, an input operation propagates instantaneously through the network and the same amount of volume is removed; (3) refinery has sufficient product to attend all the network demand; (4) tanks of the same product in a DC are aggregated; (5) simultaneous deliveries of products in two or more terminals are allowed; (6) repumping operation is possible on the upstream DC of the last segment; (7) inventory management is based on Magatão et al. (2012), also taking into account two intermediate ranges (target range and acceptable operational range), besides physical maximum capacity and empty status limits, to better control the inventory and obtain an operationally viable solution.

3. Decomposition Approach

The proposed approach is an extension of the framework introduced by Meira et al. (2017) and extended in Meira et al. (2018). Figure 1 shows the flowchart of the decomposition strategy, which combines heuristics and MILP models. The novelty is the introduction of the “Repumping Module” as an alternative for the last segment iteration of the Scheduling Module (SM) that is executed when the parameter “repumping” is set on.

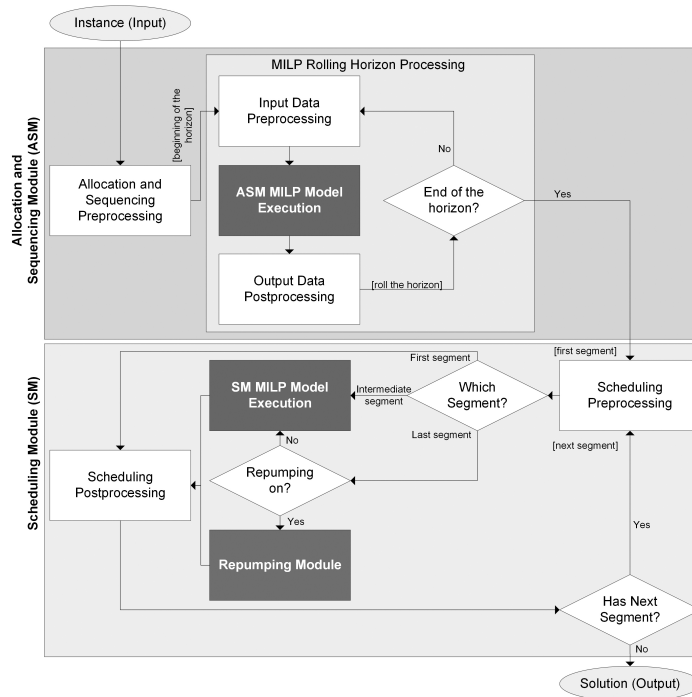

Figure 1: Flowchart of the developed decomposition approach

As input data we have the network information (terminals, pipeline, tanks, and products); demand for the considered time horizon; initialization batches; initial inventory; inventory ranges in each terminal; scheduled maintenance periods; and configuration parameters. The decomposition approach is executed and the output solution contains all the pumping, repumping (when active), and receiving operations to be performed during the considered time horizon. The decomposition approach involves two main modules: Allocation and Sequencing Module (ASM) and Scheduling Module (SM). First, the Allocation and Sequencing Module (ASM) is responsible to allocate the

volume, flow rate, product, and sequence of the batches to be pumped from the refinery during the time horizon. The ASM module receives the data, applies some heuristics in the preprocessing, and proceeds to the rolling horizon process solving part of the time horizon at each iteration by the ASM MILP model. Then, the Scheduling Module (SM) is executed taking as input the plan for the pumping operations from the ASM module and determines the detailed scheduling of all the delivery operations to be performed at each DC. The SM module applies a structural decomposition, solving one pipeline segment per iteration. Each iteration determines the receiving of the upstream DC of the segment being considered. The execution flow depends on the actual segment. The first segment goes directly to the postprocessing since it is the refinery input segment. Intermediate segments execute the SM MILP model and the last segment may execute the same SM MILP model or the Repumping Module depending on the repumping parameter.

3.1. Repumping Module

The proposed Repumping Module solves the allocation and sequencing of the batches to be pumped into the last segment from its upstream DC. The flow process is similar to the ASM MILP rolling processing part (without ASM preprocessing heuristics), where the goal is to allocate volume, flow rate, product, and sequence of batches. However, for this particular case, it allows us to study the problem as a single-source and single-destination straight pipeline topology. The Repumping MILP model considers a discrete-time for the repumping operations and demand due dates; batch constraints (size, forbidden sequences); batches tracking inside the pipeline segment; and inventory is managed for the upstream (source) and downstream DC (destination), where all the batches arriving at the upstream DC are directly received in a tank. These products' receiving are input data of the Repumping Module. Every SM postprocessing calculates the timings of batches arriving at the upstream DC of the next segment. For the long-term scheduling, a rolling horizon strategy may also be considered as in the ASM.

4. Results and Discussion

A real-world straight multiproduct pipeline network with repumping operation was considered in our case study. The considered network distributes products to part of the southeast and central-west regions of Brazil. The total pipeline length is 964 km with 164,374 m³ of internal volume. Figure 2 illustrates the considered case study. The volume dimension of each pipeline segment (S1-S5) is available. Also, the gray dashed line indicates the volumetric coordinate of each DC (DC1-DC5) in relation to the refinery. As illustrated, repumping operation is possible on DC4 to attend the demand of the last DC (DC5). Another detail is that pipeline segments S1-S4 have 20" (50.8 cm) of diameter and S5 has just 12" (30.48 cm), which makes the maximum flow rate in S5 (450 m³/h) lower than the others (1,200 m³/h). The network transports 3 products (P1-P3), where due to high contamination a batch of P3 is transported between batches of P1.

Figure 2: Real-world pipeline network in study

Although repumping operation is costly, operation managers have the possibility of using it in order to avoid possible inventory shortages or surpluses of product that, as a consequence, may decrease service level (e.g. not attending a demand) or add an even higher cost (e.g. the use of different modals, such as trucks to compensate a shortage of inventory).

The proposed approach was developed using Java programming language and IBM ILOG CPLEX Optimization Studio 12.6. Results were obtained on a PC platform with Intel i7-6500 2.5 GHz and 16 GB RAM using Windows 10 64-bits as the operational system. We solved a case of the studied network considering both flow alternatives, repumping off and on.

For a 30-day time horizon, the first execution without repumping took 308 s and the second execution with repumping took 905 s. Since the difference was only in the last segment execution, the solution for the ASM module is equal for both; in addition, the first 3 DCs have also the same solution. The Repumping Module demanded a computational time relatively higher, but the obtained solution was considerably better than the obtained in the first execution, mainly, due to the initial status of the instance. The inventory profiles of P3-DC5 of Figure 3 show the main difference between solutions. As highlighted, the SM model could not avoid a $-1,117 \text{ m}^3$ violation of the empty status in the first execution. Also, notice in Figure 2 that an initialization batch of product P3 is passing by DC1 at the beginning of the horizon, its head volumetric coordinate is $120,115 \text{ m}^3$ far from DC5. Even if a maximum flow rate ($1,200 \text{ m}^3$) is applied, which is only possible if no receiving happens upstream the P3 batch during this period, the DC5 would start receiving P3 only close to the 100 h point. Hence, it is not possible to avoid inventory shortage. In this case, operation managers would need to act in order to avoid such problem. One solution is repumping operations as shown in Figure 3(b) since DC4 has a considerable amount of P3 in stock (80 % of inventory capacity). Predicting the possibility of a shortage of P3-DC5, the Repumping Module scheduled a batch of P3 as the first to be repumped to DC5, thus, avoiding the problem. For both executions, no further inventory problem in DC4 and DC5 was observed during the entire time horizon.

Figure 3: Inventory profile of P3-DC5 with repumping off (a) and on (b)

From these results, it can be seen that repumping operation is an alternative to avoid situations where inventory problems may arise. The cause for such need may be related, for example, to unforeseen demand changes and/or unexpected events. The flexibility added from the repumping operation has a high cost involved when active for a long period. Short-term solutions may be applied, alternating between repumping on and off as necessary.

5. Conclusions

This work proposed an extension of the framework in Meira et al. (2017) and considered repumping operations as an alternative to better manage inventory levels, avoiding shortage of products. A Repumping Module was proposed using a MILP model with rolling horizon. To validate the use of repumping operation, we executed the approach considering repumping off and on in a real-world Brazilian pipeline network. As the main result, the repumping operation was effective in solving a particular inventory problem, which justifies its usage in practice.

As this is the first attempt to model repumping in a pipeline network more work can still be developed. For instance, the current Repumping MILP formulation relies on discrete-time representation, then a continuous-time approach could be explored. The proposed approach could also be extended so as to allow the application of the repumping operation in different segments of the network. Another improvement would be the proposed approach to automatically decide when to repump or not during the complete time horizon.

Abstract

Batch processing is a widely used method in process industry for its flexibility in manufacturing low-volume and high-value-added products. Due to inter-batch variations, the batch duration often varies, which may cause difficulties in operation scheduling and decision-making. The capability of predicting batch completion time offers valuable information to improved capacity utilisation, reduced workload, and reduced operating cost. To this end, several data-driven modelling methods have been reported. However, the uncertainty of the predicted completion time has not been well explored in previous research. In this paper, the challenges for batch-end prediction are discussed by stressing the importance of prediction uncertainty. This has been demonstrated by the application of probabilistic principal component analysis (PPCA) and quantitative sensitivity analysis to two batch processes. The prediction uncertainty tends to increase substantially, when the variable defining the completion time changes slowly towards the end of batch. Under such situations, we argue that the uncertainty should always be considered along with the mean prediction for practical use.

Keywords: batch process modelling, batch-end prediction, probabilistic principal component analysis, sensitivity analysis, prediction uncertainty.

1. Introduction

In today's process industry, batch processing has been widely used as it is flexibility in manufacturing low volume and high value-added products. Although often considered to be repetitive, a batch process often has variable durations due to inter-batch variations. This may cause difficulties in operation scheduling and decision-making (Li and Ierapetritou, 2008; Méndez et al., 2006). It is desired to develop mathematical models that can predict the batch completion time during the operation. Such prediction can be used to enable reactive scheduling. In practice, even if no rigorous scheduling is implemented (which is still the case in many plants), the capability of predicting batch end time still offers valuable information to help the operators make empirical decisions, which may lead to improved capacity utilisation, reduced expected workload, and overall reduced operating cost. In addition, such predictions can also be used in model-based optimisation and control of the process, for example to optimise the product quality while minimising the processing time.

In batch processes, a batch is usually considered complete when the value of the variable of primary interest reaches a predetermined threshold. Modelling with the aim to predict batch completion time has received significant interest in both academia and

industries. Generally, the prediction methods can be divided into two classes: those based on the fundamental (i.e. first-principal) models (Michaud et al., 2008) and those who are empirical (i.e. data-driven) (Montague et al., 2008). In this work, we focus on the empirical method because it has a minimum requirement on mechanistic understanding of the target process and can be established in an efficient manner. There have been a number of research efforts aimed at solving related problems. For example, Montague et al. (2008) adopted a pattern-based method named case-based reasoning (CBR) to achieve fermentation operational decision making. In CBR, the variable trajectory in the current batch is compared with the historical data. Then, the future behaviour prediction of the current batch can be made based on the pattern discovered in the most similar historical case.

Despite the achievements made to date, the existing methods only provide point estimation and ignore the uncertainty associated with the estimates. The practical goal that motivates this research is to develop a method to reveal the challenges for batch-end prediction by stressing the importance of prediction uncertainty. In detail, probabilistic principal component analysis (PPCA) (Tipping and Bishop, 1999) is adopted to predict the future batch trajectory during the operation, according to which the completion time of each batch can be inferred and the quantitative sensitivity analysis is realized. Although PPCA has been implemented in many other applications, such as process monitoring (Chen and Sun, 2009), this is the first time that it has been used for batch-end prediction. The cause studies show PPCA achieves a comparative prediction accuracy to the existing methods, such as CBR, but provides additional information about the prediction uncertainty which is useful in decision-making.

2. Probabilistic principal component analysis

Principal component analysis (Jolliffe, 2002) is a multivariate statistical projection technique for dimensionality reduction. The core idea of PCA is to project the original d -dimensional data vector, \mathbf{x} , onto a space where the variance is maximized:

$$\mathbf{x} = \mathbf{W}\mathbf{t} + \boldsymbol{\mu} + \mathbf{e} \quad (1)$$

Here \mathbf{W} refers to the eigenvector of the sample covariance matrix corresponding to the q ($q \leq d$) largest eigenvalues, \mathbf{t} is the q -dimensional score vector, $\boldsymbol{\mu}$ is the mean of the entire data set, and \mathbf{e} is the noise term.

In 1999, Tipping and Bishop (1999) proposed a probabilistic formulation of PCA from the perspective of a Gaussian latent variable model. The noise is reasonably assumed to be Gaussian distributed, i.e. $\mathbf{e} \sim G(\mathbf{0}, \sigma^2 \mathbf{I})$, which implies $\mathbf{x} | \mathbf{t} \sim G(\mathbf{W}\mathbf{t} + \boldsymbol{\mu}, \sigma^2 \mathbf{I})$. Furthermore, by adopting a Gaussian distribution assumption for the scores, i.e. $\mathbf{t} \sim G(\mathbf{0}, \mathbf{I})$, the marginal distribution of the original data is also Gaussian: $\mathbf{x} \sim G(\boldsymbol{\mu}, \mathbf{C})$, where the covariance matrix \mathbf{C} can be represented as $\mathbf{C} = \mathbf{W}\mathbf{W}^T + \sigma^2 \mathbf{I}$. Hence, the corresponding log-likelihood is

$$L = \sum_{n=1}^N \ln(p(\mathbf{x}_n)) = -\frac{N}{2} (d \ln(2\pi) + \ln|\mathbf{C}| + tr(\mathbf{C}^{-1}\mathbf{S})) \quad (2)$$

where $\mathbf{S} = \frac{1}{N} \sum_{n=1}^N (\mathbf{x}_n - \boldsymbol{\mu})(\mathbf{x}_n - \boldsymbol{\mu})^T$, N is the total number of observations, and n is the observation index. The model parameter \mathbf{W} , $\boldsymbol{\mu}$ and σ^2 can then be obtained by using the maximum likelihood (ML) or expectation maximization (EM) algorithm.

PPCA offers a natural way to handle the batch process data with uneven batch durations. Without loss of generality, suppose \mathbf{x} is data vector of the variable of primary interest and the maximum length of a batch is m . For each batch with the length smaller than m , the data vector can be divided as $\mathbf{x}^T = [\mathbf{x}_o^T \quad \mathbf{x}_u^T]$, where the sub-vectors \mathbf{x}_o and \mathbf{x}_u consist of the observed and unobserved data, respectively. In such cases, the model parameters can also be obtained by applying the EM algorithm. In the E-step, the distribution of \mathbf{x}_u is calculated based on \mathbf{x}_o and the current estimates of the parameters. In the M-step, the missing data \mathbf{x}_u are imputed by the mean and covariance of \mathbf{x}_u obtained from the E-step, while the log-likelihood function is maximised to update the parameter estimates.

In online implementation, the conditional distribution of the future measurements given the available measurements, which is Gaussian, can be predicted during the process operation. Accordingly, the batch completion time is estimated by comparing the predicted trajectory to a predetermined threshold. The performance of the prediction model is evaluated through leave-one-out cross-validation (LOOCV) and quantified using the root mean squared error (RMSE). Here, two different RMSE indices are considered, including the average RMSE for the prediction of future variable trajectory and the RMSE for the prediction of batch completion time.

3. Sensitivity analysis

Sensitivity analysis is a technique used to reveal how an output of a system is impacted by the uncertainty in the inputs (Saltelli, 2002), which is adopted in this work to illustrate that fundamentally when x does not vary significantly with respect to time around the threshold x_h , it is very difficult to predict the batch end-point. Here, x is the variable of primary interest in the investigated batch process, and the corresponding threshold is x_h . A batch is considered to be complete when the value of x is beyond the threshold. The corresponding time point is denoted as t_h .

According to PPCA, the prediction of x at any time point t can be expressed by a normal distribution with a mean value \bar{x}_t and a variance σ_t^2 where \bar{x}_t is the mathematical expectation of the estimated value and σ_t^2 indicates the uncertainty (or error) in the prediction. Around a small neighbourhood of t_h , the relationship between x and t can be well approximated by a straight line with a slope a and an offset b : $x_t = at + b$, by utilising for example the Taylor expansion. Correspondingly, the predicted time is also approximately normally distributed, i.e. $t \sim N((\bar{x}_t - b)/a, \sigma_t^2/a^2)$. Clearly, the uncertainty of the predicted t , indicated by the variance, depends on the slope term $a = dx/dt$. When a is large and thus x varies with time substantially, the prediction uncertainty is small; otherwise the estimation of time is sensitive to small change in x , and thus the predicted batch end-point carries substantial uncertainty. This conclusion seems straightforward. However, with the help of PPCA prediction, the prediction uncertainty can be evaluated in a quantitative manner. Such information can help the operators to assess the confidence and potential risk in decision-making.

4. Case studies

4.1. Beer fermentation

The first case study is a beer fermentation process in which the wort is mixed with yeast to initiate the production of alcohol. The end-point of this process can be determined by the present gravity (PG) which measures the alcohol content of the brew. As the fermentation progresses, the sugars in the wort are converted to alcohol, while the density of the brew decreases. The process is complete when all of the sugars have been consumed. In this case study, the end-point is set at gravity = 13.

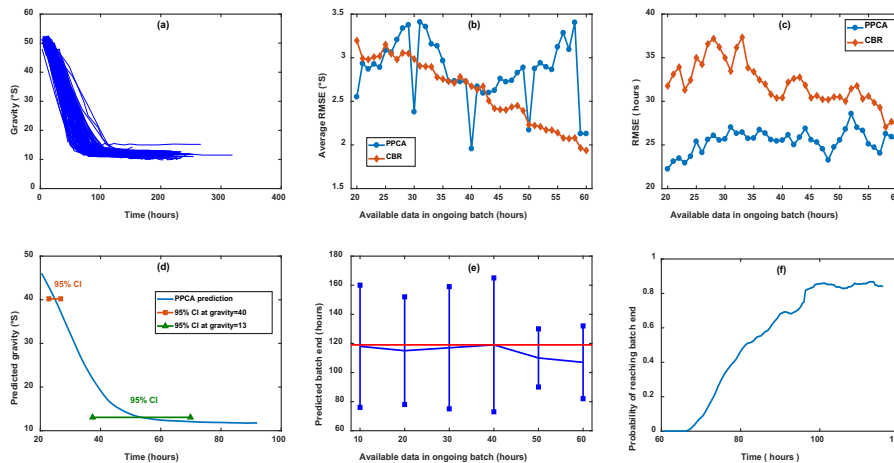

Figure 1. (a) Trajectories of present gravity, (b) average RMSE for prediction of future variable trajectory, (c) RMSE for prediction of batch completion time, (d) 95% CIs corresponding to different batch-end settings, (e) 95% CIs vs. available data points in ongoing batch, and (f) probability of reaching batch end.

Figure 1(a) shows the gravity trajectories recorded in 100 batches, from which significant inter-batch variations can be observed. For comparison, PPCA and CBR were used in the predictions. In Figure 1(b), the average RMSE for the prediction of future variable trajectory is plotted, which was calculated based on LOOCV. In this figure, the x-axis indicates the amount of the available data points in the ongoing batch when the prediction was made. In this particular case, there is no significant trend observed in the values of the average RMSE derived from the PPCA prediction results, while the performance of CBR improves with the increase of the amount of the available measurements. Figure 1(c) depicts the RMSE for the prediction of batch completion time. Here, PPCA outperforms CBR. Figure 1(d) shows the PPCA predictions of the gravity in a single batch in which the actual completion time is about the 119th hour. These results were obtained at the 20th hour of the ongoing batch. The 95% confidence intervals (CIs) of the predictions of the batch completion time are also plotted in the same figure. For the end-point at gravity = 13, the CI is plotted in green. For comparison, the CI is recalculated by assuming the end-point is set at gravity = 40 (although such an end-point selection is not practical), which is plotted in red. It is observed that the uncertainty increases when the variable trajectory turns to be flat, as verified by Figure 1(e). In Figure 1(e), the predicted values of the batch end-point are

plotted, together with the corresponding CIs. The x-axis has a similar meaning to that in Figures 1(b) and 1(c). It is noted that the prediction uncertainty does not reduced significantly with the increase of the observed data points in the ongoing batch. In addition, the probability for each time point of reaching the batch-end can be easily derived from the PPCA prediction result. The results shown in Figure 1(f) are based on the PPCA prediction made at the 60th hour in the ongoing batch. The probability for the batch to be complete at the 119th hour is larger than 50%. CBR and other conventional methods cannot provide information as in Figures 1(d)-(f), because they only make point estimations.

4.2. Rapid gravity filter

The second illustrative case is a rapid gravity filter where wastewater passes through granular materials to remove suspended particles and other impurities. In order to maintain the filter efficiency, backwashing needs to be done routinely. In some contexts, this process behaves like a batch process, where the duration between two times of backwashing can be regarded as a batch. The batch completion time, i.e. the time for backwashing, can be determined according to the solid concentration in the outlet flow. In this case study, when the concentration is larger than 0.2 mg/L, the backwashing should be carried out.

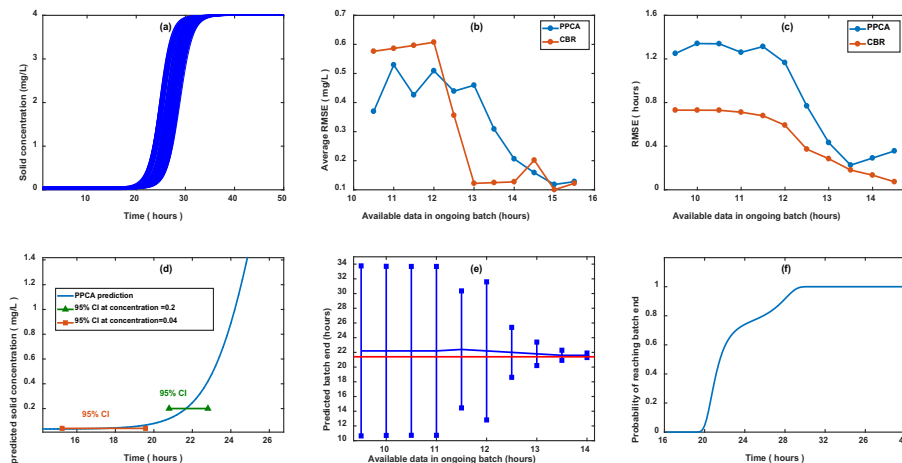

Figure 2. (a) Trajectories of concentration, (b) average RMSE for prediction of future variable trajectory, (c) RMSE for prediction of batch completion time, (d) 95% CIs corresponding to different batch-end settings, (e) 95% CIs vs. available data points in ongoing batch, and (f) probability of reaching batch end.

Figure 2(a) shows the simulated data of the solid concentration collected in 100 batches. The average RMSE values for the prediction of future variable trajectory are plotted in Figure 2(b), while the comparison results of the RMSE for the prediction of batch completion time are shown in Figure 2(c). In both figures, there is a shift in the prediction performance around the 13th hour. Such results are reasonable, because the trajectory of the solid concentration is very flat and contains little prediction information before the time close to the batch end. In addition, CBR, which is an inherently nonlinear method, outperforms the linear PPCA in this case. The possible reason is that this process is highly nonlinear. Figure 2(d) shows the PPCA predictions

of the solid concentration obtained at the 14th hour of an ongoing batch. The 95% CIs of the batch completion time predictions are plotted in the same figure, where the batch-end is set at 0.2 mg/L and 0.04 mg/L, respectively. Figure 2(e) plots the predicted batch completion time together with the CIs, which were calculated along the running time of the batch. The actual end time of this batch (corresponding to solid concentration = 0.2 mg/L) is around the 21.4th hour. A shift in the prediction uncertainty can be observed, which confirms the finding in Figures 2(b) and 2(c). Figure 2(f) shows the probability of each time point of reaching the batch end, which is calculated based on the PPCA predictions made at the 15th hour. It is noted that there is an obvious change in the probability value around the actual completion time.

5. Conclusions

In this work, the problem of batch-end prediction is studied. A PPCA-based scheme is proposed. Comparing to the conventional methods, such as CBR, PPCA provides comparative prediction accuracy and additional information of prediction uncertainty. Through sensitivity analysis, it is proved that when the variable of interest does not vary significantly with respect to time around the threshold, it is fundamentally very difficult to predict the batch end-point. Such a conclusion is verified with the experimental results. Furthermore, the case studies show the capability of PPCA to present the prediction uncertainty in a quantitative manner. The confidence intervals and the probability information can be very useful in industrial applications.

Sequential Bayesian Experimental Design for Process Optimization with Stochastic Binary Outcomes

Martin F. Luna, Ernesto C. Martínez*

INGAR (CONICET-UTN), Avellaneda 3657, Santa Fe S3002 GJC, Argentina
ecmarti@santafe-conicet.gov.ar

Abstract

For innovative products, the issue of reproducibly obtaining their desired end-use properties at industrial scale is the main problem to be addressed and solved in process development. Lacking a reliable first-principles process model, a Bayesian optimization algorithm is proposed. On this basis, a short of sequence of experimental runs for pinpointing operating conditions that maximize the probability of successfully complying with end-use product properties is defined. Bayesian optimization is able to take advantage of the full information provided by the sequence of experiments made using a probabilistic model (Gaussian process) of the probability of success based on a one-class classification method. The metric which is maximized to decide the conditions for the next experiment is designed around the expected improvement for a binary response. The proposed algorithm's performance is demonstrated using simulation data from a fed-batch reactor for emulsion polymerization of styrene.

Keywords: Bayesian optimization, end-use product properties, Gaussian processes, one-class classification, scale-up.

1. Introduction

For innovative products, the issue of reproducibly obtaining their desired end-use properties is the main problem to be addressed in process development (Colombo et al., 2016). For example, emulsion polymerization processes are well-known examples of the importance of guaranteeing reproducibility of end-use properties such as tensile strength and melt index by properly choosing the operating policy (Valappil and Georgakis, 2002). Similar problems are encountered in production of high-quality graphene sheets, single-walled carbon nanotubes and functionalized polymer nanofibers. The main drawback in the development of this type of innovative, high-value products is lacking a reliable first-principles model to predict the binary outcome (success/failure) of a production run for a given setting of the controlled variables in the face of variability due to the effect of uncontrolled factors on end-use properties. Also, even at bench scale, experiments are time consuming and/or expensive, which demand fast pinpointing operating conditions where the probability of success is maximum.

The problem of sequential experimental design for process optimization with stochastic binary outcomes is addressed by combining one-class classification with Gaussian processes (Xiao et al., 2015) and Bayesian optimization (Shahriari, et al., 2016). It is assumed that errors (failures) incurred in the sequence of runs are not punished, but instead it is of major concern the final recommendation for operating conditions once the available budget (in time and/or money) for experimental optimization is over.

2. Problem statement

Given an initial Region of Interest (ROI) $\mathbb{X} \subset \mathbb{R}^d$ for the controlled inputs, an unknown objective function $\pi: \mathbb{X} \rightarrow [0, 1]$ descriptive of the probability of complying with product end-use properties and a maximum budget of n experiments, the problem of sequentially making decisions $\mathbf{X}_i = [x_1, x_2, \dots, x_i]^T$ which are rewarded by a “success” with probability $\pi(x)$ and “failure” with probability $1 - \pi(x)$, is to recommend, after n experiments, the operating conditions x^* that maximizes π . Note that the choice of the operating conditions for each experiment x_i in the sequence is based solely on knowledge of the binary outcomes $\mathbf{y}_i = [y_1, y_2, \dots, y_i]^T$ from previous runs. The observations at x_i are considered to be drawn from a Bernoulli distribution with a success probability $p(y = 1|x_i)$. The probability of success is related to a latent function $f(x): \mathbb{R}^d \rightarrow \mathbb{R}$ that is mapped to a unit interval by a sigmoid transformation. The transformation used is the *probit* function $p(y = 1|x_i) = \Phi(f(x_i))$, where Φ denotes the cumulative probability function of the standard Normal density.

As there not exist correct examples of the success probability π over ROI but evaluative feedback from binary outcomes $\{-1, +1\}$, using Gaussian processes (GPs) for one-class classification is a more appropriate choice for probabilistic modelling of the objective function being maximized. At the observed inputs, the latent variables $\mathbf{f} = \{f(x_i)\}_{i=1}^n$ have a Gaussian prior distribution. Given a training set $D = (\mathbf{X}, \mathbf{y})$, the probabilistic model chosen $p(y_*|D, x_*)$ aims to predict the target value y_* for a new sample x_* by computing the posterior probability $p = (\mathbf{f}|\mathbf{X}) = N(\mathbf{f}|\mu, \mathbf{K}_{f,f})$, where $\mathbf{K}_{f,f}$ is the covariance matrix and μ is the mean function. Since neither of the class labels is considered more probable, the prior mean is often set to zero. As a GP generate an output z in the range $(-\infty, \infty)$, a monotonically increasing response function $\sigma(z)$ is used convert the GP outputs to values within $[-1, 1]$ which can be interpreted as class probabilities (Rasmussen and Williams, 2006). In particular, the latent GP \hat{f} defines a Gaussian probability density function p_f^x for an input $x \in \mathbb{X}$. At any given x , the corresponding probability density for the positive class (success) is defined as p_π^x .

The inference step for conditioning the posterior GP on sampled observations \mathbf{X} and \mathbf{y} require computing the following integral to determine the posterior \hat{f} at any x_* over \mathbb{X} :

$$p(\hat{f}_*|\mathbf{x}, \mathbf{y}, x_*) = \int p(\hat{f}_*|\mathbf{x}, \mathbf{y}, x_*) p(\mathbf{f}_*|\mathbf{x}, \mathbf{y}) d\mathbf{f}_* \quad (1)$$

In this equation, \mathbf{f}_* represents the GP prior on the latent function at x_* . The main idea is to use a mean of the prior with a smaller value than our positive class labels (i.e., $y=1$), such as a zero mean. This restricts the space of probable latent functions to those whose values gradually decrease when being far away from observed points. By choosing a smooth covariance function such as the simple squared exponential

$$k((\mathbf{x}_r, \mathbf{x}_m|\zeta, \ell)) = \zeta^2 \exp\left(-\frac{\|\mathbf{x}_r - \mathbf{x}_m\|^2}{2\ell^2}\right) \quad (2)$$

an important subset of latent functions is obtained. The parameter ℓ defines its characteristic length scale whose value must be optimized for improved discriminatory power, and ζ^2 is the magnitude parameter. The GP mean μ_* typically decreases for

inputs distant from the training data and can be directly utilized as a measure of membership for the positive class. Conversely, the variance σ_*^2 of the prediction is always increasing for distant inputs, which suggests that the negative variance value can serve as an alternative criterion for discriminating operating conditions for successes from those end-use properties are obtained. As it is shown by Rasmussen and Williams (2006), if σ is the Gaussian cumulative density function, the expected value of the probability of success (posterior) at x_* can be approximated by

$$\mathbb{E}[p_{\pi}^x] = \bar{\pi}(x) = \Phi\left(\frac{\mu_*}{\sqrt{1 + \sigma_*^2}}\right) \quad (3)$$

3. Bayesian optimization

Mathematically speaking, given the problem of finding a global maximum of the unknown objective function $\bar{\pi}$ over \mathbb{X} which is defined based on a priori knowledge

$$x_{best} = \arg \max \bar{\pi}(x), x \in \mathbb{X} \quad (4)$$

The sequential Bayesian experimental design algorithm in Fig. 1 selects, at each iteration i , the operating conditions x_{i+1} for the next experiment and observe the binary outcome y_{i+1} . After n experiments, the algorithm makes a final recommendation x^* which represents the algorithm's best estimate (based on the available experimental budget) of the operating conditions for which the probability of success is the global maximum.

The Bayesian optimization algorithm (see Fig. 1 for details) resorts to a selection metric (often known as *acquisition function*) that allows selecting the next experiment to be made using a trade-off between exploration and exploitation. In this work, the expected improvement for stochastic binary outcomes proposed by Tesch et al. (2013) is used. By querying the GP posterior at each point in \mathbf{X} , and letting

$$\tilde{\pi}_{max} = \max \bar{\pi}(x), x \in \mathbf{X} \quad (5)$$

The improvement I_{π} for stochastic binary outcomes at any $x \in \mathbb{X}$ is defined as follows

$$I_{\pi}(\pi(x)) = \max(\pi(x) - \tilde{\pi}_{max}, 0), x \in \mathbb{X} \quad (6)$$

The corresponding expectation for I_{π} over \mathbb{X} is

$$\mathbb{E}I_{\pi}(\tilde{\pi}_{max}) = \max \int_{\sigma^{-1}(\tilde{\pi}_{max})}^{\infty} (\sigma(z) - \tilde{\pi}_{max}) p_f^x(z) dz \quad (7)$$

4. Case study

4.1. Process description

The proposed methodology is tested by simulation of the emulsion polymerization of styrene. The reactor operates in fed-batch mode, with two inlets: the monomer feed (x_1) and the chain transfer agent (CTA) feed (x_2), both measured in mol/s. The reactor is initially charged with solvent and an initiator, and is seeded with particles of three

different sizes. As the monomer is fed, polymer chains growth unevenly, giving rise to a distribution of chain lengths (and molecular weights). The CTA modifies the length of the chains. The end-use properties of the product depend on the distribution of molecular weights, both in weight (MW_w) and in number (MW_n).

Algorithm: Bayesian optimization

- *Inputs:* $n_0, n, D_0 = \{\mathbf{X}_0, \mathbf{Y}_0\}$
- ▷ **For** $i = n_0 + 1$ to n **do**
 - Select new x_i by optimizing the expected improvement $EI_\pi(x)$

$$x_{i+1} = \arg \max EI_\pi(x, D_i), x \in \mathbb{X}$$
 - Do the next experiment at x_{i+1} and observe y_{i+1}
 - Augment dataset $D_{i+1} = \{D_i, (x_{i+1}, y_{i+1})\}$
 - Update statistical model \hat{f}
- ▷ **End for**
- $x^* = \arg \max \bar{\pi}(x), x \in \mathbf{X}_n$
- *Output:* x^*

Figure 1. Bayesian optimization algorithm for stochastic binary outcomes.

In this work, the melt flow index (MI) and the tensile strength (TS) are the end-use properties of interest. A batch is considered successful if both properties are kept within their desired intervals:

$$1.25 \times 10^{-4} < MI \leq 7.5 \times 10^{-4} [g/min]; 6900 < TS \leq 7200 [psi] \quad (8)$$

These end-use properties are correlated with the molecular weights as follows:

$$MI = \frac{30}{(MW_w^{3.4} \times 10^{-18} - 0.2)} \quad (9)$$

$$TS = 7390 - 4.51 \times 10^8 \left(\frac{1}{MW_n} \right) \quad (10)$$

The variability due to uncontrolled factors is introduced in the simulation as a 5% perturbation (normally distributed) in the initial charge of seeded particles and the initiator concentration. Details of the stochastic simulation model for the polymerization process can be found in Colombo et al. (2016). The contour lines for the probability of success in the ROI are shown in Fig. 2.

Figure 2. Contour plots for the probability of success in the case study.

4.2. Results

The proposed algorithm is tested for the case study described in Section 4.1 using the stochastic simulation model. In each trial, 50 experiments are performed before the method selects the optimal operation condition x^* that maximizes π . Experiments are divided between an initial sampling set (with n_0 points) and experiments designed based on Bayesian optimization. Thus, the algorithm in Fig. 1 is tested using 100 independent sequences generated from different number and selection of the initial experiments. The initial n_0 points were chosen using Latin hypercube sampling. A simple squared exponential covariance with fixed hyper-parameters (length scale of $e^{0.75}$ and signal variance of e^5) was used. Results obtained are shown in Table I.

Fig. 3 depicts the GP approximation $\bar{\pi}(x_1, x_2)$ of the probability of success, after 50 experiments in one of the independent trials made, obtained using the proposed algorithm in Fig. 1. It is worth noting that for the process simulation model the (assumed unknown) maximum probability of success is 0.97.

5. Concluding remarks

The role of Bayesian optimization in sequentially making decisions regarding operating conditions aiming at maximizing the probability of success in achieving the desired end-use properties has been discussed. The proposed algorithm is based on expected improvement for stochastic binary outcomes and one-class classification using Gaussian processes. Simulations results are promising bearing in mind the level of variability considered and that Bayesian optimization does not require a first-principles model.

Abstract

This paper approaches the tactical distribution planning in the downstream oil supply chain (DOSC) under uncertain market conditions by using robust optimization (RO). The tactical RO model makes use of general polyhedral uncertainty sets, which encompass the so-called ramping constraints. These restrain the maximum variation in the random parameters, so that the time correlation present in the input time series can be captured, as well as the level of conservatism of the robust solutions can be adjusted. Additionally, autoregressive integrated moving average (ARIMA) techniques and Monte Carlo simulation are used in order to determine the parameters of the uncertainty sets. An example based on the Portuguese DOSC is studied so as to confirm both the applicability and adequacy of the developed RO models to real-world problems.

Keywords: Robust optimization, Uncertainty, Downstream Oil Supply Chain.

1. Introduction

The oil supply chain (OSC) can be split up into an upstream segment, which comprises the oil production activities, a midstream segment, which encompasses the activities related to oil refining, and a downstream segment, which focuses on the distribution and marketing of oil products (Lima et al., 2016). The OSC aims to move crude oil from its reservoir, process it into refined products at oil refineries, and then deliver the oil products to the final consumers. Generally, the greatest part of oil products is majorly delivered using pipelines from oil refineries to storage depots, and by tanker trucks from these to the local markets.

Such complex supply chain is subject to uncertainties that may arise from many sources and interfere in its management. Essentially, uncertain market conditions take shape in oil production fluctuations, unsettled processing capacities, unstable prices and changeable demands. Usually, companies within this uncertain environment have imprecise information about their operation, even though they must make agile and proper decisions. A means to accomplish better performances is the optimization of the supply chain. Hence, efficient optimization tools need to be designed to further assist managers in making more robust decisions with regards to the diverse uncertainty sources inherent to the oil market.

This work follows this need and addresses the tactical problem in oil product distribution planning under exogenous uncertainties via RO. Therefore, uncertainties are introduced in price and demand for crude oil. Zugno and Conejo's robust formulation (Zugno and Conejo, 2015) is used to manage uncertainty in the random parameters by

way of budget uncertainty sets that can consider the time dependency of the input data. ARIMA models are adjusted to the input data, and then a systematic procedure to generate scenarios for the random parameters are created based on Monte Carlo simulation. Therefore, the parameters of the uncertainty sets are estimated from the simulated data.

The developed RO approach is applied to solve a real case study on the product distribution in Portugal.

2. Problem definition

The DOSC includes a set of oil companies, oil refineries, storage depots, retail service stations and transportation modes that aims to meet the oil product demands in a certain geographical area. Its planning problem under uncertainty can be stated as follows:

Given a vertically integrated DOSC, where an oil company controls the refining processes, logistics operations and trade of refined products;

Determine the optimal tactical planning, with uncertainties arising from oil demand and price, which consists of refinery production planning, distribution planning, inventory policies and customer fulfilment/satisfaction;

Subject to material balance, yield fractions, processing capacity, storage capacity and transportation capacity restrictions;

In order to maximize the total profit for the downstream oil supply chain.

3. Robust optimization approaches

Lima et al. (2018) developed a multistage stochastic programming to solve the distribution problem of refined products under different uncertainties in market conditions. The main drawback of this scenario-based approach was the great number of required scenarios to represent the random parameters over the time horizon, which lead to high problem solution times. However, the distribution planning based on a RO formulation avoids such increase in complexity and solution difficulties.

Here, the tactical DOSC problem is alternatively formulated as RO model based on the work developed by Zugno and Conejo (2015), considering the same sources of uncertainty, namely, demand and price for crude oil.

3.1. Overview of robust optimization

In RO, random parameters are described by uncertainty sets instead of using probability distributions like stochastic programming does. In general, a RO problem is formulated in order to provide the optimal solution for the worst possible value that the random parameter can take on within the established uncertainty set. In the following, the general RO formulation is presented, which considers the different uncertain parameters affecting constraints and/or objective function. Thus, a general RO problem without recourse takes the general form shown in (1) (Morales et al., 2013):

$$\begin{aligned} & \min_x \max_u \{f(x, u), u \in U\} \\ & \text{s.t. } g_i(x, u) \leq 0, \quad \forall i, \forall u \in U, \\ & \forall x \in X. \end{aligned} \tag{1}$$

Variable $x \in X$, which can be declared as continuous and/or discrete, refers to the decisions to be made before the realization of the random parameter $u \in U$. Note that u takes values within the uncertainty set U . f is a real-valued function to be minimized and $g_i, \forall i$, corresponds to a set of restrictions. Problem (1) can be rewritten as in (2):

$$\begin{aligned} & \min_{x,z} z \\ & \max_u \{f(x, u), u \in U\} \leq z, \\ & \max_u \{g_i(x, u), u \in U\} \leq 0, \quad \forall i, \\ & \forall x \in X. \end{aligned} \tag{2}$$

The unconstrained variable z represents a proxy for the objective function. Thus, the maximization of the real-valued function f over u does not exceed this new real-valued variable z , while all constraints $g_i, \forall i$, must be satisfied for all values assigned to u from within the uncertainty set U . A proper manner to solve Problem (2) is to transform this bilevel problem into a single-level problem by dualizing the lower level problems, if these u -problems are convex, and then incorporating the established dual problems to the upper level problem, the x -problem, provided that strong duality holds.

3.2. Uncertainty set definition

Assume that the uncertain parameters vary within convex and budget uncertainty sets, being defined by the following set of linear inequalities from Eq.(3) to Eq.(7):

$$\Delta u_t = \Delta u_t^+ - \Delta u_t^-, \quad \forall t \in T, \tag{3}$$

$$0 \leq \Delta u_t^+ \leq \Delta u_t^{max}, \quad \forall t \in T, \tag{4}$$

$$0 \leq \Delta u_t^- \leq \Delta u_t^{max}, \quad \forall t \in T, \tag{5}$$

$$\sum_t \frac{\Delta u_t^+ + \Delta u_t^-}{\Delta u_t^{max}} \leq \Gamma, \tag{6}$$

$$\frac{\Delta u_t}{\Delta u_t^{max}} - \frac{\Delta u_\tau}{\Delta u_\tau^{max}} \leq \rho_{t\tau}, \quad \forall t, \tau \in T. \tag{7}$$

Eq.(3) splits the deviation of the uncertain parameter Δu_t for any time point t into a positive component Δu_t^+ and a negative component Δu_t^- , which are both declared as positive variables. Eq.(4) and Eq.(5) define the lower bound (i.e., zero) and the upper bound Δu_t^{max} for both types of deviations, respectively. Eq.(6) assures that the sum of the normalized absolute values of both deviations, across all time points t , must not exceed the user-defined budget of uncertainty Γ . Eq.(7) enforces the temporal correlation between the realizations of the uncertain parameter Δu_t by limiting the difference between the normalized deviations for any two different time points (i.e., t and τ) to a given measure $\rho_{t\tau}$.

3.3. Robust optimization approach for oil demand and price uncertainties

The proposed RO model arises from a bilevel problem, whose lower-level problems aim to determine the most adverse values for the oil price and demand, and whose upper-level problem seeks to define an optimal solution even for the worst-case scenarios. The level of uncertainty is controlled by the budget of uncertainty Γ that provides a way to balance the level of conservatism of the robust solutions. After dualizing both inner problems and incorporating them into the outer max-problem (by appealing to strong

duality), a RO formulation that relies on Zugno and Conejo (2015) is established to deal with uncertainties in oil price and oil demand.

For the sake of brevity, the RO model is qualitatively stated by a description of the its objective function and its constraints. However, the objective function of the RO model comprises an unconstrained real-valued variable *Profit* that must be maximized, being subject to a constraint that enforces that the sum of margins and costs must remain below this variable *Profit*. The former comprises the margins of refineries, storage depots and retail market, while the latter includes the costs of exportation, importation, lost demand, primary and secondary transportation and oil and oil products inventories. In addition, a protection term is added to this prior constraint in order to provide the suitable protection against its violation when the oil price varies. Besides, some constraints must be defined in order to quantify the sensitivity of the system to variations in oil price. Also, the RO model is subject to the following set of network constraints: flow balance, inventory balance, oil procurement, flow capacity, storage capacity, refining capacity, yield fractions, nonnegative and integrity. The uncertainty regards the independent coefficients of the oil procurement constraint (right-hand-side), that is, the oil demands. Hence, an additional binary variable with fixed value of 1 is introduced into the model in order to include the oil demands into the coefficient matrix (left-hand-side) – see Li and Ierapetritou (2008). Additionally, the oil procurement constraint includes a buffer term to avoid violation due to variation in oil demand. Other constraints must be established to quantify the sensitivity of the system to changes in oil demands.

4. Case study

The case study is based on the Portuguese industry, which consists of two oil refineries (Sines and Matosinhos), three storage depots (Boa Nova, CLC, Mitrena), 278 local markets (i.e., all the Portuguese municipalities in mainland Europe), and four transportation modes: oil tanker, tank truck, tank wagon and pipeline. Crude oil is received at Sines and Matosinhos, which transform it into eight refined products, namely, butane, diesel, fuel oil, gas oil, gasoline 95, gasoline 98, jet fuel and propane. Both refineries supply storage depots and local markets and can export surplus of refined products abroad, while storage depots supply local markets and Mitrena depot may compensate the shortage of refined products by importing from overseas markets. The product distribution is undertaken by oil tanker, tank truck, tank wagon and pipeline for the primary distribution, and only by tank truck for the secondary distribution. The planning horizon covers six monthly cycles.

5. Results and discussion

The RO mixed integer linear programming (MILP) model was implemented in GAMS 24.5.6 and solved using CPLEX 12.6 on a processor Intel(R) Xeon(R) CPU E5-2660 v3 @ with 2.60 GHz (2 processors) and 64 GB RAM memory, for a 0% optimality gap.

5.1. Simulation study

As abovementioned, the oil demand and price are treated as stochastic processes that are characterized via ARIMA techniques. For this purpose, monthly time series for oil demand and price in Portugal from January 2008 to December 2016 are analyzed, addressing 108 observations for each time series. Through ARIMA fits, it is possible to represent the probability distributions of both random parameters through the generation of scenarios. In order to make this scenario generation process efficient and reproducible, a systematic procedure based on Monte Carlo simulation is established by replacing the

error terms ϵ_t^P and ϵ_t^D in the ARIMA fits, Eq.(8) and Eq.(9), by normal distributions with zero mean and constant variance – $N(0, \sigma_{\epsilon^P}^2)$ and $N(0, \sigma_{\epsilon^D}^2)$ distributions.

The ARIMA model below is used to generate scenarios to represent the crude oil prices for the six-month time horizon from January 2017 to June 2017:

$$\ln(y_t^P) = \ln(y_{t-1}^P) + \phi_1 \ln(y_{t-1}^P) - \phi_1 \ln(y_{t-2}^P) + \epsilon_t^P, \quad \forall t \in T, \quad (8)$$

where y_t^P represents the oil price stochastic process, ϕ_1 is the autoregressive parameter of order 1, whose value estimate is 0.401 at 5% significance level, and ϵ_t^P is a white noise.

Additionally, the next seasonal ARIMA model is employed to produce scenarios to represent the crude oil demands for the same six-month time horizon:

$$\ln(y_t^D) = \ln(y_{t-1}^D) + \ln(y_{t-12}^D) - \ln(y_{t-13}^D) + \epsilon_t^D - \theta_1(\epsilon_{t-1}^D) - \theta_1(\epsilon_{t-12}^D) + \theta_1\theta_1(\epsilon_{t-13}^D), \quad \forall t \in T, \quad (9)$$

where y_t^D is the oil demand stochastic process, θ_1 is the regular moving average parameter of order 1 and θ_1 is the seasonal moving average parameter of order 1, whose values are respectively -0.869 and -0.856 at 5% significance level, and ϵ_t^D is a white noise. For more details about the adjustment of these autoregressive models, the interested reader is referred to Lima et al. (2018).

After running 10000 simulations and, hence, 10000 scenarios are generated for oil price and demand, the nominal values and deviation amplitudes of the uncertainty sets are estimated from the simulated data, which correspond respectively to the forecast mean and maximum deviation for oil price and demand at each time point over the time horizon. In addition, the values for the budgets of uncertainty Γ^{price} and Γ^{demand} are also estimated from the simulated data as the average relative deviations. Thus, the budget of uncertainty Γ^{price} , which takes values within the range [0,6], is defined as 1.16, while the budget of uncertainty Γ^{demand} , which in turn assumes values within the range [0,1], is set as 0.20. However, the values of ρ_{tt}^{price} and ρ_{tt}^{demand} are estimated as the maximum total relative deviation between time points observed in the simulated data.

5.2. Comparison between robust and stochastic approaches

Compared to the scenario-based stochastic programming approach with 1024 scenarios and 1365 tree nodes (Lima et al., 2018), the robust optimization approach has the major benefit of not leading to a large optimization problem due to the number of random parameters and their possible realizations. Table 1 reports the statistics for both optimization models. Indeed, the case study solved by the stochastic programming (SP) model results in many more constraints and variables than the robust optimization (RO) model, even though this RO formulation comprises a binary variable. The computational effort to solve the SP model is extremely high when compared to the one needed to solve the RO model, as highlighted by the solution time required by the solver to settle the optimization problem.

Table 1: Model statistics

Cases	Scenarios	Tree nodes	Variables		Constraints	Profit (€)	Solution time (s)
			Binary	Continuous			
RO	1	-	1	336,550	159,914	2,613,704,721	7.937
SP	1,024	1,365	-	12,691,756	5,346,530	2,771,474,827	1,076.700

Table 2 breaks down the network profit for the RO and SP approaches into margins and costs components, while Table 3 presents the corresponding network plans that are described by the set of decision variables that control the network flows.

Cases	Volumes					Inventory volumes					
	Exported	Imported	Lost	Oil delivery	Processed	Primary	Secondary	Crude oil	Refineries	Depots	Markets
RO	1.238	0.793	1.501	6.091	7.117	6.055	4.111	0.576	0.301	0.073	0.079
SP	1.483	0.932	1.105	6.457	7.620	6.313	4.317	0.671	0.304	0.089	0.079

The composition of the network profit is closely linked to the established network planning as reported in Table 2 and Table 3. Overall, the SP approach outperforms the RO approach with regards to network profit by 6.11%. Specifically, the stochastic approach defines an expected profit and a flexible network planning that is balanced for all the considered scenarios, while the RO approach determines a total profit associated to a network plan that is based on the worst-case scenario for oil price and demand, in accordance with the levels of uncertainty that are adjusted by the budgets of uncertainty (i.e., $\Gamma^{price} = 1.16$ and $\Gamma^{demand} = 0.20$). In conclusion, the RO approach provides robustness of the established network planning by decreasing the network profit, while the level of conservatism of the robust solutions can be adjusted by the decision maker.

6. Conclusions

In this paper, a robust optimization model based on Zugno and Conejo (2015) is developed to cope with oil price and demand uncertainties, in the tactical management of the DOSC. The robust approach is also compared with its stochastic counterpart, and the results show that the robust model with well-defined budgets of uncertainty can adequately address oil price and demand uncertainties by generating robust planning and suitable profits, but both results are lower than the ones obtained for the stochastic model. As advantage, the robust approach avoids the computational burden inherent to the stochastic one. As future works, adaptive robust optimization and decomposition methods will be explored aiming to provide dynamic robust solutions for the studied problem, where a deeper comparison between robust and stochastic models will be performed.

Abstract

In the light of the growing renewable energy generation, matching of electricity supply and demand has become increasingly challenging. By participating in demand side management programs, industry can contribute to counter this challenge. However, the frequent adjustment of operation conditions according to volatile electricity prices leads to additional dynamic loads for the equipment. In this work, a mixed-integer linear programming based discrete-time model is proposed for scheduling of a single air separation unit, explicitly considering fatigue of equipment occurring during transient operation. Besides constraints for describing the feasible region and the process dynamics, this model includes constraints for considering mechanical fatigue of some key equipment. The resulting model is applied to investigate the impact of mechanical constraints on the potentials of demand side management.

Keywords: Scheduling, Fatigue, Mechanical limitations, Air Separation, Demand Side Management

1. Introduction

Demand side management (DSM) has been recognized as one of the key enablers for a cost-efficient energy transition. Especially, energy-intensive industries can contribute to the energy transition by offering high potentials for grid stabilization in terms of DSM and at the same time mitigate their own economic risks related to volatility in energy supply. Depending on the electricity market the industry has various measures to participate in DSM programs, whereby the programs can be distinguished into two main DSM categories (Charles River Associates, 2005): Energy efficiency (EE) and demand response (DR). In the first category attempts are made to increase the efficiency of the industrial process and thus to reduce the energy consumption. The second category is focused on the load profile adjustment, driven by market incentives. A more detailed explanation of DSM as well as a comprehensive review of existing works on planning and scheduling for industrial DR is provided in the work of Zhang and Grossmann (2016). Here, contributions are listed which address the application of DR in various energy-intensive industries such as aluminum, cement, chlor-alkali, steel, and air separation.

In particular, the operational planning (scheduling) of cryogenic air separation units (ASUs) under time-sensitive electricity prices has gained considerable attention. As one of the first, the work of Daryanian et al. (1989) addressed the topic of DSM, using a simplified model. For a more accurate representation of an ASU, Ierapetritou et al. (2002) proposed the notion of operating

modes to take into account that one process may show operation regions with different configurations and states. In such a mode-based model, each operating mode is defined by a specific feasible region and the process can only operate in one of these operating modes in each time step (Zhang and Grossmann, 2016). Based on this model, Karwan and Kebulis (2007) as well as Mitra et al. (2012, 2013) further developed the concept of mode-based models. Moreover, Mitra et al. introduced additional constraints to better capture the process dynamics, plus addressing the uncertainty in forecast of electricity prices. The aspect of uncertainty related to electricity prices, product demand, and dispatchable DR is also investigated in other studies (Ierapetritou et al., 2002; Mitra et al., 2014; Zhang et al., 2015, 2016a). Once again based on the concept of mode-based models Mitra et al. (2014) described a multiscale capacity planning model for finding the optimal investment strategy for purchasing new components or upgrading existing components over a time horizon of multiple years. A further development of the mode-based modeling approach was proposed by Zhang et al. (2015), whereby each mode is specified by a Convex Region Surrogate (CRS) model according to Zhang et al. (2016b). In contrast to all aforementioned works Manenti and Rovaglio (2013) have increased the number of ASUs to investigate the optimization of gas supply networks, applying multiscale approaches to implement this so-called plant-wide or enterprise-wide optimization. The same topic was addressed in Zhang et al. (2016c) whereby the combination of mode-based modeling approach and CRS models is used to model a network of continuous power-intensive processes. A similar approach was applied by Zhou et al. (2017) to examine the optimal scheduling of a real-world production network.

As can be seen here, a great deal of effort has gone into the improvement of approaches for planning and scheduling power-intensive processes under time-sensitive electricity prices, whereby the plants (respectively process networks), the electricity markets with their energy contracts as well as uncertainties of input variables are described with increasing detail. However, the participation in DSM programs may be associated with frequent adjustment of operating conditions and thus triggers the necessity for a paradigm change in plant design and operating philosophies, away from static conditions towards transient operation. Consequently, process equipment is increasingly subjected to additional dynamic loads and the resulting stress is potentially reducing its lifetime. In order to ensure mechanical integrity of all plant components over the whole life span, the lifetime consumption due to transient operation has to be considered in both plant design and operations planning (scheduling).

2. Model formulation

In this work, a method is proposed for explicitly considering fatigue of equipment occurring during transient operation. In the following section, the method and the related optimization model is described in more detail.

Normally, a process is modeled by using detailed equations describing the heat and mass balance of each apparatus. However, the non-linear characteristic of these equations leads to a non-linear optimization model that is hard to solve in particular if the time horizon increases. For this reason, another approach is chosen. Similar to Mitra et al. (2012) the plant is described applying a data based surrogate model; more specifically, results from steady-state process simulations are used to represent the feasible region of the plant. In terms of the steady-state simulations, a highly detailed simulation model was applied to generate the data base for the surrogate model. For example, the simulation model does not only include equations for capturing the basic heat and mass balance but also detailed equations for describing the realistic behavior of the installed equipment in off-design, i.e., partial load and over load. More precisely, it covers inter alia: load-dependent efficiency and boundaries of the turbo compressors and turbines, load-dependent heat transfer, and hydraulic behavior of process equipment and piping. Consequently, by means of this detailed simulation model the steady-state behavior within the feasible region and its boundaries can be well described, but also a representative data base can be generated for the surrogate model. For

approximating the non-linear characteristic of this data base, a piecewise linear surrogate model is applied.

In a scheduling model, the time can generally be represented applying a discrete- or continuous-time formulation. Here, the optimization model is structured as discrete-time scheduling model, since in contrast to continuous-time models discrete-time model generally show better computational performance in terms of the application to large-scale problems. Castro et al. (2009) showed that only small-sized problems can be solved efficiently by continuous-time models, whereas comparable discrete-time models can handle large-scale problems.

2.1. Feasible region

Along the lines of aforementioned studies, this study also applies the approach of mode-based models, whereby a mode is defined as a set of operating points that show the same set of active discrete operating decisions (i.e., selection of running machines). By using this approach, discrete operating decisions of a plant can be distinguished by selecting various operating modes. But, within each mode the operating points vary only in terms of the continuous variables (i.e., flow rate of material). For capturing these variations each mode is separately described using the surrogate models as described above.

The focus of this study lies on investigating the impact of mechanical fatigue on optimal plant operation. For this reason, the feasible region of the plant is only considered in a reduced manner to keep the optimization model simple. More precisely, the feasible region of each mode $m \in M$ is spanned by several steady state operation points ($i \in I_m$) and the consecutive interpolation between two adjacent points results in a piecewise linear surrogate model. Note, that this surrogate model may be thought of as path of lines through the feasible region. In order to capture non-linear characteristics of various attributes within the region, the path can be easily adapted by adding further operation points within this subregion. Figure 1 illustrates such path/surrogate model in a two-dimensional product space with the products A and B .

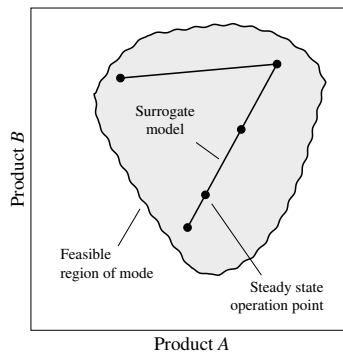

Figure 1: Visualisation of surrogate model within the feasible region of an arbitrary mode.

The plant is captured by the combination of several of these modes, whereby the feasible regions of the modes can overlap, but for each discrete time step $t \in T$ only one mode $m \in M$ can be selected.

2.2. Mass balance

A mass balance is implemented to capture the relationship between production, export and content in the storage facilities. The export EXP_c^t is defined by the demand of the respective product c .

Over the whole observation period, the production PRO_c^t must be equal to or higher than the total export to guarantee the demands of the customer. This relationship can be expressed for each product in the set C by

$$\sum_{t \in T} PRO_c^t \geq \sum_{t \in T} EXP_c^t \quad \forall c \in C. \quad (1)$$

The content CON_c^t of such storage facilities can be described by applying the mass balance:

$$CON_c^t = CON_c^{t-1} - EXP_c^t + PRO_c^t \quad \forall t \in T, \forall c \in C^{liq}, \quad (2)$$

$$CON_c^{min} \leq CON_c^t \leq CON_c^{max} \quad \forall t \in T, \forall c \in C^{liq}. \quad (3)$$

Additionally, the content must satisfy the technical requirements of the installed storage facility (CON_c^{min} and CON_c^{max}), whereby the Equation (2) is only valid for the reduced set of liquid products C^{liq} .

2.3. Transitions

The surrogate models only capture the plant itself – the steady-state behavior within the feasible region and its boundaries – but not process dynamics. However, a transient plant operation implies frequent transitions between several operating points and thus the introduction of representative transitional states and associated differential constraints is necessary to include the process dynamics in the scheduling model.

In a mode-based model all transitions can be distinguished in two major types: transitions between operating points which are assigned to one operation mode or transitions which are assigned to different operation modes. Transitions of the former type are basically dominated by a differential constraint that limits the change in power consumption within a defined time slot, whereas various logical constraints are used with respect to the second type of transitions to define permitted transitions as well as specific operation sequences.

2.4. Mechanical fatigue

As mentioned above, fatigue design is considered for some key equipment in order to ensure mechanical integrity over the whole plant lifetime. More specifically, the estimated life expectancy of machinery, e.g. compressors and of heat exchangers is integrated in the mixed-integer linear programming (MILP) problem by using equipment specific parameters. The concept may however easily be extended to other process components (e.g., piping).

The lifetime of compressors can be considered in a simplified way by limiting the number of starts according to the fatigue design of the compressor casings and the electrical drives. More precisely, the maximum number of starts per day is usually kept under a machine-specific limit following the recommendations of the machine manufactures. For integrating these recommendations binary variables and logical constraints are added to the MILP to count and limit the start per day and thus prevent excessive loads for the machines.

In terms of heat exchangers there are two aspects affecting its lifetime: Purely mechanical stress from pressure cycling and thermo-mechanical stress originating from transient temperature profiles. Similar to the previously outlined compressors, design numbers of pressure cycles at specified stress levels are specified during the fatigue design. By using this number as a reference, the lifetime consumption due to the first aspect can be described in a simplified way as a linear function of the number of pressure cycles. Lifetime consumption due to the second aspect is considered by implementing equipment-specific results of a thermo-mechanical stress analysis – generated by dynamic FEM simulations (finite element method) – in a piece-wise linear function. As worst-case scenario, both aspects can be captured by applying the approach of linear damage accumulation.

2.5. Electricity market

Specifics about energy markets are primarily dependent upon their geographical location and originate from differences in power generation technology portfolios, degrees of integration of local electric energy grids as well as regulatory background. The location of the plant and its associated energy market thus imply large impact upon the optimal operation strategy. Consequently, the energy market requires modeling in an adequate manner.

2.6. Objective function

As mentioned in section 1 the objective of DR is the load profile adjustment according to market incentives and thus the minimization of operational expenditure (OPEX). With regard to ASUs the OPEX is primarily characterized by energy costs, caused by the electric-driven machines of the compressors. Hence, the objective can be formulated as the sum of the product of the electrical power consumption and the corresponding electricity price for each time step.

3. Illustrative Examples

The above outlined model is used to generate illustrative examples investigating the impact of mechanical fatigue on the potentials of DSM, more precisely on the objective during the operation of a specific ASU.

The examples are performed using an air separation plant, which mainly produces two products, liquid oxygen (LOX) and liquid nitrogen (LIN). Each liquid product can be stored in a separate storage tank. Gaseous products like nitrogen are not considered as such to keep the example simple. Consequently, a merchant liquid plant is considered that supplies a local gas market without having on-site customers.

The demand of each liquid product and state of the storage facilities are described by applying the constraint (1) and (2), respectively. Since, the impact of technical limitations on the plant operation can be investigated independently of the fluctuating product delivery rate, a constant average demand is specified for each product.

The plant is described using this work's approach along with realistic constraints in order to capture its performance, dynamics and the fatigue design of its key equipment. More precisely, the maximum number of starts per day is specified for each machine as well as the design number of allowed pressure cycles and the equipment-specific results of thermo-mechanical stress analyses for heat exchangers. Note, that these results are specific to the installed type of heat exchanger and strongly depend on the assumed operation schemes for shutting down the plant, leaving it in cold standby, and restarting it.

For this study, the European Electricity Exchange (EEX) electricity market is considered, more precisely the hourly-based day-ahead prices of 2016 are applied for an integral period of 31 days (January 1, 2016 to January 31, 2016). The period is represented by using a moving horizon approach with 7 days forecast updated on a daily basis.

In order to investigate the impact of mechanical fatigue on the potentials of DSM, various cases with different fatigue specifications, regulatory constraints and tank volumes are defined. As a detailed discussion on all parameters is beyond the scope and will be supplied in future publications, only exemplary findings of a simplified reference scenario will be given at this point.

In this scenario, the consideration of mechanical fatigue during the operational scheduling leads to a modified operation profile. As a result, the plant is operated in a manner where the specified equipment lifetimes of 25 years can be met, whereas non-consideration would lead to the reduction of individual equipment lifetimes as much as one order of magnitude. However, the operation is

restricted by additional constraints and thereby is less optimal in terms of adjusting plant operation to the variations of the electricity market. In doing so, the objective function is increased only by about 2% maintaining the mechanical integrity of the plant on a long-term basis.

4. Conclusions & Outlook

This contribution demonstrates that the consideration of mechanical fatigue during operation scheduling is essential to avoid excessive stress on equipment as well as associated production losses due to damage driven down-times. Note, that equipment specific fatigue design may impact the potentials of scheduling of DSM strongly. Therefore, it is concluded that the proposed method allows the assessment of different equipment designs regarding their suitability for transient operation and thus allows for the optimization of plant designs for different energy market requirements.

In future work, the method shall be extended to include a more detailed description of the plant performance to exclude effects due to the reduced description of the feasible region.

Abstract

Optimal control of chemical reactors represents a challenging task, as their behaviour is non-linear, asymmetric, and highly affected by various uncertainties. The paper presents multivariable control of a laboratory chemical reactor, in which acetic acid reacts with sodium hydroxide and the neutralization process runs in the reaction mixture. The challenge is to optimize the set-point tracking of pH in the presence of parametric uncertainties. The control inputs are the volumetric flow rates of acid and base. The robust model predictive control was designed to fulfil the control task. To make the optimization problem more tractable, the LMI-based formulation of the convex optimization problem is implemented. The optimization problem has a special structure to ensure offset-free control performance and satisfaction of constraints on control inputs. Moreover, optimal control actions are calculated considering the multiple input system. As only the controlled output is measured, the state observer was designed and used. The main contribution of the paper is the experimental investigation of the LMI-based and state-observer-based robust model predictive control with integral action designed subject to input constraints. Control performance of the laboratory neutralization chemical reactor satisfies all control requirements.

Keywords: Robust control, model predictive control, chemical reactor, linear matrix inequalities.

1. Introduction

Continuous stirred-tank reactors (CSTRs) are frequently used plants in the chemical and food industries. Control of CSTRs is a challenging problem due to the non-linear behaviour, multiple steady-states, heat effect of the chemical reactions, time delay, and effect of various time-varying uncertainties, see (Luyben, 2007, chap. 1). The model predictive control (MPC) represents the state-of-art in the optimization-based control for complex systems (Maciejowski, 2000). The robust model predictive control optimizes control action according to the bounded uncertain parameters (Bemporad and Morari, 1999). LMI-based robust MPC represents an intensively developed class of control strategies, as it is handled via the convex optimization (Kothare et al., 1996). MPC requires the system model in the proper form. To find a suitable mathematical formulation for a complex system can be a challenging task. The model of monomer semi-batch emulsion copolymerization for MPC design was investigated in Chaloupka et al. (2017). The multi-parametric MPC enables to speed up the online evaluation of the complex controller, see Charitopoulos et al. (2017). Another perspective branch of predictive control, the economic MPC for an uncertain model of a heat exchanger was designed in Pour et al. (2017). The possibility to control a CSTR using the novel algorithm of hierarchical MPC providing the exact, global and multi-parametric solution of bi-level programming was investigated in Avraamidou and Pistikopoulos (2017). In Ho-

laza et al. (2018) an advanced reference-governor-based control of the chemical reactor was analysed. When comes to implementing the advanced control strategy, it is not straightforward to develop the software tool for the different groups of users, e.g., industrial users, technology developers, and researchers, see Varbanov et al. (2017). The software tool MUP for robust MPC design suitable for researchers is proposed in Oravec et al. (2017).

This paper presents particular results of our research focused on the advanced LMI-based robust MPC design for the chemical reactors. The work directly extends the results of previous work Oravec et al. (2017), where robust MPC was designed for the considered neutralization chemical reactor, but in the different control setup. In comparison to Oravec et al. (2017), the main contribution of this work originates in the investigation of the control performance by using two control inputs, i.e., the volumetric flow-rates of acid and base, respectively. The controlled output was pH of the solution in the outlet stream. As only the controlled output was measured, the state observer had to be used to estimate the system states. We redesigned the robust MPC subject to the extended vector of the system states and the integral action. The weighting matrices in the quadratic cost function optimizing the control performance were experimentally tuned. The paper demonstrates the benefits of the proposed robust MPC design strategy for set-point tracking problem.

2. Controlled Chemical Reactor

The controlled plant was a laboratory continuous stirred-tank reactor (CSTR) of Armfield PCT40. The main part of the chemical reactor is a reaction vessel that has volume $V = 1.5 \text{ dm}^3$. In the reaction vessel neutralization of sodium hydroxide (NaOH) and acetic acid (CH_3COOH) ran. The products of neutralization were sodium acetate (CH_3COONa) and water (H_2O). The chemical reaction is described as follows: $\text{NaOH}(\text{aq}) + \text{CH}_3\text{COOH}(\text{aq}) \rightarrow \text{CH}_3\text{COONa}(\text{aq}) + \text{H}_2\text{O}(\text{l})$. The controlled variable was pH (potential of hydrogen) of the outlet flow from the reaction vessel. The actual pH value was measured using a pH probe. Two retention tanks were used to store acid and base, and their volumes were $V_A, V_B = 100 \text{ dm}^3$, respectively. Two peristaltic pumps delivered solutions into the reaction vessel. Pump A ensured the required volumetric flow rate of acid and pump B dosed base into the reactor. Concentrations of input solutions were $c_A = 0.01 \text{ mol dm}^{-3}$ for acid, and $c_B = 0.01 \text{ mol dm}^{-3}$ for base. The volumetric flow rates of inlet streams were within $[0, 10] \text{ ml s}^{-1}$. The detail non-linear model of CSTR was derived in Holaza et al. (2018). For robust MPC design, the discrete-time domain of the uncertain controlled system was considered. Vertices of the controlled system were the linear state-space systems derived for all combinations of limit values of uncertain parameters. The set of uncertain controlled systems \mathbb{A} was represented by all systems lying in the convex hull of the vertices given by:

$$x(k+1) = A^{(v)}x(k) + B^{(v)}u(k), \quad x(0) = x_0, \quad y(k) = Cx(k), \quad (1a)$$

$$\left[A^{(v)}, B^{(v)} \right] \in \mathbb{A}, \quad \mathbb{A} = \text{convhull} \left(\left\{ \left[A^{(v)}, B^{(v)} \right], \forall v \right\} \right), \quad (1b)$$

where $k \geq 0$ is an element of the discrete-time domain, $x(k) \in \mathbb{R}^{n_x}$ is the real-valued vector of system states, $u(k) \in \mathbb{R}^{n_u}$ are control inputs, $y(k) \in \mathbb{R}^{n_y}$ are system outputs, x_0 is the measured or estimated vector of system initial conditions, $A \in \mathbb{R}^{n_x \times n_x}$ denotes the system-state matrix, $B \in \mathbb{R}^{n_x \times n_u}$ is the matrix of system inputs, $C \in \mathbb{R}^{n_y \times n_x}$ is the matrix of system outputs and $v = 1, \dots, n_v$. Parameter n_v represents the total number of uncertain system vertices. The matrix superscript (v) denotes the v -th vertex system of \mathbb{A} . Function convhull denotes the convex hull that maps original set to the smallest-volume convex set that includes the original set.

The system in (1) was normalized for the robust MPC design. The steady-state values were moved into the origin. The novelty of this experimental case study originates in using two actuators, i.e., the pump feeding the solution of acid and the pump dosing the solution of base into the reactor. The

vector of manipulated variables was defined as $u(k) = [q_A(k) - q_A^s, q_B(k) - q_B^s]^T$ and the vector of unmeasurable system states was $x(k) = [x_A(k) - x_A^s, x_B(k) - x_B^s]^T$. The measurable system output was $y(k) = [\text{pH}(k) - \text{pH}^s]$. The superscript s denotes the steady-state values that correspond with the operation point: $q_A^s = q_A = 5 \text{ ml s}^{-1}$ and $\text{pH}^s = 7$.

The experimental step-response-based identification of CSTR was performed to obtain the uncertain state-space system in (1) suitable for robust MPC design. The behavior of the chemical reactor was significantly non-linear and asymmetric and therefore the sets of upwards and downwards step responses were measured. As two actuators were considered, the step responses were measured as follows: (i) step changes of the volumetric flow rate of acid were done at the fixed volumetric flow rate of base, and (ii) step changes of the volumetric flow rate of base were done at the fixed volumetric flow rate of acid. The normalized step responses were identified to obtain two mathematical models:

$$G_A(s) = \frac{\Delta \text{pH}(s)}{\Delta q_A(s)} = \frac{Z_A}{T_A s + 1} e^{-D_A s}, \quad G_B(s) = \frac{\Delta \text{pH}(s)}{\Delta q_B(s)} = \frac{Z_B}{T_B s + 1} e^{-D_B s}, \quad (2)$$

where G_A, G_B are the transfer functions of the chemical reactor, Z_A, Z_B are the system gains, T_A, T_B are the time constants, and D_A, D_B are the time delays. The subscripts A, B denote the identification subject to the step changes of the volumetric flow rates of acid and base, respectively. The system parameters were identified in the form of interval uncertainties taking into account also the measurement noise to increase the robust control performance. The minimum, maximum and mean values of the parameter intervals are summarized in Tab. 1. The mean values represent the nominal system, i.e., an idealized system with no uncertain parameters. Without loss of the robustness guarantee, the time delays D_A, D_B were neglected, as their values were low in comparison with the associated time constants T_A, T_B . Finally, for the robust MPC design, the experimentally identified parameters of the transfer functions in (2) were transformed into the state-space system in the discrete-time domain (1) considering the sampling time $t_s = 10 \text{ s}$.

3. Robust MPC with Integral Action and State Observer

For robust MPC design, the neutralization chemical reactor was modelled using the state space system in (1). The task was to calculate the gain matrix $F \in \mathbb{R}^{n_u \times n_x}$ of the state-feedback control law: $u(k) = F(k)x(k)$, to ensure the robust stability of the closed-loop system. The feedback law is based on the values of the system states $x(k) \in \mathbb{R}^2$. We measured only one output $y(k)$, i.e., the actual pH value of the solution in the outlet stream. Therefore, the state observer had to be implemented. The Luenberger observer was designed to estimate the vector of system states in each control step. Based on the nominal model of CSTR, the LQR-based strategy was applied to evaluate the optimal matrix of the observer $L \in \mathbb{R}^{n_x \times n_y}$. The weighting matrices were tuned as follows: $Q_L = \begin{bmatrix} 0.5 & 0 \\ 0 & 1 \end{bmatrix}$, $R_L = [0.1]$, to calculate the matrix of the state observer $L = [-1.1646 \quad 2.3917]$. In contrast to the well-known LQG, H_2 and H_∞ -based strategies, the main advantage of the proposed LMI-based robust MPC approach lies in its possibility to respect the constraints on control

Table 1: Identified parameters of the system transfer functions.

value	Z_A [s/ml]	Z_B [s/ml]	T_A [s]	T_B [s]	D_A [s]	D_B [s]
minimum	-2.7	0.7	92.9	94.6	2.9	1.8
mean	-1.5	1.5	137.9	134.2	4.1	3.3
maximum	-0.6	2.3	182.8	174.0	5.3	4.7

inputs and system outputs: $-u_{\text{sat}} \preceq u(k) \preceq u_{\text{sat}}$, $-y_{\text{sat}} \preceq y(k) \preceq y_{\text{sat}}$, $\forall k \geq 0$, where $u_{\text{sat}} \in \mathbb{R}^{n_u}$ and $y_{\text{sat}} \in \mathbb{R}^{n_y}$ are the symmetric boundaries. Moreover, the robust MPC implemented in the receding horizon control fashion significantly reduces the process-model mismatch. Control performance was optimized subject to minimization of the LQR-based quadratic quality criterion $J_{0 \rightarrow n_k} = \sum_{k=0}^{n_k} J(k) = \sum_{k=0}^{n_k} \left(\|x(k)\|_Q^2 + \|u(k)\|_R^2 \right)$, where $Q \in \mathbb{R}^{n_x \times n_x} \succeq 0$, $R \in \mathbb{R}^{n_u \times n_u} \succ 0$ are the weighting matrices, and n_k is the total number of control steps. For the considered robust MPC design procedure, the future performance of the controlled plant was calculated considering the infinity prediction horizon, i.e., $n_k \rightarrow \infty$. The control task was to ensure the offset-free set-point tracking for pH value. Therefore, the state-space system was extended to implement the robust MPC with integral action. Hence, the vector of system states $z \in \mathbb{R}^{(n_x+n_y)}$ was in the form: $z(k) = [x(k) \quad \sum_{i=0}^k e(i)]^T$, where e is the control error given by: $e = w - y$, and $w \in \mathbb{R}^{n_y}$ is the reference value. The technical details how to extend system in (1) using an integrator are in Oravec et al. (2017). The quadratic criterion had to be updated subject to the extended vector z :

$$\tilde{J}_{0 \rightarrow n_k} = \sum_{k=0}^{n_k} \tilde{J}(k) = \left(\|z(k)\|_{\tilde{Q}}^2 + \|u(k)\|_R^2 \right), \quad (3)$$

where $R \in \mathbb{R}^{n_u \times n_u} \succ 0$ is the weighting matrix of the control inputs, i.e., the volumetric flow rates of acid and base, respectively. $\tilde{Q} \in \mathbb{R}^{(n_x+n_y) \times (n_x+n_y)} \succeq 0$ is the weighting matrix for the extended vector of states z , and has the form: $\tilde{Q} = \begin{bmatrix} Q & 0 \\ 0 & Q_I \end{bmatrix}$, where $Q \in \mathbb{R}^{n_x \times n_x} \succeq 0$ is the partial weighting of the proportional controller action and $Q_I \in \mathbb{R}^{n_y \times n_y} \succeq 0$ is the partial weighting of the integral action. From the implementation point of view, it is not the straightforward task to set the weighting matrices of robust MPC, as one needs to tune at least $(n_x + n_y + n_u)$ parameters of the principal diagonals of the matrices Q , Q_I , R in (3). In the considered case of robust MPC design for CSTR, five parameters had to be tuned. The robust MPC designed by Kothare et al. (1996) and extended subject to the integral action solves the following optimization problem in each control step:

$$\min_{\gamma, X, Y, U} \gamma \quad \text{s.t.:} \quad \begin{bmatrix} 1 & \star \\ z & X \end{bmatrix} \succeq 0, \quad \begin{bmatrix} X & \star \\ Y & U \end{bmatrix} \succeq 0, \quad U_{i,i} \leq u_{\text{sat},i}, \forall i \in \mathbb{N}_1^{n_u}, \quad (4a)$$

$$\begin{bmatrix} X & \star \\ \tilde{C}(\tilde{A}^{(v)}X + \tilde{B}^{(v)}Y) & y_{\text{sat}}^2 I \end{bmatrix} \succeq 0, \quad \begin{bmatrix} X & \star & \star & \star \\ \tilde{A}^{(v)}X + \tilde{B}^{(v)}Y & X & \star & \star \\ \tilde{Q}^{1/2}X & 0 & \gamma I & \star \\ R^{1/2}Y & 0 & 0 & \gamma I \end{bmatrix} \succeq 0, \quad (4b)$$

where $v = 1, 2, \dots, n_v$, $i = 1, 2, \dots, n_u$, and the decision variables are: $X \in \mathbb{R}^{n_x \times n_x}$, $Y \in \mathbb{R}^{n_u \times n_x}$, $U \in \mathbb{R}^{n_u \times n_u}$, and $\gamma \in \mathbb{R}^{1 \times 1}$. The matrices A , B , C of the system in (1) extended subject to the integral action were derived in Oravec et al. (2017). The symbol \star denotes the symmetric structure of the matrix. y_{sat}^2 denotes the element-wise power of 2. Technical details of the optimization problem are in Kothare et al. (1996). Then the state-feedback gain-matrix-controller of the control law is $F = YX^{-1}$. Although the nominal system was considered for the state estimation, the robustness of the control performance was ensured through the receding-horizon-based controller design, and the reference tracking was ensured by the integral action.

4. Results and Discussion

To obtain the results comparable to the results of the work Oravec et al. (2017), analogous setup of the robust MPC with integral action was considered, i.e., the laboratory chemical reactor of

Figure 1: Set-point tracking: increasing step change of the set-point.

Figure 2: Set-point tracking: decreasing step change of the set-point.

Armfiled PC40 was controlled by CPU i7 3.4 GHz and 8 GB RAM. The robust MPC was implemented using MATLAB/Simulink R2012b environment, and the communication with the plant was ensured by the Real-Time Windows Target v4.1 toolbox. The robust MPC design was provided using MUP toolbox (Oravec et al., 2017), the optimization problem in (4) was evaluated via toolbox YALMIP (Löfberg, 2004), and solved by solver SeDuMi (Sturm, 1999). The sampling time of robust MPC was $t_s = 10.0$ s, meanwhile the plant-computer communication time was $t_c = 0.2$ s. The closed-loop control performance was investigated considering $t_{RMPC} = 800$ s, i.e., the $n_k = 80$ control steps. The matrices in the quadratic criterion in (3) were tuned subject to the matrices Q_L, R_L as follows: $Q = I, Q_I = 10, R = 10 \times I$ with appropriate dimensions, where I is the identity matrix. The constraints on the both manipulated variables and the system output were set to ensure the technical constraints in the controlled chemical reactor. The volumetric flow rates q_A, q_B were within the interval $[0, 10]$ ml s⁻¹, and the value of pH was within the interval $[0, 14]$. So, $u_{\text{sat}} = 5.0$ ml s⁻¹, $y_{\text{sat}} = 7.0$. The closed-loop set-point tracking was investigated for two control scenarios, see Figures 1–2. Figure 1(a) depicts the control performance of pH value for the increasing step change of the set-point value: $6 \rightarrow 7$, and Figure 2(a) shows the results for

the decreasing step change of the set-point value: $8 \rightarrow 7$. The associated control input trajectories are plotted in Figures 1(b), 2(b), respectively. In both control cases, the estimated pH tracks very well the measured pH, see Figures 1(a), 2(a) (dashed). Based on the estimated system states, robust MPC computed the optimal volumetric flow-rates of acid (Figures 1(b), 2(b), solid) and base (Figures 1(b), 2(b), dashed). It is seen in Figures 1–2 that the robust MPC with integral action ensured the offset-free control in both control cases. It has been observed, that for the same value of the set-point, various steady-state inputs were computed. This phenomenon could be caused by the real uncertainties that influence the dynamics of the laboratory reactor, as e.g. not exactly the same concentration of the acid and base solutions and not exactly the same laboratory conditions in different experiments.

5. Conclusion

The laboratory implementation of LMI-based multivariable robust MPC with integral action for the neutralization chemical reactor is presented in the paper. The state observer was used to solve the control task for the controlled process with two control inputs and one measured controlled output. The control performance of the complex non-linear CSTR with asymmetric behaviour was investigated in the set-point tracking problem. The next research is focused on the robust MPC design in economic fashion.

Abstract

A neodymium, a high value rare earth element (REE), is widely used as a rare earth magnet. Neodymium magnets (also known as NdFeB) are permanent magnets made of neodymium, iron and boron alloy. These magnets used in several products require low magnet mass or strong magnetic fields such as microphones, in-ear headphones, and computer hard disks. As neodymium is a precious metal, high purity separation of neodymium from low concentrate is required. A hollow fiber supported liquid membrane (HFSLM) is a viable technique for metal extraction at very low concentration because it has a larger mass transfer per unit surface area, high selectivity property, and low energy consumption. Moreover, the HFSLM consumes lower amount of extractant solution than conventional solvent extraction methods. This research is aimed at studying the extraction of neodymium ions Nd(III) through the HFSLM by mean of synergistic extraction systems to increase in extraction efficiency. The separation of Nd(III) in nitric solution is carried out by 0.5 M of di-2-ethylhexyl phosphoric acid (D2EHPA) and 0.5 M of trioctyl phosphine oxide (TOPO) in the liquid membrane, and 1 M of sulfuric acid in the stripping solution. To achieve good separation of the Nd(III) throughout the continuous process, a Model Predictive Control (MPC) technique is applied to control the concentration of extracted neodymium at a desired set point by manipulating the flow rate of feed solution and its control performance is compared with that of a Proportional Integral Derivative (PID) controller. Simulation study has shown that the optimum extraction of 94.5 % can be achieved and the MPC and PID controllers can control the concentration of neodymium ions at the desired set point. However, the MPC provides better control responses than the PID controller does in both nominal and parameter mismatch cases.

Keywords: Model predictive control, Neodymium ions, Synergistic, Hollow fiber supported liquid membrane

1. Introduction

Neodymium, one of rare earth elements, is the raw material used in high-strength permanent magnets (Nd–B–Fe). The separation and purification are hardly achieved because of similar chemical and physical properties of neighboring rare earth elements.

The technique employed in this study is separation via hollow fiber supported liquid membrane (HFSLM). It is the technique that has carrier-mediated transport through HFSLM where simultaneous extraction and stripping process of target ions occurs in a single step operation. The HFSLM process has several advantages, such as low energy

consumption and low amount of extractant solution used. It also has a larger mass transfer per unit surface area (Kittisupakorn et al. 2007, Pancharoen et al. 2010).

In this work, an extraction of neodymium ions by HFSLM that operated in a once-through-mode has been studied. Di-2-ethylhexyl phosphoric acid (D2EHPA) and trioctyl phosphine oxide (TOPO) are used as the mixtures of the synergistic extractant. Sulfuric acid is used as stripping solution. Model predictive control (MPC) is applied to determine the feed flow rate to achieve maximum extraction of the neodymium. Fluid-flow models describing the transport phenomena of neodymium ions at unsteady-state condition were solved by a developed software (Wongsawa et al. 2013).

2. Theory

2.1. Hollow Fiber Supported Liquid Membrane (HFSLM)

Figure 1 Schematic counter current flow diagram for once-through-mode operation in HFSLM.

The HFSLM system consists of a feed solution (containing metal ions) and a stripping solution. Both feed and stripping phases are separated by a supported liquid membrane embedded with one type of organic extractant or a mixture of two types of extractant to enhance the separation. Figure 1 shows the counter current flow pattern for once-through-mode operation in the hollow fiber supported liquid membrane. The mixture (Q_f) is fed at the feed inlet with the feed concentration (C_i) and the stripping mixture (Q_s) is fed counter-currently.

In this work, the liquid membrane phase consists of the mixture of D2EHPA and TOPO, and sulfuric acid is used as stripping solution. The feed solution containing neodymium ions and the stripping solution are generally fed counter-currently in the tube and shell of the hollow fiber module, respectively. The characteristics of the hollow fiber modules are referred to Wannachod et al. 2014.

2.2. Transportation Mechanism of Neodymium Ion in HFSLM

Neodymium ions in the feed solution is reacted with D2EHPA and TOPO (extractant) at the feed membrane interface to form complex substances. Subsequently, the neodymium complex substances diffuse across the liquid membrane to react with sulfuric acid (stripping solution) at the liquid membrane-stripping interface. Then, the neodymium complex substances are stripped into the stripping phase. Thus, neodymium ions can be extracted and stripped simultaneously in a single step, as shown in Figure 2.

The driving force in this transportation mechanism is the concentration gradient of hydrogen ions, H^+ , between the feed and stripping phases.

Eqs. (1) – (3) show the extraction of Neodymium ions with D2EHPA, TOPO, and synergistic extractants (mixture of D2EHPA and TOPO), respectively.

where the overbar represents the species in the liquid membrane phase, $(HA)_2$ is the dimer form of D2EHPA and k_{ex} is the reaction rate constant of extraction. The neutral donor (L) captures the inorganic anion (NO_3^-) in the feed phase to form the second extractant. Subsequently, it reacts with Neodymium to produce complex ions ($Nd(NO_3)_3 \cdot L_3$).

The stripping reactions involved are summarized in Eqs. (4) – (6).

2.3. Transportation Mechanism of Neodymium Ion in HFSLM

The model in feed phase is developed referred to Wannachod et al. 2014 for predicting the outlet concentration of Neodymium at any time in the feed phase. The model equation was derived from mass conservation where the conventional as well as reaction flux was taken into account, as shown in Eq. (7).

[Rate of mass transport into the system by convection] - [Rate of mass transport out of the system by convection] + [Rate of mass transport through the system by diffusion] - [Rate of mass extracted by extraction reaction] = [Rate of mass accumulation within the system]

$$q_f C_{z-1,i}^k - q_f C_{z,f}^k + \frac{A_{c,f} D_f}{\Delta x} (C_{z,i}^k - C_{z-1,i}^k) - \Delta x A_{c,f} \langle r_{C_{z,i}^k} \rangle = \frac{\Delta x A_{c,f}}{\Delta t} (C_{z,i}^k - C_{z,i}^{k-1}) \quad (7)$$

2.4. Transportation Mechanism of Neodymium Ion in HFSLM

The percentage of Neodymium extraction from experiment can be calculated by Eq. (8).

$$\% \text{Extraction} = \frac{[Nd^{3+}]_{f,in} - [Nd^{3+}]_{f,out}}{[Nd^{3+}]_{f,in}} \times 100 \quad (8)$$

3. Controllers

The control objective is to control the concentration of neodymium ions extracted via the hollow fiber supported liquid membrane. The formulations of the PID and MPC are demonstrated below.

3.1. The concentration control of neodymium ions in feed solution by MPC controller

The basic idea of the MPC controller is to determine the manipulated input profile (q) by minimizing an objective function which is the sum of squares of the deviation of set point and predicted value on output and inputs over the next time step. The general structure of the MPC system is given in Equation (9) - (13).

$$\text{Objective function: } \min \int_0^{120} \left\{ W_1 \left([Nd^{3+}] - [Nd^{3+}]_{sp} \right)^2 + W_2 (\Delta q_f)^2 \right\} dt \quad (9)$$

Subject to

$$\text{State equations: } \dot{X} = f(X(t), U(t)) \quad (10)$$

$$\text{Bound on the manipulate variable: } 50 < q(t) < 300 \quad (11)$$

$$\text{Bound on the control variable: } 0 < [Nd^{3+}]_t < 100 \quad (12)$$

$$\text{Constraint: } [Nd^{3+}]_{(t+t_f)} = 4.12 \quad (13)$$

Where W_1 is a weighting matrix on outputs, W_2 is a weighting matrix on inputs and t_f is final time. The optimization problem is then formulated in the discrete-time via a simple Euler's approach with a step size of 0.01 minutes. Next, the problem is solved by minimizing a constrained nonlinear optimization problem using a MATLAB program.

4. Figures and tables

4.1. The response of the open-loop system

Figure 2 The concentration of neodymium ions in the feed solution at various times

Figure 2 shows the comparison of neodymium concentration in feed solution between experimental data by Wannachod et al. 2014 and simulation data based on the developed model. It was found that the developed model provides good estimates of the neodymium ions concentration in feed solution; the absolute error of 15.68 % is obtained and most discrepancy occurs in the early stages of operation.

4.2. The response of the closed-loop system

Figure 3 and 4 show the response of the process control by PID and MPC controllers respectively. The PID tuning parameters are determined by a Ziegler-Nichols method and then fine-tuned by a trial and error approach. It can be seen that the PID controller can control the concentration of neodymium ions at the set point with the IAE of 2069.5. The manipulated variable, feed flowrate, is adjusted and reduced to a constant value.

Figure 3 The neodymium ions concentration under the PID controller in the nominal case

The MPC controller can control the concentration of the extracted neodymium ions at the set point with the IAE of 1928.2. and can provide tracking of the set point faster than the PID does.

Figure 4 The neodymium ions concentration under the MPC controller in the nominal case

4.3. Effect of the volumetric flowrate in feed solution

The performance and robustness of each controller are evaluated in nominal and parameter mismatch cases. In parameter mismatch cases, three key parameters (cross

sectional area, A , reaction rate constant, k_{ex} , and diffusion coefficient, D_f) are changed of 20 % around the nominal value. It was found that the MPC controller gives better control performance than the PID in the nominal case and is robust in almost all cases as seen in Table 1.

Table 1 Integral Absolute Error of PID and MPC controllers in nominal and parameter mismatches

Case	Integral Absolute Error	
	PID	MPC
Normal case	2069.5	1928.2
A increase 20 %	2015.5	1905.9
A decrease 20 %	2893.0	2859.6
k_{ex} increase 20 %	1735.7	1850.5
k_{ex} decrease 20 %	2527.2	1909.9
D_f increase 20 %	2048.6	1928.2
D_f decrease 20 %	2069.5	1928.3

5. Conclusions

In this work, a hollow fiber supported liquid membrane system has been studied to provide the synergistic extraction of neodymium ions using 0.5M D2EHPA and 0.5M TOPO mixtures and once-through-mode operation. Simulation results of the developed systems are in good agreement with the experimental data reported. Model Predictive Control (MPC) has been applied to control the extracted neodymium at a desired set point and its control performance is compared with the PID one. It was found that both MPC and PID can control the concentration at the set point with achieved optimum extraction of 94.5 %. However, the MPC provides better control response than the PID in both nominal and parameter mismatch cases.

pmcastro@fc.ul.pt

Abstract

We propose a mixed-integer linear programming formulation for scheduling treelike systems with unidirectional flow. Refined products are converted to batches as they enter the pipeline so as to facilitate modeling the movement between pipeline segments. The novelty is the handling of multilevel branches, frequent in practice as illustrated with a real-life case study. Through the solution of three benchmark problems from the literature, we show that the new formulation is capable of finding better solutions in less time than a state-of-the-art product-centric formulation.

Keywords: Optimization; Petroleum industry; Iranian pipelines; Computational logistics.

1. Introduction

In the oil supply chain, refined petroleum products are frequently transported from refineries to distribution centers by pipeline. Multiproduct pipelines range from the simplest configuration with an input node at one extreme and an output node at the other, to complex treelike and mesh structures with multiple input and output nodes. Flow is typically unidirectional but systems with reversible flow can also be encountered. Batches pumped from a refinery take different routes, may increase/decrease in size while passing through input/output nodes, pipeline segments vary in diameter and some product sequences are forbidden. These features turn it into one of the most challenging scheduling problems.

Research on pipeline scheduling can be divided into product- (Rejowski and Pinto, 2003; Magatão et al., 2004) and batch-centric approaches (Cafaro and Cerdá, 2004; Relvas et al., 2006; MirHassani and Jahromi, 2011; Cafaro and Cerdá, 2011; Mostafaei and Ghaffari-Hadigheh, 2014; Mostafaei et al. 2016). Batch-centric models have the advantage of requiring fewer continuous-time slots to represent a schedule, a parameter strongly related to computational performance. It is because multiple batches/products can enter/leave a segment during a slot (Mostafaei and Castro, 2017) compared to just one product in the models by Castro and Mostafaei (2017) and Castro (2017). The disadvantages are that forbidden product sequences cannot be rigorously enforced, we need to postulate the total number of batches, and properly assign the initial products in the pipeline to batches, to avoid losing the optimal solution (Mostafaei and Castro, 2017). The latter is no longer an issue in systems without intermediate input nodes, like in the treelike configuration considered here.

In this work, we extend the batch-centric model for straight pipelines of Mostafaei and Castro (2017) to generic treelike systems. This is a modular and simpler approach than

other batch-centric models in the literature. The reason for returning to batch-centric models after developing the most general formulation for pipeline systems (Castro, 2017), is that the latter failed to solve in reasonable time, a treelike problem with eight segments, one refinery and six output nodes, a tractable problem with the formulation by Mostafaei et al. (2015), which however cannot handle systems with multilevel branches.

2. Motivating problem

The Tabriz-Urmia pipeline in Iran starts in Tabriz refinery (R1) and conveys three oil products (gasoline, kerosene and gasoil) to three cities, Maragheh (depot D1), Miandoab (D2) and Urmia (Figure 1). The 278-km trunk line connecting Tabriz to Urmia City (D3) is wider in diameter (10.8 inches) until Miandoab, decreasing to 8'' in the last 138 km. As a consequence, the operating flowrate range decreases from $[90, 164]$ to $[70, 120]$ m^3/h . The line has multiple branches, one to connect to Maragheh (through segment S2) and a two-level branch to connect to the power plant (D4) and petrochemical complex (D5) in Urmia. The pipeline is operated by the Iranian Oil Pipelines and Telecommunication Company (IOPTC), which delivered the volumes given in Table 1 in the first week of November 2017, except for D4. We added 1000 m^3 of gasoil to force the activation of segment S7 so as to validate our model for multilevel treelike systems.

Figure 1. The Tabriz-Urmia Iranian pipeline.

Table 1. Problem data for motivating problem

Product/Destination	D1	D2	D3	D4	D5
Gasoline (P1)	800	2400	4600	-	-
Kerosene (P2)	900	2100	4000	-	1800
Gasoil (P3)	800	3000	3500	1000	-

The real-life problem was solved with the objective of minimizing makespan while respecting the flowrate bounds on the different segments. The schedule in Figure 2 considers $|T|=13$ event points and $|I|=6$ batches, and features a makespan of 161.405 h. Notice the simultaneous product delivery to two or more depots and that supply sometimes exceeds demand (e.g. 950.7 m^3 of P2 in D1). The schedule shows the refinery operating at the maximum flowrate of 164 m^3/h , during 80.9% of the time.

Unfortunately, this schedule cannot be implemented in practice since gasoil cannot immediately follow gasoline (check S2 during $[61.04, 74.27]$ h), i.e. P1-P3 (also P3-P1) are forbidden product sequences. The model given next, has a constraint to avoid forbidden sequences at injection points but they can still occur at delivery points.

3. Mathematical model

The mathematical formulation adopts a continuous-time representation with a single reference grid consisting of $|T|$ event points, i.e. $|T|-1$ time slots (Mostafaei and Castro,

2017). The makespan MS will be the absolute time of the last event point, Eq. (1), with Eq. (2) relating the absolute time (T_t) and slot duration variables (L_t).

$$\min T_{|T|} \quad (1)$$

$$T_{t+1} = T_t + L_t \quad \forall t \neq |T| \quad (2)$$

We consider a treelike system with a single input node and multiple output nodes. Let binary variable $X_{i,t}^R=1$ if the refinery is pumping batch i during slot t . Exactly one batch is injected during a slot, Eq. (3). Eq. (4) states that the injected volume $F_{i,t}^R$ must be within minimum and maximum values (given parameters). We also need to define disaggregated variables $F_{i,p,t}^{R,d}$ to relate batches with the actual products p , Eq. (5). Eq. (6) enforces the flowrate out of the refinery to be within given lower ($\rho_p^{R,\min}$) and upper bounds ($\rho_p^{R,\max}$), where h is the given time horizon (upper bound on the makespan). To save space, we do not show the depot constraints, which are similar to Eqs. (3)-(6).

$$\sum_i X_{i,t}^R = 1 \quad \forall t \neq |T| \quad (3)$$

$$f_p^{R,\min} X_{i,t}^R \leq F_{i,t}^R \leq f_p^{R,\max} X_{i,t}^R \quad \forall i, t \neq |T| \quad (4)$$

$$F_{i,t}^R = \sum_p F_{i,p,t}^{R,d} \quad \forall i, t \neq |T| \quad (5)$$

$$\sum_i \sum_p \frac{F_{i,p,t}^{R,d}}{\rho_p^{R,\max}} \leq L_t \leq \sum_i \sum_p \frac{F_{i,p,t}^{R,d}}{\rho_p^{R,\min}} + h \cdot (1 - \sum_i X_{i,t}^R) \quad \forall t \neq |T| \quad (6)$$

A batch needs to be linked to exactly one product, Eqs. (7)-(8). From the initial products in the pipeline, the user defines old batches (I^{old}) and parameters $y_{i,p}$ (e.g. $y_{I1,P3} = y_{I2,P2} = y_{I3,P1} = 1$, in Figure 1). The total number of batches specified by the user, $|I|$, will also include new batches I^{new} , with assignment variables $Y_{i,p}$. Assignment of a product to a batch needs to be associated to the injection of a minimum amount of product, to avoid dummy batches, see left side of Eq. (9). The delivery to depots in Eq. (10) only features the upper bound since we need to account for the possibility of the last injected batch(es) to not leave the pipeline. Notice the additional depot index d in disaggregated variables $F_{d,i,p,t}^{D,d}$.

$$\sum_p Y_{i,p} = 1 \quad \forall i \in I^{new} \quad (7)$$

$$Y_{i,p} = y_{i,p} \quad \forall i \in I^{old}, p \quad (8)$$

$$f_p^{P,\min} Y_{i,p} \leq \sum_{t \neq |T|} F_{i,p,t}^{D,d} \leq f_p^{P,\max} Y_{i,p} \quad \forall i, p \quad (9)$$

$$\sum_d \sum_{t \neq |T|} F_{d,i,p,t}^{D,d} \leq f_p^{P,\max} Y_{i,p} \quad \forall i, p \quad (10)$$

Forbidden sequences at the injection point can be avoided by Eq. (11), where $p' \in P_p$ indicates that p' cannot follow p . Since batches can take different routes, it is possible for batch $i+2$ featuring p' to immediately follow i (product p) at some delivery node d . Thus, forbidden sequences may still appear, e.g. I3 (P1) and I5 (P3) in Figure 2 ([61.04, 74.27]).

$$Y_{i,p} + \sum_{p' \in P_p} Y_{i+1,p'} \leq 1 \quad \forall i, p \quad (11)$$

We assume that the refinery is connected to the left of segment S1 (by convention, flow goes from left to right in the diagrams), and so the volume entering the segment ($F_{s,i,t}^{S,in}$) is equal to the volume leaving the refinery, Eq. (12). When branching, the volume leaving

segment s must be equal to the sum of the volumes entering the branches (and depot). In Eq. (13), subsets S_s and D_s hold respectively the segment branches of s and the depot located at its end. Eq. (14) ensures that if batch i is delivered to depot d during slot t ($X_{d,i,t}^D=1$), then i is the only batch leaving the segment during t ($X_{s,i,t}^{S,out} = 1$); otherwise multiple batches can leave. While multiple batches can enter a segment, we cannot allow this to happen simultaneously in branches s' and s'' originating from s . This is the same as saying that if batch i enters s' , no other batch i' can enter s'' , see Eq. (15).

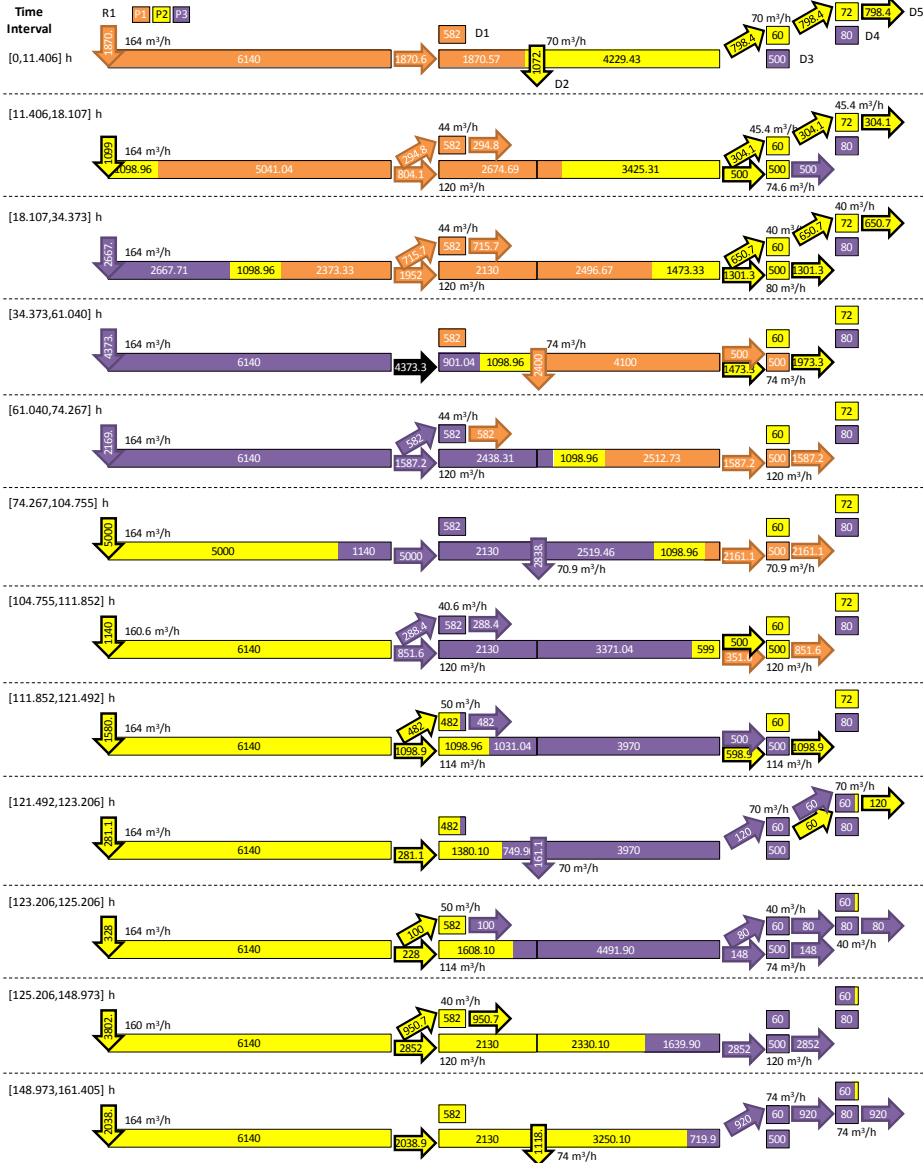

Figure 2. Best-found schedule for real-life motivating problem ($|T|=13$ and $|I|=6$).

$$F_{S_1,i,t}^{S,in} = F_{i,t}^R \quad \forall i, t \neq |T| \quad (12)$$

$$F_{S,i,t}^{S,out} = \sum_{s' \in S_s} F_{s',i,t}^{S,in} + \sum_{d \in D_s} F_{d,i,t}^D \quad \forall s, i, t \neq |T| \quad (13)$$

$$\sum_i X_{S,i,t}^{S,out} \leq 1 + (|I_s| - 1) \cdot (1 - \sum_i X_{d,i,t}^D) \quad \forall s, d \in D_s, t \neq |T| \quad (14)$$

$$X_{S,i,t}^{S,in} + X_{s',i',t}^{S,in} \leq 1 \quad \forall s, s' \in S_s, s'' \in S_s, s'' \neq s', i, i' \neq i, t \neq |T| \quad (15)$$

Other constraints are needed to model what goes on inside a pipeline segment. Since they are shared with Mostafaei and Castro (2017), they are omitted due to lack of space.

4. Computational results

The performance of the proposed batch-centric continuous-time formulation is evaluated on three benchmark problems from the literature involving single-level treelike systems (Mostafaei et al., 2015). It is compared to the product-centric formulation of Castro (2017), which is able to solve Ex1 and Ex2 in reasonable time but not the motivating problem neither Ex3, since it requires too many event points to represent the schedule (intractable problem). The new formulation was implemented in GAMS 24.9.2 and solved with CPLEX 12.7 running in parallel deterministic mode using up to eight threads. The termination criteria were either a relative optimality tolerance of 10^{-6} or a maximum wall time limit of 18,000 CPUs. The hardware consisted of a Windows 10, 64-bit desktop with an Intel i7-4790 (3.6 GHz) processor and 8 GB of RAM.

By allowing multiple products to enter/leave a segment during a time slot, our new batch-centric formulation generates at least the same solution as the product-centric formulation for a given number of event points ($|T|$), see results in Table 2. Since this a parameter strongly affecting computational time, it means we can further explore the solution space, ending up with better solutions for Ex1 and Ex2 (151.43 vs. 162 h). For Ex3, we even know that the solution is the global optimum, since the makespan of 125.25 h is equal to the value of the LP relaxation, which does not change with $|T|$. Our formulation does need an additional parameter, the total number of batches ($|I|$), but we found that it only affected solution quality until finding the first feasible solution. It is thus not as critical as for systems with multiple input nodes (Hosseini and Castro, 2017). Analysis of the schedules for Ex1-Ex3 did not show forbidden sequences in the pipeline system.

5. Conclusions

This paper has presented a new batch-centric continuous-time formulation for scheduling multilevel treelike systems with a single input and multiple output nodes, motivated by a real-life problem from the company responsible for operating the Iranian pipelines. We have shown that the new monolithic formulation can cope with a weekly demand plan but still requires additional constraints to enforce forbidden product sequences in all pipeline segments after the first. They will be part of the extended version of this paper. For this specific system configuration, it is significantly more powerful than the most general formulation for pipeline scheduling.

Abstract

Over the last decade, cooperative optimization approaches, that combine metaheuristics with exact methods, have been attracting a lot of interest to solve mixed integer linear programming (MILP) problems. In this paper, we present such a hybrid technique for the batch plant design problem with parallel production lines. The aim of this MILP problem is to minimize capital and setup costs through the optimization of 3 decisions: the number of lines to install on the plant, their design, and the assignment of products and production quantities to the installed lines. These different types of decisions lead to a natural separation of the global problem into subproblems, each of which can be solved with adequate solution methods. More specifically, we applied an iterative local search (ILS) metaheuristic for the discrete design decisions for every stage of every line, whereas the product-to-line assignments are optimized with an exact MILP solver. We present a case study of a lubricant plant to compare the performance of the proposed methodology to an exact method, and to illustrate its operation. We found that our cooperative optimization approach obtained very good solutions in significantly lower computing time.

Keywords: batch plant design, cooperative optimization, hybrid metaheuristics, parallel lines

1. Introduction

Over the past decades metaheuristics have been very successful in solving combinatorial optimization problems. Especially in real-life situations, where the dimensionality of the problem becomes too large to solve the problem by means of an exact method within a reasonable amount of time, metaheuristics have proven to be very powerful (Sörensen and Glover, 2013). Also for the multiproduct batch plant design problem successful metaheuristics such as e.g. simulated annealing (Patel et al., 1991) and genetic algorithms (Dedieu et al., 2003) were developed.

Although metaheuristics do exist to tackle optimization problems involving continuous variables (see e.g. Mladenović et al. (2008)), these methods are not so well adapted. On the contrary, exact methods perform extremely well for (linear) optimization problems involving no discrete variables. Hence, in case of a MILP, it could be rewarding to combine both techniques: a metaheuristic and an exact method. This is referred to as a cooperative optimization approach.

In this paper we present such a cooperative optimization approach for the batch plant design problem extended for parallel production lines as introduced in Verbiest et al. (2017). This optimization problem involves 3 decisions: number of lines to install, their design, i.e. number and size of equipment units at every stage (out of a discrete set of options), and assignment of products and produc-

tion quantities to the installed lines, where a product may be assigned to multiple lines (product duplication). The existence of these different types of decisions leads to a natural separation of the global optimization problem into subproblems. This is the main idea behind the cooperative approach presented here: to split the optimization problem into easier to solve subproblems and to exploit the characteristics of every subproblem. Indeed, we start with a metaheuristic framework to solve one of the subproblems. The hereby obtained solution is then used as an input to another subproblem, solved by an exact mathematical programming method. This results into another part of the global solution, which is fed back as a context to solve again the subproblem by means of a metaheuristic. This type of cooperative approach is called a (hierarchical) decomposition approach (Ball, 2011), of which the application in the context of the batch plant design problem is rather limited (Xi-Gang and Zhong-Zhou, 1997).

In Section 2 of this paper, a brief description of the multiproduct batch plant design problem with parallel lines is presented. In Section 3, the cooperative optimization approach, developed for this problem, is discussed. The performance of our approach is illustrated in Section 4 through a case study of a lubricant plant, and we end with some conclusions in the last section.

2. Problem formulation: design of a multiproduct batch plant with parallel production lines

We consider a multiproduct plant designed for a multistage process. More specifically, P products i are to be produced over J stages j , where every stage performs a batch operation. There is the possibility to install at most L production lines l on the production site, each consisting of the same stages J . The demand for every product and the total production horizon are known upfront, as well as the characteristic size factors and the fixed batch processing times. The main assumptions are: at most N identical parallel batch equipment per stage, operating out-of-phase; a discrete set of S equipment sizes for all stages to choose from and operation in single product campaign mode.

We formulated an MILP model to determine the optimal design of a plant that should be large enough to produce all products within the given horizon. The aim is to minimize the total cost, which consists of capital, startup and contamination costs. Due to space limitations, only the objective function is presented here (see Verbiest et al. (2017) for a description of the entire model):

$$\min \left[\sum_{l=1}^L \sum_{j=1}^J \sum_{n=1}^N \left(\sum_{s=1}^S c_{js} z_{ljn} u_{ljs} + \sum_{i=1}^P C_{start_i} z_{ljn} t_{li} + \sum_{f=1}^F C_{cont} b_{fl} g_l z_{ljn} \right) \right]$$

The first term defines the capital costs, with c_{js} the stage dependent cost coefficients for equipment of size s . The binary z_{ljn} indicates if unit n of stage j of line l exists and binary u_{ljs} defines if units of stage j of line l have size s . The second term represents the startup costs for preparing the equipment units at the start of every series of batches of product i . We assumed a given product dependent startup cost (C_{start_i}) and the binary t_{li} that indicates if product i is produced on line l . Finally, the last term is the contamination cost. Products with similar characteristics are often grouped into product families and the fixed contamination cost C_{cont} is a penalisation for producing multiple families on 1 line. Binary b_{fl} defines if product family f is produced on line l , and the binary g_l is introduced to avoid a contamination cost when there is a single family on a line. This nonlinear goal function is linearized using known techniques.

3. Overview of the cooperative optimization approach

As introduced, we have implemented a cooperative optimization approach, hereafter referred to as COA-design, in which the problem is decomposed into 3 subproblems: determining the number of lines to install, their design, and the assignment of products to the installed lines. Specific solution methods are applied to the different subproblems. More specifically, the COA-design proceeds

according to the following steps. At first, the number of lines is fixed in an incremental manner (from 1 to L) with after every incrementation an evaluation of the absolute lower bound in terms of costs, to exclude too large and thus too expensive plants. Next, for every feasible given number of lines, the optimal design and product-to-line assignments are determined by iteratively solving both problems, until an optimal combination is found.

More explicitly, for every given number of lines, a first product-to-line assignment is based on grouping products by product families, so as to minimize the contamination cost. After determining the optimal design for this first assignment, the product assignment is re-optimized by keeping this design fixed. This is repeated until an optimal combination is found, meaning that we can not find a new assignment or design anymore that lowers total costs. To escape from this (local) optimal combination, a perturbation step is performed in which a certain percentage of products are reassigned (via simple rules) to another line. With this new assignment, the iterative procedure is started again. After a certain number of perturbations, which is determined experimentally, without an improvement of the best solution for this number of lines, we compare this solution with the best solution found so far and, if needed, update the latter. Then, we increment the number of lines and restart the procedure.

The solution method applied for the product-to-line assignment subproblem for a fixed design, meaning binaries $z_{l,jn}$ and u_{ljs} are given, is an MILP calculation. On the contrary, to optimize the discrete design decisions when the product assignment is given, an iterated local search metaheuristic (ILS) is used (Lourenço et al., 2010). This ILS starts with a maximal plant layout as the initial solution, to ensure feasibility. This means that for every stage of every line the maximal number of units and the largest sizes are chosen. To improve this solution, two different move types are considered: for a specific stage, decrease the number of units with 1 or decrease the equipment size. The selection of the move type is done randomly, with a higher chance of decreasing the number of units (as this has the largest impact on the objective function). A steepest descent strategy is used to pick, out of all stages, the stage to perform the move on. When no more improvements can be made, a local optimal solution is found which is compared to the cheapest design found so far. To escape from this local optimum, a perturbation step is performed in which a certain percentage of stages get again the maximum number of units or largest sizes. The entire procedure is repeated until a certain number of perturbations is reached without an improvement of the best solution.

During the development of this COA-design, we noticed that when the assignment involves product duplication over the lines, the above ILS is not the most suitable technique to determine the design. Indeed, with product duplication, the constraint calculation, i.e. checking if the performed move, and thus new design, is feasible, is more complex and requires an LP-solver to determine the (continuous) amounts of these duplicated products for every line. Since a steepest descent strategy is used, the LP-solver is called for every stage before a move is made. In fact, the numerous number of calls made to the LP-solver takes longer than a 1-time call to solve the MILP problem exactly for a given product-to-line assignment (variable t_{li}). Hence, the use of ILS is less effective. Analogous conclusions can be drawn for the assignment problem: intuitively, one would expect the binary t_{li} to be determined heuristically. However, the number of product combinations, duplication yes or no and if yes, over how many lines, leads again to (too) many evaluations of new assignments, justifying the use of 1 MILP calculation. The iterative optimization procedure for a given number of lines, together with the eventual chosen solution methods to solve both subproblems, is visualized in Figure 1.

Figure 1: Iterative optimization procedure, and solution methods used, to determine the optimal assignment and design for a given number of lines

4. Case study: design of a lubricant plant

In this section, the performance and operation of the COA-design is discussed via an example of a lubricant plant.

4.1. Process description and solution

We assume a lubricant plant that has to produce the demand for 35 lubricants, belonging to 3 product families, within a given horizon. A single product campaign mode of operation is assumed. The production process consists of 5 stages, and equipment sizes can be chosen out of a discrete set of 5 options. The plant surface area allows for the installation of at most 6 parallel lines and 4 units per stage, operating out-of-phase. The main production data are summarized in Table 1.

Table 1: Main data case study - lubricant plant

Demand data (in kg): range between 3000 - 35,000 Horizon H (in h) = 6500
Cost coefficients: Capital costs: $\alpha_j = \{468, 357, 168, 402, 286\}$; $\beta_j = \{0.47, 0.49, 0.61, 0.43, 0.46\}$ Startup costs: 750 Contamination costs: 3000
Product families: 3 $Pf_1 = \{1, 3, 5, 9, 14, 16, 23, 25, 27, 28, 32, 35\}$ $Pf_2 = \{2, 4, 8, 11, 13, 17, 19, 20, 21, 26, 30, 33\}$ $Pf_3 = \{6, 7, 10, 12, 15, 18, 22, 24, 29, 31, 34\}$

We solved this example for the minimization of case (a) only capital costs, and case (b) capital and setup costs. Table 2 compares the results for an exact method and our COA-design. For the COA-design, we report the best solutions found over 10 runs, and the time needed. The exact solutions were found solving the entire MILP problem with Gurobi Optimizer 7.0 and are aborted after 24 h of CPU-time. In such a case, the best solution found so far is reported. As can be seen, the COA algorithm provides very good solutions in significantly lower computation time. For case (a) the exact solver could not solve the problem up to optimality after 24 h, and found the current best solution in 25,918 s (7 h). The same solution was found with our COA-design in only 2.5 % of the time (639.67 s). For case (b), the optimal solution was found by both methods, but again in significantly less time with the COA-design. The average gap, being the gap between the goal function value obtained by the exact method and its average over 10 runs of the COA-design, is in both cases small. This implies a low variation in solution quality. The last three columns of the table provide some details on the problem sizes.

Table 2: Results for minimization of (a) capital and (b) capital and setup costs

	Sol. Gurobi	CPU (s-Gurobi)	Sol. COA-design	avg.gap (%)	CPU (s-COA-design)	Vars.	Bin. Vars	Const.
(a) Capit.	116,708 (gap:12%)	24 h	116,708	0.8	639.67	13,410	1230	38,626
(b) Capit.Setup.	278,551	19,345	278,551	0.0	13.92	18,354	6174	44,188

All numerical results were obtained using an Intel(R) Core(TM) i7-4790 CPU, 3.60GHz and 16 GB of RAM

In Table 3 the chosen designs for the two cases are presented, and the corresponding product-to-line assignments are shown in Table 4. For case (a), it is optimal to install 2 parallel lines and there is product duplication for products 3 and 34. When including setup costs in case (b), it appeared optimal to install an extra production line so that product families can be grouped and a single line is used for every product. This is at the expense of a higher capital cost (+26 %).

Table 3: Solution at minimum (a) capital and (b) capital and setup cost

	(a) Capit. costs = 116,708		(b) Capit.Setup. costs = 278,551 (with Capit.:147,301)

4.2. Progress of the COA-design approach

The progress of our COA-design is presented in Figure 2 for the minimization of capital costs and in Figure 3 for the minimization of capital and setup costs. The blue crosses *perturbed-design* refer to the design solutions found after the initial product-to-line assignments based on product family grouping or after the perturbation step (shuffling of products over the lines). *MILP-design* are the solutions found for the design problem with the exact solver (Gurobi) whereas *ILS-design* refers to the design solutions found with the ILS metaheuristic. Finally, *MILP-assignment* stands for the optimal product-to-line assignments found with the exact solver. The figures show the total cost associated with every solution and the L-points mark the start of the iterative optimization procedure for every new (incremented) number of lines.

A first observation when comparing the two figures is the difference in total running time. In case (b), our COA-design reaches the stopping criterion after 13.92 s whereas in case (a), it takes 639.67 s. This is for a great extent due to the application of the ILS metaheuristic in case (b) to solve the design problems. Indeed, in case (a), it appeared that the optimal product-to-line assignment in every iteration has duplicated products. Hence, the design problem (MILP) is always (except for 1 time) solved using the exact solver. The horizontal distance between the *MILP-assignment* solution (red dots) and the *MILP-design* solution (green triangles) in Figure 2, so the time needed to solve the MILP-design problem, is on average larger than the distance between the *MILP-assignment* solution and the *ILS-design* solution (green squares) in Figure 3. Furthermore, case (a) and (b) stop after investigating respectively 2 and 3 lines. This means that for more lines the minimum costs associated with these plants would already be higher than the best cost found so far. Thirdly, it is apparent that the progress in case (b) is much more volatile than in case (a). After every product-to-line perturbation, a much worse solution is found and larger drops are achieved when optimizing the assignments. This indicates the influence of the setup costs on obtaining the optimal solution. When minimizing only capital costs, much more product combinations and possibilities for spreading production quantities over multiple lines can be considered.

Finally, from Figure 3, and verified by Table 4, it can be seen that the optimal solution is the one where products are grouped into product families on equipment. As after every line incrementation, this is the initial assignment to start the iterative procedure from, the first design found with this assignment (*perturbed-design*) when 3 lines are investigated is the optimal one.

Figure 2: Case (a)-progress of COA-design for capital costs (best solution: 116,708)

Figure 3: Case (b)-progress of COA-design for capital and setup costs (best solution: 278,551)

5. Conclusion

In this paper, we described a cooperative optimization approach for the batch plant design problem with parallel production lines. In this MILP problem, the decisions to optimize are 3-fold: number of lines to install, their design and the product-to-line assignment with corresponding production quantities. As this problem consists of different types of decisions, a cooperative optimization approach (COA-design), that separates the different decisions and exploits their individual characteristics, seemed a useful technique. More specifically, the first decision is to fix the number of lines in an incremental manner. Then, for every given number of lines, the design and assignment subproblems are iteratively solved, until an optimal combination is found. The solutions of the former are considered given in the latter, and vice versa. The solution methods applied for both subproblems are exact MILP calculations for the assignment problem and an exact MILP calculation and an ILS metaheuristic for the design problem. The performance of our proposed optimization approach is illustrated through a case study of a lubricant plant. From this example, we can conclude that our approach found very good solutions in significantly lower computation times. Moreover, also the search process of the COA-design was analyzed. This showed that the application of the ILS metaheuristic as well as a calculation reduction strongly contribute to the efficiency of our COA-design. Given the good performance of our approach, a possible progression of this work is to investigate its application for more extended batch plant design problems, such as e.g. considering multiple objectives.

Abstract

This paper emphasizes the use of graphs for model analysis and simplification within industrial flowsheet simulators. A procedure for developing a complexity measure for models based on weighted cycles and paths in attributed graphs is highlighted. This procedure uses an interface to the process simulator for graph generation. The novel complexity measure serves as the basis for a model reduction approach using attributed graphs and is applied to the real industrial example of an ethylene plant model.

Keywords: flowsheet simulation, model reduction, graph theory

1. Motivation

The use of commercial process simulation tools is state of the art in chemical engineering. Their applications range from simple mass balances in basic or conceptional design to real-time optimization during operation, case studies for retrofit of existing equipment or assessment of alternative operating modes of existing compound systems such as refineries. Because in every stage of chemical engineering projects simulation models are developed for a specific purpose, model reuse or integration of plant models into enterprise or site-wide models pose a challenge. Especially if utility supply is to be analyzed in addition to production plants, a holistic approach is required. By adding these additional points of consideration, the models themselves need to be simplified, which implies the question of how to conceptualize a model that is as accurate as required, but as simple as possible. This paper aims at systematically describing the impacts of severe model simplifications on prediction quality and proposes a novel decision support for model simplification based on graph theory.

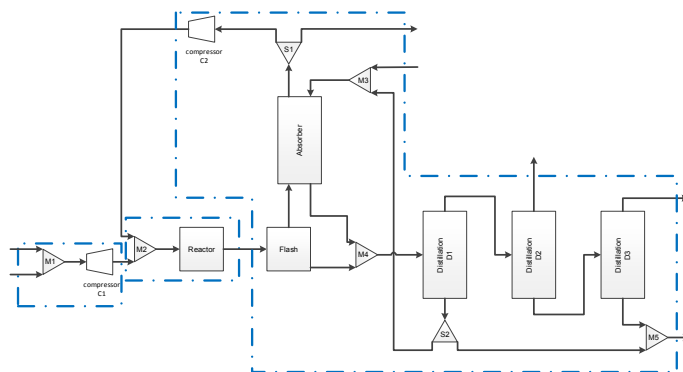

2. Graphs in chemical engineering

While graph or network theory is currently experiencing increasing popularity in connection with social networks (Barabasi (2016)), it has a long history with chemical engineering. The broad applicability of graphs in chemical engineering has been highlighted by Mah (1983). Surma and Braunschweig (1996) are using graph representations to develop similarity measures for flowsheets.

Graph theory has been applied for analysis of large scale systems in chemical industry with focus on mathematical modeling (Mangold et al. (2002)), visual modeling (Preisig (2014b)), Preisig

(2015)) or for closing mass and energy balances or describing pressure distribution in plant operation (Preisig (2007), Preisig (2014a)). In contrast, this work focuses on describing models of industrial flowsheet simulators.

Graphs and model simplification have been addressed by Dones and Preisig (2009) lumping trays in distillation columns in order to obtain a simplified model. This concept is extended to a lower level of detail where unit operations in a simulator may be lumped or neglected as illustrated by the example given in Biegler et al. (1997). For black box splitter models, the real system is decomposed into sub-systems. Figure 1a shows an example of a process consisting of a reactor, the feed preparation and the purification of the products.

(a) detailed flowsheet

(b) Block flow diagram

Figure 1: (a): Balance envelopes in the detailed flowsheet. (b): Block flow diagram. After Biegler et al. (1997)

These three main parts can be grouped to three blocks (see Figure 1b), as illustrated by the balance envelopes. In this case there is only one recycle stream, in contrast to the original representation with two recycles. This aggregation could even be further simplified to only one black box, the total process. In process simulation these blocks are commonly modeled using subflowsheets or even further simplified by black box components splitters. All three representations describe the same process but have different properties, which can easily be visualized and analyzed using graphs.

3. Approach

Previous work has developed a graph theoretic methodology for the reduction and optimization of the modeling depth of flowsheet models. Within the present paper this simplification strategy is extended and validated using the real industrial application of integrating an ethylene plant model into a refinery wide model. Graph theory provides a very general framework for the representation

of networks, in the present case applied to networks of unit operations in chemical plants. In this case all unit operations or aggregated black boxes are considered as nodes whereas any streams of mass, energy or information are regarded as links, as proposed by Gilles (1998). In contrast, the P-graph approach developed by Friedler et al. (1992) considers both operating units and process streams as nodes.

It is assumed that the setup of a model is mainly determined by

- the selection of representative sub-systems or elements of a model that can range from single molecules or phases over equilibrium stages to black box aggregations of unit operations or plants and
- the calculation method that is used to simulate these model elements, e.g. rigorous column, shortcut column or component splitter.

Each of these model elements interacts with another by exchanging streams of material, energy or information. As illustrated in Figure 2, this procedure results in a attributed graph (for basic examples see Bothorel et al. (2015)), that represents a meta-model (in terms of a model of a model) describing the flowsheet model in the process simulator.

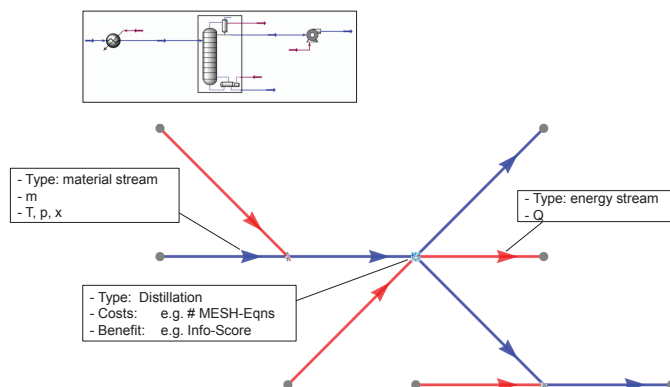

Figure 2: Attributed graph of a simple distillation flowsheet

Based on these graphs, different key figures are calculated and combined to a complexity measure that can be used as a target criterion of a simplification algorithm.

The term complexity is widely used in literature having many different meanings ranging from complex mixtures over complex column configurations to time and space complexity of algorithms. For the complexity and entropy of graphs, extensive reviews (Boccaletti et al. (2006), Costa et al. (2007)) and applications (Han et al. (2012), Holzinger et al. (2014), Kim and Wilhelm (2008), Dehmer and Mowshowitz (2011)) are available.

Common simplification strategies are based on aggregating nodes (unit operations) or identifying main links, that remain in a simplified graph. This can be achieved by

- using the mass flow as additional information as weight of edges and removing edges with a weight below a threshold value (see Fig. 3a, skeletal reduction),
- by weighting the edges according to their similarity to a reference main product of the plant (see Fig. 3b, main product cuts) or
- via searching graph communities or graph partitions and merge them to a black box.

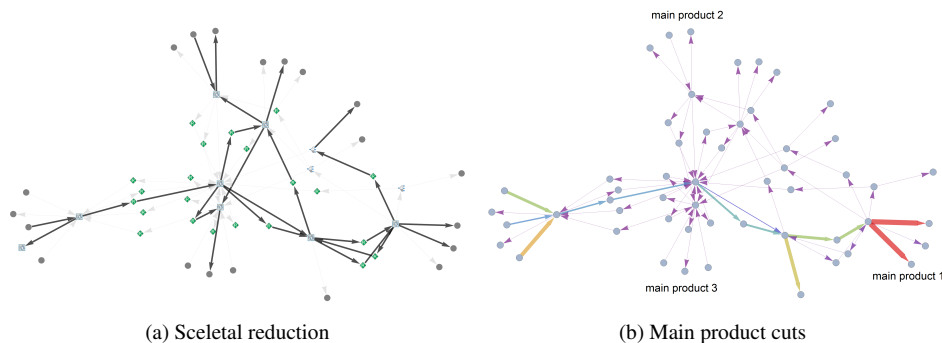

Figure 3: (a): Sceletal reduction of a flowsheet graph inspired from reaction mechanism reduction (Lu and Law (2005)). Gray links have a mass flow below threshold, black links remain in simplified graph. (b): Visualization of main product cuts in a graph. Link style indicates the contribution of the representing stream to a main product

4. Methodology

In order to rate modeling alternatives, representative sub-flowsheets are selected, for which all suitable permutations in the modeling concept of each unit operation (e.g. rigorous column, shortcut column or component splitter) and possible aggregations of multiple unit operations to a single black box component splitter are investigated. Within this procedure for generating modeling alternatives constant temperature and pressure or composition of the main products of each unit operation serve as constraints for changes in the calculation method.

For all these models j graphs are generated in Wolfram Mathematica using an interface to KBC Petro-SIMTM. In addition to calculating standard graph measures, cycles and paths are searched and categorized for each graph. Along these cycles and paths, statistics that rate unit operations according to costs (number of MESH-equations) and benefits (rating of information obtained) of the simulation are applied. This procedure yields a set of n graph measures m comprising standard graph measures and chemical engineering expert knowledge. Under the assumption that a linear combination of these measures

$$C_j = \sum_{i=1}^n m_{i,j} \cdot w_i \quad (1)$$

approximates the costs of solving the flowsheet, which are represented by the calculation time, the investigated models are compared manually according to the expected simulation costs. Within this assessment for every model a corresponding model is selected, that only differs in the simulation method of one unit operation (e.g. rigorous column or shortcut column), which implies the hypothesis that one model is more complex than the other.

The resulting set of inequalities, $C_j > C_{j+1}$, is then solved using linear programming. For each pair of models $\Delta m_{i,j,j+1} = m_{i,j} - m_{i,j+1}$ and a penalty variable $d_{j,j+1}$ is defined.

The linear program minimizes the sum of penalties

$$\sum_{j=1}^{p-1} d_{j,j+1} \quad (2)$$

constrained that

$$\begin{pmatrix} \Delta m_{1,1,2} & \Delta m_{2,1,2} & \dots & \Delta m_{n,1,2} & 1 & 0 & \dots & 0 \\ \Delta m_{1,1,3} & \Delta m_{2,1,3} & \dots & \Delta m_{n,1,3} & 0 & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \Delta m_{1,p-1,p} & \Delta m_{2,p-1,p} & \dots & \Delta m_{n,p-1,p} & 0 & 0 & \dots & 1 \end{pmatrix} \cdot \begin{pmatrix} w_0 \\ w_1 \\ \vdots \\ w_n \\ d_{1,2} \\ d_{2,3} \\ \vdots \\ d_{p-1,p} \end{pmatrix} \geq \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 0 \\ 0 \\ \vdots \\ 0 \end{pmatrix} \quad (3)$$

For validation a test sequence is carried out with all models, where the calculation time as well the deviation from real operating data is monitored. It is shown that a linear combination of graph measures is capable of predicting influences of model set up on calculation time and prediction quality. The effective use of the methodology is demonstrated by an exemplary model reduction tasks of an ethylene plant (Figure 4).

Figure 4: Calculation times of a feed variation test sequence for 96 modeling alternatives of a C3 splitter flowsheet plotted versus a complexity measure obtained from linear programming

The clusters in Figure 4 show that

- in the time-dimension on the ordinate: the real calculation time is determined by the model setup, as models within one clusters share the same simulation method for key unit operations
- in the complexity-dimension on the abscissa: the linear program successfully distinguishes between them.

5. Conclusions

The developed algorithm yields simplification proposals comparable to those of experienced professional engineers, providing a decision support for model set-up for large scale flowsheet models.

The authors admit that sophisticated knowledge management systems in process analysis, such as OntoCAPE developed by Morbach et al. (2007), cover even more information on models. However, the simple concept of unit operations connected by streams in a graph is easy to understand and visualize for application orientated software users that are not familiar with system theory or ontology.

In a next step the use of multiple linear regression for predicting the calculation time or deviations from real measurements is to be carried out as an alternative to linear programming.

Abstract

The aim of the present work is to provide an integrated decision support approach for the design and scheduling of multipurpose batch plants under demand uncertainty allowing the assessment of alternative risk profile solutions. Based on two-stage mixed integer linear programming (MILP) model, the goal is to maximize the annualized profit of the plant operation under a set of scenarios while minimizing the associated financial risk, evaluated by the Conditional Value at Risk (*CVaR*) using the augmented ε -constraint method. Considering a literature example, the conclusions highlight the advantages of the proposed approach for the decision-support in industrial plant design and scheduling solutions by considering the explicit risk measure assessment towards expected financial outcomes

Keywords: Multipurpose batch plants, risk assessment, conditional value-at-risk, stochastic programming, augmented ε -constraint method.

1. Introduction

One of the most important issues in the management of current industrial processes relates to the uncertainty level of most operational parameters. This uncertainty typically arises from the demand market variability, which impacts on the resources availability, equipment efficiency and capacity reliability (Shah, 2005). One of the major research topics relies in the complexity of industrial design and scheduling decisions, where several works have focused on optimal modelling solutions that can encompass the overall supply chain (Cardoso et al., 2016). The design flexibility of multipurpose batch plants in uncertain environments has also been addressed, as noted by Pinto-Varela et al. (2009), with the use of stochastic models to compare expected performance to a deterministic approach. However, most of these works do not provide the analysis of the alternative possible outcomes by assessing different risk management profiles, since stochastic models optimize the total expected performance assuming that the decision maker is risk-neutral. As one of few examples, the work by Bonfill et al. (2004) has addressed the short-term scheduling of batch plants incorporating the solution trade-offs between risk and profit at the decision level. By allowing to evaluate

alternative scheduling policies for different scenarios, it becomes a highly valuable tool to identify the best strategy according to the decision makers' attitude toward risk. A similar analysis has not yet been performed for the simultaneous design and scheduling of batch plants.

In this work, a modelling approach to the design and scheduling of multipurpose batch plants is simultaneously addressed considering demand uncertainty, where a risk measure optimization is evaluated against the annualized profit performance maximization. For the scope of this study, was find suitable the risk measure given by the Conditional Value at Risk (*CVaR*), which is explicitly modelled into the stochastic programming problem. A bi-objective model is formulated using the augmented ε -constraint method (Mavrotas, 2009) to generate an approximation to the Pareto-optimal curve and the obtained results for an industrial literature example are discussed.

2. Methodology

The problem under study consists in determining plant design and scheduling decisions at a project level, evaluating the risk associated to the demand uncertainty. Several methods exist to model with uncertainty, such as stochastic programming, fuzzy programming or robust optimization. In this study, we considered as baseline the stochastic two-stage mixed integer linear programming (MILP) model proposed by Pinto-Varela et al. (2009), based on the adapted Resource Task Network (RTN) framework with a discrete-time representation. This model was extended to consider simultaneously the two objective functions with augmented ε -constraint method, the maximization of the economic profit performance and the minimization of the financial risk. Given the plant and process data for a set of products, the model determines the plant configuration and process schedule with an optimal economic and risk performance for the planning horizon, suitable according to risk profile of decision-maker (for further model detail please check the seminal paper). In this two-stage stochastic optimization approach, each uncertain parameter is considered as a random variable with an associated probability distribution, and the decision variables are classified into two stages. In this case, the products demand is considered in a scenario tree which presents the advantage of allowing the discretization of the stochastic data and provide a flexible approach that can be adjusted during the planning horizon. In the scenario tree, a node represents a possible state and the arcs the different evolutions it may have, where each node has a specific probability (pb_s) for the corresponding state occurrence and the path from the root node to a leaf node represents a scenario.

To integrate the risk assessment in the model, and acknowledging that several measures could be considered, as noted by Conejo et al. (2010), for this study we have considered the *CVaR* as a coherent risk management approach. *CVaR* allows to evaluate the likelihood that a specific loss will exceed a certain value at risk (*VaR*), which is the minimum profit obtained for a given confidence level. Eq. (1) shows the objective function that describes the annualized profit performance (*PR*) deducting the plant costs, namely operating cost (*OC*), raw material costs (*RMC*) and capital cost ($CC*CCF$) over all of the scenarios for planning horizon *H* and cycle time *T*. For discrete distributions, *CVaR* is defined as the weighted average between *VaR* and the expected profit lower than *VaR*. Rockafellar and Uryasev (2002) defined the linear approximation of *CVaR* shown in Eq. (2), where *a* represents the confidence level between 0 and 1 defined by the decision maker, and δ_s measures the positive difference between the *VaR* and the profit obtained in each scenario.

$$Max Profit = (PR - OC - RMC) \cdot \frac{H}{T} - CC \times CCF \tag{1}$$

$$Min CVaR_a = Var + \frac{1}{1-a} \sum_s pb_s \times \delta_s \tag{2}$$

3. Case study

3.1. Problem definition

In order to apply the previously described methodology, the risk assessment to support the optimal design and scheduling of a multipurpose batch plant with a periodic mode of operation of an industrial example available from literature is solved, considering a horizon of 720 h with a cycle of 10 h. The objective is to define the optimal design and the operating schedule for a plant where five products (S5, S6, S9, S10, and S11) are produced using three raw materials (S1, S2, and S7) by the appropriate equipment, reactors (R) and storage vessels (V) accordingly to the product recipe illustrated on Figure 1, in order to maximize profit. The plant costs are defined by a fixed and variable terms and expressed in monetary units (c.u.), while the demand uses a maximum variable range in mass units (m.u.), and the design capacity is defined in terms of mass units per square meter (mu/ m²). Detailed information about the process data can be found in the seminal work by Pinto-Varela et al. (2009).

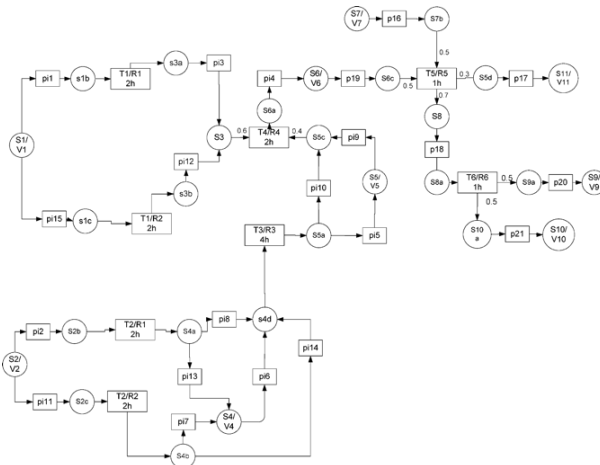

Figure 1. Products' recipe from Pinto-Varela et al. (2009)

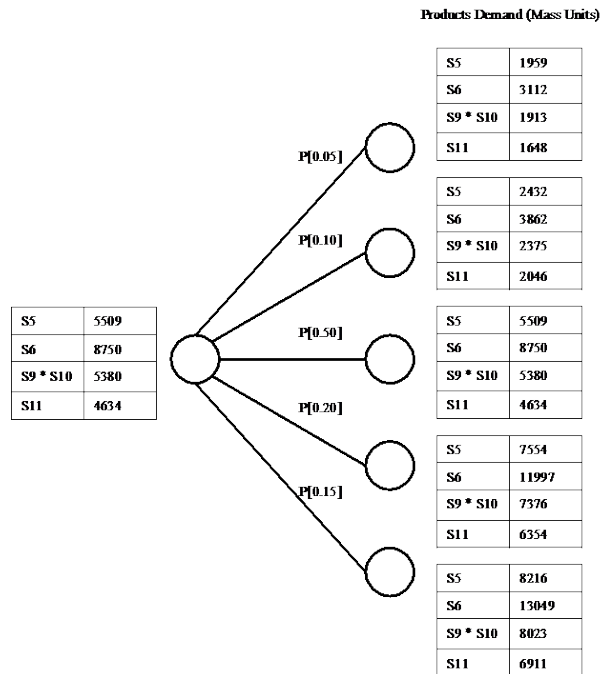

Figure 2. Scenario tree with demand uncertainty

For the given problem, the modelling approach describes the uncertainty in products demand as a scenario tree displayed in Figure 2. The uncertainty in demand is assumed

known for the actual market conditions and a total of five scenarios are considered as possible demand patterns for the next time period. The expected product demand for each scenario and respective probabilities were determined by discretizing a probability distribution function based on historical data to forecast the market trends.

Acknowledging the main objective of the proposed approach as to provide the decision maker with an enhanced decision assessment that enables the trade-off evaluation between risk and profit, the bi-objective model generates the Pareto optimal curve subject to the analysis of the alternative solution. The model was implemented in GAMS (24.5.6 ver.), using CPLEX (12.6.2 ver.) solver in an Intel(R) Xenon(R) CPU ES-2660v3 @2.60GHz with 64GB RAM and a 1% optimality gap as stopping criteria.

For the given illustrative example, three different cases are tested, analysed and compared: (1) one that considers the products demand as a deterministic information; (2) a second study that considers the demand uncertainty in a stochastic approach without considering a risk measure (risk-neutral); (3) and finally, a study that evaluates the results regarding the trade-off between the expected profits and the associated financial risk using *CVaR* as a risk measure, where two extreme scenarios are analysed in more detail: higher profit has a high risk (risk prone); and a lower profit has a lower risk (risk averse).

3.2. Results

In order to compare the results for each case, we focus on the analysis of the expected profit value (or profit value for the deterministic case) and the decision variables related with the equipment selection and capacity utilization. These results are summarized in Table 1. Due to the extent of problem example, in this study we focus only on the reactors design and capacities, given that only reactors R1 and R2 are multitask. Else, each storage vessel is dedicated to a single task and are always required to production, with a designed capacity that verifies the mass balance restrictions dedicated to storage of intermediate and final products produced in the different reactors.

Considering the deterministic approach, it is possible to observe a profit of 191 408 c.u. and a design structure that includes the installation of the reactor R1, R3, R4, R5, and R6. The stochastic problem (risk neutral), presents a value for the expected profit of 202 380 c.u., whereas some reactors are required to install considerable different capacities. The increase on the capacity for reactors R1 and R4 is, respectively, 61% and 49%, and the reduction for reactors R3, R5, and R6 is approximately 30%.

Now considering the integration *CVaR* to make possible to evaluate the likelihood of obtain a profit value lower than the *VaR*, i.e. the minimum expected plant profit for a given confidence level for a given time period. To obtain the *VaR*, it is necessary to compute the model for each scenario of demand and build the cumulative distribution function, as shown in Figure 2. It is noted that for scenario 1, that corresponds to the lower products demand, the profit is 65% lower than the deterministic solution, though in each demand scenario the profit exhibits steady variations from 67 410 to 285 103 c.u. For the given case with a confidence level of 95%, the determined *VaR* value is 83 856 c.u., meaning that, at the end of time horizon with a 95% of probability, the plant profit of the design and scheduling solution is going to be, at least, that value. Using this value, the Pareto-optimal curve using *CVaR* as a risk measure was obtained, shown in Figure 4.

Figure 3. Cumulative distribution function to determine VaR

As expected, the results show that as the profit increases, so does the risk associated with that decision. However, the Pareto curve can provide the assessment of different solutions, from one extreme point where a low profit scenario has a low risk (risk averse), to the other extreme point where a higher profit has a higher risk (risk prone). As detailed in Table 1, significant design differences can be found when the extreme points of the Pareto curve are compared, not only in terms of expected profit but also in terms of equipment’s capacity. For a low profit - low risk scenario, the chosen reactors can differ from all the other solutions, with R2 elected instead of R1. Comparing the results for reactors R3 and R4, 29% and 52% lower capacities are used on the risk averse scenario. The results also generate different plant schedules for the two extreme points decisions, as shown in Figure 5. The multipurpose operation of reactors R1 and R2 is displayed in the scenarios of largest probability P[0.50], as only the high profit - high risk scenario is able to nearly fulfil the demand (99,5%) at the end of planning horizon (720h).

Table 1 – Summary of the results for optimal profit and equipment design

	Profit/ Expected Profit (c.u.)	Equipment capacity (mu/m ²)					
		R1	R2	R3	R4	R5	R6
Deterministic	191408.0	83.91	-	167.82	114.14	106.75	74.72
Stochastic (risk neutral)	202380.9	135.23	-	115.05	170.21	75.91	53.14
(CVaR) High Profit - High Risk	202839.9	125.14	-	83.91	170.21	79.59	55.71
(CVaR) Low Profit - Low Risk	154073.9	-	74.08	59.69	81.12	75.91	54.14

4. Conclusions

In this work, we have developed a modelling approach to provide decision-support on the design and scheduling of multipurpose batch plants, where the maximization of the economic plant profit was considered against the minimization of financial risk. In order to assess risk, the integration of *CVaR* risk measure in a bi-objective optimization framework was extended to a literature MILP model using the augmented ε -constraint method. The Pareto optimal curve enables the evaluation of the different solutions trade-offs, while considering the uncertainty in the products demand modelled through a scenario tree approach. From the results, it is clear that different risk strategies lead to different results and so the accountability of risk is very important in the management of batch plants. As future work, further analysis on the solution strategies derived from different risk measures and scenario trees to support robust decision-support in the optimization of design and scheduling industrial solutions.

Abstract

Only few applications of Model Predictive Control (MPC) for continuous crystallization processes are found in the open literature. A reason for this may be the nonlinear behaviour of this process. This work applies the MPC approach to improve the control of a Mixed Suspension – Mixed Product Removal (MSMPR) evaporative crystallizer. The modelling of the process was developed for potassium sulphate crystallization due to its well established kinetics for nucleation and growth. The model is described by six equations: the Population Balance Equations (PBE), integrated in moment equations; solute mass balance and the energy balance. The main objective was the regulatory control for the most common disturbances in the process: the feed solute concentration and the feed flowrate. The considered manipulated variables were temperature and steam outflow rate. The results showed that MPC is a feasible control strategy for the process. This is observed especially when the main interest is keeping under regulatory control more easily measured output variables, such as the second order momentum (related to the superficial area of crystals), the concentration, and the suspension temperature. The MPC controller was also compared to PI controllers, presenting better performance and desirable zero offsets for the outputs of greater interest.

Keywords: crystallization control, MPC, continuous crystallization, PBE, crystallization dynamics.

1. Introduction

Only few applications of Model Predictive Control (MPC) for continuous crystallization processes are found in the open literature. According to Kalbasenka et al. (2012), this scarcity is due to the nonlinear behaviour of this process. Rohami et al. (1999) showed that an offset-free control of the outputs was not possible to achieve using linear model-based MPC, attributing this shortcoming to possible model inaccuracies. Moreover, Moldoványi et al. (2005) have shown that a linear MPC was a capable and feasible controller for continuous Mixed Suspension – Mixed Product Removal (MSMPR) crystallizers, but the authors did not consider the energy balance in the model.

The online measurement of important variables, such as the solute concentration and the Crystal Size Distribution (CSD), make the MPC implementation viable. In addition to that, observers for unmeasured outputs are also robust enough to enable the MPC applications (DAMOUR et al., 2010; KALBASENKA et al., 2012).

In this work, the dynamic model of Andrade (1974) for a continuous MSMPR evaporative crystallizer was simulated. The potassium sulphate crystallization is considered due to the established kinetics for nucleation and growth of these crystals. Andrade (1974) had proposed the use of PI controllers to control the process. The MPC approach is presented here as a way to improve the process control of the crystallizer.

For the synthesis of MPC system, a multi-variable state space model was developed and the designed MPC controller was used to control both linear and nonlinear process models. The focus was in the regulatory control, evaluating the behaviour under unmeasured disturbances. The dynamics under PI and MPC controllers were then evaluated and compared.

2. Mathematical Modelling

The mathematical model was initially structured using the population balance of the crystals (ANDRADE, 1974). As the particle size distribution is difficult to observe, the transition to a macroscopic scale model can be performed using properties that can be measured in practice. As the first four moments have physical meaning, these moments were used to obtain the equations of the model: the zero order moment (μ_0) represents the total number of particles; the first order moment (μ_1) represents the sum of all characteristic lengths of the crystals; the second order moment (μ_2) is associated with the specific total area of the crystals; and the third order moment (μ_3) is associated with the specific total mass of the crystals – determined experimentally.

The moment equations (Equations 1-4) are obtained by performing the necessary integrations in the PBE.

$$\frac{d\mu_0}{dt} = \left(\frac{v_o}{\rho_w} - Q_i\right) \frac{\mu_0}{V} + B^0 \quad (1)$$

$$\frac{d\mu_1}{dt} = \left(\frac{v_o}{\rho_w} - Q_i\right) \frac{\mu_1}{V} + G^0(a\mu_0 + b\mu_1) \quad (2)$$

$$\frac{d\mu_2}{dt} = \left(\frac{v_o}{\rho_w} - Q_i\right) \frac{\mu_2}{V} + 2G^0(a\mu_1 + b\mu_2) \quad (3)$$

$$\frac{d\mu_3}{dt} = \left(\frac{v_o}{\rho_w} - Q_i\right) \frac{\mu_3}{V} + 3G^0(a\mu_2 + b\mu_3) \quad (4)$$

where V is the active volume inside the crystallizer; ρ_c and ρ_w are the specific mass of crystal and solvent (water), respectively; Q_i is the volumetric flow rate in the feed stream; v_o is the steam flow rate; B^0 is the nucleation rate; and G^0 is the initial growth rate. The mass balance of the solute is described by Equation 5.

$$\frac{dC_o}{dt} = \left(\frac{v_o}{\rho_w} - Q_i\right) \frac{C_o}{V} + \frac{Q_i C_i}{V} - \frac{1}{2} \rho_c k_A G^0 (a\mu_2 + b\mu_3) \quad (5)$$

where C_i and C_o is the solute concentration in the feed stream and in the suspended product stream, respectively. The energy balance was developed using the following assumptions: the accumulation of energy in the crystals and steam can be neglected; the sensible heat of the crystals is negligible compared to the sensible heat of the solution and produced steam; the steam is saturated, so that the enthalpy of vaporization is written as a function of temperature only. The energy balance yields the sixth equation of the model (Equation 6), in terms of the suspended product temperature T_o :

$$\frac{dT_o}{dt} = \frac{1}{(\rho_w + C_o)(a_1 - 2 a_2 T_o)} \left\{ \frac{Q_i}{V} (\rho_w + C_i) (h_i - h_o) + \frac{1}{2} \rho_c k_A G^0 (a \mu_2 \frac{v_o}{V} (h_o - H_{vap}) + b \mu_3) (h_o + \Delta H_{cryst}) \right\} \quad (6)$$

where $h_i = h_i(T_i, C_i)$, $h_o = h_o(T_o, C_o)$, $H_{vap} = H_{vap}(T_o)$ and $\Delta H_{cryst} = \Delta H_{cryst}(T_o, C_o)$ are mass based enthalpies.

3. Control Objectives and MPC Design

This work aims at the development of a strategy based on MPC for the multivariate process of the continuous crystallizer. The comparison of the MPC results with both conventional and optimal PI controllers was realized. The state variables, based on the model described in Section 2, are: $\mu_o, \mu_1, \mu_2, \mu_3, C_o$ and T_o . The variables T_i and v_o are manipulated variables. The disturbances are Q_i and C_i , assumed unmeasured. For the states variables, the vector of normalized state is defined $\mathbf{X} = [X_1 \ X_2 \ X_3 \ X_4 \ X_5 \ X_6]^T$. The vector \mathbf{U} represents the combined normalized manipulated (U_1 e U_2) and unmeasured disturbance (P_1 e P_2) vector ($\mathbf{U} = [U_1 \ U_2 \ P_1 \ P_2]^T$).

The regulatory control is applied to X_3, X_5 and X_6 (related to the superficial area of crystals, the suspension solute concentration and temperature, respectively), because they are possible to be directly measured in an easier way. The dimensionless time (t/τ) takes into consideration the normalization by the crystallizer residence time, τ .

The MPC formulation minimizes the process performance index J , the objective function of the problem (Equation 7). The MPC control horizon N_c was chosen as 5 and the prediction horizon N as 10 sampling intervals. The matrices \mathbf{Q} and \mathbf{R} are weighting matrices for the outputs and increment inputs, respectively; $\hat{\mathbf{y}}(k+j)$ is the predicted output and $\mathbf{y}_{ref}(k+j)$, its reference value. The decision variables of the optimization problem are the input control actions (\mathbf{u}). In the incremental formulation (Equation 7), $\Delta \mathbf{u}(k+j-1)$ is the vector of input increments (Equation 8).

$$J = \sum_{j=1}^N \left(\hat{\mathbf{y}}(k+j) - \mathbf{y}_{ref}(k+j) \right)^T \mathbf{Q} \left(\hat{\mathbf{y}}(k+j) - \mathbf{y}_{ref}(k+j) \right) + \sum_{j=1}^{N_c} \Delta \mathbf{u}(k+j-1)^T \mathbf{R} \Delta \mathbf{u}(k+j-1) \quad (7)$$

$$\Delta \mathbf{u}(k+j-1) = \mathbf{u}(k+j-1) - \mathbf{u}(k+j-2) \quad (8)$$

The rate weights for the inputs (U_1 e U_2), elements of \mathbf{R} , were maintained as 0.1. For the matrix \mathbf{Q} , since the main objective is the best performance for simpler direct measurable variables X_3, X_5 and X_6 , the results for the regulatory control were chosen with weights equal to 1 for these outputs. The variables were considered unconstrained in this study.

4. Results and Discussion

First, the linearization of the model was taken in the form of a state space model. The linear and nonlinear models were compared, for step responses. The linear model presents a good agreement with the nonlinear for the operation process transient

response and small steady-state errors. Figure 1 presents the results (X_2, X_4, X_5, X_6) for a 5% step in Q_i .

Table 1 presents the offset response values for -10% step in P_1 for the nonlinear plant model. The results allow the comparison of the MPC strategy with the continuous and discrete-time optimal PI controllers, as well as with the open-loop system. The tuning parameters for the PI controllers were: $K_{C_1} = 0.45$ and $\tau_{I_1} = 0.30$ for the first loop (v_o controlling C_o), using Ziegler-Nichols; $K_{C_2} = 15.0$ and $\tau_{I_2} = 0.026$ for the second loop (T_i controlling T_o), considering the closed-loop time as half of the residence time and the damping ratio equal to 0.3. For the discrete time controller, the dimensionless sampling time was 0.0333. The results show that the MPC presented the best performance.

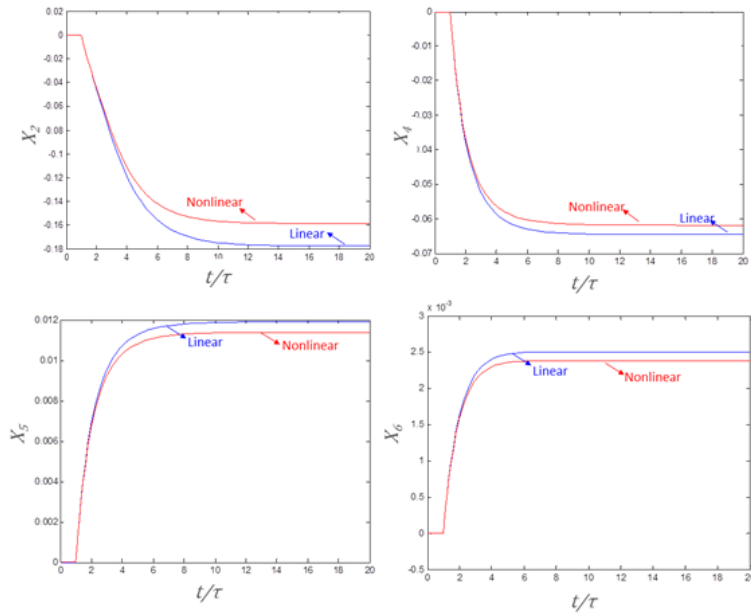

Figure 1 – Example of open-loop response for 5% step in Q_i ($P_i = 0,05$) for X_2, X_4, X_5 and X_6

Table 1- Comparison of offset for the negative step (-10%) in P_1

Variable	Offset			
	Open-Loop	Continuous PI	Discrete-time optimal PI	MPC
X_1	0,63	0,21	0,12	0,13
X_2	0,46	0,098	0,075	0,077
X_3	0,28	0,019	-0,020	0
X_4	0,157	-0,061	-0,078	-0,065
X_5	-0,026	0	0,0071	$5,4 \times 10^{-5}$

The output responses are shown in Figure 2, for a step disturbance in Q_i ($P_1 = -0.1$), using the nonlinear model as the plant model. Figure 3 shows the responses for a step disturbance in C_i ($P_2 = -0.1$).

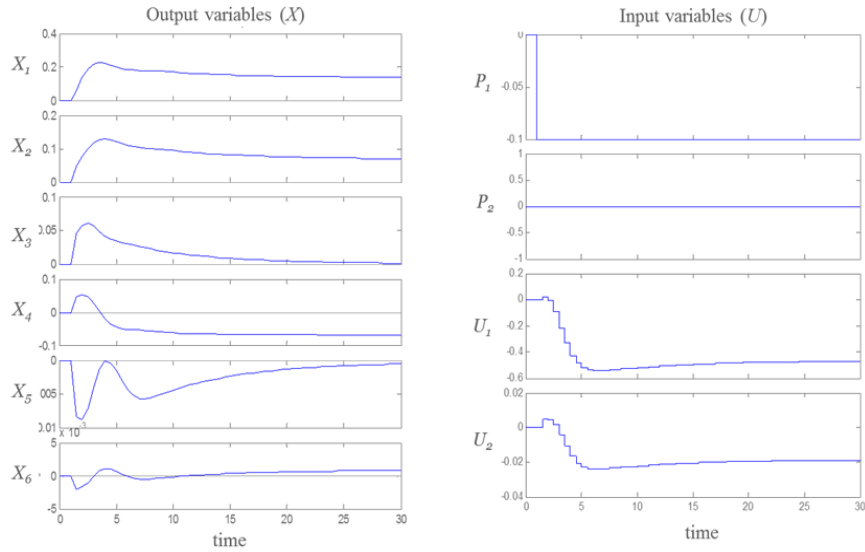

Figure 2 – MPC output responses and inputs for -10% step in Q_i ($P_1=-10\%$) for nonlinear plant model.

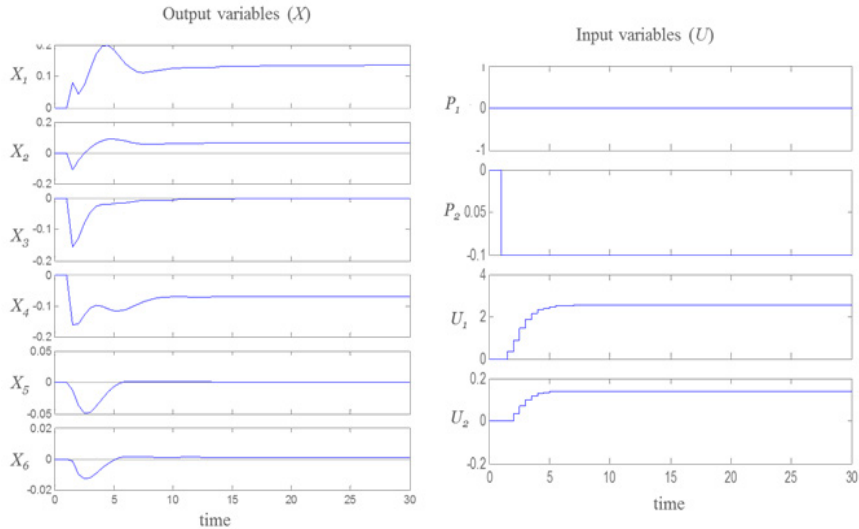

Figure 3– MPC output responses and inputs for -10% step in C_i ($P_2=-10\%$) for nonlinear plant model.

Preliminary evaluation using the linear plant model exhibits very close response to the observed in Figures 2 and 3, suggesting that the linearized plant model is The results prove the feasibility of MPC to control the variables X_3, X_5 and X_6 , in a regulatory system due to disturbances P_1 and P_2 . The variables X_1, X_2 and X_4 were not maintained in the exact original values (that is, in deviation, equal zero) but the changes and the offset for these variables are acceptable for the crystallization process. The successful

control results may be attributed to the good agreement between the nonlinear and linear models shown in Figure 1.

It is worth pointing out that some outputs are physically unmeasured in practice. If the outputs X_1 , X_2 and X_4 were declared as unmeasured, the obtained results (not shown due to lack of space), using a steady-state Kalman filter for state estimation in MPC, are very close to those pointed in Figures 1 and 2 for the same load perturbations.

5. Conclusion and prospects

In this work, an MPC was developed for a MSMMPR continuous crystallizer to improve the process control of this industrial process. The importance of the energy balance (that was not considered in the work of Moldoványi et al. (2005) to the mathematical model for the crystallizer is highlighted. In this sense, the open-loop dynamics of the input temperature of the solution is the most important one. This fact justifies the use of T_i as manipulated variable, being crucial for the control of the process.

The six state variables for the process were considered as possible to be directly measured. This is not easily achievable in practice due the difficulty in experimental determination of all moments. In order to solve this problem, the use of internal state observers in MPC formulation is a good strategy.

The MPC presented a better performance than PI controllers for most of the available cases. In some cases, it was possible to reach the desirable steady state values for the three outputs of greatest interest (X_3 , X_5 and X_6).

Moreover, it is suggested to incorporate feedforward actions to the MPC strategies, since the loads Q_i e C_i (P_1 and P_2 in normalized variables) can be measurable variables. The study of more complex models for the crystallization phenomena is interesting to be conducted with this MPC formulation, which can be a good alternative for the crystallization process control. For example, the description of crystals break and aggregation in PBE equations or the consideration of recycle of fine particles can be relevant to other models for crystallization process.

Abstract

We introduce a sequence to sequence deep learning algorithm to learn and predict sequences of process alarms and warnings. The proposed recurrent neural network model utilizes an encoder layer of Long Short-Term Memory (LSTM) units to map the input sequence of discrete events into a vector of fixed dimensionality, and a decoder LSTM layer to form a prediction of the sequence of future events. We demonstrate that the information extracted by this model from alarm log databases can be used to suppress alarms with low information content which reduces the operator workload. To generate easily reproducible results and stimulate the development of alarm management algorithms we define an alarm management benchmark problem based on the simulator of a vinyl acetate production technology. The results confirm that sequence to sequence learning is a useful tool in alarm rationalization and, in more general, for process engineers interested in predicting the occurrence of discrete events.

Keywords: alarm management, operator support system, recurrent neural networks

1. Introduction

Forecasting of discrete events has critical importance in process (safety) engineering (Baptista et al., 2018). In complex chemical production systems faults generate long sequences of alarm and warning signals. Although - according to alarm management guidelines - a single abnormal event should produce a unique and informative alarm, the high number of interacting components in modern production systems makes the co-occurring and redundant alarms almost inevitable (Mehta and Reddy, 2015). Since most of the signals are redundant, the handling of the malfunctions is a challenging task even for well-trained operators due to the unnecessarily high information overload. The concept of advanced alarm management is that the occurring alarms should be grouped and the prediction of future events should be used for the suppression of predictable, nuisance alarms.

The core concept of our methodology is based on the assumption of predictable alarms do not contain any novel information, so the state of the process can be already characterized based on the previously registered signals, so this information is enough to determine what operator actions are required in the given situation. As the efficiency of this approach relies on the performance of the model used for the prediction of the events, we selected the most advanced sequence to sequence deep learning neural network structure (Kiros et al., 2015) to realize our concept.

2. Methodology

2.1. Formulation of the sequence to sequence prediction problem

In process engineering practice, we frequently need to predict the occurrence of a discrete event. This task is highly relevant in alarm management, where the problem can be formulated as follows. Alarm and warning signals can be treated as *states* of the technology. Each state (denoted by s) is represented by $\langle pv, a \rangle$ data couples, where pv is the index of the process variable and a is the attribute showing the process variable's value related to the alarm and warning limits, such as $a \in \{Low A, Low W, High W, High A\}$, where A stands for Alarm and W stands for Warning. For example the description of a state can be represented as follows: $s_e := \langle Column Top Temperature, High A \rangle$. An *event* is the time interval in which the defined state occurs, denoted by e . We suppose that the $\Phi = (e_1, \dots, e_T)$ sequence of events (present and past alarms) defines the state of the process and we assume that based on this information we can predict the sequence of future events $\Phi \Rightarrow \hat{\Phi}$, where $\hat{\Phi} = (\hat{e}_1, \dots, \hat{e}_{\hat{T}})$. Therefore, we look for a $\hat{\Phi} = f(\Phi)$ model that efficiently handles this sequence to sequence modeling problem.

2.2. Encoder-decoder recurrent neural network based sequence prediction

The most advanced approach of sequence to sequence learning is based on deep learning neural networks. Although Nguyen et al. (2017) applied these models for event prediction, according to our knowledge, our work is the first example when it is used for the prediction of alarm and warning signals. The application of this unique recurrent neural network is not trivial, so in this section, we describe the proposed goal-oriented model structure (presented in Figure 1).

Forming the input of the model: Figure 1 highlights the important characteristics of the input sequences. As can be seen, an end-of-sequence (EOS) tag is appended to the sequence. To ensure fixed sequence length, we completed the sequences to the T -th element by adding padding symbols (PAD) after the EOS tag. Moreover, the order of the events in the input sequence is reversed, since Sutskever et al. (2014) found that the prediction accuracy improves when the beginning of the input sequence is "closer" to the beginning of the predicted sequence.

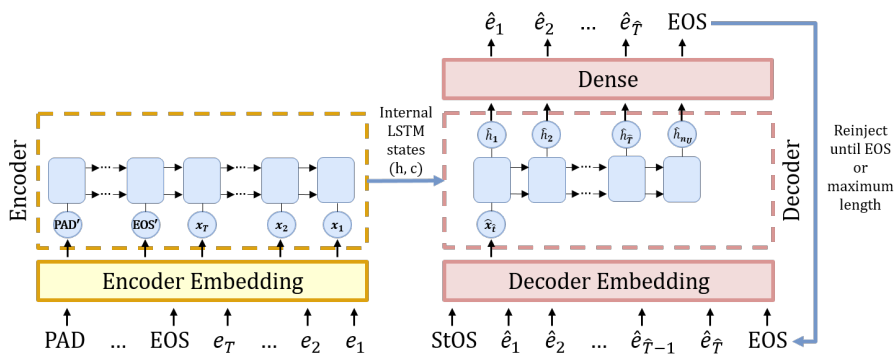

Figure 1: The schematic illustration of the proposed methodology. The encoder maps the input sequence into a fixed length vector representation. Using this vector as initial state the decoder layer determines the next event with the highest probability by the argmax function of the dense layer.

Embedding layer: To utilize the sequences of symbols as inputs of the neural network, we encode the symbols of the events as one-hot encoded vectors, \mathbf{oh}_t , where only one bit related to the encoded signal is fired among the n_d bits, where n_d represents the number of symbols. The embedding layer realises a $\mathbf{x}_t = \mathbf{W}_{emb} \mathbf{oh}_t$ linear transformation, which maps the one-hot encoded vectors into a lower (n_e) dimension of continuous values. Note that in Figure 1 the embedded form of the EOS and PAD symbols are represented as EOS' and PAD' respectively.

Encoder and decoder layers: The encoder LSTM layer maps the embedded input sequence into its internal states. The vector of the internal states and the activity values of the encoder layer are used for the conditioning of the LSTM units of the decoder layer, which means the transferring of information about what has happened in the process and what kind of prediction should the decoder layer generate. The decoder itself is trained to predict the next event of the predicted sequence, so the procedure is repeated until the prediction of an EOS signal or reaching the maximum sequence length.

Dense layer: The decoder layer maps the $\hat{\mathbf{x}}_t$ input event into a $\hat{\mathbf{h}}_t$ vector of real values represented as $\hat{\mathbf{h}}_t = [\hat{h}_1, \dots, \hat{h}_t^{n_U}]$ and used to calculate the probabilities of the occurrences of the events by the softmax activation function represented by the dense layer in Figure 1,

$$P(\hat{e}_{t+1} | \hat{\mathbf{x}}_t) = P(\hat{e}_{t+1} | \hat{\mathbf{h}}_t) = \frac{\exp(\hat{\mathbf{h}}_t^T \mathbf{w}_{s,j} + b_j)}{\sum_{j=1}^{n_d} \exp(\hat{\mathbf{h}}_t^T \mathbf{w}_{s,j} + b_j)} \quad (1)$$

where $\mathbf{w}_{s,j}$ represents the j -th column vector of the \mathbf{W}_s weight matrix of the output dense layer of the network, and b_j represents the bias.

Training: Deep learning requires a high number of training sequences which can be extracted from the log files of the process control system. When the malfunctions are also logged, special sequences can be defined that can be also used for fault classification (Dorgo et al., 2018). For the training of the model, we have to encode the input data to the one-hot vectorized form. The input data of the decoder is the one-hot vectorized form of the sequences that we want to predict. The decoder target data is also identical to the decoder input data, but it is shifted by one timestep since from the e_t event we would like to predict the e_{t+1} event. This training approach is referred as teacher forcing, which means that we use the expected future output from the training dataset at the current time step as input in the next time step, rather than the predicted output generated by the model, (J. Williams and Zipser, 1998). Using this technique, we train all of the layers (the two embedding, the encoder, the decoder and the dense layers) simultaneously.

Prediction: Prior to the prediction, we need to encode the sequence defining the internal state vector. The internal states of the encoder network are transferred to the decoder layer. The prediction starts with the start-of-sequence symbol (marked as StOS in Figure 1). The layer generates a prediction for the next event which will also be applied to the input of the next time step. The generated events are always appended to the predicted target sequence. This prediction process is repeated until the layer generates the end-of-sequence symbol or hit the previously set limit of the length of the predicted target sequence.

Evaluation: The evaluation of the model should be related to its intended application. Since we are focusing to build an alarm suppression algorithm, we defined two measures to evaluate the performance of the resulted models. Firstly, we defined val_1 as the percent of sequences having at least one well-predicted event, secondly, we calculate the percent of the well-predicted events (val_2).

3. Results

We present a reproducible benchmark example to ensure the comparability and reproducibility of our results. We extended the widespread dynamic simulator of a vinyl-acetate production system (VAC Chen et al. (2003)) to be able to serve case studies of alarm management and event analysis. The used dynamic simulator of the vinyl acetate (VAc) process contains 27 controlled and 26 manipulated variables, therefore it is complex enough to define alarm management problems. The model is available from the website of the authors (www.abonyilab.com). The extended simulator handles 11 malfunctions related to the fault of valves or actuators (see Figure 2). The events (alarms and warnings) were defined when the process variables exceeded certain threshold limits used to determine the normal operating range. The details of the alarms are given in our previous publication (Dorgo et al., 2018). In this study, the faults have lognormal time distribution, and their effects were simulated in 200 one-hour-long operating periods. A 100-minute time window was used to identify events that we consider as direct consequences of the malfunctions. We transformed these events into sequences based on their start time. The resulted sequences were filtered for the minimal length of five events, and the first half of the sequence was used as the encoder input sequence, and the rest of the sequence was used as the target sequence for prediction. From the originally generated 2200 sequences 1289 satisfied the minimal sequence length condition.

The simulation and the data preprocessing were carried out in MATLAB environment. Since we are interested in the development of open source and industrially applicable solutions, the deep neural network was identified and applied in Python/Keras using Tensorflow as backend. We trained the model using a Nvidia GeForce GTX 1060 6GB GPU with the application of CUDA. We selected the optimal model structure by 7-fold cross-validation experiments. The final model has an embedding dimension of 40. The number of LSTM units in both the encoder and decoder layer was 256. The number of epochs was set to 4000, with 256 as batch size using the RMSProp optimizer of Keras.

The performance of the resulted model is shown in Figure 3. As the 7-fold cross validation illustrates, the model has consistently excellent performance in case of all fault types.

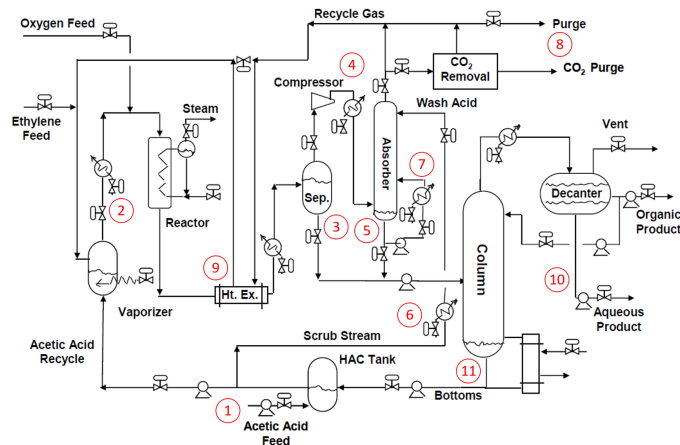

Figure 2: Flow chart of the vinyl acetate production technology (The numbers in circle (red) show the type of the implemented fault)

Figure 3: 7-fold cross validation of the prediction performance. Val_1 represents the percent of the sequences with at least one correctly predicted event, while Val_2 shows the average percent of the correctly predicted events. The first column shows the overall performance, while the other columns show the prediction power of the model in a given fault type.

Table 1 gives a didactic example for sequence prediction and for the evaluation process. In case of the first sequence two event tags, T_{14}^{LW} and Q_{20}^{HW} are correctly predicted, therefore $val_2 = 66\%$, while in the case of the second sequence, all of the events are predicted correctly (however, not in the correct order), therefore $val_2 = 100\%$.

Table 1: Illustration of the sequence prediction procedure. We denote the alarms by capital letters of T, Q and L to show the type of the measure variable, i.e. temperature, quality and level respectively. The letters L, H, W and A stand for low, high, warning and alarm respectively, and the numbers in lower script show the No. of the process variable. The prediction is based on input sequences used to represent the current operating state. To demonstrate how we evaluate the model performance the predicted and the logged sequences are also shown in two particular example.

Input Sequence					True Sequence					Predicted sequence								
T_{14}^{HA}	T_{14}^{LA}	T_7^{LW}	EOS		T_{14}^{LW}	Q_{20}^{HW}	L_{12}^{LW}	EOS		T_{14}^{LW}	Q_{20}^{HW}	L_{12}^{HW}	EOS					
L_3^{LW}	T_{16}^{HW}	T_{16}^{HA}	L_3^{LA}	T_{16}^{LA}	EOS		L_3^{LW}	T_{16}^{LW}	T_{16}^{HW}	L_{12}^{HW}	EOS		L_3^{LW}	T_{16}^{LW}	L_{12}^{HW}	T_{16}^{HW}	EOS	

4. Conclusions

We proposed a sequence to sequence learning based methodology to model the temporal patterns of discrete events related to the operation of complex chemical processes.

As we were interested in "translating" the sequence of past events that define the state of the technology and utilized operating strategy into the future sequence of events, the structure of the proposed recurrent neural network model has been inspired by the deep learning models used for language translation. The model consists of long short-term memory units which are specifically designed to handle long-term time-dependency, so ideal for the prediction of discrete events. The encoder layer maps the input sequence into a vector with fix length, while the decoder layer generates the next prediction based on the previously predicted elements. Both the inputs of the encoder and the decoder layer utilize embedding layers to map the set of discrete events into a lower dimension of continuous variables, while the prediction of the decoder layer is calculated by the argmax function of the dense layer.

We designed a benchmark simulation example to evaluate the effectiveness of alarm suppression algorithms. The results demonstrate the applicability of the proposed methodology for the extraction of useful operating patterns, which can be transformed to alarm suppression rules.

A two-stage stochastic programming approach to integrated day-ahead electricity commitment and production scheduling

Egidio Leo^{a*} and Sebastian Engell^a

Abstract

To ensure stability of the power grid, the electricity suppliers impose a daily day-ahead hourly electricity commitment to large consumers. In case the actual electricity consumption differs from the committed profile, the consumer is obliged to pay penalties. The challenge addressed in this work is to simultaneously determine the optimal day-ahead electricity commitment and the optimal production scheduling. Since the consumers have to commit themselves to the amount of energy they are going to purchase and use for a period of 24 hours one day before the actual electricity demand is realized, a major challenge lies in the uncertainty: equipment failures may reduce the production capacity and can make the actual electricity consumption drastically deviating from the day-ahead electricity commitment. For this purpose a two-stage stochastic mixed-integer linear programming model that considers equipment breakdowns is proposed. The application of the proposed approach to a continuous power intensive plant shows the improvement achieved by solving the stochastic model.

Keywords: Production scheduling, Two-stage stochastic programming, Demand Side Management, Load deviations, Conditional value-at-risk.

1. Introduction

Industrial Demand Side Response is a promising technology that is aiming at reducing operating costs for energy-intensive industries exploiting production flexibility to take advantage of time-sensitive electricity prices (Merkert et al., 2014). The volatility of the electricity prices, due to the availability of renewable energy sources, for electricity consumers constitutes a potential saving and for electricity suppliers an increased effort to match demand and supply. To ensure the stability of the power grid, the electricity suppliers impose a daily day-ahead hourly electricity commitment to large consumers and in case the actual consumption deviates from the pre-agreed values, financial penalties, which are often in the same range as the net electricity cost, are incurred. This is known in literature as the load-deviation problem. Nolde and Morari (2010) proposed a scheduling solution for electrical load tracking of a steel plant. The schedule is defined such that the total electricity consumption tracks the load curve as closely as possible while respecting all production constraints. In (Hadera et al., 2015), the authors take into account multiple electricity sources (Base load and Time-Of-Use (TOU) power contracts, day-ahead market, onsite generation) and the load deviation problem to determine the optimal production schedule. However, in these contributions the load

commitment decisions are assumed as given and are not optimized. In this work, we address the challenge of determining simultaneously the optimal day-ahead electricity commitment and the optimal production scheduling. Since decisions regarding the electricity commitment have to be made before the actual electricity demand is known for the time horizon of interest, it is crucial to account for uncertainties in the decision-making process. To this challenge we propose a two-stage stochastic programming approach (Birge and Louveaux, 2011). The first-stage variables represent the day-ahead electricity commitment decisions. The second stage faces plant capacity uncertainty and second-stage variables for each breakdown scenario are the plant operating decisions (production levels, inventories...) and the electricity consumption deviations from the day-ahead commitment. A similar approach has not been considered in this context before. In Section 2, the problem statement is presented highlighting the uncertainty modelling strategy and the proposed two-stage MILP. Section 3 applies the proposed framework to a power-intensive process and the results are summarized in terms of the Value of the Stochastic Solution (VSS) for risk-neutral and risk-averse optimization. The main insights from the results are discussed in Section 4 before providing some final conclusion in Section 5.

2. Problem statement

2.1. Uncertainty modeling strategy

To integrate day-ahead electricity commitment and production scheduling, we propose a two-stage stochastic programming approach (Birge and Louveaux, 2011). In two-stage stochastic programming (2SSP), uncertainty is represented by discrete scenarios, and decisions are made at two different stages which are defined by the realization of the uncertainty. Therefore we can divide the decision variables in two sets: here-and-now (or first-stage) decisions that have to be made at the beginning and cannot be changed over the scheduling horizon, and wait-and-see (or second-stage) decisions that can be adjusted after the realization of the uncertainty. In the proposed approach, we consider equipment breakdowns as source of uncertainty and three different levels of uncertainty—low, medium, and high. The low, medium and high uncertainty levels represent respectively 10, 30 and 40 percent reduction of the maximum plant production capacity. The production capacity reduction is modelled by 8 breakdown scenarios: in scenario 1 no breakdown occurs, whereas in Schemes 2–8 the breakdown occur in periods 1-4,...,22-24, respectively. The probabilities are 50% for scenario 1 and (50/7) % for scenarios 2–8.

2.2. Plant model

To demonstrate the main features of the proposed approach, we apply it to a continuous-production plant. The plant is the same as in (Zhang et al., 2016). In the proposed mathematical formulation *here-and-now* decisions have no scenario subscript and *wait-and-see* decisions have the scenario subscript s . The plant produces two products i ($P1$ and $P2$) and it can operate in three different modes m : *off*, *startup*, and *on*. The possible mode transitions are *off* to *startup*, *startup* to *on*, and *on* to *off* and they can happen only after fixed period of time that have been spent in the modes (*off*: 8 h, *startup*:2 h, *on*:6 h) (Eq.6). The transitions between the modes of operation and the relations with the active modes are modelled by Eq.(7). The binary variable (Eq.(4)) is 1 if mode m is selected in time period t of the horizon T . For each mode, the operating conditions are expressed as a convex combination of the extreme points v_{mjis} of the feasible region of

operation (Eq.(2)). Eq.(1)-(2) define the hourly production levels \overline{PD}_{mits} for each product i and operating mode m and the aggregated production PD_{its} .

$$PD_{its} = \sum_m \overline{PD}_{mits} \quad \forall i, t \in T, s \quad (1)$$

$$\overline{PD}_{mits} = \sum_j \lambda_{mjts} * v_{mjis} \quad \forall i, t \in T, m \in M, s \quad (2)$$

$$\sum_j \lambda_{mjts} = y_{mt} \quad \forall m, t \in T, s \quad (3)$$

$$\sum_m y_{mt} = 1 \quad \forall t \in T \quad (4)$$

$$EU_{ts} = \sum_m \left(\delta_m * y_{mt} + \sum_i \gamma_{mi} * \overline{PD}_{mits} \right) \quad \forall t \in T, s \quad (5)$$

$$\sum_{k=1}^{\theta_{mm'}} z_{mm't-k} \leq y_{m't} \quad \forall (m, m') \in M, t \in T \quad (6)$$

$$\sum_{m'} z_{m'm,t-1} - \sum_{m'} z_{mm',t-1} = y_{mt} - y_{m,t-1} \quad \forall m, t \in T \quad (7)$$

Eq. (8) defines the inventory level IV_{its} at time t as the sum of the inventory level at time period $t-1$ and the production at time t , PD_{its} , minus the amount of product sold, SL_{its} , and the amount of products wasted, PW_{its} , at time period t . Note that all these variables are *wait-and-see* variables and therefore they are defined for each scenario s . Eq. (9) sets upper and lower bounds of the inventory levels and Eq. (10) ensures that the demand of product i as the sum of the amount of product sold, SL_{its} , and the amount of products purchased from other sources, PC_{its} , is satisfied.

$$IV_{its} = IV_{i,t-1,s} + PD_{its} - SL_{its} - PW_{its} \quad \forall i, t \in T, s \quad (8)$$

$$IV_{it}^{min} \leq IV_{its} \leq IV_{it}^{max} \quad \forall i, t \in T, s \quad (9)$$

$$SL_{its} + PC_{its} = D_{it} \quad \forall i, t \in T, s \quad (10)$$

Eq. (11) - (14) provide the initial and final condition of the plant in terms of inventory levels and active operating modes.

$$IV_{i,0,s} = IV_i^{initial} \quad \forall i, s \quad (11)$$

$$y_{m,0} = y_m^{initial} \quad \forall m \quad (12)$$

$$IV_{i,t^{final},s} \geq IV_i^{final} \quad \forall i, s \quad (13)$$

$$z_{mm't} = z_{mm't}^{ini} \quad \forall (m, m') \in M, s, -\theta^{max} + 1 \leq t \leq -1 \quad (14)$$

2.3. Day-ahead electricity commitment

Eq. (15) defines the day-ahead electricity commitment, ES_t , the over-consumptions Δe_{ts}^+ and the under-consumptions Δe_{ts}^- . Since the consumers have to commit themselves to the amount of energy they are going to purchase for a period of 24 hours one day before the actual electricity demand is realized, the electricity commitment decisions are first-stage variables and the load deviations and the actual electricity consumptions are second stage variables.

$$EU_{ts} - ES_t = \Delta e_{ts}^+ - \Delta e_{ts}^- \quad \forall t \in T, s \quad (15)$$

2.4. Objective function

We solve the proposed stochastic formulation considering both risk-neutral and risk-averse optimization. The two approaches mainly differ in the objective functions. The

risk-neutral optimization minimizes the expected operating cost; the risk-averse optimization balances two conflicting objectives: the expected cost and the risk, defined as the expected cost over the worst scenarios.

2.4.1. Risk-neutral optimization

The model minimizes the total expected operating costs, z , defined in Eq.(16) as the first-stage cost of day-ahead electricity commitment and the expected second-stage cost of deviation penalties and purchasing of products on the market.

$$z = \sum_t \left(p_t^{\text{day-ahead}} ES_t + \sum_s \varphi_s \left(p_t^+ \Delta e_{ts}^+ + p_t^- \Delta e_{ts}^- + \sum_i p_i PC_{its} \right) \right) \quad (16)$$

where $p_t^{\text{day-ahead}}$, p_t^+ , p_t^- , p_i represent the day-ahead electricity price, the penalty cost for over consumption and under consumption and the product purchasing prices; φ_s denotes the probability of scenario s .

2.4.2. Risk-averse optimization

Different risk measures have been presented in the literature: value-at-risk (VaR), downside risk, Conditional value-at-risk (CVaR) (Rockafellar and Uryasev (2000)). We adopted the CVaR (Rockafellar and Uryasev (2000)), since it is a coherent risk measure (it preserves convexity) and it is able to consider the tail of the probability density function. The CVaR is defined by Eq.(17)-(18).

$$CV = k + \frac{1}{1 - \alpha} \sum_s \varphi_s \theta_s \quad (17)$$

$$\sum_t \left[p_t^{\text{day-ahead}} ES_t + p_t^+ \Delta e_{ts}^+ + p_t^- \Delta e_{ts}^- + \sum_i p_i PC_{its} \right] - k \leq \theta_s \quad \forall s \quad (18)$$

$$\min\{\delta * CV + (1 - \delta) * z\} \quad (19)$$

where k, θ_s are continuous variables with $k \in \mathbb{R}$ and $\theta_s \geq 0$. Eq. (19) defines the objective function as the weighted sum of the total expected cost and the CVaR ($\delta = 0.5$).

3. Results

To measure the improvement that can be achieved by solving the stochastic model instead of its deterministic counterpart, we compute the value of the stochastic solution (VSS). The VSS and the relative \overline{VSS} , defined in Eq.(20)-(21), show the impact of the uncertainty on the first-stage variables:

$$VSS = z_{det}^* - z_{stoc}^* \quad (20) \quad \overline{VSS} = \frac{z_{det}^* - z_{stoc}^*}{z_{det}^*} \quad (21)$$

where z_{stoc}^* is the optimal solution of the stochastic problem and z_{det}^* is the optimal solution of the stochastic problem with first-stage variables fixed to the values at the optimal solution of the deterministic problem. Table 1 shows the VSS for risk-neutral and risk-averse optimization: the VSS can be quite significant and that it grows with the uncertainty level. The high values of the VSS demonstrate that there is a significant benefit from considering breakdown uncertainty in the integrated day-ahead electricity procurement and production scheduling. The VSS obtained for the risk-averse optimization are considerably higher than those obtained in risk-neutral optimization. Each model has up to approximately 6,500 continuous variables, 209 binary variables, and 3,900 constraints. All models were solved to zero integrality gap in less than 10 s

on an Intel(R) Core(TM) i7-4790 machine at 3.60 GHz with eight processors and 16 GB RAM. All models were implemented in GAMS 24.7.4 (GAMS Development Corporation, 2015), and the MILPs were solved applying the commercial solver CPLEX 12.6.3.0.

Table 1 Value of the stochastic solution for risk-neutral and risk-averse optimization for different levels of uncertainty

Uncertainty level	Risk-neutral optimization		Risk-averse optimization	
	VSS [€]	\bar{VSS} [%]	VSS [€]	\bar{VSS} [%]
Low	84.4	2.8%	367.3	3.7%
Medium	214.6	6.4%	1029.5	10.6%
High	247.9	7.0%	1210.2	12.9%

4. Discussion

Fig.1 shows the electricity purchase profiles that were obtained solving the risk-neutral stochastic model and the deterministic model for the medium uncertainty level. Time-of-Use (TOU) and base load profiles represent the amount of energy purchased from the power contracts. TOU and base load profiles are supposed to be given and therefore not optimized since contract related decisions have to be made before the time horizon of interest (1 week before for the TOU contract and 1 year before for the base load contract). The comparison between the two solutions shows the impact on the day-ahead electricity commitment (first-stage variables) of accounting for other scenario besides the expected one. In the deterministic solution (Fig.1b) the day-ahead commitment depends exclusively on the day-ahead electricity price: in case of price peak (at 9-10 h and 20-21 h) the electricity purchase is drastically reduced and the production is shifted to time periods when the electricity price decreases. In the stochastic solution (Fig.1a), instead, during the price peaks more electricity is purchased in order to be able to compensate reductions of the production capacity. By doing so, lower penalties for deviating from the day-ahead commitment are incurred.

5. Conclusion

This work addresses the integrated day-ahead electricity commitment and production scheduling for continuous power-intensive processes. A two-stage stochastic programming approach is proposed to model uncertainty of equipment breakdowns. The application of the proposed approach to a power intensive plant shows the benefit of the stochastic model. Risk is taken into account by incorporating the CVaR into the optimization model.

Changing between Active Constraint Regions for Optimal Operation: Classical Advanced Control versus Model Predictive Control

Adriana Reyes-Lúa^a, Cristina Zotică^a, Tamal Das^a, Dinesh Krishnamoorthy^a and Sigurd Skogestad^{a*}

Abstract

Control structures must be properly designed and implemented to maintain optimality. The two options for the supervisory control layer are Advanced Control Structures (ACS) and Model Predictive Control (MPC). To systematically design the supervisory layer to maintain optimal operation, the constraints that can be given up when switching active constraint regions should be prioritized. We analyze a case study in which we control the temperature and the flow in a cooler with two degrees of freedom (DOF) represented by two valves, one for each of the two streams. Either valve can saturate and make a constraint active, forcing other constraints to be given-up, and thus changing the set of active constraints. We show that optimal or *near*-optimal operation can be reached with both ACS and MPC. We do a fair comparison of ACS and MPC as candidates for the supervisory layer, and provide some guidelines to help steer the choice.

Keywords: Process control, supervisory control, PID control, MPC, optimal control, active constraints

1. Introduction

On a time-scale basis, the overall control problem of a process plant can be decomposed into different layers. The upper layers are explicitly related to slow time scale economic optimization, which sends economic setpoints to the lower and faster control layer. The control layer is divided into supervisory layer and regulatory layer. The latter follows the set-points given by the former and stabilizes the plant. Most process are operated under a set of constraints, which can be operational limitations, quality specifications, or safety and environmental requirements. “Active constraints” are related to variables that should be kept at their limiting value to achieve optimality. These can be either Manipulated Variables (MVs) or Controlled Variables (CVs). The MVs correspond to the dynamic (physical) DOF used by the control system, and a typical MV constraint is the maximum opening of a valve. An example of CV constraint is the maximum pressure in a distillation column. Every process is subject to disturbances, such as changes in feed rate or product specification. It is the task of the supervisory or “advanced” control layer to maintain optimal operation despite disturbances. The supervisory control layer has three main tasks (Skogestad, 2012):

1. Switch between the set of CVs and control strategies when active constraint changes occur due to disturbances.

2. Supervise the regulatory layer, avoiding saturation of the MVs used for regulatory control.
3. Follow economic objectives by using the setpoints to the regulatory layer as MVs .

The supervisory control layer could be designed using classical ACS with PID controllers, or using MPC, which achieves optimal operation and handles constraints and interactions by design. With ACS, we refer to PID-based structures such as split range control (SRC), input resetting (valve positioning), and use of selectors, to name a few.

2. Changes in active constraint regions and optimal operation

When a disturbance occurs, the process might start operating in a different active constraint region. If the supervisory layer is well-designed, it is possible to maintain optimal operation by using ACS with PID controllers, or by using MPC.

2.1. Optimal control in the presence of active constraint changes

Regardless of whether we choose ACS or MPC, the first step to systematically design the supervisory control layer is to identify and prioritize all constraints. It is useful to visualize how disturbances may cause new constraints to become active. In some cases, we can generate a plot showing the active constraint regions (optimal operation) as a function of variations in important disturbances by solving a series of optimization problems. This may be very time consuming and, in some cases, difficult due to the lack of an appropriate model. Moreover, it can also be difficult to visualize for more than two variables. Alternatively, we can use process knowledge and engineering insight to minimize the need for numerical calculations (Jacobsen and Skogestad, 2011). This information is useful regardless of the type of controller used in the supervisory layer.

Prioritization of constraints has been implemented in a few industrial MPC applications (Qin and Badgwell, 2003). Reyes-Lúa et al. (2018) propose a guideline to generate a priority list of constraints that can be used also for ACS. Under this scheme, the constraints with the lowest priority should be the first given-up when it is not feasible to fulfill all constraints. This way, controlling a high priority constraint will never be sacrificed in order to fulfill a low priority constraint.

2.2. Advanced control structures in the supervisory layer

ACS requires a choice of pairings, which can become challenging with changing active constraints. When implementing ACS, Reyes-Lúa et al. (2018) propose to start designing the control system for the nominal point, with few active constraints and with most of the priorities satisfied. Then, to minimize the need for reassignment of pairings when there are changes in active constraints, we should pair MVs with CVs according to the *Pairing Rule* (Minasidis et al., 2015): *An important controlled variable (CV) (which cannot be given up) should be paired with a manipulated variables (MV) that is not likely to saturate.*

When a disturbance occurs and the process starts operating in a different active constraint region, two types of constraints might be reached:

- MV constraint: we must give up controlling the corresponding CV. If the pairing rule is followed, this MV is paired with a low priority CV, which can be given-up. However, if it is not possible to follow the *pairing* rule, the high priority CV must be reassigned to an MV which is controlling a low priority CV. This requires the use of ACS such as input resetting (valve position control) or SRC combined with a selector block.
- CV constraint: we should give up controlling a CV with a lower priority. We can do this using a *min/max* selector.

2.3. Model predictive control in the supervisory layer

MPC uses an explicit process model to predict the future response of the plant and, by computing a sequence of future MV adjustments, optimizes the plant behavior. The first input of the sequence is applied to the plant, and the entire calculation is repeated at every sampling time (Qin and Badgwell, 2003).

The main challenge when using MPC is that expertise and a good model is required. This is either difficult to have ready at startup, or the modelling effort is too expensive. To achieve a truly optimal operation, the model would need to be perfect, and all the measurements would need to be available and reliable, which is unrealistic from a practical point of view. There are methods to circumvent this, but there is no universal solution and this analysis is out of the scope of this paper.

When an application lacks DOF to meet all control specifications, standard text-book MPC does not handle changes in active constraints effectively. The standard approach is to use weights in the objective function to assign the priorities. Having weights in the objectives function implies a trade-off between the control objectives. An optimal weights selection can assure that a CV is completely given-up, or that the solution will lie at the constraint, as explained in Section 3.4.2. However, there is no systematic way of choosing the weights, as there are no tuning rules for MPC, and this has to be done by trial and error.

An alternative approach consists of implementing a two-stage MPC with a priority list. The first stage has the purpose of finding the solution of a sequence of local steady-state optimization problems (LPs and/or QPs). In this sequence constraints are added in order of priority. The resulting information regarding feasibility is used in the formulation of the dynamic optimization problem for the MPC in the second stage (Qin and Badgwell, 2003).

3. Case study

We study a cooler in which the main control objective is to keep the outlet temperature in the hot stream to a desired setpoint ($T_H = T_H^{sp}$) by using cooling water (F_C). Additionally, the setpoint for the flow of the hot stream (F_H^{sp}) can be changed.

There are two MVs, one corresponding to the cooling water (F_C) and another to the hot stream (F_H). Desired operation is at maximum throughput, with $F_H^{sp} = F_H^{max}$. The primary input (F_C) may saturate for a large disturbance (T_c^{in}). This case is an extension of what is presented by Reyes-Lúa et al. (2018).

3.1. Process model

We consider a countercurrent cooler, represented by the dynamic lumped model in Eq. (1). The cooler is discretized in space into a series of $n = 10$ cells, as depicted in Fig. 1. Incompressible fluids and constant heat capacities are assumed. The boundary conditions are: $T_{H_0} = T_{H_{in}}$ for cell $i = 1$ (inlet), and $T_{C_{11}} = T_{C_{in}}$ for cells $i = 10$ (outlet). The energy balance for cell $i = 1 \dots n$ is:

$$\frac{dT_{C_i}}{dt} = \frac{F_C}{\rho_C V_{C_i}} (T_{C_{i+1}} - T_{C_i}) + \frac{UA_i(T_{H_i} - T_{C_i})}{\rho_C V_{C_i} c_{pC}} \quad (1a)$$

$$\frac{dT_{H_i}}{dt} = \frac{F_H}{\rho_H V_{H_i}} (T_{H_{i-1}} - T_{H_i}) + \frac{UA_i(T_{H_i} - T_{C_i})}{\rho_H V_{H_i} c_{pH}} \quad (1b)$$

Figure 1: Lumped model for the studied cooler.

3.2. List of priorities

Table 1 shows the priority list of constraints for the cooler we are analyzing.

Table 1: Constraints for the studied cooler.

Priority level	Description	Constraints
1	MV inequality constraints which define the feasibility region	$F_H \leq F_H^{max}$ $F_C \leq F_C^{max}$
2	MV or CV equality constraints, which is the control objective	$T_H = T_H^{sp}$
3	Desired throughput	$F_H = F_H^{sp}$
4	CV inequality constraints or self optimizing variables	none

3.3. Active constraint regions for cooler

As we want to keep $T_H = T_H^{sp}$, this constraint is always active and only one DOF remains. With one DOF and three potential constraints we have three possible active constraint regions, which are shown as a function of the throughput (F_H) and the disturbance (T_c^{in}) in Fig. 2.

Active constraint in each region:

- Region 1: $F_H = F_H^{sp}$
- Region 2: $F_H = F_H^{max}$
- Region 3: $F_C = F_C^{max}$

Figure 2: Active constraint regions for the cooler

3.4. Design of the supervisory layer for the cooler

We consider nominal operation in Region 2 ($F_H^{sp} = F_H^{max}$). According to the priority list, when T_c^{in} is so high that $F_C = F_C^{max}$, the controller should give up controlling $F_H = F_H^{max}$ and reduce F_H to keep $T_H = T_H^{sp}$, thus switching to Region 1. We design both an ACS and an MPC for this case.

3.4.1. Classical advanced control structures for optimal operation

To design the supervisory layer using ACS, we implement SRC with a *min* selector block, as in Fig. 3. The controller is tuned by fitting a first order plus delay model obtained from the open-loop step response of the process, and applying the SIMC rule (Skogestad, 2003) with $\tau_c = 80$ s and $K_c = -0.06$. To account for the different gains that F_C (negative) and F_H (positive) have on T_H , the MVs were respectively multiplied with a gain of 1 and -2 .

Figure 3: Split range control structure for cooler.

3.4.2. Model predictive control for optimal operation

The optimal control problem is discretized into a finite dimensional optimization problem divided into $N = 40$ control intervals. We use a third order direct collocation scheme for a polynomial approximation of the system dynamics for each time interval.

The dynamic optimization problem is setup in CasADi (Andersson, 2013), which is an algorithmic differentiation tool. According to Eq. 1, the dynamic model is non-linear. The resulting NLP problem is thus solved using IPOPT (Wächter and Biegler, 2005). The prediction horizon is set to 400 s with a sampling time of $\Delta t = 10$ s. We assume we have full state feedback and the disturbance, T_c^{in} , is measured.

In this paper, we chose to implement the standard MPC formulation given by Eq. 2, and to assign different weights for the two control objectives. A high weight is assigned to the high priority CV (T_H) and a low weight is assigned to the low priority CV (F_H). The values $\omega_1 = 3$ and $\omega_2 = 0.1$ are used. These were found by trial and error. In addition, the MVs are restricted to a rate of change of 10% of F_H^{max} and F_C^{max} respectively.

$$\begin{aligned}
 \min \quad & \sum_{k=1}^N \left(\omega_1 \| (T_{H_k} - T_H^{sp}) \|^2 + \omega_2 \| (F_{H_k}^{max} - F_{H_k}) \|^2 \right) \\
 \text{s.t.} \quad & \left. \begin{aligned}
 T_{k,i} &= f(T_{H_{k,i}}, T_{H_{k,i-1}}, T_{C_{k,i}}, T_{C_{k,i+1}}, F_{H_k}, F_{C_k}) \\
 0 &\leq F_{H_k} \leq F_H^{max} \\
 0 &\leq F_{C_k} \leq F_C^{max}
 \end{aligned} \right\} \quad \forall k \in \{1, \dots, N\} \\
 & \left. \begin{aligned}
 0 &\leq \Delta F_{H_k} \leq 0.1 F_H^{max} \\
 0 &\leq \Delta F_{C_k} \leq 0.1 F_C^{max}
 \end{aligned} \right\} \quad \forall k \in \{1, \dots, N-1\}
 \end{aligned} \tag{2}$$

where $\Delta F_k = F_k - F_{k-1}, \forall k \in \{1, \dots, N-1\}$. For $k = 1$, F_{k-1} represents the flow at the nominal operation point.

3.4.3. Simulation results

Fig. 4 shows the simulation results for the case study. T_H^{sp} is 26.3°C . MPC and SRC are tested for the same step disturbances in T_c^{in} : $+2^\circ\text{C}$ at $t = 10\text{s}$, and an additional $+4^\circ\text{C}$ at $t = 1000\text{s}$. Both MPC and SRC follow the priority list and reach optimal operation at steady state. Once $F_C = F_C^{max}$, the control structure gives-up controlling $F_H = F_H^{max}$, and F_H is used as MV to maintain $T_H = T_H^{sp}$.

Figure 4: Simulation results for MPC and SRC.

4. Discussion and conclusion

The supervisory control layer can be designed using MPC or ACS. MPC uses the manipulated variables to achieve optimal operation by design, but it requires expertise and a model, which may be difficult to obtain. Well designed ACS can also maintain optimal operation, require much less model information, and are usually easier to implement and tune. In our example, SRC efficiently switches the MVs, achieving optimal operation. Compared to ACS, MPC implementation requires more effort as the tuning of weights in the objective function is more challenging because it is done by trial and error. As it is seen in Fig 4, for a short transient time during the first disturbance in the MPC implementation, $F_H \neq F_H^{max}$. This could be improved by increasing ω_2 relative to ω_1 . This would however be at the expense of having an offset for T_H from T_H^{sp} , as its weight in the objective function would be smaller. Therefore, we should point out that a different MPC implementation or tuning could have better performance, especially on the input usage.

We recommend to use priority lists as a tool for analyzing and designing the supervisory layer. Understanding the process is an important step to decide which controller should be implemented. Both ACS and MPC have advantages and disadvantages, and the designer of the control layer should be aware of these. While in simple cases such as the presented case study, ACS seems better fitted due to achieving optimality with less implementation effort, in multivariable systems with more interactions, MPC should be considered as the most convenient alternative.

Health-Aware Operation of a Subsea Compression System Subject to Degradation

Adriaen Verheyleweghen^a, Julie Marie Gjøby^a and Johannes Jäschke^{a,*}

^a*Dept. of Chemical Engineering, NTNU, N-7491 Trondheim, Norway*
jaschke@ntnu.no

Abstract

We propose an health-aware operation approach for combining short-term control objectives with long-term profit and reliability targets. In particular, we present a hierarchical approach for operating a compressor subject to degradation. We consider a case study of a subsea compressor, where the goal is to maximize the gas throughput, while ensuring that the compressor can be operated continuously until a planned maintenance stop. In the top layer, we repeatedly solve a dynamic optimization problem to find the optimal long-term operation strategy, subject to load-induced compressor degradation. The supervisory control layer below receives the computed setpoints and operational parameters, and applies them in a self-optimizing control structure to ensure near-optimal operation in the presence of disturbances. The regulatory control layer in the bottom stabilizes operation in an otherwise unstable operating region (surge). We show the efficacy of our health-aware operation approach by comparing it to traditional control structures where the equipment health is not explicitly considered as part of the production optimization. Our approach results in higher average production, without jeopardizing the health of the system.

Keywords: Health-aware operation, Control, Reliability, Optimal Operation, Rotating Machinery

1. Introduction

Unplanned maintenance intervention of subsea systems are costly, so it is necessary to ensure that operation does not reduce the system reliability to unacceptable levels. Traditionally, this has been achieved by introducing large safety margins and enforcing conservative operational strategies. Better economical performance can be achieved by employing prognostics and health monitoring (PHM), which means that the system state is monitored and projected into the future. A natural extension of PHM is health-aware control, in which we combine control and reliability objectives, yielding a control structure that maximizes plant profitability while keeping the plant health within acceptable limits (Sanchez et al., 2015; Verheyleweghen and Jäschke, 2017).

Health-aware control is achieved by repeatedly solving a shrinking horizon dynamic optimization problem to find an operating strategy based on the current compressor health and its predicted development. The time horizon is from the present until the next planned maintenance intervention, and the objective is to maximize the profit subject to health constraints. The dynamics of this layer are on the time-scale of weeks to months. On a more frequent basis, disturbances are rejected by a supervisory control layer in order to keep operation close to the desired (optimal) operating point. We use self-optimizing control ideas (Skogestad, 2000) to achieve this. The lowest and fastest control layer is in charge of surge control. Surge is an unwanted mode of operation characterized by limit-cycle oscillations in flow and pressure, which can harm the internals of the compressor (McMillan, 1983). Traditionally, operation is restricted by a generous safety margin from the surge

line. However, it is often desirable to operate closer to the surge line, as this leads to increased efficiency and lower operating costs. An alternative to surge avoidance is active surge control. For this purpose, a close-coupled valve (CCV) is introduced to the system. Using the CCV, we can control the compressor characteristic, thereby stabilizing operation in an otherwise unstable region (Gravdahl and Egeland, 1999). A feedback linearizing controller proposed by Backi et al. (2016), is used for this purpose. An illustration of the proposed control structure is shown in Figure 1.

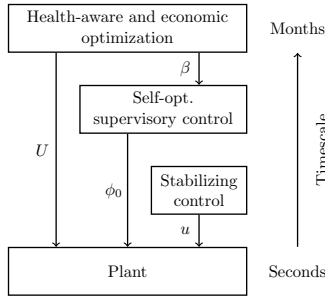

Figure 1: Multi-layer control structure for stable, health-aware operation.

of the non-dimensional compressor mass flow ϕ and the non-dimensional pressure rise across the plenum, ψ . A detailed description and derivation of the model is given in Gravdahl and Egeland (1999), but a summary is given below for completeness. An illustration of the system is given in Fig. 2. Three degrees of freedom are available for control in the system: the compressor speed, the CCV opening and the throttle opening.

The two-state Greitzer model is given as:

$$\dot{\hat{\phi}} = B [\hat{\Psi}_C(\hat{\phi}) - \hat{\psi} - u] \quad (1)$$

$$\dot{\hat{\psi}} = \frac{1}{B} [\hat{\phi} - \hat{\Phi}_T(\hat{\phi})], \quad (2)$$

where the ($\hat{\cdot}$)-symbol is used to denote deviation from the specified operating points, $\hat{\phi} = \phi - \phi_0$ and $\hat{\psi} = \psi - \psi_0$. (ϕ_0, ψ_0) is the specified operating point. In the above expression, B is the Greitzer parameter, which is proportional to the compressor blade tip speed U , $B = kU$, where k is a geometry-dependent constant. $\hat{\Psi}_C$ is the cubic approximation of the axisymmetric compressor characteristic, $\hat{\Phi}_T$ is the throttle characteristic, and the input u is the pressure drop across the CCV (as determined by its opening). The compressor and throttle characteristics is shown in Figure 3.

The compressor characteristic $\hat{\Psi}_C$ indicates the pressure rise for a given flow, and is unique for every compressor. The characteristic is approximated by the cubic

$$\hat{\Psi}_C(\hat{\phi}) = -k_3\hat{\phi}^3 - k_2\hat{\phi}^2 - k_1\hat{\phi}, \quad (3)$$

where $k_1 = \frac{3H\phi_0}{2W^2} \left(\frac{\phi_0}{W} - 2 \right)$, $k_2 = \frac{3H}{2W^2} \left(\frac{\phi_0}{W} - 1 \right)$ and $k_3 = \frac{H}{2W^3}$. H and W are equipment-specific parameters relating to the peak and valley points of the compressor characteristic. The peak point, $(\phi^*, \psi^*) = (2W, \psi^*)$, is assumed to be the surge point, with all points left of the peak being unstable.

The main contributions of this paper are the following: 1) We propose a three level control structure for health-aware control of a compression system. 2) We show that the method outperforms traditional control methods

2. Model description

2.1. Short timescale dynamics: Surge

The surge model used here is that of a centrifugal compressor with an added CCV for surge control, which as described by Simon (1993). We use the transformed version of the model presented by Gravdahl and Egeland (1999), by which the system can be described in terms

Figure 2: Flowsheet of the Greitzer compressor model

Figure 3: Cubic approximation of the axisymmetric compressor characteristic (blue) and the throttle characteristic (red). The operating point (ϕ_0, ψ_0) is shown in purple and the surge point $(\phi^*, \psi^*) = (2W, \psi^*)$ is shown in orange. The surge line (surge point at various compressor speeds) is shown as the dashed line.

The throttle characteristic is given as

$$\hat{\Phi}_T(\hat{\Psi}) = \frac{\phi_0}{\sqrt{\psi_0}} \left(\text{sign}(\psi) \sqrt{|\psi|} - \sqrt{\psi_0} \right). \quad (4)$$

The intersection between $\hat{\Psi}_C$ and $\hat{\Phi}_T$ gives the operating point (ϕ_0, ψ_0) , shown in purple in Figure 3.

2.2. Long timescale dynamics: Compressor degradation

Variations in pressure and flow rate (as caused by surge) lead to radial vibrations, axial thrust displacement and a large temperature rise. This will in turn damage bearings, blades and other internal components (McMillan, 1983). We lump the accumulated damage on all internal components into a health indicator state x , whose propagation is modeled as

$$\dot{x} = \mathbb{E} \left(p_1 \phi_0 + \int_0^\infty \left(p_2 |\hat{\phi}(d)| + p_3 |\hat{\psi}(d)| \right) dt \right), \quad (5)$$

where \mathbb{E} is the expected value operator, $d = [W \ H \ \psi_{C_0}]^\top$ are independently normal distributed disturbances and p_i are weights. The p_1 -term is the damage caused by regular operation, which is proportional with the throughput. The harder the compressor is run (in terms of throughput), the more rapidly it degrades. The p_2 -term is damage caused by oscillations in pressure and flow, caused by surge. The p_3 -term accounts for high-frequency oscillations, as these are thought to be more harmful to the compressor than low-frequency oscillations.

3. Hierarchical control structure for the subsea compressor

Due to the large difference in time scales for the problem, it is natural to divide it into several timescale-separated layers. The lowest layer stabilizes operation, the middle layer rejects disturbances, and the top layer is used to ensure reliable operation. Three degrees of freedom are available to achieve this: the pressure drop over the CCV, u , the blade tip speed, U , and the flow through the compressor, ϕ_0 , as determined by the throttle. The three layers are described in more detail in the following subsections.

3.1. Stabilizing control layer

The purpose of the lowest control layer is to stabilize the compressor beyond the surge line. For this purpose, we use a feedback linearizing controller which adjusts the CCV. Feedback linearizing control enables controlling non-linear systems with a linear control law, allowing for higher sampling frequencies due to the reduced computational complexity. Since the surge phenomenon happens on a short time scale, while simultaneously being non-linear, the use of feedback linearization is appropriate. We use the feedback linearizing controller presented by Backi et al. (2016). A full description and derivation of the control law is given there.

The proposed feedback linearizing controller for the CCV is:

$$u = \mu_1 \hat{\phi} + \mu_2 \hat{\psi}, \quad (6)$$

where u is the pressure drop across the CCV and μ_1 and μ_2 are controller tuning parameters.

3.2. Supervisory control layer (Local disturbance rejection: Self-optimizing control)

After stabilizing the system with the CCV, we can optimize operation by adjusting the flow through the system. The operational objective is to maximize the compressor efficiency, but operation too close to the surge point is penalized.

$$\min_{\phi_0, U} \quad J^{SOC} = -\eta(\phi_0) + \beta(2W - \phi_0). \quad (7)$$

In the above expression η is the efficiency and β is the penalty weight. Using self-optimizing control (Skogestad, 2000; Jäschke et al., 2017), we can keep the operation such that it is near optimal in the sense of (7) by controlling a combination of carefully chosen plant measurements y , to a predetermined set-point:

$$c = H^{SOC}y \quad (8)$$

In this case, the plant measurements are augmented by disturbance measurements, $d = [W \quad H \quad \Psi_{C_0}]^T$, such that $y = [\phi \quad \psi \quad d]^T$. A measurement combination matrix H^{SOC} that can be shown to minimize the average loss $L = J(\phi_0, d) - J^{opt}(\phi_0^{opt}, d)$ is (Yelchuru and Skogestad, 2010)

$$(H^{SOC})^T = (YY^T)^{-1}G^y, \quad (9)$$

where

$$Y = [FW_d \quad W_{n^y}], \quad (10)$$

and $G^y = \left. \frac{\partial y}{\partial \phi_0} \right|_{\phi_0^{nom}}$ is the linearized system model evaluated at the nominal operating point, $F = \frac{dy^{opt}}{dd}$ is the optimal sensitivity matrix, and W_{n^y} and W_d are diagonal matrices of appropriate sizes with the variances of the measurement errors / noise n^y and the variances of d .

3.3. Optimal economic and reliable operation

In the top control layer, we devise a dynamic real-time optimization (DRTO) scheme to calculate the optimal compressor speed U and penalty weight β for the SOC layer. The purpose of this layer is to adjust operation for the other layers to ensure both economic optimality and satisfaction of operational and reliability constraints. At each time step we solve the following dynamic optimization problem

$$\min_{\beta, U} \quad J^{DRTO} = -\int_0^{t_f} NPV(\phi_0)dt = -\int_0^{t_f} \frac{\phi_0}{(1+i)^t} dt \quad (11)$$

$$s.t. \quad x < x_{max} \quad (12)$$

$$\Psi_{out} > \Psi_{out, min}, \quad (13)$$

where NPV signifies the net present value with discount rate i and x is the degradation from (5). $\Psi_{out} = \hat{\Psi} + \psi_{res}$ is the outlet pressure from the compressor.

4. Simulations

The system described in Section 2 and the control structure described in Section 3, are implemented in MATLAB/Simulink and Casadi 3.0.0 (Andersson, 2013). IPOPT 3.12.3 (Wächter and Biegler, 2006) is used to solve the optimization problems (7) and (11).

4.1. Stabilizing control

Figure 4 shows the response of the system with the surge controller turned off (solid blue line) and with the surge controller turned on (dashed blue line) to a step change in ϕ_0 . After the step, the new set-point lies within the unstable operating region, causing the limit cycle behavior in the uncontrolled case.

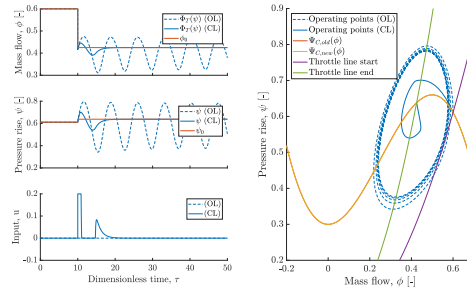

Figure 4: Closed-loop (CL) and open-loop (OL) responses to a set-point change in ϕ_0 into the unstable region.

4.2. Local disturbance rejection (Self-optimizing control)

Fig. 5 shows the response of the SOC structure (open loop (OL) and closed loop (CL)). As can be seen, the CL structure drives operation back to the optimal point. The OL structure, while stable thanks to the surge controller, does not. Operation continues at a sub-optimal operating point, resulting in higher cost. Note that for the simulated disturbance in H and ψ_{c0} , the steady state loss for the CL structure is higher than that of the OL structure. On the other hand, a step in W results in a lower loss, illustrating that it is the average loss that is minimized by (9), not the loss for each individual disturbance.

Figure 5: Open loop (OL) and closed loop (CL) losses for the SOC structure for the disturbances W , H and ψ_{c0}

4.3. Optimal economic and reliable operation

We consider three cases of DRTO. The DRTO1 and DRTO2 do not take the degradation constraint into account, and differ in terms of the maximum allowable shaft speed. DRTO1 allows higher shaft speed. DRTO2 is more conservative with a lower maximum allowable shaft speed. The DRTO3 is health-aware and does not have constraints on the shaft speed, but instead ensures that the degradation is not exceeded. The closed-loop responses of the DRTOs are shown in Fig. 6. It can be seen that operation is adjusted to maximize the NPV of the production in all three cases by gradually reducing the production over time. However, only the "conservative" DRTO2 with the lower maximum allowable speed and the health aware DRTO structures satisfy the reliability constraints. The non-health-aware DRTOs do not "see" the compressor degradation. The system is disturbed at around $t = 1.5$ and again at $t = 2.5$, by stepping first up, then down in the degradation speed, to show that the health-aware control structure takes into account the updated health information.

5. Concluding remarks and future work

We have proposed a control structure for a compression system subject to long-term load-induced degradation. By using time scale separation it is possible to counteract surge and reject disturbances, while also achieving long term optimality and satisfaction of reliability constraints. We have shown that the proposed method is better than a "regular" DRTO scheme, in which reliability considerations are not taken into account when planning future production.

Figure 6: Closed loop responses of the regular DRTOs and the health-aware DRTO to disturbances in degradation speed.

Several assumptions have been made in this work: we assume perfect state feedback for the DRTO, meaning that we can measure the health indicator state directly and without errors. This is somewhat unrealistic. In practice, we need to estimate the health indicator from other measurements. In the DRTO, we did not use parameter estimation to adapt the model when the operating conditions changed. Finally, the DRTO has to be made robust towards model uncertainty by formulating a robust/stochastic optimization problem. This will be addressed in future work.

Application of CFD modelling to external nuclear reactor vessel cooling

Marco Colombo*, Michael Fairweather

School of Chemical and Process Engineering, University of Leeds, Leeds LS2 9JT, UK

**M.Colombo@leeds.ac.uk*

Abstract

In nuclear power plants, passive cooling can increase the safety of reactors whilst reducing costs and design complexity. However, the effectiveness of passive mechanisms needs to be carefully proved with reliable computational modelling. This work focuses on assessing the external reactor vessel cooling (ERVC) strategy by means of computational fluid dynamics (CFD). The accuracy of a two-fluid Eulerian-Eulerian CFD model with boiling capabilities is first assessed, as subsequently is its ability to predict ERVC. The CFD model described proves to be a valuable tool for predicting passive cooling by detecting local boiling incipience and providing three-dimensional vessel temperature distributions, as well as thermal stratification and velocity field predictions in the cooling pool. This work is part of a larger programme aimed at assessing CFD capabilities for predicting passive cooling strategies, with a quantitative assessment of ERVC currently ongoing.

Keywords: Computational fluid dynamics, natural convection, passive cooling, boiling

1. Introduction

Natural convection relies solely on naturally occurring phenomena, possibly lasting indefinitely without interruption, and does not require any active power or moving parts. Therefore, it is regarded as an efficient, cost-effective and reliable heat transfer mechanism and is used in numerous heat transfer applications (e.g. air ventilation and thermal storage). In the nuclear sector, there has been a gradual increase in reactor design reliance on passive cooling mechanisms. As the recent events in Fukushima have shown, there is a great benefit in ensuring that the necessary cooling of the reactor can be entirely provided by natural processes for a significant amount of time before any power intervention is needed. Because of this, many modern designs adopt the so-called external reactor vessel cooling (ERVC) strategy. In a severe accident scenario that involves damage to and melting of the fuel rods, the melted corium is retained inside the reactor vessel. After flooding the region outside the vessel, heat is removed passively by natural convection on the outside vessel wall (Kim et al., 2012). Boiling is also expected to occur on that wall, and the maximum amount of heat safely removable from the system is limited by the critical heat flux. This must not be exceeded to avoid overheating of the vessel to temperatures potentially well-beyond operating limits.

Although passive cooling may appear simple and reliable, there are many underlying complexities. Thermal and velocity fields are strongly coupled, and buoyancy effects may increase or suppress turbulence in the flow (Hanjalic, 2002). Buoyancy-driven flows are also often prone to flow instabilities (Basu et al., 2014) and thermal stratification may

prevent the required amount of heat being effectively removed (Minocha et al., 2016). Therefore, numerical tools of proven accuracy become essential in demonstrating that the required heat removal can always be guaranteed, and the design and engineering limits, which safeguard the safety and integrity of the reactor, met. With respect to more traditional one-dimensional approaches currently used in the industry, CFD can fully account for three-dimensional effects at a much finer space resolution, providing detailed temperature distributions as well as identifying higher thermal load regions and hot spots. However, CFD has not been extensively applied to ERVC and more generally to buoyancy-driven boiling flows, although boiling needs to be detected by any CFD model that aims at predicting ERVC. Krepper et al. (2002) used single-phase CFD to study thermal stratification of a condenser submerged in a pool. Minocha et al. (2016) also predicted the single-phase flow in an isolation condenser pool, with the same group also studying thermal stratification for a vertical rod submerged in a rectangular (Ghandi et al., 2013a) and a cylindrical (Ghandi et al., 2013b) pool with boiling at the wall.

In this paper, the predictive capabilities of a two-fluid Eulerian-Eulerian boiling CFD model are assessed. Initially, model results are compared against measurements for a submerged cylindrical heated rod (Ghandi et al., 2013b). Subsequently, the model is used to predict natural convection on the outside of a horizontal cylindrical vessel, scaled on the calandria vessel of the Indian pressurized heavy water reactor. Model capabilities to detect boiling and predict the distinctive features of ERVC are qualitatively assessed. The work is part of a larger programme aimed at proving that CFD approaches of this kind can be confidently used for the assessment of ERVC, and identifying and implementing any model improvements that might be required.

2. CFD Model

The Eulerian-Eulerian, two-fluid boiling model solves a set of mass, momentum and energy conservation equations for each phase. Because of averaging, closure models are required for mass, momentum and energy interphase transfers. In the continuous phase, buoyancy is accounted for in the gravitational term of the momentum equation, adopting the Boussinesq approximation, which is acceptable provided that changes in temperature and density are limited. Turbulence is solved in the continuous phase with a multiphase formulation of the standard k - ε model that also accounts for production of turbulence by buoyancy (CD-adapco, 2016). Previous studies reported how high-Reynolds wall treatments, and the logarithmic law of the wall, cease to be valid in natural convection boundary layers (Omranian et al., 2014). For this reason, the two-layer formulation proposed by Xu et al. (1998) for natural convection flows is employed. The model solves for the turbulence kinetic energy k , but prescribes algebraically the turbulence energy dissipation rate in the first computational cell near the wall using $\varepsilon = k^{3/2} / l_\varepsilon$. The length scale l_ε and the turbulent viscosity ratio are obtained from:

$$l_\varepsilon = \frac{8.8y}{1 + 10/y_v^* + 0.0515y_v^*} \quad \frac{\mu_t}{\mu} = \frac{0.544y}{1 + 50250y_v^{*1.65}} \quad (1)$$

In the previous equations, y is the normal distance from the nearest wall and y_v^* is a function of the wall normal stress $\overline{v\overline{v}}$, modelled as a function of the dimensionless wall distance $y^* = yk^{0.5} / \nu$, where ν is the kinematic viscosity (Xu et al., 1998). The turbulent heat fluxes are modelled by extending the eddy-viscosity approach (CD-adapco, 2016).

Heat flux from the wall, following the Rensselaer Polytechnic Institute (RPI) heat flux partitioning approach (Kurul and Podowski, 1990), is partitioned between convection to the single-phase liquid, evaporation and quenching. The evaporative contribution to the heat flux q_{ev} is equal to:

$$q_{ev} = Nf \left(\frac{\pi d_w^3}{6} \right) \rho_v h_{lv} \quad (2)$$

Active nucleation site density N is calculated from Hibiki and Ishii (2006), the bubble departure diameter d_w from Kocamustafaogullari (1983) and the bubble departure frequency f from Cole (1960). The average bubble diameter in the flow is related to the local subcooling (Kurul and Podowski, 1990), and evaporation/condensation in the bulk is evaluated using the Ranz and Marshall (1952) correlation.

Simulations were performed using the STAR-CCM+ code (CD-adapco, 2016). For the cylindrical rod submerged in a pool, a three-dimensional, 45° radial section of the geometry was employed with symmetry boundary conditions applied at the two ends. The no-slip boundary condition was imposed at the walls of the tank and the heated rod, which had an imposed temperature of 140° C. The simulation was run for a total of 200 s, starting from fluid initially at rest at 27°C. The fluid had a thermal expansion coefficient $\beta = 0.00068$ and a Rayleigh number $Ra = 5.9 \times 10^{11}$. A full three-dimensional horizontal cylindrical vessel submerged in a rectangular pool geometry was built for the calandria vessel case. No-slip boundary conditions were imposed on the walls. Vapour is not expected to reach the top of the pool but to entirely condense in the subcooled water. A radial decreasing heat flux distribution was imposed on the outside vessel wall. Values were selected to represent an experiment conducted on a similar geometry at the Bhabha Atomic Research Centre that is being used for an ongoing detailed quantitative assessment of the model. Time transients represent the timescale of the experiment, with the computed flow time reaching 3600 s. In both cases, sensitivity studies assured that the obtained solutions were grid independent.

3. Results and Discussion

A preliminary assessment of the model was made against the experimental data of Ghandi et al. (2013b). Some results are shown in Fig. 1 for the temperature distribution on a radial plane, and radial profiles of the vertical velocity at two different heights. Warm water flows upwards near the heated rod, reaches the free-surface and circulates back downward near the outside wall of the pool. The tank gradually heats up and thermal stratification increases with time. Temperature profiles were found to be in reasonable agreement with the experiment, although excessive stratification was predicted. This is most probably related to the heat flux turbulence modelling being limited to a gradient assumption at the present time (Colombo and Fairweather, 2017). Radial velocity profiles show good agreement with data, the main discrepancies being the underestimation of the extent of the downward flow at $z/H = 0.9$. The necessity for a near-wall model is confirmed by the majority of the flow being restricted to a very thin boundary layer region. Boiling at the wall was correctly detected, but the amount of vapour generated was minimal and almost entirely condensed in the subcooled liquid without reaching the free surface, in agreement with experimental observations.

Figure 1. Temperature distribution in the pool (left) and comparison of radial velocity profiles against the experimental data of Ghandi et al. (2013a) (right).

In the calandria vessel case, to study the capabilities of CFD to detect local heat transfer and boiling conditions, the imposed heat flux distribution varies in space and time. In the context of ERVC, the heat to be removed is mainly due to radioactive decay and, consequently, decreases with time. External wall temperatures are given in Fig. 2 as a function of time and angle, where 0° is the bottom and 180° the top of vessel. Although the flow is mainly single-phase, subcooled boiling is observed on the bottom of the vessel for more than 30 minutes, as demonstrated by the flat temperature profile at 0° in Fig. 2.

Figure 2. Behaviour with time of (a) the temperature on the outside wall of the vessel at different radial locations, and (b) of the temperature in the pool at different heights.

As the water in the external pool heats up, thermal stratification occurs (Fig. 2(b)). This is also evident in Fig. 3, which shows temperature and velocity fields inside the pool. Water heats up and flows upward, generating a plume above the cylindrical vessel and two large recirculation regions. Detailed heat transfer coefficient distribution can be obtained from the CFD (Fig. 4(a)). As shown, heat transfer is a maximum on the side of the vessel and, once boiling ends, a minimum at the top and bottom of the vessel. Although boiling was detected, boiling conditions were not sustained for the entire duration of the transient simulation. Therefore, a second simulation was undertaken with higher heat fluxes, greater than 85 kW m^{-2} at the beginning of the transient. In

these conditions, boiling lasts for the entire duration of the transient, as demonstrated by the wall temperatures remaining close to saturation in Fig. 4(b). Even if more sustained, boiling was still in the subcooled nucleate boiling regime and distant from film boiling or critical heat flux, and these conditions were successfully handled by the model.

Figure 3. Temperature distribution (left) and velocity field (right) in the water pool of the calandria vessel.

Figure 4. (a) Heat transfer coefficient distribution on the vessel external wall, and (b) time behaviour of the vessel wall temperature at higher heat flux.

4. Conclusions

The ability of a two-fluid Eulerian-Eulerian CFD boiling model to predict natural convection and boiling at a wall, as well as to assess the effectiveness of the ERVC strategy in nuclear reactors, has been studied. Comparison with experimental data for a heated cylindrical rod in a pool demonstrates that the model correctly predicts the onset of boiling and recirculation, and thermal stratification in the pool. The quantitative accuracy of these predictions are, however, likely to be improved by more advanced turbulent heat flux modelling. The qualitative features of an ERVC transient in a scaled cylindrical calandria vessel of the Indian pressure-tube type were also predicted. The model provides a detailed three-dimensional distribution of the vessel wall temperature and local boiling conditions, as well as recirculation and thermal stratification in the pool. These results confirm the capability of the present model to detect the distinctive features of ERVC and, therefore, to evaluate the effectiveness of the passive cooling. A detailed quantitative assessment against experimental data is currently ongoing.

Abstract

Scheduling of multitasking multipurpose batch industry has not gained adequate attention in the literature. In this work, two novel mathematical models for scheduling of multitasking multipurpose batch processes in scientific service facilities are developed. The first model is developed based on unit-specific event-based approach, while the second is based on task-specific event-based approach. By solving a number of examples with both proposed models and the existing ones in the literature, it seems that both proposed models reduce the model size. The proposed unit-specific event-based model is superior to others, significantly reducing the model size and requiring at least one order of magnitude less computational time to generate the optimum solution, especially for the case of makespan minimization.

Keywords: Scheduling, Multitasking, Scientific service facilities, Mixed-integer linear programming

1. Introduction

Scientific service facilities examine a number of samples from different customers for their physical and chemical properties using a number of units. Each unit can examine one property and process samples from more than one customer simultaneously due to its large capacity, which allows multitasking. Due to the high competitive market, scientific service seeks ways to minimize the use of units and raw materials.

Even though, process scheduling has been considered in the last three decades (Harjunkoski et al., 2014), most of the existing models only allow single tasking and they cannot be directly applied to this class of problem. Recently, Patil et al. (2015) developed a discrete-time model for scheduling scientific service facilities. Lagzi et al. (2017a) used the global event time approach for the same problem. However, both models require large amount of computational time due to their large model sizes.

The advantages of the unit-specific event-based approach have been well established in the literature (Shaik and Floudas, 2009; Li and Floudas, 2010), where the scheduling horizon is divided based on units. Although there are some models that divide the scheduling horizon based on tasks, they are also classified as unit-specific event-based models (Shaik and Floudas 2009), which are actually task specific.

In this work, two novel models based on unit-specific and task-specific event-based approaches are developed for this problem. Both models allow multitasking to take

place in a unit. New tightening constraints are developed for the task-specific event-based model. The computational results show that the proposed unit-specific event-based model is superior to the proposed task-specific event-based model and the existing ones (Patil et al., 2015; Lagzi et al., 2017a) with smaller model size and at least one magnitude less computational time to generate the optimum solution, especially for the case of makespan minimization.

2. Problem description

A scientific service facility (Figure 1) examines Pr ($Pr = 1, 2, \dots, Pr$) properties, using J ($J = 1, 2, \dots, J$) units. Each unit is able to process only one property denoted by a set J_{pr} . The facility has to examine m sample groups, each one for different properties. In each unit more than one groups can be processed simultaneously. Given the total sample groups, the number of samples in each group, the processing path, the scheduling horizon H , as well as the capacity and processing time of each unit, the scheduling problem is to determine the optimal production schedule, including batch sizes, allocations, sequences, timings on processing units. It is assumed that each unit requires a fix time to examine a property, regardless of the samples that are processed. Furthermore, unlimited storage capacity (UIS) for all samples is considered.

3. Mathematical formulations

3.1. Unit-specific event-based model

We first develop a novel unit-specific event-based model for scheduling multitasking batch processes.

3.1.1. Allocation constraints

A unit must start and end only at one event point.

$$\sum_{n-\Delta n \leq n' \leq n} \sum_{n \leq n' \leq n' + \Delta n} w_{j,n',n'} \leq 1 \quad \forall j, n, \Delta n > 0 \tag{1}$$

3.1.2. Capacity constraints

The total batch sizes taking place in a unit should be constrained at an event point.

$$\sum_{i \in I_j} b_{i,j,n,n'} \leq B_j^{\max} w_{j,n,n'} \quad \forall j, n, n \leq n' \leq n + \Delta n \tag{2}$$

3.1.3. Material balance constraints

$$ST_{s,n} = ST_{s,n-1} + \sum_{i \in I_s^c} \rho_{i,s} \sum_j \sum_{n-1-\Delta n \leq n' \leq n-1} b_{i,j,n',n-1} + \sum_{i \in I_s^c} \rho_{i,s} \sum_j \sum_{n \leq n' \leq n+\Delta n} b_{i,j,n,n'} \quad \forall s, n > 1 \quad (3)$$

$$ST_{s,n} = ST0_s + \sum_{i \in I_s^c} \rho_{i,s} \sum_j \sum_{n \leq n' \leq n+\Delta n} b_{i,j,n,n'} \quad \forall s, n = 1 \quad (4)$$

3.1.4. Duration constraints

The finish time of unit j must be after the start time of the unit at the same event point plus the processing time required to process task.

$$Tf_{j,n'} \geq Ts_{j,n} + \alpha_j w_{j,n,n'} \quad \forall j, n, n \leq n' \leq n + \Delta n \quad (5)$$

3.1.5. Time matching constraints

A state is available to be consumed after the finish time of the production task.

$$T_{s,n} \geq Tf_{j,n} - M \left(1 - \sum_{n-\Delta n \leq n' \leq n} w_{j,n',n} \right) \quad \forall s \in S^{in}, j, n, \sum_{i \in I_j} \rho_{i,s} > 0 \quad (6)$$

The start time of a unit, that consumes a state s at event point $n+1$, should be after the time that the state is available to be consumed at event n .

$$T_{s,n} \leq Ts_{j,n+1} + M \left(1 - \sum_{n+1 \leq n' \leq n+1+\Delta n} w_{j,n+1,n'} \right) \quad \forall s \in S^{in}, j, n < N, \sum_{i \in I_j} \rho_{i,s} < 0 \quad (7)$$

3.1.6. Sequencing constraints

The start time of unit j at event $n+1$ must be after the finish time at the event n .

$$Ts_{j,n+1} \geq Tf_{j,n} \quad \forall j, n < N \quad (8)$$

The time that a state is available at a time event point should be earlier that the time that the same state is available at the next event point.

$$T_{s,n} \leq T_{s,n+1} \quad \forall s \in S^{in}, n < N \quad (9)$$

3.1.7. Objective functions

Both maximization of productivity during a specific scheduling horizon and minimization of makespan have been considered.

$$z = \sum_s p_s \sum_{i \in I_s^p} \sum_j \sum_{n \leq n' \leq n+\Delta n} \rho_{i,s} b_{i,j,n,n'} \quad \forall s \in S^{in}, n < N \quad (10)$$

$$MS \geq Tf_{j,N} \quad \forall j \quad (11)$$

In the latter case all properties in all samples should be examined at the last event point

$$ST_{s,N} + \sum_{i \in I_s^c} \rho_{i,s} \sum_j \sum_{N-\Delta n \leq n' \leq N} b_{i,j,n',N} \leq D_s \quad \forall s \quad (12)$$

3.2. Task-specific event-based model

The task-specific event-based model of Shaik and Floudas (2009) for scheduling of single-tasking multipurpose batch processes was modified to consider multitasking. In this section, the modified constraints are only presented.

3.2.1. Allocation constraints

Shaik and Floudas (2009) introduced several allocation constraints where only one task is processed in a unit in event n . We replace these constraints with a new set of allocation constraints, which allows multitasking.

$$\sum_{n-\Delta n \leq n' \leq n} \sum_{n \leq n' \leq n' + \Delta n} w_{i,n',n} \leq 1 \quad \forall j, n, \Delta n > 0 \quad (13)$$

A binary variable $y_{j,n,n'}$ is defined as one if unit j is active from event n to n' .

$$y_{j,n,n'} \geq w_{i,n',n} \quad \forall i \in I_j, j, n, n \leq n' \leq n + \Delta n \quad (14)$$

$$y_{j,n,n'} \leq \sum_{i \in I_j} w_{i,n',n} \quad \forall j, n, n \leq n' \leq n + \Delta n \quad (15)$$

3.2.2. Capacity constraints

In multitasking, the summation of the batch sizes of all tasks that are able to be processed in a unit should be constrained.

$$\sum_{i \in I_j} b_{i,n,n'} \leq B_j^{\max} y_{j,n,n'} \quad \forall j, n, n \leq n' \leq n + \Delta n \quad (16)$$

3.2.3. Tightening constraints

The tightening constraints in Shaik and Floudas (2009) are only effective for single tasking in a unit. New tightening constraints below are introduced for multitasking.

$$Tj f_{j,n'} \geq Tj s_{j,n} + [\max_{i \in I_j} (\alpha_i)] y_{j,n,n'} \quad \forall j, n, n \leq n' \leq n + \Delta n \quad (17)$$

$$Tj s_{j,n+1} \geq Tj f_{j,n} \quad \forall j, n < N \quad (18)$$

4. Computational results

Five examples were solved using proposed models as well as the existing models of Patil et al. (2015) and Lagzi et al. (2017a). In example 1, a small-scale facility presented in Patil et al. (2015) was considered, while for the next 3 examples a random facility was generated. The last example uses a representation of an actual scientific service facility as presented by Lagzi et al. (2017b). Both maximization of productivity and minimization of makespan were considered as objective. All examples were solved in a machine using GAMS 24.6.1. CPLEX 12 in an Intel® Core™ i5-2500 3.3 GHz and 8 GB RAM running windows 7.

The comparative results with maximization of productivity are given on Table 1. Both proposed models require less number of event points, which decrease the model size.

However, the unit-specific event-based model leads to significantly smaller model size and therefore less computational time. The discrete-time model of Patil et al. (2015) also seems competitive due to the fact that it has the tightest relaxation. In cases of very detailed processing times, though such as example 4, the model size makes it infeasible to generate a feasible solution after one hour. By comparing continuous-time models, it seems that the proposed models improve the relaxation of the problem.

Table 1 Comparative results for examples 1-5 for maximization of productivity as objective

The results for the same examples using minimization of makespan as objective are presented on Table 2. In that case, the unit-specific event-based model is superior to others with smaller model size and tighter relaxation. Consequently, it generates the optimum solution in at least one order of magnitude less computational time. The superiority of the model is also illustrated in example 3, where the unit-specific event-based model generates the optimum solution in less than one minute, while reported models are not even able to generate a feasible solution after one hour. The task-specific event-based model has also a better relaxation and leads to smaller model sizes than the models previously reported in the literature.

5. Conclusions

In this work, two novel mathematical models, based on task-specific and unit-specific event-based approaches for scheduling of multitasking batch process in scientific service facilities were presented. Both mathematical models lead to smaller model size with less number of event points, variables and constraints than previous reported formulations. The unit-specific event-based model is superior model than other models

with significantly smaller model, much tighter relaxation and at least one magnitude less computational time to generate optimal solution, especially for the case of makespan minimization.

Abstract

Current predictive analytics approaches are strongly focused on optimizing accuracy metrics, leaving little room to incorporate a priori knowledge about the processes under analysis and relegating to a secondary concern the interpretation of results. However, in the analysis of complex systems, one of the main interests is precisely the induction of relevant associations and dependencies, in order to understand or clarify the way systems operate. On the other hand, there is often information available regarding the structure of the underlying processes, which could be used in benefit of the analysis and to enhance the interpretation of results. The importance of this issue was recognized and led to the development of multiblock approaches. In this paper, two classes of multiblock frameworks are addressed, that present interpretational-oriented features, while allowing components of the system's structure to be incorporated, maximizing the use of existing knowledge about the process. The two classes of methodologies are comparatively tested using a real world dataset. Their performance is also compared with their single-block counterparts, namely principal components regression and partial least squares. Results confirm the added value of adopting suitable multiblock predictive methodologies, when variables present a block-wise or network structure.

Keywords: Multiblock methods, Network-Induced Supervised Learning, Concatenated PLS, Multiblock PLS, Hierarchical PLS, Sequential Orthogonalised PLS.

1. Introduction

Modeling is a fundamental part of any workflow for process improvement, monitoring and control. With the increasing availability of data in the Big Data era and with the emergence of Industry 4.0, there is a strong emphasis in developing data-driven modeling approaches to address these tasks. In the domain of data-driven predictive frameworks, the mainstream methods tend to treat all variables *a priori* in the same way. The different methodologies vary according to the way variables are selected and/or combined in order to compound the final model. We call these methods “single-block”, as they treat all regressors equally in a first stage.

Taking a closer look to the recurrent structures found in data and to the way systems generating them actually work, one can notice that, most often, not all variables are actively contributing to the phenomenon under study (as assumed in multivariate methods) nor are they bringing independent and isolated pieces of information to the model (for which variable selection schemes would be adequate). Rather, the prevailing

structure seems to present the form of clusters of variables – modules – composed by sets of variables, where each cluster is relative to a given functional mechanism. Variables falling in the same cluster exhibit some degree of mutual correlation, and may be aggregated in a super level, in an hierarchical way (Clauset et al., 2008; Guimerà and Amaral, 2005; Newman, 2006; Ravasz et al., 2002). In this context, instead of multivariate or variable selection schemes for handling high-dimensional systems, methods should enable the definition and selection of clusters of variables that better reflect the system structure, which can then be selected for integrating the model according to their predictive power (Reis, 2013a, b). This setting calls for methods that are able to handle simultaneously several heterogeneous blocks of variables in their formulation, called hereafter as multiblock methods.

Upon a close analysis of the available literature, two classes of multiblock methods can be identified. On one side, there are methods where the blocks of variables are defined based on *a priori* knowledge about the system's structure, e.g., when variables regard different process units, arise from different analytical measurement sources or are related to distinct and identifiable functional modules of the system. On the other side, one can find methods where such knowledge is not explicitly known, but a modular structure is believed to exist, that must be inferred and extracted from the available existing data. It is the purpose of this work to briefly provide an overview of both classes of multiblock methods and to illustrate their application with resort to a real world case study.

This article is organized as follows. In the next section, the main representatives of the two classes of methods, that will also integrated the present work, are briefly presented. Then, in Section 3, the results obtained are presented and discussed. Section 4 concludes this paper, with an overview of its contents and some concluding remarks about the relevance of considering multiblock methods in the analysis of high-dimensional systems.

2. Multiblock methods for predictive analytics

Classical data analysis is focused on handling isolated variables, which should be selected and/or weighted differently, during the construction of predictive models. Multiblock methods, on the other hand, constitute a class of analytical methodologies that maintain the integrity of clusters of variables in the analysis. The objects of analysis are no longer isolated variables, but variable clusters. These clusters carry information about different phenomena, functions, process units, stages, etc., and therefore increase the interpretability of the models developed. There are two types of multiblock methods, depending on whether the clusters are formed using *a priori* knowledge, or they are inferred from data, i.e., extracted in a data-driven way.

2.1. Blocks known a priori

Belong to this class all multiblock methods that assume the composition of the different blocks to be known beforehand. This attribution is often possible to be made when there is sufficient knowledge about the system, and the way variables are naturally organized regarding how they contribute to the final outcome. Several multi- and megavariate methods fall in this category, and we will contemplate in this work the mainstream ones, namely, Concatenated PLS (CPLS), Hierarchical PLS (HPLS), Multiblock PLS

(MPLS), as well as recent advances in this field, such as Sequential and Orthogonalised PLS (SO-PLS).

In brief terms, Concatenated PLS (CPLS) consists in concatenating all blocks of variables in a single augmented matrix and perform the classical PLS method over the entire data array. The different blocks should be weighted before being used in the model in order to give equal importance to all or to increase/decrease the importance of a given block in the model. Typically, two block-scaling methods are described in the literature: soft block scaling and hard block scaling (Eriksson et al., 2006).

In Hierarchical PLS (HPLS), each data block is considered as a separate source of information and the multiblock model extracts the common structure for all the different blocks. This common structure forms the so-called super level of the model, combining information from all blocks of predictors at the lower levels. This means that block scores, loadings and weights for each separate block are available for interpretation in the lower level and super scores, loadings and weights are available in the super level for the interpretation of the global model.

Multiblock PLS (MBPLS) was proposed by Wold et al. (Wold et al., 1983) and later by Wangen and Kowalski (Wangen and Kowalski, 1988). Similarly to the HPLS method, this method also presents two levels: the super level with global information and the lower level with information from each block. The main difference between this method and HPLS is that the Y block is regressed on all descriptor X blocks, whereas in HPLS the Y block is only regressed on the super block, which means that the block scores are calculated in an unsupervised way. This causes the block scores to be different in these two methods.

Sequential and Orthogonalized Partial Least Squares (SO-PLS) was proposed by Naes et al. (2013) and is a methodology that incorporates several blocks of variables in the model, one at a time, while evaluating/interpreting the incremental or additional contribution of the different blocks for improving the model predictions. This capability is relevant when one wants to assess the gain of introducing an additional source of information. The sequential nature of SO-PLS implies that the order chosen for including the blocks in the model can influence the final result.

2.2. Blocks inferred from data

When the composition of the blocks is unknown, then it must be induced from data. Network Induced Supervised Learning Regression (NI-SL) is a method proposed by M. S. Reis (Reis, 2013a, b), with the goal of bringing interpretation features to the forefront of the analysis goals. The method is divided in two stages. The first stage (Network-Induced Clustering) aims at finding functionally related groups of variables (clusters), which form meaningful X blocks with predictive power for Y. The second stage consists in developing a predictive model, based on the variates (i.e., linear combinations) computed for the blocks induced in the first stage. For such, classical PLS models are developed separately between each X block and the Y response, and a predefined number of latent variables are retrieved from each block (in the present study five latent variables were retrieved from each block). These latent variables are gathered into a super block and a forward stepwise regression procedure is implemented to select the subgroup of latent variables leading to the best fit.

3. Measurement units, numbers

We illustrate the application of multi-block methodologies with resort to a real world case study taken from the food & drink industry: wine production. More specifically, this example is focused on the prediction of ageing time in Madeira wine, based on different analytical measurement sources: volatile profile (1st block), the polyphenols and two furanic compounds (2nd block), the organic acids quantification (3rd block) and the ultraviolet-visible spectra (4th block). The volatile profile was analysed by gas chromatography coupled to mass spectrometry (GC-MS), preceded by solid phase extraction; the second block of data was obtained by High-Performance Liquid Chromatography combined with Photodiode Array Detection (HPLC-DAD; direct injection); organic acids (the 3rd block of variables) were also quantified by Liquid Chromatography combined with Photodiode Array Detection; UV-Vis absorbance spectra (4th block of variables) was done in a Perkin-Elmer Lambda 2 spectrophotometer (Waltham, MA, USA). More information about the data used in the analysis of this case study is available in ref. (Campos et al., 2017).

A total of 26 samples were analysed, covering a range of 20 years (2-3 wine samples were taken per ageing year, with 2 year intervals). All samples correspond to wines produced from the same grape variety (Malvasia) and were supplied from the same Madeira wine producer.

In this paper, and due to space limitations, the analysis will be focused on the predictive capabilities of the methods, which is assessed in a robust way, according to the following protocol: 50 data sets are formed from the original dataset, through Monte Carlo random assignment of samples; for each Monte Carlo assignment, the dataset is randomly divided into a training set (80%) and a test set (20%); the training set is used to calibrate the models and to determine the respective hyper-parameters based on 10-fold cross validation method; this procedure originates 50 different models for each multiblock method (one for each randomly generated data set). The test sets are used for prediction based on which one computes the root mean square error of prediction (RMSEP), for each Monte Carlo run and for each method, using equation 1.

$$RMSEP = \sqrt{\frac{\sum_{i=1}^{n_{test}} (y_{pred,i} - y_{obs,i})^2}{n_{test}}} \quad (1)$$

The distribution of the RMSEP over the 50 trials characterizes the methods performance in terms of prediction accuracy and robustness. Moreover it can be used to compare different methods by evaluating the statistical significance of the difference between the prediction errors obtained under similar testing conditions.

Table 1. Average root mean square error of prediction and the respective interquartil range (IQR) obtained for the different multiblock methods tested in this paper.

Method	\overline{RMSE}	IQR (75%-25%)
Concatenated PLS (CPLS)	0.93	0.61
Hierarchical PLS (HPLS)	1.48	0.44
Multiblock PLS (MBPLS) - Block Scores deflation	1.36	0.58
Multiblock PLS (MBPLS) - Super Scores deflation	1.34	0.54
Network Induced Supervised Learning (NI-SL)	1.17	0.85
Sequential Orthogonal-Partial Least Squares (SO-PLS)	0.97	0.49

Table 2. Average root mean square error of prediction and the respective interquartil range (IQR) obtained in the Monte Carlo Cross-Validation for single block approaches.

Chemical Data	Method	\overline{RMSEP}
Polyphenol Content	PCR	1.18
	PLS	1.17
Volatile Composition	PCR	1.55
	PLS	1.43
UV-Vis	PCR	2.23
	PLS	2.86
Organic Acids	PCR	2.93
	PLS	2.86

Table 1 presents the mean RMSEPs obtained for the several multiblock methods studied in this article. The methods leading to better performance are CPLS (with a new scaling methodology developed by the authors; see ref. (Campos et al., 2017)) and SO-PLS, followed by NI-SL. The first two methods present superior predictive performances than the best linear multivariate methodologies applied to each block separately – see results for Principal Component Regression (PCR) and Partial Least Squares (PLS) in Table 2 (Rendall et al., 2017). These results indicate that it is possible to synergistically combine different sources of information for improving the predictive performance of the methods, even though the single-block methods based on the Polyphenol Content already lead to interesting predictive results. Moreover, the multiblock methodologies bring other interpretational dimensions to the analysis, namely regarding the importance of the different blocks for predicting the response and their redundancy or overlap, which are not addressed in this short article.

4. Conclusions

In this work, we illustrate the potential of using multiblock predictive methods in datasets composed by natural blocks of variables. The case study illustrates the advantage of using all blocks of variables simultaneously, in a structured way, rather than in an isolated fashion.

Even though multiblock methods represent constrained versions of their single-block counterparts, the predictive ability found may not be inferior. On the contrary, it was often found to be superior, which is due to their more parsimonious nature that leads to a more stable parameter estimation and finally to more accurate predictions (Reis, 2013a, b). If, on top of this, one considers the expected higher interpretability of the multiblock methods, one can easily conclude about the increasing interest in adopting this modeling formalism to address the analysis of data collected from complex processes and phenomena, a situation that will be increasingly frequent in the Industry 4.0 era.

Abstract

This paper studies a dynamic real-time optimization in the context of model-based time-optimal operation of batch processes under parametric model mismatch. A class of batch membrane separation processes is in the scope of the presented applications. In order to tackle the model-mismatch issue, a receding-horizon policy is usually followed with frequent re-optimization. The main problem addressed in this study is high computational burden that is usually required by such schemes. We propose an approach that uses parametrized conditions of optimality in the adaptive predictive-control fashion. The uncertainty in the model predictions is treated explicitly using reachable sets that are projected into the optimality conditions.

Keywords: real-time optimization, Pontryagin's minimum principle, membrane processes, parameter estimation

1. Introduction

In this paper we consider a real-time implementation of a control policy that optimizes a process by assigning dynamic degrees of freedom such that a certain performance index is optimized:

$$\min_{u(t) \in [u_L, u_U], t_f} \mathcal{J} := \min_{u(t) \in [u_L, u_U], t_f} \int_0^{t_f} F_0(x(t), p) + F_u(x(t), p)u(t) dt \quad (1a)$$

$$\text{s.t. } \dot{x}(t) = f_0(x(t), p) + f_u(x(t), p)u(t), \quad x(0) = x_0, \quad x(t_f) = x_f, \quad (1b)$$

where t is time with $t \in [0, t_f]$, $x(t)$ is an n -dimensional vector of state variables, p is an m -dimensional vector of model parameters, $u(t)$ is a (scalar) manipulated variable, $F_0(\cdot)$, $F_u(\cdot)$, $f_0(\cdot)$, and $f_u(\cdot)$ are continuously differentiable functions, x_0 represents a vector of initial conditions, and x_f are specified final conditions. We note here that an inclusion of multi-input and/or state-constrained cases is a straightforward extension but it is not considered in this study for sake of simplicity of the presentation. We also note that the specific class of input-affine systems is a suitable representation for a large variety of the controlled objects (Hangos et al., 2006).

The presented problem was studied in many previous works using on-line or batch-to-batch adaptation of the optimality conditions (Francois and Bonvin, 2013) or by design of robust controller for tracking the conditions of optimality (Nagy and Braatz, 2003). Recently, several advanced robust strategies were presented in the framework of model predictive control (Lucia et al., 2013).

Acknowledgements: The research leading to these results has received funding from the Slovak Research and Development Agency under the project APVV 15-0007 and from the Scientific Grant Agency of the Slovak Republic under the grant 1/0004/17.

This paper proposes an adaptation of these approaches to the problem of dynamic real-time optimization of batch processes. This task is not straightforward because if one uses a preceding-horizon control strategy, the prediction horizons need to be quite long, because of the presence of terminal constraints, which might compromise the real-time feasibility of the scheme.

We base the presented methodology on parameterization of the optimal operation using the conditions of optimality given by Pontryagin's minimum principle. This makes the dynamic decision problem (1) to boil down to identification of switching times of the optimal control policy. Such approach reduces computational burden while allowing for the use of sufficiently long prediction horizons when projecting the parametric uncertainty in controller performance and feasibility, particularly w.r.t. terminal time conditions. Robustness w.r.t. parametric uncertainty is addressed by taking into account the imprecision of parameter estimates such that it is projected into the uncertainty of the switching times. In order to improve performance of such a controller, i.e., to reduce conservatism introduced by uncertain switching times, we use on-line parameter estimation.

2. Preliminaries

2.1. Conditions for Optimality

Pontryagin's minimum principle can be used (Srinivasan et al., 2003) to identify the optimal solution to (1) via enforcing the necessary conditions for minimization of a Hamiltonian

$$H := \mu_L(u_L - u) + \mu_U(u - u_U) + \underbrace{F_0 + \lambda^T f_0}_{H_0(x(t), \lambda(t), p)} + \underbrace{(F_u + \lambda^T f_u)u}_{H_u(x(t), \lambda(t), p)}, \quad (2)$$

where $\lambda(t)$ is a vector of adjoint variables, and $\mu_L(t)$ and $\mu_U(t)$ are corresponding Lagrange multipliers. The optimality conditions of (1) can then be stated as (Srinivasan et al., 2003): $\forall t \in [0, t_f]$

$$\frac{\partial H}{\partial u} := H_u(x(t), \lambda(t), p) - \mu_L(t) + \mu_U(t) = 0, \quad (3)$$

$$H(x(t), \lambda(t), p, u(t), \mu_L(t), \mu_U(t)) = 0, \quad H_0(x(t), \lambda(t), p) = 0, \quad x(t_f) - x_f = 0. \quad (4)$$

The condition $H = 0$ arises from the transversality, since the final time is free (Pontryagin et al., 1962), and from the fact that the optimal Hamiltonian is constant over the whole time horizon, as it is not an explicit function of time. The condition $H_0 = 0$ is the consequence of the former two conditions. Since the Hamiltonian is affine in input (see (2)), the optimal trajectory of control variable is either determined by active input constraints or it evolves inside the feasible region.

Assume that for some point t we have $H_u = 0$ and $u_L < u(t) < u_U$. It follows from (3) that the optimal control maintains $H_u(t) = 0$. Such control is traditionally denoted as singular. Further properties of the singular arc, such as switching conditions or state-feedback control trajectory can be obtained by differentiation of H_u with respect to time (sufficiently many times) and by requiring the derivatives to be zero. The time derivatives of H and H_0 must be equal to zero as well. Earlier results on derivation of optimal control for input-affine systems (Srinivasan et al., 2003) suggest that it is possible to eliminate $\lambda(t)$ from the optimality conditions and thus arrive at analytical characterization of switching conditions between singular and saturated-control arcs.

As the optimality conditions obtained by the differentiation w.r.t. time are linear in the adjoint variables, the differentiation of H_u (or H_0) can be carried out until it is possible to transform the obtained conditions to a pure state-dependent switching function $S(x(t), p)$. It is usually convenient to use a determinant of the coefficient matrix of the equation system $A\lambda = 0$ for this. The singular control $u_s(x(t), p)$ can be found from differentiation of switching function w.r.t. time as

$$\frac{dS}{dt} = \frac{\partial S}{\partial x^T} \frac{dx}{dt} = \frac{\partial S}{\partial x^T} (f_0 + f_u u_s) = 0 \quad \Rightarrow \quad u_s(x(t), p) = -\frac{\partial S}{\partial x^T} f_0 \Big/ \frac{\partial S}{\partial x^T} f_u. \quad (5)$$

The resulting optimal-control policy is then given as a step-wise strategy (Paulen et al., 2015) by

$$u^*(t, \pi) := \begin{cases} u_L, & t \in [0, t_1], S(x(t), p) > 0, \\ u_U, & t \in [0, t_1], S(x(t), p) < 0, \\ u_s(x(t), p), & t \in [t_1, t_2], S(x(t), p) = 0, \\ u_L, & t \in [t_2, t_f], S(x_f, p) < 0, \\ u_U, & t \in [t_2, t_f], S(x_f, p) > 0, \end{cases} \quad (6)$$

$$x_f = x(t_2) + \int_{t_2}^{t_f} f_0(x(t), p) + f_u(x(t), p)u^*(t) dt, \quad (7)$$

where $\pi := (p^T, t_1, t_2, t_f)^T$ is the vector that parameterizes the optimal control strategy. Note that the presented optimal-control strategy determines implicitly the switching times t_1 , t_2 and the terminal time t_f as functions of model parameters p .

2.2. Set-membership estimation

In order to estimate model parameters we will assume the model being linear in parameters as

$$\hat{y}(p) = c^T p, \quad (8)$$

where \hat{y} is the prediction of the plant output y and c is a so-called regressor vector. The linearity of the model in parameters is not restrictive, the presented methodology applies to systems that are non-linear in parameters too. We will further assume that the measurement noise is bounded with

$$|y - \hat{y}(p)| \leq \sigma. \quad (9)$$

Under these assumptions a recursive set-membership estimation scheme was presented in Fogel and Huang (1982), which over-bounds the set of all parameter values that satisfy (9) as an ellipsoid

$$(p - \hat{p})^T V^{-1} (p - \hat{p}) \leq 1, \quad (10)$$

where \hat{p} is the expected true value of the parameters and V is parameter covariance matrix. Upon receiving a new measurement y , \hat{p} and V are updated by

$$\hat{p}_+ = \hat{p} + \frac{\beta d}{1 + \beta g} V \tilde{c}, \quad V_+ = \left(1 + \beta - \frac{\beta d^2}{1 + \beta g}\right) \left(V - \frac{\beta}{1 + \beta g} V \tilde{c} \tilde{c}^T V\right), \quad (11)$$

where $\tilde{c} := c/\sigma$, $g := \tilde{c}^T V \tilde{c}$, $d := y/\sigma - \tilde{c}^T \hat{p}$. The parameter $\beta \in (0, 1)$ can be selected in order to minimize trace or determinant of the covariance matrix V (Fogel and Huang, 1982). The updated bounds of parameters (parameter confidence intervals) can be found via

$$P_+ := \left[\hat{p}_+ - \text{diag} \left(V_+^{\frac{1}{2}} \right), \hat{p}_+ + \text{diag} \left(V_+^{\frac{1}{2}} \right) \right]. \quad (12)$$

3. Dynamic real-time optimization

As the optimal control structure is a function of uncertain parameters, the uncertainty should be taken into account when devising a real-time implementation of the optimal control on the process. We will assume a bounded uncertainty $p \in P := [p^L, p^U]$ with a nominal realization $p_0 := \text{mid}(P)$.

Given the structure of the optimal-control policy (6) one can project the parametric uncertainty into uncertainty of the switching times and singular control as

$$t_i(p) \in [t_i^L(P), t_i^U(P)] := T_i, \quad \forall i \in \{1, 2, f\}, \quad (13)$$

$$u_s(t, p) \in [u_s^L(t, P), u_s^U(t, P)] := U^*(t), \quad \forall t \in [t_1(p), t_2(p)], \quad (14)$$

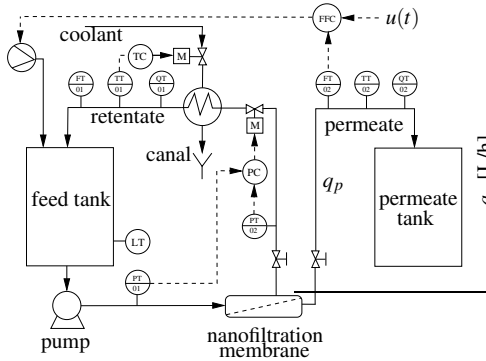

Figure 1: Diafiltration process scheme.

Figure 2: Comparison of data and model predictions.

using some set-theoretic technique for calculating reachable sets (Chachuat et al., 2015). Here a particular technical advantage can be exploited i.e., that the integration of in (7) can be done backwards in time from the final condition. As the batch processes exhibit inherently unstable dynamics, their backward integration is stable. Such a feature can readily be exploited by modern bounding approaches for parametric ordinary differential-algebraic equations.

The result (13) then in practice establishes a parametric solution to the real-time optimization problem. Its implementation can be performed in a robust fashion to determine the parameters of the optimal-control structure that lead to the best performance in the worst case. We can then solve

$$\min_{\substack{u_s(t,p) \in U^*(t), \forall t \in [t_1(p), t_2(p)] \\ t_i \in T_i, \forall i \in \{1, 2, f\}}} \max_{p \in P} \|\mathcal{J}(p) - \mathcal{J}(p_0)\|_2^2 \quad \text{s.t. (6), (7),} \quad (15)$$

for a given $x(0) = x_0$ and P , where we propose to minimize variance of the objective under the worst-case realization of $p \in P$.

In order to reduce conservatism of a robust scheme, parameter estimation can be used for exploitation of data gathered along the process run. The employed parameter estimation scheme should take into account noise in measurements and, if applied recursively for each newly gathered measurement set, it should result in a sequence of the confidence intervals

$$P_k \subseteq P_{k-1} \subseteq \dots \subseteq P_1 \subseteq P_0 \subseteq P. \quad (16)$$

The problem (15) can then be resolved with the initial state conditions $x(k) = x_k$ and with updated parameter bounds P_k in shrinking-horizon fashion. Once the optimal value of the objective function of (15) reaches $\|\mathcal{J}(P) - \mathcal{J}(p_0)\|_2^2 < \varepsilon$, the calculated control actions can be implemented, e.g., with a feedback scheme (Francois and Bonvin, 2013), until the terminal conditions are met. Note that due to the parametrization of the optimal-control policy, the re-estimation and re-optimization do not need to be run at every sampling time but on a much coarser time scale given by range of uncertainty in the sampling times T_i . Sophisticated strategies can then be used to evaluate the trade-off between real-time feasibility and performance.

4. Case study

We consider a case study of time-optimal control of a batch diafiltration process from Paulen et al. (2012). The scheme of the plant is shown in Fig. 1. The goal is to process a solution with initial volume (V_0) that is fed into the feed tank at the start of the batch and that comprises two solutes of initial concentrations $c_{1,0}$ and $c_{2,0}$. At the end of the batch, the prescribed final concentrations

$c_{1,f}$ and $c_{2,f}$ must be met. The transmembrane pressure is controlled at a constant value. The temperature of the solution is maintained around a constant value using a heat exchanger. The manipulated variable $u(t)$ is the ratio between fresh water inflow into the tank and the permeate outflow q_p that is given by

$$q_p = \gamma_1 \ln \left(\frac{\gamma_2}{c_1 c_2^{\gamma_3}} \right) = \gamma_1 (\ln(\gamma_2) - \ln(c_1) - \gamma_3 \ln(c_2)). \quad (17)$$

and is measured at intervals of one minute with the measurement noise that is determined experimentally and bounded by $\sigma = 0.5\text{L/h}$. The model of the permeate flux can be reduced to another widely used *limiting flux model* if $\gamma_3 = 0$, so this example offers to study both parametric and non-parametric plant-model mismatch. The measurement of q_p is used for inferring the values of the parameters $\gamma_1, \gamma_2, \gamma_3$. Note that this leads to linear parameter estimation problem with the regressor $c = (1, \ln(c_1), \ln(c_2))^T$ and parameters $\hat{p} = (\gamma_1 \ln(\gamma_2), \gamma_1, \gamma_1 \gamma_3)^T$, from which the values of $\gamma_1, \gamma_2, \gamma_3$ follow directly. Concentrations of both components $c_1(t)$ and $c_2(t)$, where the first component is retained by the membrane and the second one can freely pass through, are measured as well and filtered prior to estimation.

The objective is to find a time-dependent input function $u(t)$, which guarantees the transition from the given initial $c_{1,0}, c_{2,0}$ to final $c_{1,f}, c_{2,f}$ concentrations in minimum time. This problem can be formulated as:

$$\mathcal{J}^* = \min_{u(t) \in [0, \infty)} \int_0^{t_f} 1 \, dt, \quad (18a)$$

$$\text{s.t. } \dot{c}_1 = \frac{c_1^2 q_p}{c_{1,0} V_0} (1 - u), \quad c_1(0) = c_{1,0}, \quad c_1(t_f) = c_{1,f}, \quad (18b)$$

$$\dot{c}_2 = -\frac{c_1 c_2 q_p}{c_{1,0} V_0} u, \quad c_2(0) = c_{2,0}, \quad c_2(t_f) = c_{2,f}, \quad (18c)$$

$$q_p = \gamma_1 (\ln(\gamma_2) - \ln(c_1) - \gamma_3 \ln(c_2)). \quad (18d)$$

The parameters of the problem are $c_{1,0} = 50\text{g/L}$, $c_{1,f} = 110\text{g/L}$, $c_{2,0} = 5.3\text{g/L}$, $c_{2,f} = 1\text{g/L}$, $V_0 = 21\text{L}$. The extremal values of $u(t)$ stand for a mode with no water addition, when $u(t) = 0$ and pure dilution, i.e., a certain amount of water is added at a single time instant, $u(t) = \infty$.

The preliminary run of the laboratory apparatus with $u(t) = 0$ for 0.75 h and $u(t) = 1$ for 0.65 h was used to gathered data which were subsequently used in set-membership estimation to determine the confidence intervals of parameters as $\gamma_1 = [1.86, 3.91]\text{L/h}$, $\gamma_2 = [4.1163, 0.6589] \times 10^3\text{g/L}$, $\gamma_3 = [-0.11, 0.17]$. The value of β used for the estimation is 0.5. Particularly the value of lower bound of γ_3 points to a potentially strong structural plant-model mismatch. We note for completeness that the particular advantage of used the set-membership estimation is that the assumption γ_3 , which one might like to use in this case, could be easily incorporated in the estimation.

The nominal (parametrized) optimal control of this process can be identified using Pontryagin's minimum principle (Pontryagin et al., 1962) as (6) where the singular control and the respective switching function can be found explicitly (Paulen et al., 2012) as

$$u_s(x(t), p) := \frac{1}{1 + \gamma_3}, \quad S(x(t), p) := \gamma_1 (\ln(\gamma_2) - \ln(c_1) - \gamma_3 \ln(c_2) - \gamma_3 - 1). \quad (19)$$

For the given nominal parameters of the problem, the optimal control sequence is $u^* = \{0, 0.9333, \infty\}$ with switching times $t_f = 2.86\text{h}$. This operation is taken as a base case for evaluation of the discussed control schemes.

It is clear that the real-time optimality of the operation is strongly influenced by accuracy of the parameter estimates, mostly γ_2 and γ_3 since γ_1 can be factored out from $S(\cdot)$. Preliminary

numerical tests with optimal experiment design (OED) methodology (Gottu Mikkula and Paulen, 2017) showed that for the most accurate estimation of γ_2 the manipulated variable $u(t) = 0$ and, on the other hand, the best estimation accuracy of γ_3 is reached when $u(t) = 1$. This shows mutual benefit of the optimal control strategy $u^* = \{0, 0.9333, \infty\}$ and estimation of γ_2 , and a potential conflict of accurate estimation of γ_3 and the optimal control policy. This can also be seen from (17) and (18c), where it is clear that when a controller applies $u(t) = 0$, the parameter γ_3 is unidentifiable as the concentration $c_2(t)$ remains constant. The OED studies also showed that the best time to measure the plant outputs is in the beginning of the operation. This stems from the absolute error of the measurement (see (9)) and from the fact that the measured permeate flux is highest in the beginning of the operation and drops dramatically with the increase of $c_1(t)$.

The real-time optimal operation using on-line adaptation of parameters reached the final time of operation 2.87 h, which is practically the same performance as the optimal operation, while its counterpart without parameter estimation reached the operation time 4.23 h, which clearly too conservative. This result shows the significant benefits of the proposed scheme.

5. Conclusion

We have presented a methodology for dynamic real-time optimization of batch processes (with particular application to membrane systems) via parametrization of the optimal controller using Pontryagin's minimum principle. The employed parametrization greatly reduces the computational burden in order to guarantee feasibility of the operation. In order to address parametric plant-model mismatch issue, we have suggested a robust approach, which consisted in projection of the plant uncertainty into optimality conditions. This again greatly reduces computational burden. As the uncertainty in parameters can greatly affect the optimality of the batch, we have proposed an adaptive scheme that makes use parameter estimation and, as shown in the case study, can greatly assist in reducing conservativeness of the real-time scheme.

Abstract

This work presents a generic Mixed-Integer Linear Programming model that integrates a Mid-term Energy Planning model for the optimal integration of power plants into interconnected power generation systems. The time horizon consists of a representative day for each month of the year. The Unit commitment problem is modelled in details to optimally determine the optimal operational strategy in order to meet the electricity demand at a minimum total cost by utilizing the optimal combination of a set of available power generation plants. Furthermore, the model considers the possibility of building new units selected from a set of proposed ones, as well as expanding the capacity of existing renewable energy units. The possibility of expanding the existing interconnection capacity between systems is also considered. Environmental-related constraints for the production of CO₂, NO_x, SO_x and PM_x emissions are also taken into account. The main objective is the minimization of the total annualized cost. The applicability of the proposed model is illustrated in a case study including two interconnected power systems. Finally, a sensitivity analysis is performed in order to investigate the effect of key process parameters on the final power generation policies.

Keywords: Mid-term Energy Planning, Unit commitment problem, Transmission expansion planning, Mixed integer linear programming.

1. Introduction

In recent years, the problems of climate change and environmental pollution constitute a major concern for the global community. As a result, the fossil fuels usage is constantly decreasing while the percentage of Renewable Energy Sources (RES) penetration gets higher, in order to achieve lower emissions of key air pollutants. Furthermore, a number of other challenges are to be addressed, such as the constantly electricity demand increase, the variability of the fossil fuel prices and the transmission network safety (Koltsaklis et al, 2014). Under these challenges, power systems expansion planning is of paramount importance for an affordable, secure, and sustainable energy future. Focusing on the spatial characteristics of the power system, Koltsaklis et al., (2014), presented a generic multi-regional MILP model for the optimal generation expansion problem of a power system at a national and/or regional level, incorporating also energy resources management aspects. Sadeghi et al. (2017), provide a detailed review of the technical, regulatory, environmental, and economic aspects that influence the generation expansion planning (GEP) decisions, highlighting possible directions for future works. Furthermore, Denny et al. (2012), made use of a stochastic unit commitment model to

assess the influence of increased interconnection for the island of Ireland with high penetrations of wind generation. The findings indicate that increased interconnections can decrease average prices as well as their variability, while they can enhance power system security to a significant extent. Georgiou (2016), developed a mixed integer linear programming (MILP) model for the optimal generation expansion planning (GEP) of a power system incorporating possible interconnections between mainland and insular systems. The results indicate the potential benefits of such an interconnected power system, in terms of operational flexibility and environmental impact. This work utilizes a detailed and generic mixed-integer linear programming model for the optimal power systems expansion planning problem of interconnected systems. The results indicate the optimal type of power generation technologies of each system along with their daily operation, their capacity and location of new units under several technical, economic, regulatory, and environmental constraints.

2. Problem Statement

The problem under consideration is formally defined in terms of the following items. The period under consideration is annual and is divided into a set of monthly periods $m \in M$, through the introduction of specific representative days. The duration of each representative day of each month $m \in M$ (in days) is represented by the parameter DUR_m . A set of power generating units $i \in I$ are installed in each power system $s \in S$. The producing power generation of each unit is represented by the variable $P_{i,m,t}$. This set of power generating units can include thermal power units $th \in TH$, hydroelectric units $j \in J$, and renewable (except hydroelectric) units $ren \in REN$. The thermal units are described by their efficiency and their conversion factor of fuel to energy, given by the parameters EF_{th} and $HEATVALUE_{th}$, and they also have a fixed operating cost given by the parameter $OTHERS_{th}$, while there is also a minimum penetration level of renewable energy units $MINREN$ ($MAXREN$). Each renewable unit, $ren \in REN$, is characterized by a specific availability during each time interval $t \in T$ and month $m \in M$ given by $AV_{ren,m,t}$. The subset which includes the new candidates for construction units, is denoted by $n \in N$, while the binary variable UB_n is equal to 1 if a new unit is constructed. Furthermore, the capacity of the renewable units is able to be expanded up to an upper expansion limit represented by the parameter $MAXEXP_{ren}$. The expansion is given by the variable $PEXP_{ren}$. The new units are characterized by a specific investment cost INV_n (subject to a specific capital recovery factor CRF), as the expansion cost for the renewables is represented by $INVR_{ren}$. Each power system, $s \in S$, can be interconnected with other power systems ($s' \neq s$) $\in S$ according to a specific network structure. Each power system $s \in S$ is characterized by a certain electricity demand in each time period $t \in T$ and month $m \in M$ given by the parameter $D_{s,m,t}$. The transmitted power between interconnected power systems $s \in S$ and $s' \in S$, $s \neq s'$, given by the variable $CFL_{s,s',m,t}$. Each interconnector between the interconnected system is characterized by a specific ramp-up, CUP , and ramp-down, CDN , rate. Its transmission expansion cost is described by the parameter $TRANS_COST$, while the expansion level is given by the variable $COREX_{s,s'}$. There is also a maximum transmission capacity expansion value given by $MAXTRANSM$. Each power generating unit $i \in I$ is identified based on specific technical characteristics including technical minimum (maximum) of each power unit $i \in I$, $PMIN_i$ ($PMAX_i$). Emissions rate coefficients (COE_{th} , NOX_{th} , SOX_{th} and PM_{th}) describe the CO_2 , the NO_x the SO_x and the PM_x emissions as the CO_2 emission cost is described by the parameter $CCOST_{th}$.

Each thermal unit $th \in TH$ has a specific fuel cost $FCOST_{th}$. The environmental standards of the studied power system include: (i) Upper annual CO2 emissions limit $MAXCO2_{th}$, (ii) Upper annual NOX emissions limit $MAXNOX_{th}$, (iii) Upper annual SOX emissions limit $MAXSOX_{th}$, and (iv) Upper annual PMX emissions limit $MAXPM_{th}$.

3. Mathematical Formulation

The objective function (1) includes the operating costs of all production units and systems. In particular, the first term expresses the variable cost that depends on the output power of all thermal units over the examined period. The second term refers to the annualized construction cost of all the new units which are decided to be constructed. Similarly, the next term represents the annualized expansion cost of each RES power unit under expansion. The next two terms refer to the interconnection grid between the energy systems. The first term describes the total electricity flow between the energy systems and the last term quantifies the cost of the transmission grid expansion.

$$\begin{aligned} \min & \left[\left(\sum_{m \in M} \sum_{i \in I} \sum_{t \in T} \frac{FCOST_{th}}{HEATVALUE_{th} \cdot 0.277778 \cdot EF_{th}} + COE_{th} \cdot CCOST + OTHERS_{th} \right) P_{i,m,t} \cdot DUR_m \right. \\ & + CRF \cdot \left(\sum_{n \in N} UB_n \cdot INV_N + \sum_{ren \in REN} PEXP_{ren} \cdot INVR_{ren} \right) + \\ & \left. + \left(\sum_{s \in S} \sum_{s' \in S} (CFL_{s,s',m,t}) + \sum_{s \in S} \sum_{s' \in S} COREX_{s,s'} \cdot \frac{TRANS_COST}{2} \right) \right] \end{aligned} \quad (1)$$

$$\sum_{i \in IS} P_{i,m,t} + \sum_{s' \in INT} CFL_{s',s,m,t} = D_{s,m,t} + \sum_{s' \in INT} CFL_{s,s',m,t} \quad \forall s \in S, m \in M, t \in T, type_i \neq 4 \quad (2)$$

Constraint (2) quantify the energy balance of the problem. The first term is a sum referring to the total power output generated by all units at each time period $t \in T$, while the second sum refers to the total energy entering the system $s \in S$ from the all the other interconnected options. The third term is the demand of each system $s \in S$ at each time period $t \in T$, while the fourth term refers to the total energy exporting from a system $s \in S$ to the other interconnected power systems.

$$CEXP_{s,s'} \leq COREX_{s,s'} \cdot MAXTRANSM \quad \forall s \in S, s' \in S, s' \neq s \quad (3)$$

According to constraint (3), the expansion of the interconnection network $CEXP_{s,s'}$ has an upper limit, expressed by parameter $MAXTRANSM$. The binary variable $COREX_{s,s'}$ takes the value 1 if the transmission grid is decided to be expanded.

$$CFL_{s,s',m,t} - CFL_{s,s',m,t-1} \leq CUP \cdot CFL_{s,s',m,t-1} \quad \forall s \in S, s' \in S, m \in M, t \in T \quad (4)$$

$$CFL_{s,s',m,t-1} - CFL_{s,s',m,t} \leq CDN \cdot CFL_{s,s',m,t-1} \quad \forall s \in S, s' \in S, m \in M, t \in T \quad (5)$$

Constraints (4) and (5), indicate that both the increase and decrease of the transmitted power between two hours $CFL_{s,s',m,t}$, should be lower than the two percentages, expressed by parameters, CUP and CDN, respectively.

Additional constraints of the model include: (i) Units' power capacity constraints, (ii) power adequacy constraint, (iii) maximum and minimum penetration of RES constraints, (iv) new units construction and RES units expansion constraints, (v) hydroelectric units' constraints, (vi) environmental impact constraints and (vii) ramp-up and down limits of power units. The overall problem is formulated as an MILP problem, involving a cost minimization objective function and subject to the above constraints.

4. Case Study

The applicability of the proposed model is illustrated using a representative case study, in which the annual energy production of two interconnected systems, S1 and S2, is considered. Each system consists of a set of power generation units. These units are sorted into thermal units (lignite-fired and natural gas units), hydroelectric units and renewable energy sources (RES) units (solar and wind units). The possibility of building new units in system S1, selected from a set of proposed ones, as well as expanding the capacity of existing renewable energy units is also taken into account. The possibility of expanding the existing interconnection capacity between systems is also considered, as well as the air pollutants emissions and more specifically the emissions of CO_2 , NO_x , SO_x , and PM_x . The objective corresponds to the minimization of the total annualized cost. Figure 1 presents the total capacity per technology type in each power system.

Figure 1: Total capacity per technology type in each power system (MW)

The parameters' values that have been used are based on data from the U.S. Energy Information Administration (U.S. Energy Information Administration, 2016)

5. Results

The problem has been solved to global optimality making use of the ILOG CPLEX 12.6.0.0 solver incorporated in the General Algebraic Modelling System tool (GAMS, 2017). An integrality gap of 1% has been imposed in all Scenarios.

Figure 2: Annual production mix per selected Scenario (TWh)

Figure 3: a) Total power flow between the two systems in each case (TWh) b) New units' capacity in each case by each technology type (MW)

The first sensitivity analysis bears upon the variation of the CO₂ emissions cost. Beginning with a reference value (6 €/tn), the price is firstly increased to 10 €/tn and then reaches gradually the value of 50 €/tn. Figure 2 presents the total production for each type of units in each case. It is clear that the gradual increase of the CO₂ emission value, causes a decrease in the total lignite units' production, while a remarkable

increase in the natural gas units' contribution also appears. More precisely, the annual production of lignite units is reduced from 25 TWh initially to the half, when the CO₂ cost is equal to 15 €/tn and it is going up to zero for higher CO₂ prices. On the contrary, the total annual production of natural gas units is doubled for a CO₂ cost value equal to 15 €/tn, and reaches an upper production limit of 35 TWh for a CO₂ cost price of 25 €/tn.

The marginal cost for the transmission grid expansion which connects the two systems is also studied. As shown in Figure 3(a), this cost is 120,000 €/MW. In case the expansion cost is higher than this marginal value, no extension of the interconnection grid takes place and the total transmitted power is lower, whereas the construction of an additional natural gas unit is decided, as illustrated in Figure (3b). On the contrary, for a transmission cost equal or lower than the marginal cost, the power unit is not built.

6. Conclusions

The main objective of the present work is the development of a mathematical model for the optimal mid-term power systems planning, which implements the generation and transmission expansion planning of interconnected power systems on an annual scale. The proposed model can be utilized by decision makers to take strategic decision-making such as the construction of new units, expansion of renewable ones, as well as the capacity of transmission lines between the interconnected power systems. Furthermore, the proposed approach incorporates several environmental constraints in terms of gaseous pollutants such as CO₂, NO_x, SO_x and particulate matter PM_x. In addition, the proposed model can be used in order to study two or more interconnected power systems which represent either individual power systems of a country or each system represents separately the overall power system of a country.

Abstract

Energy system design should take into account the hourly, daily and seasonal variations of both the energy demand and the considered utilities, and therefore requires a multi-time-resolution problem formulation. Multi-period / multi-time optimization is needed when a multi-time (e.g. hourly) optimization is performed inside another multi-period (e.g. typical day) optimization. However, optimizations over large temporal or spatial horizons tend to become computationally expensive, due to the large number of variables and constraints indexed over the times and over the periods. Employing typical operating periods (e.g. a number of typical operating days during the year) offers an interesting solution for problem size reduction. A variety of data clustering algorithms have been proposed in literature in order to select the best typical periods for different applications. This work uses a MILP formulation of a k-medoids based algorithm (PAM) in order to obtain typical operating periods which pass energy from one period to another, in view of performing long term energy storage. The algorithm is used coupled with an optimization of a CO₂ based district energy network in a typical urban center. The intra-daily resolution allows the exploration of short term energy storage in the form of batteries located in the medium and low voltage grid. Coupled with the seasonal resolution, it offers a better understanding of the impact of daily storage on the long term storage and on the total energy requirement. The results show that implementing short-term energy storage leads to reductions of 2% in the size of the long term storage tank and 7.5 - 7.8% in the size of the main energy providers (PV panels).

Keywords: multi-period optimization, short and long term energy storage, district energy networks, CO₂ network

1. Introduction and motivation

Multi-period models are used to optimize the design and operation scheduling of energy systems. Optimal operation scheduling has been extensively reviewed across different fields (Floudas and Lin, 2004; Méndez et al., 2006; Phanden et al., 2011; Maravelias, 2012). However, such optimizations have a large number of variables and are computationally expensive. Typical operating periods represent an efficient solution which reduces the number of variables. Indeed, appropriate typical operating periods allow to reduce the data, while keeping the key features of the different profiles and ensuring a proper sizing of the equipment. However, a trade-off between the desired precision and the quality of the results must be found.

Data clustering techniques were first introduced by Lloyd in 1957, and published in 1982 (Lloyd, 1982). These techniques have been used across different fields, such as machine learning, biomedical research (Xu and Wunsch, 2010), or energy system engineering (Fazlollahi et al., 2014; Bungener et al., 2013).

The selection of typical operating periods has been approached in different ways. (Fazlollahi et al., 2014) used a k-means algorithm (Seber, 1984) and ϵ -constraints (a parametric optimization which minimizes the number of operating periods while maximizing their quality (Steuer, 1989)). In the k-means algorithm, the yearly profile is grouped in clusters and the period closest to the center of each cluster is used as the typical period which represents the cluster. Peak load periods are added as isolated clusters to ensure that the system is able to operate at these conditions.

(Domínguez-Muñoz et al., 2011) proposed a k-medoids algorithm to select representative operating periods. The main difference with the previous approach is that k-medoids selects the center of the cluster using a data point from within the cluster, and that scaling factors are used on the cluster days in order to ensure the annual energy balance. Similar to k-means, the peak load periods are added manually.

Other approaches are present in the literature. (Marechal and Kalitventzeff, 2003) and (Bungener et al., 2013) used an evolutionary algorithm to select typical operating periods for industrial energy systems. (Ortiga et al., 2011) proposed a graphical algorithm to reduce the number of operating periods in order to reproduce heating and cooling load duration curves. (Lozano et al., 2009) used 24 typical operating days, 2 for each month: one using averaged data over the working days and one using averaged data over the weekends.

In this paper, a mixed integer linear programming (MILP) formulation of a k-medoids based algorithm is used in order to find typical operating periods for an urban energy system (Rager, 2015; Stadler et al., 2016). A typical urban center (Suciú et al., 2017) using a CO₂ based district energy network (DEN) is used as case study. CO₂ networks have already been integrated with power to gas (P2G) systems for long term energy storage (Suciú et al., 2017, 2016). However, the intraday resolution has not been addressed. In view of this the current study further integrates the system with batteries located in the medium and low voltage grids, in order to explore short-term energy storage and to better understand the impact of daily storage on the size of the long term energy storage tank and of the main energy providers (the PV panels).

2. Methodology

2.1. Selection of typical periods

Since the problem computational time increases drastically with the problem size (figure 1a), in this work a k-medoids based data clustering algorithm is used to reduce the complexity of the problem studied. This approach selects the cluster centers based on the smallest sum of distances within each cluster, while the cluster size is chosen based on a series of performance indicators (Stadler et al., 2016; Rager, 2015).

Two input parameters are considered for the clustering process, namely the ambient temperature (T_{ext}) and the global solar irradiation (GI). Other data such as consumption profiles and their corresponding temperatures of demand are defined based on the computed cluster centers. The k-medoids algorithm is run between 2 and 25 typical days. A maximum of 12% error in the load duration curve (ELDC) is set and consequently the number of typical days should be higher than 5 (figure 1b). In order to select the optimal number of typical days, the Davies-Bouldin (DB) index is used. The DB index is a measure of how good the clustering scheme is (Davies and Bouldin, 1979). It accounts for the separation between the clusters, which ideally has to be as large as possible, and the within cluster scatter, which has to be as low as possible. The index is defined as the ratio of the cluster separation and the within the cluster distance, and the lower the value, the better the separation of the clusters and the 'tightness' inside the clusters. As observed in figure 1c, for this problem the DB index has the lowest value for 7 typical days. Therefore, this value is used for further analysis.

Figure 1. Computational time (a), error load duration curves (b), and Davies-Bouldin index (c) for different # of typical days

2.2. CO₂ based district energy networks

A detailed description of the refrigerant based network using CO₂ as the heat transfer fluid is given by (Weber and Favrat, 2007) and possible energy conversion technologies have been investigated by (Henchoz, 2011, 2016; Henchoz et al., 2015). The network has been integrated with electrolysis and methanation units to convert electricity to natural gas for energy storage and with co-generation solid oxide fuel cell (SOFC)-gas turbine units to convert natural gas back to electricity and heat (Suciu et al., 2017, 2016).

A typical urban area is studied (Suciu et al., 2017). The energy demands considered are heating in the form of space heating and domestic hot water, cooling in the form of air cooling and refrigeration, and the demand for electrical appliances (utilities) (figure 2b). The decentralized energy technologies used are: heat pumps for space heating and domestic hot water, heat exchangers for air cooling, and vapor compression chillers for refrigeration. The centralized energy technologies used are: a central plant which balances the network (in the form of a lake or geothermal wells), photo-voltaic (PV) panels, a solid oxide fuel cell (SOFC) - solid oxide electrolysis cell (SOEC) co-generation unit, and a boiler-steam network installed at the waste incinerator (figure 2a).

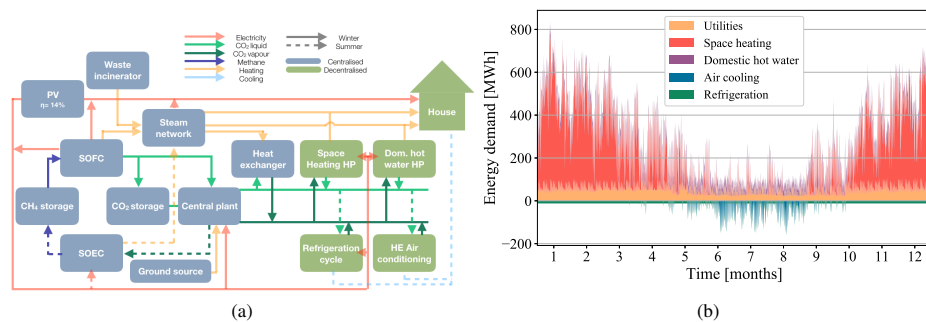

Figure 2. Schematic description of CO₂ DENs (a) and service energy demand (b)

Details on the models and cost parameters used can be found in (Suciu et al., 2017, 2016). The system is further integrated with batteries to explore the influence of daily storage on the size of the long term storage tank and of the PV panels. The problem uses a mixed integer linear programming (MILP) formulation based on optimal utility selection (Marechal and Kalitventzeff, 2003). The objective function is the minimization of the operating cost and the main constraints are the heat cascade equations and the resource balance equations. Additional constraints such as energy conversion technology sizing (and selection) apply.

3. Results and discussion

First, the impact of the short term energy storage on the size of the long term (methane) storage tank is shown. Figures 3 and 4 show the profile of the methane tank level for 7 typical days without and with short-term storage, respectively. When short term storage is used, the size of the methane tank reduces by approximately 2%, since the battery performs a peak load shifting during the day (see close-ups in figures 3 and 4).

Figure 3. Long term energy storage level, 7 typical days

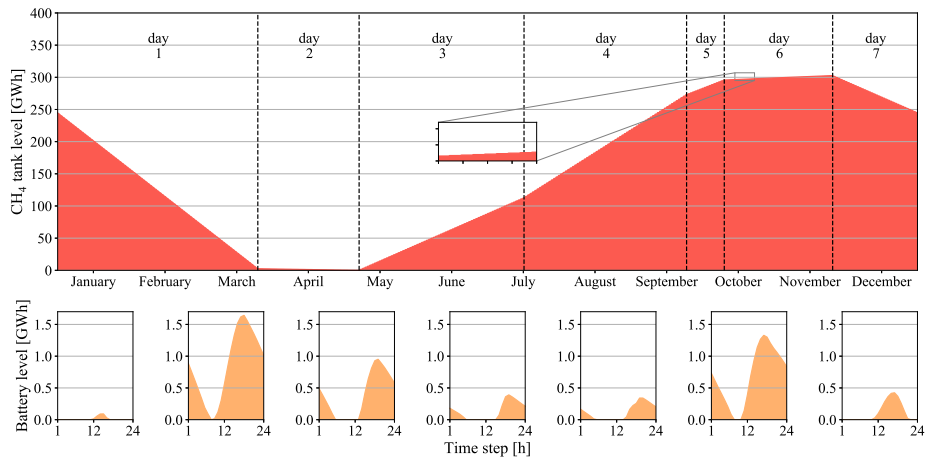

Figure 4. Long and short term energy storage levels, 7 typical days

Taking a closer look at the methane and battery storage levels, one can see that the methane tank charges during summer, when the solar irradiation is high and the excess electricity is used to produce methane and discharges in winter, when the heating demand is high and methane is consumed in the SOFC to produce electricity (for the heating heat pumps).

The short term storage has a few typical operating modes. In days 2, 3, 4, 5, and 6 the battery charges in the afternoon, when the global irradiation is high, and discharges during the night to provide energy services such as electricity for utilities, domestic hot water, or refrigeration. In this case the battery performs a load-shifting from day to night. Typical days 1 and 7 depict a load shifting during the afternoon. In these cases, the battery is charging in the early afternoon and discharging in the late afternoon.

Next, the economic impact of the solution is analyzed. Six cases are considered, 3 scenarios without short term energy storage (a) and their corresponding scenarios with short term energy storage (b). The first scenario (1) is the base case, in which the heat from the environment is provided by a lake, in the second scenario (2) the municipal solid waste produced in the area is valorised, and in the third scenario (3) the municipal solid waste is valorised and the heat from the environment is provided by geothermal wells.

Details on the costs of the different equipments can be found in (Suciu et al., 2017, 2016) and on the battery cost in (Nick et al., 2017). The breakdown of the investment cost for the different cases can be observed in figure 5 and the fixed and variable investment costs for the main contributors in table 1.

Figure 5. Investment cost breakdown

Table 1. Parameters for investment cost

Unit	Fixed cost	Var. cost	Attribute
SOEC/FC	-	4760 [€/kW]	\dot{E}_{SOEC}
PV	-	247 [€/m ²]	A_{PV}
HPs SH	5680 [€]	1240 [€/kW]	\dot{E}_{comp}
Pipes	5670 [€]	613 [€/m]	$d_{network}$
Battery	20000 [€]	200 [€/kW]	$\dot{E}_{Battery}$

When the waste incinerator-steam network provides part of the electricity, the PV panel size reduces by approximately 4.6%. When the heat from the environment is provided by geothermal wells, the overall electricity consumption decreases (Suciu et al., 2017, 2016) and therefore the size of the PV panels decreases further by 5.4%. When short term energy storage is considered, the PV panel size decreases by 7.5 - 7.8% for the different scenarios. The size of the co-generation unit also decreases, but the size of the SH HPs and the network pipe diameter increase, since less waste heat is available from the co-generation units. For scenarios (1) and (2) the savings in the investment cost of the PV panels and of the co-generation units are smaller than the investment cost of the battery, making the short-term storage implementation unattractive from an economic point of view. However, in scenario (3) the savings due to the use of short-term energy storage are higher than the investment cost of the batteries, making the use of batteries for intra-daily load shifting economically favorable.

4. Conclusion

This work uses a multi-period (7 typical days) multi-time (24 hours) resolution to optimize CO₂-based district energy networks. The intra-daily resolution offers a better understanding of the impact of daily electricity storage on the size of the long term energy storage tank and on the size of the main energy providers (the PV panels). When daily storage is used, the long term energy storage (methane) tank reduces by approximately 2%, since the batteries perform daily load-shifting.

The size of the PV panels is compared for 3 different scenarios, with and without short term energy storage. The size reduces by 4.6 % when waste is considered since the steam network satisfies part of the electricity demand and it reduces further by 5.4 % when geothermal wells are used since the overall electricity consumption decreases. The short term storage leads to reductions in the PV panel size of 7.6% for scenario (1), 7.5% for scenario (2), and 7.8% for scenario (3). While for scenarios (1) and (2) investing in short-term energy storage is not economically favorable,

in scenario (3) the savings in investment cost from using short-term storage are higher than the investment cost of the battery, making it a economically attractive solution.

Abstract

Reuse and regeneration of water is becoming increasingly important in the food industry. Planning both water reuse and production while at the same time ensuring food safety is a challenge. We propose a novel scheduling methodology to simultaneously plan water reuse and production in food production processes utilizing real time water quality data. We develop a two-stage predictive scheduling and reactive scheduling approach taking into account the dynamic nature of water quality. Overall, our approach can prevent undesired contamination of food products due to reuse of water and achieve higher water efficiency.

Keywords: data driven approach, real-time scheduling, water efficiency, online water quality measurement, food industry.

1. Introduction

Increasing population, economic growth, and demographic changes have all contributed to an increased consumption of processed foods. Water is both an essential ingredient for food processing in its pure form, and an unwanted byproduct that poses significant financial and environmental burden. Many food processing plants are investing in advanced water treatment technologies to reuse wastewater streams in daily production and cleaning requirements. Ensuring that water of appropriate quality reaches a water-demanding process at the correct time is key to achieving efficient water reuse. As a result, managing water flows in food industries becomes inseparable from production planning and scheduling. Additionally, in order to ensure safe water reuse, real-time water quality monitoring technologies are also increasingly deployed. Such systems are often used to raise alarms in case of water quality abnormalities that require operator intervention. However, using such measurements to provide early warnings and make necessary operational decisions remains a challenge.

Integrated water minimization and production management in process plants is a relevant field of research in this context, and has been actively contributed to by both operations research and process systems engineering communities. Several mixed integer linear programming models have been developed in the last decade to integrate production scheduling with water network planning (Gouws et al. 2010). Recent works have also addressed aspects like water–production efficiency tradeoffs (Chaturvedi & Bandyopadhyay 2014, Pulluru & Akkerman 2017), sequence-dependent cleanings (Adekola et al. 2017), and water quality classifications (Pulluru & Akkerman 2017). A

major shortcoming of these works is that they assume either pre-determined water qualities or model ideal process systems. In practice, there is a high margin for error in these estimates, due to e.g. treatment equipment failures, temperature variations, non-ideal mixing, feed quality variations, or insufficient cleaning. Undesirable fluctuations from these estimates/assumptions can render carefully constructed water-efficient production schedules infeasible resulting in significant efficiency losses. Augmenting water-integrated production scheduling with real-time water quality data obtained from online monitoring systems is a potential way to tackle this problem.

In this paper, we present a two-stage scheduling approach capable of scheduling production and planning water reuse in multi-stage flow shops employing real-time water quality data collected from online monitoring systems. We apply statistical inferences to characterize fluctuations in the quality of water obtained from regeneration systems like reverse osmosis (RO) and predict the extreme behaviour of the process. We formulate a scheduling model to model production in multi-stage flow shops combining both discrete and continuous time representations in order to capture both timely water flows/inventories and quality fluctuation behaviour of water obtained from treatment equipment. Based on observed quality data during schedule execution, our approach is capable of making various rescheduling decisions such as cleaning/maintenance of potentially contaminated equipment, delaying of batches, usage of different water sources, or additional treatment of water. This leads to increased adherence to production and water efficiency targets, and safety standards for food production. We illustrate our approach using a case of cheese production with whey treatment as a source of regenerated water.

2. Intelligent water-efficient scheduling model

To include real-time water quality data in our scheduling approach, we use extreme value theory to analyse the extreme measurements of water quality arising from regeneration units. This results in suitable probability density function described by shape parameter ξ , scale parameter a , and location parameter b which is then used to predict the magnitude of extreme measurements, also known as return level x as a function of time T . These functions represent a performance decay process in which water quality fluctuation gradually increases over time. For more details on extreme value analysis, its development and applications, we refer to Gomes & Guillou (2015) and Skou et al. (2017).

Using these analyses, we developed a sensor-data-driven hybrid discrete-continuous time scheduling model to make decisions on reuse of treated water, and scheduling of production and cleaning activities in multi-stage flow shops. Due to space limitations, we only present the key model characteristics and illustrate this in Figure 1. We assume a lot-by-lot sequencing in our flow shop to reflect real-life practice of producing lots consisting of several identical batches of the same product. For simplicity reasons, we only model sequence-dependent and time-dependent cleanings. We use constraints similar to Stefansdottir et al. (2017) to model the time-dependent cleanings. However, in their formulation, modelling of sequence-dependent cleanings is not explicit due to the use of a global precedence relationship between tasks. As our work requires determination of exact start and finish times (to be able to track water production and consumption), we instead use an immediate precedence relationship to model the sequencing of product lots and batches in the flow shop.

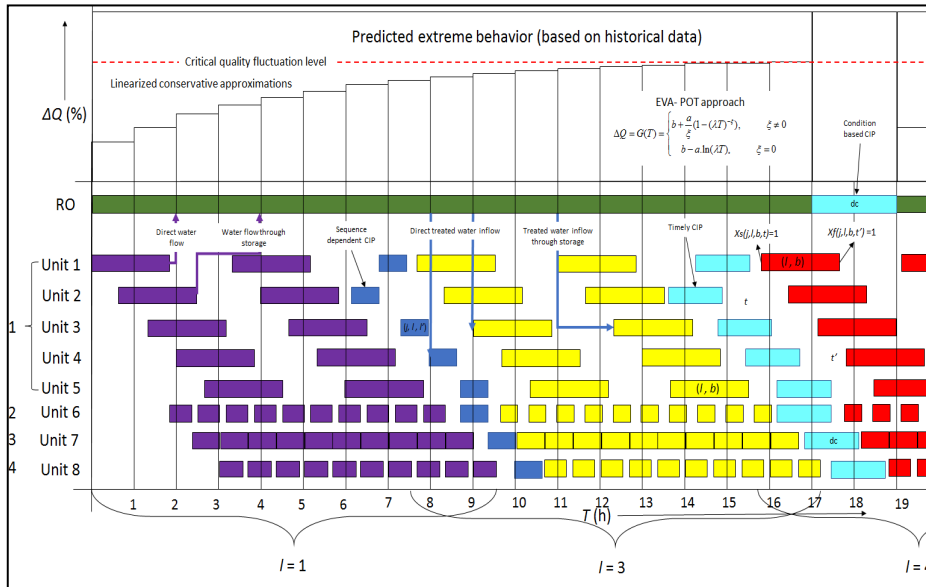

Figure 1: Illustration of the hybrid discrete-continuous-time scheduling model. Dynamic water quality degradation behaviour is used to determine treatment equipment cleaning and water reuse.

Another important decision that is crucial for our model is the sizing of lots. Usually, the number of lots to be produced for each product and the number of batches per lot is predetermined at a production planning level based on market demands (referred to as lot sizing). However, in case of water-integrated scheduling, moving the lot sizing decision to a production planning level may result in inflexible production schedules and suboptimal planning of water reuse. Therefore, we allow for calculation and recalculation of lot sizes based on water availability and other system characteristics encountered during both the scheduling and execution levels. This allows us to move batches between lots of the same product if that would benefit water or production efficiency.

Our water network has two key parts, exchange of water between cleaning-in place (CIP) operations and usage of treated water obtained from treatment of water-rich side streams. We model exchange of water between CIPs happening on different units at different times to capture the reuse of last flush effluent as an input for first flush. We further allow CIPs to use both treated water and fresh water for the first flush. However, use of treated water and CIP effluent for last flush is legally prohibited in most of the food industries, to prevent accumulation of contaminants in processing equipment. Therefore, we restrict such reuse in our model. Similarly, the requirement of water by processing tasks can either be met by fresh water or treated water.

In order to model treated water reuse and extreme water quality behaviour, we connect the continuous time scheduling model to a discrete time grid of fixed granularity. For this, we use grid connection variables that place task starts and finishes in relation to the discrete time grid. We use constraints similar to Hadera et al. (2015) to link the discrete time grid with continuous start and finish time variables. We model treatment equipment cleaning and other related decisions using the discrete time grid. This approach allows us to have both exact modelling of production and cleaning times and

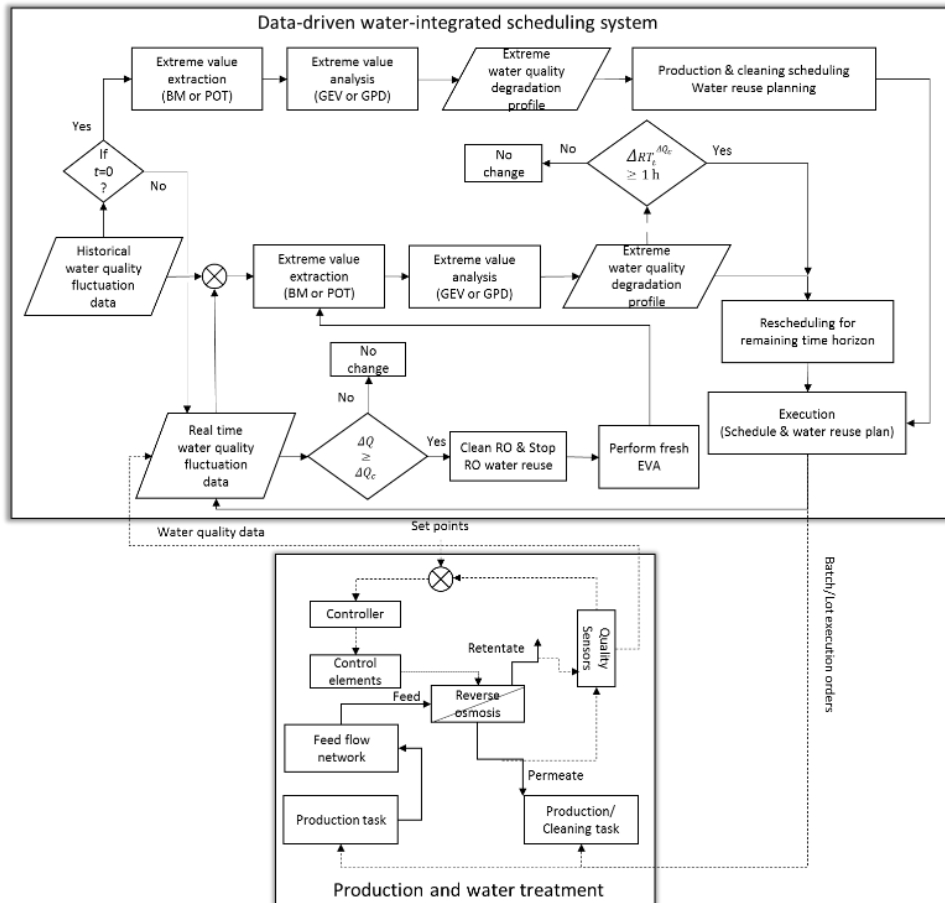

Figure 2: Data-driven water-integrated scheduling algorithm

also simplified representation of treated water withdrawal by production and cleaning tasks, extreme water quality behaviour, and water inventory. A piecewise linear approximation of the extreme water quality degradation is used to make cleaning decisions for treatment units.

Finally, for simplification of the problem, we use the constant batch ordering rule proposed by Marchetti & Cerda (2009). This concept relies on sequencing of lots on non-bottleneck stages based on the requirements of a bottleneck stage. We optimize our scheduling model to minimize total costs associated with fresh water usage and wastewater disposal. In case of rescheduling, we minimize deviation of the total cost from the minimal cost obtained during scheduling level.

3. Data-driven water-integrated scheduling algorithm

Based on the scheduling model and the production system characteristics described above, we propose a data-driven water-integrated scheduling algorithm that can use real-time water quality data from the online sensors. A schematic diagram of the algorithm is shown in Figure 2. At the start, relevant historical water quality data is

Figure 3: Illustrative water integrated production schedule, stored water/effluent levels and extreme water quality degradation behaviour of RO unit.

considered to generate extreme water quality fluctuation behaviour using EVA. Based on this predicted behaviour, a critical quality fluctuation level ΔQ_c is defined and the return time $RT^{\Delta Q_c}$ for corresponding quality fluctuation level is determined. This measure is then used to schedule timely cleanings on the water treatment equipment. It is assumed that all cleanings are perfect and restore the treatment unit to a return level of 0% and return time of 0 h after a cleaning. Similarly, production and cleaning tasks on other units are scheduled according to the treated water availability and extreme water quality behaviour. During execution of this schedule, water quality data obtained from various sensors is monitored and updates to the water quality data are made. Based on these updates, the extreme value behaviour curve of the system is constantly updated. Corrective rescheduling of production and water reuse is triggered based on two measures of system behaviour: the quality fluctuation level ΔQ_c and the change in return time $\Delta RT^{\Delta Q_c}$, calculated as the difference between currently calculated critical fluctuation return time $RT^{\Delta Q_c}$ from the value calculated immediately after last known treatment equipment cleaning. Rescheduling is done if (1) ΔQ_c exceeds a critical quality fluctuation level or (2) $\Delta RT^{\Delta Q_c}$ exceeds a specific limit. In the first case, treatment equipment is cleaned immediately, and production and cleaning tasks are rescheduled in view of this action. In the second case, rescheduling actions taken in this case are early cleaning of treatment equipment, and reorganization of processes as described earlier.

4. Illustrative results

In order to test our approach, we developed a problem instance resembling a typical cheese production setting. We assume a flow shop with five fermentation tanks feeding into prepressing, form filling, and postpressing. Equipment is cleaned on sequence changes and at the end of the day, requiring water. Further, water from the last CIP flush is used as an input to the first flush. Fermentation and prepressing operations result in whey that is treated in UF and RO units. RO permeates are reused to meet water requirements in production and cleaning operations. RO permeates may contain traces of undesired organic compounds. Presence of these compounds may cause the growth of microorganisms in the water and the product in which the water is used, resulting in safety

risks. We generate concentration fluctuation data with highly infrequent, randomly occurring extreme values resembling data collected from online quality sensors. Using the POT approach of EVA, we obtain shape, location, and scale parameters as inputs from the data and provide them as model inputs. For this, we set a threshold of 102 mg/m^3 for the contaminant under consideration. Similarly, we extract these parameters during execution of the data-driven real-time scheduling algorithm. For this, we set ΔQ_c equal to 110 mg/m^3 . The values we choose are illustrative; in real-life food production settings, these can be selected based on previous knowledge on the effect of water contamination levels on product quality. Figure 3 presents the resulting production schedule, together with water storage levels, effluent discharge, and extreme water quality behaviour of the RO units in one of the test instances. In this figure, the drop in contaminant concentration and resetting of the degradation behaviour results from cleaning of the RO units, which is done when the quality reaches a critical contamination value. A total water related cost of 6741.2 units was obtained for a 48h period, which improves a scenario with no water reuse with 62.45%. Further, safety of water reuse is ensured by only cleaning RO units when the prediction of extreme water quality exceeds a critical contamination limit.

5. Conclusions

To support food production plants in reusing wastewater streams in a safe and cost-effective manner, we developed an online water quality sensor-data-driven water-integrated scheduling algorithm. Using a hybrid discrete-continuous time scheduling formulation to capture scheduling, sequencing, water flow, and water quality aspects, our algorithm is capable of both scheduling and rescheduling production and cleaning operations both in a predictive and reactive manner. Despite the explicit modelling of quality, an important aspect of potential contamination of products due to reuse is not yet discussed in this paper. Further development requires integration of batch dispersion measures into the water-integrated scheduling model, and allocation of water streams to less risky products, when their contamination can be potentially high. Further, our model suffers from high integrality gaps due to a large number of binary variables and big-M constraints. Future research is then also directed towards computational improvements.

Abstract

The Concept Drift (CD) effect is often involved in most of the chemical manufacturing processes, and could easily lead to the decay of the Fault Detection and Diagnosis (FDD) system performance. This paper proposes a methodology for the online quantification of the CD amount. The method is based on the combination of an incremental learned classifier (Hyperplane Distance- Support Vector Machines (HD-SVM)) and a non-automatic clustering method (K-means technique). The incremental learned classifier is employed to examine and characterized the classes (i.e. normal, fault-type 1, fault-type 2, etc.) of the measured online datasets. Then, the CD amount is tracked through the monitoring of the matching extent between the latent pattern of the online dataset (regarding each class) and the latent pattern extracted from a certain reference dataset (for the corresponding class). The results of the method application to a benchmark case study involving a Continuous Stirred Tank Reactor (CSTR) indicate promising capabilities for tracking the CD amount along the operating time.

Keywords: Fault detection and diagnosis, Incremental learning, Concept drift, Clustering

1. Introduction

Data-driven FDD approaches have gained a wide popularity due to their application flexibility and robustness. As these approaches neither require the process detailed analytical model nor a deep knowledge about the process units and structure. However, their main limitation is that their efficiency is strictly conditioned by the quality of the available process history data used for their training. But, chemical manufacturing processes habitually involve time varying behaviors, due to several reasons as the process aging, fouling and drifting, which is consequently reflected to the online recorded data, leading to what is called Concept Drift (CD). Widmer et al. (1996) have defined the CD as the change of the target concept that is caused by changes in some hidden context.

The CD is usually associated to online supervised machine learning, where the statistical properties of the observed variables change over the time. Consequently, this leads to the deterioration of the FDD system performance/accuracy as the time passes. Therefore, many methods have been developed for the continuous updating of the data driven FDD systems with information about the process new or changeable conditions, in order to maintain their performance efficiency. Among several updating methods that

deal with the CD, the incremental learning have been deeply investigated by several researchers. Especially the HD-SVM incremental learning technique (Li et al., 2009) is receiving a growing interest. Recently, Ardakani et al. (2016) have proposed a HD-SVM-based algorithm for updating the FDD system against the CD effects due to the reduction in heat transfer coefficient through the time. Their algorithm have been able to efficiently keep the FDD performance at constant high level. Although almost all the methods available for updating the data driven FDD systems are able to successfully keep the FDD system accuracy at acceptable range, however, they do not provide any information about amount of the CD affecting the process. The assessment of the CD amount is of essential importance, as the continuous blind updating of the FDD system, without any information about the CD amount could easily drive the process to an unsafe operating conditions.

This work presents a methodology for the online quantification/tracing of the CD amount using incremental learned classifier and non-automatic clustering techniques. The proposed method is applied to a benchmark case study of a CSTR. The results indicate the promising capabilities of the method to track the CD amount along the operating time.

2. Tools and techniques

2.1. Clustering techniques

Clustering is an unsupervised pattern recognition method, which characterizes the possible latent patterns in a set of observations. It divides a set of observations or samples into subsets (i.e. clusters), in such a way that samples of the same cluster are similar, while samples of different clusters are distinct according to a certain criterion (Ouyang et al., 2011). The K-means algorithm is a non-automatic clustering method that has been commonly used in different areas (Chen et al., 2014), because of its efficiency, flexibility and ease of implementations. The basic idea of this method is the initiation of a centroid for each one of the clusters. Then the samples are assigned to the clusters in such a way that minimizes a metric relate to the distance measures between each sample and its cluster centroid. The shape of the obtained clusters are affected by the selected metric and also the definition of distance measure (He et al., 2005). The main limitations of the K-means method are the selection difficulty of the most suitable number of clusters, and also the initialization of the clusters centroid. Besides, the algorithm may converge to a local minimum, but several runs of the algorithm can solve this weakness (Yin et al., 2012).

2.2. Hyper distance support vector machines (HD-SVM)

The Support Vector Machines (SVM) technique is a type of supervised pattern recognitions methods that has been widely used for the data-driven FDD. It is used to assign (i.e. classify) a new unknown sample into one of the predefined classes or labels. In order to adapt the SVM classification performance when it is applied for the FDD of processes involving time varying conditions, the incremental learned SVM has been proposed. It utilizes the arriving online samples to update the original support vectors, only if they violate the Karush-Kuhn-Tucker (KKT) conditions (Wang et al., 2014; Yin et al., 2014). Thus, new samples satisfying KKT conditions are supposed to have no influence for updating the hyperplane.

The HD-SVM (Li et al., 2009) algorithm is a development of the incremental learned SVM. The algorithm considers that in addition to the samples that violate KKT conditions, other samples could be treated as support vectors too, based on the geometric distance of each new sample from the center of each class and the separating hyperplane. In this work, the performance of the SVM is reported in term of the F1score (Eq. (1)). It is calculated as a weighted average of precision and recall, where the precision is the portion of retrieved samples that are relevant, and recall is the portion of relevant samples that are retrieved. The F1-score reaches its best value at 1 and worst value at 0 (Ardakani et al., 2016).

$$F1 = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (1)$$

3. Proposed methodology

The proposed method for the monitoring/quantifications of the CD amount involves two phases, including offline and online ones. The offline phase encompasses the training and validation of the classifier using the early or the initial dataset X^0 of the process measured variables. This initial dataset is assumed to be measured under the process nominal conditions and include all the possible information about the process classes (normal and different faulty situations). Thus, $X^0 = [x_{cl_1}^0, x_{cl_2}^0, \dots, x_{cl_i}^0, \dots, x_{cl_N}^0]$, where cl_i is the i^{th} class type, i could be normal or any of the $N-1$ possible fault types and each $x_{cl_i}^0$ may contain different number of observations.

In the online phase, the process measurements are assumed to be collected along the time over j discrete periods in the form of discrete datasets. Where, each online dataset X_j^{onl} includes the same number of samples and may contain any possible combination of the process aforementioned classes.

The first stage of the online phase is the FDD, which encompasses the application of the trained HD-SVM classifier in order to detect and diagnose the possible faults that may affect the process using the j^{th} arriving dataset X_j^{onl} . Thus, the outcome of this stage is the assignment of the samples of the dataset X_j^{onl} into specific class(es), i.e. $X_j^{\text{onl}} = [x_{j,cl_1}^{\text{onl}}, \dots, x_{j,cl_i}^{\text{onl}}, \dots]$.

The second stage of the online phase, is the tracing of the CD amount based on monitoring the extent of matching between the latent pattern(s) in each class of the online dataset and the corresponding class of the initial dataset. Accordingly, an augmented dataset X_{j,cl_i}^{aug} for each class must be synthesized, through combining the samples of the specific i^{th} class of the initial dataset as a first part, and the samples of the corresponding i^{th} class of the online dataset as a second part, thus $X_{j,cl_i}^{\text{aug}} = [x_{cl_i}^0, x_{j,cl_i}^{\text{onl}}]$. After that, the non-automatic clustering technique is used to cluster the samples of each augmented dataset (X_{j,cl_i}^{aug}) –independently– into two clusters. Finally, the matching between the pattern of the clusters included in the online dataset x_{j,cl_i}^{onl} and the pattern of the clusters in the initial data $x_{cl_i}^0$ is assessed. This task is achieved through the comparison of the clustering labels that the K-means algorithm has assigned to the online dataset samples x_{j,cl_i}^{onl} and the labels assigned to the initial dataset samples x_{j,cl_i}^0 . In more details, the label of the first sample in the online dataset is compared to the label of the first sample in the initial dataset, and so on.

A relative Matching Measure MM_{j,cl_i} is calculated for each augmented set X_{j,cl_i}^{aug} , where MM_{j,cl_i} equals to the number of the similar clustered samples of x_{j,cl_i}^{onl} relative to x_{j,cl_i}^0 , divided by the total number of samples of x_{j,cl_i}^{onl} . In other words, MM_{j,cl_i} is an index that expresses the matching between the clusters pattern of the online dataset x_{j,cl_i}^{onl} , and the clusters pattern of the initial dataset $x_{cl_i}^0$. Figure 1 illustrates the framework, considering only two classes of the process, including normal class cl_1 and faulty class cl_2 .

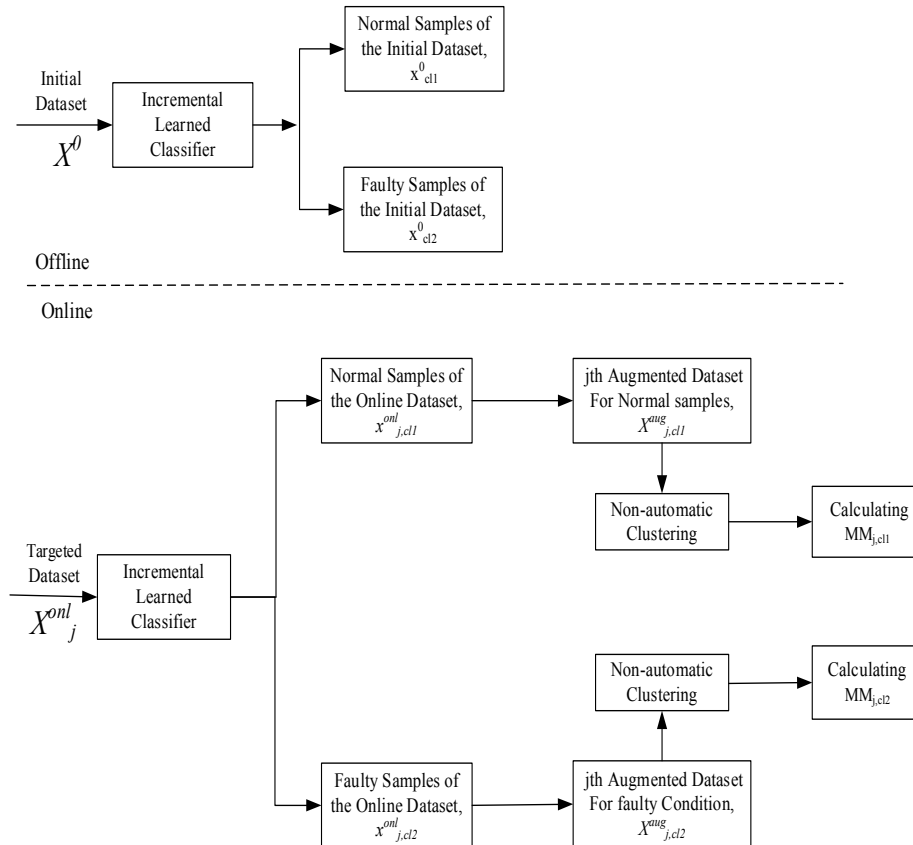

Figure 1. Proposed framework.

4. Case Study

The addressed case study involves a simulation model of a CSTR running the “Van der Vusse” reactions: $A \rightarrow B \rightarrow C$ and $2A \rightarrow C$ (Chen et al., 1995). The CSTR is used to produce cyclopentenol (desired product B) from cyclopentadienyl (reactant A) by mean of acid-catalysed electrophilic hydration in aqueous solution. Four process variables are assumed to be measured including the reactant concentration C_A , the product concentration C_B , the reactor temperature T_R and the cooling jacket temperature T_J . The nominal (normal) inlet concentration of the reactant equals to $5.1+v_o \text{ mol/L}$, where $v_o \approx \mathcal{N}(\mu = 0, \sigma = 0.045 \text{ mol/L})$ is a Gaussian white noise. In this work, one type of faults is considered to influence the process, which is defined as a step change in the

inlet concentration C_A from its predefined normal value to $5.13+v_o$ mol/L. The gradual change of the heat transfer coefficient through the time is treated as the source of the CD. Thus, the nominal/initial magnitude of the heat transfer coefficient ($k_w=4032$ KJ/hr.m².K) is linearly decreased over the time, so as to reach 95% of its nominal value at the end of the operating time.

5. Results

Along the total simulation/operation time, twelve datasets are collected in a successive way at discrete time intervals. The datasets have been collected with equal sizes (each dataset includes 4000 sample), assuming that the fault may take place at any time within any of the sets. The first/initial dataset measured at the earliest time of the process operation is used to train and validate the classifier (i.e. offline phase). Then, each of the subsequent eleven datasets is fed to the classifier and the clustering system in order to monitor the processes and to trace the CD amount (i.e. online phase).

For the sake of comparison, the FDD performance of the proposed framework based on the HD-SVM is compared to its performance when a classical SVM is used for classification, instead. The HD-SVM is able to maintain its high level of accuracy (F1 score of 94.89%) along the operating time and adapt its performance to the continuously changing conditions (heat transfer coefficient). In contrary, the SVM shows a decaying performance along the operating time, until it reaches to a very worthless performance (F1 score of 65.00%) at the last dataset.

Figure (2) displays the MM_{j,cl_i} of the online datasets. As previously mentioned in the methodology, the MM_{j,cl_i} has been calculated for each of the process classes independently (top plot for normal samples, and bottom plot for faulty samples). The figure also shows how the proposed algorithm is able to trace the involved CD in the process over the time. For normal samples, the matching measure drops from 99.0% in the second dataset ($j=2$) to 84.5% in the last dataset ($j=12$). While for the faulty samples, the matching measure decreases from 99.2% at in second dataset ($j=2$) to 68.7% in the last dataset ($j=12$). It can be noticed that after the 6th dataset, the MM of the faulty samples does not significantly change, which could be justified because of the limited number of faulty samples in those datasets.

Figure 2. MM of the normal and faulty samples for the applied scenario.

6. Conclusions

Existing methods for updating supervised data-driven FDD systems do not provide any information about the amount of the CD influencing the process. This paper presents a data-driven methodology for the FDD of chemical processes involving time varying conditions, which relies on the combination of an incremental learned classifier and a non-automatic clustering technique. The methodology tracks the CD amount via monitoring the matching extent between the clusters pattern of the online datasets and a reference dataset. The application results of the method to a benchmark case study illustrate promising capabilities, as the method is able to maintain the FDD system performance over the operating time. More significantly, the method is able to provide valuable information about the CD amount along the time, which can be used to prevent the process to reach unsafe operating conditions. Although of the simplicity of the addressed case study, but it was sufficient for the initial assessment of this new method. The future work will consider the exploration of the method performance when handling more complex and realistic cases.

Abstract

The production scheduling of a real-life multi-product, mixed batch and continuous food industrial facility is considered in this work. More specifically, the scheduling of canned fish production in a large-scale Spanish industry is studied in detail. The deployment of an efficient solution strategy is proposed to handle the computationally challenging scheduling problem. In particular, a Mixed-Integer Linear Programming (MILP) model is used, in parallel with a decomposition technique. The problem under consideration focuses on two important stages of the plant, the sterilization and the packaging. The proposed strategy takes into account the specific characteristics of the canned fish production facility resulting in interesting results. It should be noted that the same methodology can be used with appropriate modifications in other food process industries with similar production characteristics.

Keywords: production scheduling, multistage, food industry, mixed integer programming, decomposition.

1. Introduction

The scientific community has widely recognised the importance of applying scheduling solutions to industrial cases which so far is not adequately applied in real-life plants (Harjunoski et al., 2014). Therefore, there is a growing interest in the theoretical implementation to industrial practice. Many challenges exist due to the complexity of such cases in terms of number of stages and their mode of operation, number of products and shared resources typically met in real-life processes. In this work the canned fish production is considered, which comprises of multiple batch and continuous production operations, thus working in a semicontinuous production mode. Numerous studies addressing batch or continuous production modes are found in literature (Mendez et al., 2006). Nevertheless, not much work has been done considering

semicontinuous processes, despite being very common in food industries. Amorim et. al (2011) developed a hybrid genetic algorithm, for the lot-sizing and scheduling problem of a dairy industry considering perishability issues. Kopanos et. al (2010) studied a real-life yoghurt production process and proposed a novel mixed discrete/continuous time representation. The problem was mainly focused on the packaging stage, since it was identified as the production bottleneck. The main challenge in the efficient scheduling of food process industries is the integrated modelling of all production stages. Optimizing all processing stages increases the plant production capacity by reducing unnecessary idle times and reduces the production cost of final products.

2. Problem Statement

This work considers the scheduling of canned fish production in a real-life industrial facility. In particular, the production process of FRINSA, one of the largest canned fish industries in Europe is investigated using realistic process data. The plant can produce more than 400 final products and has a production capacity of 3-4 million cans per day. Several stages, mixed batch and continuous, are required for the production of each can (Fig.1). Initially, the fish stored in blocks is unfrozen and then filled in cans along with the ingredients (e.g. oil, tomatoes, etc.) required by the recipe. The next stage is the sterilization which guarantees the microbiological quality of the product. Finally, the sterilized cans are packaged (labelling, packing into cartons, boxes etc.) into the final products.

Figure 1: Canned fish production line layout

The plant is a multiproduct multistage facility combining both batch (unfreezing, sterilizing) and continuous (sealing and filling, packaging) processes with multiple parallel units. In general, the large production demand and high production flexibility (multiple units can process every single final product) increases significantly the complexity. The sterilization and packaging stages are the most intensive processes of the plant and they constitute the main production bottlenecks. The short-term scheduling horizon of interest is 5 days, whereas the sterilizers and packaging units are available 24 hours. Sequence-dependent changeovers and inventory limitations are considered. The salient characteristics of the scheduling problem is to take into account a large number of design and operating constraints while ensuring demand satisfaction. The overall production schedule is affected by rather conflicting goals such as the optimal use of resources, the minimization of makespan and the reduction of costs and optimal energy use.

3. MILP-based Solution Strategy

The key decisions to be made are related to: a) the required number of product batches to be scheduled, b) the allocation of batches to units in every stage, c) the relative sequence of product batches in each stage and d) the start and completion time of product batches in each stage. The proposed MILP-based solution strategy consists of: (i) a pre-optimization step, where the batching problem is solved, (ii) the MILP model which is used to optimize the schedule based on a specific objective and (iii) an order-

based decomposition technique, to split the initial problem into sets of tractable subproblems.

3.1. Pre-optimization step

In most food industries, such as the one studied in this work, the industrial practice imposes operations of the intermediate batch processes in their maximum capacity. The maximum utilization of the batch stage, allows for high production levels and minimization of changeovers between products. Hence the batching problem can be solved a priori. Constraints (1) define the minimum number of batches, β_p , to fully satisfy the demand based on the total demand, the capacity of sterilizers and storage limitations. Constraints (2) calculate the required time $t_{p,b}$ to process each batch in the packaging stage.

$$\beta_p^{\min} = \left(\frac{dem_p - s_p^{init} + s_p^{\min}}{BC_p} \right), \quad \forall p \tag{1}$$

$$t_{p,b}^{pack} = \frac{BC_p}{rate_p}, \quad \forall p, b \neq b_{last} \tag{2}$$

3.2. MILP model

The MILP model employed is based on an extension of a general precedence framework as developed in our previous work (Kopanos et. al, 2011). A brief description of the model follows due to the lack of space.

$$\sum_{j \in (J_p \cap J_s)} Y_{p,b,s,j} = 1, \quad \forall p, b \leq \beta_p^{\min}, s \tag{3}$$

$$L_{p,b,s} + t_p^{ster} = C_{p,b,s}, \quad \forall p, b \leq \beta_p^{\min}, s : s = 1 \tag{4}$$

$$L_{p,b,s} + t_{p,b}^{pack} = C_{p,b,s}, \quad \forall p, b \leq \beta_p^{\min}, s : s = 2 \tag{5}$$

$$L_{p,b,s} = C_{p,b,s-1}, \quad \forall p, b \leq \beta_p^{\min}, s : s = 2 \tag{6}$$

$$C_{p,b,s} = L_{p,b+1,s}, \quad \forall p, b \leq \beta_p^{\min}, s : s = 2 \tag{7}$$

$$L_{p',b',s} > C_{p,b,s} + ch_{p,p',j} - M * (1 - \bar{X}_{p,b,p',b'}) - M * (2 - Y_{p,b,s,j} - Y_{p',b',s,j}), \tag{8}$$

$$\forall p, b \leq \beta_p^{\min}, p', b' \leq \beta_{p'}^{\min}, s, j \in (J_p \cap J_{p'} \cap S_j) : p < p', s = 2$$

$$L_{p',b',s} > C_{p,b,s} + ch_{p,p',j} - M * (1 - X_{p,p'}) - M * (2 - Y_{p,b,s,j} - Y_{p',b',s,j}), \tag{9}$$

$$\forall p, b \leq \beta_p^{\min}, p', b' \leq \beta_{p'}^{\min}, s, j \in (J_p \cap J_{p'} \cap S_j) : p < p', s = 1$$

$$C_{max} > C_{p,b,s}, \quad \forall p, b, s : s = 2 \tag{10}$$

Constraints (3) ensure that each product batch p,b will go through one unit j in every stage s , utilizing the binary variable $Y_{p,b,s,j}$. The timing constraints (4) and (5) are imposed for a product batch in the same production stage. In particular, constraints (4) ensure that the completion time of a product batch in the sterilization stage $C_{p,b,s}$ is equal to the starting time of the process $L_{p,b,s}$ plus the required sterilization time t_p^{ster} for the specific product. Same holds for constraints (5), which express the connection between the start and finish of the packaging processes based on the required packing time for each product batch $t_{p,b}^{pack}$. Constraints (6) state that the packaging process of product batch starts exactly when the sterilization process is completed. A single production campaign policy is guaranteed by constraints (7). The sequencing constraints between product batches in both processing stages are portrayed in constraints (8) and (9). More specifically, constraints (8) enforce the starting time of a product batch p',b' to be greater than the completion time of a product batch p,b processed beforehand, plus the corresponding changeover time $ch_{p,p',j}$, when both batches are allocated to the same packing line. Similarly, constraints (9) define the sequencing of different products in the sterilization stage. Two general precedence binary variables are employed, $X_{p,p'}$, $\bar{X}_{p,b,p',b'}$, while M is a big-M parameter. The objective function of the model is expressed by constraints (10), which is the minimization of the total production makespan, C_{max} , hence it also considers the minimization of changeovers and unnecessary idle times.

3.3. Decomposition Strategy

The goal of the decomposition strategy is to split the initial problem into several tractable subproblems, which can be solved by the proposed MILP model in a reasonable time. In each subproblem a predefined number of products are scheduled. Basic parameters of the decomposition algorithm are the position of the last scheduled product z and the number of products scheduled at each iteration step.

Fig. 2. illustrates the flowchart of the solution strategy algorithm. Initially, the batching decisions are made in the preoptimization step. Afterwards, the decomposition algorithm parameters are defined and the subproblem is solved utilizing the aforementioned MILP model. Next, the derived decisions made for the specific subproblem are fixed and the algorithm continues to the next iteration. Finally, when all products are considered, the final schedule is generated.

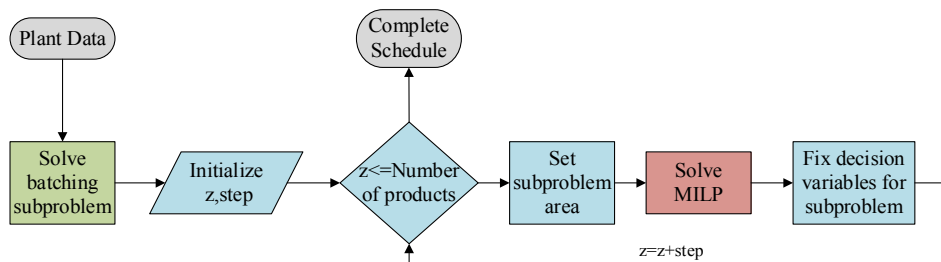

Figure 2: Solution strategy algorithm equivalent flowchart

4. Case study

An industrial case for the scheduling of 100 final products using realistic data from the FRINSA production plant is demonstrated. The preoptimization step calculates that 362 batches are required in total to satisfy the demand. Utilizing the proposed decomposition technique, 20 final products are scheduled in each iteration. The MILP model was implemented in GAMS 24.9 and solved using CPLEX 12.0. Optimality is reached for all iterations of the suggested solution strategy. Figure 3 illustrates the complete schedule generated for the sterilization units, while in figure 4 the corresponding schedule of the packaging units is depicted.

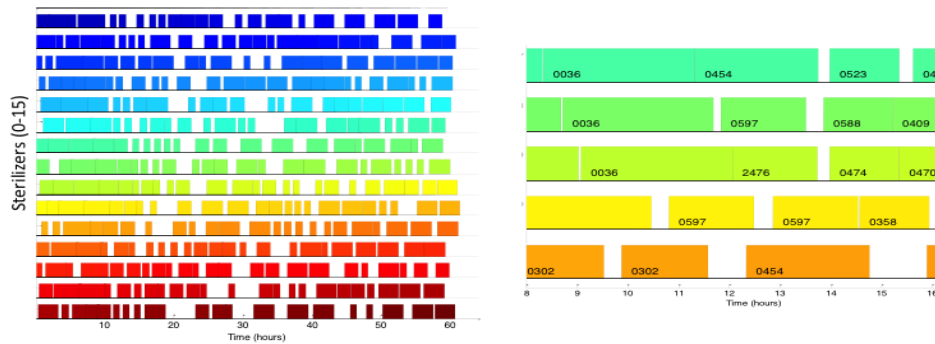

Figure 3: a) Gantt chart of the sterilization units, b) indicative schedule with product codes for the ST7-11 sterilization unit during 8hrs

Figure 4: Gantt chart of the packaging units

It is evident from the Gantt charts (Fig. 3) that the sterilizers are more active than the packaging units. On the other hand, the utilization in the packaging stage depends on the demand profile, since each product can be processed only at specific packaging units, whereas all products can be processed in any sterilizer. Nevertheless, all packaging units are underutilized compared to the sterilizers. Hence, the sterilization stage is identified as the production’s bottleneck in line with conclusions made by the plan operators. This is also illustrated at Fig. 5, where the utilization of all units is illustrated.

Figure 5: a) Utilization of sterilizers and b) packaging units

5. Conclusions

This work presents the production scheduling of a real-life industrial problem. More specifically, the sterilization and packaging stage of a canned fish production facility have been scheduled using recent advancements on mathematical programming-based scheduling. The aforementioned plant structure (a batch process followed by a packing stage) is typically met in many industries such as food and consumer packaged goods, hence, the applicability of the presented solution strategy can be implemented in other industrial problems. It was demonstrated, that the proposed MILP-based solution strategy can successfully solve a scheduling problem with significant degree of complexity in terms of number of products, shared resources, stages and multiple operational and quality constraints. The results illustrate that the sterilization stage is the main production bottleneck, an important conclusion for further investigation. As future steps, the integration of all production stages of the plant will be considered. Moreover, cost related objectives and the introduction of uncertainty in product orders will be considered in a rolling horizon scheduling framework.

Abstract

This work presents an extension of the Modifier-Adaptation (MA) methodology for Real-Time Optimization (RTO), to include the available information of uncontrolled input variables in the estimation of plant gradients. The idea is to extend the applicability of this method for processes where disturbances affect the quantities involved in the necessary conditions of optimality of the process. The implementation was carried out in a simulated flotation column, including the effect disturbances coming from of contiguous units. The dual approach was used to estimate the process gradients. Results show that the system is able to follow the trajectory of the real optimum of the process under continuously changing scenario, unlike traditional MA.

Keywords: Real-Time optimization, Modifier adaptation, Disturbances, Flotation column, Process optimization.

1. Introduction

The global competition drives to improve the performance of processes in the industry. The RTO is a powerful tool to increase the efficiency of a process. However, there is an inherent difficulty to reach optimal operating points, due to the available models represent partially the process phenomenology. Modifier Adaptation is a RTO methodology capable to find a point that satisfies the necessary conditions of optimality of an uncertain process using models with structural mismatch. To do so, MA uses available measurements to correct the model-based optimization with experimental gradients of the objective function J_m and constraints C_m . This methodology was defined by Chachuat et al. (2009) and afterward by Marchetti et al. (2009) Eq. (1) shows the modified optimization problem, which includes the modifier of the objective function λ_k , and the modifiers of the constraints γ_k and ε_k .

$$\begin{aligned} \min_{u \in U} J_m(u, \alpha) + \lambda_k(u - u_k) \\ \text{s.t. :} \\ C_m(u, \alpha) + \gamma_k^T(u - u_k) + \varepsilon_k \leq 0 \end{aligned} \quad (1)$$

$$\begin{aligned}
\lambda_k^T &:= \nabla_u J_p(u_k) - \nabla_u J_m(u_k, \alpha) \\
\gamma_k^T &:= \nabla_u C_p(u_k) - \nabla_u C_m(u_k, \alpha) \\
\varepsilon_k^T &:= C_p(u_k) - C_m(u_k, \alpha)
\end{aligned} \tag{2}$$

Where $u_k \in \mathfrak{R}^{n_u}$ represents the actual operating point, which is calculated at the previous RTO iteration, and subscripts m and p indicates if the quantity either has been calculated using the available model or estimated from the process, respectively. The modifiers $\lambda_k \in \mathfrak{R}^{n_u}$, $\gamma_k \in \mathfrak{R}^{n_c \times n_u}$ and $\varepsilon_k \in \mathfrak{R}^{n_c}$ are estimated using Eq. (2).

In the last few years, research has advanced focusing the efforts on improving the estimation of the modifiers, whether searching for a more reliable and robust gradient estimation (Bunin et al., 2012; Marchetti et al., 2010; Gao et al., 2016) or avoiding the gradient estimation step (Navia et al., 2015), among others.

Regarding MA applications, it has been performed with low numbers of input variables and with known noise characteristics. Also, in MA application it has been assumed that the rate of change of the disturbances is lower than settling time of the process (Darby et al., 2011), which implies that the performance of the algorithms has been evaluated assuming either constant uncontrolled variables, or disturbances with low frequency changes, such as step or ramp functions (Wenzel et al., 2015). However, in practice, it is expectable that disturbances may change with higher frequencies, which can affect the gradient estimation step using previous measurements. This fact motivates the study of methods to take into account the available information of disturbances in the estimation of process gradients.

In this work, it is presented a proposal to take into account the information of both decision variables (u) and disturbances (ξ), in order to obtain an accurate estimation of the gradient of the process with respect to u . With this in mind, the aim is to have an optimization layer capable of tracking and maintaining the optimal condition of the plant, in spite of changes in measured or estimated disturbances.

The paper is organized as follows. Section 2 describes the proposed method that includes the information of disturbances. Section 3 presents the application of proposed methodology in a simulated flotation column for copper concentration. Section 4 shows the results, and section 5 presents the conclusions.

2. Extended method for systems with disturbances

In this work, we propose the extension of the dual methodology for experimental gradient estimation, to take into account explicitly the available information of ξ , assuming that these variables can be measured or estimated. To compute the experimental gradients it is necessary to use the differences of the actual measurements with respect to the $n = n_u + n_\xi$ previous operating points, as Eq. (3) shows.

$$\bar{\mu}_k^j \approx \bar{S}_k \nabla_{\bar{u}} y_{p,k}^j, \quad j = 1, \dots, n_c + 1 \tag{3}$$

Where $\bar{u} := [u, \xi]^T$, $\bar{S}_k := [\Delta \bar{u}_{k,1}, \dots, \Delta \bar{u}_{k,n}]$ and $\bar{\mu}_k^j = [\Delta y_{p,k,1}^j \dots \Delta y_{p,k,n_u}^j]^T$, with $\Delta \bar{u}_{k,i} = \bar{u}_k - \bar{u}_{k-i}$. Under the assumption that \bar{S}_k is nonsingular, the gradient of process variable y_p^j , with respect to the input variables can be obtained from Eq. (4).

$$\nabla_{\bar{u}} y_{p,k}^j \approx (\bar{S}_k)^{-1} \bar{\psi}_k^j \tag{4}$$

To ensure identifiability, an additional constraint must be added to the modified optimization problem, as Eq. (5) shows. This restriction is analogous to the dual constraint presented in Marchetti et al. (2010).

$$\begin{aligned} \min_{u \in U} & J_m(u, \alpha) + \lambda_k^T (u - u_k) \\ \text{s.t. :} & \\ & C_m(u, \alpha) + \gamma_k^T (u - u_k) + \varepsilon_k \leq 0 \\ & |\Delta \bar{u}_{k+1,1}^T \tau_k| \geq \delta \end{aligned} \tag{5}$$

Where τ_k is the vector orthonormal to the subspace formed by $W_k = \langle \{\Delta \bar{u}_{k,1}, \dots, \Delta \bar{u}_{k,n-1}\} \rangle$, and δ is a value greater than zero. As the value of ξ_{k+1} is unknown when the RTO is solved, this must be estimated from available models using previous values. Once the system reaches the steady state, the dual constraint must be reevaluated with the measured or estimated value of ξ_k . Since matrix \bar{S}_k has an independent part, it is necessary to evaluate the cases of ξ when identifiability problems may arise. However, lineal dependency in disturbances is an improbable case, considering the expected stochastic nature of uncontrolled process variables.

3. Application to flotation column

The process simulated in this work is the flotation of copper sulphides, which represent the species with more abundance in Chile. Industrial flotation has three main interconnected zones: rougher, scavenger and cleaner, plus a regrinding stage (Fig. 1b). In particular, we are interested in the cleaning zone of the flotation circuit, where columns are used because of their capability to increase the concentration of the product.

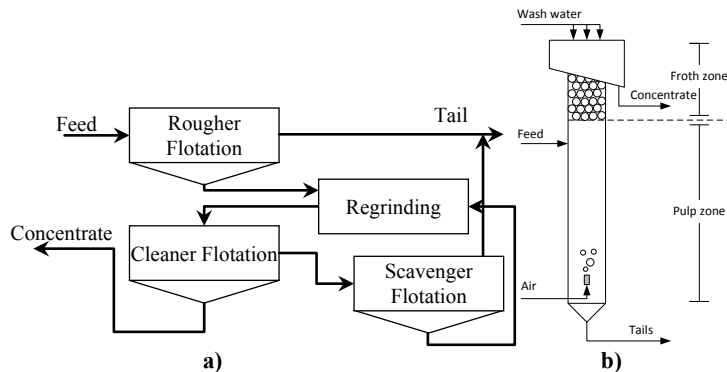

Figure 1. a) Diagram of flotation circuit. b) Diagram of flotation column.

Fig. 1b shows a diagram of a flotation column. This equipment has three inflows: feed pulp, air and wash water; and two outflows: concentrate and tail. Feed pulp with the valuable mineral comes from rougher cells and enters in the middle section of the column. Airflow is injected into the bottom to generate bubbles to collect the floatable particles. Wash water is introduced at the top of the column by countercurrent with

respect to air to decrease the concentration of gangue in the top outflow (concentrate). On the other hand, the tail flow leaves the column at the bottom. It is possible to distinguish two zones in the flotation column (Fig. 1b): collection and cleaning zone. In the collection zone, floatable particles from the feed pulp collide with air bubbles and they are transported to the top. In the cleaning zone, the froth is formed because of the addition of chemical reagents and wash water cleans the froth from gangue particles.

The decision variables of the process are the froth level (H_f), and air hold-up (ε_G). On the other hand, the input variables that are not controlled (ξ) correspond to the characteristics of the feed: concentration of copper, solid percentage and particle diameter.

The metallurgical model used in this work is a combination of phenomenological and empiric models of the flotation process, that represents a three-phase system with variable inputs conditions proposed by Finch & Dobby (1990), and the use of exponential functions to calculate the recovery in the zones of the column proposed by Yianatos et al. (1998, 2005).

Although flotation can be described as a pseudo-first-order reaction, the physical dependencies for recovery are still not fully understood (Savassi, 2005). Taking this into account, the uncertainty has been implemented as a modelling mismatch in the physicochemical description of the recovery of valuable mineral and gangue, as it was presented by Navia et al. (2016). This implies a structural uncertainty, since the influence of operational conditions in the kinetic constant has been neglected in the model, unlike the process, where they depend on internal flows.

The objective function J_m is the profit in the flotation column, where the effect of contiguous units are included, see Eq. (6).

$$J_m := C_E + C_L + C_R - I \quad (6)$$

In Eq. (6), C_E is the cost of the energy for pumping the slurry and compressing the air, C_L is the cost of the metallurgical losses in the scavenger stage (proportional to the copper that cannot be recuperated in the column stage), C_R is the cost associated to the regrinding process, and I represents the incomes of the process. The inequality constraints in the optimization problem are related to operational limitations and with the metallurgical result. Table 1 shows the values of upper and lower bounds for the constraints and for the decision variables.

Table 1. Upper and lower bounds of the optimization problem.

Bounds	J_G [cm/s]	J_w [cm/s]	J_B [cm/s]	R_{Cu} [%]	x_C [%]	H_f [cm]	ε_G [%]
Lower	1.0	0.04	0.0	55	22	40	8
Upper	2.0	0.4	0.28	100	34	120	15

Where J_i represents the superficial velocity inside the column, for $i = G, w, B$, where G means gas, w wash water and B is the Bias, defined as the difference between wash water and tails flow. Also, R_{Cu} is the copper recovery and x_C is the concentrate grade.

4. Results

In this section are shown the simulation results obtained in the flotation column system. In each graph, the optimum of the model (u_m^*) is the red dashed line, the optimum of the process (u_p^*) is the blue dash-dot line and the operating value of the variable (u_k) is the

solid black line. Additionally, the limits of the decision variables are the dashed grey lines (u^L, u^U), and the disturbances (ξ_k) are the solid black lines.

Figure 2. Inputs variables versus iterations number.

Figure 3. Decision variables in simulation a) without corrections and b) with correction in the estimation of process gradients.

For the simulation of the process, it is assumed that both decision variables and disturbances changes between each steady state. Fig.2 shows the changes of ξ during

the application of the optimization layer. These data were simulated using an ARIMA model, trained with real data.

The Fig. 3a shows the evolution of the decision variables without the correction in the estimation of the experimental gradient. It can be noted that even when the gradient was estimated using the traditional dual approach, and the value of the disturbances were updated in the model based optimization, the RTO couldn't detect the optimum of the process, which in fact changes because of the perturbations. On the other hand, Figure 3b shows the evolution of the decision variables correcting the gradient with the proposed extended dual approach. It can be seen that the adjustment of the gradient allows the RTO to converge and track the optimum of the process, in spite of changes in the disturbances. As the only difference between the results shown in Fig. 3a and Fig. 3b is the estimation of the gradient, it can be said that neglecting the effect of disturbances in the calculation of the process derivatives, can compromise the convergence properties of the MA methodology.

5. Conclusions

The results presented in this work show that the optimal operation of the system changes under time-varying input conditions. Therefore, if the gradient estimation step does not consider the disturbances, the system could not converge to the desired operational point. In other words, the use of the proposed extended gradient estimation method allows tracking the optimal operational conditions with continuously changing disturbances, assuming that they can be measured or estimated. In the studied process, this represents an increase in the profit of 3.5%.

Abstract

This contribution presents the proof of concept for a consensus-based approach for the design and assessment of control structures in chemical plants. The applicability of the proposed approach is demonstrated on an existing mini-plant. For this purpose, a reduced dynamic model that considers a simplified structure of the plant, consisting of feed preparation, reaction, and downstream processing, is used to assess the control structure of the mini-plant using the consensus algorithm. The reduced model is used to assess the control structure of the mini-plant reactor, considering the relevant operational and safety variables.

Keywords: consensus problem, cooperative control, optimal control, multi-agent networks

1. Introduction

Modern large-scale industrial plants are complex dynamical systems which consist of highly interconnected and interdependent elements. The control of such systems is usually achieved via hierarchical multi-layered structures, benefitting from their inherent properties such as modularity, scalability, adaptability, flexibility, and robustness (Stanković et al, 2008). However, with the rapid development of Industry 4.0, there are continuously new requirements for controllers to meet. In the control layer, the controllers should automatically adapt to the changed systems structures, process parameters, and production planning with high efficiency and good quality. Thus, highly flexible dynamic optimal control with high performance is required. To this end, the consensus problem has received extensive attention in the distributed coordination and cooperative control of dynamic agents (Ren & Beard, 2005; Hui, 2010; Zhao et al, 2011; Tan et al, 2015; Lee et al, 2017), but less or no attention in chemical process engineering. Many consensus approaches focus on networks of homogeneous agents, where the states have exactly the same dimensions (Qin et al, 2017), hence they are considered states of the consensus protocol as well. In chemical engineering applications, the states of the agents have different dimensions, as the process units will often have non-identical dynamics, which will make impossible to achieve an internal state agreement at this level. An agent represents an element of a system's network composed of (many) interacting sub-systems, connected via flow of energy, materials, information, etc. Each element may consist of a series of sub-systems in itself, and might or might not be controlled. In the following sections an approach for applying the consensus problem to assess the control structure of a chemical mini-plant

is presented. To reduce the computational effort of the proposed algorithm, a structure-retaining model reduction (Dorneanu, 2017) is applied to the full dynamic model.

2. Cooperative control problems

The key idea of cooperative control is that a team of agents (or dynamic systems) must be able to respond to unanticipated changes in the environment by agreeing to what change took place, and by asymptotically approaching a common value of a shared variable of interest. In networks of agents, a consensus algorithm (or protocol) is an interaction rule that specifies the information exchange between an agent and all of its neighbours on a network (Olfati-Saber et al, 2007).

Considering the process system, S , that includes a number of N units, described by the following model:

$$\begin{aligned} \frac{dx_i(t)}{dt} &= f_i(x_i(t), u_i(t)) \\ y_i(t) &= g_i(x_i(t), u_i(t), p_i) \end{aligned} \quad (1)$$

With the initial conditions:

$$x_i(t_0) = x_{i,0} \quad (2)$$

Where t is the time variables, $x_i(t) \in \mathfrak{R}^{n_i}$ is the state variables vector of unit i , $u_i(t) \in \mathfrak{R}^{m_i}$ is the input variables vector of unit i , $y_i(t) \in \mathfrak{R}^{p_i}$ is the output variables vector of unit i , n_i is the state space dimension of unit i , m_i is the dimension of the input vector of unit i , p_i is the dimension of the output vector of unit i , f_i is the function describing the dynamics of the unit i , while g_i is the function describing the way in which the observations are deduced from the state and the input.

A simple consensus algorithm to reach an agreement regarding the state of n_z agents can be expressed as (Olfati-Saber et al, 2007):

$$\frac{dz_i(t)}{dt} = \sum_{j \in N_{z,i}} (z_j(t) - z_i(t)) \quad (3)$$

Where $z_i \in \mathfrak{R}^{n_z}$ is the protocol state.

The consensus protocol defined by equation (3) is said to solve the consensus problem for the system (1) if the following condition holds:

$$\lim_{t \rightarrow \infty} \|z_j(t) - z_i(t)\| = 0 \quad \forall i, j = 1, \dots, n_z \quad (4)$$

The cooperative protocol is defined as shown in Figure 1: the dynamic controller i receives information from the process unit i , in the form of the difference of the steady state value of the output variable y_i^P , as well as information from the dynamic controller

of the neighboring agents j , in the form of the consensus variable v_i , and corrects the input u_i^P . For an agent i , the variable v_i is calculated as:

$$v_i = \sum_{j \in N_{z,i}} (z_j(t) - z_i(t)) \quad (5)$$

Figure 1. Block diagram of the cooperative control

The dynamics of the controller is defined as the linear model:

$$\begin{aligned} \frac{dz_i(t)}{dt} &= A_i^C z_i(t) + B_i^C u_i^C(t) + F_i^C v_i(t) \\ y_i^C(t) &= C_i^C z_i(t) + D_i^C u_i^C(t) + G_i^C v_i(t) \end{aligned} \quad (6)$$

Where A_i^C , B_i^C , C_i^C , D_i^C , F_i^C , G_i^C are matrices to be determined.

3. The mini-plant

3.1. Process description

The plant (Figure 2) produces sodium ion solution as sodium chloride (saline) solution for sale to fine chemical, pharmaceutical and food industry. The raw material is sodium chloride (NaCl) contaminated with calcium chloride (CaCl_2), which is pre-mixed with a stoichiometrically calculated amount of sodium bicarbonate (NaHCO_3). This feedstock is fed into a reactor vessel charged with pre-heated water and the reaction temperature is maintained at 65°C .

The following two reactions take place inside the reactor:

The suspension is then pumped by a positive displacement pump through a plate filter, which removes a high proportion of the CaCO_3 . The output stream splits into a product and a recycle line. The recycle is fed back to the reactor, while the product is passed through a polishing filter, to remove any remaining solids, and then to the lot tank. The CO_2 resulted in the first reaction is then adsorbed in an alkaline solution.

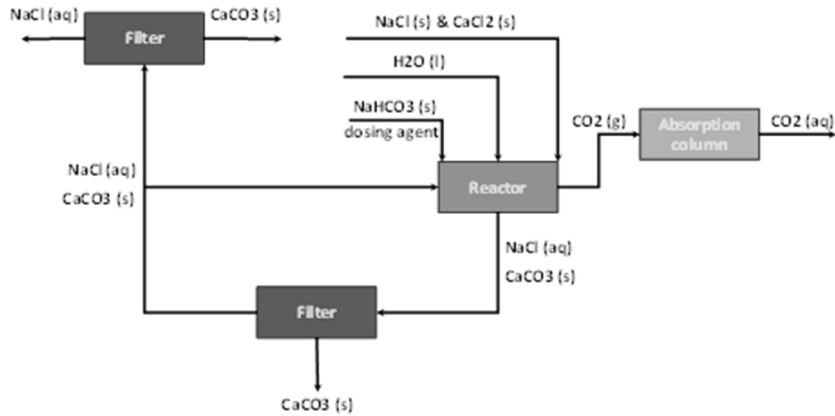

Figure 2. Simplified structure of the mini plant

3.2. Dynamic model

A dynamic model for the simplified process presented in Figure 2 is developed using Aspen Plus[®] Dynamics. The reactor is modelled using the RStoic model from the software library, assuming a conversion of 75% for each of the two reactions. The reactor dimensions are specified as follows: length, $L = 1$ m, and diameter, $D = 0.62$ m. A single stage flash separator is used for the CO_2 adsorption unit, with the dimensions specified as: $L = 0.8$ m, and $D = 0.1$ m. All the other units in the process flowsheet are assumed to be instantaneous. The dynamic model can be written in mathematical form as shown in equation (1).

3.3. Reduced model

To reduce the computational effort required by the proposed algorithm, the structure-retaining model reduction (Dorneanu, 2011) was applied to the full dynamic model: the model is decomposed into models of individual units by cutting streams of material, these models are linearized and a balanced model-order reduction is applied to obtain their reduced models.

Following the application of this approach, the dynamic model in equations (1) is approximated in state-space form as:

$$\frac{d\tilde{x}_i(t)}{dt} = \tilde{A}_i \tilde{x}_i(t) + \tilde{B}_i \tilde{u}_i(t) \quad (1')$$

$$\tilde{y}_i(t) = \tilde{C}_i \tilde{x}_i(t) + \tilde{D}_i \tilde{u}_i(t)$$

Figure 3. Response of the reactor level to disturbance on the flowrate of NaHCO_3

The linearization leads to a model with 9 states, which is reduced using Matlab[®] to a model with 6 states using model-order reduction via balanced realization. The reactor duty, the flowrates of the reactor's inlet feed streams (NaCl + CaCl₂, NaHCO₃ and the Recycle), and the mass fraction of their components are defined as input variables, while the reactor's pressure, temperature and level, as well as the reactor outlet stream and the mass fraction of its components are defined as the output variables for the linearization.

The agreement between the full dynamic model and the linear model, and between the linear model and the reduced model are presented in Figure 3. The graphs show the changes in the reactor level when a change is applied on the NaHCO₃ feed flowrate. The results are presented as variation from the steady state values.

3.4. Consensus-based control of the mini-plant

The condition defined by equation (4) implies the solution of an optimization problem defined as:

$$\text{Minimize} \quad \|v_i\| \quad (7)$$

$$\begin{aligned} \text{subject to} \quad & \frac{d \tilde{x}_i^P(t)}{dt} = \tilde{A}_i \tilde{x}_i^P(t) + \tilde{B}_i \tilde{u}_i^P(t) \\ & \tilde{y}_i^P(t) = \tilde{C}_i \tilde{x}_i^P(t) + \tilde{D}_i \tilde{u}_i^P(t) \\ & \tilde{y}_i^P(t) \geq 0 \\ & \frac{dz_i(t)}{dt} = A_i^C z_i(t) + B_i^C u_i^C(t) + F_i^C v_i(t) \\ & y_i^C(t) = C_i^C z_i(t) + D_i^C u_i^C(t) + G_i^C v_i(t) \end{aligned}$$

The optimization problem resulting from applying the consensus protocol for the reactor system defined in equation (1') is implemented in GAMS[®] (Tawarmalani & Sahinidis, 2005).

As the software cannot handle differential equations, the equations (1') and (6) are discretized for 100 time steps. The state-space models are discretized using the Matlab[®] c2d toolbox, using the zero-order hold method. Thus, equations (1') are rewritten as:

$$\tilde{x}_i^P[k+1] = \tilde{x}_i^P[k] + \tilde{A}_{i,d} \tilde{x}_i^P[k] + \tilde{B}_{i,d} \tilde{u}_i^P[k] \quad (1'')$$

$$\tilde{y}_i^P[k] = \tilde{C}_{i,d} \tilde{x}_i^P[k] + \tilde{D}_{i,d} \tilde{u}_i^P[k]$$

Where $\tilde{A}_{i,d}$, $\tilde{B}_{i,d}$, $\tilde{C}_{i,d}$, $\tilde{D}_{i,d}$ are the discretized forms of the state-space matrices.

Moreover, in order to make the optimization more computationally efficient, the $\|v_i\|$ is rewritten as:

$$\|v_i\| = \sqrt{(v_i)^2 + \varepsilon} \quad (8)$$

Where $\varepsilon \geq 0$

For applying the consensus approach, the inlet feed stream of NaHCO_3 is initially decreased by 5% (from its steady state value) between the times steps 20 and 40. All the other input variables are fixed at their steady state values. In the same time, between the time steps 30 and 50, it is assumed that the first filter unit in the process flowsheet is sending information in the form of the state variable of its controller, fixed at the value of $z_j(k) = 1e - 4$. The reactor level is bounded between 0.7 and 0.9 m. The reactor temperature and pressure are fixed at their steady state values, 65 °C and 1 bar, respectively.

4. Conclusions

An approach to apply the consensus algorithm for the design and control structures of chemical plants is presented. The approach is applied for the control of the reactor inside an existing mini-plant, while it receives information from the controller of only one other neighbouring unit in the form of a constant value of its state for a fixed amount of time. Moreover, a disturbance is applied on one of the reactor's inlet feed stream. The reactor level is kept between defined bounds.

Future work involves, in a first stage, the application of the algorithm when both units communicate in real time the state of their controller, followed by solving the consensus problem for all the units in the mini-plant flowsheet.

A multiparametric analysis of molecular complexities vs. economic data towards the continuous pharmaceutical manufacturing (CPM) of antibiotics

Mabel E. Ellerker, Samir Diab, Dimitrios I. Gerogiorgis*

School of Engineering (IMP), University of Edinburgh, Edinburgh, EH9 3FB, UK

D.Gerogiorgis@ed.ac.uk

Abstract

Continuous pharmaceutical manufacturing (CPM) has a documented potential to reduce production costs, offering opportunities to simultaneously streamline product development and improve economics for the pharmaceutical industry. Selecting technically feasible and economically viable candidate active pharmaceutical ingredients (APIs) for CPM is imperative for this transition to succeed. The present paper outlines a statistical correlation analysis of structural complexity and trade statistics for antibiotics, towards establishing economically viable CPM candidates. Bertz molecular complexity indices (CIs) are compared with molecular weights and price, sales and revenue data to identify the strength of correlation among variables. Sales data show that penicillins and quinolones are the most economically promising antibiotic families, composing 60% of total antibiotic revenues in the period 2009-2011. Spearman's rank correlation coefficients confirm strong monotonic relationships between antibiotic Bertz CIs and trade parameters. To the best of our knowledge, this is the first study highlighting promising antibiotics towards systematising CPM pursuits.

Keywords: Continuous Pharmaceutical Manufacturing (CPM), statistics, antibiotics.

1. Introduction

The pharmaceutical industry faces increasing financial pressure due to globalised competition and rapidly increasing R&D expenditure: these pressing challenges can be alleviated by a judicious shift from the currently prevalent batch production to Continuous Pharmaceutical Manufacturing (CPM) (Anderson, 2012). Economic analyses are required for systematic evaluation to identify economically viable compounds for CPM. Antibacterial drugs, also known as antibiotics, have revolutionized modern medicine, and are an essential part of human life; however, their production is often expensive due to the elaborate processes required to obtain their complex molecular structures. Previous work has established that antibiotics have a particularly high economic potential for CPM, based on recent UK trade data for a vast dataset of currently marketed and regulated antibiotics (Nagy et al., 2016). While it is essential to ensure a robust continuous flow synthetic route is established for a candidate API prior to CPM implementation (Plutschack et al., 2017), identifying the economic viability of a new production paradigm for an API is equally important.

Statistical analysis of economic trade data for antibiotics can highlight promising candidates for CPM implementation, if a continuous route is established and scalable.

Molecular complexity indices (CIs) are important tools for predicting toxicological and physicochemical properties of chemical structures in drug design and pharmaceutical development (Li and Eastgate, 2015). This paper conducts statistical analyses between structural metrics and pharmaceutical trade data, to identify correlations between CIs and demand of various antibiotics, potentially highlighting promising API candidates for CPM implementation. We emphasise that such a statistical correlation analysis can be a very useful (not the sole) criterion for CPM opportunity identification, and must be used in tandem with pharmacokinetic, pharmacodynamic (PKPD) and clinical evidence.

2. Methodology and Analysis

2.1 Economic Data

Acquiring recent economic trade data is essential for conducting an accurate economic analysis of candidate antibiotics for CPM implementation. Sales and price data for the period 2009-2011 for 37 antibiotics from lists of the best performing antibiotics by sales (Vitaku, 2010; FDA, 2010; FDA, 2012) and those on the World Health Organisation (WHO) essential medicine lists (WHO, 2017) have been compiled. These antibiotics represent societally important products with high economic potential: the most recent economic data have been used, to ensure relevance to pharmaceutical industry trends.

2.2 Molecular Complexity

In this work, we quantify complexity via the Bertz CI, which is a weighted sum of numbers of different groups on organic molecules, including rings, non-aromatic unsaturated C-atoms, heteroatoms and chiral centres (Bertz, 1981). Bertz CI values for the full list of antibiotics considered are available in the literature (PubChem, 2017).

2.3 Statistical Correlations

A wide range of statistical correlation coefficients exist to determine the strength of different types of correlation between two sets of data. Spearman's rank correlation coefficients (r_s , Eq. 1) have been calculated to determine the strength of a monotonic relationship between two data sets. Here, d is the difference in rank of members of each dataset and n is the length of the dataset. The strength of correlation is quantified by the magnitude of the coefficient: $r_s = 0.6-0.8$ indicates a "strong" correlation and $r_s > 0.80$ shows a "very strong" indication of a monotonic relationship between two data sets.

$$r_s = 1 - \frac{6 \sum d^2}{n(n^2 - 1)} \quad (1)$$

3. Results and Discussion

3.1 Economic Data vs. Antibiotic Complexity Indices and Families

Fig. 1 shows Bertz CIs for the full set of antibiotics considered here; antibiotics are arranged in order of ascending MW. Bertz CI values generally increase with MW, reflecting the increasing number bond connections and variety of functional groups present in larger molecules. Economic data were compiled and compared for this set of antibiotics to establish promising antibiotics with high potential for CPM application.

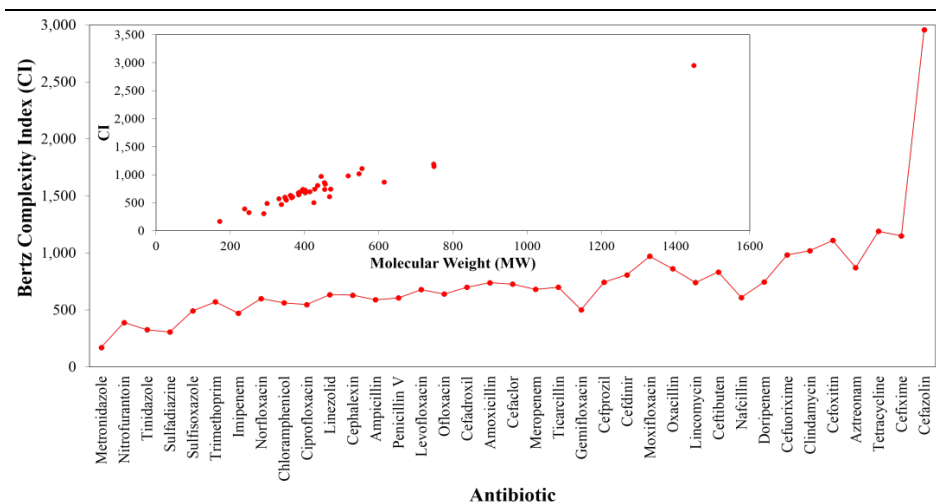

Figure 1: Bertz complexity index (CI) as a function of antibiotic molecular weight.

Fig. 2 shows compiled sales and price data for the total list of antibiotics. Antibiotics are arranged in order of ascending average sales (by mass) over the period of 2009-2011. From the set of antibiotics considered, amoxicillin has significantly higher sales over other antibiotics. Amoxicillin is a broad-spectrum antibiotic with various applications, and thus its wide utility makes it particularly important in modern society (Kaur et al., 2011). Cephalexin, ciprofloxacin, piperacillin and penicillin V are the subsequent best-performing antibiotics in terms of sales. Comparison of the economic performance of different antibiotic families can give an indication of antibiotics with CPM potential. Prices for different antibiotics vary significantly, thus annual revenues from different antibiotics allow an alternative economic comparison of promising antibiotic families.

Figure 2: Average antibiotic annual sales (2009-2011) and unit prices (mass bases).

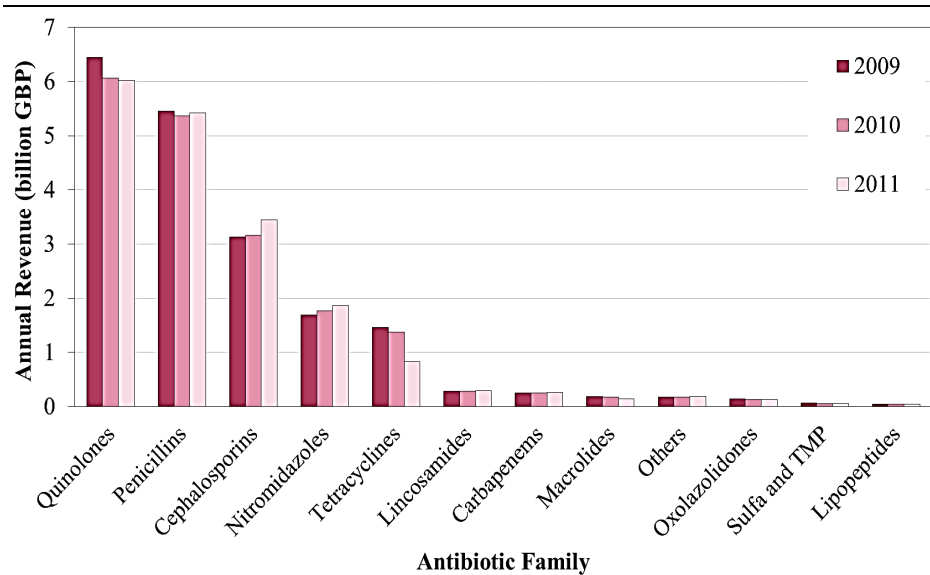

Figure 3: Annual revenues of different antibiotic families (2009-2011).

Fig. 3 compares annual revenues of the highest performing antibiotic families over the years for which sales and price data are available (2009-2011). Quinolones and penicillins dominate the pharmaceutical industry for antibiotics, contributing 60% of the total antibiotic revenue and are thus of high commercial importance. Fluctuation is recognised in all families of antibiotics present, but most notably for quinolones (a reduction of 0.38 billion GBP is clear in 2009-2010). Nevertheless, these families of antibiotics are consistently high performers, presenting strong economic incentives.

Figure 4: Bertz complexity index (CI) for the top 10 antibiotics by annual sales.

Over the period 2009-2011, revenues for quinolones, tetracyclines and macrolides decrease annually, while revenues for cephalosporins and nitromidazoles increase. Despite these changes, the overall market revenue remains relatively consistent between 2009-2011 (average = $\pm 3\%$), indicating a consistently high market for antibiotics. Economic stability of revenues is a key factor in new product R&D (Teoh et al., 2015), as is ensuring a technically feasible continuous flow synthesis (CPM) route for the API.

Fig. 4 shows sales volumes (bubble radius) of the top 10 antibiotics by sales and their Bertz CIs over the period 2009-2011. Amoxicillin and cephalexin contribute the highest sales volumes and thus strong market opportunities for UK production are evident. Amoxicillin, piperacillin and penicillin V belong to the penicillin family and ciprofloxacin and levofloxacin belong to the quinolone family, those that dominate the pharmaceutical industry (Fig. 3). Size variation for bubbles of each antibiotic is minimal over the period considered (2009-2011), indicating little variation in sales volumes; thus, each antibiotic listed is a consistently high marketing drug. All antibiotics shown in Fig. 4 are strong performers based on structure-trade correlation, thus potentially promising CPM implementation candidates, if continuous synthesis routes are available.

3.2 Statistical Correlation of Complexity Index with Economic Data

Spearman's rank correlation coefficients between different datasets are shown in Table 1. A "very strong" correlation ($r_s > 0.8$) exists between Bertz CI and MW due to the increasing size and complexity of molecules with increasing number and diversity of functional groups and bond types present as MW increases. as expected from the results presented in Fig. 1. "Strong" correlations ($0.6 < r_s < 0.8$) exist between sales and price data and molecular complexity. Fig. 5 shows average antibiotic sales (2009-2011) and prices versus Bertz CIs associated with the correlation Spearman's rank coefficients presented in Table 1. The strength of correlation between economic data and molecular complexity is directly related to the high performance of the antibiotics considered in the data set; correlations are made between the most recent economic data available.

Table 1: Spearman's rank correlation coefficient between paired data sets.

	$\log_{10}(\text{Bertz CI})$	$\log_{10}(\text{Average Sales, 2009-2011})$	$\log_{10}(\text{Price})$
MW	0.976	0.621	0.687
Bertz CI	n/a	0.634	0.718

3.3 Discussion

The present work has established penicillins and quinolones as economically promising candidates for CPM, based on previous work highlighting antibiotics as a promising class of APIs for CPM implementation (Nagy et al., 2016). Statistical analyses indicate strong monotonic relationships between Bertz CIs and economic data for the set of antibiotics considered here, which can be further validated with a wider data set where available. Addressing technical challenges in switching from batch to continuous manufacturing routes for candidate APIs is equally important to highlighting economic potential of antibiotics (Bana et al., 2017); these efforts must be conducted in tandem to establish the strongest candidate APIs for CPM implementation (Teoh et al., 2015) to facilitate the rapid transition of manufacturing paradigm in the pharmaceutical industry.

Figure 5: Antibiotic average sales (2009-2011) and prices vs. Bertz complexity index.

4. Conclusions

The statistical analysis of economic data indicates that penicillins and quinolones dominate the antibiotic market in terms of annual sales volumes and revenue, emerging as the most promising candidates for CPM. Amoxicillin contributes the most significant portion of total revenue (2009-2011) for the antibiotics considered here, followed by cephalexin and ciprofloxacin. Bertz CIs of a wide variety of antibiotics have been compiled and analysed vs. relevant economic data. Statistical analysis highlights a strong correlation between molecular complexity (MW, Bertz CI) with sales and price. The need for systematic evaluation of more trade data over a longer horizon is clear, as is the high incentive for selecting penicillins and quinolones as viable CPM candidates.

Abstract

Multi-objective optimization (MOO) has emerged as the preferable approach to tackle sustainability problems. The solution of MOO models is generally expressed as a set of Pareto optima, representing optimal trade-offs between given criteria. Identifying the final Pareto solution from this set for practical implementation is a challenging task, particularly when several criteria and decision-makers are involved in the analysis. In this work, we propose the rigorous method based on bilevel optimization and MOO to support decision-making in the post-optimal analysis of Pareto fronts. Our approach is capable of selecting non-dominated solutions which are particularly appealing for decision-makers, quantifying the distance between any suboptimal point of a MOO model and its Pareto front, and establishing improvement targets for suboptimal solutions that if attained would make them optimal. Overall, our method allows analyzing Pareto fronts and identifying a final Pareto point to be implemented in practice without the need to define explicit weights. We illustrate the capabilities of our approach through its application to the optimization of the UK electricity mix according to several sustainability indicators.

Keywords: Multi-objective optimization, Bilevel optimization, Sustainable development, Sustainability targets, Electricity generation

1. Introduction

Developing more sustainable systems requires the simultaneous consideration of a wide range of economic, environmental and social indicators. However, this task is quite challenging since inherent trade-offs between these criteria naturally arise.

Multi-objective optimization (MOO) has emerged as one of the most common techniques employed in sustainability problems. One major advantage of MOO is that it requires no articulation of decision makers' preferences via subjective weights. The typical outcome of MOO models, as applied to sustainability problems, is given by a Pareto front representing optimal trade-offs between economic, environmental and social criteria. The key characteristic of this frontier is non-inferiority, which means that by moving along its trajectory no objective can be improved without deteriorating at least another one. Unfortunately, these Pareto fronts are seldom analyzed in detail, leaving the task of selecting a final Pareto solution to be implemented in practice to decision-makers.

In this work, the task of exploring the Pareto frontier and selecting a final solution is posed as a bilevel programming problem. Hence, we combine multi-objective optimization and bilevel programming to facilitate the post-optimal analysis of Pareto fronts and avoid the need to define subjective weights in an explicit manner.

The paper starts by presenting mathematical background and proposed method in Section 2. A real-world case study of the UK electricity mix is illustrated in Section 3, followed by the results in Section 4. Finally, the conclusions are drawn at the end of the paper.

2. Methodology

In this section, we first introduce the mathematical background and address problem statement, followed by proposing mathematical approach to tackle this task.

2.1. Mathematical background and problem statement

Consider the following multi-objective problem (M.1):

$$\begin{aligned} \min_x \quad & \{f_1(x), \dots, f_k(x)\} \\ \text{s.t.} \quad & g(x) \leq 0 \\ & h(x) = 0 \end{aligned} \tag{M.1}$$

Where x denotes decision variables, $f_1(x)$ to $f_k(x)$ represent economic, environmental and social concerns, and $g(x)$ and $h(x)$ are the inequality and equality constraints given by the system under study. Consider the multi-dimensional function $f: R^n \rightarrow R^m$ and let X be the set of feasible solutions in the space R^n , and Y the feasible set of objectives values in R^m such that $Y = \{y \in R^m : y = f(x), x \in X\}$. Let $P(Y)$ defined as the Pareto frontier of the model, then the goal of the analysis sought is to find a point y^* in $P(Y)$ and its corresponding vector of decisions variables values x^* in X that optimizes a function $F(x, y)$ of x and y . That is, we aim to identify the values x^*, y^* such that $y^* = f(x^*)$, and at the same time $(x^*, y^*) = \arg \min F(x, y)$.

2.2. Proposed mathematical approach

2.2.1. Identifying specific points in the Pareto front using bilevel optimization:

Our approach to find Pareto points that minimize a given function $F(x, y)$ relies on formulating and solving a bilevel optimization problem. Bilevel programming problems consist of two nested optimization problems where the outer one is constrained by the optimal solution of the inner one. Here, the inner problem representing MOO guarantees the solution found is Pareto optimal, while the outer one minimizes a distance metric calculated considering a given suboptimal solution whose performance needs to be improved. Note that function $F(x, y)$ can accommodate any different distance metrics and alternative objective functions that reflect decision makers' preferences.

We next apply the ε -constraint method to the MOO problem, where $f_1(x)$ is kept as a main objective to be minimized subject to the others being less than or equal to the epsilon value. Hence, this task can be formulated as a bilevel optimization problem as follows:

$$\begin{aligned} \min_{\varepsilon_i} \quad & F(x, y_1(x), \dots, y_m(x)) \\ \text{s.t.} \quad & \min_x y_1(x) \\ & g(x) \leq 0 \\ & h(x) = 0 \\ & y_i(x) \leq \varepsilon_i \quad \forall i, i \neq 1 \end{aligned} \tag{M.2}$$

That is, the outer problem seeks the epsilon value ε_i^* that lead to an associated Pareto solution x^* calculated by the inner one. Note that it is possible to solve the bilevel problem by replacing the inner problem with its KKT conditions if the problem is LPs and convex NLPs. However, solving bilevel MILPs, MINLPs and nonconvex NLPs is more challenging, since this approach does not ensure convergence to the global

optimum. Some algorithms (Bard and Moore, 1990; Colson et al., 2007) have been put forward to solve the latter problems efficiently but the area is still under development.

2.2.2. Simplifying the post-optimal analysis and establishing improvement targets:

Furthermore, we can define improvement targets for any suboptimal solution based on the performance of point x^* . More precisely, let x^{sub} be a suboptimal solution of model M.2 and $\%imp_i$ denotes the percentage improvement in objective i that solution x^{sub} needs to accomplish to become optimal. We can define improvement targets for this solution as percentage difference between its performance and the performance of point x^* as follow: $\%imp_i = (y_i(x^*) - y_i(x^{sub})) / y_i(x^{sub}) \times 100\%$.

3. Case study: Application to the redesign of the UK electricity mix

We illustrate the capabilities of our approach through a case study addressing the improvements of the current UK electricity mix. Generally, the business as usual solutions are suboptimal and need to be improved to become efficient. Hence, the goal of the analysis is to identify a Pareto point representing an efficient electricity mix such that its distance with respect to the current mix is minimal.

3.1. Data sources and assumptions

The data used in this study was retrieved from the work by Stamford and Azapagic (2014). We selected six specific electricity generation technologies which are expected to play a vital role in the UK mix. For simplicity, we selected total levelized cost as economic indicator and global warming potential (gwp) as environmental indicator.

3.2. Mathematical formulation

Here, we aim to minimize all indicators subject to bounds on the electricity generation of each technology and a constraint for demand satisfaction. The ε -constraint method and KKT condition were applied to the MOO problem. The economic objective is kept as main objective while the environmental objective is treated as auxiliary ε -constraint. The general model which can be applied with multi-criteria case is given below.

$$\min_{\varepsilon_i} \sum_{j \in J} ((GEN_j^{p*} - GEN_j^{bau}) / GEN_j^{bau})^2 \quad (M.3a)$$

$$s.t. \quad \underline{\varepsilon}_i \leq \varepsilon_i \leq \overline{\varepsilon}_i \quad \forall i, i \neq cost \quad (M.3b)$$

$$x_{cost,j} - \mu_j^{\leq} + \mu_j^{\geq} + \lambda + \sum_{i, i \neq cost} (x_{i,j} \times \mu_i^{\leq}) = 0 \quad \forall j \quad (M.3c)$$

$$\sum_{j \in J} GEN_j = dem \quad (M.3d)$$

$$\underline{GEN}_j + s_j^{\leq} = GEN_j \quad \forall j \quad (M.3e)$$

$$\overline{GEN}_j + s_j^{\geq} = \overline{GEN}_j \quad \forall j \quad (M.3f)$$

$$\sum_{j \in J} (x_{i,j} \times GEN_j) + s_i^{\leq} = \varepsilon_i \quad \forall i, i \neq cost \quad (M.3g)$$

$$\mu_j^{\leq} - UY_j^{\leq} \leq 0 \quad \forall j \quad (M.3h)$$

$$s_j^{\leq} - U(1 - Y_j^{\leq}) \leq 0 \quad \forall j \quad (M.3i)$$

$$\mu_j^{\geq} - UY_j^{\geq} \leq 0 \quad \forall j \quad (M.3j)$$

$$s_j^{\geq} - U(1 - Y_j^{\geq}) \leq 0 \quad \forall j \quad (M.3k)$$

$$\mu_i^{\leq} - UY_i^{\leq} \leq 0 \quad \forall i, i \neq cost \quad (M.3l)$$

$$s_i^{\leq} - U(1 - Y_i^{\leq}) \leq 0 \quad \forall i, i \neq cost \quad (M.3m)$$

$$\mu_j^{\leq}, \mu_j^{\geq}, \mu_{i, i \neq cost}^{\leq}, s_j^{\leq}, s_j^{\geq}, s_{i, i \neq cost}^{\leq}, GEN_j \geq 0; Y_j^{\leq}, Y_j^{\geq}, Y_{i, i \neq cost}^{\leq} \in \{0, 1\}$$

Where the associated notation is given below:

Indexes/sets	J	Set of electricity generation technologies indexed by j
	I	Set of objectives indexed by i
Variables	GEN_j	Electricity generation of technology j , GWh/year
	ε_i	The value of objective i
Parameters	\overline{GEN}_j	Upper bound on the generation of technology j , GWh/year
	\underline{GEN}_j	Lower bound on the generation of technology j , GWh/year
	GEN_j^{bau}	The business as usual generation of technology j , GWh/year
	$x_{cost,j}$	Cost per GWh of technology j , £/GWh
	$x_{i,j}$	Attribute value of objective i where $i \neq cost$
	dem	Total UK electricity demand, GWh/year
	λ	Multiplier for the electricity demand equality constraint
	$\mu_j^{\leq}, \mu_j^{\geq}, \mu_{i,i \neq cost}^{\leq}$	Multiplier variable for the upper, lower bound, ε -constraint
	$s_j^{\leq}, s_j^{\geq}, s_{i,i \neq cost}^{\leq}$	Slack variable for the upper, lower bound, ε -constraint
	$Y_j^{\leq}, Y_j^{\geq}, Y_{i,i \neq cost}^{\leq}$	Binary variable for the epsilon inequality constraint
	U	Large parameter, assumed equal to 10^6

The outer problem of the model defines the distance with respect to the original mix. This objective function reflects the following decision-making strategy: to improve the sustainability performance of the UK electricity mix so as to achieve the Pareto optimality subject to minimum changes in the generation of each technology. Note that this model allows the decision-makers to focus on a specific suboptimal point, for example, the current electricity mix in this study. Hence, the solution to the model would represent the best Pareto optimal point to which the given suboptimal point could approach with least effort to change from its original state. The choices of a given suboptimal point could, therefore, possibly lead to different points in the Pareto set. Moreover, this model can also accommodate the different distance metrics by just simply modify the objective function of the outer problem in M.3a. For instance, we want to minimize the distance, however, this time in terms of objective space rather than the generation space. Where $x_{i,total}$ is defined as the total value of objective i , $\forall i \in I$, we can replace M.3a with the following equation: $\min_{\varepsilon_i} \sum_{i \in I} ((x_{i,total} - \sum_{j \in J} (x_{i,j} \times GEN_j)) / x_{i,total})^2$.

4. Results and discussion

4.1. Bi-criteria case

4.1.1. Pareto front analysis

In this case study, we consider two objectives to be minimized i.e. cost and gwp. The Pareto frontier shows three major different sections as shown in Figure1. In section A, at low level of cost, significant improvements of up to 35% reductions in gwp can be achieved at a marginal increase (1%) in cost. Figure2 shows the corresponding mix of technologies of the Pareto points presented in Figure1. For the entire section A, gas – as the cheapest alternative – is at its upper bound to ensure minimum cost. Moving away from the minimum cost point where the gwp objective gains more importance, the model decides to reduce coal (the greatest gwp contributor) until reach its lower bound in which 14% decrease in its generation could substantially trim down gwp. In section B, gas is

Figure1. Pareto frontier for bi-criteria case

Figure2. Breakdown of technologies for bi-criteria case

replaced by nuclear to reduce further the gwp. Nuclear generation continuously increases until reaches its upper bound at the beginning of section C. From this point forward, coal stays at its lower bound and gas gradually decreases to its lower bound to minimize gwp. This is compensated by an increase in the generation of wind. Note that the results shown above may vary if the lower and upper bounds on the technologies are changed.

4.1.2. Analysis of projections and its improvement targets

We next solve model M.3 to identify the point in the Pareto set with respect to two projecting objective functions as mentioned in section 3.2. The bilevel model was solved by reformulating the inner problem using the KKT conditions, thereby leading to a convex MINLP. The mathematical model was implemented in GAMS 24.7.1 and solved with CPLEX 12.6.3.0 on an Intel® Core™ i7-3770 processor operating at 3.40 GHz. It took around 0.171 CPUs to achieve global optimality. The BAU solution has a total cost of £28.67bn and a gwp of 183.97 Mt. The first projection point with minimum changes in the generation has a cost of £26.60bn and a gwp of 171.65 Mt. To achieve this point, the current UK mix needs to reduce its cost and gwp by 7.20% and 6.70%, respectively. This could be done by increasing further the generation from gas and reducing the generation of nuclear, wind and biomass2 until they reach their lower bound as shown in Figure2. The second projection point with minimum changes in objective values corresponds to the minimum cost point, implying a 7.22% decrease in cost and 5.28% decrease in gwp. These targets are similar to the previous ones including their corresponding electricity portfolio as shown in Figure2. However, comparing between the two projected points, the first shows a lower reduction in cost (7.20% vs 7.22%), but leads to a significantly larger reduction in gwp (6.70% vs 5.28%).

4.2. Multi-criteria case

Incorporating more objectives could lead to a more realistic representation of the problem but add complexity to the bilevel model. In this case, we additionally incorporate working injuries (wi) into the problem as social indicator. We generated 1000 points of the Pareto set following a similar approach as before, but this time sampling the epsilon values from a uniform distribution with given lower and upper bounds. The Pareto solutions are depicted in Figure3. We next solved the model M.3 with another objective of wi to be minimized. It was implemented in GAMS and solved with CPLEX 12.6.3.0 which took around 0.094 CPUs to solve each instance of the problem. The Pareto solution that is closest in generation values to the BAU alternative has a cost of £28.27bn, emissions of 134.86 Mt, and injuries of 427.71 people/year. Taken the BAU solution as starting point, this solution entails reduction targets of 1.38% in cost, 26.69% in gwp, and 38.14% in wi. Compared to the bi-criteria case, the projected point shows larger cost but better value of

Figure3. Pareto frontier for 3Obj case

Figure4. Breakdown of technologies for 3Obj case

gwp. These targets could be achieved by reducing coal (the greatest gwp and wi contributor) to its lower bound and increasing gas and nuclear as shown in Figure4. The second projection point with minimum changes in objective values yields the same targets as bi-criteria case, which corresponds to £26.60bn in cost, 174.25 Mt of gwp and 495 people/year of wi, leading to reductions of 7.22%, 5.28% and 28.43% in these objectives, respectively. Comparing between the two projected solutions, the first shows a much lower reduction in cost, but brings about a significantly larger reduction in gwp and wi.

5. Conclusions

Multi-objective optimization (MOO) has been perceived as a common tool to address sustainability problems. The solution of MOO models is given by a Pareto front that requires decision-makers to identify the final solution to be implemented. In this study, we proposed a systematic approach based on bilevel programming and MOO to facilitate the analysis of Pareto front and establish optimal targets for suboptimal alternatives. We have implemented our approach to optimize the UK electricity mix according to some sustainability criteria, where a bi-criteria and multi-criteria cases were explored with two different projecting functions. The analysis of the Pareto frontier reveals that there are clear inherent trade-offs between the given criteria, which are strongly connected to the performance of each technology. The example of two projecting objective functions, i.e. minimum changes in generation and minimum changes in objective values, gives two different projected targets. This means that the model offers the flexibility to adopt any distance metric that particularly reflects decision makers' preferences. Overall, our bilevel-MOO-based approach allows analyzing Pareto fronts and selecting a final Pareto point to be implemented in practice without the need to define subjective weights. Our goal is to guide policy-makers and engineers in the transition towards a more sustainable society by supporting multi-criteria decision-making in sustainability problems.

^a*Department of Chemical and Biomolecular Engineering, Yonsei University, 50 Yonsei-ro, Seodamun-gu, Seoul 03722, Republic of Korea*

ilmoon@yonsei.ac.kr

Abstract

Hydrogen has been widely recognized as an energy source to replace fossil fuel due to its environmental friendly element and renewable properties. However, it also has disadvantages such as a wide range of flammability (4~75%), low minimum ignition energy (0.2mJ), etc. So, there have been studies to prevent explosions by creating ventilation systems which focus on effectively releasing leaked hydrogen gas. Despite hours of ventilation, several experimental results show the concentration still being maintained higher than 4%. Therefore, it is necessary to consider the countermeasures to minimize damage when explosion actually occurs due to the incomplete effect of ventilation. In this study, the FLACS Computational Fluid Dynamics(CFD) program was used to verify the reduced damage when the Explosion Venting Panel(EVP), which discharges overpressure and unburned gas, is applied in comparison to the enclosed hydrogen facilities that can give the biggest damage. The model was designed based on the test bed created with the same specifications as the low-pressure hydrogen facilities built in Ulsan, Korea. Until now, existing EVP studies attempted to prove how well their models fit with the actual experiments. However, those studies did not show the level of damage caused by overpressure. So, this study aims to provide a concrete numerical value of the damage caused by the explosion and to express damaging levels this value can cause. First, the size, number, and location of the EVP are selected to find the optimal placement. Second, scenarios are chosen according to the Korea Occupational Safety and Health Agency(KOSHA) guide. They are then, simulated based on the first criterion. Lastly, the installation distance of the blast wall is suggested in consideration of the damage to the surrounding facilities. As a result, with the frequently occurring accident case, the measured overpressure in the EVP applied case was 35% lower than that of the enclosed hydrogen facilities. In addition, the pressure measured less than 0.069 barg, a safely considered measure in all methods applied in the first criterion, proving the installation of the EVP as an effective solution. However, in the worst case, even with the installation of the EVP, the overpressure over the 0.069 barg was measured up to a 5m radius to the low-pressure hydrogen facilities. Therefore, it was confirmed that installation of blast wall was necessary as a mitigation plan. In conclusion, with the occurrence of hydrogen explosion, EVP applied resulted in lower overpressure than that of the enclosed hydrogen facilities. This study provides concrete numerical values for both the overpressure and the damage distance caused by the explosion. It also suggests an alternative to minimizing the damage, which is expected to be important reference when applying EVP and building a blast wall in various hydrogen related facilities.

Keywords: CFD, Explosion venting panel, Explosion, Blast wall

1. Introduction

Hydrogen is a clean energy and a new approach to answering the environmental pollution from the consumption of fossil fuel, but hydrogen working systems have potential safety problems (Yong Cao et al. 2017). Hydrogen has large laminar burning velocity (up to 3.50 m/s in NTP air) and wide flammability (4~75%). These properties may lead to hydrogen explosions which will give severe damages (D. Makarov et al. 2009). Therefore, it is important to take measures against the possibility of an explosion. Explosion venting panel(EVP) is the cheapest and most practical explosion mitigation method for the enclosure by discharging the overpressure of burned and unburned gas (Jingde Li et al. 2017). Many studies have been extensively conducted to figure out mechanism and phenomena of explosion. Qi bao et al. (2006) performed lots of experiments to investigate the generation mechanisms of the dominant overpressure transients. C. Regis Bauwens et al. (2009) suggested a simple model that agrees with experimental data based on the ignition location, obstacles, and vent size. E. Vyazmina (2016) approached numerically using CFD programs to validate experiments related to the explosion when EVP applied. Through those researches, EVP design standards like EN-14994 (2007), NFPA-68 (2013) were established and adopted (Jingde Li et al. 2017). However, studies have been focused on the validation process between their model and experiment data. Therefore, not many studies on the effect of EVP compared to the enclosed hydrogen facilities have been carried out.

In this work, explosion simulations are performed to find the optimal EVP systems according to the selected scenarios while changing the ignition position, EVP area, and size. In addition, based on the result of the scenario, the blast wall installation is additionally proposed as a mitigation plan to minimize damages to the internal facilities as well as the surrounding area.

2. CFD simulation and scenario decision

2.1. Modelling

A hydrogen town which uses low-pressure (below 0.1bar) hydrogen for its facilities was built at Ulsan, Korea in 2012. By making petrochemical products in a petrochemical industry park, the resulting by-product of hydrogen is produced and transported to the hydrogen town. Amongst several sectors, the fuel cell sector, which produces and supplies electricity to each apartment, is the most important sector that must be managed safely. The model was designed based on the test bed built in the Korea Gas Safety Research Centre to experiment several cases of hydrogen dispersion and explosion. The dimension of the fuel cell sector is 2.6m, 2.8m, and 2.1m in x, y, and z direction, respectively. Inside of the fuel cell sector, there are several components such as fuel cell, pipes, and fans. The schemes of the hydrogen town and the fuel cell sector are shown in Figure 1. In this work,

Figure 1. The hydrogen town and test bed (the fuel cell sector)

all the simulations are carried out by the CFD based software FLACS v10.4. The k-epsilon turbulence model is used, and the SIMPLE pressure correction algorithm is applied to calculate the compressible flows. All the components are illustrated through boxes and cylinders in pre-processor CASD of FLACS.

2.2. Scenarios decision

The scenarios are chosen based on the Korea Occupational Safety and Health Agency (KOSHA) guide. It is important to choose applicable scenarios since we are not able to conduct every accident case. KOSHA guide suggests the selection of the worst leakage scenario and the arbitrary leakage scenario. The worst leakage scenario is a virtual accident with the longest distance from the end point where the explosion occurred. The end point is the overpressure above 0.069 barg which can cause fatal damage to the human body. In this study, the worst leakage scenario of the 20mm pipe in the fuel cell sector being completely broken is selected because the amount of leakage is the greatest. In the case of the arbitrary leakage scenario, it is defined as a virtual accident that can occur frequently in exception to the worst leakage scenario. The arbitrary leakage scenario is assumed to have a leakage with the gap area of 20% of the 20mm pipe. Therefore, specific scenarios were determined by checking whether the concentration in the fuel cell sector was within the flammability when it leaked for 100 seconds to each corresponding area.

2.3. Case studies

To confirm the effectiveness of the EVP, the area of the EVP, the number of the EVP, and ignition positions were changed in each of the selected scenarios and compared to the enclosed hydrogen facilities using the FLACS v10.4. In terms of the selected scenarios, explosion simulations with different variables including three areas of the EVP ($0.64, 0.81, 1.00 \text{ m}^2$) and three cases of the number is carried out and recorded by 26 monitor points inside and outside of the fuel cell sector. The simulation conditions are shown in Figure 2 and Figure 3. The EVP was opened at 0.002 barg to allow quick opening even at small pressures, and the POPOUT relief panel model was applied in FLACS. Table 1 can be referred to configure the effect of the overpressure from each case on structure and the human body. The effect of the EVP is confirmed by checking the distance of the end point and whether there is a pressure above 0.069 barg in the internal facility or outside. The installation of the blast wall is considered based on the EVP simulation results.

3. Results

3.1. Scenario results

The concentration changes of the fuel cell sector due to leakage and dispersion according to each leakage scenario with time are shown in Table 2. In the worst leakage scenario,

Figure 2. EVP conditions on the fuel cell sector

Figure 3. The geometry of the fuel cell sector

Table 1. Effect of the overpressure on structures and the human body

Overpressure (barg)	wind speed (m/s)	Effect on the human body	Effect on structures
0.069	16.987	Light injuries from fragments occur	Window glass shatters
0.138	31.292	People injured by flying glass and debris	Moderate damage to houses (windows and doors blown out and severe damage to roofs)
0.207	45.598	Serious injuries are common, fatalities may occur	Residential structures collapse
0.689	131.429	Most people are killed	Reinforced concrete buildings are severely damaged or demolished
1.379	224.414	Fatalities approach 100%	Heavily built concrete buildings are severely damaged or demolished

there is a total hydrogen flammability distribution change from 4% to 75% within 35 seconds of the leak. In this work, explosion simulation was validated with the experiments conducted by Korea Gas Safety by varying the hydrogen-air mixture(ER0) to determine which concentration has the greatest overpressure (Young-Do Jo et al. 2010). The maximum explosion pressure of hydrogen-air mixture is shown in Figure 4; the value at 31% was selected as the worst leakage scenario result. In the case of an arbitrary leakage scenario, the flammability is first observed at the leakage area with a high concentration as soon as leakage occurs. Then, the entire internal fuel cell sector gains concentration that can cause explosion 17 seconds after the leak. The arbitrary leakage scenarios are selected at both the leakage area and around the fan, as these serve as high chances of an ignition source within the fuel cell sector. Therefore, three scenarios in total were selected and EVP was applied to each scenario.

Table 2. The concentration changes of the fuel cell sector after the leakage

The worst leakage scenario (D=20mm, whole destruction)	Time(s)	0.0	1.0	2.0	5.0	10.0	15.0	20.0	35.0
	Concentration leakage start (%)		4.0	9.0	23.0	38.0	50.0	61.0	75.0
The arbitrary leakage scenario (D=20mm, partial destruction (20%))	Time(s)	0.0	0.1~15.0	17.0	32.0	40.0			
	Concentration leakage start (%)		28.0 (leakage area)	4.0 (Inside)	8.0 (Inside)	10.0 (Inside)			

Figure 4. Maximum explosion pressure of hydrogen-air mixture

3.2. Simulation results

As seen from Table 3, EVP simulation conducted under the conditions mentioned in Section 2.3. In the worst leakage scenario, the overpressure is reduced when applied EVP in all cases. However, since the worst leakage scenario causes the greatest damage in all cases, the overpressure is higher than the largest value of the reference table. This can lead to not only the complete destruction of the internal facilities, but also the surrounding facilities as well. Therefore, a blast wall must be installed to minimize damage to surrounding facilities. The effect of the blast wall is shown in Figure 5. Unlike the worst leakage scenario, the overpressure result is significantly reduced to less than the end point pressure of 0.069 barg by installing the EVP in two arbitrary leakage scenarios. As the area of the EVP increases from 0.64 to 1.00, the overpressure gradually decreases. With case of increasing of the EVP number, the overpressure decreases sharply.

Table 3. The overpressure in the worst leakage scenario and the arbitrary leakage scenario

	EVP size (m ²)	The worst leakage scenario		The arbitrary leakage scenario			
				Leakage area		Around Fan	
		H ₂ (%)	Maximum pressure (barg)	H ₂ (%)	Maximum pressure (barg)	H ₂ (%)	Maximum pressure (barg)
(1) Confined	X		7.151		0.279		2.697
	0.64		4.691		0.046		0.042
(2) EVP size	0.81	31.55	4.307	28	0.034	7.73	0.020
	1.00		3.554		0.022		0.013
(3) The number of EVP	0.64 (#2)		2.697		0.013		0.008

4. Conclusion

This research suggests the effect of EVP to minimize damage caused by explosion in a hydrogen facility. Because many validation studies have resulted in the reliability of the simulation results, FLACS v10.4 is used to perform research. Based on the KOSHA guide, the worst leakage scenario and the arbitrary leakage scenario are determined by the actual leakage and dispersion simulation results. The arbitrary leakage scenario shows a significant reduction in overpressure when EVP is installed. However, in the worst leakage scenario, because of the large damage, installation of EVP is hard to reduce damage below the pressure of end point and can cause damage to surrounding facilities. Therefore, a blast wall must be installed. Further research is needed on the installation

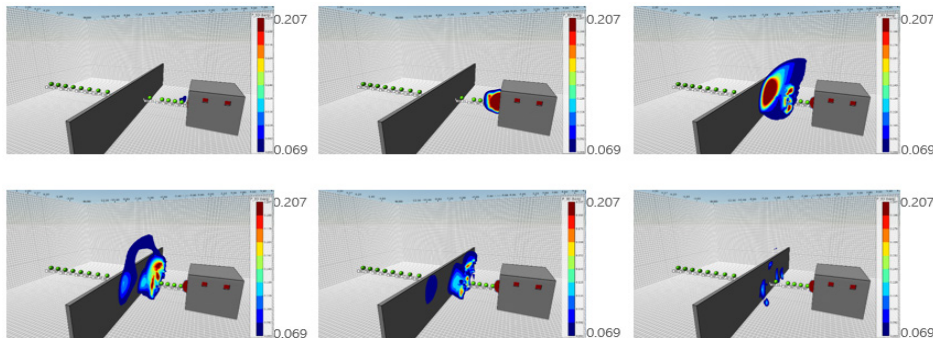

Figure 5. The overpressure changes in the blast wall installed

cost and installation distance of the blast walls. This EVP research provides specific numerical values for the damage distance and overpressure of internal facilities and the surroundings. This study aims to serve as reference to addressing the safety issues related to the overpressure caused by hydrogen explosion at facilities similar in size to the fuel cell sector.

Abstract

This paper presents the application of a steady-state real-time optimization strategy using transient measurements to an ammonia synthesis reactor case. We apply a new method for estimating the steady-state gradient of the cost function based on linearizing a dynamic model at the present operating point. The gradient is controlled to zero using a standard feedback controller, for example, a PI-controller. The applied method is able to adjust fast to the new optimal operation in case of disturbances. The advantage compared to standard steady-state real-time optimization is that it reaches the optimum much faster and without the need to wait for steady-state to update the model. It is significantly faster than classical extremum-seeking control and does not require the measurement of the cost function and additional process excitation. Compared to self-optimizing control, it allows the process to achieve the true optimum.

Keywords: Optimal Control, Extremum-Seeking Control, Reactor Control, Measurement Based Optimization

1. Introduction

The general aim of a process plant is to operate at the economic optimum. Different approaches are available in the literature for driving a process to its optimal operation point. The traditional approach is steady-state real-time optimization (RTO) in which a rigorous steady-state model is used for computing optimal setpoints. The necessary model reconciliation requires however that the plant is at steady-state before each reoptimization. This is a fundamental limitation of RTO as it may lead to suboptimal operation most of the time (Darby et al., 2011).

Self-optimizing control (SOC) (Skogestad, 2000) alleviates this problem through keeping the operation close to the optimum at all times by controlling selected controlled variable at a constant setpoint. Therefore, it can be used for close to optimal operation while waiting for the steady-state. The implementation is very fast and simple, but in case of unknown or large disturbances, the setpoints need to be updated using some other approach.

An alternative to RTO is a data-based approach, e.g. extremum-seeking control (ESC), which uses the plant measurements to drive the process to its optimal operation (Krstić and Wang, 2000). This is achieved by estimating the steady-state gradient from the input to the cost and using a small I-controller to drive the gradient to zero. Closely related approaches are the “hill-climbing” controller of Shinsky used recently by Kumar and Kaistha (2014) and the NCO-tracking approach

of Bonvin and coauthors (Franois et al., 2005). Their main advantage is that they are model free. The main challenge in these methods is the accurate estimation of the steady-state gradient from dynamic measurements. This normally requires constant excitations that are slow enough such that the dynamic system can be approximated as a static map (Krstić and Wang, 2000). As a result the convergence to the optimum is usually very slow. In the presence of abrupt disturbances, extremum-seeking control also causes unwanted deviations as discussed by Kumar and Kaistha (2014) and Krishnamoorthy et al. (2016).

A newer method for optimal operation is economic nonlinear model predictive control (E-NMPC), which handles the dynamic process behaviour, operational constraints, and leads to the optimal inputs for multivariable processes. Nevertheless, solving the optimization problem for a large-scale problem is computationally intensive and can potentially lead to computational delay.

In this paper, a new model-based dynamic gradient estimation (Krishnamoorthy et al., 2018, in preparation) is applied to drive the process to optimal operation. In contrast to standard ESC, the exact steady-state gradients is estimated based on the dynamic model of the process and hence no excitations are required. For the proposed method there is no need to measure the cost directly. Moreover, reoptimization is done by feedback control and solving the optimization problem is not necessary.

Heat-integrated processes, like the ammonia synthesis reactor (Morud and Skogestad, 1998) considered in this paper, are widespread in case of exothermic reactions to utilize the reaction heat. However, limit-cycle behaviour and reaction extinction may occur in the case of disturbances due to the positive feedback imposed through the heat integration (Morud and Skogestad, 1998). Straus and Skogestad (2017) proposed the application of E-NMPC for optimal control of the ammonia reactor to avoid this behaviour. In this paper, the application of the new feedback method is suggested to drive this process to optimal operation without the need of nonlinear dynamic optimization as is the case with E-NMPC or dynamic RTO.

2. Steady-state gradient control using transient measurements

We consider a process that can be modelled as a nonlinear dynamic system of the form

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}, \mathbf{d}) \quad (1)$$

$$\mathbf{y} = \mathbf{h}_y(\mathbf{x}, \mathbf{u}) \quad (2)$$

where $\mathbf{x} \in \mathbb{R}^{n_x}$, $\mathbf{u} \in \mathbb{R}^{n_u}$, $\mathbf{d} \in \mathbb{R}^{n_d}$, and $\mathbf{y} \in \mathbb{R}^{n_y}$ are the states, available control inputs, disturbances, and measurements. The cost does not need to be directly measured. In the proposed method, a state estimator such as an extended Kalman filter (EKF) (Simon, 2006) is applied to estimate the states \mathbf{x} of the system by using the measurements and the dynamic model, given in Eqs. (1) and (2).

Let the cost be modelled as $J = h_J(\mathbf{x}, \mathbf{u})$ with $h_J : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \rightarrow \mathbb{R}$. A local linear state-space model, given by the Eqs. (3) and (4), can be obtained through linearization around the current operation point, as shown by Krishnamoorthy et al. (2018, in preparation).

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \quad (3)$$

$$J = \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u} \quad (4)$$

where $\mathbf{A} = \partial\mathbf{f}/\partial\mathbf{x}$, $\mathbf{B} = \partial\mathbf{f}/\partial\mathbf{u}$, $\mathbf{C} = \partial h_J/\partial\mathbf{x}$, and $\mathbf{D} = \partial h_J/\partial\mathbf{u}$. In order to derive the steady state gradient, we set $\dot{\mathbf{x}} = 0$ and can derive in deviation variables

$$\Delta J = (-\mathbf{C}\mathbf{A}^{-1}\mathbf{B} + \mathbf{D})\Delta\mathbf{u} \quad (5)$$

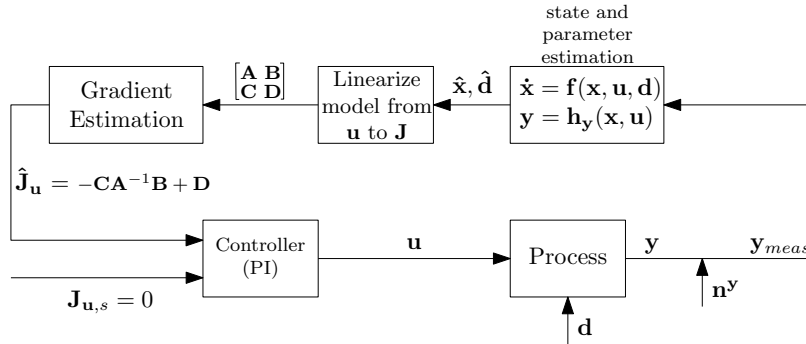

Figure 1: Block diagram of the proposed method.

which, since $\Delta J = \mathbf{J}_u \Delta \mathbf{u}$, gives the following estimate or prediction of the steady-state gradient:

$$\hat{\mathbf{J}}_u = -\mathbf{C}\mathbf{A}^{-1}\mathbf{B} + \mathbf{D} \quad (6)$$

We want to drive the system to an optimal steady-state where $\mathbf{J}_u = 0$, so even if the system is not at steady-state, we can use feedback control with $\mathbf{y} = \hat{\mathbf{J}}_u$ as “measurements” to drive the system to the optimal steady-state and by that satisfying the necessary conditions of optimality (Krishnamoorthy et al., 2018, in preparation). Any feedback controller, such as a PI controller, can be used to bring the gradient to zero. It is important to note that by using a nonlinear state estimator and a dynamic model for estimating the steady-state gradient \mathbf{J}_u , we can use transient measurements, without the need to wait for steady-state, as in traditional RTO. The scheme of the proposed method is shown in Figure 1. The disturbances can be estimated as well through the extension of Eq. (1) to an augmented system (Simon, 2006).

3. Model and problem formulation

The model of the ammonia reactor and all the model assumptions are based on Morud and Skogestad (1998)’s stability analysis. The process, shown in Figure 2, consists of 3 sequential reactor beds and the feed is split into 4 streams. The model is a differential algebraic system, where the differential equations describe the temperature evolution in the reactor beds and the algebraic equations represent the corresponding mass fraction of ammonia. There are 3 split-ratios or $\mathbf{u}_0 = [u_{0,1} \ u_{0,2} \ u_{0,3}]^T$ which are controlled by local temperature controllers. This is necessary for stabilizing the process. The temperature controllers are incorporated into the model in continuous time increasing the number of states by 3. This leads to $\mathbf{u} = [T_{m,1}^{sp} \ T_{m,2}^{sp} \ T_{m,3}^{sp}]^T$. The temperature controllers are modelled as single-input single-output integrator controllers, as the response can be approximated as a proportional process. The SIMC rules (Skogestad and Grimholt, 2012) were applied for the slave controllers tuning.

The state estimation is performed using an EKF (Simon, 2006). To this end, the model was reformulated as a system of ordinary differential equations. Each reactor bed in the model consists of n discrete volumes, which can be modelled as a CSTR cascade. This leads for each reactor bed to a total of $2n$ state variables per time step. For any CSTR reactor j in the CSTR cascade, the differential equations for the ammonia weight fractions $w_{\text{NH}_3,j}$ can be formulated as seen in Eq. (7), in which $\alpha = 0.33$ represents the bed void fraction, $\rho_g = 50 \text{ kg/m}^3$ the density of the gas,

Figure 2: Heat-integrated 3 bed ammonia synthesis reactor with cascade control. The setpoint of the slave temperature loop is given by the proposed method.

and $V_j = V_{bed}/n$ the volume of each CSTR reactor j (Morud, 1995).

$$\frac{dw_{NH_3,j}}{dt} = \frac{\dot{m}_{j-1}w_{NH_3,j-1} - \dot{m}_jw_{NH_3,j} + m_{cat,j}r_{NH_3,j}}{V_j\rho_g\alpha} \quad (7)$$

To summarize, we can write, $\mathbf{x} \in \mathbb{R}^{6n+3}$, $\mathbf{u} \in \mathbb{R}^3$ in the system, given in Eqs. (1) and (2).

In contrast to Straus and Skogestad (2017), full state knowledge is not assumed in this paper. The measurement set for state estimation is given by the inlet and outlet temperature of each reactor as well as the outlet temperature of the heat exchanger (see Figure 2). In real plants the catalyst activity is changing over time, which is difficult or impossible to measure and leads to a plant-model mismatch. To take into account industrial applicability, we assume, that the catalyst activity is not measured, but included in the model as an uncertain parameter. Hence, the states and the uncertain parameter are combined to the augmented states with $d = [a_{cat}]$, what results in an augmented system. To optimize the operation, we want to maximize the (mass) extent of reaction.

$$\xi = \dot{m}_{in}(w_{NH_3,3n} - w_{NH_3,in}) \quad (8)$$

This results in a cost function $J = -\xi$. In this case, a cascade control is used, where the master controllers drive the three gradients to zero by giving new set points to three slave control loops. The EKF and the proposed method were implemented in discrete time. The controller of the proposed method are single-input single-output controllers. The continuous time process model, given in Eq. (1), was modelled using CasADi (Andersson, 2013) and integrated with CVODES, which is part of the SUNDIALS package (Hindmarsh et al., 2005)

4. Results

In the following section, we consider a disturbance in the feed flow and a plant-model mismatch, given by a mismatch in the catalyst activity. In all cases, we have three inner stabilizing temperature loops as indicated by the letter ‘‘T’’ on the plots. In addition, the results are compared to pure self-optimizing control (SOC) and extremum-seeking control (ESC) in the optimization layer. The integrated cost difference (loss) J_{int} is used for comparison of the different methods,

$$J_{int}(t) = \int_0^t [\xi_{opt,SS}(t') - \xi(t')] dt' \quad (9)$$

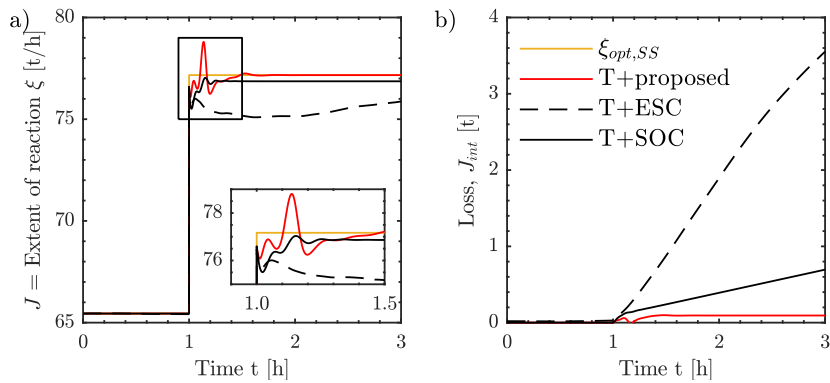

Figure 3: Responses of the alternative methods in a) the extent of reaction and b) the integrated loss to a disturbance in the feed flowrate of $\Delta \dot{m}_{in} = -15$ kg/s at time $t = 1$ h. $\xi_{opt,SS}$ represents the steady-state optimal extent of reaction.

First we simulate a disturbance change in the inlet flowrate \dot{m}_{in} to evaluate the performance of the control structure. The results for a decrease in the feed flowrate of $\Delta \dot{m}_{in} = -15$ kg/s at time $t = 1$ h are presented in Figure 3. The new proposed method gives fast disturbance rejection and settles down at the new optimal operation after about 30 min, as seen Figure 3 a). SOC is equally fast, but it does not quite reach the new optimum. This leads to a continuous increase in the integrated loss for SOC as seen in Figure 3 b). If we compare the proposed method to ESC as optimizing control, the proposed method is much faster and therefore causes a lower integrated cost difference of $J_{int}(t_{end}) = 0.1$ t. This is because the data-based gradient estimation takes longer time for accurate gradient estimation and the controller gain has to be small to satisfy stability. The application of extremum-seeking controllers does not converge to the steady-state optimum in the investigate time frame and requires 13 h.

In the second simulation, we consider plant-model mismatch. The results for a decreased catalyst activity Δa_{cat} by 20 % at time $t = 1$ h, which normally occurs slowly over a longer period of time, are presented in Figure 4. Therefore, the activity of the catalyst, or more specifically the

Figure 4: Responses of the alternative methods in a) the extent of reaction and b) the integrated loss to a plant-model mismatch of $\Delta a_{cat} = -20$ % at time $t = 1$ h. $\xi_{opt,SS}$ represents the steady-state optimal extent of reaction.

pre-exponential factor of the Arrhenius equation, spontaneously changes between the model used for the simulations and the model for the state estimation. The simulation shows that the proposed method is performing well even in the presence of a plant-model mismatch. This is because we are able to estimate the real value of the catalyst activity using the augmented EKF framework. About 1.5 minutes after the activity change, the mismatch as well as the states are estimated correctly. The proposed method is much faster than T+ESC, which in turn results in a lower total loss as seen in Figure 4 b). Again, SOC is equally fast, but the real optimum is not reached. The proposed method causes a total integrated cost difference of about $J_{int}(t_{end}) = 0.12$ t of ammonia for the considered case with plant-model mismatch.

5. Conclusion

We have applied a new method of utilizing transient measurements and a dynamic estimator to estimate the steady-state gradient and then using a simple PI controller for driving the process to its optimal operation. For an ammonia synthesis reactor with both disturbances and plant-model mismatch, the proposed method outperforms comparable control strategies. The industrial applicability is conceivable due to the usage of only seven measurements of the process besides the used dynamic model. An extended Kalman filter (EKF) allows the estimation of the steady-state gradients, even in case of plant-model mismatch by including unmeasured but modelled parameters in the estimator.

Abstract

Key polymer properties are substantially related to the polymer molecular weight distribution (MWD). Kinetic-based MWD models involves mass balances for all chain types and for all possible chain lengths. These models are predictive and exhibit a large-scale nature. The numerical solution is expensive, especially for on-line optimization in a state/parameter estimator. Thus, MWD monitoring using first-principles models has rarely been studied. In this work, we developed a simultaneous parameter and state estimator for MWD in the framework of moving horizon estimation (MHE). A reduced order model is proposed based on null-space projection method. The reformulated model predicts a MWD profile without calculating all possible chains. The large-scale MWD model is reduced to a manageable number of equations. Then, the MHE framework is designed based on the reformulated model, where the parameters and states are estimated simultaneously. Numerical results show that by introducing MWD as state variables, the prediction accuracy is significantly improved. It is advantageous to introduce the slow measurement of MWD for polymer quality monitoring/control although the different measurement rates need to be coordinated.

Keywords: Reduced model, molecular weight distribution, moving horizon estimation.

1. Introduction

Key polymer properties are substantially related to the polymer molecular weight distribution (MWD) (Soares et al. 2012). On-line monitoring and prediction of dynamic MWD profiles are highly important for quality control of polymerization processes. High-dimensional MWD profiles and time-variant features are hard to describe with data-driven models. The use of first-principles models for on-line monitoring and control has received significant attention in recent years. Modelling MWD based on first principles involves writing the mass balances for all chain types and for all possible chain lengths. However, theoretically this requires simultaneously solving an infinite number of equations. Solving such a large system is challenging and computationally expensive, especially for on-line applications. Thus, MWD monitoring using first principles models has rarely been studied. In the previous work, we developed a fast sensor for dynamic MWD based on rigorous models (Kang et al. 2017). The prediction accuracy is maintained by correcting the model parameters through off-line

measurement. A common problem encounters in the model-based estimators due to the drifting and distortion of the model parameters (Baranwal et al. 2015). Thus, to improve prediction performance of the estimator, parameters need to be estimated simultaneously with the states by introducing on-line measurement.

In polymerization processes, measurements are not available at the same rate. The temperatures or pressures can be measured very quickly, but the polymer quality indices take longer. The common estimators usually use the fast measurements under the assumption that all states of interests are observable from them. However, this assumption does not always hold. López-Negrete and Biegler (2012) developed a moving horizon estimator by introducing slow measurement to improve the prediction quality of average molecular weight (AMW). Given that AMW is derived by MWD measurements, it is worth investigating the estimator based on MWD.

In this work, we developed a simultaneous parameter and state estimator in the framework of moving horizon estimation (MHE). The most challenging problem is that the MWD is a profile measurement and the state variables can be 10000 or more. Therefore, model order reduction is required to reduce the degrees of freedom (DOF) and improve the computational efficiency of the estimator. A reformulated MWD model is proposed based on null-space projection method (Nie et al. 2013). The estimator is designed based on the reduced order model. Numerical results show that by introducing MWD as state variables, prediction accuracy is significantly improved. The slowly measured MWD profile provides much more information, which benefits the performance of the estimator.

2. Dynamic Reduced Order Models for MWD

Population balances are widely accepted in modelling the polymerization process. Mass balances for all chain types and for all possible chain lengths are simultaneously solved and MWD and AMW can be derived based on the molecule fraction of each chain calculated. For most macro quality indices such as AMW, moment method (Mastan et al, 2015) is practical way to reduce the complexity of population balances. However, the information about individual chains is sacrificed and thus is not able to predict MWD. Though the Flory distribution is applied in many steady state situations, it does not apply for dynamic processes. Population balances are still necessary in most cases.

A simplified butadiene rubber (BR) polymerization process is investigated in this study. The catalyst system is hydrolyzed with complex reactions, and monomer-free sites are generated. The polymer chains grow at the active sites and transfer to the ethylene monomer. The mechanism can be very complex, but here only the fundamental polymerization kinetics are modelled. By assuming that the polymerization happens in a CSTR, the following population balances are derived:

$$\frac{dP_0(j)}{dt} = r_a(j) - k_p(j)MP_0(j) + k_{iM}(j)M \sum_{r=1}^{N_r} P_r(j) - k_d(j)P_0(j) \quad (1a)$$

$$\frac{dP_r(j)}{dt} = -k_p(j)M(P_r(j) - P_{r-1}(j)) - k_{iM}(j)MP_r(j) \quad (1b)$$

$$\frac{dD_r(j)}{dt} = k_{iM}(j)MP_r(j) \quad (1c)$$

$$\frac{dM}{dt} = - \sum_{j=1}^{N_s} \sum_{r=0}^{N_r} (k_p(j) + k_{iM}(j))MP_r(j) \quad (1d)$$

where $P_0(j)$, $P_r(j)$, $D_r(j)$ and M represent the concentration of active sites, living chains with length r , dead chains with length r and monomer, respectively; $j \in \{1, 2, \dots, N_s\}$ is the active sites type and N_s is supposed to 2; N_T is the maximum length of chains considered, which could be 100000 or more. The catalyst hydrolysis reaction is not included because the moisture content of water is unmeasurable in the plant. Consequently, the kinetic parameters of the hydrolysis reaction are hard to estimate. We simplify this reaction to a source term of $P_0(j)$, denoted as $r_a(j)$ in Eq. (1a).

The dynamic MWD is calculated by

$$w_r(t) = \sum_{j=1}^{N_s} (P_r(j) + D_r(j)) / \sum_{r=0}^{N_T} \sum_i^{N_s} (P_r(j) + D_r(j)) \quad (2)$$

Eq. (1)(2) contain $2N_T N_s + N_s + 1$ differential equations and N_T algebraic equations. This model exhibits a large-scale nature. Although the dynamic MWD can be calculated by accumulating the instantaneous distribution in short time intervals (see Soares et al. 2012). It is not applied for the estimators because of its nested calculation nature. To overcome these computational difficulties, a reduced order model is presented.

In polymerization processes, the propagation rates k_p are significantly higher than the other rates. Consequently, the living and dead polymer chains represent quite different behaviours. The living polymer chains are fast consuming, and the life time is in the order of seconds. The dead polymer chains are slowly cumulative, and the life time can be as long as the resistance time of the reactor. Eq. (1)(2) result in a two-time scale model and incur numerical calculation issues.

Null-space projection method (Nie et al. 2012) is a systematic reformulation procedure of reaction equation systems. The fast and slow reactions are separated after a sequence of matrix operations. By employing this method, mass balance of the monomer-free sites in Eq. (1a) can be reformulated as:

$$\frac{dP_0(j)}{dt} = r_a(j) - k_d(j)P_0(j) \quad (3a)$$

The fast reactions are sketched by two equilibrium equations:

$$k_p(j)MP_0(j) - k_{iM}(j)MY(j) = 0 \quad (3b)$$

$$-k_p(j)M(P_r(j) - P_{r-1}(j)) - k_{iM}(j)MP_r(j) = 0 \quad (3c)$$

where $Y(j) = \sum_{r=1}^{N_T} P_r(j)$ is introduced as a pseudo component.

By further substitution of Eq. (3b)(3c), the decomposition of coupling living chain lengths is accomplished:

$$P_r(j) = \left(\frac{k_p(j)}{k_p(j) + k_{iM}(j)} \right)^r P_0(j) \quad (3d)$$

The population balances of slow reactions remain, i.e., (1c)(1d).

The dynamic MWD is calculated by adding another differential equation:

$$\frac{dC}{dt} = \sum_{j=1}^{N_s} (k_p(j) + k_{iM}(j))MY(j) \quad (4a)$$

$$w_r(t) = \sum_{j=1}^{N_s} (P_r(j) + D_r(j)) / C \quad (4b)$$

By combining Eq. (1c)(1d), (3a)(3b)(3d) and (4), a chain decoupling model is obtained. This model provides the property of sampling in large chain intervals instead of all the chains. The reformulated model can figure out a MWD profile using $\delta N_T N_s + N_s + 2$

differential equations and $\delta N_T N_s + \delta N_T + N_s$ algebraic equations, where the sampling chains δN_T can be less than 100 but N_T can be 100000 or more.

3. Moving Horizon Estimation Based on MWD

Moving horizon estimation is an efficient strategy for constrained state estimation in nonlinear systems. The basic idea of MHE is to estimate the state trajectory using only the past N measurements, where N is referred to the length of horizon window. A nonlinear programming (NLP) problem is formulated at each sample time where a batch of past measurements is introduced and the states are estimated simultaneously. The horizon window allows incorporation of both frequent and infrequent measurements where the slow ones can be introduced as they are available.

The MHE formulation is shown as

$$\min_{z_{l-N}} \|z_{l-N} - \bar{z}_{l-N}\|^2 W_z + \sum_{l=0}^N \|y_l - \bar{y}_{l+k-N}\|^2 W_y \quad (5a)$$

$$\text{s.t. } z_{l+1} = f(z_l, u_l) + w_l \quad (5b)$$

$$y_l = h(z_l) + v_l \quad (5c)$$

where the process is assumed to be modelled by Eq. (5b)(5c), z_l is the vector of states, u_l is the vector of inputs, y_l is the vector of measurements, w_l is the vector of unknown disturbances, and v_l is the vector of measurement noise. The noise variables are assumed to be independent of states and $w_l \sim N(0, Q_l)$ and $v_l \sim N(0, R_l)$. W_z , W_y represent the inverse of the covariance matrices of the prior state estimates \bar{z}_{l-N} and measurement \bar{y}_{l+k-N} , respectively. The state vector in Eq. 5. is denoted as $z_l = [x_l, p_l]$, where x_l are the reactant concentrations, and p_l are kinetic parameters and $r_a(j)$. It is also assumed the bounds and constraints of states can be further added in the NLP formulation.

The determination of states that can be estimated depends on how much information is contained in the measurement. MWD is a profile measurement and has much more information than other scalar measurements such as AMW and monomer concentration. The reduced order model avoids calculating all the chains and allows estimating the MWD states $D_i(j)$ directly.

4. Results & Discussion

4.1. Model validation

The proposed dynamic MWD model is validated in a simulation of grade transition. The conventional method is compared for predictive consistence and computational efficiency. The reduced order model allows sampling in large chain intervals. In this case, the chain lengths are sampled evenly in logarithm scale with $\delta N_T = 40$. Fig. 1. shows the MWDs predicted by the reduced model and cumulative Flory method. The MWDs predicted by the two methods overlapped. The reduced order model predicted the same results using 40 chains rather than 50000 chains in cumulative Flory method.

The computational efficiency is also investigated. The cumulative Flory method cannot deal with the large-scale population balances, and a moment model is used instead. This approach spends most computational efforts in cumulate the instantaneous distributions. The total time cost is 78.3 s. However, the reduced order model uses manageable number of population balances to predict the dynamic MWD with time cost of 8.7 s. Over 90% time cost is saved. Moreover, the model scale is significantly smaller which can be implemented in a state estimator.

Fig. 1. Dynamic MWDs along time

4.2. Estimation case study

In this section, the reduced order model (i.e. Eq. (1c)(1d), (3a)(3b)(3d) and (4)) is used to estimate dynamic MWD of the BR process. We assume that the fast measurements are given by the monomer concentrations which can be measured by a refractometer. The MWDs are measured slowly through GPC. We also assume that the monomer concentrations are sampled every 10 min while the MWDs are sampled every 30 min. The horizon is set as 60 min. The unknown catalyst term $r_a(j)$ is chosen as model parameters p_l to be estimated. It is also assumed that $r_a(j)$ can be formulated as a random walk, i.e., $p_{l+1} = p_l + w_k^p$, where w_k^p is a Gaussian noise associated with p_l .

Three estimation schemes are designed for comparison as shown in Table 1. The difference lies in what kind of slow measurement is used. MHE-M only uses fast measurement but MMHE-MW and MMHE-MWD introduce slow measurement of AMW and MWD, respectively. The information contained in the measurements determines how many DOF of z_{l-N} in Eq. (5a) can be introduced.

Table 1. Three estimation schemes

Estimator scheme	Fast measurement	Slow measurement	DOF of z_{l-N}
MHE-M	Monomer concentration	-	$r_a(j)$
MMHE-MW	Monomer concentration	AMW	M, $r_a(j)$
MMHE-MWD	Monomer concentration	MWD	M, $D_r(j), r_a(j)$

Fig. 2. shows the comparison between some of the estimated states using the three estimation schemes, with respect to the real values. Fig. 2(a). shows the estimated AMW. MHE-M predicts AMW by correcting the catalyst hydrolysis parameters. The trend of the dynamics is captured but visible error exists between the estimated and real AMW. By introducing slow measurement of the polymer quality indices (AMW or MWD), the prediction error of AMW is significantly reduced. In other words, the observability is improved in MMHE-AMW and MMHE-MWD. The performance of MWD prediction is characterized by the sum square error (SSE) to the real MWD profile. Fig. 2(b). shows the benefit by introducing the full MWD profile as state

variables. The MMHE-MWD achieves the best prediction accuracy. The SSE of estimated MWD using MMHE-MWD is about 50% less than that of MHE-M and MMHE-MW. Besides, the estimation results of MMHE-MWD converges faster than the others. The slow measurement of MWD profile provides much more information which benefits the estimability of parameters and observability of states.

Fig. 2. (a) estimated AMW (b) SSE of estimated MWD

5. Conclusions

In this paper, we proposed a simultaneous parameter and state estimator for MWD in the MHE framework. It is challenging to estimate the MWDs directly due to the large-scale nature of the MWD model. To overcome this issue, a reformulated MWD model is proposed based on null-space projection method. The large-scale MWD model is reduced to a manageable one without essentially affects the predictive performance. The estimator is designed based on the reduced order model. The numerical results show that by introducing MWD as state variables, the prediction accuracy is significantly improved. The slow measurement of MWD profile provides much more information which benefits the performance of the estimator.

Abstract

Novelty Detection (ND) methods are mainly developed to detect novel samples without a clear and general strategy for updating the Fault Detection and Diagnosis (FDD) system. The present study addresses this problem through developing an automatic unsupervised data driven framework for updating FDD systems for the ND purpose. The proposed method is based on the combination of One Class Classifiers (OCCs) that is used to detect samples following novel patterns (i.e. faults), and automatic clustering technique to diagnose them according to novel clusters (i.e. figure out the specific novel fault type). The FDD updating is performed by modifying the existing clusters and detecting new clusters for assembling models in an unsupervised automatic mode. An observer is also incorporated for data processing and enhancing the FDD robustness. The proposed framework is studied and validated via its application to a simulated benchmark case study consisting of three coupled tanks. The results show that the framework can efficiently manage classification models, learn novel clusters, and update FDD system.

Keywords: Updating, Novelty detection, One class classifier, Clustering, Observer

1. Introduction

Supervised FDD approaches are based on the assumption that the available process data could be labeled regarding normal and different faulty conditions (Qin, 2012). On the other hand, unsupervised approaches are usually applied in more realistic situations, when there is no prior information about the fault types in the process.

Clustering is an unsupervised learning method which partitions an unlabeled dataset into subgroups (i.e. clusters) of similar objects based on the knowledge extracted from these data (Das, et al., 2008). Clustering methods can be divided into automatic and non-automatic techniques. For the non-automatic type, the number of clusters must be priori specified for the clustering technique, while in automatic clustering, the optimal number of clusters is determined by the clustering technique without any prior knowledge.

Gama (2010) defines ND as recognizing novel concepts that could refer to the appearance of new concepts, changes in available concepts or presence of the noise in predefined concepts. OCC is a type of algorithm mainly developed for dealing with ND. The OCC algorithm determines the smallest hypersphere enclosing the training samples (Shawe et al., 2004) and next all samples lying outside the hypersphere are classified as

novel/ negative. A particular advantage of the OCC algorithm is that its training requires only positive examples, while other machine learning algorithms need positive and negative samples. One Class Support Vector Machines (OCS) is an applicable algorithm of OCC and there are different kernel types that could be applied with it. The kernel methods compromise between the module that maps the input data from original space to the feature space and a learning algorithm that understands linear patterns in the feature space.

Most of the researches in ND is only concentrated in detecting new classes, but not to the exploitation of these new knowledge. This study presents a data driven FDD framework based on the use of OCC and automatic clustering, allowing both novelty detection and FDD updating in an unsupervised manner. The framework automatically updates the FDD after diagnosing new class(es) by a set of OCCs and unsupervised automatic clustering.

2. Methodology

2.1. Problem definition and proposed framework

The problem consists in periodically updating the classification models to automatically learn changing conditions and new process faults. Consider an initial dataset, X , that is a collection of $s=1,2,\dots,S$ process vector states, which are in turn a set of $i=1,2,\dots,I$ scaler measurements, $X = \{\mathbf{x}_s\} = \{\mathbf{x}_{si}\}$. Assume no simultaneous faults so that this initial dataset X may be automatically clustered into F disjoint subsets by a clustering function, Eq.(1), $C(X, \beta)$:

$$C(X, \beta) \Rightarrow \begin{cases} A_f \subseteq X & \forall f : A_f \cap A_{f \neq f} = \emptyset \wedge |A_f| \geq \beta \\ B = X \setminus A & (A \equiv \cup A_f) \\ \bar{C}(\mathbf{x}_s) = f & \forall \mathbf{x}_s \in A_f \\ \bar{C}(\mathbf{x}_s) = 0 & \forall \mathbf{x}_s \in B \end{cases} \quad (1)$$

Which produces the set of labeled set A , a set of unlabeled samples B , and the function $\bar{C}(\mathbf{x}_s)$ providing the label for each sample \mathbf{x}_s . A cluster threshold parameter (β) needs to be tuned as a minimum size for each cluster, $\beta \leq |A_f|$, and consequently determines the complementary set B . If the true label of each sample $L(\mathbf{x}_s)$ was a priori known, then the Clustering Accuracy (CA) of each subset/cluster can be assessed as Eq. (2).

$$CA_f = \sum_{x_s \in A_f} \frac{\neg \{ \bar{C}(x_s), L(x_s) \}}{|A_f|}, \quad \forall f \quad (2)$$

Given the F clusters, supervised classifiers are developed accordingly. In order to set up the OCCs, each cluster is randomly divided into two disjoint subsets including training, A_f^t , and validation subset, A_f^v , Eq. (3):

$$A_f^t \cup A_f^v = A_f, \quad A_f^t \cap A_f^v = \emptyset \quad \text{being} \quad |A_f^t| = \alpha |A_f| \quad \text{and} \quad |A_f^v| = (1 - \alpha) |A_f| \quad (3)$$

In which α needs to be selected. The prediction of each OCC for each sample, $h_f(\mathbf{x}_s)$ is set to meet the conditions in Eq. (4):

$$h_f(\mathbf{x}_s) = \begin{cases} 1 & \text{if } \mathbf{x}_s \in A_f \\ 0 & \text{if } \mathbf{x}_s \notin A_f \end{cases}, \forall \mathbf{x}_s \quad (4)$$

The Individual Prediction Performance (IPP) of each OCC could be estimated for new dataset $X^* = \{\mathbf{x}_{s^*}\}$ using Eq. (5):

$$IPP_f = \sum_{\mathbf{x}_{s^*} \in X^*} \frac{\neg \vee \{h_f(\mathbf{x}_{s^*}), L(\mathbf{x}_{s^*})\}}{|X^*|} \quad \forall f \quad (5)$$

The assumption of no simultaneous faults allows defining a net prediction given by the whole set of OCCs for each new sample $H(\mathbf{x}_{s^*})$, which also allows assigning the new sample to the A or B subsets; this is given by Eq. (6)

$$H(\mathbf{x}_{s^*}) = \begin{cases} f & \text{if } \neg \vee \{h_f(\mathbf{x}_{s^*}), \forall f \in F\} \wedge h_f(\mathbf{x}_{s^*}) \\ 0 & \text{otherwise } \left(\neg \vee \{h_f(\mathbf{x}_{s^*}), \forall f \in F\} \right) \end{cases} \quad (6)$$

Finally, the Net Prediction Performance (NPP) for dataset X^* can be calculated based on Eq. (7):

$$NPP = \sum_{\mathbf{x}_{s^*} \in X^*} \frac{\neg \vee \{H(\mathbf{x}_{s^*}), L(\mathbf{x}_{s^*})\}}{|X^*|} \quad (7)$$

The implementation of this scheme is done with the framework proposed in this study, Figure (1) and Figure (2), that has two main modules:

- The Offline Model Updating (OMU) module, Figure (2) , and
- The Online Monitoring (OM) module, Figure (3).

The initial dataset, X , must be processed by the OMU module in order to determine the cluster dataset(A), the classification models (OCCs), the Updating Threshold (UT) value, and the unlabeled dataset, B . UT is minimum number of samples in B^* for calling OMU, based on Figure (2), and B^* is the unlabeled dataset for online samples. UT is successively updated by the summation of the Updating Threshold Parameter (UTP) and the number of samples in the current dataset B ($UT \leftarrow UTP + |B|$).

Figure 1. Proposed framework: OMU module.

UTP is a parameter that must be tuned, experimentally. In the OM module, Figure (2), the online samples are initially processed by observer and then are classified by set of OCCs, Eq. (6). The online samples that are diagnosed as elements of subsets A_f are discarded, while those that do not clearly belong to any of the subsets are kept and assigned to the unlabeled dataset for online samples B^* . After adding each sample to the unlabeled dataset, B^* , in online monitoring module, a condition must be checked: “Do number of samples in unlabeled dataset, B^* , meet the UT?”

Furthermore, for practical implementation another condition must be checked: “it is not updating?” that implies OMU is on progressing or not. If answers of both conditions are “Yes” then OMU will be triggered by online monitoring module. In this case, the inlet dataset of the OMU X^* is the total of B^* and clusters datasets A , Figure (2).

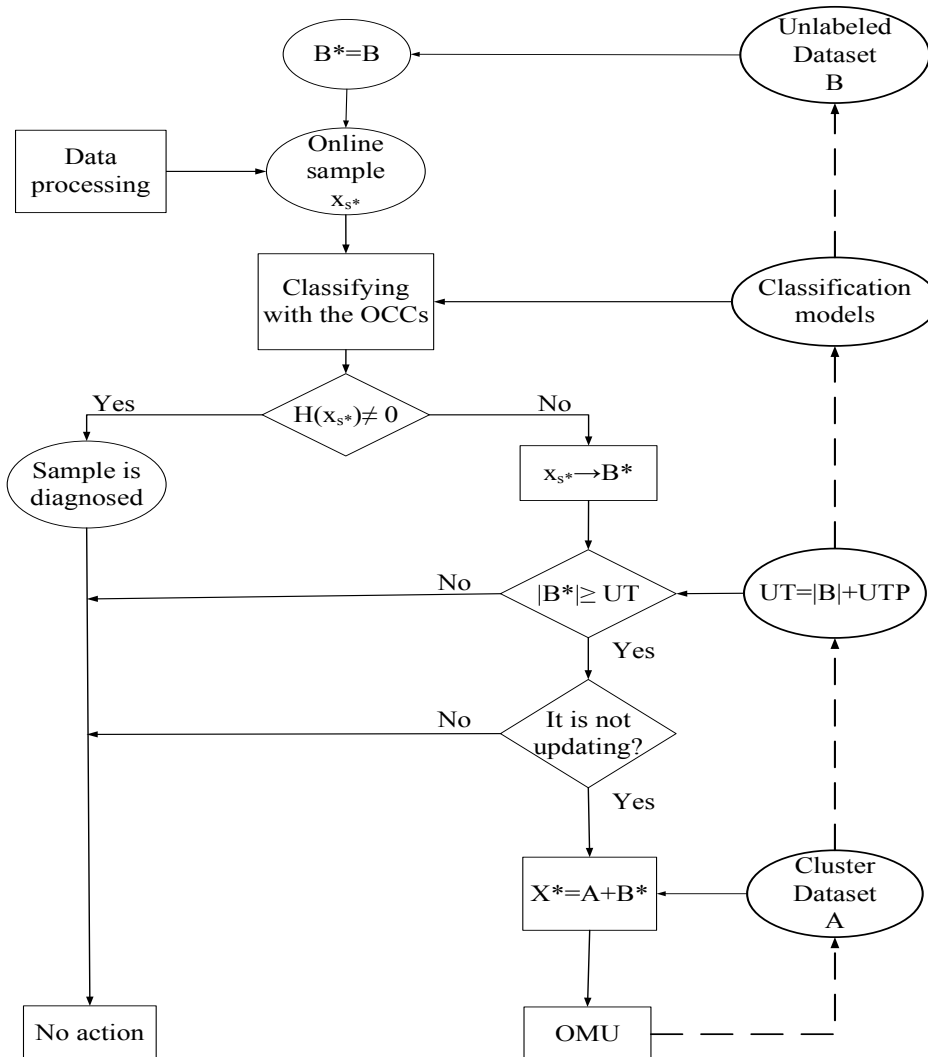

Figure 2. Proposed framework: OM module.

3. Case Study

A benchmark case study (Patton, et al., 1994) is used to validated the proposed framework. The system consists of three interconnected tanks, which are supplied with liquid by two pumps with flowrates $Q_1(t)$ and $Q_2(t)$. The tank levels $h_1(t)$, $h_2(t)$ and $h_3(t)$ are considered as the measured variables with sampling period each second. In addition to Normal (Nr) condition, the process is subjected to three faults: Fault 1 (F1) is the leaking in tank 1, Fault 2 (F2) is the plugging in tank 2 and Fault 3 (F3) is the leaking in tank 3. Both of the inlet flowrates are steady at magnitudes of $Q_1(t)=3 \times 10^{-3} (m^3/s)$ and $Q_2(t)=2.5 \times 10^{-3} (m^3/s)$. The Leaking and plugging flowrates are set to be between 10% and 25% of the inlet flow. Gaussian errors are introduced to the measured variables representing the sensors noise, for more details about the case setting see (Shokry, et al., 2016). Figure (3) presents the considered fault pattern influencing the process, where it is assumed that in the initial dataset X , there are two clusters including Nr and F1. During the 1000 seconds two new faults (F2 and F3) appear, while during the four time intervals (separated by dashed vertical lines) the fault pattern is switched. In Figure (3), during each time interval, the faults sequence are arranged from top to bottom: as an example, in the first interval, the normal condition occurs along the first 100 s. , F2 takes place along the subsequent 50 s. then F1 happens along the following 100 s.

Figure 3. Fault pattern.

4. Application and Results

α , β and UTP are selected, experimentally, to be 0.8, 30 and 80, respectively. For the initial dataset the CA is 99%, while the CPU time is 3.2 second. During 1000 second based on fault pattern two times OMU is called. For the first call of OMU the CA is 95% and CPU time is 15.7 s., while for the second call these amounts are 95.2% and 15.7 s., respectively. In the first 250 seconds NPP is 95.2% and after detecting 80 new samples the first call of OMU starts at 475 s. and also from 491 s. the OCS_F2 is available. The second call of OMU starts at 760 s. and from 776 s. the OCS_F3 starts to monitor the system. Table (1) presents overall IPPs of the classifiers and also overall NPP.

Table 1. Overall IPP and NPP

$1 \leq t \leq 1000 \text{ s}$	Correct	Incorrect	IPP/NPP (%)
OCS Nr	964	36	96.4
OCS_F1	980	20	98.0
OCS_F2	478	31	93.9
OCS_F3	224	0	100.0
H (Net prediction)	931	69	93.1

F3 samples before 776 s. are labeled as B^* and then they are diagnosed as F3. Overall NPP is 93.1%, implying 931 correct predictions. Figure (4) presents overall

performance of the framework. In Figure (4), the thin striped rectangle in front of the F2 from 1 s. till 491 s. indicates during that time interval F2 samples are not diagnosed as defined class. For F3 samples the thin striped rectangle is drawn till 776 s. and after that they are diagnosed as defined class.

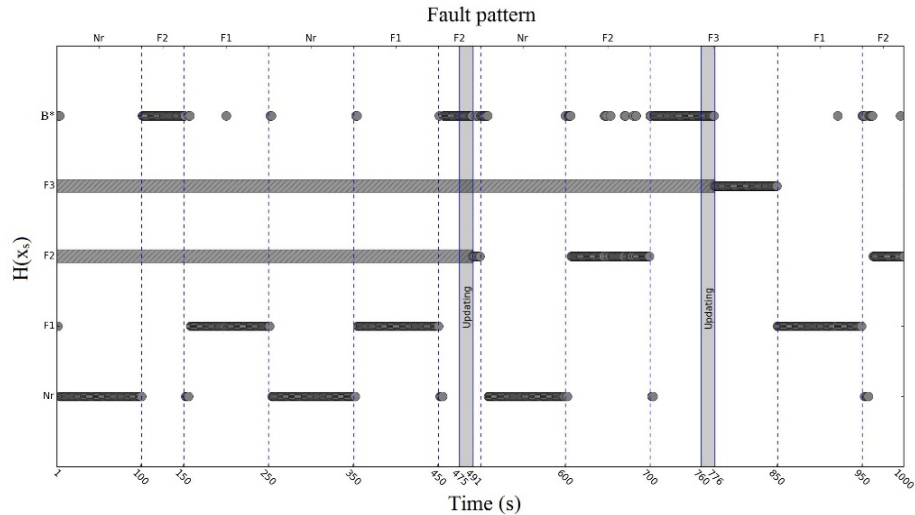

Figure 4. Performance of the framework.

5. Conclusions

In the present study a framework for unsupervised automatic updating of data driven FDD is addressed that is based on applying automatic clustering, OCCs and observer. While observer provides the error features for being replaced with the measured features, OCCs do ND and automatic clustering recognizes the new classes. Based on the framework, always the most relevant samples to the current conditions of the system are employed to train and update the FDD. The investigation is done by applying three tank benchmark while 1000 seconds are studied in which two new clusters appear in the system. Reasonable performance and accuracy of different tasks of the framework imply reliability of it.

Abstract

One very important bioprocess is the cultivation of recombinant *E. coli* for expression of heterologous protein. For this, High Cell Density Cultures is one of the most widely used technique. Therefore, researchers from the Chemical Engineering Department of Federal University of São Carlos (UFSCar) developed a very useful computer program (SUPERSYS_HCDC) that, among other functions, presents a hybrid system with a PID for agitation and a decision tree for air and oxygen flow rates that controls the percentage of dissolved oxygen in the cultivation (nowadays some commercial controllers also offers this cascade control). However, in particular, delays may occur in the device responsible for air and oxygen injection into the bioreactor, since the decision tree provides no smooth responses. The original system presented operates by introducing steps in the air and oxygen flow rates. Under the light of the above-mentioned facts, fuzzy reasoning was used to develop a fuzzy controller, aiming to improve dissolved oxygen control in recombinant *E. coli* cultivation for heterologous protein production. At first, fuzzy logic toolbox was used to generate a control algorithm implemented in a MATLAB code. Secondly, the membership function parameters were optimized using ANFIS tool. Finally, in order to perform tests using the fuzzy controller, it was coupled to a neural network model of the process. This was created using artificial neural network toolbox and *E. coli* cultivation data. Results for oxygen and air flow rates indicated that the trends of aeration required by *E. coli* cultivation were fulfilled. Using the fuzzy controller, it was possible to maintain the percentage of dissolved oxygen around the set point value of 30%. In general, the fuzzy controller responses were smoother than those provided by the decision tree, in a way that the dissolved oxygen peaks were softened.

Keywords: Fuzzy Logic, Dissolved Oxygen, Artificial Neural Network, recombinant *Escherichia coli*, SUPERSYS_HCDC.

1. Introduction

The *Streptococcus pneumoniae* or pneumococcus is an important human pathogen, whose virulence factor is in its polysaccharide capsule. Thus, a capsular polysaccharide (PS) vaccine was created based on the idea that antibodies formed against the PS are effective in immunizing. However, the capsular polysaccharide does not have the capacity of activating T lymphocytes cells, responsible for the immunological memory.

One solution found was the conjugation of the polysaccharide with a protein that enhances the immune response (generating immunological memory).

Well characterized genetics and physiology and a established recombinant DNA technology were determinant factors that made *Escherichia coli* the pioneer organism for recombinant protein production. One of the wildest known technic for *E. coli* culture is the High-Cell-Density Cultivation (HCDC). Within this context, researchers from LaDABio Laboratory at the Chemical Engineering Department of Federal University of São Carlos (DEQ/UFSCar) developed the SUPERSYS_HCDC (Horta et al., 2014). The program in equipped with, among other functions, a hybrid system that aims to control the dissolved oxygen in the cultures. It is composed by a PID controller to manipulate agitation speed and a decision tree to manipulate air and oxygen flow rates. However, in particular, the decision tree does not provide smooth responses, revealing the need of improvements in the automatic control system of air and oxygen flow rates (Horta, 2011). Thus, this work aimed to develop a fuzzy system for dissolved oxygen control in a recombinant *E. coli* cultivation for heterologous protein expression.

2. Literature Review

The SUPERSYS_HCDC was developed in LabView platform and MATLAB code. It has, among its control modules, an automatic hierarchic hybrid module for dissolved oxygen concentration control. In order to meet the high oxygen consumption rates in a HCDC of *E coli*, the dissolved oxygen concentration control was designed using a hybrid system. It was composed by a PID controller (acting directly in the agitation speed) and a heuristic algorithm (modulating air and oxygen flow rates). The code for this heuristic control action consists of a decision tree as it is shown in Figure 1.

```

SCENARIO 1:
  If  $Agit < 0.7 * Agit_{SL}$  and  $QO2_{-1} > 0$ 
     $QAIR = QAIR_{-1} + \Delta$ 
     $QO2 = QO2_{-1} - \Delta$ 

SCENARIO 2:
  If  $Agit \geq 0.99 * Agit_{SL}$  and  $DO < DO_{IL}$ 
    SCENARIO 2a:
      If  $QAIR_{-1} + QO2_{-1} \geq Q_{MAX}$ 
         $QAIR = QAIR_{-1} - \Delta$ 
         $QO2 = QO2_{-1} + \Delta$ 
      SCENARIO 2b:
        If  $QAIR_{-1} + QO2_{-1} < Q_{MAX}$ 
           $QAIR = QAIR_{-1} + \Delta$ 
           $QO2 = QO2_{-1}$ 
  
```

Figure 1: Pseudocode for air and oxygen flow rate control

In Figure 1, $Agit$ and $Agit_{SL}$ are agitation speed and agitation superior limit, $QO2$ and $QAIR$ are oxygen and air flow rates, respectively, Δ is a constant value, DO and DO_{IL} are dissolved oxygen and dissolved oxygen inferior limit and Q_{MAX} is the maximum gas flow rate. The pseudocode is interpreted as it follows: if the agitation speed is low (lower than 70% of the agitation superior limit) in a scenario where oxygen is already being injected in the system, air flow rate should be increased and oxygen enrichment in the system should be decreased. However, if the agitation speed is near its maximum (equal to or higher than 99% of the agitation superior limit) and even so, the dissolved oxygen concentration in the system is low, two options are presented: it is observed if

air and oxygen flow rates sum exceeds the maximum gas flow rate. If yes, then air flow rate should be decreased and oxygen enrichment should be increased. If not, air flow rate should be increased and oxygen enrichment should be maintained. This original system operates by introducing steps in the oxygen and air flow rates (Horta, 2011). Thus, in this work, fuzzy reasoning (Zadeh, 1994) was used to improve it.

3. Methodology

The development of the fuzzy control system, which includes the establishment of the linguistic variables, the membership functions (and its optimum parameters) and the fuzzy rules, was carried out using two powerful computational tools: Fuzzy Inference System (FIS) and the Adaptive Neuro Fuzzy Inference System (ANFIS), both of them available on MATLAB Fuzzy Logic Toolbox.

Initially, three subroutines were created using MATLAB FIS editor. The first, called “Delta” (responsible for analysing the size of the variations in air and oxygen flow rates), and two subroutines called “Princ” (responsible for verifying if there will be an increment or a decrease of delta in air (“Princ1”) and oxygen (“Princ2”) flow rates). Figure 2 shows the input and output linguistic variables of each subroutine along with their respective linguistic values.

Subroutine	Input variable	Linguistic Value	Output variable
“Delta”	QO2ant: Previous Oxygen Flow Rate (L/min)	LP: Low and Positive MP: Medium and Positive HP: High and Positive	Delta
“Princ1”	CX: Microorganism Concentration (g/L)	LP: Low and Positive HP: High and Positive	QarEscolha
	AgitMed: Agitation Speed (rpm)	LP: Low and Positive HP: High and Positive VHP: Very High and Positive	
	DO: Dissolved Oxygen (%)	LP: Low and Positive MP: Medium and Positive HP: High and Positive	
	QarSe: Auxiliary Variable	NO YES	
	Mi: Specific Growth Rate (1/h)	LP: Low and Positive MP: Medium and Positive	
“Princ2”	CX: Microorganism Concentration (g/L)	LP: Low and Positive HP: High and Positive	QO2Escolha
	AgitMed: Agitation Speed (rpm)	LP: Low and Positive HP: High and Positive VHP: Very High and Positive	
	DO: Dissolved Oxygen (%)	LP: Low and Positive MP: Medium and Positive HP: High and Positive	
	QarSe: Auxiliary Variable	NO YES	
	Mi: Specific Growth Rate (1/h)	LP: Low and Positive MP: Medium and Positive	

Figure 2: Input (along with their linguistic values) and output variables of the subroutines

The input variable for “Delta” subroutine is QO2ant. Its output variable is Delta. For both “Princ1” and “Princ2” subroutines, the input variables are: CX, AgitMed, DO, QarSe (which is an auxiliary variable that allows the choice between the IF or IF NOT option in the decision tree, after air and oxygen flow rates sum) and Mi. Their output variables are QarEscolha e QO2Escolha, respectively, that determine whether there will be an increase or a decrease of delta in air or oxygen flow rates (respectively).

FIS editor allows users to define the membership function's shape and parameters. However, when discerning them heuristically by simple data analysis becomes impractical, the Adaptive Neuro Fuzzy Inference System is a valuable asset. It can perform membership function parameters optimization, using a set of functions, in order to build a fuzzy inference system from input and output data available.

For the "Delta" fuzzy inference system, the parameter optimization was performed using MATLAB Gaussian type 2 membership function (gauss2mf) for input variables, as it is shown by Equation 1:

$$f(x, \sigma, c) = e^{-\frac{(x-c)^2}{2\sigma^2}} \quad (1)$$

Gauss2mf is a combination of two sets of parameters. The first one, specified by σ_1 e c_1 , determines the left part of the curve. The second set, specified by σ_2 e c_2 , determines the right part of the curve.

Three fuzzy rules were adjusted for "Delta" by ANFIS tool, one of them exemplified by Equation 2:

$$\text{If } QO2_{ant} \text{ is LP then Delta is } F_1. \quad (2)$$

In which F_1 is a linear function, as it is shown in Equation 3:

$$F_1 = \alpha QO2_{ant} + \beta \quad (3)$$

In which α is the input variable (QO2ant) coefficient and β is the linear coefficient.

For the "Princ" fuzzy inference systems, the parameter optimization was performed using MATLAB Gaussian type 1 membership function (gauss1mf).

72 fuzzy rules were adjusted for both "Princ1" and "Princ2" using ANFIS tool, one of them exemplified by Equation 4:

$$\text{If } CX \text{ is LP and AgitMed is LP and DO is LP and QarSe is NO and Mi is LP then } QarEscolha \text{ is } F_1' \quad (4)$$

In which F_1' is a linear function, as it is shown by Equation 5:

$$F_1' = a \cdot Cx + b \cdot AgitMed + c \cdot DO + d \cdot QarSe + e \cdot Mi + f \quad (5)$$

In which a, b, c, d, and e are CX, AgitMed, DO, QarSe and Mi coefficients respectively, and f is the linear coefficient.

In order to test the fuzzy controller, it was coupled to a neural network model of the process. This was created using MATLAB Artificial Neural Network toolbox and *E. coli* cultivation data. The optimized (by ANFIS) fuzzy controller was coupled with the neural model of the process and with the PID controller for agitation speed. From

previous values of microorganism concentration (CX_{t-1}), dissolved oxygen (DO_{t-1}), Agitation speed ($Agit_{t-1}$), Air (Qar_{t-1}) and oxygen ($QO2_{t-1}$) flow rates and specific growth rate (μ_{t-1}), the fuzzy controller provides the subsequent air and oxygen flow rates. These data are passed on to a first neural network, which estimates the dissolved oxygen percentage. This result is used to update the agitation speed by the PID controller. This new set of data (DO_t , $Agit_t$, Qar_t and $QO2_t$) is passed on to a second neural network in order to assess microorganism concentration (CX_t). This result is used to estimate the specific growth rate (μ_t). For the next step, the simulator feeds back and updates all these values to the fuzzy controller. The flowchart of the simulator is described in Figure 3.

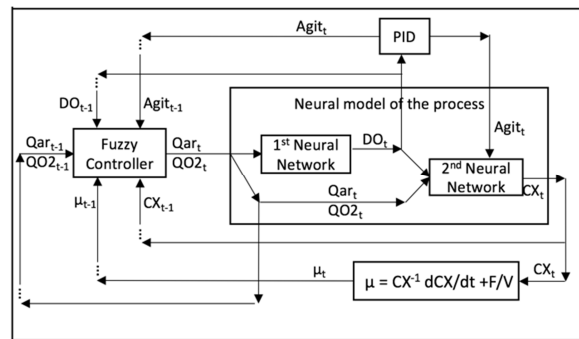

Figure 3: Flowchart of the simulator

For the purpose of this article dynamic neural networks were used, since they are more powerful than the static ones (due to the presence of memory). The neural networks were created using MATLAB Neural Network Time series application. To train the first neural network, a nonlinear input-output problem was selected. Data set was randomly divided by the application for training (70%), validation (15%) and testing (15%). The architecture chosen was one hidden layer (with 15 neurons, 4 delays and a sigmoidal activation function) and one output layer (with one neuron and a linear activation function). To train the second neural network an analogous procedure was adopted. However, in this case, a hidden layer with 4 neurons and 4 delays was employed.

E coli cultivation data sets for heterologous protein production employed in the development (through ANFIS) of the fuzzy controller and in the construction of the neural model of the process were provided by Horta (for details, see Horta, 2011).

4. Results

After parameters optimization by ANFIS and extensive training of several neural networks, the finest simulated results for air and oxygen flow rates are shown in Figures 4A and 4B, respectively. Using the fuzzy controller, it was possible to maintain the dissolved oxygen percentage near its optimum value of 30%, with almost no offset, as it is shown in Figure 4C. The dotted line represents the experimental data controlled using the original decision tree. The continuous line represents the simulated data controlled using the new fuzzy logic system (fuzzy controller).

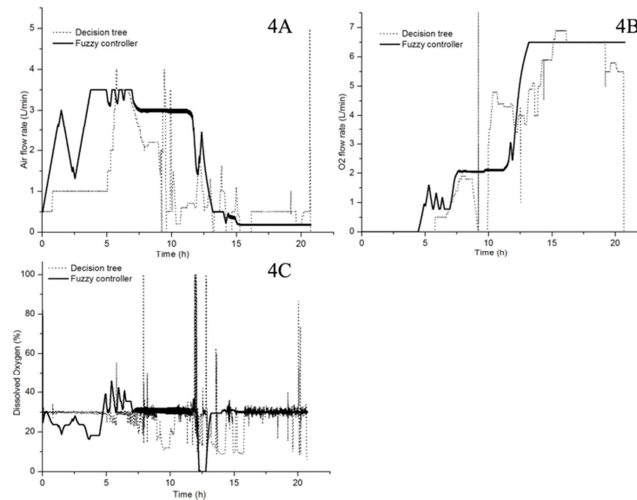

Figure 4: Results of the fuzzy controller using the simulator

The trends in air and oxygen flow rates required by the *E. coli* cultivation for heterologous protein production were followed successfully by the fuzzy controller. In general, the dissolved oxygen peaks were softened, that is, fuzzy controller responses were smoother than those provided by the decision tree. Very important to say that this smoother behaviour leads to an increase in the flow meter's lifetime, given its sensitivity to abrupt oscillations in air and oxygen flow rates.

5. Conclusions

It can be concluded that it was possible to fuzzyfy the existing decision tree/pseudocode for dissolved oxygen control. This new controller provided smoother responses than those provided by the previous one. In general, the dissolved oxygen peaks were softened, that is, the fuzzy controller responses were smoother than those provided by the decision tree. This could lead to a decrease in the metabolic stress suffered by the microorganism and consequently an increase in productivity, given its sensitivity to abrupt oscillations in dissolved oxygen percentage during the cultivation.

Abstract

At the edge of the manufacturing of crude-oil distillates into refined final products, the production scheduling and distribution gap can be reduced by optimizing production rundown switches of dispositions of distillates in a mixed-integer linear model (MILP) considering discrete time-steps of days, shifts or hours for a delivery horizon of weeks or months. From the process network down to the product distribution side, there are definitions on the assignments and amounts of distillates to be dispatched downstream for further process- and blend-shops considering diverse tank farms and nodes for the distribution. However, such integration of the refining process and tank storage systems can become intractable for industrial-sized problems with complex scheduling configurations considering time-varying rundown supply rates, product demands and pricing. For this, we propose to model the dispositions of distillates using unit-operations as modes of transportation from the distillation sources to the tanks of process-shops and blend-shops for downstream processing and blending before the primary distribution. Additionally, by solving with pooling (groups of tanks) first then post-solve to depool by disaggregating the pooled solution, the determination of the distillate dispositions to tank assignments is facilitated given that scaling to industrial-sized cases without tank aggregation is complicated as highlighted in the examples. Better prediction of the operations scheduling by using small discrete time-steps within a planning horizon allows opportunities for exploring the contract and spot market plays of the finished products.

Keywords: crude-oil distillates, product scheduling, rundown switches, depooling.

1. Introduction

In the process industries with a wide variety of different quality feeds and products, especially in oil-refining and petro-chemicals manufacturing, the high-performance and complex refining of crude-oils into products can be achieved, for example, considering integrated approaches of the following subsystems: a) raw material or feed procurement, shipping, unloading, storage, dieting and charging, b) combined operations of process-

shops and blend-shops, c) management of intermediate and final product inventories, d) sales and distribution of refined products.

From the monthly and weekly procurement planning cycle up to the daily and hourly production scheduling from crude-oils to distilled products or distillates, an enterprise-wide optimization (EWO) strategy can feedback decisions from a lower to an upper level for a new search of a solution, updating lower level results as targets and reducing time-grids in upper level re-optimizations (Menezes et al., 2017). However, there are many challenges to develop such an EWO approach from the scheduling of product to the primary distribution management that typically evolves from time-steps of an hour, shift, day to those found in planning considering weeks, months and quarters.

First, to efficiently maintain the production for downstream process units, tanks or any modes of transport, a wide scheduling optimization shall determine production rundown switches in days, shifts or hours (small-buckets) for a delivery horizon of weeks or months (big-buckets), yielding models with hundreds or thousands of time-periods. Therefore, despite the quality and nonlinear aspects in the production network, which in turn can still be modified in downstream process-shops and blend-shops, a logistics optimization primarily must find the dispatching routes or dispositions of the distillates using a mixed-integer linear (MILP) model. This quantity and logic programming involves variables of networked amounts of flows and holdups, assignment of dispatching routes modeled as modes of operations, constraints for running-gauge and standing-gauge tanks of intermediate and final inventories, operations of blend-shops, multiproduct liftings via multiple mode of transport such as trucks, pipelines, ships, rails, etc.

Second, the complex scope of the MILP logistics optimization for disposition of distillates may count on simplifications to be solvable. We address the use of a depooling heuristic to facilitate the scaling to industrial-sized cases. Pooling and depooling is shown to help manage the temporal and structural degeneracy and symmetry of stocking and dispatching the intermediate tanks with distillates. Logistics pooling or group of tanks to depooling of individual ones is determined in a post-optimization step and sometimes referred to in industry as tank rotation, swinging or round-robin. The assignment of each disposition to the multiple tanks of the pooled group is performed before the processing and blending operations are executed. If an infeasibility occurs in the depooling sub-problem, then a modification to the filling (stocking) and/or drawing (dispatching) side of the tank flows can be made and the pooled problem re-run.

By solving such complicated logistics problem with a discrete time-step of around hours for a month as the time horizon, makes the production-distribution business more competitive since both fixed contracts and variable spot markets of feeds and products compete and complement each other. It maintains the balance between sustainability and profitability, the former via long-term contracts and the latter relying on short-term opportunities in the spot markets. Finally, we highlight examples varying the topology (unpooled vs. pooled) for some distillate inventories. They are solved for 1, 2 and 4 hours as time-step using the best MILP solvers in the market considering both feasibility and optimality as their focus since there is a balance between finding new feasible solutions and proving that the current solution is optimal. Although we expect a faster first solution in the feasibility focus, the optimality one maybe faster overall as seen in the examples.

2. Scheduling and primary distribution of products

In the logistics mixed-integer linear programming (MILP) problem (P), the objective function (1) maximizes the gross margin of product revenues considering the production scheduling and distribution network represented in Figure 1, which is constructed in the unit-operation-port-state superstructure (UOPSS) formulation (Kelly, 2005; Zyngier and Kelly, 2012). The UOPSS objects are: a) unit-operations m for sources and sinks of perimeters (\diamond), tanks (\triangle) and continuous-processes (\boxtimes) and b) the connectivity or routes involving arrows (\rightarrow), in-port-states i (\circ) and out-port-states j (\otimes). Unit-operations and arrows have binary and continuous variables (y and x , respectively).

The semi-continuous constraints in Eq. (2) control the networked quantity-flows for the connections $x_{j,i,t}$, the throughputs or charge-sizes of the unit-operations $x_{m,t}$ (except tanks) and tank holdups, inventory levels or lot-sizes $xh_{m,t}$, where x_t and y_t are generic continuous and binary variables. Eq (3) imposes that the sum of the connected arrows arriving in the inlet-ports i (or mixers) of unit-operation m ($m \notin M_{TK}$) are bounded by their throughputs (flows). Similarly, in Eq. (4) the sum of the arrows leaving from the outlet-ports j (or splitters) of m ($m \notin M_{TK}$) must be between bounds of their throughputs. The quantity balance of inventory or holdup for unit-operations of tanks ($m \in M_{TK}$) in Eq. (5) considers initial inventories $xh_{m,t-1}$ and inlet and outlet streams of the tanks. Eq. (6) is a material balance in blenders M_{BL} to assure that there is no accumulation of material in these types of units. In Eq. (7), for all physical units, at most one unit-operation m (as $y_{m,t}$ for procedures, modes, dispositions or tasks) is permitted in U at a time t . The remaining logistics calculations can be found in Kelly et al. (2017). Unit-operations m for tanks, blenders, and products belong, respectively, to the sets M_{TK} , M_{BL} , and M_P . The port-states j' and i'' represent upstream and downstream ports connected, respectively, to the in-port-states i and out-port-states j of unit-operations m . For $x \in \mathbb{R}^+$ and $y \in \{0,1\}$:

$$(P) \text{ Max } Z = \sum_t \sum_{m \in M_P} \text{price}_{m,t} x_{m,t} \quad (1)$$

$$\bar{x}_t^L y_t \leq x_t \leq \bar{x}_t^U y_t \quad \forall t \quad (2)$$

$$\frac{1}{\bar{x}_{m,t}^U} \sum_{j'} x_{j',i,t} \leq y_{m,t} \leq \frac{1}{\bar{x}_{m,t}^L} \sum_{j'} x_{j',i,t} \quad \forall i, m, t \quad (3)$$

$$\frac{1}{\bar{x}_{m,t}^U} \sum_{i''} x_{j,i'',t} \leq y_{m,t} \leq \frac{1}{\bar{x}_{m,t}^L} \sum_{i''} x_{j,i'',t} \quad \forall j, m, t \quad (4)$$

$$xh_{m,t} = xh_{m,t-1} + \sum_{j'} x_{j',i,t} - \sum_{i''} x_{j,i'',t} \quad \forall m \in M_{TK}, t \quad (5)$$

$$\sum_i \sum_{j'} x_{j',i,t} = \sum_{i''} x_{j,i'',t} \quad \forall m \in M_{BL}, t \quad (6)$$

$$\sum_{m \in U} y_{m,t} \leq 1 \quad \forall t \quad (7)$$

The flowsheet in Figure 1 shows an example of a typical crude-oil refinery network for the production and distribution of medium to heavy final fuels considering given amounts of distillates produced in two crude-oil distillation units CDU1 and CDU2. The distilled kerosene (KERO), light gasoil (LGO) and heavy gasoil (HGO) streams can be dispatched to feed tanks for processing in units such as hydrotreaters, dryers, blenders or directly to a finishing tank for commercialization. The transport of products considers pipelines, trucks, ships, rails and other local market deliveries to supply the multiple consumers under precise product demands.

Figure 1. Medium to heavy distillates: production and distribution scheduling flowsheet.

In Figure 1, DHT-JET and DHT-GO represent the same physical hydrotreater DHT with JET (Jet Fuel) and GO (Gasoil) as modes of operation. VHT is a hydrotreating unit for HGO, the dryers of light and heavy HGO are the units DRYER and DRYER2 and the blender of HGO is the unit GOBLEND. The dispositions of the distillates in Figure 1 show: a single mode for KERO from CDU1, 3 modes of operations for CDU2-KERO and LGO from both CDU1 and CDU2 towers and HGO from both CDU1 and CDU2 with 4 modes. Transformations in DHT and VHT are disregarded, although a reduction on the yields of the medium distillates are expected by the secondary carbon chain cracking and the replacement of heteroatoms and metals by hydrogen. Both T2 and T3 in Figure 1 are pooled tanks with 5 and 2 aggregated tanks, respectively.

3. Dispositions and depooling of networked amounts or allocations

Figure 1 shows the dispositions of the distillates as modes of operations for KERO, LGO and HGO streams. However, to avoid degeneracy and symmetry among the assignments of the dispositions to their possible connected tanks, a *pooled* problem can be solved first and the disposed amounts of the distillates can be considered as sources (e.g., CDU1-LGO) in a *depooling* step of the downstream processing unit-operations (e.g., DHT-GO), as seen in Figure 2 for 5 physical tanks in the depooling of T2. Additional constraints to the depooling are related to multi-use of the source and sink ports, fill-draw delays and switching-when-full, switching-when-empty, etc. (Zyngier and Kelly, 2009).

Figure 2. Depooling sub-network for tank T2 in Figure 1.

4. Examples

The example in Figure 1 is performed in the structural-based UOPSS framework found in the semantic-oriented modeling and solving platform *IMPL* (Industrial Modeling and Programming Language) from Industrial Algorithms Limited using Intel Core i7 machine at 3.70 GHz (in 8 threads) with 64GB of RAM. The logistics optimization for the proposed MILP in a time-horizon of 31 days with 1, 2 and 4 hours as time-step is solved using the latest version of CPLEX (v 12.71) and GUROBI (v 7.5.1). As seen in Table 1, the fastest solution for 1h time-step without pooling or aggregation of the tanks T2 and T3 (the unpooled problem) is optimized with GUROBI in about one half of an hour where its pooled problem is solved in around 2 minutes. For the pooled cases, the post-optimized sub-problems for depooling of T2 and T3 are solved within seconds with no infeasibilities. The depooling problem of T2 (Figure 2) has (in thousands) 13.6 equations and 8.2 continuous and 7.4 binary variables.

Table 1. Statistics of the problems for 1, 2 and 4 hours as time-step (at 1% MILP gap).

Topology	Focus	CPU (min)			GUROBI			Equations (in thousands)	Continuous/ Binary Variables for 1h
		CPLEX 1h	2h	4h	1h	2h	4h		
unpooled	feasibility	333.3	65.4	23.9	33.5	23.0	1.2	380.3	125.0 / 112.9
	optimality	785.3	190.0	32.2	29.1	18.5	1.0		
pooled	feasibility	60.7	18.6	4.1	4.3	2.8	0.7	304.7	107.6 / 85.8
	optimality	35.3	112.4	0.8	1.7	2.0	0.4		

Figure 3 shows the dispositions of the CDU1-HGO considering the possible destinations.

Figure 3. CDU1-HGO dispositions throughout the network.

5. Conclusions

A wide scope and scale for mapping of flows and holdups of intermediate and final products are determined in our proposed logistics optimization for the oil-refinery production- and demand-chains specific to distillates. This can potentially guide operational and marketing / sales teams to explore both contract and spot market opportunities on a day-by-day business basis taking advantage of a short-term hourly production-based scheduling solution within a planning perspective. At the edge of the modeling and solving capabilities, the aggregation, grouping or pooling of tanks and its disaggregation or depooling into individual and detailed tank assignments, has been shown to significantly reduce the computing time without any or limited loss in the accuracy of the scheduling results.

Abstract

The energy system in the iron and steel industry significantly contributes to the large energy consumption and emissions of CO₂ and some air pollutants such as SO₂ and NO_x. Therefore, optimization of the energy system is highly desired in order to reduce energy consumption and those emissions. In this paper, a multi-objective multi-period planning model is developed for optimization of the energy system in an iron and steel plant, incorporating some important practical features such as fuel selection, gasholder level control, minimum heating requirements for single and mixed consuming users and ramp rate limits. The objective is to minimize the economic cost and environmental impact simultaneously. To solve the multi-objective optimization model, a new improved multi-objective particle swarm optimization algorithm is proposed, incorporating self-adaptive mutation and effective constraint handling strategies. The results demonstrate the superiority of the proposed approach to solve the multi-objective optimization problem.

Keywords: multi-objective optimization, environmental impact, integrated energy system, improved multi-objective particle swarm, iron and steel

1. Introduction

The iron and steel industry is one of the largest energy consumers and emission sources of CO₂ and some air pollutants such as SO₂ and NO_x, accounting for about 18% of total industry final energy consumption and about 7% of the total CO₂ emissions in the world. The energy system in the iron and steel plant significantly contributes to the large energy consumption and those emissions. Therefore, optimization of the energy system is highly desired in order to reduce energy consumption and emissions of CO₂ and air pollutants.

The energy system in a typical iron and steel plant is illustrated in Figure 1, which is usually integrated with the production system. Optimization of such energy system involves simultaneous optimization of byproduct gases, steam and electricity distributions in production units, fuel boilers, steam turbines, combined heat and power units and waste heat and energy recovery units, which is not trivial. Generation rates of byproduct gases and demands of byproduct gases, steam and electricity from production units vary from time to time, increasing complexity. Decisions on burner switches in a

boiler and electricity purchase or sale make a combinatorial problem. With strict environmental regulations, environmental impact should be minimized simultaneously with economic indicators, resulting in a multi-objective optimization problem.

Many efforts have been made on planning and scheduling of production processes, such as steelmaking and continuous casting process (Li et al., 2012) and steelmaking continuous casting-hot rolling process (Tang et al., 2016) without considering energy optimization. Very few contributions related to optimization of the energy system in an iron and steel plant have been reported (Junior et al., 2016). They mainly focused on optimal supply of byproduct gases in gasholders and boilers. Zeng et al. (2018) developed a multi-period mixed-integer linear programming model for simultaneous optimization of byproduct gases, steam and electricity distributions. All of them mainly involve minimization of the economic impact of the energy system without considering the environmental impact.

In this paper, we develop a multi-objective multi-period planning model for the integrated energy system in an iron and steel plant. Some important practical features such as fuel selection, gasholder level control, minimum heating requirements for single and mixed consuming users and ramp rate limits are also incorporated into the model. The objective is to minimize the economic cost and environmental impact simultaneously. The environmental impact is assessed in terms of the release cost of the emissions including CO_2 , SO_2 , and NO_x . To solve the developed multi-objective optimization model, a new improved multi-objective particle swarm optimization (MOPSO) algorithm is proposed, incorporating self-adaptive mutation and effective constraint handling strategies. The results demonstrate that the proposed approach successfully solves the multi-objective optimization problem and obtains better solutions than actual operation. Compared with the single objective optimization, the proposed approach can generate nondominated solutions which span well over the entire Pareto optimal front surface.

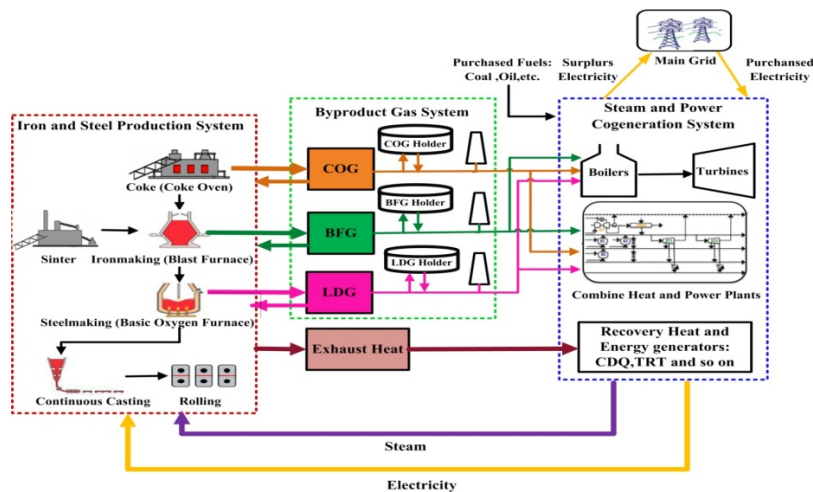

Figure 1 Integrated energy system in a typical iron and steel plant

2. Problem statement

Figure 1 illustrates the integrated energy system in a typical iron and steel plant. There are G ($g = 1, 2, \dots, G$) byproduct gas holders, I ($i = 1, 2, \dots, I$) fuel boilers, J ($j = 1, 2, \dots, J$) steam turbines, K ($k = 1, 2, \dots, K$) CHP units, M ($M = 1, 2, \dots, M$) waste heat and energy recovery units and U ($u = 1, 2, \dots, U$) production units. There are also D ($d = 1, 2, \dots, D$) pollutants including CO₂. **Given:** 1) Data of byproduct gas holders, fuel boilers, steam turbines, CHP units and waste heat and energy recovery units; 2) generation rate profiles of byproduct gases and demand profiles of byproduct gases, steam and electricity of production units; 3) economic and environmental data of the energy system; 4) planning horizon. **Determine:** 1) selection of byproduct gases, coal, and natural gas in boilers; 2) optimal byproduct gas distribution among production units, boilers, and CHP units; 3) inventory profiles of gasholders; 4) power generation plan; 5) operational plan for boiler burners. **Assumptions:** 1) all parameters are deterministic; 2) byproduct gas generation are piecewise constant; 3) demands of byproduct gases, steam, and electricity in production units are piecewise constant; 4) startups and shutdowns are not involved. More details can be referred to Zeng et al. (2018).

3. Mathematical formulation

The planning horizon is divided into T periods ($t = 1, 2, \dots, T$) based on the piecewise constant generation rate and demand profiles of byproduct gases, steam and electricity. The length of each period t is denoted as τ_t .

3.1. Objective functions

The economic objective is the minimization of total operating cost denoted as EOC , which is the same as that in Zeng et al. (2018).

$$EOC = C_{fuel} + C_{electricity} + C_{Penalty_1} + C_{Penalty_2} + C_{Penalty_3} + C_{Penalty_4} + C_{maintenance} \quad (1)$$

The environmental impact is assessed in terms of the release cost of emissions including CO₂ and some air pollutants such as SO₂ and NO_x, which is denoted as EVC .

$$EVC = \sum_{t=1}^T EV_d \cdot PE_{d,t} \cdot \tau_t \quad (2)$$

where, EV_d is environmental value for pollutant d , $PE_{d,t}$ is the emission amount of pollutant d in period t .

3.2. Pollutant emission calculation

The amount of CO₂, SO₂ and NO_x released can be calculated as:

$$PE_{CO_2,t} = 1.964 \times 10^{-6} \times \sum_g R_{g,t} \alpha_{CO_2}^g + 1.964 \times 10^{-6} \times \sum_g R_{g,t} (\alpha_{CO}^g + \alpha_{CO_2}^g + \alpha_{CH_4}^g) + 3.667 \times \sum_{i=1}^I F_{i,t}^{coal} \beta_C^{coal} \gamma_{CO_2}^{coal} + 3.667 \times \sum_{i=1}^I F_{i,t}^{oil} \beta_C^{oil} \gamma_{CO_2}^{oil} \quad (3)$$

$$PE_{SO_2,t} = 2 \times 0.8 \times \sum_{i=1}^I F_{i,t}^{coal} \beta_S^{coal} (1 - \eta_S^{coal}) + 2 \times \sum_{i=1}^I F_{i,t}^{oil} \beta_S^{oil} (1 - \eta_S^{oil}) \quad (4)$$

$$PE_{NO_x,t} = 1.63 \times \sum_{i=1}^I F_{i,t}^{oil} (\beta_N^{oil} \gamma_N^{oil} + 0.000938) \quad (5)$$

where, α_{CO} , α_{CO_2} , and α_{CH_4} are volume fraction of CO, CO₂ and CH₄ in the byproduct gas, respectively; β_C , β_S and β_N are mass fraction of carbon, sulfur and nitrogen in the fossil fuel, respectively; γ_{CO_2} is the conversion rate of carbon to CO₂; η_s is desulfurization efficiency; γ_N is the conversion rate of nitrogen to nitrogen oxides.

3.3. Pollutant emission limits

$$PE_{d,i} \leq LEM_d \quad (6)$$

where LEM_d is maximum emissions of pollutant d .

3.4. Other constraints

The other constraints include energy balance for byproduct gas, steam and power, operational constraint of gasholders and boiler burners, ramp rate limits of power generation units, and byproduct gas constraints for production units. These constraints can also be found in Zeng et al. (2018).

4. Improved multi-objective particle swarm optimization algorithm

An improved multi-objective particle swarm optimization (IMOPSO) is proposed for solving the proposed model by combining the classical MOPSO with time variant parameters, a self-adaptive mutation operator and effective constraint handling strategies.

(1) Time variant parameters

Time variant parameters are adopted to help the algorithm explore the search space more efficiently. The inertia weight w and acceleration coefficient c_1 are allowed to decrease linearly with iteration, while acceleration coefficient c_2 is allowed to increase linearly with iteration from $c_{2,min}$ to $c_{2,max}$.

(2) Self-adaptive mutation

To enhance the diversity of nondominated solutions, a self-adaptive mutation strategy is introduced to IMOPSO by incorporating two different mutation operators below,

$$x_{mutant,1}(k) = x_k(k) + Y \cdot [x_{r_1}(k) - x_{r_2}(k)] + (1 - Y) \cdot [x_{r_3}(k) - x_{r_4}(k)] \quad (10)$$

$$x_{mutant,2}(k) = x_k(k) \cdot [1 + gaussian(\sigma)] \quad (11)$$

where, r_1 , r_2 , r_3 and r_4 are random integers distributed uniformly between 1 and the population size. $r_1 \neq r_2 \neq r_3 \neq r_4$; Y is a uniform random number within [0, 1]; $gaussian(\sigma)$ is a Gaussian distributed random number with mean of 0 and a variance of σ .

After all velocities and positions of the particles have been updated, the above operators are used to generate two temporary positions for each particle based on the original positions. The better one between the original position and the temporary position is accepted as the next generation position of the particle.

(3) Constraints handling

The most popular way to handle constraints is to impose penalties for violated constraints. However, it requires a careful fine tuning of the penalty factors in order to approach the feasible region efficiently. In this work, we adopt multiple powerful

constraint handling strategies which can bias the optimization toward the feasible region without enforcing any restrictions. A heuristic strategy based on priority is used to handle energy balance constraints and a feasibility-based selection technique is employed to deal with inequality constraints. Details of these strategies can be referred to Zeng and Sum (2014).

5. Computational results

We use the proposed model and Improved MOPSO algorithm to solve three industrial examples from an iron and steel plant in China. All data can be found in Zeng et al. (2018). The planning horizon is 24 hours, which is divided into 12 intervals with sampling rate of 2 hours based on energy demand profiles. Examples 1-2 have single objectives. While Example 1 involves minimization of the operating cost, Example 2 is to minimize environmental cost only. Example 3 is to minimize economic cost and environmental impact simultaneously.

Figure 2 depicts a Pareto-optimal front for Example 3 from the proposed improved MOPSO approach. The Pareto optimal solution set including 20 nondominated solutions is generated in a single run. It can be observed that a high reduction in the economic cost is gained when passing from the left extreme C (minimum environmental cost) to point B than when passing from point B to the right extreme A (minimum operating cost). This means that passing from solution C to B provides a small increment in the environmental cost but produces a high decrease in the operating cost.

Figure 2 Pareto-optimal front for Example 3 from the proposed approach

Table 1 gives a detailed comparison for Examples 1-3 and actual operation. The results show that both the operating cost and environmental impact for Examples 1-3 are reduced compared to the actual operation. It is also can be observed that the results from the proposed approach are almost identical to those with single objective optimization. This demonstrates the effectiveness of the proposed improved MOPSO for solving the multi-objective problem as the best solution of each objective along with a set of nondominated solutions can be obtained in a single run.

6. Conclusions

In this paper, a multi-objective multi-period MILP model was developed for optimal distribution of byproduct gas, electricity and steam in an iron and steel plant. The objective is to minimize total operating cost and environmental impact simultaneously. A new improved MOPSO algorithm was proposed for solving the proposed model. The results demonstrated that the proposed approach successfully solved the multi-objective optimization problem and obtained better solutions than actual operation. Compared with the single objective optimization, the proposed approach can generate nondominated solutions which span well over the entire Pareto optimal front surface.

Table 1 Comparative results for Examples 1-3 and actual operation

	Actual operation	Proposed Approach		Single objective optimization	
		Minimize EOC	Minimize EVC	Minimize EOC	Minimize EVC
EOC (¥)	5,802,752	5,548,557	10,078,123	5,544,182	9,772,964
EVC (¥)	1,138,382	1,029,659	855,723	1,032,942	858,457
CO ₂ (t)	4,861	4,161	3,455	4,175	3,466
SO ₂ (t)	49.62	45.94	38.24	46.09	38.36
NO _x (t)	90.84	82.28	68.35	82.55	68.56

Dynamic process simulation based process malfunction analysis

Alex Kummer, Tamás Varga

Department of process engineering, University of Pannonia, H-8200 Veszprém, Hungary

kummera@fmt.uni-pannon.hu

Abstract

With improving industrial chemical technologies the Hazard and Operability Analysis (HAZOP) or other safety analysis becomes more difficult to perform, because the technologies become more integrated and complex. Applying dynamic HAZOP can help the experts to explore all hazard situations in a technology based on dynamic process simulation. In this work a framework for exploring hazard events is suggested to support the safety analysis. The proposed framework works via OPC (Open Platform Communication) connection between MATLAB and Aspen HYSYS dynamic process simulator. Concentration of cumene-hydroperoxide (CHP) in vacuum column is chosen as a case study to show how the framework can be applied to analyze process safety related situations. The hazard events are generated through controller failures with significant changes in setpoints for a specific time. The events can be ranked based on the consequences, which can be significant in different perspectives. The most important is to analyze the temperature and pressure trajectories during the event, although the required time and energy to reach the normal conditions again can be evaluated too. All these parameters are considered in the qualification and ranking process of each investigated process malfunction.

Keywords: HYSYS-MATLAB connection, controller failure, consequence matrix, dynamic HAZOP, safety analysis

1. Introduction

A chemical process often uses operating conditions (temperature, pressure) that may represent a risk, and may lead to deviations that can generate hazardous events. Plant equipment, including pumps, compressors, and control equipment may fail too in spite of the correct maintenance policy. Possibility of human error is present in chemical industry, because operators can make mistakes which may lead to a hazard situation. Finally, chemicals by themselves may be toxic, flammable and/or explosive. All of these elements, and their interactions constitute process safety (Stoessel 2008).

Risk identification is essential for ensuring acceptable safe operation of a process (Berdouzi et al. 2017). In literature, there are several definition of risk, Aven and Renn proposed 9 general risk definitions, like expected value loss, probability of an undesirable event, uncertainty of outcome, or combination of probability and consequence (Villa et al. 2016). The most often used risk definition is the measure of the probability and severity of adverse effects. Risk can be calculated for different hazard scenarios, like cooling water loss, pump failure, etc. Hazard scenarios are

determined using Process Hazard Analysis (PHA) methods. The most commonly used PHA method is Hazard and Operability (HAZOP) study (Baybutt 2015). Basically, HAZOP study is a qualitative method, but without knowing the system behavior during malfunctions, a completely reliable safety study cannot be performed. Applying dynamic process simulators (DPS) can reveal the effects of different malfunctions, and the evolution of variables can be analyzed.

Many simulations of chemical processes can be found in literature related to process safety analysis. Eizenberg examined the possible deviations at the oxidation of 2-octanol and determined practical safety threshold values (Eizenberg, Shacham, and Brauner 2006). Wende Tian proposed DynSim-HAZOP using Aspen Dynamics, and based on the developed DPS, next to the well-defined deviations (high feed temperature, low feed flow, etc.), it is able to quantitatively analyze the out of control incidents too (clogged valve, pipeline leakage, scale formation, etc.) (Tian, Du, and Mu 2015).

In this work the analysis of vacuum distillation column is chosen to investigate different process malfunctions. The examined process unit is applied in an internal step in phenol production technology. The cumene-hydroperoxide (CHP) route to phenol was developed by Hercules and BP Chemicals. Almost all produced phenol is from synthetic processes. Nowadays worldwide phenol production is based on this technology. The simulator of vacuum distillation column is built in Aspen HYSYS.

An Open Platform Communication (OPC) is built between MATLAB and Aspen HYSYS. Therefore, data from dynamic simulator can be evaluated easily in MATLAB, and consequence matrix can be calculated. Quantifying the severity of consequences is important in hazard analysis, DPS based consequence matrix can give more precise and valuable information about the possible operation malfunctions. Values of consequence are determined for different process malfunctions based on a dynamic process simulator.

2. Methodology to assess consequence

Fatine Berdouzi suggested a methodology to quantify and decrease the risk of operation (Berdouzi et al. 2017). Their consequence identification method is extended with taking into account the energy consumption, and the time of malfunction. First of all, thermokinetic and thermal stability data are required in order to characterize the system. Besides that, a detailed description of the process is necessary to get information about the process units, control strategies, operating conditions and about the dynamic characteristics of the system. Reliable safety study cannot be done without knowing the process in detail. Second of all, based on a qualitative HAZOP analysis the crucial scenarios need to be simulated. Simulation results allow quantifying the effects of malfunctions according to temperature and pressure amplitude, malfunction duration, and energy consumption. Luyben suggests different levels of safety constraints and actions for reactor safety analysis (Luyben 2012). In our case, the suggested threshold values are presented in consequence matrix (Table 1), where *AH* means high alarm value, *op* means operating value, t_{PS} and t_{mf} mean plant start (or unit) and malfunction duration, *des* means design parameter, *set* stands for Pressure Safety Valve set pressure. C_{AEC} and C_{MD} constants are applied to define the threshold values of average energy (AEC) consumption and malfunction duration (MD).

Table 1 Consequence matrix

CI	Pressure	Temperature	Average energy consumption (AEC)	Malfunction duration (MD)
0	$P_{op} < P_{AH}$	$T_{op} < T_{AH}$	$Q_{op} < c_{AEC1} Q_{op}$	$t_{mf} < c_{MD1} t_{PS}$
1	$P_{AH} < P_{op} < P_{set}$	$T_{AH} < T_{op} < T_{des}$	$c_{AEC1} Q_{op} < Q_{op} < c_{AEC2} Q_{op}$	$c_{MD1} t_{PS} < t_{mf} < c_{MD2} t_{PS}$
2	$P_{set} < P_{op} < P_{des}$	-	$c_{AEC2} Q_{op} < Q_{op} < c_{AEC3} Q_{op}$	$c_{MD2} t_{PS} < t_{mf} < c_{MD3} t_{PS}$
3	$P_{des} < P_{op}$	$T_{des} < T_{op}$	$c_{AEC3} Q_{op} < Q_{op}$	$c_{MD3} t_{PS} < t_{mf}$

An override condition is applied in defining the consequence index of average energy consumption and malfunction duration. If the operating pressure or temperature exceed the design parameter, then the average energy consumption (AEC) and malfunction duration (MD) consequence index (CI) automatically becomes three.

$$IF P_{des} < P_{op} \text{ or } T_{des} < T_{op} \text{ THEN } CI_{AEC} = 3 \text{ and } CI_{MD} = 3$$

The “0” CI index value refers the lowest severity, and the “3” CI index refers the highest severity in risk calculation.

3. Case study

The first step in phenol production is oxidation of cumene to cumene-hydroperoxide (CHP) with 25-30% conversion. Phenol comes from cleavage of CHP, but in the previous step the diluted CHP has to be concentrated. The concentration of CHP (to ~60w%) is done in vacuum distillation column, where the bottom product is the concentrated CHP, and cumene comes as a distillate. The developed process simulator of vacuum distillation column is shown in Figure 1. DPS include hydrodynamics and hydrostatic calculations, therefore it helps to develop an adequate simulator of the process unit.

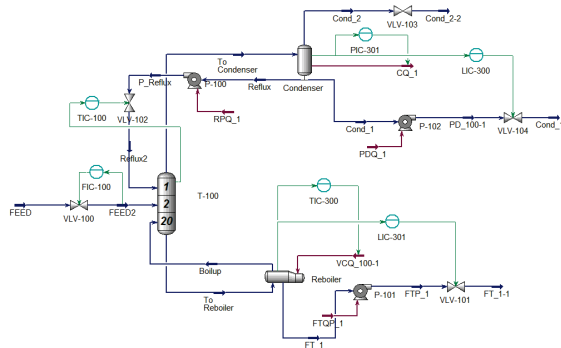

Figure 1 Process simulator of vacuum distillation column

The operation of T-100 vacuum column is controlled by tuned PI controllers. Tuning is done by Aspen HYSYS Autotuner module. FIC-100 controls the flow rate of feed cumene-CHP mixture. LIC-300 and LIC-301 controls the level in the reflux drum and reboiler by opening the outlet valve. The temperature of reboiler is controlled by TIC-300 controller. TIC-100 controls the tray temperature by reflux flow rate. The pressure of condensate tank is controlled via PIC-301 by cooling the condensate tank with cooling water.

4. Consequence assessment

Seven process malfunctions are chosen to test the suggested consequence quantification and corresponding consequences are analyzed. Five controller failure are simulated, where the setpoint of controllers are increased by twenty percent for two minutes. Beside controller failures, reflux pump failure and lack of cooling water are simulated too, both of them lasted two minutes. Every malfunction occurs at the start of the third minute. The trajectories of some important state variables as a result of malfunctions can be seen in Figure 2-3.

Figure 2 Pressure and temperature trajectories due to process malfunctions (FIC-100 failure: red, PIC-301 failure: green, TIC-100 failure: cyan, LIC-300 failure: magenta, TIC-300 failure: yellow, , lack of cooling water (CW): blue, P-100 reflux pump failure: black)

Figure 3 Energy consumption trajectories due to process malfunctions (FIC-100 failure: red, PIC-301 failure: green, TIC-100 failure: cyan, LIC-300 failure: magenta, TIC-300 failure: yellow, , lack of cooling water (CW): blue, P-100 reflux pump failure: black)

The trajectories are analyzed according to the described method (in methodology section), and the consequence indexes are calculated. The threshold values are listed in Table 2. Threshold values are defined for this case, and for every other case it should be

checked based on a DPS of the investigated system. Last two columns are the value of constant parameters from Table 1.

Table 2 Threshold values in consequence matrix calculation

	Pressure [kPa]	Temperature in reflux drum [°C]	Temperature in reboiler [°C]		AEC [-]	MD [-]
Alarm HIGH	32	116	158	$c_{AEC1-CMD1}$	0.005	0.05
Set pressure	110	-	-	$c_{AEC2-CMD2}$	0.01	0.1
Design parameter	120	140	200	$c_{AEC3-CMD3}$	0.05	0.5

Table 3 shows the critical values during process malfunctions. Maximum pressure in the reflux drum, maximum temperature in reflux drum and in reboiler, AEC for returning the system into normal operating conditions, and the required time to return into normal operating point can be seen.

Table 3 Critic values for calculation of consequence matrix

	P_{max} [kPa]	$T_{max\ reflux}$ [°C]	$T_{max\ reb}$ [°C]	AEC [kW]	MD [h]
FIC-100 failure	31.37	114.80	154.04	8.26	0.67
PIC-301 failure	33.30	115.13	154.12	27.57	0.95
TIC-100 failure	34.69	121.43	154.28	27.07	1.09
LIC-300 failure	30.76	114.17	154.02	10.32	0.59
TIC-300 failure	32.06	114.76	161.37	24.06	0.54
lack of CW	39.03	118.94	154.22	48.23	0.71
P-100 failure	31.99	121.89	154.24	-4.78	0.60

Table 4 Consequence matrix of T-100 malfunctions

	CI_p	CI_T	CI_o	CI_t	$\sum CI$
FIC-100 failure	0	0	0	2	2
PIC-301 failure	1	0	2	2	5
TIC-100 failure	1	1	2	2	6
LIC-300 failure	0	0	1	2	3
TIC-300 failure	1	1	2	2	6
lack of CW	1	1	2	2	6
P-100 failure	0	1	0	2	3

Table 4 shows the result of consequence analysis. Under CI_p and CI_T columns the value "1" means the analyzed process malfunctions does not cause any dangerous situation, although it indicates alarm sign. However, the analyzed process malfunctions cause higher energy consumption, and it takes relatively long time to get the operating unit back to normal operating condition. The sum of consequence indexes can be used in risk calculation as severity.

$$Risk = \sum CI \cdot Probability \quad (1)$$

5. Conclusions

In this work, a quantitative definition of process malfunction consequences is suggested. Dynamic process simulators are helpful in identifying hazard events, and relevant information can be collected about the evolution of variables during process malfunctions. Aspen HYSYS is used to analyze several process malfunction of vacuum distillation column. MATLAB and Aspen HYSYS are connected via OPC to evaluate the gained data. DPS allows the quantification of consequences. Consequence matrix includes the effect on pressure, temperature, average energy consumption and malfunction time duration. The operation malfunctions can be ranked based on the consequence matrix. In our case TIC-300, TIC-100 controller failure and the lack of cooling water has the highest severity, therefore these malfunctions need higher attention during unit operation. Severity is included in consequence matrix, therefore the risk can be defined using consequence matrix.

Virtual inflow estimation with simplified tuning using cascaded and Kalman-like least squares observers

Christoph Josef Backi^{a,*} and Sigurd Skogestad^a

^a*Department of Chemical Engineering, Norwegian University of Science and Technology (NTNU), NO-7491 Trondheim, Norway*
christoph.backi@ntnu.no

Abstract

Multiphase metering is often unavailable, unreliable or expensive, which makes model-based, virtual monitoring a cheap and reliable alternative in order to obtain information about e.g. the inflows to a device. This paper presents an approach for inflow estimation to a gravity separator based on a standard Extended Kalman Filter. Potential improvements include a cascaded structure, a Kalman-like least squares observer with forgetting factor, and a combination of these.

Keywords: Virtual metering, estimation, observer design, gravity separator, oil and gas

1. Introduction

Gravity separators are used in the oil- and gas-industry for bulk separation of gas, water and hydrocarbons (oil and condensate). Further purification is achieved in downstream equipment such as hydrocyclones, gas scrubbers, gas flotation units or membranes. Backi and Skogestad (2017a) introduced a simple model for gravity separators based on first principles. A schematic of the model is presented on the left side in Figure 1, where the multiphase stream enters the inlet zone, flows through the active separation zone (length L) and leaves in the outlet zone.

Figure 1: Schematics of the separator (left) and the droplet evolution in the active separation zone (right)

The model regards the in- and outflow dynamics of a multiphase stream consisting of oil, gas and water. Furthermore, the model incorporates static droplet calculations primarily based on *Stokes' law*, which gives vertical velocities for a droplet size class dispersed in a continuous phase. These

vertical velocities of droplets are compared to the droplets' horizontal velocity as they move along the separator and ultimately give the volume of separated droplets (the ones that reach the oil-water-interface). A schematic of the droplet evolution is presented on the right-hand side in Figure 1. For now, we do neither consider coalescence and breakage nor a dense-packed (emulsion) layer between the water- and oil-continuous phases.

It is desired to obtain as much information about the separator conditions as possible. For example, quantifying the inflows of gas and liquid to the separator and consequently also to the downstream equipment is advantageous regarding optimal operation and, in case of severe slugging events, to launch counter-measures. Multiphase metering, however, is often not applicable, too expensive or unreliable and thus the exact composition of the inlet stream to the gravity separator might be unknown. Therefore, dynamic model-based monitoring and estimation can be a reliable and cheap solution to determine these inflows (Backi and Skogestad, 2017b).

The remainder of the paper is structured as follows: Section 2 introduces the mathematical model, whereas Section 3 provides the methodology behind the observer designs. The results are presented in Section 4, while the paper is concluded in Section 5.

2. Mathematical Model

The three dynamic state variables in the original model (Backi and Skogestad, 2017a) are the total liquid level h_L , the water level h_W and the gas pressure p . This model serves as plant in the simulations. For the observer model, the state equations are augmented by quasi-stationary equations for the two inflows $q_{L,in}$ and $q_{G,in}$, which act as disturbances, as well as the effective split ratio γ , which defines the split of oil and water entering the water-continuous phase:

$$\frac{d\hat{h}_L}{dt} = \hat{f}_1 = \frac{\hat{q}_{L,in} - q_{W,out} - q_{O,out}}{2L\sqrt{\hat{h}_L}(2r - \hat{h}_L)}, \quad \frac{d\hat{q}_{L,in}}{dt} = \hat{f}_4 = 0, \quad (1)$$

$$\frac{d\hat{h}_W}{dt} = \hat{f}_2 = \frac{\hat{q}_{L,in}\hat{\gamma} - q_{W,out}}{2L\sqrt{\hat{h}_W}(2r - \hat{h}_W)}, \quad \frac{d\hat{q}_{G,in}}{dt} = \hat{f}_5 = 0, \quad (2)$$

$$\frac{d\hat{p}}{dt} = \hat{f}_3 = \frac{RT\frac{\rho_G}{M_G}(\hat{q}_{G,in} - q_{G,out}) + \hat{p}(\hat{q}_{L,in} - q_{L,out})}{V_{Sep} - \hat{V}_L}, \quad \frac{d\hat{\gamma}}{dt} = \hat{f}_6 = 0, \quad (3)$$

where r denotes the radius of the separator, L indicates the length of the active separation zone, $\mathbf{u} = [q_{W,out} \ q_{O,out} \ q_{G,out}]^T$ is the vector of manipulated variables (outflows of continuous water, oil and gas phases, respectively), universal gas constant R , gas temperature T , gas density ρ_G and molar gas mass M_G . Furthermore, V_{Sep} indicates the volume of the active separation zone and the estimated liquid volume is given as

$$\hat{V}_L = \frac{r^2L}{2} \left[2\cos^{-1}\left(\frac{r - \hat{h}_L}{r}\right) - \sin\left(2\cos^{-1}\left(\frac{r - \hat{h}_L}{r}\right)\right) \right].$$

The state vector of estimates can be written as $\hat{\mathbf{x}} = [\hat{h}_L \ \hat{h}_W \ \hat{p} \ \hat{q}_{L,in} \ \hat{q}_{G,in} \ \hat{\gamma}]^T$ whose first three states are assumed measurable. Hence, the output matrix is $\mathbf{y} = \mathbf{C}\hat{\mathbf{x}}$ with $\mathbf{C} = [\mathbf{I}_3 \ \mathbf{0}_{(3 \times 3)}]$, where \mathbf{I}_3 denotes an identity matrix of size 3 and $\mathbf{0}_{(3 \times 3)}$ indicates a matrix of zeros of size 3×3 . Note that in simulations the pressure differential equation is scaled to the unit bar.

3. Methods

We design an observer that estimates the inflows of liquid and gas to the separator as well as the effective split ratio in the water-continuous phase. The inflows constitute disturbances to the process

and hence an observer should be able to track these fluctuations. In Backi and Skogestad (2017b), an Extended Kalman Filter (EKF) in its standard continuous-time formulation was designed and implemented for the given estimation task providing full observability.

For the EKF design, the well-known differential Matrix-Riccati-Equation (DMRE) is solved in order to obtain the time-varying Kalman feedback gain $\mathbf{K}(t)$

$$\frac{d\mathbf{P}(t)}{dt} = \mathbf{A}(t)\mathbf{P}(t) + \mathbf{P}(t)\mathbf{A}^T(t) - \mathbf{K}(t)\mathbf{C}\mathbf{P}(t) + \mathbf{Q}, \quad \mathbf{K}(t) = \mathbf{P}(t)\mathbf{C}^T\mathbf{R}^{-1}, \quad (4)$$

where $\mathbf{P}(t)_{(6 \times 6)}$ is the state covariance matrix, $\mathbf{A}(t)_{(6 \times 6)} = \frac{\partial \hat{\mathbf{f}}(\hat{\mathbf{x}}, \mathbf{u})}{\partial \hat{\mathbf{x}}}$ denotes the time-varying Jacobian of (1)–(3), $\mathbf{Q}_{(6 \times 6)}$ and $\mathbf{R}_{(3 \times 3)}$ are the process and measurement noise covariance matrices.

3.1. Alternative observer design

An alternative, simple and practical observer design with potentially improved performance can be a Kalman-like least squares observer (KF-like LSO) with forgetting factor, as introduced in its discrete-time formulation in Johnstone et al. (1982) and further developments by Hammouri and De Leon Morales (1990) as well as Haring (2016), who introduced a continuous-time formulation.

In its deterministic sense, the Kalman Filter is a least-squares observer and hence the KF-like LSO is closely related to the EKF. In fact, the only difference between the two observer designs is found in the way the DRME is calculated, which looks as follows for the KF-like LSO

$$\frac{d\mathbf{P}(t)}{dt} = \mathbf{A}(t)\mathbf{P}(t) + \mathbf{P}(t)\mathbf{A}^T(t) - \mathbf{K}(t)\mathbf{C}\mathbf{P}(t) + \lambda\mathbf{P}(t), \quad \mathbf{K}(t) = \lambda\mathbf{P}(t)\mathbf{C}^T\mathbf{R}^{-1}, \quad (5)$$

where λ is the scalar forgetting factor.

The implementation of the observer design (5) can be advantageous compared to the EKF since the tuning procedure is simpler. Instead of tuning the process covariance matrix $\mathbf{Q}_{(6 \times 6)}$, which typically is a diagonal matrix with 6 tuning parameters, now only the scalar λ has to be defined, in addition to the measurement noise covariance matrix $\mathbf{R}_{(3 \times 3)}$.

3.2. Cascaded observer design

Investigating the structure of the model (1)–(3), it can be seen that the two equations (1) can be decoupled from the remaining equations, since estimation of $\hat{q}_{L,in}$ can be solely achieved by using (1) in 'Observer 1'. Consequently, the estimates of \hat{h}_L and $\hat{q}_{L,in}$ can be utilized in a cascaded structure as inputs to 'Observer 2', which includes the remaining four equations in (2) and (3).

A schematic of this cascaded structure is shown in Figure 2. By implementing the cascaded design,

Figure 2: Schematic of the cascaded observer design in combination with the plant model

the tuning procedure for (5) gains one tuning variable, since now two observers instead of one are designed, each with a tuning variable λ .

The cascaded structure can not only be advantageous for the observer design (5), but the decoupling into two observers also has benefits when tuning the standard EKF (4). The original matrix $\mathbf{Q}_{(6 \times 6)}$ gets split up into two matrices $\mathbf{Q}_{1,(2 \times 2)}$ and $\mathbf{Q}_{2,(4 \times 4)}$, for which the tunings can be chosen more easily since there is less coupling between the single entries.

3.3. PI controller

The three state variables h_L , h_W and p are controlled by simple PI controllers, which rely solely on the estimated state variables. The controllers have the form $K(s) = K_p \left(1 + \frac{1}{\tau_I s}\right)$ and have been tuned by applying the SIMC tuning rules (Skogestad, 2003). The parameters K_p and τ_I as well as the tuning variable τ_c are shown in Table 1.

Table 1: Parameters for the three PI controllers

	τ_c	K_p	τ_I
water level	5 s	6.49	20 s
liquid level	5 s	5.063	20 s
pressure	5 s	0.0541	20 s

The rates of change for controller action are limited to $\pm 0.05 \text{ m}^3 \text{ s}^{-2}$ and the respective outputs are bounded between 0 and $1 \text{ m}^3 \text{ s}^{-1}$, respectively.

4. Results

In this Section, we present simulation results for the cascaded KF-like LSO and compare its performance to the EKF, both for cascaded and standard formulations. The simulation parameters can be found in Backi and Skogestad (2017a,b), but the tuning parameters for the observers will be presented. To render the simulations more realistic, we added white noise to all measurements, to the state derivatives in the plant model (process noise) and to the nominal inflows $q_{L,in}$ and $q_{G,in}$. These have been implemented in MATLAB Simulink as band-limited white noise processes with a noise power of 10^{-1} , sample time 0.1 s and a seed of [23341].

4.1. EKF

Here, we present results for the EKF both in standard and cascaded formulations. Figure 3 shows the results for the standard EKF design, whereas the simulations for the cascaded EKF design are presented in Figure 4 for direct comparison. The estimation of the measurable state variables do not differ for both cases, however, there is a clear improvement for the cascaded structure in terms of estimating the liquid inflow. A slight drawback is the noisier estimation of the split factor $\hat{\gamma}$. It must be noted that the split factor cannot reach its nominal value since the static droplet calculations are included in the plant model, but not in the observer model, hence a plant-model-mismatch is the consequence.

The observer parameters have been chosen as $\mathbf{Q} = \text{diag} [10^{-2} \ 10^{-1} \ 10^4 \ 10^1 \ 10^0 \ 10^0]$ and $\mathbf{R} = \text{diag} [10^0 \ 10^0 \ 10^4]$ for the standard EKF and $\mathbf{Q}_1 = \text{diag} [10^0 \ 10^1]$, $\mathbf{R}_1 = 10^1$ as well as $\mathbf{Q}_2 = \text{diag} [10^{-2} \ 10^4 \ 10^0 \ 10^0]$ and $\mathbf{R}_2 = \text{diag} [10^{-1} \ 10^4]$ for the cascaded design.

4.2. KF-like LSO

This Section presents results for the KF-like LSO for both the standard implementation and the cascaded structure in Figures 5 and 6, respectively. It can be seen that the overall estimation

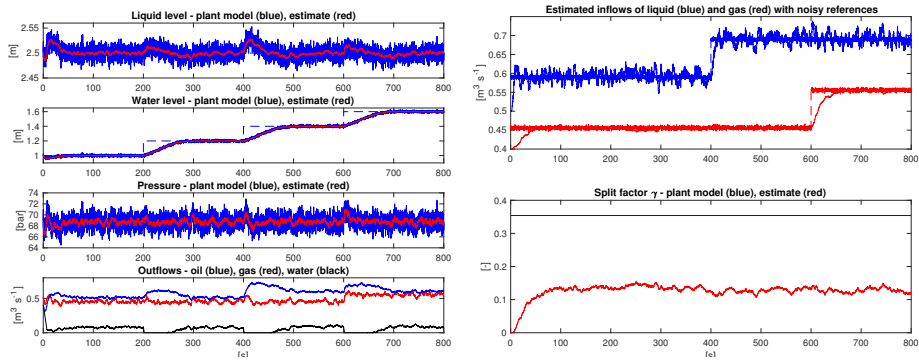

Figure 3: Results for the EKF in standard form: Measurable state variables, their estimates and manipulated variables on the left, disturbance variables and their estimates on the right

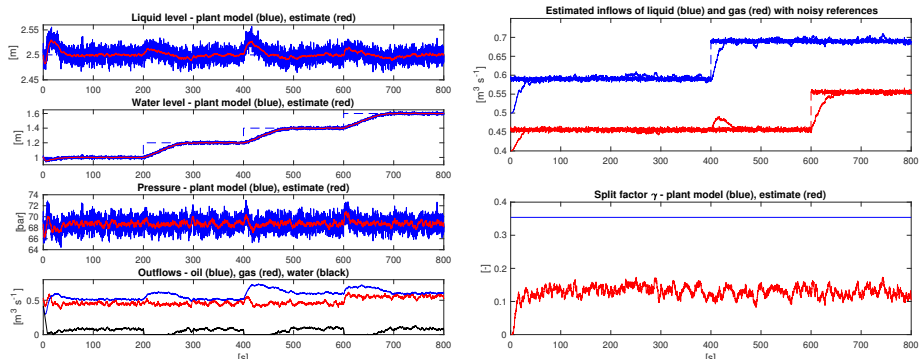

Figure 4: Results for the EKF in cascaded form: Same order of plots and signals as before

performance is much better compared to the EKF in the previous example. What is remarkable is that the cascaded structure in Figure 6 shows slightly worse performance compared to the standard structure in Figure 5, especially when comparing the estimate for the gas inflow after $t = 400$ s. This phenomenon, however, can also be seen in the EKF and might be caused by some delay introduced by the cascaded structure.

The observer parameters have been chosen to be $\lambda = 10^{-1}$ and $R = \text{diag} [10^0 \quad 10^0 \quad 10^4]$ for the standard formulation and $\lambda_1 = 10^{-1}$, $R_1 = 10^1$ as well as $\lambda_2 = 10^{-1}$ and $R_2 = \text{diag} [10^{-1} \quad 10^2]$ for the cascaded structure.

5. Discussion

In this paper, we presented observer designs for virtual inflow monitoring in gravity separation devices with simplified tuning procedures. We demonstrated in simulations that the KF-like LSO, compared to the EKF, performs generally better despite its simpler tuning. The cascaded structure clearly has a positive influence on the estimate of the liquid inflow for the EKF, but does not improve the overall performance of the KF-like LSO. The simpler tuning of the KF-like LSO makes it superior to the EKF, at least for the presented application, where a better noise suppression is the consequence.

Generalization of the results to virtual flow metering in other applications is not automatically

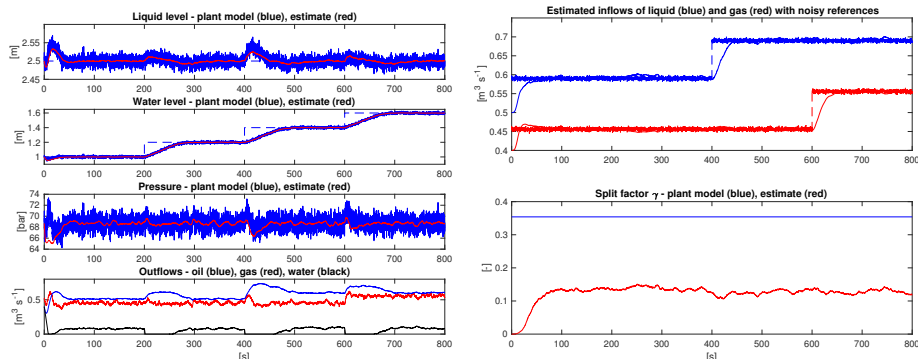

Figure 5: Results for the KF-like LSO in standard form: Same order of plots and signals as before

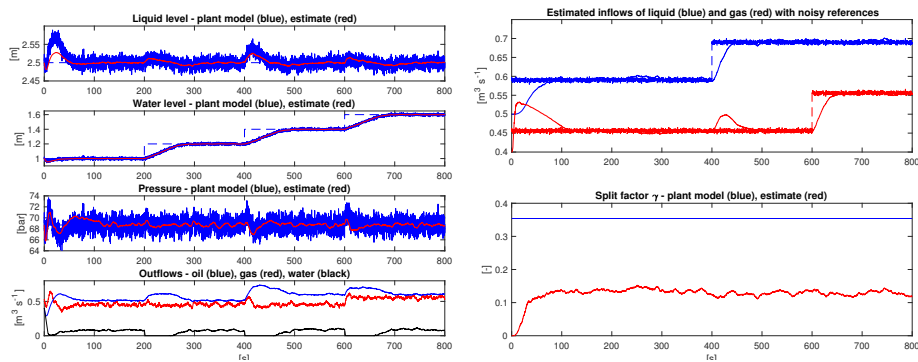

Figure 6: Results for the KF-like LSO in cascaded form: Same order of plots and signals as before

implied. The presented observer designs are based on a process model together with available measurements, which might be substantially different for other applications.

Smarter process engineering across the plant life-cycle: CAPE 4.0 in industrial practice

David Elixmann*, Michael Imle, Markus Feist, Rolf-Dieter Becher

BASF SE, Carl-Bosch-Straße 38, 67056 Ludwigshafen/Rhein, Germany

david.elixmann@basf.com

Abstract

Digital trends in industry 4.0 are rapidly moving towards comprehensive connectivity and higher transparency in all manufacturing processes. It is expected that “process engineering 4.0” will turn data into value for chemical companies by increasing efficiency throughout the plant life-cycle. By improving efficiency in design and planning processes, by helping plant operators and engineers to better understand and operate their processes, and by reducing the effort required for “high end” CAPE techniques. These are dynamic simulation, operator training simulation, and real time optimization. First examples are soft sensors that enable operators to understand and optimize the process in real time based on simulations of dedicated equipment, as towers or heat exchangers.

Keywords: process operations, operator support system, process design & optimization, industry 4.0, Process industry

1. Introduction

“Data is the new oil” is the paradigm for an information industry that regards today’s data flows as a resource much like oil: Immensely useful for a plethora of new applications, and immensely valuable for those who control its sources and know how to process it into products and services. (cf. Simon and de Prato, 2015)

BASF’s own 4.0 initiatives in the field of computer-aided process engineering focus on the fields of predictive maintenance, supply chain optimization on the “Verbund” level, and engineering data management. They are expected to have a high impact on process simulation, plant design, process control and automation. It is expected that “process engineering 4.0” will turn data into value for BASF by increasing efficiency throughout the plant life-cycle:

Modern CAPE software with better mathematical solvers, improved user interfaces and better access to engineering databanks are expected to reduce the effort required for modelling and simulation activities in plant design. (cf. Marquardt 1996)

The integration of real-time plant data interfaces within process simulation tools is expected to significantly reduce the effort required to deploy process simulation models as online advisory tools. This will make it easier for process engineers to provide simulation consultancy and advice to plant operators, enabling them to better understand and operate their plants.

The simplification of process simulation work flows and the improved accessibility of equation-oriented modelling techniques is expected to make “high-level” CAPE techniques such as dynamic simulation and real-time optimization (RTO) sufficiently accessible to no longer require highly trained specialists, but young professionals with only a few years of process modelling experience. This would let young professionals quickly learn and apply these techniques on their own, greatly reducing the effort to create and maintain applications based on these techniques. (cf. Elixmann et al. 2014; Engl et al. 2010; Müller et al. 2017)

Key to these expectations is the concept of the “virtual plant” which embodies the idea of fully digitally supported engineering, operation and maintenance. The virtual plant is the digital representation of a real or planned chemical plant’s process behaviour, its control system configuration, the three-dimensional arrangement of its mechanical and electric equipment, its piping system, and its civil engineering structure.

BASF’s engineering & maintenance unit is investigating lighthouse projects to test whether these expectations are justified. There is a high willingness to invest into tools and training, should these lighthouse projects identify potential added value for the company’s process engineering discipline.

2. Results and discussion

An initial lighthouse project centres on soft sensors for heat exchanger fouling coefficients. Besides of this, foaming factors in absorption columns, supersaturation in absorption columns, and infrequently measured product concentrations in distillation units can be predicted and used as soft sensor (Burdorf et al. 2017; Imle et al. 2014). The modelling concepts behind these applications are not new, and have been taught to engineering students for decades (cf. Klatt and Marquardt 2007). However, the deployment and maintenance of such applications has in the past been regarded as too time consuming to allow these to become a routine activity. Experiences at BASF indicate that this is no longer the case, and that these applications can be justified on relatively small project budgets, or even as “side products” of conventional debottlenecking projects.

Other lighthouse projects involve the set-up of dynamic process simulation models in advance of plant modification projects and distributed control system (DCS) migration projects, and the conversion of process simulation models built for plant design projects into predictive process models for RTO projects. In the past, dynamic simulation models or predictive RTO models have only rarely been developed within BASF’s process engineering unit, since the effort to train engineers in the highly specialized tools for these complex modelling tasks could not be economically justified. There are indications that newer process simulation software and better deployment tools may change this situation, enabling a much higher degree of in-house development or preparation of such process models.

3. Outlook

It is possible that within a short time the assessment of software tool capabilities may change drastically from “It’s too complex for anyone but a specialist” to “Maybe we can actually train young professionals on these tools without putting them on a track to become expert specialists”.

If this were to change, demands on process engineers’ skills and methods could be expected to change substantially. To take advantage of more capable CAPE tools and plant data interfaces, process engineers must possess skills that at present are not considered to be critical in chemical engineering education.

Process engineers on “virtual plant” projects must develop a deeper understanding of their chemical plants. To develop practical CAPE 4.0 solutions, they must work with plant dynamics, process control, plant hydraulics, and measurement technology. They need to understand the chemistry and thermodynamics of their plants not just at the plants’ design conditions, but also under transient conditions, to build a predictive process model. This goes beyond the level of understanding required for a conventional steady-state process design task.

Their process models must robustly simulate plant behaviour not just at steady-state design conditions, but also across a wide range of plant operating conditions. Simulated equipment conditions must match actual observed operating conditions with higher accuracy than required for the original equipment design. Heat exchanger models must be able to accurately predict outlet temperatures and heat loads depending on inlet temperatures and process flow rates. Compressor models need to be extended to include performance curves across the expected operating range of the compressor unit.

Since these and other, similar requirements generally make the simulation models more complex and less robust, process engineers involved in “CAPE 4.0” projects must also become familiar with previously little used simulation techniques and rarely considered technical aspects of their simulation models. Troubleshooting a complex, equation-oriented steady-state simulation intended for a real-time online application requires that the engineer understands certain mathematical concepts such over/under-specification of equation systems, and diagnosing ill-posedness of process models (a frequent problem when on-line process models are automatically parameterized with plant data). Troubleshooting a dynamic process simulation requires some knowledge of the different ways in which a differential-algebraic equation system can become unsolvable.

Lastly, there is the challenge of interdisciplinary environments. “CAPE 4.0” projects will involve not just process engineers who develop sophisticated models, but also plant managers and operators who are the custodians of process know-how, and automation engineers who deploy those process simulation models as part of advanced process control systems. There exists at present only a fuzzily delineated division of work between process modelling experts and automation experts, because both roles are usually staffed with people from similar education backgrounds. The plant manager and operators, on the other hand, may often have no prior experience with simulation methods at all. It is very important that capabilities and limitations of the CAPE tools are clearly communicated at the beginning of these projects.

Some young process engineers who are now graduating from universities already possess deeper modelling and simulation know-how than past generations. Nevertheless, we see that there is still a skill gap between the requirements of the

“CAPE 4.0” working environment, and the skills that universities teach their chemical engineering students. Because CAPE teams are frequently the entry points and initial training environment for young graduates, a personnel turnover in CAPE teams of 50% within 5 years is not uncommon. Furthermore, internal demand for engineering skills within chemical corporations tends to place a higher emphasis on training young professionals well-rounded engineering skills rather than training them to a high degree of specialization in CAPE techniques. This implies that young professionals will only have a limited time available for learning the above mentioned “CAPE 4.0” skills on the job, if they were not acquired at university. We foresee a high demand from the chemical industry for engineers with strong foundations in systems engineering, process dynamics and control engineering.

We call on university educators who are now teaching the next generation of process engineers to place emphasis on these skills which are the key to interdisciplinary understanding and problem solving problem-solving skills in the field of CAPE 4.0.

4. Conclusions

Virtual plant based workflow and methods are only getting started now. There are great possibilities once their feasibility is proven, and the best ways to deploy state of the art software have been identified.

Soft sensor methods are already at the point where such applications can easily be developed by individual process engineers using state of the art process simulation software. Demand for dynamic simulations and RTO applications can be expected to take off rapidly once expectations for easier model development are realized.

Education of future process engineers is key to enable wider spread of high end “CAPE 4.0” methods.

Abstract

Parallel production lines are a design option often used in chemical batch plants. In recent research, this option has been introduced into the strategic multiproduct batch plant design problem, assuming a single product campaign mode of operation. However, to accommodate for other modes of operation and different production strategies, more explicit scheduling should be considered. In this paper, the combined design and scheduling optimization of multiple lines multistage plants is addressed. More specifically, we explored the Resource-Task Network formulation, in which constraints were included to exploit the sequential characteristics of the problem under study. Furthermore, two solution approaches were studied: a general holistic one and, triggered by the rapid increase in problem size and computational expense, a decomposition approach. In this decomposition approach, the problem is divided into smaller subproblems, by fixing the number of lines, which are iteratively solved. The performance of both approaches are compared via several illustrative examples.

Keywords: design and scheduling, batch plants, parallel lines, Resource-Task Network

1. Introduction

The strategic design of chemical batch plants is a challenging research problem that has been studied extensively in the past decades. Over the years, the design models have been extended with strategic choices on e.g. different modes of operation and several design options (Barbosa-Póvoa, 2007). Recently, Verbiest et al. (2017) introduced parallel production lines, as a new design option, into the multiproduct multistage batch plant design problem. The aim of the corresponding MILP is to determine the optimal number of lines to install, the number and size of equipment units at every stage of every line and the assignment of products to every line, assuming a single product campaign mode of operation. However, despite the work already developed, other modes of operation and different production strategies need to be accounted for, which triggers the introduction of more explicit scheduling.

The optimization of plant design in combination with scheduling has already been explored via different methodologies, such as network formulations (Barbosa-Póvoa, 2007). These network formulations are proven to be powerful for this combined optimization, mainly for multipurpose plants (Pinto et al., 2008). However, in recent years, researchers have shown an increased interest

in applying these formulations to multiproduct multistage problems, i.e. sequential processes, as well (e.g. Castro and Grossmann (2005); Sundaramoorthy and Maravelias (2011)).

Motivated by these successful applications and the inherent flexibility of network representations (Méndez et al., 2006), this work explores the applicability of the Resource-Task Network (RTN) formulation, with discrete time representation, for the design and scheduling of multiproduct multistage batch plants with parallel lines. The RTN is a generic representation, originally formulated by Pantelides (1994), that is characterized by resources and tasks. The resources can be non-renewable resources, e.g. materials, or renewable resources, e.g. equipment units, that are produced and consumed by tasks (i.e. operations). Due to its generality, however, RTN models tend to increase fast in size, and accordingly in computational complexity (Méndez et al., 2006), so that adapted solution approaches are requested.

In the next section (Section 2), an overview of the problem considered is given together with the application of the RTN formulation. To tackle the computational complexity that is coupled with larger problems, an adapted (decomposed) solution approach is presented in Section 3. Some illustrative examples are studied in Section 4, where we compare the results of the adapted solution approach with the results obtained from solving the general (holistic) model. We end with a conclusion and some directions for future research.

2. Modeling framework

2.1. Problem characterization

The installation of parallel production lines in chemical batch plants is a design option frequently used in industry (Hill et al., 2016). These parallel lines are installed on the same production site and operate simultaneously, but independently, from one another. The lines have the same number of stages, so that production may be split over the optimal number of lines installed (see Figure 1). The presence of such parallel lines often allows for a reduction in total cost as not all products have to share all equipment any more, leading to smaller equipment and lower operating costs. Furthermore, products with similar characteristics are often grouped into product families and the dedication of these lines to particular products or product families may again reduce total operating costs by avoiding high contamination costs (Verbiest et al., 2017).

Within this setting, the aim of the problem is to determine:

- The optimal design of the plant. This encompasses the number of lines to install and, for every installed line, the number and size of units for every stage.
- The optimal schedule of the plant. This includes the product-to-line assignment, the number and size of batches of every product on every line and the corresponding timings and sequences of the batches on every line.

so as to minimize investment and operating costs.

2.2. Mathematical representation

The problem under study considers a multistage multiple lines batch plant producing P products i over ST stages st , where every stage performs a batch operation. There is the possibility to install at most L lines l with the same number of stages ST . The demand for every product and the total horizon are known upfront. A more detailed description is given in Verbiest et al. (2017).

In the RTN formulation of this plant, the sets considered are: (1) non-renewable resources r that represent the raw materials, intermediate states and finished products (the latter are equal to number of products P); (2) renewable resources j which are all the equipment units installed in every stage st of every line l and, finally, (3) tasks k that represent an operation in stage st of line l needed to produce product i . Every task k is characterized by a pair of variables: an integer variable N_{kt}

and a continuous one ξ_{kt} . These variables can be interpreted, respectively, as the number of units used by task k at time t and the total amount of material processed by these tasks (i.e. batch sizes). Moreover, every task has a fixed processing time (τ_k) and is linked to a unit j with a utilization factor (ϕ_{kj}), comparable to size factors defined in Verbiest et al. (2017).

Figure 1 illustrates an RTN representation of a batch process to produce one product (FP1). This process consists of 3 stages and at most 3 lines are allowed to be installed. The RTN requires 8 non-renewable resources r , 9 renewable resources j and 9 tasks k . Finally, the task-to-unit relation is shown as well

Figure 1: RTN representation of a batch multiple lines plant, producing 1 product

The main assumptions considered are: (1) Process/recipes are determined upfront; (2) Deterministic demand and process parameters, with the demand fulfilment for every product a hard constraint; (3) Only batch processing equipment is considered, with known unit-task compatibility; (4) Zero-wait policy between batch stages; (5) No batch splitting or mixing is allowed; (6) Identical parallel batch equipment per unit j , at most Δ^{max} , operating in-phase and used by one task at a time; (7) Discrete set of S equipment sizes V_s for all renewable resources j to choose from.

The objective of the developed MILP is to minimize the total cost, given by:

$$\sum_j \left(CCf_j \Delta_j + \sum_s V_s^{CCv_j} z_{js} \right) + \sum_k \sum_t N_{kt} CO_k \tag{1}$$

The first term are the capital costs that consist of a fixed component and a volume dependent component. The cost coefficients CCf_j, CCv_j are given, with $CCv_j < 1$ and equal costs for units j belonging to the same stage st . Δ_j is an integer variable indicating the number of identical units installed of resource j . The size choice of every unit is defined by V_s , the equipment size s chosen out of the given set, and the binary variable z_{js} that indicates if unit j has size s . The second term represents the operating cost, with CO_k being a known task-dependent cost coefficient and N_{kt} the integer variable that defines the number of units used by task k at time t .

As products in multistage multiple lines plants, once assigned to lines, go sequentially through all the stages of that line, batch preservation has to be guaranteed and constraints (2) and (3) are included in comparison to general (multipurpose) network models.

$$\xi_{kt} = \xi_{k'(t+\tau_k)} \quad \forall t, k, k' \text{ with } k' \text{ the task performed in the next stage after } k \tag{2}$$

This constraint enforces the batch integrity over the process, and states that if a task k at time t was executed, then exactly τ_k later, the task k' on the following stage of the same line will start and will have the same continuous extent.

An analogous constraint (Eq.(3)) is posed on the integer extent of the task (N_{kt}). However, it is an inequality since the units used by every task may differ from stage to stage because of possible differences in the units installed in every stage of a line.

$$N_{kt} \leq \Delta^{max} N_{k'(t+\tau_k)} \quad \forall t, k, k' \text{ with } k' \text{ the task performed in the next stage after } k \tag{3}$$

The remaining constraints are taken from the general RTN-model (see (Pantelides, 1994)), hence they will not be discussed. The two solution approaches studied use the mathematical representation presented above, with the holistic approach solving this model as it is using the Gurobi 7.0

solver. The adaptations made in the decomposition approach are discussed in the next section.

3. Decomposition solution approach

Since in the RTN formulation of the multistage multiple lines design problem the number of tasks and states increase very fast, the problem as such becomes difficult to solve in a reasonable computation time. In order to tackle the computational complexity, we propose a decomposition solution approach in which the holistic problem is divided into smaller problems, which are iteratively solved. The decomposition is done by fixing the number of lines, as this decision has a high impact on the model size (for every line l , for every product i , st numbers of tasks have to be specified). The procedure contains the following steps:

Step 1 Set the number of lines (NumbLin) equal to 1 and include a very large upper bound (UB) on the objective function

Step 2 Solve the subproblem (min. *TotalCost*, with a fixed NumbLin) using RTN with the extra constraint $UB > TotalCost$.

If the subproblem is infeasible - stop calculation and go directly to Step 4

Step 3 Update upper bound: $UB = TotalCost$

Step 4 If $NumbLin < L$, increase NumbLin with 1 and go back to Step 2.

The expected gains of this approach in comparison to solving the general holistic model are 3-fold: Firstly, at every iteration, the models considered are smaller in size, and thus, easier to solve. This can be illustrated on Figure 1: when solving a fixed 1 line model, we only have to consider 3 tasks, 4 non-renewable resources and 3 renewable resources, instead of respectively 9, 8 and 9. Secondly, after every iteration, the best solution found so far is updated and included as an upper bound in the next iteration. With this extra constraint, it might be unnecessary to solve all L models as worse solutions would make the calculations stop. Finally, as in every model the number of lines is fixed, the following constraint, existent in the original model, can be modified:

$$\sum_s z_{js} \leq 1 \quad \forall j \quad \rightarrow \quad \sum_s z_{js} = 1 \quad \forall j \quad (4)$$

and an additional constraint can be included:

$$\Delta_j \geq 1 \quad \forall j \quad (5)$$

With these constraints, the model is forced to install at least 1 unit of every renewable resource and to choose exactly 1 size out of the set of sizes. So, we limit the search possibilities given to the model.

4. Examples

To illustrate the performance of the proposed decomposition approach (Case a) and its comparison with the holistic formulation (Case b), three examples are used.

4.1. Process description

The processes can be described as chemical batch plants in which the demand for a certain number of products, belonging to certain product families, needs to be fulfilled within a predefined planning horizon. In order to produce these products, different operations (stages) are needed. For every stage a maximum number of identical units are operating in-phase and sizes are chosen out of a given set. Furthermore, the number of lines that can be installed on the production sites is limited. Table 1 gives a summary of the production data for every example, whereas the cost coefficients are given in Table 2. Note that capital costs are identical for units j belonging to the same stage st and operating costs are assumed the same for all tasks per product per line.

Table 1: Main production data - 3 illustrative examples

	Products	Prod Fam.	Stages	Parallel Equipm.	Sizes	Lines	Horizon	Demand (x10 ³)						
								P1	P2	P3	P4	P5	P6	P7

Ex3	{450, 400, 380}	{0.67, 0.65, 0.60}	{50, 90, 90}; {90, 50, 65}; {90, 65, 50}			

4.2. Results

The results of the 3 examples, and the computational statistics of the 2 approaches, are shown in Table 3. The optimality gap was set to 0% and the computational time was limited to 3 h.

Table 3: Results - Case (a) Decomposition (Decomp.) vs Case (b) Holistic (Hol.) approach

	Example 1 (3 Prod., 4 Stages, max.4 lines - H15)				Example 2 (7 Prod., 3 Stages, max.3 lines - H12)				Example 3 (3Prod, 3 Stages, max.3 lines - H24)

All numerical results were obtained using the Gurobi 7.0 optimizer on an Intel(R) Core(TM) i7-4790 CPU, 3.60GHz and 16 GB of RAM

As can be seen from Table 3, the proposed decomposition approach obtained the same solutions as the holistic approach. These solutions correspond to the installation of 2 parallel lines in examples 1 and 3, and of 3 lines in example 2. However, the decomposition approach reaches the optimal solutions with a significant lower computation time. For example 1, both solution methods found the optimal solution (gap: 0%), but the decomposition approach uses only 3% of the time when compared to the holistic approach. For example 2 and 3, the holistic approach was not able to reach an optimality gap of 0% after 3h, while the decomposition approach reached the optimal solutions in 1.5h and 45min, respectively. Finally, the problem characteristics are listed in the last 3 rows. It can be seen that in the decomposition approach smaller problems are solved, leading to reduced computing times.

Due to space limitations, we will only discuss example 3 more in detail. For this case, it is optimal to install a plant that consists of 2 lines (with a capital cost of 4351 and an operating cost of 3375). It is feasible to produce all products on 1 line, however, this is more expensive: the lower capital costs of 4021 (-7.5%) do not offset the high operating costs of 5670 (+68%) that are incurred when all product(families) are produced together. Furthermore, the solution of the 2-lines model considered as an upper bound in the 3-lines model leads to an early termination of the procedure, as this extra constraint could not be satisfied.

The selected equipment units (size and number) in every stage of the 2-lines plant as well as the proposed schedule are shown in Figure 2. Product 1 is produced entirely on line 1 and product 2 on line 2. Although it is less expensive to produce product 3 in combination with product 2 (lower operating costs per task as specified in Table 2), it is not feasible to make all the batches of 3 on line 2 (without having to increase the design). Hence, it is also produced on line 1.

As the present work is an extension of the work of Verbiest et al. (2017), it is important to compare the solution found in this work with the one obtained when solving the original MILP model with

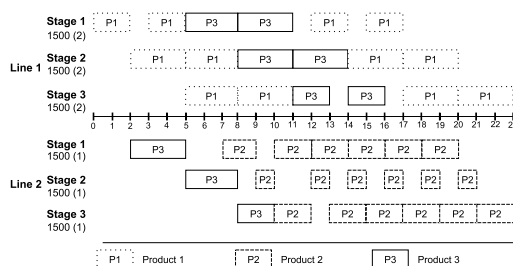

Figure 2: Optimal plant design and corresponding schedule of example 3

single product campaign mode of operation. The optimal solution found there is a 3-lines plant, instead of a 2-lines plant, that has a lower total cost. However, the proposed solution as it is, is infeasible since no detailed schedule was considered. Indeed, the total time spent on every product is based on the product cycle times, which is an underestimation. Hence, the combined design and scheduling problem results in more realistic solutions, supporting more thorough testing of the decomposition solution approach and further investigation of other adaptations in the future.

5. Conclusion

In this paper, the design and scheduling of multiproduct multistage chemical batch plants equipped with parallel production lines is investigated. More specifically, we applied the RTN formulation to solve this problem, in which some constraints that account for the sequential process were included. Besides solving the RTN model holistically, a decomposition solution approach is proposed to address the computational burden that is coupled with the rapid increase in problem sizes. In this approach, the problem is divided into smaller RTN-based subproblems, each with a fixed (incrementing) number of lines, which are solved iteratively. Three illustrative examples were solved with both approaches and it was found that the decomposition solution approach reached the optimal solutions with significantly lower computation times. Finally, the importance of simultaneously designing and scheduling batch plants is also demonstrated. As future work, further research should be carried out to explore other problem specific-adaptations and to thoroughly test the approach, so that ultimately the models can account for more responsive production strategies.

Abstract

Fault detection is becoming an important issue in fermentation processes. Any improper formulation or contamination in the fermentation may change the kinetic model parameters and lead to a process fault. In this work, a square system of parametric nonlinear algebraic equations is formulated and solved symbolically to obtain the kinetic model parameters as an explicit function of measurements, so as to estimate the parameters to detect and diagnose the faults in fermentation processes. A number of scenarios are considered to show the effectiveness of the presented approach. The proposed approach successfully estimates the model parameters and detects the faults in the system.

Keywords: Fault detection, fermentation, parameter estimation, multiparametric programming

1. Introduction

Fermentation is a process in which biomass gets converted into products such as alcohol or acid. Fermentation process is highly sensitive to small changes in operating limits that may affect the final product quality if changes happen during crucial stages of operation. Therefore the operation of fermentation must be maintained within specific limits. The process of detecting and diagnosing fault in industrial processes is thus required to be implemented in early operation to maintain the product quality and reduce production cost (Isermann, 1993; Mhaskar et al., 2006; Venkatasubramanian et al., 2003).

A number of studies have demonstrated the fault diagnosis in fermentation processes (Birol et al., 2002; Monroy et al., 2012). For glutamic acid fermentation, the diagnosis has been reported using wavelet analysis (Zhao et al., 1999; Ma et al., 2003), using extended Kalman filter and neural networks (Liu, 1999), and using support vector machines (Ma et al., 2007). However, the mentioned approaches are computationally demanding (Liu, 1999) and the diagnosis becomes difficult when more than one fault takes place simultaneously. In this work we propose a method to detect faults using multiparametric programming to address some of these issues for fermentation processes.

In our earlier work (Che Mid & Dua, 2017) a methodology based on multiparametric programming, to obtain the model parameters as an explicit function of the measurements, was presented. In that work a square system of parametric nonlinear algebraic equations was obtained by formulating optimality condition. These equations were then solved symbolically to obtain model parameters as an explicit function of measurements. In glutamic acid fermentation process (Ma et al., 2003), the state

variables are represented by the concentration of biomass, substrate and product. These state variables cannot be measured online and therefore this methodology cannot be directly applied. Therefore in this work, we present a methodology for the cases where the state variables cannot be measured but can be estimated from other measurable quantities such as pH, dissolved oxygen and temperature. By monitoring the estimated kinetic model parameters, process faults can be detected and diagnosed. The estimated kinetic model parameters should be close to observed parameters when no fault is present and any substantial discrepancy between the estimated and observed parameters indicates changes in the process and can be interpreted as a fault.

2. Fault detection using Multiparametric Programming

In fault detection, the objective is to estimate parameters, $\boldsymbol{\theta}$, such that the error, ε_{FD} , between the measurements, \hat{x}_j , and the model predicted value of state variables, x_j , is minimized as follows:

$$\varepsilon_{FD} = \min_{\boldsymbol{\theta}, \mathbf{x}(t)} \sum_{j \in J} \sum_{i \in I} \{\hat{x}_j(t_i) - x_j(t_i)\}^2 \quad (1)$$

Subject to:

$$\frac{dx_j(t)}{dt} = f_j(\mathbf{x}(t), \mathbf{u}(t), \boldsymbol{\theta}, t), j \in J \quad (2)$$

$$x_j(t=0) = x_j^0, j \in J \quad (3)$$

$$t \in [0, t_f] \quad (4)$$

where $\mathbf{x}(t)$ is the J-dimensional vector of state variable in the given ODE system, $\mathbf{u}(t)$ is the vector of control variables, and $\boldsymbol{\theta}$ is the vector of parameters. In our previous work (Che Mid & Dua, 2017), a solution technique for fault detection using multiparametric programming (MPP) to estimate the model parameters, $\boldsymbol{\theta}$, was presented. The model parameters, $\boldsymbol{\theta}$, are considered as optimization variables and the measurements, $\hat{x}_j(k+1)$, as the parameters in the context of multiparametric programming. The algorithm for model-based parameter estimation for fault detection using multiparametric programming is summarized as below (Che Mid & Dua, 2017):

(i) Discretize nonlinear ODE model in Equation (2) to algebraic equations using Euler's method and solve on the interval, $t \in [0, t_f]$ and step size, Δt , as given in Equation (5)

$$x_j(k+1) = x_j(k) + \Delta t f_j(\mathbf{x}(k), \mathbf{u}(k), \boldsymbol{\theta}) \quad (5)$$

(ii) Formulate fault detection optimization problem as a nonlinear programming (NLP) problem. For $I=1$, substituting Equation (5) in Equation (2), the fault detection problem is given as in Equations (6) to (8)

$$\varepsilon_{MPP} = \min_{\boldsymbol{\theta}, \mathbf{x}_j(k=1)} \sum_{j \in J} \{\hat{x}_j(k+1) - x_j(k+1)\}^2 \quad (6)$$

Subject to:

$$h_j = x_j(k+1) - x_j(k) - \Delta t f_j(\mathbf{x}(k), \mathbf{u}(k), \boldsymbol{\theta}) = 0, j \in J \quad (7)$$

$$x_j(k=0) = x_j^0, j \in J \quad (8)$$

where h_j represents the set of nonlinear algebraic equations obtained by discretizing the ODEs given by Equation (2) and shown in Equation (5).

(iii) Formulate Karush-Kuhn-Tucker (KKT) conditions for Equations (6) to (8) as given by Equations (9) to (12). The Lagrangian function is given by

$$L = g + \sum_{j \in J} \lambda_j h_j \quad (9)$$

$$\text{where } g = \{\hat{x}_j(k+1) - x_j(k+1)\}^2 \quad (10)$$

The KKT conditions are given by the Equality Constraints as follows

$$\nabla_{\theta} L = \nabla_{\theta} g + \nabla_{\theta_j} \sum \lambda_j h_j = 0 \quad (11)$$

$$h_j = 0 \quad (12)$$

(iv) Solve the Equality Constrains in Equations (11) and (12) of the KKT conditions parametrically to obtain Lagrange multiplies and model parameters, $\theta(\hat{x})$, as a function of measurements.

(v) Screen the solutions obtained in the previous step and ignore solutions with imaginary parts.

(vi) Calculate the estimated model parameters, θ , using the measurement, \hat{x} by simple evaluation of $\theta(\hat{x})$.

(vii) Diagnose fault by monitoring the changes of the model parameters. The estimated model parameters should be close to observed parameters when no fault is present. Any substantial discrepancy between the estimated and observed parameters indicates changes in the process and can be interpreted as a fault.

3. Fermentation Processes

The dynamic model of the glutamic acid fermentation process is as follow (Ma et al., 2003):

$$\frac{dX}{dt} = \mu X \quad (13)$$

$$\frac{dP}{dt} = bX \left(\frac{S}{K_s + S} \right) \quad (14)$$

$$\frac{dS}{dt} = -\frac{1}{Y_G} \frac{dX}{dt} - \frac{1}{Y_P} \frac{dP}{dt} - mX \quad (15)$$

where X , P and S are the concentrations of biomass, product and substrate with $X(0) = 0.03g/l$, $P(0) = 0g/l$ and $S(0) = 101.2g/l$. These state variables can not be measured on-line but can be estimated from other measurable quantities such as pH, dissolved oxygen and temperature. μ is the growth rate of the biomass and given as $\mu = \mu_m(1 - X/x_m)$. $b = 0.358h^{-1}$ is the maximum production rate, $K_s = 12.04g/l$ is the saturation constant of substrate, $Y_G = 0.436$ is the yield coefficient of biomass, $Y_P = 0.645$ is the yield coefficient of product, $m = 0.105h^{-1}$ is the maintenance coefficient of the biomass, $\mu_m = 0.767h^{-1}$ is the maximum growth rate of the biomass and $x_m = 6.43g/l$ is the maximum biomass concentration. Any improper formulation or contamination in the fermentation will change the kinetic model parameters, such as

μ_m and Y_p , and lead to a process fault (Ma et al., 2003). In this work, the kinetic model parameters, μ_m and Y_p , are obtained as explicit functions of measurements and estimated for fault detection using multiparametric programming algorithm as described in the previous section. The discrete-time fault detection problem is formulated as the nonlinear programming (NLP) problem using the discretization of ODE model as follows:

$$\varepsilon_{MPP} = \min_{\mu_m, Y_p} \sum_{k=0}^K \left\{ (\hat{X}(k+1) - X(k+1))^2 + (\hat{P}(k+1) - P(k+1))^2 + (\hat{S}(k+1) - S(k+1))^2 \right\} \quad (16)$$

Subject to:

$$h_1 = X(k+1) - X(k) - \Delta t \mu_m \left(1 - \frac{X(k)}{x_m} \right) X(k) = 0 \quad (17)$$

$$h_2 = P(k+1) - P(k) - \Delta t b X(k) \left(\frac{S(k)}{K_s + S(k)} \right) = 0 \quad (18)$$

$$h_3 = S(k+1) - S(k) - \Delta t \left(-\frac{1}{Y_G} \mu_m \left(1 - \frac{X(k)}{x_m} \right) X(k) - \frac{1}{Y_P} b X(k) \left(\frac{S(k)}{K_s + S(k)} \right) - m X(k) \right) = 0 \quad (19)$$

The Equations (17) to (19) are substituted into Equation (16) to obtain:

$$g = (\hat{X}(k+1) - (\Delta t \mu_m \left(1 - \frac{X(k)}{x_m} \right) X(k) + X(k)))^2 + (\hat{P}(k+1) - (\Delta t b X(k) \left(\frac{S(k)}{K_s + S(k)} \right) + P(k)))^2 + (\hat{S}(k+1) - (\Delta t \left(-\frac{1}{Y_G} \mu_m \left(1 - \frac{X(k)}{x_m} \right) X(k) - \frac{1}{Y_P} b X(k) \left(\frac{S(k)}{K_s + S(k)} \right) - m X(k) \right) + S(k)))^2 \quad (20)$$

The gradient of g with respect to μ_m and Y_p are given by

$$\frac{\partial g}{\partial \mu_m} = ((2X(k)(\Delta t X(k) - \Delta t x_m)(\hat{X}(k+1) + (X(k)(\Delta t \mu_m X(k) - x_m - \Delta t \mu_m x_m)) / x_m)) / \mu_m) + ((2\Delta t X(k)(1 - X(k)/x_m)(\hat{S}(k+1) - \Delta t (S(k)/\Delta t - mX(k) - (\mu_m X(k)(1 - X(k)/x_m)) / Y_G - (bS(k)X(k)) / ((K_s + S(k)) Y_P)))) / Y_G = 0 \quad (21)$$

$$\frac{\partial g}{\partial Y_p} = -(2b\Delta t S(k)X(k)(\hat{S}(k+1) - \Delta t (S(k)/\Delta t - mX(k) - (\mu_m X(k)(1 - X(k)/x_m)) / Y_G - (bS(k)X(k)) / ((K_s + S(k)) Y_P)))) / ((K_s + S) Y_P^2) = 0 \quad (22)$$

The equality constraints in Equations (21) and (22) are solved analytically in Mathematica, and the solution is given by

$$\mu_m = \frac{(X(k) - \hat{X}(k+1))x_m}{\Delta t X(k)(X(k) - x_m)} \quad (23)$$

$$Y_p = \frac{b\Delta t S(k)X(k)Y_G}{(K_s + S(k))(X(k) - \hat{X}(k+1) + S(k)Y_G - \hat{S}(k+1)Y_G - \Delta t m X(k)Y_G)} \quad (24)$$

The kinetic model parameters, μ_m and Y_p , are given by Equations (23) and (24) are obtained as explicit function of measurements and estimated by simple function evaluation.

4. Result

The whole fermentation period is of about 15 hours. In this work, the state variables X , P and S are estimated from other measurable quantities such as pH, dissolved oxygen and temperature. The kinetic model parameters values are estimated by Equations (23) and (24) for every minute sampling time for two scenarios, fault free and faulty scenarios. In fault free scenario, the measurement for X , P and S are shown in Figure 1 with noise included. The estimated kinetic model parameters, μ_m and Y_p , are shown in Figure 2. The figure shows that estimated kinetic model parameters are close to the true value and no fault was detected. In faulty scenario, the kinetic model parameters are changed as shown in Table 1 and the measurement for X , P and S for all the faults are shown in Figure 3. The estimated maximum growth rate of the biomass and yield coefficient of product are shown in Figures 4 and 5. From these figures, we can see that after 5 h, the estimated values of μ_m and Y_p change for each faulty scenario. It indicates that process fault has started occurring in the fermentation process. Fault is declared in the system after 5h.

Figure 1: State variables profile for fault free scenario

Figure 2: Estimated model parameters, μ_m and Y_p for fault free scenario

Table 1. Faulty scenario for glutamic acid fermentation

Faulty kinetic parameters	Fault 1	Fault 2	Fault 3	Fault 4
μ_m	Decrease 10 %	Increase 10 %	Decrease 15 %	Increase 15 %
Y_p	Decrease 10 %	Increase 10 %	Decrease 15 %	Increase 15 %

Figure 3: State variables profile for faulty scenarios

Figure 4: Estimated μ_m for faulty scenariosFigure 5: Estimated Y_p for faulty scenarios

5. Concluding Remarks

Parameter estimation based fault detection of fermentation processes is proposed using multiparametric programming. By monitoring the kinetic model parameters, process faults can be detected and diagnosed. In this work, a square system of parametric nonlinear algebraic equations was solved symbolically to obtain the model parameters as an explicit function of measurements. The model parameters are thus computed efficiently by performing simple function evaluations, without the need to solve an online optimization problem. This method is able to obtain model parameters as an explicit function of measurements and accurately estimate the kinetic model parameters value. The issues pertaining to fault tolerant control will be the subject of future work.

Abstract

This work investigates the application of Nonlinear Model Predictive Control (NMPC) using Hammerstein Models in an offshore oil production well with gas-lift. The problem is especially challenging from the control point of view because it presents regions with gain sign inversion. This reversion of the gain direction makes this problem difficult to control with the usual Model Predictive Control (MPC) or even with the traditional Proportional-Integral-Derivative (PID) controllers. Thus, it is proposed to investigate the use of methodologies applying NMPC based on Hammerstein model combined with the Moving Horizon Estimator (MHE) approach. The oil flow rate is controlled by the gas-lift flow rate through the gas-lift choke valve. The plant was described by a mathematical model including the gas-lift well, the flowline and the production choke valve. Some control scenarios were tested and the nonlinear model predictive controller was capable to successfully stabilize the process.

Keywords: Nonlinear Model Predictive Control, Gas-lift, Process Control, Hammerstein Model, Moving Horizon Estimator.

1. Introduction

Artificial lifting techniques were developed due to the need of extracting oil from reservoirs which do not have enough energy to push the oil from its bottom to the platform, being the gas-lift one of the most widely applied methods. It consists in adding gas to the upcoming fluid, what increases the fraction of dissolved gas and lowers the mixture density. Despite the gas-lift's advantages such as low costs and simple operation, according to Eikrem et al. (2006), the technique can be affected by severe flow oscillations due to the casing-heading instability, a phenomenon that is originated by the interaction between the injected gas and the multiphase fluid inside the tubing. Once this effect happens, it decreases average production and the oscillations generated may also damage downstream equipment.

In the related literature, many papers focus on gas-lift optimization, for instance, the work of Alarcón et al. (2002). This work introduces a function in order to model the steady state oil production flow according to the gas-lift flow.

Plucenio et al. (2009) apply an extension of the predictive control to a simulated well that operates by continuous gas injection. The control algorithm does not consider constraints and the internal model was obtained from the linearization of the system by parts along the prediction horizon. The controlled variables of the system are the pressure drop in the production tube and the wellbore pressure. While the manipulated variables are based on the reference values of the gas-lift flow controller and the reference value of the wellhead pressure controller.

Cota and Reis (2012) investigate the application of linear multivariable predictive control applied in offshore systems. The approaches were tested using multi-layer MPC to increase oil productivity and to maintain BSW (basic sediments and water) and TOG (oil and grease content) indices within a range of acceptable values. As result, it was verified that the approach based on a linear model, despite stabilizing the process, presents limitations due to the presence of nonlinearities associated to the manipulated variables.

Eikrem et al. (2006) proposed a dynamic nonlinear model of a production well to implement a simulation that aims to stabilize the oscillations by applying a PI controller. However, when considering more complex implementations and more severe conditions, a more sophisticated control strategy may be required.

The work of Miyoshi et al. (2017) analyzed a class of problems that present static gain sign inversion, leading to unreachable setpoints, and proposed the use of Hammerstein block-oriented models in a nonlinear predictive control (NMPC) whose states are previously obtained by the application of a moving horizon estimator (MHE). As the oil production well studied in this current work belongs to this class of problems, the approach proposed by Miyoshi et al. (2017) was applied to control this process.

2. Methodology

The model of the gas-lift well was based on the work of Eikrem et al. (2006), considering the adaptations suggested by Ribeiro et al. (2016), to approximate the simulation of an actual well behavior, and was implemented in MATLAB and solved with ode15s. The well is composed by an annular, through which the gas is injected, and the production tube, through which the fluid flows from the reservoir to the production choke.

As the chosen NMPC approach was based on Hammerstein internal model, after selecting the variables of interest, it was necessary to make the identification of the steady state and the dynamic models of the process subject to gas-lift changes.

Once the nonlinear steady state profile of the variables was known, the MATLAB Curve Fitting Toolbox™ was applied to fit the functions proposed by Alarcón et al. (2002), corresponding to the nonlinear block of the Hammerstein model. The quality of the fit was based on the value of R^2 .

Based on the dynamic behavior of the oil production to the step changes in the input variables, the linear dynamic model was built as a combination of two first order transfer functions in parallel, corresponding to the dynamic block of the Hammerstein model. Then, the following parameters were estimated: k_1 , k_2 , τ_1 and τ_2 , solving a least-square problem with the Nelder–Mead optimization method.

The MHE was implemented based on Rao and Rawlings (2001) and Miyoshi et al. (2017) and the NMPC was implemented based on Miyoshi et al. (2017). Table 1

summarizes the applied control strategies and the respective controlled and manipulated variables.

Table 1 – Control Strategies Summary

Control Strategy	Controlled Variable	Manipulated Variable
PI	Wellbore pressure	Gas-lift choke valve opening
NMPC	Oil production flow	Gas-lift flow

3. Results

3.1. System Simulation

The results obtained for the system simulation obtained by applying the modified model developed by Eikrem et al. (2006) and Ribeiro et al. (2016) are shown in Figure 1.

Figure 1 – Nonlinear static behavior obtained from steady state solutions for both gas-lift injection and oil production flow rates.

Figure 1 represents the static behavior that relates gas injection flow rate (kg/s) with oil production flow rate (kg/h). The graphical behavior indicates a convex profile, typical in this type of system. It can be observed that the oil rate increases until it reaches a maximum value, then it starts to decrease. This result shows that the increase of the gas-lift flow rate does not necessarily lead to an increase in the oil production.

The steady state function that represents the graphical behavior of the system was determined, with the use of MATLAB’s curve fitting tool, as presented in Equation (1). This function was obtained by empirically modifying the equation suggested by Alarcón et al. (2002), resulting in an R^2 value of 0.9812. The variable x represents the gas-lift flow rate (kg/s), while y is the oil production flow rate (kg/h).

$$y = -3.246x + 35.18x^2 - 237.3x^3 + 0.2603x^{-0.1361} - \frac{1.954 \times 10^{-5}}{x} + 0.08193 \ln(x) + 0.05311 \exp(x) \quad (1)$$

The obtained dynamic model was a second order transfer function that corresponds to the sum of two first order systems in parallel. Table 2 summarizes the estimated parameters. The parameters k_1 and k_2 represent the transfer function gains, while τ_1 and τ_2 are the time constants.

Table 2 – Transfer Function Parameters.

k_1	k_2	τ_1 (s)	τ_2 (s)
2.50	-1.88	3.50	5.53

The resulting Hammerstein model was tested with a step disturbance in gas-lift flow to verify if it could represent the oil production system as shown in Figure 2.

Figure 2 – Response of Hammerstein model compared to oil production system response to a step disturbance in gas-lift flow.

As result, the mean absolute percentage error between the Hammerstein model and the simulated well behavior was lower than 1%.

3.2. Moving Horizon Estimator

Another simulation was carried out to verify the performance of the moving horizon estimator, which is shown in Figure 3. This step is also important to provide the states required by the NMPC.

Figure 3 – MHE parameters estimation. CV represents the controlled variable (oil flow); the dots indicate the real values and the asterisks indicate the measured values, while the circles are the estimated values.

Figure 3 shows that after a short period the method can accurately estimate the real value, based on previously obtained measured values, successfully estimating the model states.

3.3. Nonlinear Predictive Control

The results of the application of the NMPC can be observed in Figure 4, showing how it can successfully stabilize the system oscillations. The setpoint is intentionally increased until it reaches an infeasible region. Then, it is finally decreased. This procedure is executed to observe the controller behavior when submitted to a gain sign inversion.

Figure 4 – NMPC results. MV in the bottom graph represents the manipulated variable (gas flow); the continuous line in the top graph indicates the setpoint and the dots are the predicted values of the controlled variable.

It is clear how the predictive control is able to overcome the gain sign inversion problem. These results were only possible due to the MHE accurate state predictions which were applied to the Hammerstein block-oriented model, also considering the Equation (1). Another significant result is the reduction of the computational costs.

Figure 4 shows that the NMPC can control this system in an infeasible setpoint region. The regular approaches of linear MPC controllers and the PID are not usually able to control the system after this region due to the occurrence of a gain sign inversion (Miyoshi et al., 2017).

4. Conclusions

In this paper, a NMPC based on Hammerstein models was applied to an offshore oil production well, in which gas-lift is used as lifting technique. The application aimed to control the oil production flow rate in an infeasible setpoint region by manipulating the gas-lift flow rate. A nonlinear function that represents the dynamic model was obtained with a relative error below 1%, and a moving horizon estimator could successfully estimate the states of the Hammerstein model to fulfill the predictive control structure.

The results showed that the proposed structure can control the system even in regions of gain sign inversion, which could not be achieved with linear control strategies. Therefore, the application of this methodology has potential to perform a significant increase in oil production at short processing time and low computational cost.

Abstract

This paper is aimed to analyse possible approaches for addressing multivariable system identification in presence of persistent disturbances. The main objective is to find a solution that is applicable to systems like wastewater treatment plants. Indeed, this type of processes can effectively improve their efficiency by means of advanced controllers, but their identification is quite difficult for the presence of continuous time varying characteristics of the feed flow rate. Optimal design of experiments is applied to the Benchmark Simulation Model no. 1 (Gernaey et al., 2014), and an adequate estimation of the process gains is obtained with multivariable identification if nonlinear models are used to describe the manipulated inputs – outputs relationships.

Keywords: system identification, disturbances, multivariable system, NARX

1. Introduction

Process control is an essential aspect for all industrial plants to guarantee safety, ambient protection and specifications. The development of control systems requires accurate mathematical models, which can be obtained either with a first principles approach or from experimental black-box model identification (Ghadipasha et al., 2015; Cogoni et al., 2014). In the latter case, experimental tests done on plant are needed. During these trials, the normal functioning of the plant is suspended. Based on the time needed, which is typically long, the economic efforts for this activity suspension can be significant. For example, the design of a Model Predictive Control needs about 50% of the time of the whole project (Darby and Nikolau, 2012). This need of time is due because, even though typical industrial system present a large amount of inputs and outputs, experimental tests for model identification are done singularly for each manipulated input. A multivariable system identification can contribute to reduce the amount of time needed for these activities and therefore costs. This is especially true when historical databases of the plant do not contain the required input-output information or they are not even available.

In this work, the possibility to perform a multivariable system identification for a wastewater treatment plant has been studied. For this purpose, the Benchmark Simulation Model no. 1 (hereafter referred as BSM1) has been used. This benchmark is a simulation environment which consents to simulate a wastewater plant composed of five reactors and one settler connected in series. The inlet flow (the wastewater) enters, together with the internal recycle and the external recycle, to the first reactor (which is an anoxic environment), passes through all the reactors and finally comes to the settler where clarified water and wastage are separated. In Figure 1 a simplified scheme of the plant is reported (for more technical details about the Benchmark please refer to Gernaey et al., 2014).

Figure 1: scheme of BSM1 plant.

The system identification methodology studied in this work focused only on the biological part of the plant, and it is an improvement of the methodology already applied in Foscoliano et al. (2016) and Mulas et al. (2015), where model predictive controllers were applied for controlling the concentration of nitrite and ammonia nitrogen on the reactors. Because of this the outputs chosen for the identification approach reported in the present paper are NO_2^- and NO_3^- nitrogen concentration in reactor 2 (SNO-R2) and NH_4^+ and NH_3 nitrogen concentration in reactor 5 (SNH-R5), according with Foscoliano et al (2016a,b). To control these two outputs, it was decided to use five manipulated inputs: the set-point of oxygen concentrations in reactor 2, 3, 4 and 5 (SP-SO_i , $i=2,\dots,5$) and the flow rate of internal recycle (Q_A). For the control of oxygen concentration four PI controllers have been designed to act on the transfer rate of oxygen in each aerated reactor. The crucial aspect is represented by the choice of variations to apply on manipulated inputs during the system identification phase, in order to maximize the amount of information about the system in the shortest possible time.

2. Inputs generation

For the choice of the best combination of uncorrelated inputs to use during the identification phase, the D-optimal design was used (Goodwin and Payne, 1977) with the objective to reduce the tests for system identification. In fact, the system should be excited in such a way that all interesting areas of the input space and the relevant frequencies are covered. Let us consider a multi-input and multi-output (MIMO) system composed of m outputs and n inputs. Such system can be describe as reported in Eq. (1), where $\mathbf{y}(t) \in \mathcal{R}^{m \times 1}$ is the outputs vector, $\mathbf{u}(t) \in \mathcal{R}^{n \times 1}$ is the manipulated inputs vector, $\mathbf{G}(t) \in \mathcal{R}^{m \times n}$ is the gains matrix and $\mathbf{e}(t) \in \mathcal{R}^{m \times 1}$ is the noise measurements vector.

$$\mathbf{y}(t) = \mathbf{G} \cdot \mathbf{u}(t) + \mathbf{e}(t) \quad (1)$$

Assuming the number of outputs and inputs equal to N , it is possible to write the matrices \mathbf{Y} and \mathbf{U} containing, respectively, the values of the m outputs and n inputs for each N -nth sampling time (Eq. (2) and (3)).

$$\mathbf{Y} = \begin{bmatrix} y_1(1) & \cdots & y_m(1) \\ \vdots & \ddots & \vdots \\ y_1(N) & \cdots & y_m(N) \end{bmatrix} \quad (2)$$

$$\mathbf{U} = \begin{bmatrix} u_1(1) & \cdots & u_n(1) \\ \vdots & \ddots & \vdots \\ u_1(N) & \cdots & u_n(N) \end{bmatrix} \quad (3)$$

Applying the least squares method, it is possible to define the estimator $\hat{\mathbf{G}}$ of \mathbf{G} (Eq. 4), where $\mathbf{X} = \mathbf{U}^T \mathbf{U}$ is called ‘information matrix’.

$$\hat{\mathbf{G}}^T = (\mathbf{U}^T \mathbf{U})^{-1} \mathbf{U}^T \mathbf{Y} = (\mathbf{X})^{-1} \mathbf{U}^T \mathbf{Y} \quad (4)$$

The D-optimal design is based on the maximization of the determinant of the \mathbf{X} matrix. If the number of samples N is relatively high and the estimator is impartial, the covariance matrix C_m can be found as reported in Eq. (5) (Goodwin and Payne, 1977; Darby and Nikolaou, 2014).

$$C_m \approx \frac{\mathbf{X}}{N-1} \quad (5)$$

If the determinant of C_m is near 1 the obtained inputs are uncorrelated and the determinant of the \mathbf{X} matrix is maximized, meaning that this combination of inputs can be used for the identification.

To study the possibility of multivariable identification in different cases, various configurations of uncorrelated inputs have been used. These designs have been generated in order to satisfy the conditions explained before. Each input variable can assume only its minimum or its maximum value, according to Table 1, varying according to step functions. For each design, three parameters, reported in Table 2, have been settled: the total time, representing the duration of the simulation (and, in real condition, of the identification performed on the plant); the step time, representing the minimal duration of a step; the switching frequency, representing the probability that a step has a value opposite to the previous step.

Table 1: minimum and maximum values for manipulated inputs

Manipulated input	Min	Max
Oxygen in reactor 2	0.25 g/m ³	0.75 g/m ³
Oxygen in reactor 3	1.50 g/m ³	2.50 g/m ³
Oxygen in reactor 4	1.75 g/m ³	2.25 g/m ³
Oxygen in reactor 5	1.25 g/m ³	1.75 g/m ³
Internal recycle	49804.2 m ³ /d	60871.8 m ³ /d

3. Multivariable system identification

To simulate the behaviour of the plant when a multivariable system identification is performed in real condition, the system was simulated using an inlet flow rate consisting of 17 variables describing typical dynamic variations for a wastewater flow. Details about this flow can be found at benchmark group website: <http://www.benchmarkwwtp.org/>.

The identification was carried out using the conditions reported in Tables 1 and 2, and before starting the step variations the system has been initialized simulating it for 15 days using a constant inlet flow and constant inputs. Then, for further 15 days, the variable inlet flow and constant manipulated inputs were used. Finally, for a period of time depending on the selected design, simulations were carried on using the variable

inlet flow and the manipulated variable inputs designed as described in the previous chapter.

Because the goal of this work is to assess if a multivariable system identification can be successfully applied to a system with time varying disturbances, some simulations were carried out to obtain reference values for the process. In particular, ideal conditions with constant pollutant loads were considered for calculating the gains of the process and comparing them with the ones obtained performing the identification as we were in a real plant (varying disturbances).

Table 2: parameters for the designed simulations

Design	Total time [d]	Step time [d]	Switching frequency
1	60	1	0.2
2	60	2	0.2
3	120	5	0.2
4	120	5	0.5
5	120	0.5	0.2
6	60	0.5	0.2
7	30	1	0.2
8	30	0.5	0.2
9	90	1	0.2
10	90	2	0.2

For every simulation, the obtained data of nitrate and nitrite nitrogen in reactor 2 (SNO-R2) and NH_4^+ and NH_3 nitrogen in reactor 5 (SNH-R5) were used separately for the identification process. The description of the data obtained for the multivariable identification process was first performed by means of a linear model. Such approach failed because the output signals were not correctly described. A nonlinear approach was therefore used and 10 nonlinear autoregressive models with exogenous inputs (1 for each couple output – input) were trained to describe the behaviour of the selected output in response to a step test (both positive and negative variations) of the selected input. Every single neural network was considered capable of describing the system if the following criterions were satisfied: 1) sign of the gain consistent with the process; 2) comparable order of magnitude both for positive and negative variations (bearing in mind the non-linearity of the process); 3) order of magnitude consistent with the process by considering the ideal situations of constant inlet conditions as described in the previous paragraph.

4. Results

Among all the designs studied, design number 3 is the one who returned the best results, therefore at least four months of experimental tests are needed. Figure 2 shows inlet ammonia flow rate, which is one example of the several process disturbances, the step applied to the manipulated inputs and the outputs (SNO-R2, SNH-R5) behaviour. The identification procedure should properly separate the effects of the disturbances to that of the manipulated inputs on the outputs and 10 NARX models formed by 2 past inputs and 2 past measured outputs (sampling time equal to 15 minutes) were able to give the

better description of input-output relationships. It is important to note the disturbances are not used as inputs of the NARX models, because in real plants they are not usually measured.

To evaluate the identification carried on, the gains of the 5x2 system have been predicted with the autoregressive models considering average process conditions and the obtained values are compared with the one calculated in the ideal case (single step and constant disturbances).

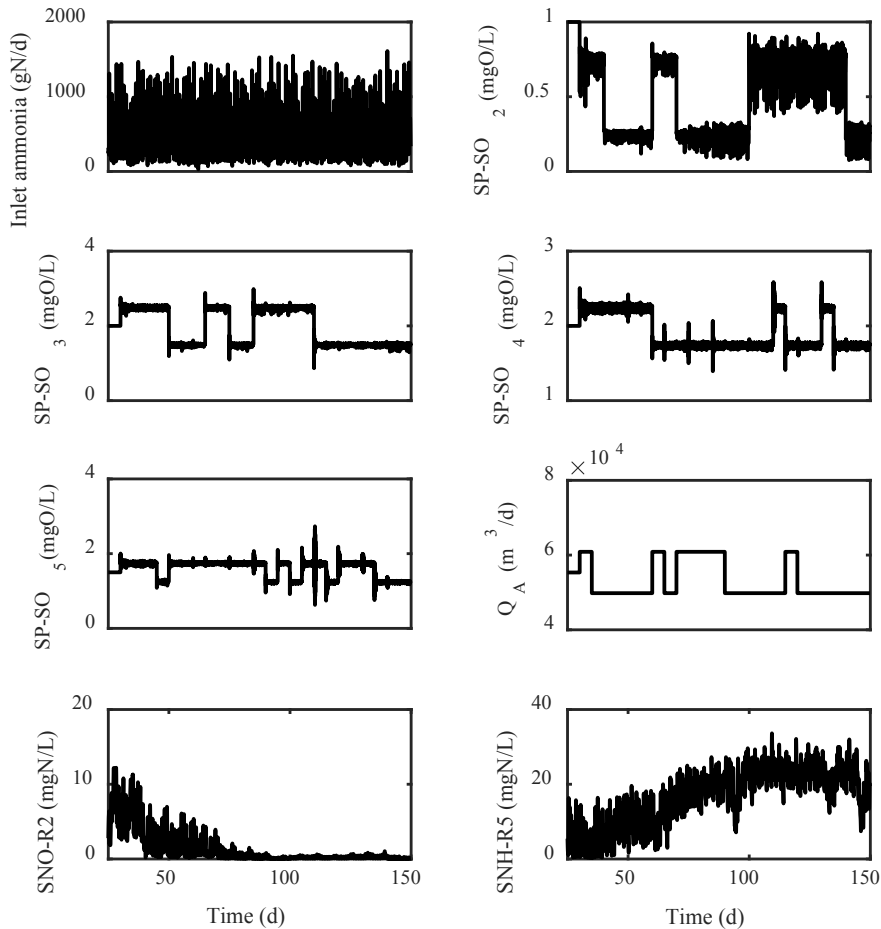

Figure 2: inputs and outputs behaviour during the multivariable step-tests.

The results are reported in Table 3, and it can be observed that the sign of the constant gain is correct for each multivariable identification, but the values are generally different of one order magnitude with respect to the single step. It is worth noting that the process shows highly nonlinear behaviour and that the multivariable identification with NARX has been conducted when the influent is subjected to large variations in terms of concentration, wastewater flow rate and temperature.

5. Conclusions

System identification for a multivariable system continuously excited by varying disturbances was accomplished using optimal design of experiment to establish the step changes program. The proposed system identification strategy could potentially reduce the amount of time needed for an input-output system identification done singularly in plant and therefore reduce costs. The obtained results are promising for evaluating information related to process gain, but the procedure did not allow the obtainment of reliable characteristic times of the process, and this aspect will be addressed in the future.

Table 3: results of the multivariable identifications compared to single step identifications

Manipulated input	SNO-R2		SNH-R5	
	Multivariable identification	Single step identification	Multivariable identification	Single step identification
Oxygen in reactor 2	0.126263	1.054	-0.875272	-0.106
Oxygen in reactor 3	0.044981	0.374	-0.245492	-0.116
Oxygen in reactor 4	0.379313	0.339	-1.740404	-0.113
Oxygen in reactor 5	0.021692	1.247	-0.125783	-0.201
Internal recycle	3.628257e-06	7.049E-05	0.000855	3.740E-06

Abstract

To minimize human errors (principal reasons for accidents in process industries) it is imperative to understand their cognitive workload, the excess of which is often a preliminary state leading to human errors. In this work, we have devised a methodology based on an eye tracking parameter—gaze entropy—to gauge the variation of cognitive work load on a control room operator. The study highlights the potential of gaze entropy in observing the variation of cognitive workload with learning. The patterns observed have a potential to minimize human errors and improve safety in process industries.

Keywords: Human errors, eye tracking, cognitive workload, process safety, learning

1. Introduction

Industries have developed and adopted numerous technological advancements to enhance safety in the workplace. Despite these advancements, incidents continue to happen in process industries leading to financial and human losses (Mannan, 2004; Fernholz, 2014). A detailed analysis of various incidents reveal that human error is one of the principal causes for failure to control the plant in the process industries. Incorrect decisions made by the human operator could severely impact the process safety as exemplified by the incidents at Three Mile Island Nuclear plant (1979), BP's Texas City chemical plant (2005), Bayer CropScience pesticide production facility (2008) and Indonesian Air Asia QZ-8501 (2014) aviation accident. The traditional approach has been to look at human error as the initiating event of incidents, one that has a given likelihood of occurrence, similar to the way that a piece of hardware is expected to fail at some frequency. However, understanding of human errors is a challenging task—there is limited availability of human error data in public domain due to various sensitivity and propriety issues. Further, unlike machines, humans are more unpredictable as their thought process is influenced by various internal factors (like fatigue, sleep, ability, etc.) as well as external factors (like organisational culture, work environment, etc.). For machines the failure probability is predicted by using historical failure data related to the equipment. To minimize equipment failures, periodic checks and maintenance are required to maintain their health. The relatively high frequency of change in the thought process of humans demands a procedure to tackle human errors in a different way from that of machines. There is a need for continuous monitoring of the thought process in humans, and understand how learning impacts the thought process. Improvement in performance due to learning can be seen as analogous to equipment

improvement after periodic maintenances. Improvement in learning needs to be gauged in real time. This real time monitoring of humans has to be based on some measures which allow us to continuously trace the changing thought process so that real time interventions could be introduced to check for any aberrant behaviour or activity, and accordingly kick in preventive measures. Such interventions can reduce the human errors by inducing learning and reducing the amount of cognitive workload. Experts have already suggested the need to understand the cognitive aspects and of process operators (such as information processing, workload and decision making) under various conditions to understand and mitigate human errors (Bullemer and Nimmo, 1994; Manca et al., 2013). We believe that cognitive workload is an important component to understand human errors. There is a strong relation between the two—while human errors are defined as a mismatch between the demands of a process and the human capability (Embrey, 1994), mental workload, at the most general level, is defined as a relation between the mental resources demanded by a process and the resources that can be supplied by the operator (Parasuraman, 2008). Thus, addressing the issue of cognitive workload (overload). Further, we believe that the changes in cognitive workload are also strongly associated with learning—a significant parameter to minimize mistakes and errors. Its developments with learning will help address the broad issue of human errors and, hence, process safety.

2. Literature Survey

Cognitive Workload is defined as the total amount of mental effort and resources required by a human at any given time to handle a situation (Parasuraman, 2008). Cognitive workload is experienced when the working memory processing demands, for a task, exceed the learner's cognitive capacity (Mayer and Marenco, 2003). Cognitive workload is one of the important cognitive engineering constructs that influences the decision making process of the humans (Parasuraman, 2008; Zheng et al., 2015; Rodríguez et al., 2015). Researchers in safety critical domains such as aviation, driving and healthcare industries have attempted to understand cognitive workload by measuring various psychophysiological quantities such as Electroencephalography (EEG), galvanic skin resistance, heart rate, eye movements and pupil diameter. Due to its non-invasive nature and ease of use, eye tracking measures have been widely used to understand the cognitive workload of humans. For instance, during simulated surgical tasks, it was observed that higher pupil dilations correlated with increase in task complexity (Zheng et al., 2015). Experiments conducted to assess the workload of air traffic controller concluded that increase in subjective workload translated into an increase in the pupil diameter amplitude (Rodríguez et al., 2015). Another study revealed that changes in mental workload can be quantified by frequency domain analysis of pupil size measurements, with an increase in workload correlated with increase in power level at low frequencies (Peysakhovich et al., 2015).

More recently, we have conducted experimental studies on ethanol simulator plant to understand the cognitive behaviour of control room operators. In these studies, participants were attending various tasks that required them to take intervening actions upon alarm(s) to bring the plant back to normal conditions. Eye gaze studies revealed the existence of specific pattern in participants who have completed the task using single manipulated variable (Sharma et al., 2016). Pupillometry studies indicate that the size of the pupil correlates closely with their ability to successfully perform the necessary tasks to keep the process within safe limits (Bhavsar et al., 2015).

A lot of work has been done, as already discussed, to investigate various facets of cognition, there have been a few studies also to assess the impact of learning on cognitive workload. According to cognitive load theory when a person learns a task the effort needed to carry the task decreases because of the reduced need to process the information, a portion of which goes to long-term memory. Sibley et al. (2011) showed that the cognitive workload, as measured by pupil diameter, decreases with learning as the participants perform a heading task involving virtual unmanned aircraft vehicle. Burge et al. (2013) studied the mechanism underlying change in performance by analysing the pupil diameter variation. They concluded that the participants' performance increases because of the increase in efficiency due to improved allocation of cognitive resources by training. Literature related to the understanding of cognitive behaviour during tasks involving plant operators trying to tackle abnormal situations in real time is at best limited (Bhavsar et al., 2015). Further, the assessment of learning by measuring the entropy changes in real time during similar disturbance rejection tasks is hardly available, to the best of our knowledge. In this work we have attempted to find a relation between learning and cognitive workload (an overload of which increases the chances of error) using gaze entropy. By tracing the cognitive workload we can predict whether learning is occurring, and according take measures to make both these parameters favourable.

3. Experimental Methodology

The experiment consists of monitoring an ethanol production plant (See Figure 1), and taking appropriate action (s) (by an operator) to bring the plant back to normal state if any disturbance occurs. For detailed description of the experimental set-up and process the reader is referred to Iqbal and Srinivasan (2017).

The study involved 5 post graduate students of chemical engineering at Indian Institute of Technology Gandhinagar. They were given a reading manual that explained the ethanol production process, followed by a video training on how to operate the plant. To keep trace of the participants' gaze during the experiment we used a Tobii TX 300 remote eye tracker, and followed standard five point eye tracking calibration procedure to ensure validity of gaze data. The nature of the tasks performed by the participants and results obtained are discussed in next section.

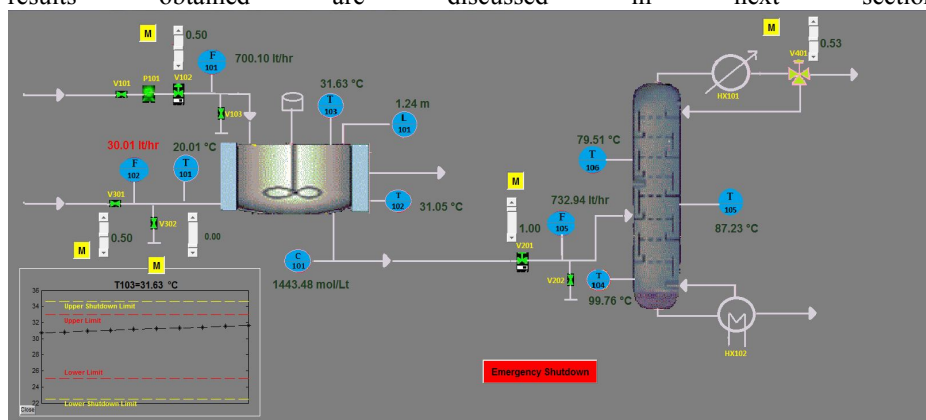

Figure 1 Human Machine Interface of an ethanol production plant

4. Results and Discussion

A typical task involves bringing a process variable(s) to within the acceptable limits as specified by the region between upper limit and lower limit in Figure 1. As soon as the alarm is triggered the participant gets to know about the disturbance in the plant, tries to comprehend the situation and accordingly takes some action(s). Now consider a typical scenario involving such a

Figure 2 Slider position trend with time

task. The participant clicks on the start button to activate the Human Machine interface (Figure 1) at around 15 seconds (Figure 2). At around 25 seconds, the flow rate of the coolant goes outside the alarm-limits, turning the tag F102's value from blue to red, and simultaneously triggers an alarm (shown by inverted triangle). These developments alert the operator and possibly result in change in his cognitive workload. The operator tries to bring the disturbed process variable to within acceptable limits by changing the slider position to control the flow through coolant valve. The shift in slider position is shown in the figure by changing height of the stems in Figure 2. Thus, at around 33s the operator starts to move the slider controlling the coolant flow rate, and the alarm is cleared at around 42 s, as shown by the box 'F102' in Figure 2. Comparative analysis for gaze entropy during these tasks was done for five participants. The gaze entropy was determined for two time regions of the experiment: i) Region one: From first slider action to the last slider action (i.e. from around 33s to 53s) ii) From first alarm (shown by inverted triangle) to first slider action (i.e. the region from 25s to 33 s).

Task one involved handling a disturbance which involved change in coolant flow rate to outside the alarm limits. The correct action involved moving the coolant slider to appropriate position to bring the flowrate back to acceptable limits. It is not necessary that a participant always started with the correct slider action. Task two also involved the same disturbance but an additional problem of coolant valve getting stuck and hence not responding. The operators had to identify a bypass valve (V302) and use it to bring the disturbed coolant flow rate to within acceptable limits. Task two and one are similar in a way that both involve bringing the coolant flowrate to within acceptable limits by increasing the flow in the coolant line. Figure 3 shows the gaze entropy for different participants performing two similar tasks—Task 1 and Task 2—in region one (already defined). However, for the Task 2, the first slider action corresponds to a normally working slider which could be a bypass valve or any other slider which he or she perceives to be the correct one. Figure 4 shows gaze entropy in the region starting with time when the first alarm occurs to the time when he identifies the first perceived correct slider.

Figure 3 Comparative gaze entropy for different participants from first slider to last slider action

Figure 4 Comparative gaze entropy for different participants from first alarm to first slider action

The results shown in Figure 3 show that the gaze entropy for four participants decreases as they go to perform Task 2 after previously performing Task 1. The decrease in entropy demonstrates learning by a participant and the change in his mental state from having ‘more entropy’ to ‘less entropy’. The decrease in entropy and hence cognitive workload can be attributed to relative relief of the working memory load due to compensation from prior belief/learning (Joseph, 2013). We believe that if learning fails, gaze entropy may not decrease significantly as it decreases during learning. There are some zero values of entropy as well as can be seen in Figure 3. These signify that the participant might have been confident while performing the task. He might have been sure that a particular slider action is going to bring the process variable back to within acceptable limits, and as such is fixing his gaze in the same region on HMI. Thus, gauging this parameter will help us to keep track of the operator’s cognitive load and consequently learning.

The results from Figure 4 depict that the cognitive work load of a participant can increase if things go against the intuition developed by previous experience. The participants, after the same alarm is triggered and after their learning experience, would try to bring back the coolant flow rate to within acceptable limits by using the coolant valve but since the coolant valve had got stuck for Task 2, it takes them some time to realize that, and during that realization time their cognitive workload increases. Thus, as shown in Figure 4, the gaze entropy increases for four participants as the participant goes to perform Task 2, after having performed Task 1 previously.

5. Conclusions

In this work we have proposed a technique based on measurement of gaze entropy to gauge the cognitive workload of a human operators induced by the interaction between the nature of task and their abilities and/or perception about the task. Gaze entropy gives us a deep insight into the learning by an operator. Higher gaze entropy signifies a higher cognitive workload. Lower values of gaze entropy while performing a similar task previously reflects the potential of gaze entropy being a measure of learning. Knowing the real time trend of cognitive workload on operators and aberrations (if any) has a potential of minimizing human errors by providing necessary interventions in real time. These interventions may even include triggering of a warning to a more expert special-

operator asking for his intervention if the variables involved are critical safety variables, thereby enhancing learning. In this way human errors can be obviated in real time and will also allow for self-introspection by operators to improve their skills with the passage of time. This will ensure not just the existence of a safer workplace, but will also minimize the effects of various accidents on our environment by eliminating, or at least minimizing, their frequency of occurrence. Our future work will focus on developing a robust index based on many gaze parameters to measure cognitive workload on control room operators in real time.

Online Monitoring of an Enzymatic Reactor based on Density Measurements

Emilio Granada-Vecino, Mauricio Sales-Cruz, Teresa Lopez-Arenas*

Departamento de Procesos y Tecnología, Universidad Autónoma Metropolitana - Cuajimalpa, Av. Vasco de Quiroga 4871, 05300 Mexico City, Mexico

mtlopez@correo.cua.uam.mx

Abstract

In this work, a monitoring strategy is presented to infer unmeasured concentrations and estimate the kinetic parameter of inhibition in an enzymatic reactor. The reaction corresponds to the hydrolysis of cellulose to produce glucose, in batch and isothermal conditions. The strategy is based on a softsensor that consists of a model-based state estimator and considering only density measurements. The reactor model and the softsensor performances are validated with experimental data, obtaining satisfactory estimates. The strategy could be extended to other bioreactors.

Keywords: Bioreactor, monitoring, state estimator, density.

1. Introduction

Online monitoring of bioreactors is increasingly important in industrial processes. First, bioreactors are relevant because more products (pharmaceuticals, food, fuel, etc.) are obtained sustainably through biotechnology. In particular, sugars (as glucose, sucrose, etc.) are essential compounds in bioreactors, as they participate in enzymatic or fermentation reactions as substrates or products. Undoubtedly, an important problem for the correct bioreactors monitoring and control is the sugar concentration inference, preferably through low-cost, reliable and fast-response sensors (Pohlscheidt et al., 2013). Through its monitoring, it is possible to control the substrate feed, to avoid the reaction inhibitions, to ensure the process operability, and to guarantee the product quality. Today, new sensors provide more possibilities for online monitoring, which are based on the measuring of physical, chemical or biological properties such as refractometers, viscometers, respirators, etc. Sugars are commonly measured using a biochemical analyser (as Life Sciences YSI), whose use is off line, with delay time and moderate operating cost. It is useful, accurate and reliable for research purposes, but not for industrial purposes.

In this work, an online monitoring system is proposed to infer the glucose (product) concentration in an enzymatic hydrolysis reactor, using cellulose as substrate and *Trichoderma reesei* as enzyme. The isothermal batch reaction is carried out in an experimental lab reactor, where density is measured by an online densitometer for monitoring purposes, and glucose concentration is measured by an off line biochemical analyser for validation purposes. First, a dynamic model is considered assuming a Michaelis-Menten reaction including product inhibition. Then, the online monitoring strategy is based on the development of a soft-sensor that is the association of: (a) a sensor (hardware), which allows online measurements; and (b) a state estimation algorithm (software), which can provide online estimates of unmeasurable states. For

the latter, a nonlinear geometric state estimator (Alvarez and Lopez, 1999) is used that relies on a dynamic process model and the observability property, presenting advantages in terms of mathematical solvability, convergence criteria, systematic construction and manageable tuning technique.

The results obtained are satisfactory for the states and parameter estimation. First, the reactor model is experimentally validated using the off line glucose concentration measurements. Next, it is determined that state estimation is feasible from an observability analysis. Finally, the dynamic softsensor is implemented, achieving an adequate estimation of the sugar concentration (with small deviation) and an inference of the non-measurable concentration of cellulose.

2. Process Description

2.1. Enzymatic hydrolysis reaction

The enzymatic hydrolysis reaction of α -cellulose (substrate, S) is considered to produce glucose (product, P), catalysed by *Trichoderma reesei* cellulase (enzyme, E). The initial concentrations were $S_0 = 15$ g/L of cellulose and $E_0 = 2$ ml/L of enzyme, pH was set at 4.5 with a buffer solution, and temperature was fixed at 50 °C. In particular, the enzymatic hydrolysis reaction of cellulose follows a Michaelis-Menten type kinetics with competitive product inhibition (Bisswanger, 2008), given by the following reaction rate (r_p):

$$r_p = \frac{V_{max} S}{K_m + S + (K_m / K_I) P} \quad (1)$$

Where the kinetic parameters defined by V_{max} , K_m and K_I are the fundamental pillars to understand the behaviour of enzymes. V_{max} represents the maximum rate at which the reaction rate can occur, K_m can be assumed as an inverse measure of the enzyme affinity for the substrate, and K_I is an inverse measure of the affinity of the enzyme for the inhibitor. In a previous work (Lopez-Arenas et al., 2017), the kinetic parameters were estimated for several initial substrate concentrations ($5 \text{ g/L} \leq S_0 \leq 15 \text{ g/L}$) through optimization, finding the optimum values of $V_{max} = 0.683 \text{ g/L/h}$ and $K_m = 13.634 \text{ g/L}$; while the value of K_I was S_0 -dependent ($0.3 \text{ g/L} < K_I < 1.5 \text{ g/L}$).

2.2. Experimental System

A stirred tank (stainless steel) reactor was used, operated in batch under isothermal conditions, with a nominal volume of 1 L (Figure 1a). The reactor has a mechanical agitation system, steam condenser, heating / cooling jacket, and automatic measurement sensors for pH and temperature. The experimental system is connected to a computer for heating control and data acquisition (Figure 1b).

Several samples were taken and filtered (since cellulose is not soluble) to measure the glucose concentration and the mixture density. The glucose concentration was measured off-line with a biochemical analyser (YSI 2900), to have measurements that allow the validation of the reactor model. While density measurements were taken with a density meter (Anton Paar, DMA 35), to be used in the online monitoring system.

Figure 1. Experimental system: (a) reactor and (b) data acquisition and control system.

3. Methodology

3.1. Reactor Model

The dynamic model of the reactor is given by the mass balances of substrate and product, additionally the inhibition parameter K_I is added as a system state with to its online estimation:

$$\frac{dS}{dt} = -r_p, \quad S(0) = S_0; \quad \frac{dP}{dt} = r_p, \quad P(0) = 0; \quad \frac{dK_I}{dt} = 0, \quad K_I(0) = K_{I0} \quad (2)$$

The mixture density (ρ) was calculated according to the additivity of specific volumes:

$$\underbrace{\frac{1}{\bar{V}_m}}_{\text{mixture}} = \underbrace{\frac{x_s}{\bar{V}_s}}_{\text{buffer solution}} + \underbrace{\frac{x_g}{\bar{V}_g}}_{\text{glucose}} \quad (3)$$

Leading to the following expression (were α , β , γ are constant values):

$$\rho = \frac{\alpha + P}{\beta + \gamma P} := h(P) \quad (4)$$

3.2. The observability analysis

First, the reactor model, Eq. (2), is written in vector form, together with the density as unique measure variable ($y = \rho$):

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}), \quad \mathbf{x}(0) = \mathbf{x}_0; \quad y = h(x); \quad \text{where } \mathbf{x} = [S, P, K_I]^T \quad (5)$$

The reactor motion $\mathbf{x}(t)$ is RE (robustly exponentially) - detectable (i.e. partial observable) with the observability index $\kappa = 2$, and the state partition

$$\mathbf{x}_I = [P, K_I]^T \quad \text{observable states}; \quad \mathbf{x}_{II} = [S]^T \quad \text{unobservable state} \quad (6)$$

if the two following conditions are met along the reactor motion $\mathbf{x}(t)$: (a) an invertibility condition, which means the map $\phi(\mathbf{x})$ is invertible for \mathbf{x}_I , and (b) a stability condition, which means the unobservable dynamics $\mathbf{x}_{II}(t)$ is stable. Where the map ϕ (given by the measured outputs and some of their time-derivatives) and the observability matrix \mathbf{Q} are given by:

$$\phi(x) = [y, \dot{y}]^T = [h(x), g(x)]^T; \quad \mathbf{Q} = \frac{\partial \phi}{\partial \mathbf{x}_I} \quad (7)$$

The assessment of the invertibility condition can be verified if $\text{Rank}[\mathbf{Q}] = \kappa = 2$, or else, if $\det[\mathbf{Q}] \neq 0$ for all time. In fact this condition was evaluated numerically as can be seen in Figure 2a, showing that $\det[\mathbf{Q}] > 0$ for $P \neq 0$ and $P \neq S_0$. The stability condition is equivalent to verify that the dynamics $\dot{S} = -r_p$ is stable, considering $P(t)$ and $K_I(t)$ as nominal known motions. The dynamics is stable if the eigenvalue of its linear equation has strictly negative real part. This is verified also numerically along the reactor motion as shown in Figure 2b.

As the two conditions are met, therefore the reactor motion is RE-detectable for all time, except for $P = 0$ and $P = S_0$; which are the extremes of the reaction (the initial point at $t = 0$ and the end point when the conversion is 100%). The first one can be avoided for the implementation of the softsensor (it can be implemented a few seconds after the start of the reaction), and the last point is not reachable physically since there is product inhibition, thus a complete conversion cannot be reached.

Figure 2. Observability analysis: (a) determinant of \mathbf{Q} , (b) eigenvalues of $\dot{\mathbf{x}}_{II}$.

3.3. State estimator design

The construction of the geometric estimator (Luenberger-like high-gain) follows from a straightforward consequence of the detectability property, according to the following expression (see Theorem 1 in Alvarez and Lopez, 1999). So that the estimator for the case study is given by

$$\dot{\hat{\mathbf{x}}}_I = \mathbf{f}_I + \mathbf{Q}^{-1} \mathbf{K}_o (y - \hat{y}) + \mathbf{Q}^{-1} \mathbf{\Pi} \mathbf{K}_{int} \int_0^\tau (y - \hat{y}) d\tau, \quad \hat{\mathbf{x}}_I(0) = \hat{\mathbf{x}}_{I0} \quad (8)$$

$$\dot{\hat{\mathbf{x}}}_II = \mathbf{f}_{II}, \quad \hat{\mathbf{x}}_{II}(0) = \hat{\mathbf{x}}_{II0}; \quad \hat{y} = h(\hat{\mathbf{x}}_I) \quad (9)$$

Here \mathbf{K}_o and \mathbf{K}_I are the gain matrices which should be chosen such that the estimation error dynamics is stable. It can be seen that the observable dynamics [Eq. (8)] has three terms: (i) a predictor term given by the model, (ii) a proportional corrector term driven by the estimation error, and (iii) an integral corrector. While the unobservable part [Eq. (9)] only has a predictor term given by the model. According to the tuning strategies for the geometric estimator given in Alvarez and Lopez (1999), the gains can be evaluated as follows:

$$\mathbf{K}_o = \begin{bmatrix} k_1 \\ k_2 \end{bmatrix}, \quad \mathbf{K}_{int} = \begin{bmatrix} 0 \\ k_{int} \end{bmatrix}; \quad k_1 = (2\zeta + 1)\omega_o s_o, \quad k_2 = (2\zeta + 1)\omega_o^2 s_o^2, \quad k_{int} = \omega_o^3 s_o^3 \quad (10)$$

Where ζ is the damping factor, which can be set as $\zeta = 0.71$ in order to have a response with moderate oscillations. While ω_o is the characteristic frequency, which can be selected for a reactor as $4/(\text{total reaction time})$. So that the only tuning parameter is s_o , which is the settlement factor of the estimator, which must be greater than 1.

4. Results and Discussion

Here is worth of mention that the experimental data for glucose concentration (shown in Figure 3) are off-line lab analysis plotted for comparison purposes, while density measurements are the only measured output used in the softsensor implementation. Several experiments were carried out with different initial concentration of substrate (S_0), but due to the lack of space only one case study is shown for $S_0 = 15$ g/L.

First the reactor model, Eq. (2), was validated using the known parameters (V_{max} , K_m) and assuming a value of $K_I = 0.8$ g/L. It can be seen in Figure 3a that the dynamic response for glucose concentration (thin lines) has the tendency behaviour but is does not match correctly. Similar response occurs for the density model, Eq. (4), as shown in Figure 3b, where the density is underestimated.

Then the softsensor was implemented, Eqs. (8)-(9), assuming same previous initial conditions and a parameter tuning fixed at $s_o = 13$. Figure 3a shows the concentration dynamic response, where it can be seen that the softsensor is able to infer quite close to the experimental trajectory, due to the correction done to the density estimation (as shown in Figure 3b). While the kinetic parameter K_I was online estimated according the changes of the reactor motion, reaching a quasi-constant end value of 0.34 g/L (see Figure 3c). Finally, Figure 3d shows how the measured output converges in an approximate time of 50 h, which means that from this point the estimated values are reliable.

Figure 3. Dynamic response of the model and the softsensor: (a) estimated (unmeasured) concentrations, (b) measured density, (c) estimated inhibition parameter, (d) integral error.

5. Conclusions

An online monitoring strategy has been proposed to estimate unmeasured concentrations and a kinetic parameter in an enzymatic reactor, using only online measurements of density. The strategy minimizes time delays during monitoring, which raises an alternative of lower cost and greater accessibility, compared to the monitoring systems currently used based on discrete concentration measurements. The methodology proposed in this work can be extended to monitor other kind of reactors, such fermenters, but it could be also combined with other techniques for parameter estimation.

Abstract

In this work we develop a novel multi-objective multi-period MINLP model for optimal strategic planning of entire petroleum and petrochemical supply chain (PPSC) to support decision making for petroleum and petrochemical industries. Nonlinear behaviour of the oil reservoir is considered for accurate prediction of crude production. More important, environmental impact based on Eco-indicator 99 is introduced as an objective function in addition to economic performance. The multi-objective model is converted to a single-objective by employing the weighting-sum method, which is solved to ε - global optimality using the proposed two-step procedure. An industrial-scale example is solved to show the capability of the proposed model and solution approach. The results clearly demonstrate the effect of considering environmental impact on the operation of PPSC.

Keywords: Petroleum supply chain, multi-objective, environmental impact, mixed-integer nonlinear programming (MINLP)

1. Introduction

The petroleum and petrochemical industry plays an important role in satisfying world energy demand and supporting our daily life. Petroleum-based fuel still owns the largest contribution of the global energy consumption by 30% in 2040 (U.S. Energy Information Administration, 2016). It is compulsory for these industries to develop optimal strategical plan for their supply chain to improve total profit and reduce environmental impact.

The entire petroleum and petrochemical supply chain (PPSC) can be divided into upstream, midstream, and downstream segments (Sahebi et al., 2014). While the upstream refers to crude exploration, production and transportation of crude oil to refineries, the midstream covers activities in refineries, petrochemical plants and chemical plants. The downstream focuses on storage and distribution to the customers.

A considerable amount of efforts encompassed the upstream of PPSC only (Gupta and Grossmann, 2012; Sahebi et al., 2015). For instance, Gupta and Grossmann (2012) developed an efficient multi-period MINLP model for optimal planning of offshore oil and gas field infrastructure. Nonlinear behaviour of the reservoir was considered for accurate prediction of crude production. Sahebi et al. (2015) designed the upstream crude supply chain by simultaneously considering economic performance and environmental impact. Some recent efforts addressed the integrated upstream and

midstream segments of PPSC (Azadeh et al., 2017). Azadeh et al., (2017) proposed a MILP model for design of upstream and midstream segments of PPSC to maximize economic performance only. It is clear that there is no strategic planning optimization model covering all segments of PPSC to optimize economic performance and environmental impact simultaneously.

In this work, we develop a novel multi-objective multi-period MINLP model for strategic planning of entire PPSC covering upstream, midstream and downstream segments to support decision making for petroleum and petrochemical industries. The entities in PPSC include oil wells, production platforms, refineries, petrochemical and chemical plants as well as an external market in each segment. The decisions include selection of potential facilities, technologies, locations, products and transportation modes, as well as establishment time of each facility. To predict the crude production accurately, nonlinear behaviour of the reservoir is considered. Environmental impact based on Eco-indicator 99 method (Goedkopp and Mark, 2015) is introduced as an objective function in addition to economic performance. The multi-objective model is converted to a single-objective by employing the weighting-sum method, which is solved to ϵ - global optimality using the proposed two-step procedure. An industrial-scale example is to illustrate the capability of the proposed model and solution approach. The results clearly demonstrate the effect of considering environmental impact on the operation of PPSC.

2. Problem Statement

A general PPSC is illustrated in Figure 1. There are W ($w = 1, 2, \dots, W$) oil wells, PP ($pp = 1, 2, \dots, PP$) platforms, F ($f = 1, 2, \dots, F$) refineries, PC ($pc = 1, 2, \dots, PC$) petrochemical plants, DC ($dc = 1, 2, \dots, DC$) chemical plants, and MD ($md = 1, 2, \dots, MD$) markets. Different technologies are used in some entities including WT ($wt = 1, 2, \dots, WT$) extraction technologies in oil wells, PT technologies ($pt = 1, 2, \dots, PT$) separating water from the crude oil and ST ($st = 1, 2, \dots, ST$) storage technologies in platforms, RT ($rt = 1, 2, \dots, RT$) refining technologies in refineries, CT ($ct = 1, 2, \dots, CT$) transforming technologies in petrochemical plants, and TT ($tt = 1, 2, \dots, TT$) technologies in chemical plants. Between two entities, there are TM ($tm = 1, 2, \dots, TM$) transportation modes.

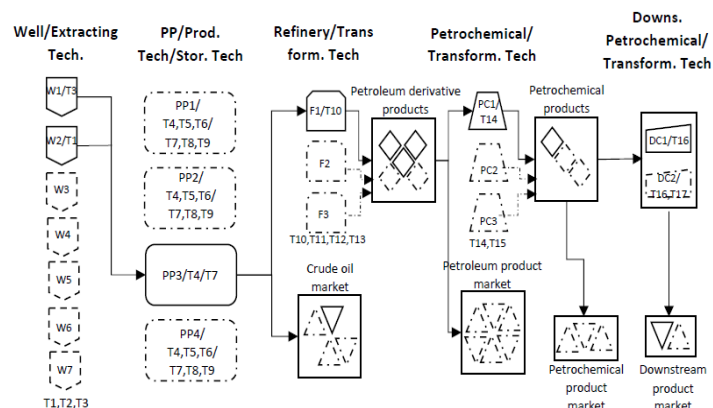

Figure 1 Petroleum and petrochemical supply chain where the dotted line represents the potential facilities and the steady line means readily operated facilities

Given: (1) economic data such as capital cost for establishment of each entity, unit operating cost of each potential technology, and capital and operating cost of every transportation mode; (2) potential location of each entity and capacity; (3) nonlinear behavior of oil reservoir; (4) demand and price of commodity; (5) environmental data for all entities and transportation modes; (6) the planning horizon. *Determine:* (1) allocation and establishment of each facility; (2) selection of technology for each built facility; (3) selection of transportation modes between two entities; (4) selection and allocation of external market; (5) selling amount of each product to external market and subsequent processing plant. *Assume:* oil wells produce the same type of crude oil. The objective is to maximize economic performance and minimize environmental impact, simultaneously.

3. Mathematical Formulation

The planning horizon is divided into T ($t = 1, 2, \dots, T$) periods with the length of each period as $\tau(t)$.

3.1. Economic objective

The economic objective is to maximize net present value (NPV), represented as follows,

$$NPV = \sum_t \frac{TCF(t)}{(1+i)^{(t-1)}} \quad (1)$$

where, TCF_t is total cash flow in period t and i is the interest rate. Details about the calculation of total cash flow can be referred to Azadeh et al. (2017).

3.2. Environmental impact

The environmental impact ($Eco99$) is counted based on Eco-indicator 99 method.

$$Eco99 = \sum_d f(d) \times Dam(d) \quad (2)$$

where, $Dam(d)$ is defined as the environmental damage d . $f(d)$ is the normalised weight of damage d . The environmental damage includes human health, ecosystem quality and resources depletion, which is contributed from contaminants released from utility consumption and direct emissions. More details can be referred to Sahebi et al. (2015).

3.3. Oil well constraints

We define binary variables $yw(w, wt, t)$ to represent if an oil well w uses extraction technology wt in period t . At most one technology is used for a well at a time. Then,

$$\sum_{wt} yw(w, wt, t) \leq 1 \quad \forall w, t \quad (3)$$

The total crudes extracted from the well is defined as $WTQ(w, t)$, the crude extracted from the oil reservoir using technology wt at a time is denoted as $WQ(w, wt, t)$.

$$WTQ(w, t) = \sum_{wt} WQ(w, wt, t) \quad \forall w, t \quad (4)$$

The capacity for each technology is represented as,

$$cl^L(w, wt) \cdot yw(w, wt, t) \leq WQ(w, wt, t) \leq cl^U(w, wt, t) \cdot yw(w, wt, t) \quad \forall w, wt, t \quad (5)$$

$$WTQ(w,t) \leq capw(w,t) \quad \forall w, t \quad (6)$$

0-1 continuous variables $xw(w,wt,t)$ are defined as the establishment of new well w using technology wt at period t .

$$\sum_{wt} \sum_t xw(w,wt,t) \leq 1 \quad \forall w \quad (7)$$

$$xw(w,wt,t) = yw(w,wt,t) - yw(w,wt,t-1) \quad \forall w, wt, t \quad (8)$$

We introduce binary variables $y1(w,pp,tm,t)$ as the existence of transportation mode between oil well w and production platform pp . The amount of crudes transported from well w and platform pp using transportation mode tm at t is denoted as $Q1(w,pp,tm,t)$.

$$WTQ(w,t) = \sum_{pp} \sum_{tm} Q1(w,pp,tm,t) \quad \forall w, t \quad (9)$$

$$c^L(tm) \cdot y1(w,pp,tm,t) \leq Q1(w,pp,tm,t) \leq c^U(tm) \cdot y1(w,pp,tm,t) \quad \forall w, t \quad (10)$$

We define 0-1 continuous variables $x1(w,pp,tm,t)$ to exhibit the establishment of new transportation mode between well w and platform pp .

$$\sum_t x1(w,pp,tm,t) \leq 1 \quad \forall w, pp, tm \quad (11)$$

$$x1(w,pp,tm,t) = y1(w,pp,tm,t) - y1(w,pp,tm,t-1) \quad \forall w, pp, tm, t \quad (12)$$

3.4. Crude production constraints for platforms

$$PTQ(pp,t) = \sum_w \sum_{tm} Q1(w,pp,tm,t) \cdot ofr(w,t) \quad \forall pp, t \quad (13)$$

where, $ofr(w,t)$ is the water-oil ratio from well w at period t and $PTQ(pp,t)$ denotes crude oil volume produced from a production platform.

3.5. Other constraints

We have many similar constraints for production platform, refineries, petrochemical plants, chemical plants and external markets for oil, petroleum products, petrochemicals, and chemicals as those for oil wells, which are not given in this paper.

3.6. Nonlinear behavior for oil reservoir

The maximum crude oil flowrate and the water-oil ratio changes nonlinearly with the fraction of oil recovered due to the decreasing reservoir pressure as the crude oil extraction progressing. More details can be referred to Gupta and Grossmann (2012).

$$capw(w,t+1) = a1(w) \cdot fc^3(w,t) + b1(w) \cdot fc^2(w,t) + c1(w) \cdot fc(w,t) + d1(w) \quad \forall w, t < T \quad (14)$$

$$fc(w,t) = \sum_{s < t} WTQ(w,s) / REC(w) \quad \forall w, t < T \quad (15)$$

The oil fraction in the 'raw' crude oil by the end of period t is represented by,

$$ofr(w,t) = a2(w) \cdot fc^3(w,t) + b2(w) \cdot fc^2(w,t) + c2(w) \cdot fc(w,t) + d2(w) \quad \forall w, t \quad (16)$$

We complete our novel optimization model for all segments of PPSC, which is a large-scale multi-objective multi-period MINLP model.

4. Solution approach

The multi-objective feature is handled using weighting sum method (Sahebi et al., 2015) by firstly normalizing each objective function using its maximum and minimum values.

$$\tilde{f}_1 = \frac{NPV - NPV^L}{NPV^U - NPV^L} \quad \tilde{f}_2 = \frac{Eco99^U - Eco99}{Eco99^U - Eco99^L} \quad (17-18)$$

Then, a new combined objective is expressed using respective weight factors w_1 and w_2 .

$$f_3 = w_1 \cdot \tilde{f}_1 + w_2 \cdot \tilde{f}_2 \quad (19)$$

To solve the model to ε - global optimality, two-step procedure is proposed as follows,

Two-step procedure: For each combination of w_1 and w_2 , the solution with $w_1 = 1$ and $w_2 = 0$ is used to initialize DICOPT for the generation of a good feasible solution. Then the obtained feasible solution from DICOPT is used as a start point for ANTIGONE for ε - global optimality.

5. Computational Studies

An industrial-scale example is solved to demonstrate the capability of the proposed model and solution approach. There are 7 oil wells with 2 operated and 5 potential wells, 4 production platforms with 1 operated and 3 potential platforms, 3 refineries with 1 operated and 2 potential, 3 petrochemical plants with 1 operated and 2 potential, and 2 chemical plants with 1 operated and 1 potential, as illustrated in Figure 1. Each entity involves different potential technologies for potential facilities such as 3 extraction technologies for oil wells, 3 production and 3 storage technologies for platforms, 4 for refineries, 2 for petrochemical plants and 2 for chemical plants. Five transportation modes are considered including offshore and onshore pipelines, oil tanker, railcar and truck. This example is solved using DICOPT and ANTIGONE in GAMS 24.7 on a workstation with Intel® Core™ i5-6200U CPU 2.30 GHz with 8 GB RAM under Windows 10 Home 64.

Table 1 Computational results for the example with different weight factors

No.	f_3	NPV		EQ		RD	HH	$Eco99$
		w_1	(1×10^6 USD)	w_2	(1×10^9 USD)	(1×10^9 USD)	(1×10^9 USD)	(1×10^9 USD)
1	1.003	0.000	183.666	1.000	282.212	1118.028	624.252	586.191

8	0.962	0.875	14183.189	0.125	768.178	3020.074	1692.074	1588.116
9	1.001	1.000	14136.932	0.000	766.423	3010.489	1687.122	1583.588

Note that HH is human health, EQ is ecosystem quality and RD is resources depletion

The MINLP model consists of 18,588 binary variables, 59,358 continuous variables and 81,633 constraints. The results are presented in Table 1. As seen in Table 1, the values of $Eco99$ increase with the increase of w_1 , whereas NPV values is increased gradually, indicating the environmental performance conflicts with the economic objective. Table 2 gives different technologies selected in each facility. From Table 2, when w_1 increases,

the technology with lower cost is selected such as oil extraction technology wt1 since the technology with lower cost usually produce worse environmental impact, which can be seen from wells #2, #3, #6, and #7. Since the well #1 uses the extraction technology wt3 in the beginning, it do not change technology throughout the entire period. This is also true for the well #4 and #5 with fixed technology of wt2. By taking higher consideration of environmental impact, the technology selection will switch from more economical technologies to more environmentally friendly technologies (e.g., wt1 to wt3).

6. Conclusions

In this work, we developed a novel multi-objective multi-period MINLP model for strategic planning of entire PPSC covering upstream, midstream and downstream segments to support decision making for petroleum and petrochemical industries. Nonlinear behaviour of the reservoir was employed for accurate prediction of crude production. Environmental impact as well as economic performance was optimized simultaneously. The multi-objective model was converted to a single-objective by employing the weighting-sum method, which was solved to ϵ - global optimality using the proposed two-step procedure. The computational results clearly demonstrate the effect of considering environmental impact on the operation of PPSC.

Abstract

A high order Geometric Observer (GO) and a *hybrid* discrete-time extended Kalman filter (*h*-DEKF) are assessed in real-time towards data reconciliation and comprehensive polymer characterization. The nonlinear estimators are tested under a set of experiments using the data provided by the state-of-the-art smart sensor Automatic Continuous Online Monitoring of Polymerization reactions (ACOMP). To design the GO three different high-order structures are evaluated in terms of their robustness and performance. The gains of the GO are set following a systematic approach with a distinction between pure measurements and Lie derivatives. The *h*-DEKF design follows an auto-tuned error driven initialization of the free-parameters where different metaheuristic algorithms are employed for tuning. Both nonlinear estimators are contrasted for applications in the Smart Manufacturing of polymers. The aqueous polymerization of acrylamide using potassium persulfate as initiator demonstrates the effectiveness and flexibility of the estimator for real-time applications.

Keywords: Free-radical polymerization, nonlinear state estimation, geometric observer, extended Kalman filter.

1. Introduction

The chemical industry demands practical tools for the Smart Manufacturing of chemicals with target final properties. Polymers represent a significant portion of this industry, and its synthesis involves complex processes. Major concerns in polymerization include the intricacy of the mathematical model as well as inadequate or nonexistent real-time characterization techniques. A major goal in polymerization facilities is to achieve a target molecular weight distribution (MWD). After the chemical structure, MWD is the most important parameter controlling the physical, mechanical and processing properties of polymers. Nonetheless, the online monitoring of MWD by hardware sensors is currently not feasible at industrial scale. This scenario motivates the search for adequate state observers to generate a basis for model-based monitoring/control systems.

The utilization of state observers has a significant role on establishing the necessary model-based tools for the polymerization industry. The prevalent high cost of reliable sensors represents a major concern. Even if measurements are economically available

for the system, they are often inaccurate or contaminated by noise. In this context, state observers can suffice the lack of genuine measurements for control systems. State observers can infer significant unmeasured properties of the polymer during synthesis, providing model-centric monitoring and control capability that prevent shifting from desired final key properties.

In this work, a high-order GO and an h -DEKF are compared based on their ability in data reconciliation and state estimation. The comparison criteria includes robustness, estimation of unmeasured properties and stability. The ACOMP provides real-time measurements of monomer concentration, weight-average molecular weight and volume of contents inside the reactor (Reed, 2013). Using the available measurements and an upgraded version of the model developed by Ghadipasha et al. (2016), both nonlinear estimators are adapted to the underlying process. The GO (Alvarez & Fernandez, 2009) is principally characterized by its applicability to either observable or detectable systems. The design of the GO includes a robust local convergence and a systematic construction-tuning procedure. The h -DEKF is constructed in a similar fashion to the one in Salas et al. (2017). The difference resides in the determination of covariance error matrices, which are obtained following an auto-tuned error-driven approach. Then, both nonlinear state estimation methods are contrasted for applications in the Smart Manufacturing of polymers. The aqueous polymerization of acrylamide using potassium persulfate as initiator serves as an illustrative example to demonstrate the effectiveness of the real-time nonlinear state estimation and enhanced monitoring. The estimation strategies are tested under a range of conditions.

2. Background

2.1 Nonlinear Model

The adopted model of the polymerization reactor was based on Ghadipasha et al. (2016) and is here summarized

$$\frac{dN_m}{dt} = -(k_p + k_{fm})P_0N_m + F_mC_{mf} - F_{out}C_m \quad (1a)$$

$$\frac{dN_i}{dt} = -k_dN_i + F_iC_{if} - F_{out}C_i \quad (1b)$$

$$\frac{dN_s}{dt} = -k_{fs}N_sP_0 + F_iC_{sif} + F_mC_{smf} - F_{out}C_s \quad (1c)$$

$$\frac{d(\lambda_0V)}{dt} = (k_{fm}N_m + k_{td}P_0V + k_{fs}N_s)\alpha P_0 + \frac{1}{2}k_{tc}P_0^2V - F_{out}(\lambda_0) \quad (1d)$$

$$\frac{d(\lambda_1V)}{dt} = [(k_{fm}N_m + k_{td}P_0V + k_{fs}N_s)(2\alpha - \alpha^2) + k_{tc}P_0V] \frac{P_0}{(1-\alpha)} - F_{out}(\lambda_1) \quad (1e)$$

$$\frac{d(\lambda_2V)}{dt} = [(k_{fm}N_m + k_{td}P_0V + k_{fs}N_s)(\alpha^3 - 3\alpha^2 + 4\alpha) + k_{tc}P_0V(\alpha + 2)] \frac{P_0}{(1-\alpha)^2} - F_{out}(\lambda_2) \quad (1f)$$

The available measurements, along with their dependency on the state variables, are

$$C_m = \frac{N_m}{V}, \quad M_w = w_m \frac{\lambda_2}{\lambda_1}, \quad V = \frac{\lambda_1 V w_m}{\rho_p} + \frac{N_m w_m}{\rho_m} + \frac{N_s w_s}{\rho_s} + \frac{N_i w_i}{\rho_i} \quad (2)$$

The other not measured polymer properties to be estimated are

$$M_n = w_m \frac{\lambda_1}{\lambda_0} \quad (3a)$$

$$\frac{d g(m,n)}{dt} = \frac{k_p N_m P_0}{\lambda_1 V} \left[\left(\frac{m(1-\alpha)+\alpha}{\alpha} \right) \alpha^{m-1} - \left(\frac{(n+1)(1-\alpha)+\alpha}{\alpha} \right) \alpha^n \right] - \frac{1}{\lambda_1 V} g(m,n) \frac{d(\lambda_1 V)}{dt} \quad (3b)$$

For a detailed model description and definition of variables and constants, please see Ghadipasha et al. (2016). The above model could be recast, in compact notation, as

$$\dot{\mathbf{x}}(t) = f(\mathbf{x}, \mathbf{u}), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \quad (4a)$$

$$\mathbf{y} = \mathbf{h}(\mathbf{x}) \quad (4b)$$

where, $\mathbf{x} = [N_m, N_i, N_s, \lambda_0 V, \lambda_1 V, \lambda_2 V]^T$ is the 6-dimensional state vector, $\mathbf{u} = [F_m, F_i, T]^T$ and $\mathbf{y} = [C_m, M_w, V]^T = [h_1(\mathbf{x}), h_2(\mathbf{x}), h_3(\mathbf{x})]^T$ are the 3-dimensional vectors of controlled variables and measurement ones.

2.2 Observability and Detectability

Even though the ACOMP represents a major advancement in providing online measurements of polymer properties, the complete state vector can seldom be measured. The number of online measurements is lower than the number of states required to fully describe the dynamics of the system. The implementation of a dynamic nonlinear state estimator is necessary for better comprehension of the evolution of state variables as well as to improve the available measurements. The effectiveness of the process monitoring depends on basic properties of the model: the observability and detectability. As reported by *Alvarez & Fernandez (2009)*, it is possible to assess the observability of a nonlinear system through the definition of the observability map $\boldsymbol{\phi}(\mathbf{x}, \mathbf{u}) = [\phi_1, \phi_2, \dots, \phi_m]^T$.

$$\boldsymbol{\phi}(\mathbf{x}, \mathbf{u}) = [\phi_1, \phi_2, \dots, \phi_m]^T, \quad \phi_i = (h_i, L_f^1 h_i, \dots, L_f^{k_i-1} h_i) \quad (5a)$$

where, $L_f^j h_i$ are the recursive j^{th} Lie derivatives of the time varying scalar field h_i along the vector f , k_i is the observability index of the i^{th} output and k is the estimator order given in Eq. (5b).

$$k = k_1 + k_2 + \dots + k_m \quad (5b)$$

For n states, the system is observable if the rank of the observability matrix is $k = n$. When $k < n$, there are unobservable states and the system is RE-exponentially estimable if the unobservable motion is stable. In this case, there is a differentiation between distinguishable and undistinguishable states.

2.3 Geometric Observer

The nonlinear estimation here reconstructs the polymerization dynamics (1-3) based on the GO proposed by *Alvarez & Fernandez (2009)*. The observer is reported in compact notation in Eq. (6a) for innovated and in Eq. (6b) for non-innovated states. Innovated states are those states which are corrected using the available measurements, while non-innovated states are obtained from the model (open-loop).

$$\hat{\mathbf{x}}_i(t) = f_i(\hat{\mathbf{x}}, \mathbf{u}) + (\partial_x \boldsymbol{\phi}(\hat{\mathbf{x}}, \mathbf{u}))^{-1} \mathbf{K}[\mathbf{y} - \mathbf{h}(\hat{\mathbf{x}})] \quad (6a)$$

$$\hat{\mathbf{x}}_v(t) = f_v(\hat{\mathbf{x}}, \mathbf{u}) \quad (6b)$$

In Eq. 6, $\hat{\mathbf{x}} = (\hat{\mathbf{x}}_i, \hat{\mathbf{x}}_v)$ is the estimated state vector; $\hat{\mathbf{x}}_i$ and $\hat{\mathbf{x}}_v$ are the vectors of the innovated and non-innovated states (*Tronci et al., 2005*), respectively; \mathbf{K} is a block diagonal matrix and its values are set in such a way that the error dynamics remain stable.

2.4 h-DEKF Implementation

The *h-DEKF* follows a similar structure as presented by *Salas et al. (2017)*. Here, it is enough to outline the basic concepts on which the DEKF relies. For details on the governing equations, please refer to *Simon (2006)*. The inferential procedure is,

$$\hat{\mathbf{x}}_{j+1/j+1} = \hat{\mathbf{x}}_{j+1/j} + \mathbf{K}_{j+1}[\mathbf{y}_{j+1} - \mathbf{h}_{j+1}(\hat{\mathbf{x}})]. \quad (7)$$

where $\hat{\mathbf{x}}_{j+1/j+1}$ represents the state estimate at time $(j + 1)$ on the basis of the model prediction $\hat{\mathbf{x}}_{j+1/j}$. \mathbf{K}_{j+1} is the filter gain matrix that weights the relative importance given to the model predictions and to the actual measurements. The filter gain matrix is constructed on the basis of the error covariance matrices of the measurements (\mathbf{R}) and the model (\mathbf{Q}) (Simon, 2006) that can be regarded as tuning parameters. The tuning problem of the filter is expressed as the minimization of the sum of the product between an absolute error vector, the inverse of the measurement error covariance matrix and the transposed absolute error vector, as given in Eq. (8).

$$\min \sum_{j=1}^n [\bar{y}_j - h(\hat{\mathbf{x}}_j)] \mathbf{R}^{-1} [\bar{y}_j - h(\hat{\mathbf{x}}_j)]^T \quad (8)$$

The *h-DEKF* tuning was performed using a genetic algorithm (GA) (Kapanoglu et al, 2007), differential evolution (DE) (Storn & Price, 1997) and particle swarm optimization (PSO) (Poli et al, 2007). Each algorithm has 30 independent runs of 1500 fitness function evaluations each, and, because the methods are population-based, 50 generations of a population size of 30 are chosen for all cases. For the GA, the selected crossover fraction is 0.6, extra-range for crossover is 0.4, mutation fraction set to 0.4, mutation rate to 0.1 and the selection method is fixed as random. Regarding the DE, the crossover rate is 0.7 and the scaling factor is randomly selected between the bounds [0.2, 0.8]. Finally, the PSO uses as parameters 1 for the initial inertia weight, 0.99 for the damping ratio, 1.5 for the cognitive coefficient and 2.0 for the social coefficient.

3. Results

The proposed nonlinear state estimation approaches were tested on a polymerization pilot plant consisting of a 1.5 L reactor monitored by the ACOMP system and auxiliary fittings and instruments (Salas et al. 2017). Recipes for three optimal semi-batch experiments corresponding to increasing, constant, and decreasing M_w time-evolution trajectories are generated by the minimization of a multi-objective dynamic optimization problem (Ghadipasha et al. 2016).

The analysis of the observability matrix shows that only 5 out of 6 states are observable, in which $\lambda_0 V$ is the not observable state. For the high-order estimator, the Lie derivative of two measurements are necessary. The combinations of possible integer k_i include: $(k_1, k_2, k_3) = (2, 2, 1)$, $(k_1, k_2, k_3) = (2, 1, 2)$ and $(k_1, k_2, k_3) = (1, 2, 2)$, where the first integer refers to C_m , the second to M_w and the third to V . The values of the coefficient of the gain matrix \mathbf{K} in (4) have been selected analyzing the natural frequencies of the system and they are set equal 0.4 for measurements and 10^{-8} for the Lie derivatives.

The different observer structures are compared in terms of the minimum singular value (σ_0), and condition number ($\eta = \sigma_{max}/\sigma_0$) of the observability matrix, in the understanding that the better estimation should be characterized by the highest σ_0 and the lowest η (Porru & Özkan, 2017). For this purpose, three different trajectories of M_w have been studied and the observability matrix was calculated along the trajectories. Results for the initial condition are reported in Table 1 and show that the innovation of 5 states with structures $(2, 2, 1)$ and $(1, 2, 2)$ depict a higher σ_0 with respect to $(2, 1, 2)$ in all cases. This behavior does not change along the trajectories. These phenomena can be explained by considering that h_2 is the only function depending on $\lambda_2 V$; therefore, by using its Lie derivative, it is possible to gain more information on $\lambda_2 V$. Configuration $(2, 2, 1)$ shows the lowest condition number for all cases, and appears to be the most promising structure. However, this structure fails to converge in some of the studied

trajectories (Increasing M_w trajectory) when tested in the set of available experiments. Thus, the structure that shows better performance is $(1,2,2)$, which can be explained by considering that C_m is more susceptible to introduce errors to the system with respect to V , which can have an impact on the robustness of the estimation.

The h -DEKF exhibits stable behaviour and ability in predicting unmeasured properties. In addition, the DE algorithm showed the best performance in achieving the best minimum value in average during tuning. The GO shows a slightly better ability in data reconciliation as it accomplishes better the task of reducing the noise of measurements, but the h -DEKF shows a better performance with respect to GO in predicting unmeasured properties for all cases. The comparison of the GO and h -DEKF is illustrated by Figure 1 and 2, for a representative increasing and decreasing M_w experiments.

Table 1: Minimum singular values and condition number for high order structures

Trajectory	Structure	$(2,2,1)$	$(2,1,2)$	$(1,2,2)$
Increasing M_w	σ_0	7.67E-05	1.13E-19	7.67E-05
	η	2.08E+10	4.83E+23	6.55E+14
Constant M_w	σ_0	7.82E-05	1.14E-21	6.13E-20
	η	2.68E+10	4.79E+25	8.9E+23
Decreasing M_w	σ_0	7.75E-05	3.76E-20	8.08E-20
	η	2.85E+10	1.45E+24	6.74E+23

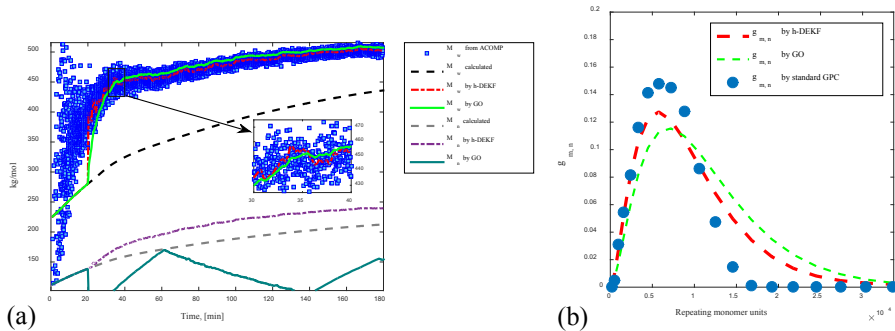

Figure 1: Increasing M_w trajectory. a) Weight average and number average molecular weight evolution, b) Experimental and estimated final chain length distribution.

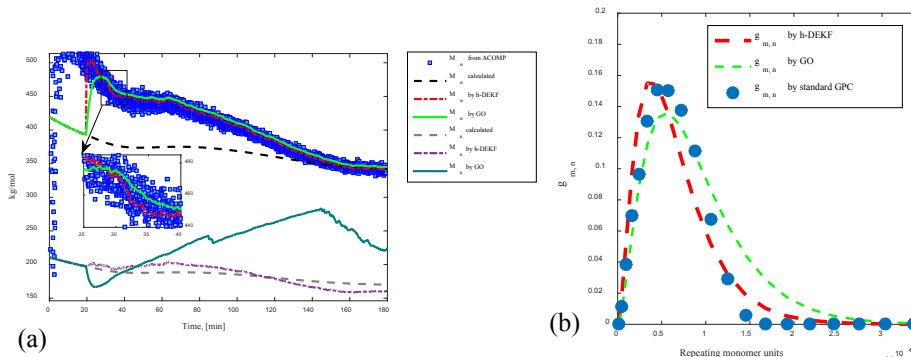

Figure 2: Decreasing M_w trajectory. a) Weight average and number average molecular weight evolution, b) Experimental and estimated final chain length distribution.

4. Conclusions

In this work, two different nonlinear state observers, GO and h -DEKF, are assessed and compared for reconstructing unmeasured properties i.e., number-average molecular weight and molecular weight distribution, while performing signal processing for the Smart Manufacturing of polymers. A response analysis determines the performance of each nonlinear observer. The h -DEKF leads to better results with respect to GO to infer MWD, but the GO offers better capability in data reconciliation. However, the h -DEKF presents for this case a better performance overall. The reasons of such finding could be related to the selected GO structure, which involves a high order structure that utilizes all possible Lie derivatives of the measured variables. This makes the estimation more sensitive to measurement and model errors/noise.

Therefore, a full order GO might not be the best choice for this application, which opens a venue to study in the future. The possibility of implementing lower order structures to increase the observer robustness without reducing the estimation performances represents a deeper study on the possible structures and combination of innovated states. The inclusion of robust and flexible state observers in model-centric tools permits a more efficient and effective operation during polymer synthesis.

Abstract

Water resources availability, in terms of quality and quantity, is a very crucial issue in many areas of the world; especially in areas with water shortage and varying and time dependent water demand. Lately, it has become obvious that water supply chain problems are also inherently linked to the energy availability and quality of an area, leading to the so called water – energy nexus problems. The present work is a continuation of our ongoing research in the optimisation of water and energy supply chain in terms of maximising the overall benefit of the integrated system, whilst satisfying the conflicting demands. The objective of the work is to expand the model for water supply optimisation to take into account all the potential water supply sources intending to support decision making in investments planning, with environmental considerations.

Keywords: water resources optimisation, water energy integration, economic and environmental criteria

1. Introduction. Scope and objectives of the work

Water resources availability, in terms of quality and quantity, is a very crucial issue in many areas of the world; especially in areas with water shortage and varying and time dependent water demand. Lately, it has become obvious that water supply chain problems are also inherently linked to the energy availability and quality of an area, leading to the so called water – energy nexus problems. In parallel, energy is a focal point in the water supply since in many cases it is in fact the limiting factor for the implementation of various water supply methods. For example, desalination methods being technologically mature and easily accessible, could provide easy and not particularly expensive water. However, the high energy demand of desalination methods sets constraints in the implementation of the method.

Furthermore, water recycle from waste water treatment plants may also provide a very important water supply method in various areas where there is no other method that

could be applied. However, the water transportation from the production point to the distribution network requires energy and again the two problems may be considered in an integrated manner. For the application of the developed framework, a case study in Cyclades island has been carried out in order to designate optimum water supply chain characteristics, along with the solution of the energy supply chain (ESC) problem, ultimately aiming to maximise the total benefit of the systems – as this is defined in the work. The results of the problem solution, the applicability of the model in various water – energy nexus as well as the importance and relevance of the issue in the CAPE community are also highlighted in the work.

Over the past decade, the integrated approach for the solution of water and energy problems, i.e. the so called ‘water – energy nexus’ has become a topic of increasing attention for the scientific communities and practitioners in the field. There is a continuous increase in the academic papers as well as in the professional studies demonstrating the improving capacity of the scientific community to assess in an integrated approach the water and energy problems.

Indicatively some of the most recent works related to the water – energy nexus may be cited. Saeed Kaddoura and SamehEl Khatib (2017) make a detailed review of the existing nexus modelling tools used for integrated policy making and identify the capabilities and limitations of each modelling tool in order to help readers select the appropriate tool for their objective.

Jiangyu Daia et al (2018) in their very recent research work make an extensive survey of recent scientific literature on the water-energy nexus, where 70 studies were identified and 35 were selected as comprehensive case studies for review. From this review it is clear that the research on water-energy nexus has seen a significant increase in both the number of studies and the capacity of the scientific community to productively assess water and energy interlinkages at a higher resolution. Fewer approaches are designed to support governance and implementation of technical solutions, and this is considered to be a priority challenge area for the scientific community if it aims to achieve greater impact on resource policy and management.

Daniel J. Garcia and Fengqi You (2016) relate the Water – Energy – Food nexus approach with Process Systems Engineering principles and identify process systems engineering research opportunities to appropriately model and optimize the nexus. It is clear from their work that there are further challenges with appropriate system boundary definitions and challenges in modeling the decision-making and conflicting objectives of multiple stakeholders in the nexus.

Focusing attention in the very crucial issue of water resources management and its sustainability considerations, Pires et al evaluate how indicators related to water use and management perform against a set of sustainability criteria assessing 170 indicators through an international panel of experts that evaluated whether they fulfil the four sustainability criteria: social, economic, environmental, and institutional.

Studying all these works it is obvious that very significant progress has been achieved but still there is a very wide scope for further work in the field since there are many features of the integrated problem that are not well understood yet and there is a very challenging area of problems that is focused either in specific geographical regions or in very specific characteristics of the problem itself.

The present work is a continuation of our ongoing research in the optimisation of water and energy supply chain in terms of maximising the overall benefit of the integrated system, whilst satisfying the conflicting demands. The objective of the work is to expand the model for water supply optimisation to take into account all the potential water supply sources along with their environmental and social impacts intending to support decision making in investments planning.

2. Case study

The optimisation model that has been developed in Papapostolou et al (2017) is implemented for a small island in Cyclades complex, called Iraklia. Iraklia - named after the Greek mythological god Hercules - is the westernmost island of the Small Cyclades complex with an area of 18 thousand square kilometres, located 18 nautical miles southern of Naxos, the largest island of Cyclades complex. The small island has 151 inhabitants settled in Panagia and Agios Georgios, the main settlement and the port, respectively.

At each aforementioned locations, there are two water tanks: the one in Panagia can store up to 1000m³, while the capacity of the Agios Georgios is 500m³. The latter presents significant water shortages, especially during the summer months which up till now have been met via ship-transfers (Figure 1), with a specific water transportation cost of ~15€/m³. For that purpose, the state has financially supported the installation of a desalination plant (300m³/day), which will be powered by a local diesel power station.

Figure 1: Annual water shipments to Iraklia throughout 2013 (YPEKA, 2016)

In Iraklia, as in most of the Aegean Sea islands, the electricity needs present a large fluctuation between winter and summer seasons, mainly attributed to tourism. More specifically, the load peak, which occurs during August, is nearly 4 times the average load during winter. The water demand has also a similar profile through time. Considering that the new desalination plant will produce as much water as is currently transported and the existing water supply strategy wherein the available water tanks' level should remain constantly at their maximum capacity, the electricity demand fluctuation will further be increased.

To deal with the load demand additions and to further reduce the total operational cost of the system, the option of installing RES is evaluated, accounting typical investment costs per kW installed for the diesel (850€/kW), wind (1400€/kW), PV (1200€/kW) and

for the energy-storage (Batteries 650€/kWh), desalination (1667 €/m³) for a project life-span of 25 years and granting typical annual fixed costs (See Tables 1, 2) whilst only for the diesel power station the specific fuel cost at (1.7€/lt) applies. Additionally, in an effort to predict more accurately the actual costs, the replacement of infrastructure parts has also been considered, as follows in Eq. (1):

$$\begin{aligned}
 & \text{ECONV} \\
 &= \frac{\sum_r \left[\frac{Pr_r * INVr_r}{*(1+n*FCr_r)} \right] + \sum_s \left[\frac{Ps_s * INVs_s}{*(1+n*FCs_s)} \right] + \sum_{wr} \left[\frac{Pwr_{wr} * INVwr_{wr}}{*(1+n*FCwr_{wr})} \right]}{(1+i)^n} \\
 &+ \frac{n * (\sum_t \sum_r EGrt_r * FCr_r + \sum_t \sum_s ESgt_s * FCs_s + \sum_t \sum_{wr} Fwrt_{wr} * FCwr_{wr})}{(1+i)^n} \quad (1)
 \end{aligned}$$

where the “r”, represents the different set of resources (wind, diesel and PV), “s” the storage station(s), “wr” the water resources (shipment and desalination) and “P” the nominal capacity of the resources, storage stations and water resources accordingly. Moreover, the installation cost “INV”, and the annual fixed cost “FC” are also considered for a time horizon “n” of 25 years, with an inflation rate “i” of 3%.

Table 1: Problem design parameters

Parameter	Assigned Values
Ship transfer water - cost (€/m ³)	10
Diesel fuel cost	1.7€/lt
Desalination capacity	300 m ³ /day
Water reservoir	500 m ³
Initial water level	100m ³
Batteries Depth of Discharge	90%
Desalination energy consumption	5kWh/m ³
Inflation rate	3%

Table 2: Problem cost parameters

Cost Parameter	Assigned Values
*Wind park installation cost (€/kW) ¹	1,350
*PV park installation cost (€/kW) ²	1,200
*Diesel station cost (€/kW) ³	850
*Battery specific cost (€/kWh) ⁴	650
*RO desalination plant cost (€/m ³) ⁵	1667
Annual fixed cost	3% x total initial cost ¹ 1.5% x total initial cost ² 5% x total initial cost ³ 0.5% x total initial cost ⁴ 2% x total initial cost ⁵

So, under the model setup introduced by Papapostolou et al. (2017), energy and water demand fulfillment will be investigated under a set of energy SCs (wind, PV, diesel and battery energy storage). The following equation describes the energy balance to be preserved, for each time step t (8760 hours per year), for s=1, one battery storage station Eq. (2):

$$\sum_r EGrt_r + ESgt_s - ESst_s - Edwrt_{wr} - \sum_u Edu_u = 0 \quad (2)$$

Where, $EGrt_r$ is the energy production of the specific resource (wind, PV, diesel), $ESgt_s$ is the energy retrieved from the battery bank, $ESst_s$ is the energy stored at the battery bank, Edu_u represents the electricity needs of the island users “u” and $Edwrt_{wr}$ stands for the electricity needs of the desalination plant. The hourly electricity requirements of the desalination plant are estimated by utilizing commercialized desalination infrastructure

technical specifications and by considering monthly sea water temperature factors. The water salinity is assumed equal to 39 psu. The water demand profile is estimated by considering the annual needs and typical monthly factors of water consumption, as arisen by historical data.

3. Results – Discussion

With the constraints of 100% energy and water demand fulfilment, and in search of the optimal sizing in terms of nominal power of the ESCs, the aforementioned model has been implemented. The most cost-efficient solution, in long term, with a great environmental performance is presented at Table 3: a small-scale PV, a wind turbine, a conventional power plant and an energy storage station have been selected in order to cover the electricity needs, including the desalination plant’s load demand.

Table 3: Results in terms of Nominal Power (NP)nominal power of the energy SCs

NP of the Diesel Power Plant (MW)	NP of the Wind Farm (MW)	NP of the PV Park (MW)		Capacity of the Energy Storage System (MWh)	NP of the Desalination (MW)
0.35	0.81	0.4		0.5	0.06

The proposed solution satisfies the electricity needs through RES, by approx. 92%, reducing the CO₂ emissions from 1110 tn/y, a value that corresponds to 100% coverage by a diesel-fired power plant, to 83 tn/y. The proposed solution requires a relative high capital expenditure due to the RES investment incorporation (approx. 1.87 MEUROS), however leads to the minimum possible present value of the total costs for a 25year operation of the system.

For the selected ESCs, representative operational profiles are depicted in Figure 2, for a set of typical days during the summer (August) period. As one may observe, under the resulted reasonable energy ESCs sizing, energy demand is met, allowing the minimum possible operation of the diesel power plant whilst also storing energy in days of RES surplus.

Figure 2: ESCs operation during August

4. Conclusions

In this work an integrated framework for the optimisation of water and energy supply systems is investigated through the model implementation in a small island in Cyclades. This small island faces electrical power and water outages, especially during the summer months, when the local population increases by approximately 500%. The implementation of the proposed framework results in the most cost-efficient solution, while it has a huge positive impact in the system's environmental performance. More specifically, model implementation results in the sizing of the RES- based desalination configuration (desalination plant and the associated wind, PV and battery energy supply system), of the diesel power station. In addition, it satisfies both the energy and water demand profile of the island, all accounting economic and environmental considerations.

This is an interesting case study on its own, as well as compared to the current proposed-by-the state water supply solution for the island which involves only a desalination plant powered by a diesel station, with no provision for load-demand increase and relevant shut downs that may occur during the touristic infusion of summer months. Especially when in operation the environmental criteria, the selection of RES-based desalination plant is grounded. The proposed framework may equally be applied to more complicated water and energy SCs with different not only resources on the demand side but also more end customers that need to be satisfied simultaneously.

Planning the Drilling Rig Activities – Routing and Allocation

M. Sadegh Tavallali^{*}, Marzieh Zare

Department of Chemical Engineering, Shiraz Branch, Islamic Azad University, Shiraz, Iran 71987-74731

tavallali@iaushiraz.ac.ir

Abstract

Drilling well in petroleum fields is a highly complex task and managing a drilling rig fleet is even a more difficult issue, with various financial motivations and threads. Probably the most challenging issue is to efficiently allocate rigs to potential drilling sites and also to effectively determine the path of rig movements between the target drilling locations. The latter is rarely addressed in the open literature. Mathematical programming offers promising decision support models for such problems, hence in this study a time continuous optimization model is developed to minimize the overall drilling costs, and simultaneously plan the rig activities. The possibility of rig outsourcing is also embedded in the model and tested on an example. The results indicate 5.6% less total drilling costs.

Keywords: Drilling Rig, Routing, Planning, Mathematical Programming

1. Introduction

In contrast to the crude oil price, the energy demand is constantly increasing. This situation has created a sophisticated challenge for drilling companies, i.e. drilling activities should expand in spite of the current tight economic situation. Moreover, drilling is not a static activity, rather it is inherently a dynamic process (Tavallali et al. 2013), where not only the timing for well drilling, and rig movement should be rigorously planned, but also the rig routing, and possible rig outsourcing should be considered over the project horizon. Finally, the various alternatives for decisions such as rig-to-drilling site allocation, rig movement path selection, drilling timing make the drilling management problem an excessively combinatorial issue. Although there has been some attempts to study this complex problem (Van Den Heever and Grossmann 2000), still there exists important gaps (Tavallali et al. 2016). Firstly, this problem (and well placement as a tightly related task) is mostly modelled as a discrete time problem (Iyer et al. 1998, Tavallali 2015), thus there are many limitations in determining the practical drilling or movement durations. Secondly, to our knowledge, rig outsourcing is not addressed in the open literature, whereas this is a usual practice, especially for private drilling companies. Thirdly, although rig-to-well allocation is studied, however we are only aware of the study by (Iyer et al. 1998), who tackled rig movement planning in different regions of a field.

There exists a problem similar to the drilling rig planning in petroleum upstream industry and that is workover rig planning (WRP) (Aloise et al. 2006). Workover rigs are used to service wells which were already in operation. WRP is usually modelled as a time-discrete problem, with the objective of minimizing petroleum production loss.

That is an approximation for the volume of hydrocarbon that could be produced if the well was in service. In contrast to drilling operations, there are no standard drilling activities involved in WRP.

A practical approach for addressing the planning problem of drilling rig activities can be to use and modify the WRP concept to address the technical demands of drilling industry. This approach is utilized in this study. Moreover, we focus on the rig routing and movement problem, and tackle the three limitations of drilling planning studies mentioned above with a continuous time model.

2. Problem Definition

A drilling company should plan for drilling N wells using Y number of drilling rigs during a time window of T days. To be specific, the problem is as follows:

Given: Number and location of target wells, drilling rigs and rig terminals, geometry and the duration of each drilling, economic and financial data

Assumption: No idle duration between drilling activity of each rig

Policy: No drilling happens at the terminals and if required, new rigs can be outsourced from specific terminals.

Aim: Minimizing the overall costs of the project.

By determining: The drilling plan, rig-to-well allocation, and rig routing (movement from well-to-well)

3. Modeling

Sets and indices: Here we use $i = 1, 2, 3, \dots, I$ to refer to drilling rigs, $j = 1, 2, 3, \dots, J$ to show the target drilling wells/sites, and $k = 0, 1, 2, 3, \dots, K$ to represent the activity sequence. The sequence idea is defined to ensure the flexibility of tailoring a time continuous model. Finally, we define $OI \subseteq I$ to refer to the owned and outsourced rigs, and $JT \subset J$ to show the terminal sites were rigs can be stored.

Binary variables: y_{ij}^k is 1 if rig i starts drilling well j in the k -th sequence and 0 otherwise. Moreover $z_{ijj'}^k$ is 1 if rig i moves from site/well j to the site/well j' in the k -th sequence and 0 otherwise. Finally, it is assumed that the initial sequence shows the initial condition were no drilling was in operation, hence we set $y_{ij}^0 = 0$ and $z_{ijj'}^0 = 0$;

Constraints: Various logical, and techno-economic constraints are involved in this problem. In the interest of space, the most important ones are presented here.

Each well is drilled only once and obviously by at most one drilling rig. No drilling happens at terminals.

$$\sum_i \sum_k y_{ij}^k \alpha_{ij} = 1 \quad j \notin JT \quad (1)$$

Here α_{ij} is a binary parameter which is 1 if rig i can drill well j and 0 otherwise. This is fixed priori based on the technical requirements of well j and capabilities of rig i .

Moreover, each rig can drill only one well during each sequence.

$$\sum_j y_{ij}^k \alpha_{ij} \leq 1 \quad j \notin JT \quad (2)$$

The maximum allowable drilling length of each rig (q_i) is limited and hence that should not be more than the length of target well j .

$$l_j \sum_k y_{ij}^k \alpha_{ij} \leq q_i \quad j \notin JT \quad (3)$$

Based on the policies of the company, the operations are continuous and back-to-back.

$$y_{ij}^k \alpha_{ij} \leq \sum_{j'} y_{ij'}^{k-1} \alpha_{ij'} \quad j \neq j' \quad (4)$$

Rig routing is done by tracking the sequential activities of each rig at different sites.

$$z_{ijj'}^k \alpha_{ij} \alpha_{ij'} \leq (y_{ij}^k \alpha_{ij} + y_{ij'}^{k+1} \alpha_{ij'}) - 1 \quad j \neq j'; \quad k < K \quad (5)$$

Additionally, once rig i moves out of site j it should reach only one site. This is similar to a logical mass balance.

$$\sum_{j'} \sum_i z_{ijj'}^k \alpha_{ij} \alpha_{ij'} \leq 1 \quad j \neq j'; \quad k < K \quad (6)$$

Moreover, we assume that only one rig can move between two sites in a same sequence.

$$\sum_j \sum_{j'} z_{ijj'}^k \alpha_{ij} \alpha_{ij'} \leq 1 \quad j \neq j'; \quad k < K \quad (7)$$

The allocation decision is tightly related to the drilling time duration of each well. Considering the required rig travelling time from its initial position to the site j to be ft_{ij} , i.e. first traveling time. The very first drilling begins at least after this time duration is passed:

$$\sum_i ft_{ij} y_{ij}^1 \alpha_{ij} \leq dt_j \quad j \notin JT \quad (8)$$

where dt_j is the time of drilling initiation. Drillings should be finished before the end of contract deadline:

$$dt_j + \sum_i \sum_k \left(d_{ij} y_{ij}^k \alpha_{ij} + tt_{ij} z_{ij}^k \alpha_{ij} \right) \leq T \quad j \notin JT \quad (9)$$

Here d_{ij} is a parameter showing the drilling duration of well j by rig i , and tt_{ij} is a parameter showing the traveling time of rig i from initial site j to the final site j' .

Objective function: The total project cost (TC) should be minimized, by minimizing the costs of outsourcing rigs (C_{OS}), drilling (C_D), and rig movement:

$$\min TC = C_{OS} + C_D + C_{RM} \quad (10)$$

$$C_{OS} = \sum_{i \in OI} \sum_{j \notin JT} \sum_k C_{1ij} \left(d_{ij} y_{ij}^k \alpha_{ij} + \sum_{j'} tt_{ij} z_{ij}^k \alpha_{ij} \alpha_{ij'} \right) \quad (11)$$

$$C_D = \sum_i \sum_{j \notin JT} \sum_k \left(Cv_{ij} lv_j + Cd_{ij} ld_j \right) y_{ij}^k \alpha_{ij} \quad (12)$$

$$C_{RM} = \sum_i \sum_j \sum_{j'} \sum_k C_{2ij} t_{ij} z_{ij}^k \alpha_{ij} \alpha_{ij'} \quad (13)$$

where C_{1ij} , Cv_{ij} , Cd_{ij} and C_{2ij} are in order the unit costs of rig outsourcing, vertical and deviated drilling, and finally the rig movement. Additionally lv_j and ld_j are vertical and deviated lengths of well j .

4. Example

We evaluated the performance of the aforementioned model for a planning project with an operational time window of 365 days, 3 drilling rigs (with different technical specifications), three terminals and 5 potential (distributed) drilling sites. Total number of sequences was set as $K = 4$. This problem had 653 equations, 209 binaries and 18 continuous variables. DICOPT solver of GAMS 24.9.1 was used on a laptop with Intel CPU 3210M @ 2.50 GHz with 5.84 GB RAM to solve that.

Figure 1 shows the potential allocations (and hence routing) with dotted arrows and the depth of each site is shown in parenthesis. To evaluate the performance of the above model, we firstly chose a base case with 76, 107 and 122 days of operation for rig $i1$ to $i3$ respectively. That yielded total cost of 28.4 MM\$. Then solve the aforementioned model. Its final solution is shown with solid lines on Figure 1. The final costs was 26.8

MM\$ based on the assumed economic coefficients, i.e. almost 5.6% lower than the base case.

Figure 1: The bird view map of the field under study.

The selected allocations are shown in solid yellow lines.

As can be seen all drillings are done by $i2$ and $i3$ rigs and $i1$ is not utilized. Analysing the solution reveals that this is due to the fact that $i1$ is offered as an option for rig outsourcing and its selection could impose higher costs for the project. Hence that is prevented.

Figure 2: The drilling plan

T and D refer to the number of days spent for traveling and drilling.

Figure 2 represents the drilling plan. In this figure T and D refer to the number of days spent for traveling and drilling. According to Figure 1 and 2, rig $i2$ has taken 3 days to move from $j2$ to reach $j5$, where it was in operation for 50 days. Then another 4 days

was spent to move this rig to the new site at $j8$ to start 59 days of drilling. A similar path vs. time description can be easily extracted for rig $i3$. The drilling tasks of Rig $i2$ and $i3$ finished at 113th and 186th days of service respectively. It shows that the postulated 365 days of operation is not a tight constraint for this problem.

5. Conclusion

In this work we presented a decision support tool for minimizing the overall drilling costs, and simultaneously plan the rig activities with focus on rig routing. Significant number of logical constraints involved in this combinatorial problem was the main challenge for efficient planning. Modeling the problem as a time continuous model could hinder this thread. The results of an example showed how mathematical programming could effectively facilitate decision making about rig outsourcing, routing and movement. It was shown that our model could outperform a base case with 5.6% lower total drilling costs.

Acknowledgement

The authors are thankful to the technical experts from North Drilling Company (Iran) who helped with the initial discussions, and Professor IA Karimi (National University of Singapore), and D. Baxendale who led the previous projects on the related topics.

Abstract

Decision support systems must provide the tools for effective problem management thus improving the whole decision process, from problem conception to solution implementation. However, model creation heavily depends on the modeler's expertise and the problem conception. This work focuses on automating the problem modeling and creating semantically enriched models. As a result, the modeler is supported in the modeling process. An automated modeling platform is developed, which encompasses mathematical models, their formal representation and the semantic model of the represented system. In addition, intelligent agents are designed in order to provide additional reasoning capabilities and create case rules for model creation, problem application storage and usage. A case study is performed using a scheduling modeling and solution example. Specifically, a systematic approach to scheduling model selection and solution implementation is achieved, thus enabling the bridge between theoretical developments and industrial practice.

Keywords: automated support system, decision support, reasoning agents, artificial intelligence.

1. Introduction

Decision support systems must provide the tools for effective problem management thus improving the whole decision process, from problem conception to solution implementation. In particular, a key piece of decision-making consists of the formal system representation, namely the system model, which captures those features that are necessary and sufficient to reach consistent decisions. However, model creation heavily depends on the modeler's expertise and the problem conception.

Likewise, the integration and management of data and information flows among different process operation levels is a common topic in the planning and scheduling areas, having a close relation with the area of supply chain. In order to improve the management of data and information flow among organizations, tools based on knowledge models seem to be a promising approach. Thus, organizations need knowledge management and organizational memory tools that encourage users and

foster collaboration while capturing, representing and interpreting corporate knowledge resources and their meaning.

Besides, during the last years the need for infrastructures continuously and coherently support for fast and reliable decision-making activities related to the production process, has revealed paramount importance (Varma et al., 2007). Moreover, efforts in this direction have result in works that presents ideas, theories, mathematical models, and practical systems in diversified domains integrated with semantics (Tanvir, 2012). Besides, Gonzales et al. 2014 uses semantic networks for improving the understanding the modeling of a physical phenomenon of engineering or other knowledge domain. This work is applied for teaching tasks, but make use of basic semantics.

The presented work develops a decision support platform based on knowledge management and intelligent agents for improving modeling. Specifically, this work focuses on the semantic and knowledge base exploitation of decision support systems. Specifically, the goal consists of automating the problem modeling and creating semantically enriched models. As a result, the modeler is supported in the modeling process and the dependence on own criteria and experience is reduced. An automated modeling platform is developed, which encompasses mathematical models, their formal representation and the semantic model of the represented system. In addition, intelligent agents are designed in order to provide additional reasoning capabilities and create case rules for model creation, problem application storage and usage. Indeed, agent routines are designed to automate the modeling and reach new decisions based on the problem description and previous experience.

2. Methodology

This work designs an agent-based structure for supporting decision-support, and applies the result to a planning and scheduling problem. Therefore, this section firstly introduces the planning and scheduling problems. Next, the operations research and mathematical modeling frameworks are established, together with the semantic approach to the problem description. Finally, the agent-based structure and rules are presented.

2.1. Planning and scheduling

Planning and scheduling problems at process industry have been tackled even before first computer appeared. The problem of what, where and how to produce has been defined as a complex problem that implies data and information of the whole production system. Information and data arrive from different layers involved in the production process, ranging from regulatory control, supervised control to single site production planning and enterprise supply chain planning.

At the production site level, the planning task aims to define how to meet the production targets in the site. Basically, this task makes decisions about resources allocation for each batch to be produced, as well as, how many batches of each product should be produced. Finally, as a result the best sequence in which resources should be used along the production is obtained.

The real-time production level, scheduling is concerned in how to predict the starting and finishing times of the required operations according to the on-going state of the plant. This level of detail is able to assure that the predicted schedule is feasible as it

involves a greater level of detail, using online information coming from the process plant. What is more, if any deviation of time occurs, this level is in charge of performing rescheduling actions resulting in changes to the predicted schedule.

2.2. Knowledge management framework (Domain knowledge)

The use of semantic models, so called ontologies or knowledge models, allow the formalization of the knowledge in different domain areas. The first ontology concern to describes the overall process system engineering environment. Such semantic model is based on ANSI/ISA-88 and 95 standards (Munoz, 2012, 2013, respectively). On the one hand, ANSI/ISA-88 standards compilation (International Society for Measurement and Control, 1995, 2003) allow the representation on the recipe model. Recipes manage the sufficient and necessary information in order to automate the data transaction task. On the other hand, ANSI/ISA-95 compilations (International Society for Measurement and Control, 2008) allow integrating information and data from recipes to the production schedule system. As a result Enterprise Ontological Project (EOP) describes semantically those specific functionalities in the process system-engineering domain reaching from operational to strategic functions.

2.3. Operations research and mathematical programming

Operations research (OR) is an interdisciplinary branch of mathematics, which uses mathematical models and tools to achieve optimal, or near optimal decisions in complex decision-making problems. OR techniques actually constitute the major part tools applied to solve problems. As one of the main tools for OR, mathematical programming is concerned with the study of problems in which one seeks to minimize or maximize a real valued function of a set of decision variables by systematically choosing the values of the decision variables from within an allowed set. The resulting mathematical model is a set of mathematical relations such as equations, inequalities, logical dependencies, etc., which correspond to physical or logical relationships in a real life problem. An OR ontology has been already developed to capture the elements involved in the creation of decision support systems (Muñoz et al. 2015).

The three initial steps to reach a problem analysis in OR and their adaptation to the problem of process planning and scheduling for this work are as follows: (i) observe the system: it includes the definition of the product(s) to be produced and the corresponding site recipe (procedure specific), the definition of the master recipe (process specific), and production order(s), including order request quantity & due date; (ii) problem definition: it consists of establishing the single or multiple objective, such as timing, financial, environmental, as well as the system constraints, represented as element – value source pairs; and, (iii) model construction: it consists of creating a basic structure for modeling, namely the objective function with inline labels, and the constraint elements which include labels and relations to the objective function.

The basic structure in an OR problem consists of a set of mathematical equations which model a problem with the aim to optimize it. Such equations are basically objective function and system constraints. An objective function is an equation with representative elements. In this work, both the objective function and the representative elements associated to the variables are assigned to representative labels, which allow further categorization and classification of the system. The objective function has to be optimized (minimization or maximization), and contains specific mathematical operations and impact values (values). As for the system constraints, their structure comprises equations, which represent the constraints based on elements within the

system. This work assigns to the constraints and the elements a representative label. Finally, additional constraints, such as those related to non-negativity and the element behavior (binary, integer, etc.) could be also considered from a given set elements or the problem structure.

2.4. Agent system structure

The proposed framework consists of a set of agents, which have different functions and communicate among them. In order to have a common vocabulary, all the agents rely on the ontologies described in sections 2.2 and 2.3.

The solution mechanisms consists of the following steps: (i) problem definition, (ii) modeling process for reaching a problem model, (iii) model analysis, (iv) model solutions, and (v) problem conclusions. Based on the solutions in (iv), we can make inferences and reach the decisions about the problem in (v). Finally, the assessment of decisions goodness is fed back to the agent system.

Each of the steps in the solution mechanism is represented as an agent of the system, which communicates with other existing agents. The multiple agents have different functions, which can be broadly classified as follows: (i) communication agents, (ii) search agents, (iii) classification agents, and (iv) solution agents.

For every problem instance, the problem features are recorded within the problem database by means of the communication agent. The problem features include the set of parameters, assumptions and decision variables required to solve the problem. In addition, the problem features must refer to any constraint (e.g. physical, design, operational) that the system has to consider. Therefore, the problem instantiation relies on the EOP ontology and the mathematical features described in the mathematical modeling ontology. Next, the optimization objective(s) are formalized within the communication agent. Overall, a specific problem statement is obtained.

Next, the communication agent prepares a problem summary for the classification agent, which analyses the problem according to a knowledge-driven classification procedure, and proposes a solution strategy based on similitude measure of the current problem instance with (i) existing problems already tackled in the past and stored in the database, (ii) existing problem approaches derived from the literature. As a result, a set of ranked solution approaches is proposed to the decision-maker.

The so-called search agent has two main functions. On the one hand, it looks for similar cases stored in the database with the current case, and compares them with the current problem instance in order to identify differences and similitudes. Therefore, it supports the classification agent and presents to the decision-maker the most similar cases. On the other hand, after the selection of the solution strategy the search agent creates the required information for the solution agent to tackle the problem.

Finally, the solution agent iterates with the solution algorithms in order to reach the optimal solution for the problem instance. The solution agent also sends the set of problem solutions to the decision maker and stores them in the database for future operation.

The different agents and the whole framework have been programmed in Jython, which combines the programming language in Python and the availability to use Java APIs, and communicate to the ontological models.

3. Case study

A case study for a multi-objective scheduling problem is solved. Specifically, a multi-product batch plant for acrylic fibers production is considered (Capon et al. 2011, 2012). The production plant consists of a 14 production stages with product dependent changeovers among three different final products. Three multi-objective optimization strategies are considered, namely a mathematical programming with a normalized constraint method (MP) (Capon et al. 2011), a genetic algorithm (GA) and a hybrid optimization approach (HA) (Capon et al. 2012). Several problem objectives are considered, such as productivity (P), total environmental impact (TEI), makespan (M) and total profit (TP). The problem instances solved in the original papers are the basis for the database of this problem, a total of 415 problem solutions are included with different problem description and objective function values.

Next, the framework including the different agents is tested with new problem parameters and results are shown in Table 1. The first column includes the problem size (number of batches for each problem), whereas the second column is related to the objective function. On the other hand, the third column presents the selection of the solution implementation, the fourth column shows the value of the objective function, and the fifth the distance to the best optimal solution found.

From Table 1, it can be seen that for small problem instances the rigorous mathematical programming approach is proposed, whereas large problem instances are better solved with genetic algorithm. In addition, the selection of the objective function also has an important role in the selection of the solution strategy. Indeed, for productivity maximization the hybrid approach is selected. In most cases, the distance of the solution proposed by the agent-based system to the optimal solution is lower than 5%. Therefore, this framework represents a systematic approach to scheduling model selection and solution implementation, thus enabling the bridge between theoretical developments and industrial practice, with high-level decision support to the engineers, who do not need to have a thorough understanding of the solution techniques.

Table 1. Results for different problem instances from agent-based framework, where (P,TEI,M,TP) stand for (productivity, total environmental impact, makespan and total profit) and (MP, GA, HA) stand for (mathematical programming, genetic algorithm and hybrid approach).

Number batches (A/B/C)	Obj. function	Solution approach	Solution value	Optimal solution value
2/2/2	P	MP	1.085	1.087
2/2/2	TEI	MP	24.1	24.1
2/2/2	M	MP	24	24
14/8/10	P	HA	1.071	1.072
14/8/10	TEI	MP	180.2	178.9
14/8/10	M	GA	164.3	162.8
16/14/12	P	HA	1.083	1.085
16/14/12	TP	MP	$2.1 \cdot 10^5$	$2.2 \cdot 10^5$

4. Conclusions

This work has developed an agent-based approach for automating the problem modeling and solution in any engineering domain, which requires model-based decision support. As a result, the decision-maker is supported in the modeling process and good solutions can be reached with limited knowledge on the solution techniques. An automated modeling platform is created, which encompasses mathematical models, their formal representation and the semantic model of the represented system. In addition, intelligent agents are designed in order to provide additional reasoning capabilities and create case rules for model creation, problem application storage and usage. For illustrating purposes, a case study is performed using a scheduling of a multiproduct batch plant. For that case, solutions within 5% optimality are obtained. As a result, a systematic approach to scheduling model selection and solution implementation is achieved, thus enabling the bridge between theoretical developments and industrial practice. Overall, this work presents a platform for enhanced problem solving and improved decision-making.

Abstract

Considering the importance of monitoring piping systems, the aim of this work is to develop a technique to detect gas leaks in pipes, based on acoustic method. A copper tubing $\frac{1}{2}$ in diameter and 53 m in length was assembled in laboratory, operating with continuous supply of compressed air, under various operating conditions with initial pressure of 1 kgf / cm². We analysed the signals of five microphones, installed inside the tubing, generated by the occurrence of gas leakage. The microphone signals in the time domain were converted to the frequency domain via the fast Fourier transform (FFT). The microphone signals in the frequency domain used as an input of the artificial neural network (ANN) of the type Echo State Network (ESN) to determine the occurrence or not of leakage (model output). From the results, it was observed that the leaks were adequately detected. The neural model presented a percentage of correctness of approximately 81% indicating the occurrence or not of leakage in the line.

Keywords: Pipeline, leak, Echo State Networks

1. Introduction

In addition to the use of piping networks as a means of transport for gases and liquids over long distances, these systems have been widely used in the distribution of gas directly in homes and at commercial points, usually called piped gas. The piped gas has become a comfort solution in civil construction. Because it is transported through pipelines in a continuous way, the gas, fuel, does not need storage, avoiding risks with deposit and releasing useful area in the buildings. On the other hand, there is a need for operational reliability of these piping systems, minimizing the risk of leakage, which can lead to disastrous consequences for families, pollution problems to the environment, and can also cause serious financial losses. There are several studies in the literature

about the detection of leaks in pipes, for example, ZHANG *et al.* (2004), TAGHVAEI *et al.* (2006), TOLSTOY *et al.* (2009), YANG *et al.* (2008), largely based on process variables measurements, as pressure and flow obtained from the pipe.

Therefore, it was intended in the present work to contribute to the development and testing of techniques to detect occurrences of leaks. The method chosen was the acoustic method, due to the great ease in detecting small leaks in ducts in a short time, as well as the low investment used in this method. The signals emitted by the acoustic sensors were used as input of a neural model (ESN) with the purpose of analysing the data in order to identify the occurrence of the leak.

Neural networks are a technique of Artificial Intelligence (AI) that has the ability to learn from experiences, improving their performances and adapting to changes in the environment. Among the main incentives for its use is the success of the works of BELSITO *et al.* (1998) and SANTOS *et al.* (2014), among others, developed studies using neural networks as a data analysis tool to detect leaks, showing promising results.

2. Methodology

In this study, the characteristics of the signals from microphones generated by gas leakage in a $\frac{1}{2}$ in diameter and 53 m long copper tubing were analysed in a laboratory under different operating conditions.

To perform the experiments, compressed air was used as the working fluid. The leaks were simulated through holes along the pipe, with different magnitudes and with a manometric pressure of 1 kgf/cm².

The experimental system was represented by a fixed gas pipe in a metal structure, as can be seen in Figure 1. The system consists of 8 pressure transducers to analyse the internal pressure along the pipe, 15 microphones, 12 points to cause rupture type leakage or to branch pipes, using ball valves, 7 holes along the pipe with different diameters for leak simulation.

In the experimental prototype, 15 microphones were installed along the tubing, but only 5 (M1, M2, M3, M4 and M14) were evaluated in the present study. The microphones M1, M2, M3, M4 and M14 are at 0.1 m; 3.3 m; 7.7 m; 11.4 and 49.3 m from the start of the pipe.

The holes were implemented in the pipe to simulate a leak as close as possible to a real situation, differing from a ruptured situation. The holes are at different locations along the pipe with different diameter sizes, varying between 0.5 and 4 mm.

In order to detect the leak more easily through the microphone signal, a digital filter was implemented in *Labview* (software used for monitoring and data acquisition). In the present work a sampling rate of 33 kHz was defined, respecting the Nyquist theorem.

The leaks were triggered manually. Before initializing the data acquisition program, a person would close the hole chosen for testing with his finger and at the right time was removed from the pipeline, causing the leak. This form was chosen in order to avoid noises inherent in valve openings if the leaks were also automated. When the data acquisition program was finalized, the data file was generated, producing acoustic sensors information in time domain and frequency domain with different leak sizes, non-leak situations, two leak cases occurring simultaneously and simulation having

branching in the line through valves connected to a 6 m long flexible pipe, according to Table 1.

Figure 1. Experimental leak detection system in gas piping.

Table 1 - Operating conditions.

Experiments	Operational situations
1	Leaks with diameters from 0.5 to 4 mm.
2	No leaks - only laboratory noise, air conditioning on and people walking.
3	No leaks - Constant beats on the pipe with a metallic instrument.
4	No leaks - constant beats in the pressure vessel with a metal instrument.
5	No leaks - line branching through the use of valves
6	Line branching and leak occurrence simultaneously
7	Occurrence of two leaks simultaneously

Branch situation in the line, means a simulation of gas consumption output in the residence, such as gas outlet to the stove, shower etc. Such situations do not represent a leak.

With the acquisition system in operation, connected to the instruments installed in the copper tubing, spectral analysis of the microphone signals (frequency domain analysis) was done through *Labview* software. Through the FFT it was possible to analyse the characteristic (predominant) frequencies in different operating situations, with and without leakage.

To determine the occurrence and size, training of a neural model with data from the fast Fourier transform (FFT) was performed, with some frequency signals chosen using as input to the neural model.

The neural modelling algorithm was implemented in MATLAB R2016a Software. The developed ANN was the echo state networks (ESN) based on JAEGER et al. (2001). This type of ANN has randomly connected hidden layer called reservoir (as a recurrent neural network). The use of ESN implies to tune some parameters in the algorithm: the number of input; the number of output; the number of neurons inside the reservoir, the weight matrix making the link between the input layer and the reservoir; the weight matrix representing the link between the reservoir and the ESN output; Spectral Radius, and Connection Percent. In the reservoir activation function was used hyperbolic tangent (tanh) and the output layer was used identity. The output weights (in ESN) were optimized by a multilinear regression (for instance by using the generalized matrix

inversion Moore-Penrose. Thus, the training process was simplified and this allowed finding the global optimum of the weight optimization problem. The performance of the model was analyzed according to error index.

An ESN is composed by input layer, the reservoir and the output layer. According to Jaeger et al. (2001), the activation of internal units is showed in Eq. (1).

$$x_{k+1} = f(W^{in}u_{(k+1)} + Wx_k + W^{back}y_k) \quad (1)$$

where $u_{(k+1)}$ is the exogenous input with dimensionality n , x_k is the internal states with dimensionality M , and y_k is the output. W^{in} and W is the input and internal (neurons in the reservoir) weights. The W^{back} is the output feedback weights and f is known as activation function which most of the time is hyperbolic tangent (tanh).

The output is calculated according to Eq. (2).

$$y_{k+1} = f^{out}(W^{out}(u_{(k+1)}, x_k, y_k)) \quad (2)$$

Where y_{k+1} is the output of the ESN, W^{out} denotes the output weights and f^{out} is the activation function of output neurons (mostly identity).

This output has recurrent connections in the reservoir. The backpropagation is given random weights (W^{back}), which are fixed and do not change during subsequent training. The connections between the reservoir and the output unit, W^{out} , are the only ones that change during training.

The signals of the five were used as inputs to the neural network to determine the occurrence or not of leaks (model output). However, the data file from each microphone subjected to fast Fourier transform consists of 9394 frequency signals (in the range between 500 and 16000 Hz), totalling 46970 frequency signals. Due to the difficulty in working with 46970 inputs in a neural model, a training was performed with 200 frequency spectrum signals (obtained from the FFT), with 40 signals from each microphone. These frequencies were determined by analysing all operational situations, verifying the frequencies that showed the greatest changes.

3. Results and analysis

With the experimental data coming from the microphones, signals of different frequencies were obtained using FFT. The Fast Fourier Transform (FFT) of the microphone signals (M1, M2, M3, M4 and M14) was performed in order to differentiate each case, that is, a frequency domain analysis for each situation mentioned in Table 1.

It can be seen from Figure 2 that for each tested situation a frequency spectrum with different profile was obtained. The first situation (letter a) refers to a normal noise from the laboratory (only air conditioning connected and possibly people walking near the system) without occurrence of leaks, the second situation (letter b) refers to an occurrence of leakage in the hole (diameter 3 mm) with 4.7 m distance from M1.

Figure 2. Frequency spectrum of microphone signals M1.

To perform the leakage detection of a low pressure gas piping system, the artificial neural networks technique was used as a tool to monitor the experimental system, receiving information from the microphones installed in the piping.

The experimental tests were performed in several operating situations (without and with leaks in different sizes), generating a database, which was divided into training data and data for the neural model offline test. In the test file was used data from an operational situation not used in training. For the training of the neural networks, the frequency signals of the microphones were used as input to the neural model to determine the occurrence or not of leaks (model output).

In order to perform the training of the neural model, the frequencies to enter the neural network were initially determined. We selected 40 frequencies of each microphone, totalling 200 entries in the neural model. These frequencies were determined by analysing all operational situations, verifying the frequencies that showed the greatest changes.

The best configuration of the parameters obtained from the various tests analysed was the number of neurons inside the reservoir 205, the weight matrix making the link between the input layer and the reservoir 1, the weight matrix representing the link between the reservoir and the ESN output 0.008, Spectral Radius 0.8 and Connection Percent 0.5, training correlation coefficient 0.9009 and training equation of the line $y = 0.8113x + 0.1315$.

The off-line test performed using 200 frequencies frequency spectrum signals obtained from the five microphones, presented a percentage of hit of approximately 80,0 %, indicating the occurrence or not of leaks in the line, according to Figure 3. All the 0.5 values, calculated by the ESN, were considered as no occurrence of leakage, while values greater than 0.5 were considered as presence of leakage. Figure 3 indicates the difference between data calculated by the ESN model and the experimental data, proving the satisfactory performance of the developed neural models.

Approximately 647 data vectors were used in test set of the developed model. Among these points, the maximum errors obtained were in situations with 0.5 mm leakage, indicating the non-occurrence of leaks and in situations with simulation of a branch on the line going at once with the leak, only indicating the branch line. But considering that there is a branch in the pipeline, the disturbance is probably something that is not permanent, so when the branch line is closed, the neural model will correctly indicate the occurrence of leaks.

Figure 3. Difference between actual data and data computed by the Echo State Network.

4. Conclusions

Through the analysis of microphone signals in the frequency domain (through the FFT), it was possible to differentiate the several situations tested with and without occurrence of leaks, thus detecting when there was actually leakage.

It was possible to determine the occurrence of leaks through developed ESN model, with promising results, due to good agreement of the predicted with experimental data. The off-line test performed using 200 frequency spectrum signals from the five microphones showed percentage accuracy of approximately 80%, indicating the occurrence or not of leaks in the line.

Abstract

To improve efficiency in wastewater treatment plants, suitable optimization and control strategies for the activated sludge process are imperative. Therefore, adequate models for estimation of the critical variables are also vital. In this work, neural networks and fuzzy models are identified from data collected from a standard benchmark simulation platform (BSM1) used to represent the activated sludge process. These models are embedded in an economic predictive controller designed to regulate critical variables to ensure the desired effluent quality with the minimum energy consumption.

Keywords: Economic model predictive control, neural networks, fuzzy systems

1. Introduction

The awareness on reducing water pollution has been reflected on stricter effluent requirements and economic penalties for discharges out of specification. Hence, the wastewater industry has focused on achieving the desired effluent quality while increasing the efficiency of the Activated-Sludge Process (ASP) which is the biological treatment at the core of most Wastewater Treatment Plants (WWTPs). This research addresses the implementation of advanced model predictive control (MPC) strategies to optimize the operation of the ASP increasing the economic efficiency of WWTPs.

Many controllers tested in the ASP are designed for the tracking of a conservative set-point for the dissolved oxygen (DO) concentration (Amand et al., 2013). Nevertheless, the variations in the influent loading could be considered for improving the economic performance of the plant given that the effort required to treat the wastewater depends on the pollution load. Some works have proposed the use of hierarchical control strategies to optimize the operating point taking advantage of the variability of the load (Vega et al., 2014). More recently, Zeng and Liu, (2015) and Revollar et al. (2017) implemented economic model predictive controllers (EMPCs) to perform the dynamic optimization of the operation of WWTPs using single layer structures.

In the execution of such tasks, the estimation of the critical variables that affect the performance of the treatment and the prediction of the plant behaviour require the use of adequate models. Non-linear dynamic models of the ASP are precisely the type needed

when dealing with high interactions (Moscoso-Vasquez, et al., 2014) in optimization and control applications. Complex, high dimensional models as the ASMs of the International Water Association, are costly to use and with parameters hard to identify. Therefore, more efficient solutions, as models based on artificial intelligence, are desirable. In Goldar et al. (2014) an artificial neural network is successfully implemented for predictions in a multivariable non-linear model predictive control strategy used for the tracking of dissolved oxygen and nitrates concentration set-points. Very few applications of these kinds of models for the optimization of economics in advanced control schemes are found in the literature. In this work, neural networks and fuzzy models are identified to be implemented as prediction models in an economic model predictive control strategy.

The paper contains a description simulation platform used to represent the activated sludge process (BSM1) in section II and the formulation of the EMPC problem in section III. Section IV presents the attainment of the neural and fuzzy models, its structure, and validation results, as well as their implementation in the EMPC strategy. Conclusions and projections of this work are outlined in section V.

2. The Activated Sludge Process

A benchmark simulation protocol representing the activated sludge process (BSM1) has been developed by working group No. 1, within COST Actions 624 and 682 (Alex et al., 2008). The BSM1 plant layout is presented in Fig. 1, the simulation platform includes simulation models, influent loads, test procedures and evaluation criteria. The model considers 13 state variables in each reactor and describes 8 biological processes. Detailed information regarding the mathematical model, physical parameters and influent profile can be found in Alex et al. (2008).

Figure 1. General scheme of the treatment plant of BSM1.

2.1. Control problem

The control strategy proposed in the BSM1 platform for the operation of the activated sludge process consist on the regulation of the dissolved oxygen (DO) concentration at the end of the aeration zone (S_{O_2}), and the nitrate concentration at the end of the anoxic zone (S_{NO_2}) using two PI control loops. The manipulated variables are the oxygen transfer coefficient (KLa) and the internal recycle flow (Q_a). The DO concentration in the aerobic zone is maintained close to the reference value that ensures an appropriated nitrification; however, an excessive amount of oxygen saturates the system and increases unnecessarily the aeration energy.

In this paper, a single layer multivariable economic model predictive control strategy is considered to achieve an efficient operation of the activated sludge process, minimizing

the energy consumption while attaining the desired effluent quality. The BSM1 dry-weather profile (Alex et al., 2008) is used to characterize the influent disturbances.

3. Economic model predictive controller (EMPC) formulation

Two approaches are distinguished in the EMPC formulation: economic optimizing controller and the economic-oriented tracking controller. In the economic optimizing control the optimal values of the control inputs (\mathbf{u}) are computed directly from the optimization of the economic performance. In the economic oriented tracking controller, an economic index is added to the classical model predictive control objective function. A generalized mathematical description including both alternatives is presented here.

3.1. General formulation of the EMPC

The standard non-linear model predictive control (MPC) cost function is a quadratic penalization of the deviation of the state (\mathbf{x}) from the desired operating point (\mathbf{x}_r) and the magnitudes of the inputs adjustment. W_x , W_u and W_n are the weights assigned to each objective.

$$J_{NMPC}(\hat{\mathbf{x}}(t), \mathbf{u}(t)) = |\hat{\mathbf{x}}(t) - \mathbf{x}_r|_{W_x}^2 + |\mathbf{u}(t) - \mathbf{u}(\tau_{k-1})|_{W_u}^2 + |\hat{\mathbf{x}}(\tau_N) - \mathbf{x}_r|_{W_n}^2 \quad (1)$$

In a general formulation including both EMPC approaches, the cost function measures the control performance (J_{NMPC}) and the economic performance (J_{ECO}).

$$\min_{\mathbf{u} \in \mathcal{S}(\tau)} \int_0^{\tau_N} (w_E \cdot J_{ECO}(\hat{\mathbf{x}}(t), \mathbf{u}(t)) + w_C \cdot J_{NMPC}(\hat{\mathbf{x}}(t), \mathbf{u}(t))) dt \quad (2)$$

The constraints and initial conditions are defined by equations (Eq. 3, 4, 5), being τ the sampling time and \mathbf{v} the measured disturbances:

$$\dot{\hat{\mathbf{x}}}(t) = f(\hat{\mathbf{x}}(t), \mathbf{u}(t), \mathbf{v}(t)) \quad (3)$$

$$\hat{\mathbf{x}}(0) = \mathbf{x}(\tau_k) \quad (4)$$

$$g(\hat{\mathbf{x}}(t), \mathbf{u}(t)) \leq 0, \quad \forall t \in [0, \tau_N) \quad (5)$$

3.2. Economic model predictive control of the activated sludge process

In the implementation of the EMPC to the activated sludge process, only the influent variables that have a major impact on the process are measured at each sampling time to perform the optimization. They are the influent flow rate (Q_{in}), the readily biodegradable substrate concentration ($S_{S,in}$) and the ammonium concentration ($S_{NH_4,in}$).

The performance indices adopted to assess dynamically the economic performance in the EMPC are the pumping energy and the aeration energy. The pumping energy (PE) represents the energy use for the pumping of internal recycle flow (Q_a).

$$PE = \frac{1}{T} \int_{t_0}^{t_f} (0.004 \cdot Q_a(t)) dt \quad [kWh/d] \quad (6)$$

The Aeration Energy (AE) is calculated from the oxygen transfer coefficient (KLa).

$$AE = \frac{S_{O,sat}}{T \cdot 1.8 \cdot 1000} \int_{t_0}^{t_f} V_2 \cdot KLa(t) dt \left[\frac{kWh}{d} \right] \quad (7)$$

The economic cost function (J_{ECO}) used in the EMPC implementation is an overall cost index (OCI) that includes PE, AE and the fines for off-specification ammonium concentration in the effluent (Ammonium concentration in the effluent is approximated by S_{NH5}). w_1 and w_2 are chosen here as $w_1 = w_2 = 1 \text{ EUR/kWh}$

$$OCI = \left(w_1 \cdot \frac{1}{T} \int_{t_0}^{t_f} (0.004 \cdot Q_a(t)) dt + w_2 \cdot \frac{S_{O,sat}}{T \cdot 1.8 \cdot 1000} \int_{t_0}^{t_f} V_2 \cdot KLa(t) dt + w_3 \cdot 8.2 \cdot \max(0, S_{NH5} - 4) \cdot Q_e \right) [EUR/d] \quad (8)$$

4. Identification of the models and implementation in the EMPC

The identification of the ASP is carried out considering the most important variables and all the biological mechanisms that govern the ASP, to provide an accurate representation of the whole non-linear process behaviour. A back-propagation feed-forward-neural-network model and a Takagi-Sugeno multidimensional fuzzy inference model are identified from data collected from the benchmark to predict the output variables: dissolved oxygen (DO) concentration at the end of the aeration zone (SO5) and the nitrate concentration at the end of the anoxic zone (SNO2).

Several test trainings are carried out, obtaining the best quality of information when perturbations are introduced as constant-frequency steps sequences of pseudo-random amplitude. This protocol is applied to the manipulated inputs KLa and Q_a or eventually superimposed to the dry weather profiles of the influent perturbations Q_{in} , SS_{in} and SNH_{in} .

For the neural model, the multi-layered, non-recurrent net structure known as Feed-forward Neural Network (FNN) is chosen because of its flexibility, and the simplicity of the training procedure when compared to recurrent networks. The structure of the neural networks is described in figure 2a. The typical training and cross validation practice is used to adjust the networks coefficients, by means of the well-known Levenberg-Marquardt algorithm, found in the Neural Networks Toolbox of Matlab [®].

For the fuzzy model, a Takagi-Sugeno fuzzy inference system (FIS) is selected, using as a consequent for each rule a linear affine function of the input variables. The FIS is based on multi-dimensional antecedent fuzzy sets (MDAFS) in such a way that a variable to variable partition is not required, instead, the partition is automatically done directly over all input variables producing a set of multi-dimensional clusters or rules. Three 3 clusters, equivalent to 3 fuzzy rules, are the best FIS configuration, which is the one used here (see figure 2b).

The FNN and FIS models are simulated under dry weather conditions and the step disturbances in oxygen mass transfer coefficient (KLa) and internal recycle flow rate (Q_a). The behaviour of the output variables estimated by the FNN and FIS models are shown in figure 3, along with the process outputs from the BSM1. The precision of the estimation is very good, for the oxygen content as well as for the nitrates-nitrites

concentration, which validates the use of the FNN or FIS as prediction model in the EMPC framework.

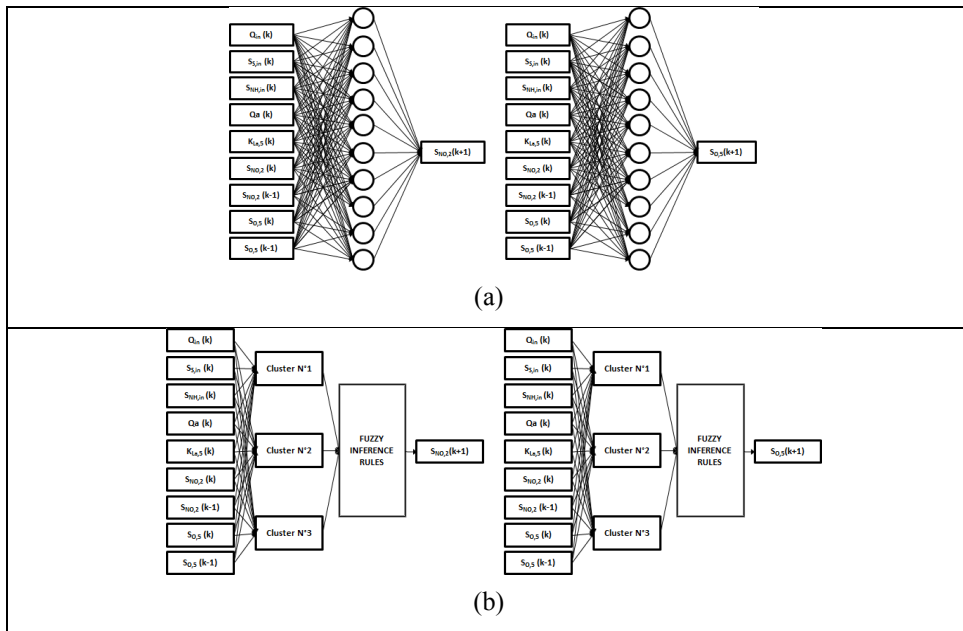

Figure 2. Structure of FNN (a) and FIS (b) models for estimation of S_{O_5} and S_{NO_2} .

Figure 3. Validation of neural and fuzzy models for nitrates concentration S_{NO_2} and for dissolved oxygen concentration S_{O_5} . Solid line: Process; dotted line: FNN; dashed line: FIS.

The FNN and FIS models are implemented for predictions in the EMPC framework and the process performance using this controller is compared with the EMPC (named P-EMPC) and NMPC proposed in Revollar et al. (2017) that uses the reduced phenomenological model of the plant as prediction model (Figure 4). The weights of the EMPC cost function are $w_1=30$, $w_2=30$, $w_3=5$.

As seen on figure 4, the implementation of EMPCs for minimizing the energy consumption leads the S_{NO} and S_O concentration to the lower limits of the controlled variables. The behaviour of the EMPC using the FNN model is different from reduced

phenomenological model controller due to its ability to capture more precisely the process non-linear dynamics.

Figure 4. Comparison of the S_{NO_2} and S_{O_5} responses with the EMPC using the FNN model and the NMPC and EMPC using a reduced phenomenological model (Revollar et al. 2017)

5. Conclusions

In this work, the identification of the activated-sludge process with neural networks and fuzzy models is carried out using as the activated sludge process plant the challenging simulation benchmark BSM1. This simulator is an excellent tool to reproduce the complete, multifaceted nitrification-de-nitrification process. The capacity of the identified FNN and FIS for predictions is exploited in an EMPC strategy. The prediction estimates are acceptable for short horizons (twelve steps ahead), which makes them perfectly usable for economic predictive control applications.

Bayesian estimation of product attributes from on-line measurements in a dropwise additive manufacturing system

Andrew J. Radcliffe*, Gintaras V. Reklaitis

Davidson School of Chemical Engineering, Purdue University, West Lafayette, IN, 47906, USA

aradcli@purdue.edu

Abstract

In the pharmaceutical industry, application of additive manufacturing technologies presents unique opportunities for monitoring and control of drug product quality through on-line image acquisition systems which estimate process output from images of emergent drops. For doses produced from pure fluids on-line imaging has demonstrated utility (Hirshfield, et al., 2015); however, processing of particulate suspensions requires consideration of uncertainty regarding gravity- and flow-mediated particle-liquid segregation. Even for well-mixed suspensions, random localization of particles during the necking of the liquid bridge results in variable drop trajectory (Furbank & Morris, 2004), which must be corrected for in the estimates of drop volume provided by an on-line imaging system. This work explores the use of Bayesian statistical models to resolve potential inaccuracy in drop volume estimates obtained by an on-line image sensor in a dropwise manufacturing process for suspension-based drug products. The framework in the case study presents a method by which uncertainty arising from on-line process measurements may be reconciled for through sufficient sampling and off-line analysis of process outputs.

Keywords: Bayesian inference, drug products, additive manufacturing

1. Introduction

Concurrent with the expansion of inkjet printing methods into precision materials (e.g. semiconductor, ceramics) industries, considerable research effort has been devoted to development/adaptation of inkjet technology for pharmaceuticals manufacturing. Applications of additive manufacturing technology have received substantial attention for production of oral solid doses (e.g. tablets, capsules, thin films). The mechanics of this fluid-based process facilitate monitoring and control of drug product properties, as the output of the system, individual drops, may be monitored in real time using an on-line imaging system (Hirshfield, et al., 2015). Recent work with homogenous fluids (solvents, melts) has demonstrated feasibility of an image capture system for process monitoring in dropwise additive manufacturing system (Hirshfield, et al., 2015, İçten, et al., 2015). However, quantification of process output with an image capture system becomes ambiguous for suspensions due the possibility of particle-liquid segregation during transit through the system. Additional uncertainty is presented by drop ejection, due to random localization of particles which may result in irregular drop trajectory; this manifests as uncertainty in the computation of drop volume from the on-line image

system. The optical sensor calibration is sensitive to the distance between drop and camera, for which variable drop trajectories would result in inaccurate drop volume estimates from the on-line image system. In this work, a Bayesian statistical model is applied to reconcile errors in computed/actual drop volumes from a set of suspension formulations and process conditions which yielded reproducible drops/products, as determined by gravimetric analysis. Multiple model structures are considered for estimation of actual drop volumes from computed drop volumes; prior information is obtained from separate experiments conducted at the same set of conditions. The estimated parameters from the statistical models are compared with predictions afforded by linear regression models, in both classical and Bayesian formulations.

2. Dropwise additive manufacturing platform, on-line image acquisition

The dropwise manufacturing system consists of a precision positive displacement pump, x-y staging, pump/staging controllers and on-line image acquisition system; the image acquisition system is comprised of a camera actuated by a motion sensor; the setup is a variant of the process described in (Hirshfield, et al., 2015). The mechanical action of the positive displacement pump forces fluid through the dispensing nozzle, which, dependent on process conditions and suspension properties, results in formation of one or more drops; the present work considered only the experimental conditions which produced a single drop per actuation event of the pump. A process diagram, including the image acquisition system, is presented in Figure 1.

Figure 1. Process diagram for dropwise additive manufacturing system.

The on-line image acquisition system computes drop volume from the two-dimensional image by estimating the volume of the sphere from a stack of equivalent cylinders, for which diameters are defined using the drop edges; further detail is available in (Hirshfield, et al., 2015). A calibration procedure which defines a unit pixel in relation to physical dimensions is necessary to complete the volume estimate; this was performed in a configuration analogous to that depicted in Figure 2, with the drop replaced by an optical standard.

Figure 2. Ray tracing diagram for image acquisition system; drop not proportionate to scale.

The calibration procedure assumes constant values for system properties: S_1 (distance of object from lens), S_2 (distance from lens to image), f (focal length), and d (dimension of image sensor). As S_1 is determined by each the drop's trajectory, deviations result in errors for computed drop volume due to a changes in the effective magnification, which for a thin lens the linear magnification would change by a factor proportional to the ratio of ($S_{1,Calibration}/ S_{1,NEW}$). For pure fluids, the assumption of constant drop trajectory (fixed S_1) has demonstrated utility (Hirshfield, et al. 2015, İçten, et al, 2015); for particle suspensions, drop trajectory appears to be a distributed parameter (variable S_1).

3. Bayesian statistical modelling for actual drop volume in suspensions

Drops produced from suspensions exhibit larger variance in volume than drops from pure fluids due to the inherent heterogeneity imparted by particles. The presence of particles disrupt thinning of the fluid filament during drop break off at a length-scale proportional to particle size; for particle samples with a size distribution, this may cause drops to pinch off at different spatial locations, dependent on the presence of (relatively) large particles in the thinning filament (Furbank & Morris, 2004). Variability in the drop break off process may lead to altered drop trajectory, which may be one of several causes for discrepancies between computed drop volume and actual drop volumes as determined by gravimetric analysis. The severity of other process disturbances (flow-induced segregation; sedimentation) depends on suspension properties, process conditions and experimental timescale, thus, potential data sets for modelling were selected based on reproducible drop production which appeared to only exhibit error in computed drop volumes. This corresponded to drops produced from suspensions with particle volume fractions of 0.15-0.25 formulated from four pharmaceutical powders in a triglyceride oil carrier fluid; details related to particle characterization and properties may be found in (Radcliffe & Reklaitis, 2017).

The use of a statistical model for estimation of actual drop volume incorporates uncertainty into parameter estimates obtained using the computed drop volume as surrogate for actual drop volume. Several Bayesian model formulations with respective parameters sets and structures are developed for estimation of actual drop volume, based on future observation of computed drop volume. The Bayesian model results are compared with predictions from a linear regression model, for which unknown parameters are estimated by (1) ordinary least squares and (2) a Bayesian formulation of ordinary least squares. In the Bayesian models, informative prior distributions were estimated from the data (actual/computed drop volume) at given set of process conditions and suspension properties; the same data was used for the linear regression and Bayesian linear regression.

The first Bayesian model was structured with the likelihood based on the assumption that each computed drop volume (Y) was drawn from a normal distribution with parameters ($\theta_1 - \theta_2, \sigma^2$), in which ($\theta_1 - \theta_2$) and σ^2 are the mean and variance of computed drop volume. Actual drop volume (θ_1), and an offset parameter (θ_2), which represented a combined estimate of errors related to drop trajectory and other process disturbances; a multivariate normal distribution was assigned to (θ_1, θ_2) in order to preserve details of the relationship between the two parameters. The variance parameter (σ^2) of the likelihood was assigned a inverse gamma prior distribution, with parameters estimated from the data set; likewise, the mean vector and covariance matrix of the prior on (θ_1, θ_2) were estimated from the experimental data. Treatment of the future observations, y_i , individually or as a sample result in different interpretations of the

available information. Treated individually, the y_i 's are used to estimate $(\theta_1, \theta_2)_i$, and when treated together, the identity of y_i 's are subsumed under the sample average. Formulations produced by the dropwise platform contain 5-50 drops per dose, which motivates treatment of y_i 's using the sample average due to the large number of drops required by a dose regimen of 30 capsules. The joint posterior distribution for this model, conditioned on a future set of observations, Y , is given in Eq. (1).

$$p(\theta_1, \theta_2, \sigma^2 | \underline{Y}) = \frac{p(\underline{Y} | \theta_1, \theta_2, \sigma^2) p(\theta_2 | \theta_1) p(\theta_1) p(\sigma^2)}{p(\underline{Y})} \quad (1)$$

The second Bayesian model considers a case in which variable drop trajectory affects computed drop volumes through a magnification re-scaling factor proportional to $(S_{1,c}/S_{1,N})$, based on the image acquisition configuration and calibration. The likelihood distribution assumes that computed drop volume(s), Y , are drawn from a normal distribution with mean and variance parameters, θ_4/θ_5 , and σ^2 , respectively, which have known prior distributions. To preserve the relationship between them, the actual drop volume (θ_4) and scale parameter (θ_5) are assigned a multivariate normal distribution, with mean vector and covariance matrix estimates obtained from the experimental data. An inverse gamma distribution is assigned to the prior on σ^2 , with parameters estimated from the experiments. The joint posterior distribution for this model is given in Eq. (2), which treats the y_i 's using the sample average.

$$p(\theta_4, \theta_5, \sigma^2 | \underline{Y}) = \frac{p(\underline{Y} | \theta_4, \theta_5, \sigma^2) p(\theta_5 | \theta_4) p(\theta_4) p(\sigma^2)}{p(\underline{Y})} \quad (2)$$

The Bayesian models were compared with a normal linear model given two sets of parameters estimates obtained by: ¹ordinary least squares and ²Bayesian linear regression. The specifications of the linear model were as follows: actual drop volume, y , was the response variable; computed drop volume, X , was the explanatory variable; with parameter vector $\beta = [\beta_1, \beta_2]$; y , X were the same data as the prior distributions, which contained $n=39$ samples. In matrix form, the model consisted of the response column vector, y_i , design matrix X_{ij} with column $j=1$ specified as the control ($=1$), and column $j=2$ as the computed drop volumes and parameter vector, β ; the Bayesian procedure used the same model, but assigned a distribution to the variance of observations. As these were standard models in both cases, additional details are not included here, but may be found in reference texts (Gelman, et al., 2014).

4. Sampling from joint posterior distributions: Markov chain simulations

The joint posterior distributions presented in Eq. (1) and Eq. (2) are used to estimate actual drop volume for a given set of process conditions and suspension properties. For a given model, the joint posterior density was sampled using the Metropolis-Hastings algorithm in Markov chain simulations, with the density ratio defined using the proportionality of the joint posterior distribution of interest. The prior distribution was selected as the jumping distribution, which is used to generate of parameter proposals, θ_1^* ; proposals are evaluated using the ratio of the proposal joint posterior density (step θ^*) to that of the joint posterior density at the previous step (θ^{t-1}). The algorithm

proceeds by comparison of a random draw from the standard uniform distribution to the density ratio, r (Eq. (4)); θ^* is accepted as step t of the Markov chain when the density ratio is greater than the standard uniform draw, otherwise the algorithm proceeds from step θ^{t-1} (Chib & Greenberg, 1995). Markov chain simulations using the Metropolis-Hastings algorithm were executed and analysed in MATLAB; for a given joint posterior density, 10 chains with unique starting positions were simulated until the vectors of “accepted” posterior samples had lengths of 1,000,000; convergence monitoring and assessment of mixing followed the framework presented by (Gelman, et al. 2014).

5. Results and Discussion

Using the dropwise additive manufacturing platform, data sets consisting of n drops were generated; the on-line image acquisition system recorded a digital photograph of each drop, which landed in a pre-weighed container for gravimetric analysis. The actual volume of each drop was estimated from its mass, with a working assumption based on constant fluid density. The linked computed image volume and corresponding mass-based volume were used for estimation of prior distribution parameters in models 1, 2 and for the data used for linear regression.

The results of one case study, based on drops produced from micronized acetaminophen (20vol%) suspensions in triglyceride oil, are presented in Figures 3,4.

Figure 3. Posterior distributions of model 1,2 parameters (θ_1, θ_4), respectively, distribution of true values corresponding to y_i 's from the likelihood, and distribution of prior data.

The simulated posterior distributions are presented in Figure 3 as a box plot, in addition to the set of future observations of actual drop volume estimated from image (y_i in model 1,2 notation); the prior distribution of actual drop volume as the fourth entry. From Figure 3, it can be observed that model 1 and model 2 provide a reasonable estimate for mean value; however, the posterior distributions appear to have much longer tails as indicated by the whiskers – from a Bayesian perspective, this is not unexpected, as the posterior distribution includes uncertainty which has been specified in the model structure. In Figure 4, the Bayesian approach results in a larger confidence region than ordinary least squares, though the difference in mean predicted values is negligible.

Figure 4. Predicted mean value, 95% confidence bounds of ordinary linear regression (dashed line, circle) and Bayesian linear regression (solid line, cross). Dots correspond to points to the associated actual/computed drop volume vectors.

6. Conclusions

In this study a Bayesian approach was developed for estimation of product parameters from observations made with offset; prior information from the pharmaceutical manufacturing system was used to update future estimates of drop volume output. The parameter estimates from the Bayesian posteriors provide reasonable estimates for items such as mean, variance, but with a more diffuse density than that observed in the data due incorporated uncertainty, which is also reflected in the respective confidence intervals of the ordinary/Bayesian linear regressions. For implementation in the dropwise manufacturing process, model complexity must at minimum reflect potential disturbances in the process, as demonstrated by peculiarities observed in using the on-line imaging system as the sole process monitor for suspension printing. An improved model necessitates additional explanatory variables such as concentration, which may assist in associating potential causes with experimental behaviour observed with suspensions.

Data Driven Reduced Order Nonlinear Multi-parametric MPC for Large Scale Systems

Panagiotis Petsagkourakis^a, Constantinos Theodoropoulos^{b*},

^a*School of Chemical Engineering and Analytical Science, The University of Manchester, M13 9PL, UK*

^{*}*k.theodoropoulos@manchester.ac.uk*

Abstract

Multiparametric model predictive control (mp-MPC) obtains an off-line feedback control law using parametric programming. Control of distributed parameter systems (DPS) remains a challenging task, as the system dynamics are infinite-dimensional. Model reduction techniques can produce a low-order system. In this work, a combined POD and recurrent artificial neural networks methodology is employed, in order to reduce the system, which can efficiently work for any simulator, including black-box ones. The reduced order model is then utilized by the mp-MPC. A novel strategy is introduced for computing the critical regions of the approximated mp nonlinear problem. The proposed algorithm produces an initial solution and accelerates the procedure, reducing the number of the required critical regions and the corresponding computational time. The effectiveness of the proposed algorithm is demonstrated for a tubular reactor where an exothermic reaction takes place.

Keywords: Model reduction, Distributed parameter systems, Artificial neural networks

1. Introduction

Model predictive control (MPC) is an online control methodology where a receding horizon is employed to compute the manipulated variables for an optimum trajectory (Theodoropoulos 2011). Online MPC may be computationally expensive, especially for the case of distributed parameter systems (DPSs) (Xie et al. 2015). The dissipative nature of such systems can be exploited for model order reduction (MOR). However, the application of online control action could be an obstacle even with the use of a reduced model. Fast MPC such as mp MPC is a powerful control methodology that computes offline the control actions as functions of the states (Pistikopoulos 2012) overcoming the online computational burden of the online MPC. Despite the fact that the majority of computations are performed off-line, the large size of the physical system may produce an intractable computational approach. Rivotti et al. 2012 combine nonlinear model order reduction, based on balancing of empirical gramians to reduce the size of the system with nonlinear multi-parametric MPC (Dominguez & Pistikopoulos, 2011). However, the latter methodology can still be prohibitive for complex large-scale systems, modelled by sets of PDEs and the complexity of equations can jeopardise the efficiency of the algorithm.

Data-driven methodology is employed in this work in order to create a considerably small approximation of the dynamical system. Proper orthogonal decomposition (POD) with recurrent artificial neural networks (rANN) is used to produce a data driven reduced order model that is then utilized in a novel mp algorithm suitable for such

systems. We propose a novel methodology that takes advantage of the collected trajectories in order to accelerate the computation of the mp MPC.

2. Artificial Neural Networks and Model Order Reduction

The focus of this work is on feedback control of spatially distributed processes described by a system of dissipative PDEs:

$$\frac{\partial x}{\partial t} = A(x, \frac{\partial x}{\partial z}, \dots, \frac{\partial^n x}{\partial z^n}) + B(z)u + F(x) \quad (1)$$

where A is a dissipative spatial differential operator, $F(x)$ is a nonlinear function and x , u , and y the states, manipulated, and output variables. Eq. 1 may be unavailable or complicated and Galerkin projection may be difficult to apply. This obstacle can be overcome employing data-driven methodology such as artificial neural networks with POD. Proper orthogonal decomposition (POD) is a widely used methodology for data compression that captures the most “energy” utilizing the method of snapshots (Sirovich 1987) in order to approximate the system eigen-functions. The ‘energy’ of a given mode is related to the magnitude of the eigenvalue corresponding to that mode. This methodology separates the spatial and temporal behaviour discretising the infinite dimensional states with a finite number of reduced states (dominant modes) that captures the most of the systems energy. The eigen-functions produced by this method are then used as global bases functions. The dominant modes can be computed using the \mathcal{L}_2 inner product as $a_i(t) = \int_V (x - \bar{x})\phi_i dz$, where $a_i(t)$ are the dominant modes, \bar{x} is the mean value of the snapshots, and ϕ_i are the computed eigen-functions.

After collecting the snapshots and computing the eigen-functions, a sub-set of snapshots can be used to train an ANN. Approximations using recurrent ANNs (rANN) is a popular methodology for nonlinear physical systems. The wide use of rANN is based on the universal approximation theorem stating that every non-linear dynamical system can be approximated to any accuracy providing enough (but always finite) hidden layers. The structure of the rANN can be relatively simple as the Nonlinear Autoregressive model process with exogenous input (NARX) or significantly complex as the so-called deep-ANN and convolutional ANN (cANN) (G et al. 2016) that have been widely used in image classification and face recognition. In this work, NARX models have been employed to keep the data set as small as possible due to their relatively simple structure. The NARX model is trained employing the back-propagation method and it is carried out in MATLAB R2017a with Neural Networks toolbox. Inputs for the rANN’s are the manipulated variables and the reduced states at the previous time instant.

At this point a special note is needed; POD and rANN are both data-driven methodologies; however a different treatment is required. The snapshots for the PODs can include steady-states; on the other hand rANN should not include steady-states (ss) as the rANN approximate the dynamical behaviour and a given ss will over-fit the network forcing it to duplicate satisfactory the ss but the transient behaviour will be jeopardised. That means that the corresponding data-sets employed for PODs and rANN should be in principle different.

3. Multiparametric Nonlinear MPC

The general optimal control problem can be seen as a continuous mp-nonlinear MPC, where the varying parameters are the current states and any other additional parameters such as set-points. This NLP problem can be formulated with $\theta = [a_0^T, u_{-1}^T, y_{ref}^T]^T$ as follows:

$$J(\theta) = \min_{a,u} h(a,u,\theta) = \min_{a,u} \sum_{i=1}^N \|y_i - y_{ref}\|_Q^2 + \sum_{i=1}^M \|\Delta u_i\|_R^2$$

$$u_i = u_{i-1} + \Delta u_i$$

$$G(a,u,\theta) = a_{i+1} - g(a_i, u_i) = 0$$

$$h_{in}(a,u,\theta) \leq 0$$

$$A\theta \leq b$$

(2)

where $\alpha_i = \alpha(t_i) = [a_1(t_i) \dots a_l(t_i)]^T$, N , M are the prediction and control horizon, respectively, u_{i-1} the manipulated variable at the previous time point, y_{ref} the set-point and g the reduced order rANN (section 2).

POD and rANN are employed, as described in section 2, to generate a reduced order model for Eq. 1 and the mp nonlinear MPC control problem uses the reduced order current states (dominant modes) a_0 reducing the size of θ . Nevertheless, the number of critical regions increases sharply, making the problem computationally intractable even for small sized problems (Grancharova and Johansen 2012). A novel algorithm is proposed in this section that produces a small number of critical regions using initially a multi-linear approximation for the system's dynamics and a step that refines the solution such that the error between the implicit NLP and the explicit approximation is within an a priori bound. The main idea behind the algorithm is to find multiple mp-QP such that the explicit solution can approximate Eq. 3 adequately enough. To do so the nonlinear components of the equation need to be linearized; however the main nonlinear function is the rANN. Therefore, an initial approximation using affine models is created by linearizing the system at multiple points. The first step of the algorithm takes advantage of the collected snapshots used in section 2. The data set is separated into a set of clusters using k-means (Hastie et al. 2009) and the corresponding centroids are computed. These points are then used as linearization points in order to construct a PWA model that is defined in polyhedral regions that are found employing Voronoi diagrams (this procedure can be enhanced using the algorithm of Breschi et al. 2016).

Subsequently, the refinement step follows, where the explicit solution is compared with the implicit NLP and more partitions are generated. The explicit solution is compared at the vertices of each critical region with the implicit solution. Every NLP problem is solved using a multiple shooting method which is suitable for stiff problems like the ones studied here, where the dynamics are given by a reduced order rANN. If the result of the comparison is not satisfactory then new approximate mp-QP is needed. In order to construct an mp-QP for each new partition the following approach is adopted; at the Chebyshev center of the partition a local mp-QP problem (one for each partition) is constructed in the form of Eq. 7:

$$\begin{aligned}
J(\theta) &= \min_U \frac{1}{2} \Delta U^T H \Delta U + (B + F(\theta - \theta_0))^T \Delta U + J^* \\
C \Delta U &\leq d \Delta \theta + E \\
A \theta &\leq b
\end{aligned} \tag{3}$$

with H, B, FC, d, E being the corresponding derivatives evaluated at the point of approximation for the computed for the optimum set of parameters. A scheme with numerical perturbations for the equality constraints is applied in order to compute the derivatives. If J^* is the optimal solution obtained with the multiple shooting method, for parameters θ_0 and optimal degrees of freedom U^* then, for example, the derivative of the objective function with respect to parameter θ_0 is computed as follows:

$$\frac{\partial h}{\partial \theta} = \frac{h(\alpha_{U^*, \theta_0 + \epsilon}, U^*, \theta_0 + \epsilon) - h(\alpha_{U^*, \theta_0 - \epsilon}, U^*, \theta_0 - \epsilon)}{2\epsilon} \tag{4}$$

where α_{U^*, θ_0} is the solution of $G(\alpha, U^*, \theta_0) = 0$ and $\alpha_{U^*, \theta_0 + \epsilon}$ the solution of $G(\alpha, U^*, \theta_0 + \epsilon) = 0$. This refinement procedure continues until an a priori tolerance is satisfied. If the new mp-approximation creates only one critical region that still does not provide an appropriate solution then the region should be divided according to a geometrical criterion (in this work a triangulation is employed). This approach may produce complex convex geometrical regions; however, overall the number of regions does not increase as steeply as in (Grancharova and Johansen 2012), and because of the good initial approximation the result doesn't produce many additional critical regions.

In the next section, this algorithm is employed to a system of PDEs after collecting a good set of snapshots in order to illustrate its computational capabilities.

4. Application

The effectiveness of the proposed algorithm is illustrated using a chemical engineering application; an exothermic tubular reactor. The physical system is described by two partial differential equations with Neumann boundary conditions:

$$\frac{\partial c}{\partial t} = \frac{1}{Pe_1} \frac{\partial^2 c}{\partial z^2} - \frac{\partial c}{\partial z} - Da c e^{\frac{\gamma T}{1+T}} \tag{5}$$

$$\frac{\partial T}{\partial t} = \frac{1}{Pe_2} \frac{\partial^2 T}{\partial z^2} - \frac{\partial T}{\partial z} - B Da c e^{\frac{\gamma T}{1+T}} + b (T_w - T) \tag{6}$$

Here c and T are the dimensionless concentration and temperature respectively, while T_w is the temperature of the cooling zone. The system's parameters are $Pe_1 = Pe_2 = 7$, $Da = 0.1$, $B = 2.5$, $b = 2$, and $\gamma = 6$. The eigenfunctions are computed employing the method described in section 2, where after the eigenanalysis 2 dominant modes capturing 99.8% of the system's energy are computed. A sub-set of the collected snapshots is utilized for the training of the rANN (rejecting the steady states). First, the

dominant modes are computed using Eq. 2 and then the rANN is trained with u_k, α_{k-1} being the inputs of the network and α_k the output. It is crucial that the validation error has to be adequately small as this model error propagates for predictions of larger time intervals during the actual simulation. The reduced model is then used to construct the NLP problem (with $Q=$ Identity matrix (I) and $R=0.01I$) at each Chebyshev center with $-1 \leq u_i \leq 1$ and $-1 \leq \alpha_i \leq 1$. Following the algorithm (section 3) the collected trajectories can then be used to identify the clusters and the mp problem is solved. Fig. 1a depicts two reduced variables at the final solution with the a priori tolerance=0.002. Overall 41 critical regions (~40 CPU-min) are constructed through the refinement process while the method proposed by Grancharova and Johansen 2012 produces 841 critical regions (over 4 CPU-hour). Then, the controllers are validated for different set-points and the results are depicted in Fig.2. The solution is adequately close to the actual implicit nonlinear MPC, and the controller approximates better the implicit NLP for the same a priori error bound. This shows the effectiveness of the proposed method. Furthermore, the error between the reduced order model and the actual system is higher than that produced by an equation-oriented methodology, thus it is important to use a method that will eliminate offsets. Here, in the on-line implementation the actual set-point is substituted by a new set-point which is actual one subtracted by the model error.

All the simulations are carried out using an i7 and 16 RAM single threaded machine. All the calculations are implemented in MATLAB, and each mp QP as well as each NLP problem, is solved using the toolbox POP (Pistikopoulos 2012) with NAG Mark 25.

5. Conclusions

We have developed a data-driven reduced order mp MPC suitable for large scale systems such as ones described by PDEs. A combined methodology of POD and rANN is employed to produce a reduced order system, without using the equations, which is then employed within a new nonlinear mp-MPC algorithm. The effectiveness of the proposed methodology is illustrated through the MPC of an exothermic tubular reactor described by complex nonlinear PDEs. The offline complexity is reduced and the approximated solution is obtained with computational efficiency using a multi-linear solution as an initial partition.

thomas.wallek@tugraz.at

Abstract

In the chemical and process industry a variety of thermal unit operations is applied in which gases or vapor mixtures must be cooled down to temperatures near the water dew point. Such mixtures often contain substances which tend to evolve corrosive characteristics in case the temperature unintentionally falls below the water dew point. In that particular case, depending on the gas composition, acids can be produced and may cause severe damage to heat exchangers. This kind of corrosion is called ‘pitting’ and may remain undetected for a long time, finally leading to a sudden failure of the equipment. One possible strategy to avoid ‘pitting’ is to use corrosion inhibitors, however, such inhibitors imply a significant increase of costs and are also difficult to dispense under varying process conditions. Consequently, most processes operate with a thermal safety distance to the water dew point in terms of pressure and temperature. A considerable drawback of this approach is that the capacity of the heat exchanging equipment is not fully utilized.

To overcome such limitations, this paper suggests a process prediction method for the real-time estimation of the lowest possible heat exchanger surface temperature in view of fully utilizing the optimization potential of the process. The key features of the new approach comprise (i) application of rigorous thermodynamics, considering all relevant facility components that are needed for a complete mass and energy balance, and (ii) a rigorous heat exchanger calculation providing surface temperatures and dead zone temperatures for the current thermodynamic state.

The thermodynamic calculation provides the theoretical water dew point as a function of the process parameters. Considering that sensitive variables such as the composition of the multicomponent process stream have a significant influence on the water dew point, the accurate thermodynamic description of the complete system poses one challenge of the method.

The customized CFD simulation which is integrated into the simulation model provides the complete spatial distribution of the heat exchanger surface temperatures and dead zone temperatures.

Both components are combined to a process prediction model, where an interface between the process prediction model and the process control system (PCS) is used for real-time transmission of the current process parameters to the model, and of

recommended process parameters generated by the model back to the PCS. These recommendations can either be used as guidelines for the operator or directly be implemented as PCS command variables in view of an automated optimal operation mode.

The proposed methodology couples rigorous thermodynamics with CFD simulation into a novel process prediction model which enhances the overall availability of the process significantly, ensures the definite prevention of ‘pitting’ and increases the efficiency of the process by at least one percentage point.

Control strategy for the Super Heat Integrated Distillation Column

Manuel Rodriguez^a, Ismael Diaz^a

^a *Universidad Politecnica de Madrid, Dpt. Of Chemical Engineering, C/ Jose Gutierrez Abascal 2, 28006 Madrid, ES*

manuel.rodriguez@upm.es

Abstract

Distillation is the most widely used in the separation section of a process. It consumes an important amount of energy (close to 40% of the energy of chemical process). Many different configurations to increase its thermodynamic efficiency have been proposed. The first modification was to add side heat exchangers and reboilers to reduce the duties of condenser and reboilers then a pressurized rectifying section was proposed so that the heat duty of the side condenser could be supplied to the side reboiler. This is basically the concept of what is called Heat Integrated Distillation Column (HIDiC). Recently Toyo Engineering Corporation has patented a new HIDiC called SuperHIDiC column concept, where it realizes the heat integration concept in a simplified manner. Using this column energy conservation is around 50% and greenhouse gas emissions are significantly reduced.

Objective is to develop a dynamic simulation of the column and to design the control structure. This will be based on a methyl ethyl ketone separation column.

First, we present the dynamic model, the designed column parameters and its performance in terms of energy consumption. After, we design and implement the control structure. This structure is evaluated under different production scenarios and disturbances and it is optimised for minimum total annual cost.

This work shows the potential of heat integrated columns and specifically of the recently developed by Toyo Eng. Corp. A control structure that minimises costs (capex and opex) is proposed and analysed showing possible operation problems and how interactions between the different control loops affect the column performance.

Dynamic simulation and process control study for enhancing operability of small-scale BOG (Boil-off gas) re-liquefaction process in LNG-fueled ship

Hyunsoo Son^a, Jin-Kuk Kim^a, Dong-Hun Kwak^a

^a*Hanyang University, Dpt. of Chemical Engineering, 222 Wangsimni-ro, Seongdong-gu, Seoul 04763, KR*

jinkukkim@hanyang.ac.kr

Abstract

There has been an increasing demand for natural gas because it emits less greenhouse gases than conventional fossil fuels. Reinforcement of international regulation to reduce exhaust gas from ship also supports to fuel a ship with LNG (Liquefied natural gas). However, as LNG stored in a tank at low temperature keeps losing its heat into surroundings, generation of BOG (Boil-off gas) occurs. This necessitates the introduction of BOG re-liquefaction process because the accumulation of BOG not only leads to abnormal state in LNG tank but also decreases profitability.

While previous studies on BOG re-liquefaction processes are mostly limited to large-shipment capacity for LNG carriers using SS (steady state) simulation, this research aims at developing a novel framework for operational optimization of small-scale BOG re-liquefaction process equipped onto LNG-fueled ship by considering both SS and DS (dynamic state) simulation. For this purpose, the process is first designed with small-scale N₂-based reverse Brayton cycle which can be operated at offshore environments. Its feasibility is verified with SS simulation in a commercial simulator. Dynamic model developed in this study shows good agreement with SS simulation, indicating that the model is suitable for analyzing dynamic behaviors and control systems. Sensitivity analysis based on the SS simulation is also carried out for key design and operating parameters with which operation strategy for dealing with unexpected changes is obtained and guidance for achieving more economic operation, leading to the reduction of shaft power consumption for the cycle, is gained.

Process dynamics can be better predicted with DS model built in this study and robust control is effectively ensured with the proposed control logic. This improvement is essential to prevent unexpected operational failure (e.g. surging and thermal shock) or unwanted deterioration in system performance, due to disturbance in the feed and operating conditions.

There are various control mechanisms available for BOG re-liquefaction process. For example, LNG temperature can be controlled by either feed-backward or feed-forward way and faster dynamic response can be achieved with feed-forward way. The most robust control scheme which has stability and high energy efficiency is chosen such that manipulated and controlled variables are paired in a logical manner followed by investigating impacts of disturbances, like change in feed gas temperature. Furthermore, various operational scenarios are systematically investigated in the context of HAZOP

(Hazards and operability study), where DS simulation is utilized for optimizing system performance or minimizing energy consumption. In conclusion, practical and cost-effective operational guidelines are systematically obtained through the proposed operating strategy and control system.

Global Optimization Algorithm for Multi-period Design and Planning of Centralized and Distributed Manufacturing Networks

Cristiana Lara^a, Ignacio Grossmann^a

^aCarnegie Mellon University, Department of Chemical Engineering, Center for Advanced Process Decision-Making, 5000 Forbes Avenue, Pittsburgh, PA 15213, US

cristianallara@cmu.edu

Abstract

Distributed and modular manufacturing has arisen as a promising option for supply chain networks in which the transportation is the main bottleneck. However, economies of scale will always favor large scale centralized production. Therefore, there is a need for a general framework that can support this decision taken into account the potential tradeoffs (Lara et al., 2016). In this paper, we address the design and planning of manufacturing networks considering the option of centralized and/or distributed facilities. This multi-period problem involves the selection of which facilities to build in each time period, and their location in the continuous 2-dimensional space, in order to meet demand and maximize profits.

The problem is formulated as a version of the continuous facility location and allocation problem with limited capacity, also known as the Capacitated Multi-facility Weber Problem (CMWP) (Brimberg et al., 2008). The objective of this type of problem is to determine locations in continuous 2-dimensional space for opening new facilities based on their maximum capacity and the given coordinates of the suppliers or customers. We propose an extension of the original CMWP that considers fixed cost for opening new facilities, fixed transportation costs, and two sets of fixed-location points: suppliers i and customers j (Lara et al., 2017), and investment decisions in different time periods. The model is a multi-period nonlinear Generalized Disjunctive Programming (GDP), reformulated as a multi-period nonconvex Mixed-Integer Nonlinear Programming (MINLP).

We develop a bilevel decomposition algorithm that consists of decomposing the problem into a master problem and a subproblem. The master problem is based on a relaxation of the nonconvex MINLP, which yields an MILP that predicts the selection of facilities and their links to suppliers and customers, as well as a lower bound on the cost of problem. The subproblem corresponds to a nonconvex NLP of reduced dimensionality that results from fixing the binary variables in the MINLP problem, according to the binary variables predicted in the MILP master problem. Based on the bounding properties of their subproblems, ϵ -convergence is proved for this algorithm.

The applicability of the proposed model and solution framework are illustrated with case studies for different industries, including biomass and shale gas. The results show that the algorithm is more effective at finding global optimal solutions than general purpose global optimization solvers tested.

Abstract

An integrated facility for the processing of waste to recover power and high value-added products is conceptually designed. The process is based on the anaerobic digestion of different types of manure (cattle, pig, poultry, and sheep). The products obtained in the process are biogas composed of methane and carbon dioxide, and a nutrient-rich effluent. The biogas produced is cleaned and used in a gas turbine to produce electrical power while the hot flue gas obtained from combustion is fed to a steam turbine to produce additional power. The nutrient-rich effluent can be processed to recover the nutrients using technologies such as filtration, coagulation, centrifugation, and struvite precipitation. The design problem is formulated as a Mixed-Integer Nonlinear Program (MINLP), which incorporates detailed physical and economic evaluation models. We have found that struvite production in fluidized beds is the technology of choice to recover nutrients from all manure sources. It was found that the power produced strongly depends on the manure composition and exhibits high cost variability. In particular, it was found that the investment cost of the power produced ranges from 4,000 €/kW in case of poultry manure to 25,000 €/kW in the case of cattle or pig manure.

Keywords: anaerobic digestion, manure, power production, optimization

1. Introduction

Countries across the globe generate large amounts of waste. While many of these waste streams can be used as a source of power and chemical products, identifying suitable cost-effective technologies to achieve this is challenging. Anaerobic digestion (AD) is deemed as a promising technology to treat these residues to produce biogas, which can be used as a source of energy or chemicals (Hernández et al., 2017). However, AD technologies also generate a nutrient-rich residual stream called digestate that must be treated to prevent soil and water contamination (Sampat et al., 2017). Diverse processing technologies exist to achieve this.

In this work, a systematic design framework is proposed to optimize the simultaneous production of energy from biogas obtained by the AD of cattle, sheep, poultry, and pig manure, along with the recovery of nitrogen and phosphorous from the digestate. The proposed framework determines the optimal technology configuration, equipment

sizing, and operational conditions for various compositions of manure and digestate and revenues for biogas, electricity, and fertilizer.

2. Process superstructure

The proposed process consists of four sections: biogas production, biogas purification, electrical power generation, and nutrient recovery from the digestate. The biomass together with water and nutrients (manure slurry) are fed to a bioreactor (1), where the mixture is anaerobically digested to produce biogas and a decomposed substrate (digestate). The biogas is sent to the purification section (2) to remove H_2S in a fixed-bed reactor and to eliminate CO_2 and traces of NH_3 in a pressure swing adsorption (PSA) system. The biogas is then fed to a gas turbine (3) and the flue gas used to produce steam for a steam turbine (4). The digestate can be processed through a number of technologies to remove nitrogen and phosphorous. Several options are considered such as filtration (5), centrifugation (6), coagulation (7), and struvite production using either a fluidized bed reactor (FBR) (8) or a continuous stirred tank reactor (CSTR), (9). Figure 1 shows a scheme of the process. Four different types of manure (cattle, pig, sheep, and poultry) are processed through this to evaluate the power production and the best nutrient recovery technology.

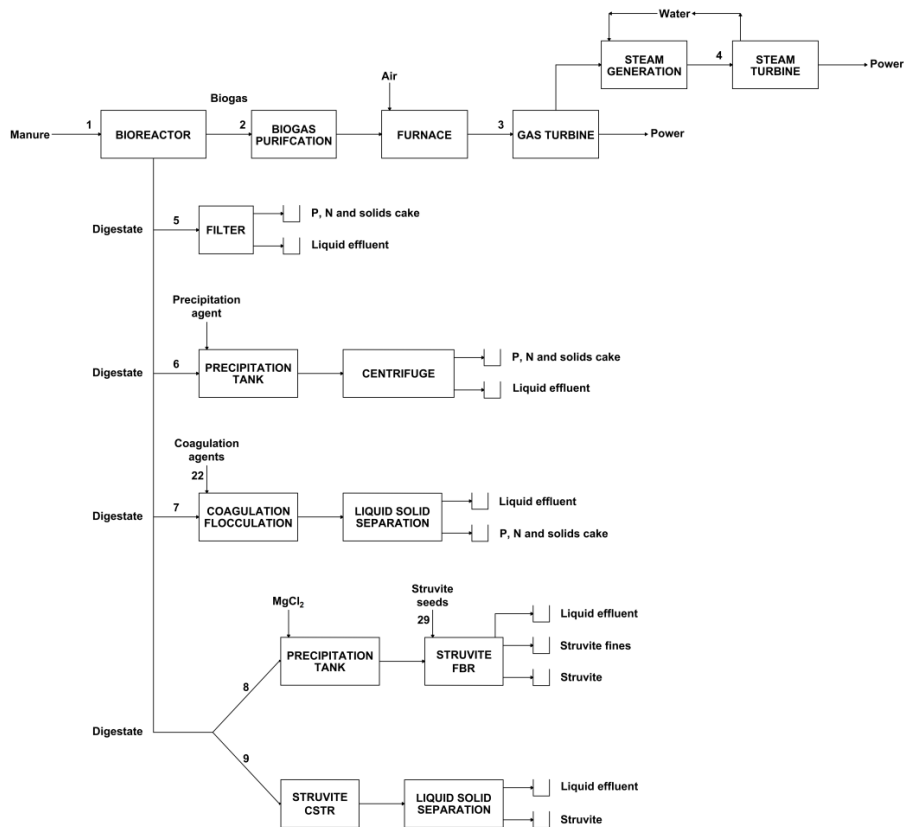

Figure 1.- Superstructure for manure processing to power and nutrients.

3. Modelling issues

The performance of the different unit operations is evaluated in the process by using detailed models that comprise mass and energy balances, thermodynamics, chemical and vapor-liquid equilibria, and product yield calculations based on experimental data.

- The anaerobic reactor: is modeled by using mass balances of the species involved in the production of biogas and digestate. Inorganic nitrogen, organic nitrogen, sulfur, carbon, and phosphorus balances are formulated by using the composition of volatile solids in manure (León and Martín, 2016)

- The gas purification section consists of a number of stages to remove H_2S , CO_2 , and NH_3 . The removal of H_2S is carried out in a bed of Fe_2O_3 that operates at 25-50 °C producing Fe_2S_3 . CO_2 is adsorbed using a packed bed of zeolite 5A. The typical operating conditions for PSA systems are low temperature (25 °C) and moderate pressure (4.5 bar). Together with CO_2 , ammonia and water are adsorbed.

- The gas turbine is modeled as a compression section for the biogas and another one for the air, a combustion chamber modeled as adiabatic and an expansion considered polytropic with a coefficient equal to 1.3, computed offline in CHEMCAD[®], and an efficiency of 85%.

- The steam turbine is modeled as a regenerative Rankine cycle. Surrogate models for the enthalpies and entropies as a function of the pressures and temperatures allow the optimization of the operating conditions (Martín and Martín, 2013).

- Four different technologies are considered for the recovery of nitrogen and phosphorous, namely, filtration, centrifugation, coagulation, and struvite production using either a stirred tank or fluidized bed reactors. These processes have been modeled using mass balances, removal yields, and equipment and operating cost correlations:

- Filtration: This technology consists of a filter that contains a reactive medium to help remove phosphorus. P removal using reactive filtration takes place through various mechanisms depending on the characteristics of the filter media. Five different types of filter media have been evaluated: wollastonite, Polonite[®], Filtra P[®], dolomite, and metallurgical slag. The removal yield of P and N for the different filter media is shown in Table 1.

Table 1. Recovered P and N yield for different filter media.

Media/Nutrient	Polonite	Filtra P	Wollastonite	Dolomite	Metal slag
P (% recovered)	96.7 ^a	98.2 ^a	51.1 ^a	44.0 ^b	85.6 ^a
N (% recovered)	18.0 ^c	50.0 ^c	70.0 ^d	50.0 ^c	67.0 ^f
	<i>a: Gustafsson et al., 2008.</i>	<i>c: Kietlinska and Renman, 2005.</i>			<i>e: Aziz et al., 2004.</i>
	<i>b Pant et al., 2001.</i>	<i>d: Lind et al., 2000.</i>			<i>f: Yang et al., 2009</i>

- Coagulation: Nutrients are recovered together with other sedimented solids by clarification. Phosphorus is removed mainly in the form of metal hydroxides, which is the dominant process at typical plant pH values. Nitrogen elimination is related to the removal of the colloidal matter (Aguilar et al., 2002). Different coagulation agents are considered: $FeCl_3$, $Fe_2(SO_4)_3$, $Al_2(SO_4)_3$, and $AlCl_3$. The removal efficiency achieved is similar for the different coagulant agents, with values up to 99% for phosphorus and 57% for nitrogen (Aguilar et al., 2002).
- Centrifugation: It separates solid and liquid phases to recover nutrients from the digestate. The advantage of this system is the simple equipment used. Precipitant agents can be added to improve the removal efficiency significantly. Previous studies show that an appropriate mixture of $CaCO_3$ and $FeCl_3$ promotes nutrients recovery. In particular, a ratio of 0.61 kg $CaCO_3$ and 0.44 kg of $FeCl_3$ per kilogram

of total solids in the raw material inlet stream, achieves a removal efficiency up to 95% and 47 % for P and N respectively (Meixner et al., 2015).

- Struvite production: P and N can be recovered from digestate through the formation of struvite, which is a phosphate mineral with a chemical formula of $MgNH_4PO_4 \cdot 6H_2O$. The advantage of this technology is that struvite is a solid with a high nutrients density, it is easy to transport, and it can be used as a slow-release fertilizer without any post-processing (Doyle and Parsons, 2002). The removal of nutrients via struvite precipitation follows the reaction shown below, which requires the addition of $MgCl_2$ and which results in the production of struvite crystals:

Due to the presence of potassium in the digestate, together with struvite, another product called potassium struvite or K-Struvite, is also produced that affects the amount of $MgCl_2$ used. In this case, the ammonia cation is substituted by the potassium cation.

Because the formation of struvite is favoured over the formation of K-Struvite, it is considered that only 15% of the potassium contained in the digestate will react to form K-Struvite (Zeng and Li, 2006). The mass balance for the reactors is given by the stoichiometry of the reactions above.

Two different types of reactors can be used to obtain struvite, either a stirred tank (CSTR) or a fluidized bed reactor (FBR). In case of the FBR, struvite is recovered from the bottoms and the liquid is processed through a hydrocyclone to avoid discharging fines. In the case of CSTR tanks, a centrifuge is used to recover the struvite. Seeding can be used to help grow the crystals (Doyle and Parsons, 2002). Due to the substantial increase in the struvite formation yield, the addition of struvite seeds in both cases is selected. The reaction takes place at about 27°C, with the addition of $MgCl_2$ at a concentration of 57.5 mg/dm³ (Zhang et al., 2014). A Mg:P molar ratio of 2 (Bhuiyan et al., 2008) is used.

The problem is formulated as an MINLP for the different filter media and coagulant agents. In the first stage, the detailed model is solved to determine the best filter and coagulant agent using economic cost functions. For that purpose the benefit obtained is maximized the benefit including the income obtained by selling the recovered nutrients minus the operational cost, which are function of recovered P and N yields, equipment cost and final cake moisture content, among other aspects.

Next, the superstructure is optimized to determine the optimal power and nutrient recovery technologies. Since the superstructure model is highly non-linear, to avoid integer variables and discontinuities when deciding on the selection digestate treatment technologies smooth approximations and continuous reformulations have been developed. The resulting problems are NLPs with 5,000 variables and 4,000 equations written in GAMS[®] that are solved using a multistart initialization procedure with CONOPT as preferred solver.

4. Results

4.1.-Operating conditions

In the case of cattle, pig, and poultry manure, the gas exhaust from the gas turbine reaches a temperature of 2,400 °C and a pressure of 8.2 bar before expansion. However, sheep manure shows different values. In particular, while the exhaust temperature is similar, the pressure is 15.6 bar, almost twice the value found for the rest of the raw materials. Furthermore, the flue gas exits the turbine at 300 °C below that when the rest of the manure types are used. This flue gas will later be used within the heat integration step. Moreover, while the high-pressure section of the steam turbine operates at 125 bar for cattle, pig, and poultry manure, in case of sheep manure it operates at 95 bar. This is related to the lower gas temperature from the gas turbine since the overheated steam needs to be produced using that stream. Intermediate and low pressures are the same in the steam turbine using any of the manure types, but the exhaust pressure of the steam is higher in case of sheep manure. Table 2 shows the products obtained from the various manure types, power, biogas, and digestate. Poultry waste is more efficient towards power production, due to its higher organic content. In all cases the FBR reactor for the production of struvite is the selected technology to recover N and P. In Table 2 it is possible to see the effect of the fact that cattle and pig manure are mostly liquids, since most of the product is digestate, almost 98%, while the use of poultry or sheep manure reduces the production of digestate to 75% and 88% respectively, increasing the production of biogas and power.

Table 2.- Process optimization results for considered manures

Manure	Power (kW)	Biogas comp. (CH ₄ /CO ₂ ratio)	Digestate treatment technology	Product recovered	Biogas / Manure ratio	Digestate / Manure ratio
Cattle	2,612	0.816	FBR struvite	Struvite	0.0208	0.9794
Pig	2,612	0.816	FBR struvite	Struvite	0.0208	0.9794
Poultry	31,349	0.818	FBR struvite	Struvite	0.2499	0.7526
Sheep	14,106	0.818	FBR struvite	Struvite	0.1217	0.8795

4.2.-Economic evaluation

Table 3- Electricity production cost and net present value (NPV) for the facility considering different raw materials

Raw material	Annual production costs (M€/y)	Electricity production cost (€/kWh)	Net Present Value
Cattle manure	12.04	0.45	-1.93x10 ⁷
Pig manure	12.07	0.45	-1.96x10 ⁷
Poultry manure	25.51	0.03	2.85x10 ⁸
Sheep manure	15.53	0.10	5.46x10 ⁷

To estimate the production cost, 20 years of plant life is considered, with a capacity factor of 98%. The equipment amortization represents at least 43% of the production costs. This share increases up to 60% in the case of poultry manure. As the investment is lower, the annual cost for other items is almost constant and their contribution to the electricity cost plays a more important role. The purchase of chemicals is the second most important contribution to the cost of electricity with a share of up to 23% for the use of cattle or pig manure and down to 16 % in the case of sheep manure. The electricity production costs obtained are presented in Table 3. The NPV has also been calculated as a measure of the project profitability. An electricity sale price of 0.06 €/kWh is assumed following current European values, to compare the profitability of this project at a discount rate of 3 %, typical in Spain.

5. Conclusions

In this work, integrated facilities for the production of biogas-based electrical power and fertilizers from manure have been designed. A two-step procedure has been used. First, the individual detailed models for each digestate treatment technology are used to formulate MINLP models aiming at selecting the best configuration for that technology: the best precipitation agent and filter media. In the second step, a superstructure is formulated including the best configuration of each technology. The results show that FBR technologies are preferred to recover nutrients. Furthermore, for poultry and sheep manure it is possible to produce electricity at a competitive price. The investment cost is highly dependent on the water and organic content of the manure type, ranging from 70 M€ to 208 M€. However, for these cases of high investment cost, the production cost of power is the most competitive due to the large production capacity. Competitive values of 4,000 €/kW for poultry manure are obtained, due to the highly concentrated manure, while large values of 25,000 €/kW installed are reported in case of cattle or pig manure.

Abstract

The paper evaluates the technical performances of an ammonia production plant having an output of 2500 t/day. Mass and energy integration aspects of natural gas conversion (conventional steam reforming, autothermal reforming and chemical looping), carbon capture unit by gas-liquid and gas-solid systems, ammonia production and associated heat recovery and their influence on the overall ammonia production performances are discussed in detail. The ammonia production concepts were modelled and simulated using a process flow modelling software (ChemCAD). The obtained simulation results were used to assess the overall technical and environmental indicators of the ammonia production plant. Three case scenarios with CO₂ capture were considered for investigation. Industrial and experimental data were used to validate the models. The results show that the chemical looping system has significant advantages compared to the natural gas reforming technologies coupled with the gas-liquid absorption technology such as: lower specific fossil energy consumption (8.3 MWth/t NH₃ vs. 9.6 - 9.9 MWth/t NH₃), higher carbon capture rate (99.9 % vs. 60 – 90 %), lower specific CO₂ emissions (7 kg/t NH₃ vs. 230 - 900 kg/t NH₃ for plants with CO₂ capture based on gas-liquid absorption and about 2000 kg/t NH₃ for plant without CO₂ capture), lower plant complexity. The presented technical analysis of the different ammonia production cases shows very promising options to significantly reduce the fossil energy consumption as well as the carbon footprint of this important industrial sector.

Keywords: Ammonia production; Carbon Capture, Utilisation and Storage (CCUS) technologies; Chemical looping; Computer Aided Process Engineering (CAPE) tools.

1. Introduction

Reducing the energy consumption and CO₂ emissions from heat and power sector as well as from other energy-intensive industrial applications (e.g. metallurgy, cement, petro-chemistry) is of paramount importance today in order to satisfy the 2 °C pathway by 2050. Carbon capture and storage (CCS) is, at present, the most suitable option for capturing CO₂ from carbon-intensive industrial processes which can arise either from energy consumption, either from the process itself (raw materials undergo chemical or physical transformations in which CO₂ is formed as by-product) (IEA, 2016).

Ammonia is the second largest inorganic chemical produced worldwide (after sulphuric acid) being used predominantly within fertilizer industry, being an indispensable

chemical in meeting society's needs. On the other hand, ammonia production is highly carbon-intensive, relying on fossil fuels both for energy production and as feedstock for H₂ synthesis, accounting for about 1.5 % of total anthropogenic CO₂ emissions.

Today, ammonia is produced in more than 90 % of the cases following the Haber-Bosch synthesis process in which hydrogen and nitrogen are reacted over an iron promoted catalyst at high temperatures and pressure. Nitrogen is taken from air, while hydrogen is largely obtained from catalytic reforming of natural gas (48 %) and in smaller fractions from oil reforming (30 %), coal gasification (18 %) and water electrolysis (4 %) (Abbasi and Abbasi, 2011). The state of the art technology for hydrogen production used industrially in ammonia production facilities is steam-methane reforming (SMR). The SMR-based ammonia process releases into the atmosphere about 1.5 tonnes of CO₂ per tonne of ammonia (without considering urea production) according to Bicer et al. (2016). Although water electrolysis-based processes have the prospect of introducing a low-carbon hydrogen production pathway, they are more energy intensive as well as more resource and cost-demanding than the currently used fossil energy carriers.

Among the various carbon capture methods suitable to be implemented in an ammonia production plant, two reactive gas-liquid and gas-solid options are evaluated in this paper in pre-combustion CO₂ capture configurations. The first evaluated CO₂ capture option (considered as a reference case) is based on gas-liquid absorption using chemical solvents (methyl-diethanol-amine - MDEA). The second capture option is based on innovative chemical looping system (using iron oxides as oxygen carrier) for pre-combustion CO₂ capture. As key advantages of chemical looping cycle in comparison to gas-liquid absorption one can mention: better high temperature heat recovery potential and improved energy conversion efficiency with subsequent reduction of fossil fuel consumption and CO₂ emissions. The carbon capture rate for chemical looping system is almost total (99.9 %) in contrast with the reforming technologies (60 % for conventional steam reforming and 90 % for autothermal reforming).

2. Cases description and modeling assumptions

There are different carbon capture options suitable for industrial applications such as: absorption (chemical or physical), adsorption and more advanced capture technologies such as chemical looping combustion. In this paper, different ammonia production routes were considered leading to the development of three case studies:

Case 1: Ammonia production with SMR and MDEA-based CO₂ capture;

Case 2: Ammonia production with ATR and MDEA-based CO₂ capture;

Case 3: Ammonia production with chemical looping.

A schematic representation of the evaluated ammonia synthesis processes is depicted in Figure 1 and a description of each case is detailed below.

Case 1 describes a conventional ammonia production process with hydrogen being produced from steam methane reforming (SMR). SMR is based on an equilibrium limited and highly endothermic reaction (Reaction 1), for which the required energy is supplied by burning additional natural gas in a secondary reformer. The obtained process gas contains up to 30 % CO and is converted to CO₂ and H₂ through the water gas shift (WGS) reaction (Reaction 2). In a next step, CO₂ is removed by gas-liquid chemical absorption using MDEA as solvent.

Chemical absorption of CO₂ by MDEA is described by an absorption-desorption cycle that takes place in two interconnected columns: absorber and desorber. The sour gas to be treated is fed into the bottom section of the absorber where it is contacted counter-currently with lean chemical solvent which gradually absorbs CO₂. The CO₂ rich solvent is then pumped to the top of the desorber column where it is regenerated by increasing the temperature and releasing the captured CO₂. Although chemical absorption using alkanolamines is a mature technology being already implemented industrially in ammonia plants, the process is highly energy intensive, more specifically the thermal energy required for the amine's solution regeneration leads to increased operating cost and reduces the energy efficiency of the plant (Sreenivasulu, 2015).

Case 2 is to a large extent similar with Case 1, containing the same process steps: desulphurization, reforming, WGS and CO₂ removal by MDEA, with the exception of the reforming section which in this case is based on autothermal reforming (ATR) instead of SMR. ATR is another catalytic reforming technology, still under development, that combines the SMR with partial oxidation of methane in the same step according to Reaction (3). In this case, the heat required for the endothermic reaction reaction is generated in-situ by the partial oxidation of the fuel.

Compared to the SMR, ATR has an improved methane conversion as it operates at higher temperatures (600-1050 °C vs. 500-900 °C); the main difference between the two reforming technologies is that SMR uses oxygen as a heat source in a secondary reformer, while ATR directly combusts part of the methane with oxygen.

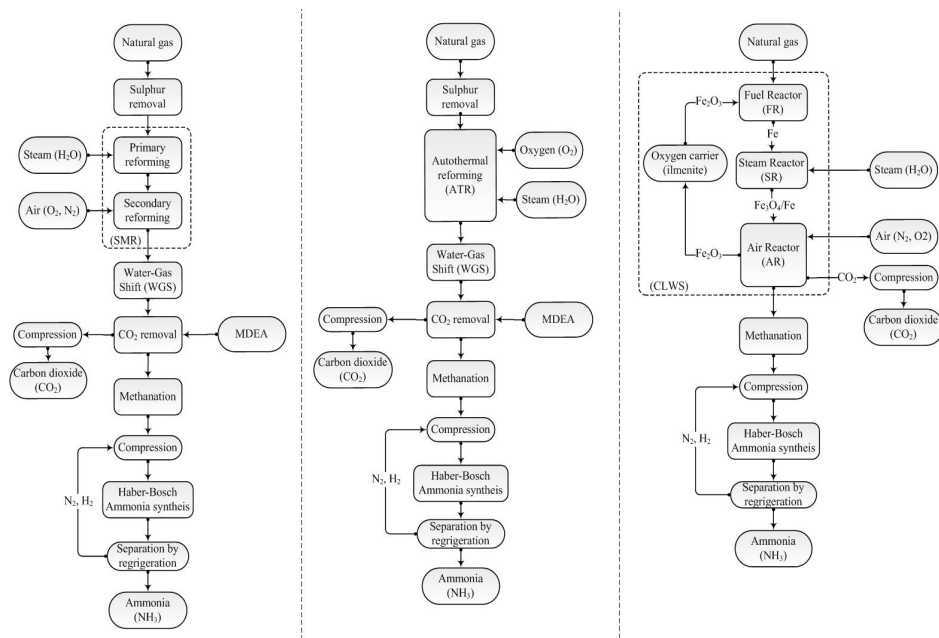

Figure 1. Ammonia production routes: Case 1 (left), Case 2 (middle), Case 3 (right)

Case 3 integrates hydrogen production and CO₂ capture in a single unit by incorporating chemical looping, a new emerging technology that received a lot of attention in the past years, into the ammonia production process. Fuel conversion takes place using the oxygen released by an oxygen carrier (OC) that circulated between two interconnected reactors: a fuel reactor (FR) where the fuel is converted to CO₂ and H₂O and an air reactor (AR) where the OC is regenerated by oxidation with air. As the air and fuel never get mixed, the combustion products are no longer diluted with nitrogen and thus an almost pure stream of CO₂ can be obtained by condensing the H₂O, eliminating a highly energy intensive separation unit. Chemical looping can also be used for hydrogen production, either by integration with the conventional reforming technologies (supplying oxygen for ATR or heat in SMR) either by taking advantage of the potential of some OC to be oxidized by steam to produce hydrogen.

The latter option is referred by Abad (2015) as chemical looping with water splitting (CLWS) and consists in replacing totally or partially the oxidation taking place in the AR with oxidation with steam in an additional steam reactor. Iron-based oxygen carriers are suitable for CLWS as they have high reactivity with the selected fuel and high conversion towards syngas production. Also they possess multiple oxidation states in order to be capable to oxidize the fuel in the fuel reactor and being partially oxidized by steam in the steam reactor, according to the following reactions (Fan, 2010):

Table 1. Design and modeling assumption of evaluated ammonia plant concepts

Process Unit	Assumptions
Air separation unit (ASU)	100 % N ₂ purity, 98.5 % O ₂ purity @ 2 bar pressure ASU power consumption: 200 kWh/t oxygen
Sulphur removal unit	>98 % H ₂ S removed
Steam methane reforming (SMR)	500-900 °C; 27-29 bar; ~3.2 steam to NG ratio; ~55 % additional NG burned in the secondary reformer
Autothermal reforming (ATR)	600-1050 °C; 28-30 bar; ~0.15 steam to NG ratio; ~0.5 O ₂ to NG ratio
MDEA CO ₂ capture unit	50 wt% MDEA solution; Absorption/desorption columns: 30/10 stages
Chemical looping unit	oxygen carrier ilmenite; air reactor temperature 1000°C; fuel reactor temperature 700 °C; steam reactor temperature 700°C; generated steam pressure 28 bar;
CO ₂ compression	120 bar CO ₂ delivery pressure; 85 % compressor efficiency
Water gas shift reactors	High temperature shift (HTS): 400-450 °C; 27-29 bar Low temperature shift (LTS): 250-260 °C; 26-28 bar
Methanation reactor	50-300 °C; 25-16 bar; 99 % CO conversion

A summary of the modeling assumption considered for all case scenarios investigated is presented in Table 1. All case scenarios produce ammonia through the Haber-Bosch synthesis process having an output of 2500 t/day; nitrogen is obtained from the atmosphere by cryogenic air separation, this being the most efficient and cost-effective method to produce nitrogen at industrial scale. After the CO₂ capture unit, in all cases, a final removal of carbon oxides is completed by a methanation step after which the actual ammonia synthesis is carried out in the Haber-Bosch process.

3. Results and discussions

The investigated case scenarios were modeled and simulated using the process simulator ChemCAD. The developed models were validated by comparison to industrial data (Voldsund et al., 2016). Thermal integration by pinch methodology was performed for all considered designs for maximizing the overall energy efficiency (10 °C was considered as minimum temperature difference between the hot and cold streams). Figure 2 depicts the hot and cold composite curves for ammonia synthesis coupled with the chemical looping processes (Case 3).

Figure 2. Hot and cold composite curves for the chemical looping unit coupled with ammonia synthesis (Case 3)

The main technical and environmental indicators of the evaluated scenarios are listed in Table 2. Looking at the results, one can notice that coupling ammonia production with chemical looping leads to a significant reduction in CO₂ emissions of about 99 % compared to the conventional ammonia production route and 64 % compared to MDEA-based capture coupled with ATR (6.43 kg/t NH₃ vs. 903.91-231.82 kg/t NH₃). Also, employing chemical looping into the ammonia production route brings a lower specific fossil energy consumption of about 14-16 % compared to Case 1 and Case 2. Although the ancillary power consumption for the chemical looping coupled ammonia production (Case 3) is about 1.6 % higher than the conventional ammonia production route (Case 1) and 1.2 % higher than in Case 2, it is covered by the additional energy production obtained from steam generation using recovered heat from the chemical looping process streams. Besides ammonia output, there is also an oxygen output for Cases 1 and 3, in comparison with Case 2 where oxygen is burned in the ATR reactor providing the heat required to drive the endothermic reforming reaction.

Table 2. Overall plant performance

Main Plant Data	Units	Case 1	Case 2	Case 3
Ammonia output	t/h	104.16	104.16	104.16
Fuel (NG) thermal energy	MW _{th}	1,025.62	1,004.46	865.65
Gross power output	MW _e	53.63	70.41	113.51
Ancillary power consumption	MW _e	53.63	70.41	84.16
Net power output	MW _e	0.00	0.00	29.35
Oxygen output	t/h	25.80	0.00	25.80
CO ₂ output (emissions)	t/h	94.15	24.14	0.67
Carbon capture rate	%	60.00	90.00	99.90
Specific CO ₂ emissions	kg/t NH ₃	903.91	231.82	6.43
Specific fossil energy consumption	MW _{th} /t NH ₃	9.84	9.64	8.31

4. Conclusions

This paper evaluates the energy and CO₂ emission reduction from an ammonia production plant considering three hydrogen production paths (conventional steam methane reforming, autothermal reforming and chemical looping) and two carbon capture technologies (gas-liquid absorption by MDEA and iron-based chemical looping). As the results show, the chemical looping system has key advantages compared to the natural gas reforming technologies coupled with CO₂ capture by gas-liquid absorption, such as lower specific fossil energy consumption, higher carbon capture rate, lower specific CO₂ emissions and lower plant complexity (the innovative chemical looping technology integrates in a single unit both hydrogen production and CO₂ capture). As overall conclusion, the chemical looping option is very promising for reducing significantly the carbon footprint and the fossil energy consumption of this important industrial sector with possible application in other industrial sectors too.

Abstract

The recovery of the wasted heat is an effective way of improving the energy efficiency of industry sites and can contribute to the reduction of the operating costs and the CO₂ emissions. In the production of low density polyethylene, the polymerisation reaction is carried out with a large excess of ethylene at very high pressure. The excess ethylene is separated at an intermediate pressure (around 280 bar and 310 °C) and then it is recycled. In this recycle, the stream is cooled in several steps to temperatures close to 35 °C before being recompressed. In some units, the first cooling is carried out with air coolers up to temperatures around 130 °C. In a unit with a recycle of 33 t/h, this cooling corresponds to releasing to the atmosphere about 4.6 MW of thermal power. We present a study of different alternatives for the use of this excess heat. We studied the implementation of a refrigeration cycle by absorption with LiBr/H₂O, the production of steam and the electricity generation by Rankine and Kalina cycles. The Aspen HYSYS process simulator was used to study the different alternatives. The capital cost was estimated for each of the evaluated options as well as the benefits expected to be obtained. In the study conditions, the absorption refrigeration cycle is the best solution presenting a return period of 3 years.

Keywords: excess heat, energy efficiency, economic evaluation.

1. Introduction

The comfort brought by technological evolution is reflected on population growth. The more people there are the more needs and demands are to satisfy, consequently increasing energy expenditure. The smashing majority of energy is obtained from non-renewable feedstock like coal, natural gas, and oil (BP, 2017). However, their finite nature, the increasing CO₂ concentrations in atmosphere and the several conflicts between nations shouldn't be overlooked. The development of both renewable energy and efficiency technologies are fashionable and useful ways to reduce fossil fuel dependency and extend its life expectancy. Heat and power integration fits the latest category (Walsh and Thornley, 2012). Although there are several definitions to excess heat, here it is treated as suggested by Viklund and Johansson (2014): a sub-product of an industrial activity, which may or may not be able to recover internally through thermodynamic optimisation of a process.

In 2010, approximately 11.3 EJ out of 26.2 EJ were rejected by the EU as industrial waste heat, which represents 43% of the total energy produced. Motivated by the recovery of the economic crisis and sustainable growth, the recovery of excess heat has become an important goal in increasing energy efficiency (Viklund and Johansson, 2014).

2. Case study

A LDPE production plant consisting of two production lines has served as basis to the study. In each line, the excess ethylene recycles at a nominal flow of 33 t/h, at 310 °C and 280 bar. During the recycling process, it is intended to reduce the stream temperature to approximately 35 °C before recompression. The first step of the cooling is taken out with an air cooler, which cools the stream down to 130 °C, releasing 4.6 MW of heat per production line.

Globally, the needs of the LDPE plant are chilled water where 4.535 MW of energy are consumed, a minimum 2.2 t/h of high pressure steam (40 bar), a maximum 4 t/h of low pressure steam (7 bar) and 385 t/h of hot water.

The heat recovery hypothesis studied throughout this work consisted strictly in commercially available technologies to recover this heat. Two power production cycles, Rankine (Chen et al., 2010) and Kalina (Rodríguez et al., 2013), a LiBr/water absorption system (Srihirin et al., 2001) and the production of hot utility by heat exchanging were explored with the aid of the simulator Aspen HYSYS.

3. Results and discussion

3.1. Power cycles

A total of 23 fluids, most of which being on the review done by Chen et al. (2010), were tested on these simulations. Property packages were chosen based on the minimum squared error between the heat of vaporisation and the property package data for each fluid, on an adequate range of pressures. For ethylene, being in supercritical state, the property for comparison was the heat capacity.

3.1.1. Rankine cycle

In the first part of this study, condensation had bottom limits of 50 °C and 1 bar, and evaporation had the upper limit of 290 °C (assuming $\Delta T_{\min} = 20^\circ\text{C}$) and the critical pressure of the working fluid. Another restriction is that no fluid can condense inside the turbine. The results of the best fluids are shown in Table 1, with R-601 (pentane) being the most promising fluid.

After selecting the most promising fluid, ethylene stream cooling was bottom bounded at 130 °C, to respect the original process restrictions. Condensation was also allowed at 45 °C, using cooling water (CW) from 25 to 35 °C. After that, an integrated Rankine cycle was built to test its own integration advantages. The integration allows the stream sited before the evaporator to heat the stream before the condenser. This requires less CW to condensate more working fluid (Table 2).

Table 1 – Preliminary performance results for the best fluids tested in the simple Rankine cycle.

Fluid	T _{condenser} (°C)	P _{condenser} (bar)	T _{max} (°C)	P _{evaporator} (bar)	Fluid flow (t/h)	CW flow (t/h)	COP ¹	W _{out} (kW)
R-245ca	45	2.04	171	37	64.2	344	0.132	815
R-601	45	1.36	195	55	30.1	338	0.148	913
R-717	45	17.8	290	112	10.7	333	0.158	788

¹Coefficient of performance, $COP = W_{out}/Q_{in} = (W_{turbine} - W_{pump})/Q_{evaporator}$

Table 2 – Comparison between simple and integrated Rankine cycle configurations for R-601, with ethylene cooling down to 130 °C.

Rankine configuration	T _{condenser} (°C)	P _{condenser} (bar)	T _{max} (°C)	P _{evaporator} (bar)	Fluid flow (t/h)	CW flow (t/h)	COP	W _{out} (kW)
Simple	45	1.36	195	33	30.1	338	0.154	713
Integrated	45	1.36	195	33	35.9	326	0.183	849

3.1.2. Kalina cycle

Previous restriction on ethylene cooling was set from the beginning and the vapour fraction in the generator was limited between 0.5 and 0.9. In this cycle, multistate turbines are also accepted (Bombarda et al., 2010). The main variable in this cycle is the mixture NH₃/H₂O, in the working fluid. Concentrations of 60, 70, 75 and 80 % (m/m) were simulated. Table 3 shows a maximum on W_{out} for 70 % NH₃, with the restrictions above. With this composition, low and high temperature heat exchangers were added, as schemed by Rodríguez (2013), to evaluate the efficiency changes in the system. Restrictions to the ΔT_{min} made it impossible to cool the ethylene down to 130 °C, but 172.2 °C instead. Still, it is interesting how the integration increases the cycle performance itself.

Table 3 – Simulation results for the Kalina cycle.

NH ₃ (%m/m)	T _{absorber} (°C)	P _{absorber} (bar)	Vapour fraction	T _{generator} (°C)	P _{generator} (bar)	Fluid flow (t/h)	CW flow (t/h)	COP	W _{out} (kW)
60	45	11.2	0.9	245	89	9.6	351	0.136	642
70	45	12.8	0.9	246	113	10.4	346	0.147	692
75	45	13.5	0.9	236	113	10.9	346	0.147	690
80	45	14.3	0.9	255	113	11.6	347	0.146	687
Kalina cycle with heat integration									
70	45	12.8	0.9	246	113	10.7	248	0.199	713

The analysis of the results obtained for the Rankine and Kalina cycles showed that the former had a better performance with a simpler configuration and at lower pressure.

3.2. Hot utility production by heat exchanging

Hot utility is produced directly by heating water with the ethylene stream. The study comprises the production of high and low pressures steam, and hot water needed in the process. Results are presented in Table 4. In the case of the production of steam at 7 bar it is possible to satisfy the needs of the process with only one of the production lines. Using both lines, ethylene temperature can be at 230 °C. The hot water process needs can be almost met by using the two production lines with ethylene at 130 °C.

Table 4 – Ethylene usage and hot utility production

Hot utility	Ethylene flow, required initial temperature	Production	Process needs
Steam, 40 bar	33 t/h, 310 °C	2.1 t/h	> 2.2 t/h
Steam, 7 bar	33 t/h, 310 °C	5.6 t/h	4 t/h
	66 t/h, 229.8 °C	4 t/h	
Hot Water, 95 °C	33 t/h, 130 °C	192 t/h	385 t/h
	66 t/h, 130 °C	384 t/h	
	33 t/h, 310 °C	1,180 t/h	

3.3. Refrigeration cycle – LiBr/H₂O absorption system

For the analysis of the refrigeration cycle, catalogues were consulted. Knowing the chilled water needed for both process lines, made possible to identify the amount of hot utility necessary to feed to the absorption system, which in turn led to the quantity of ethylene flow needed to produce that hot utility. Table 5 summarises the main results obtained for both single and double effect LiBr/H₂O absorption systems.

Table 5 – Ethylene flow to satisfy the needs in chilled water with LiBr/H₂O absorption system

Absorption cycle	Ethylene flow, required initial temperature	Production	Process needs
Single effect, hot water (90 °C)	41.7 t/h, 310 °C	4,554 kW	4,535 kW
	66 t/h, 243.4 °C		
Single effect, steam (1 bar)	46.4 t/h, 310 °C	4,676 kW	4,535 kW
	66 t/h, 256.1 °C		
Double effect, steam (8 bar)	32.3 t/h, 310 °C	4,652 kW	4,535 kW
	66 t/h, 248.6 °C		

4. Economic analysis

To carry out the economic evaluation of the different solutions studied, the following starting variables were used: annual operating time of 8,000 h, an energy price of 75 €/MWh, a low-pressure steam (7 bar) price of 18.9 €/t, an investment depreciation period of 10 years with constant rate of return, internal rate of return of 10% and project lifetime of 15 years. For this analysis, the income can be defined as the benefits in energy saving achieved with the implementation of each solution (Table 6).

Table 6 – Estimation of the annual benefits after investing on each technology.

	Power (Rankine)	Refrigeration (Double effect absorption chiller)	Hot utility (Steam 7 bar)
Net power (MW)	0.9	4.535	-
Steam (t/h)	-	-	4
Annual benefits (k€)	540	2,721	606

The equipment cost was estimated taking into account information provided by the suppliers of the solutions for Rankine and absorption cycles and with Aspen Economic Estimation for other equipment. The fixed capital cost was estimated using the Lang factors (Peters et al., 2003) and the results are present in the Table 7.

Table 7 – Fixed capital investment estimation via Lang factors.

	Rankine	Absorption chiller	Steam 7 bar
Main equipment cost (k€) ^v	1,200	528	-
2 water pumps for steam (k€) ^s	81	81	81
2 water pumps for chilled water (k€) ^s	-	Existent	-
2 cooling water pumps (k€) ^s	188	469	-
Ethylene/water heat exchanger (k€) ^s	1,000	1,000	1,000
Flash separator (k€) ^s	-	121	121
Total equipment cost, E (k€)	2,469	2,199	1,202
Equipment installation, instrumentation and control, piping and electrical installations, 142 % E (k€)	3,506	3,123	1,707
Direct plant cost (sum) (k€)	5,975	5,322	2,909
Engineering and supervision, and construction expenses, 74 % E (k€)	1,827	1,627	889
Direct and indirect costs (sum), C (k€)	7,802	6,949	3,798
Contractor's fee and contingency, 15 % C (k€)	1,170	1,042	570
Fixed capital investment (sum), FC (k€)	8,972	7,991	4,368
Annual depreciation, 10 % FC (k€)	897	799	437
Annual maintenance, 1.5 % FC (k€)	135	120	66

^v suppliers' information; ^s Aspen Economic Estimation

The cash flows for each year can be calculated taking into account the benefits, the depreciation, maintenance costs and the internal rate of return. The estimated cumulative cash flow after investing in one of the proposed solutions are present in Table 8. The refrigeration cycle by absorption with LiBr/H₂O is the solution with the best return of the investment with positive cumulative cash flow after the 3rd year.

Table 8 – Estimated cumulative cash flow after investing on each technology.

Year	Rankine	Abs. chiller	Steam 7 bar	Year	Rankine	Abs. chiller	Steam 7 bar
0	-8,973 k€	-7,995 k€	-4,370 k€	5	-4,038 k€	4,894 k€	-668 k€

4	-4,846 k€	2,783 k€	-1,274 k€	NPV=15	-382 k€	16,699 k€	2,419 k€

5. Conclusions

In this case study, lots of waste heat are available, so recovery is a right step to approach efficiency. Power cycles had efficiency limitations, with maximum performances around 20 %, reached at lower pressures in the Rankine cycle in relation to Kalina cycle. Heat driven LiBr/H₂O absorption refrigeration systems are available to substitute some power consuming traditional refrigeration cycles, due to cost benefit ratio and so the preferred solution for the use of excess heat from the ethylene recycle stream.

Abstract

This paper evaluates the dry reforming of methane (DRM) process with CO₂ capture using an alkanolamine gas - liquid absorption system for flexible hydrogen and power co-generation. The evaluated plant concepts consider a net power output of about 500 MW net with a flexible hydrogen thermal output in the range of 0 to 200 MW_{th}. The carbon capture rate of the CO₂ capture unit is higher than 90%. The evaluations used process flow modeling performed using ChemCAD process simulator, as well as, process integration techniques (e.g. thermal integration via pinch analysis) for quantification of mass & energy balances of the overall process. The analysis is geared toward assessment of key technical and environmental indicators of flexible hydrogen and power co-generation based on DRM with CO₂ capture such as: gross and net power output, hydrogen thermal output, cumulative energy efficiency, ancillary plant energy consumption, carbon capture rate, specific carbon dioxide emissions etc. As benchmark cases, conventional steam reforming and autothermal reforming, both equipped with CO₂ capture using gas-liquid absorption, are used for comparison reason of DRM technology. Potential production of other energy carriers (e.g. synthetic fuels like methanol) by dry methane reforming with CO₂ capture was also considered. As the key performance indicators show, the dry methane reforming process with CO₂ capture has some advantages in comparison to the conventional steam methane reforming and autothermal reforming such as: higher energy efficiency and carbon capture rate, lower specific CO₂ emissions, ability to process some of the captured CO₂ instead of energy-intensive steam used for conventional methane reforming etc.

Keywords: Flexible hydrogen and power co-generation; Dry methane reforming; Carbon Capture, Utilization and Storage (CCUS) technologies; CAPE tools.

1. Introduction

Carbon capture, utilization and storage (CCUS) technologies are expected to play a significant role in the near future for reducing the global greenhouse gas emissions and to ensure a sustainable development of energy - intensive industrial applications (e.g. heat and power sector, metallurgy, cement, petro - chemistry etc.). On the other hand, increasing the energy efficiency of fuel conversion processes as well as designing flexible energy conversion systems, able to timely respond to power grid variations are other significant ways to reduce both, fossil fuel consumptions and CO₂ emissions. Hydrogen is considered as one of the promising future energy carriers which is not involving fossil CO₂ emissions at the point of use. In addition, hydrogen (as well as

other chemicals used as energy carriers) has a distinct advantage in comparison to electricity that it can be easily stored to be used for power generation during the peak time or for other practical applications, like chemicals (Bailera et al., 2017).

Dry reforming of methane is a promising way to convert natural gas into syngas. According to Voldsund et al. (2016), nearly half of the global H₂ production is by natural gas steam reforming. In contrast with conventional steam reforming process, this procedure gives rise to a gas with a H₂/CO molar ratio of nearly 1:1 that is a feedstock for several processes. Garcia (2015) has reported that the main disadvantage of DRM is the catalyst deactivation due to carbon deposition. Although Ni-based catalysts are widely applied in the field, noble metal catalysts present less carbon deposits. From a kinetic perspective, the dry methane reforming process was described as methane decomposition on the catalyst followed by the gasification of these deposits.

In the present work the technology of CO₂ reforming was evaluated from a technical and environmental point of view. Comparisons between four operating scenarios were performed in order to better understand the behavior of the DMR plant. Thermal integration was applied to increase the energy efficiency. The obtained results for each scenario were compared to steam methane reforming and autothermal reforming, showing better performance in terms of natural gas consumption and efficiency.

2. Assessment methodology

While the heavy industry's energy demand is relatively constant during a 24 h cycle, private homes and small companies' power demand varies significantly. Similarly, with the constantly increase integration of the renewable energy sources (e.g. solar, wind) into the power grid, their production output depending significantly on the weather, induces fluctuations in the production / demand ratio. To counteract this issue, Gutiérrez-Martín and Rodríguez-Antón (2016) proposed the installation of a power to synthetic-natural-gas technology in the power grid to make use of the surplus energy as conventional power plants are designed to run at a constant production rate.

To catch up with today's market demand, in this paper a different approach is presented, one that uses flexible power plants to lower overproduction periods, reduce costs and lower carbon emissions. A DMR technology, offering the possibility of lowering its power output and produce H₂ during low energy demand periods, is investigated in the present paper. One of the main DMR outputs, H₂, can be later sold as a chemical or transformed into electrical energy when demand is high. For DMR simulation, the design assumptions presented in Table 1 were taken into consideration.

Table 1 Major design assumptions

Major design assumptions	
CH ₄ /CO ₂ ratio molar for reforming	1 / 1
CH ₄ purity	99.9 %wt
CO ₂ purity	99.9 %wt
Steam / carbon molar ratio for water gas shift	1.5
Oxygen source	Air

The process was build using the general structure of a reforming plant as presented in Figure 1. Methane and CO₂ are fed into the catalytic reactor that is designed as a shell and tube reactor. The catalyst is located in the tubes while in the shell the burning of methane maintains the desired temperature. Air is used as an oxygen source. The

product streams CO content is lowered using medium pressure steam in two, a high and low temperature shift reactor. The heat produced in the shift reactors is used to generate the necessary steam for it. H₂ purification is performed in the carbon capture unit where CO₂ is captured using a liquid phase absorber, 50 % wt. solution of methyl-diethanolamine (MDEA). A percentage of 98.75 % of the CO₂ is captured. The energy required for the regeneration of the solvent is obtained from the flue gases of the reactor. The leftover H₂ with CH₄ as a primary impurity is fed into the combined cycle gas turbine (CCGT) at the operating pressure of the gas turbine. High purity H₂ is obtained from the stream entering the GTCC. For power generation, a Mitsubishi Hitachi Power Systems M701G2 series gas turbine combined cycle was considered, with the following specifications: 334 MW net power output and 39.5 % net electrical efficiency for the gas turbine. The accompanying Rankin cycle was designed separately. The captured CO₂ and produced H₂ steams are compressed to 120 and to 60 bar, respectively.

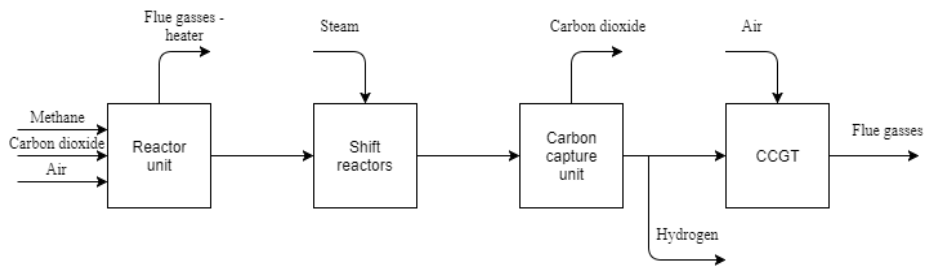

Figure 1. Process flow diagram of dry methane reforming with carbon capture

For the design of the dry methane reforming reactor, the use of kinetic data was selected. In order to verify the kinetic data available in the literature, this was compared to the results of the build-in thermodynamic functions in ChemCAD. The two showed very little difference. The reforming reactor was designed for a Ni/Al₂O₃ catalyst. This catalyst is frequently applied in the field and widely discussed in the literature (Abdullah et al., 2017). The kinetics selected is the one reported by Chein et al., (2017) applying to the two main reactions: dry reforming of methane and the reverse water-gas shift (RWGS). The side reactions describing the carbon formation were neglected. Both, previously mentioned reactions being highly endothermic, a significant amount of heat is used to maintain the desired high temperature of the reaction media. Following a thermodynamic study performed in ChemCAD, 920 °C was selected as an operating temperature. This value is in accordance with the data presented by Garcia (2015). To exemplify the impact of a carbon capture unit and of the lowered gas turbine feed rate over the system four scenarios were selected. The four scenarios are described more in detail in the following section. The base case (Case 1) was selected as having a dry reforming unit with two shift reactors connected to a CCGT to produce only power. No steps were taken to lower carbon emissions, only heat integration was performed. In Case 2, a CO₂ capture unit (based on gas-liquid absorption) is introduced to lower the greenhouse gas emissions. This scenario is important in order to quantify the energy penalty of using a CO₂ capture unit. The CO₂ stripped gasses are fed into the CCGT. In the third and fourth case studies (Cases 3 and 4) the hydrogen and power co-generation was assessed by gradually turned-down the gas turbine to produce hydrogen. The Case 3 is producing 100 MW_{th} and Case 4 200 MW_{th} of H₂. Two cases with lowered CCGT feed input were selected to easily describe linear variations in the behavior of the plant regarding lowered power production. The two lowered feed input case giving two data points and the case at full CCGT load being the third data point for each parameter.

3. Results and discussion

The previously mentioned cases, were modeled and simulated using ChemCAD 7.1 process simulator (Chemstations, 2017). The obtained models were used to calculate mass and energy balances in order to evaluate the key performance indicators and to perform thermal integration. As an example, Figure 2 presents the hot and cold composite curves of second case (dry methane reforming with carbon capture), the plant operating at full power load with carbon capture. A significant amount of energy is required for the regeneration of the CO₂ capture solvent (MDEA), which is also visible in the above - mentioned figure at about 125 °C. In the other three cases, similarly a considerable amount of energy is integrated to increase the efficiency of the plant.

Figure 2. Hot and cold composite curves

In Table 2, the key performance indicators are presented for each investigated case. The energy input is the same in all four cases but depending on the downstream configuration, the efficiency and specific CO₂ emissions vary significantly. In Cases 1 and 2, the energy generated is almost the same, the difference in the expander output and the energy recovered in the Rankine cycle can be attributed to the solvent regeneration of the carbon capture unit. The sudden increase in the Rankine cycle output can be explained by the thermal integration of the plant. The same amount of heat is used in all three cases using carbon capture for heating the gas turbine inlet stream and powering the Rankine cycle. As the amount of gasses fed into the gas turbine dropped (CO₂ removed by the carbon capture unit), the amount of energy available for the Rankine cycle increased. The same trend can be noticed in the expander output section, as this is the unit setting up the desired pressure for the gas turbine. In the present plant configuration, the energy output of the CCGT is not affected by the introduction of the carbon capture unit, as this unit uses waste heat generated by the reactor.

Adding the carbon capture unit to the dry methane reforming plant lowers the global energy efficiency of the plant by 3 % as seen in the cumulative efficiency values. In Cases 3 and 4, the energy output of the gas turbine decrease significantly as expected with the decrease of fuel, however the efficiency penalty of the CCGT was only about 0.5 % in the verified two cases. The plant uses a significant amount of power to compress the CO₂ required for the plant, as it is considered that the gas is fed from a carbon capture unit at 1.5 bar. A similarly high quantity of energy is needed for the carbon capture unit to compress the gas. As the quantity of H₂ needed to compress is relatively small, compared to the amount of CO₂, the power needed for compression is also significantly lower. The cumulative efficiency of the plant shows a sudden decrease with the use of a carbon capture unit, however by the increase of H₂ production the overall (cumulative) energy efficiency of the plant increases significantly, overtaking the base case at maximum H₂ production capacity. The specific CO₂ emissions are calculated for power production thus explains the increase of the value as the H₂ ratio increases but when consider the overall energy production CO₂ emissions decrease.

Table 2. Comparison of simulated dry methane reforming scenarios

	Units	Case 1	Case 2	Case 3	Case 4
Natural gas input	t/h	79.89	79.89	79.89	79.89
Lower heating value LHV	MJ/kg		46.73		
Feedstock energy input	MW _{th}	1,037.00	1,037.00	1,037.00	1,037.00
Gas turbine output	MW _e	334.00	334.00	287.32	248.78
Steam turbine output	MW _e	173.22	174.73	152.91	132.60
Expander output	MW _e	4.60	1.56	3.14	2.58
Rankine cycle output	MW _e	40.22	12.72	16.28	15.79
Total power output	MW _e	551.75	522.59	459.65	399.75
H ₂ thermal output	MW _{th}	0.00	0.00	100.00	200.00
CO ₂ capture unit	MW _e	0.00	14.50	14.50	14.50
H ₂ compression unit	MW _e	0.00	0.00	1.12	2.25
Plant power unit	MW _e	12.93	12.54	12.54	12.27
Total power consumption	MW _e	12.93	27.04	28.17	29.02
Net power output	MW _e	538.83	495.55	431.49	370.73
Net power efficiency	%	51.95	47.78	41.60	35.74
Hydrogen efficiency	%	0.00	0.00	9.64	19.28
Cumulative plant efficiency	%	51.95	47.78	51.24	55.03
Carbon capture rate	%	0.00	64.40	64.40	64.40
CO ₂ emissions (power)	kg/MW _e	687.12	267.67	307.41	357.79
CO ₂ emissions (H ₂ +power)	kg/MW	687.12	267.67	249.57	232.41

Table 3 compares the obtained results for dry methane reforming to conventional steam methane reforming and autothermal reforming, as reported by Salkuyeh et al., (2017). The reference plants have a similar H₂ production rate as the one reported in this paper. The specific natural gas consumption of the dry methane reforming technology is lower than in the case of conventional steam reforming, however when compared to autothermal reforming the process has a significantly higher specific consumption. In terms of methane consumption, dry methane reforming technologies is located in between the technologies of steam methane reforming and autothermal reforming.

Table 3. Comparison of various methane reforming technologies

	Dry methane reforming	Steam methane reforming	Autothermal reforming
Natural gas consumption (t/t _{H2})	4.70	5.20	3.80
CO ₂ captured (t/t _{H2})	13.97	13.20	10.20
Hydrogen production rate (MW, LHV)	566.80	630	630

4. Conclusions

Lowering the electric grid energy surpluses can decrease the energy production prices as well as the carbon emissions. Power plants with flexible energy conversion capabilities can be actively applied to combat this issue. Dry reforming of methane is a promising alternative for steam methane reforming, the technology that is used today predominantly for obtaining H₂ from natural gas. In this work, four DRM scenarios were investigated to describe the behavior and the energetic aspect of this reforming technology, when coupled to a carbon capturing unit and when the GTCC is operated at lower capacities. DRM was also compared to conventional steam methane reforming, showing benefits in term of reducing the specific fuel (methane) consumption. The flexible hydrogen and power co-generation show its benefits in term of increasing the cumulative energy efficiency of the plant as well as decreasing the specific CO₂ emissions when the hydrogen output is increasing.

Abstract

The work is motivated by an industrial environmental problem, which is ethanol removal from aqueous mixture. To complete this goal organophilic pervaporation of ethanol/water mixture through commercially available Sulzer PERVAP™ 4060 is investigated to obtain information about the removal of ethanol. The experimental results are obtained at different feed ethanol concentrations and temperatures. Our experimental data are evaluated with the semi-empirical pervaporation model (Valentinyi et al. 2013) of our improvement and it is found that the model can be applied also for this organophilic case. Linear and quadratic surfaces suiting (Model III) are also investigated in order to estimate partial permeate flux. The results of parameter estimation and modelling of the pervaporation show that the novel model that considers the concentration dependency of the transport coefficient (Model II) is also capable for the modelling of organophilic pervaporation and results in a better fit to the experimental data, than basic pervaporation model (Model I) and Model III.

Keywords: organophilic pervaporation, parameter estimation, model development, ethanol removal

1. Introduction

The pervaporation (PV) process can be used for dehydration of organics or for the removal of low concentration organics from aqueous mixtures (Ki Hong and Hi Hong 1999, Konieczny et al. 2008, Liang et al. 2004) and also for organic-organic separation. Depending on the permeating component two main areas of pervaporation can be identified: hydrophilic and organophilic pervaporation (Toth et al. 2015, Van der Bruggen and Luis 2014, Zhang et al. 1992).

Pervaporation is a separation method that is considered as green technology because of its low energy consumption. The mechanism of component separation in a liquid mixture by PV is complex but it can be explained with the solution-diffusion mechanism. It consists of the following steps: solution of the preferred component in the membrane; preferential diffusion of the component through the membrane material and desorption and evaporation on the permeate side into the vapour phase. One of the important features of describing PV is the transmembrane flux described in a general

form by Fick II equation. Apart from the simplicity of this equation the diffusion coefficient has complicated concentration dependency for non-ideal systems. Therefore scientists have been working on developing new models for pervaporation. Major models found in the literature, are the empirical model, pore-flow model; total solvent volume fraction model, and solution–diffusion model (Heintz and Stephan 1994a, b, Lipnizki and Trägårdh 2001, Luis and Van der Bruggen 2015, Marriott and Sørensen 2003, Schaetzel et al. 2004, Wijmans and Baker 1995). Crucial requirements of modelling, beside simplicity, are applicability of these models in flowsheeting environment (Valentínyi et al. 2013).

2. Material and methods

The novel model developed and tested by Valentínyi et al. (2013) on several hydrophilic PV case studies has proved to be a good one for the description of PV for engineering applications and design. The basic equation of this model is (J: partial permeate flux):

$$J_i = \frac{1}{1 + \{\bar{D}_i \cdot \exp(B \cdot x_{i1})\} / (Q_0 \cdot p_{i0} \cdot \bar{V}_i)} \cdot \frac{[\bar{D}_i \cdot \exp(B \cdot x_{i1})]}{\bar{V}_i} \cdot \left(\frac{p_{i1} - p_{i3}}{p_{i0}} \right) \quad i = (1, \dots, k) \quad (1)$$

The model is an improvement of Rautenbach's work (Rautenbach et al. 1990) and the improvements consider the concentration dependencies of the transport coefficient and the temperature dependencies of PV. First the parameters of the two models (Model I: Rautenbach, Model II: novel one) have to be estimated based on measured data. These parameters are the transport coefficients, permeability coefficients, activation energies (\bar{D}_i , Q_0 and E_i) and the B parameters that shows the concentration dependencies of the transport coefficients. The estimations are completed with the STATISTICA® program environment. Permeate flux can be also estimated directly with STATISTICA® from experiments results with surface suiting, it is called as Model III. Linear and quadratic surfaces are also applied.

The main aim of this paper is to extend Model II in the case of organophilic separation and to comparison of accuracy of these models. The verification can be obtained with objective function, that is minimized the deviation of the modelled and the measured values.

$$OF = \sum_{i=1}^n \left(\frac{J_{i,measured} - J_{i,modelled}}{J_{i,measured}} \right)^2 \quad (2)$$

PV of ethanol (EtOH) and water mixture using organophilic Sulzer PERVAP™ 4060 membrane is studied at different feed ethanol concentrations (x_{F-EtOH} : 5, 10, 15, 20 m/m%) and temperatures (T: 313K, 333K and 353K). The experimental set up is a P-28 membrane unit from CM-Celfa Membrantechnik AG. The flat sheet membrane with 28 cm² effective area is placed on a sintered disc separating the feed and the permeate sides. The volume of the feed tank is 500 ml. Cross-flow circulation velocity is kept at a permanent value of ~182 l/h. The vacuum on the permeate side is maintained with VACUUMBRAND PC2003 VARIO vacuum pump and kept at 2 torr (2.67 mbar). The isotherm conditions are assured with a thermostate. The permeate is collected in two traps connected in series and cooled with liquid nitrogen to prevent loss of the permeate (Toth and Mizsey 2015). The organic content of the feed, permeate and retentate are measured with Shimadzu GC2010Plus+AOC-20 autosampler gas chromatograph with a

CP-SIL-5CB column connected to a flame ionization detector, EGB HS 600 (Toth 2015, Toth et al. 2017).

3. Results and discussion

The minimized objective functions and estimated values for \bar{D}_i , E_i , and B parameters of the three models are shown in Table 1 (Model I: basic Rautenbach, Model II: improved model, Model III: quadratic surface model).

Table 1 Estimated parameters for ethanol-water mixture with Sulzer PERVAP™ 4060 membrane and objective functions resulted by the three models

	Model I		Model II		Model III	
	Water	EtOH	Water	EtOH	Water	EtOH
\bar{D}_i [kmol/m ² h]	0.014	0.074	0.027	0.074		
E_i [kJ/kmol]	31376	33071	31352	33077		
B [-]			-0.71	-0.04		
OF [-]	0.011	0.165	0.001	0.153	0.021	0.182

It can be seen that Model II has the lowest OF and the accuracy of PV models are better all case of water flux than ethanol flux. The comparison of the measured and calculated partial fluxes are presented in Figure 1 and Figure 2.

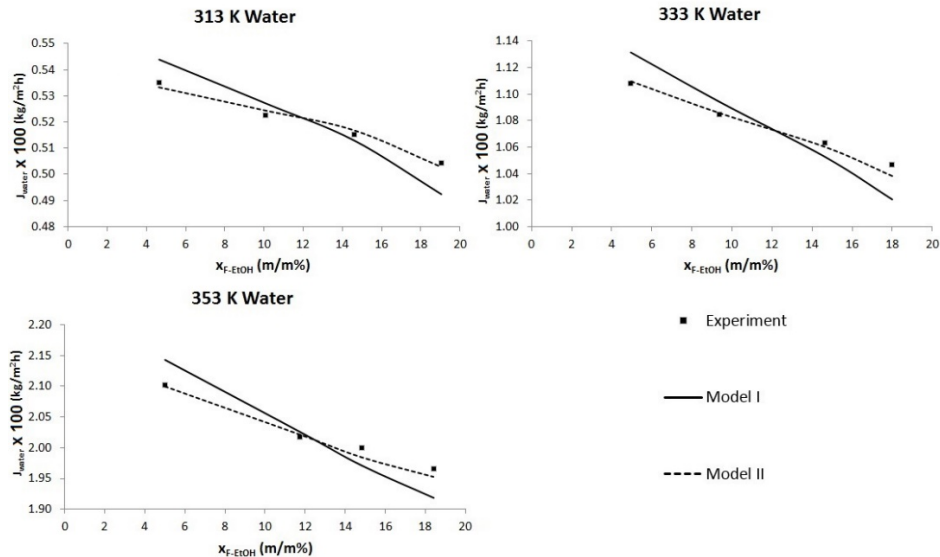

Figure 1. Measured partial fluxes of ethanol compared to fluxes calculated with Model I and Model II at 313K, 333K, 353K in a function of feed ethanol content in weight percent with Sulzer PERVAP™ 4060 membrane

Figure 2. Measured partial fluxes of ethanol compared to fluxes calculated with Model I and Model II at 313K, 333K, 353K in a function of feed ethanol content in weight percent with Sulzer PERVAP™ 4060 membrane

Figure 3 shows the linear surface suiting with STATISTICA® software. The dependent variable is ethanol flux and independent variables are x_{F-EtOH} and $x_{F-EtOH} \cdot T$. The white discrete points mean the experimental data and below Figure 3 the equation of surface can be seen (Eq. (3)). Using Eq. (3) partial ethanol flux can be calculated.

Figure 3. Linear surface in the function of ethanol flux, feed ethanol concentration and feed temperature (Virag 2007)

$$J_{EtOH} = -0.907485 \cdot x_{F-EtOH} + 0.002992 \cdot T \cdot x_{F-EtOH} \quad (3)$$

Figure 4 shows the quadratic surface suiting with STATISTICA®. In this case the dependent variable is J_{EtOH} and the independent variables are as follows: T , x_{F-EtOH} , $x_{F-EtOH} \cdot T$ and T^2 .

Figure 4. Quadratic surface in the function of ethanol flux, feed ethanol concentration and feed temperature (Virag 2007)

$$J_{EtOH} = 89.19 - 0.53 \cdot T - 0.80 \cdot x_{F-EtOH} + 0.0008 \cdot T^2 + 0.0027 \cdot x_{F-EtOH} \cdot T \quad (4)$$

It can be seen the quadratic surface model (Figure 4) estimates better the experimental data than linear surface model (Figure 3). The results suggest that linear correlation describe inaccurately the organophilic pervaporation. Many authors have suggested an exponential relationship between diffusion coefficient and feed concentration (Shelden and Thompson 1984, Valentínyi et al. 2013).

4. Conclusions

It can be concluded Model II results in a better fit to the experimental data, than Model I and III. The results of parameter estimation show that Model I estimates the measured fluxes higher than measured, especially in the case of ethanol content, because of that the transport coefficient depends on a greater extent of the feed composition. This dependency is found to be an exponential one also for our organophilic pervaporation. It can be stated the surface models, although simple and fast methods, cannot give fairly accurate estimate.

Abstract

Multistream heat exchangers (MHEXs) find application in a variety of energy intensive cryogenic processes. However, simultaneous optimization of process and MHEXs is often hindered by its nonlinear behavior and combinatory difficulties, which lead to low computational efficiency and poor solution qualities. In this paper, we present a mixed-integer nonlinear programming (MINLP) framework that comprises heat recovery of MHEXs, thermodynamics, vapor-liquid equilibrium, and other unit operations of the process. The MHEXs model combines the concept of Pinch analysis and multi-M formulation that improves solution efficiency by reducing the number of binary variables and nonconvexity of the model. The framework is applied to an industrial air separation unit (ASU) with multiple MHEXs to demonstrate its effectiveness.

Keywords: multistream heat exchangers, heat integration, process optimization

1. Introduction

Multistream heat exchanger (MHEX) is a type of processing units that simultaneously transfers heat among multiple process streams. Thanks to its compact structure and exceptional energy recovery efficiency, MHEXs find extensive applications in energy intensive processes including air separation (Pattison and Baldea, 2015), food and pharmaceutical production (Galeazzo et al., 2006), hydrocarbon processing (Shah et al., 2000), hydrogen purification and liquefaction (Christopher and Dimitrios, 2012), liquefied natural gas (LNG) production (Kamath et al., 2012), power generation (Memmott et al., 2017), and refrigeration processes (Thonon, 2008).

Much effort has been dedicated to model and optimize MHEXs to achieve higher economic-energy efficiency of process design. Hasan et al (2009) applied the concept of superstructure (Yeomans and Grossmann, 1999) to simulate MHEX, and formulated an mixed-integer nonlinear programming (MINLP) model to optimize heat recovery of MHEX. However, the complex superstructure is often computationally expensive, which brings greater difficulty to the simultaneous process and MHEX optimization. Kamath et al. (2012) presented a nonlinear programming (NLP) formulation of MHEX based on the concept of Pinch analysis (Kemp, 2011, Liang and Hui, 2016). The major challenge of the NLP formulation is the nonlinear approximation of *max* function, which can leads to error in energy balance and numerical difficulties.

Despite intensive research, MHEXs remain difficult to model due to the complexity of unknown stream data (e.g. temperatures and flow rates), resulting in bilinear function and discrete/nonlinear formulation for the heat integration model which is computationally expensive. To exacerbate the issue, simultaneous optimization of MHEXs and processes requires flash calculation of process streams and computation of other equipment that involve nonlinear thermodynamics constraints. Thus, it is significant to develop a rigorous and computationally efficient modeling framework to achieve simultaneous optimization of MHEXs and processes.

This paper aims to develop a mathematical model for simultaneous MHEXs and processes optimization. Discontinuous *max* function and nonlinear approximation of MHEX are circumvented by multi-M method (Hui, 2014) to reduce the nonconvexity and number of binary variables of the model. The resulting optimization problem is formulated as an MINLP model, which simultaneously maximizes heat recovery of the MHEXs and minimize operating cost of the process. The model subjects to the constraints of energy balance, constraints to enforce temperature difference of heat transfer in MHEXs, and constraints of the other unit operations and thermodynamics. We apply the proposed model to an industrial air separation process with multiple MHEXs to demonstrate its effectiveness.

2. Mathematical model

This section presents a framework for simultaneous MHEXs and process optimization. The framework includes heat recovery of MHEXs, thermodynamics, and other unit operations. The proposed model is formulated as an MINLP due to the bilinear function of process streams' enthalpy calculation and discrete nature of the multi-M formulation that handles the *max* functions.

Heat recovery in an MHEX can be considered as heat integration of multiple process streams without hot and cold utility. Therefore, the concept of Pinch analysis is applicable to the modeling of MHEXs. Moreover, the simultaneous MHEXs and process optimization requires modeling methods that are able to handle variable stream data. To achieve simultaneous optimization, we propose a method adapted from Hui's (2014) multi-M formulation to model the MHEXs. The model assumes counter-current of hot and cold streams at the MHEXs. Additionally, the heat capacity of a stream is assumed temperature independent in liquid phase, vapor phase, and phase change. The stream data (e.g. inlet/outlet temperatures and flow rates) can be varied or fixed. The model is formulated as follows.

$$\max \varphi(x) = \sum_{i \in H} CP_{i,e} \cdot f_{i,e}(t_{i,e}^{in} - t_{i,e}^{out}) \quad (1)$$

$$\min \psi(x) = \sum_{n \in N} cost_n \quad (2)$$

s.t.

$$\sum_{i \in H} CP_{i,e} \cdot f_{i,e}(t_{i,e}^{in} - t_{i,e}^{out}) = \sum_{i \in C} CP_{i,e} \cdot f_{i,e}(t_{i,e}^{out} - t_{i,e}^{in}) \quad e \in E \quad (3)$$

$$qsoa_{j,e} \geq qsia_{j,e} \quad j \in I, e \in E \quad (4)$$

$$qsoa_{j,e} = \sum_{i \in H} CP_{i,e} \cdot f_{i,e} (tp_{i,j,e}^{in} - tp_{i,j,e}^{out}) \quad j \in I, e \in E \quad (5)$$

$$qsia_{j,e} = \sum_{i \in C} CP_{i,e} \cdot f_{i,e} (tp_{i,j,e}^{out} - tp_{i,j,e}^{in}) \quad j \in I, e \in E \quad (6)$$

$$tp_{i,j,e}^{in} \leq t_{i,e}^{in} + M1_{i,j,e}^{in} (1 - y_{i,j,e}^{in}) \quad i \in I, j \in I, e \in E \quad (7)$$

$$t_{i,e}^{in} \leq tp_{i,j,e}^{in} \quad i \in I, j \in I, e \in IE \quad (8)$$

$$tp_{i,j,e}^{out} \geq t_{j,e}^p \quad i \in H, j \in I, e \in E \quad (14)$$

$$tp_{i,j,e}^{out} \geq t_{j,e}^p - \Delta T_e^{min} \quad i \in C, j \in I, e \in E \quad (15)$$

$$t_{j,e}^p = t_{i,e}^{in} \quad i \in H, j \in I, e \in E \quad (16)$$

$$t_{j,e}^p - \Delta T_e^{min} = t_{i,e}^{in} \quad i \in C, j \in I, e \in E \quad (17)$$

$$g(x, w) = 0 \quad (18)$$

$$h(x, w) \leq 0 \quad (19)$$

Here H and C respectively are the sets of hot and cold process streams. I is a set of process streams ($I = H \cup C$). E is a set of MHEXs. $f_{i,e}$, $CP_{i,e}$, $t_{i,e}^{in}$ and $t_{i,e}^{out}$ denote molar flow rate, heat capacity, inlet temperature, and outlet temperature of process streams, respectively. $tp_{i,j,e}^{in}$ and $tp_{i,j,e}^{out}$ respectively are pseudo inlet and outlet temperatures of stream i at MHEX e regarding pinch candidate j . $qsoa_{j,e}$ is enthalpy of hot streams above pinch candidate j , and $qsia_{j,e}$ is enthalpy of cold streams above pinch candidate j . $t_{j,e}^p$ is pinch candidate. $y_{i,j,e}^{in}$ is binary variables to determine the values of pseudo inlet temperatures. $M1_{i,j,e}^{in}$ and $M2_{i,j,e}^{in}$ are big-M parameters. ΔT_e^{min} is the minimum temperature difference for heat recovery.

Eq. (1) is the objective function to maximize overall heat recovery of MHEXs. Eq. (2) is the objective function to minimize operating cost of process. Eq. (2) represents energy balance of MHEXs, in which heat recovery obeys the conservation of energy. Eqs. (3)-(16) guarantee feasible heat transfer between hot and cold streams with temperature differences greater than or equal to ΔT_e^{min} . Eq. (3) ensures heat surplus above all pinch candidates. Eqs. (4) and (5) calculate the enthalpy of hot and cold streams above $t_{j,e}^p$ using the pseudo temperatures, which are determined by the multi-M constraints (Eqs. (6)-(14)). Eqs. (15) and (16) calculate pinch candidate $t_{j,e}^p$. Eqs. (17) and (18) represent the constraints of thermodynamics and unit operations (e.g. compressors and valves).

To illustrate the multi-M formulation, we take the calculation of pseudo temperatures of hot streams (Eqs. (6)-(9), (12) and (13)) for instance. Pseudo inlet temperature $tp_{i,j,e}^{in}$ is computed by Eqs. (6)-(9). If $t_{i,e}^{in} \geq t_{j,e}^p$, $y_{i,j,e}^{in}$ must be equal to 1, and hence Eq. (6) is reduced to $tp_{i,j,e}^{in} \leq t_{i,e}^{in}$, and Eq. (8) is relaxed into $tp_{i,j,e}^{in} \leq t_{i,e}^{in} + M1_{i,j,e}^{in}$. Together with Eq. (7), there is $tp_{i,j,e}^{in} = t_{i,e}^{in}$. Similarly, for $t_{i,e}^{in} \leq t_{j,e}^p$, we have $tp_{i,j,e}^{in} = t_{j,e}^p$. Pseudo outlet temperature $tp_{i,j,e}^{out}$ can be calculated via Eqs. (12) and (13) without using binary

variable. These constraints ensure the hot streams' enthalpy above $t_{j,e}^p$ is not overestimated. Different from previous methods, the multi-M formulation avoids nonlinear formulation and reduces the number of binary variables that improve solution efficiency of the model.

3. Case study

The proposed modeling framework is applied to an ASU process to demonstrate its performance. Figure 1 shows a simplified flowsheet of the MHEXs in an industrial ASU. The process involves 2 MHEXs, 3 hot streams, 4 cold streams, 2 water coolers, 2 air compressors, 1 expansion turbine, and 1 expansion valve. Cooling of the ASU is delivered by the compressors, and is recovered by the MHEXs. The thermodynamics of the process is modeled based on Soave-Redlich-Kwang (SRK) method (Soave, 1972). Streams' data of the ASU process are listed in Table 1. The composition of the process streams are presented in Table 2. The operating conditions of the equipment are specified in Table 3. The minimum temperature difference ΔT_e^{min} is equal to 3 K. In this example, the major variables are the flow rate and outlet temperatures of the process streams. The model is implemented on GAMS 27.4 and is solved by BARON.

Table 4 shows the optimal solutions of the example. 2 points of interest, namely the maximum heat recovery solution and minimum operating cost solution, are presented. The results suggest that increasing outlet temperature and flow rate of H2 can increase heat recovery. However, the increase flow rate of H2 results in greater energy consumption of the compressors, which leads to higher operating cost.

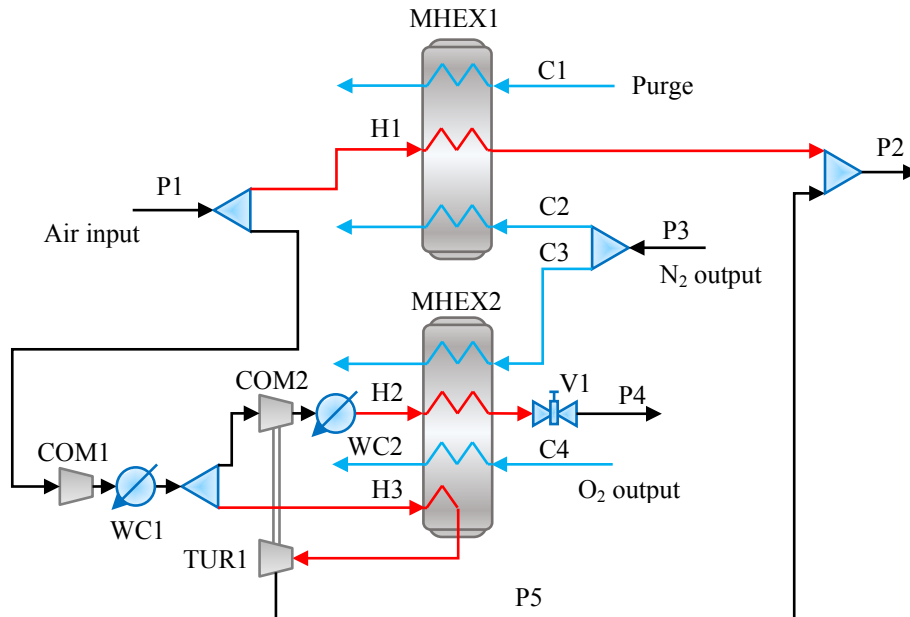

Figure 1 Simplified MHEXs of an industrial ASU.

Table 1 Data of process streams.

Stream	t_i^{in} (K)	t_i^{out} (K)	f_i (mol/s)	cp_i (J/mol·K)	p_i (kPa)
H1 (g-m)	284.2	98.15-102.2	≤ 800.0	-	610.0

C3 outlet temperature (K)	310.1	298.5
C4 outlet temperature (K)	310.1	298.5

4. Conclusions

This paper proposed a modeling framework for simultaneous MHEXs and process optimization. The framework applied the multi-M formulation (Hui, 2014) to model MHEXs that allowed variable stream data, avoided nonlinear approximation, and reduced the number of binary variables to achieve higher solution efficiency. Rigorous thermodynamics method can be integrated into the framework so that it is applicable to various process design problems. A realistic ASU design problem with multiple MHEXs was investigated using the proposed framework. The computational results demonstrated that the framework is able to solve complex process optimization problem. Ultimately the model will be extended to the entire ASU flowsheet including the separation process, which enables the analysis of the trade-offs between energy consumption, product purity, heat recovery, and investment of ASU process.

Abstract

Population Balance Equation is extended to model microalgae harvesting processes, such as centrifugation and sedimentation, to provide an accurate prediction of cell recovery rates. By analyzing changes in cell size distributions, the model can effectively examine how harvesting efficiencies would affect or be influenced by cell characteristics, such as size and density. Cell behaviors at different size ranges in the dewatering methods are studied to evaluate their variations with harvesting time as well as recovery rate for process optimization. Experiments of sedimentation and centrifugation on a microalgae species called *Chlorella* are carried out to validate the model. With measurements of optical densities and size distributions of the cell cultures, size specific densities of microalgae are derived to further improve the mathematical model.

Keywords: Microalgae harvesting, Cell characteristics, Population Balance Equation

1. Introduction

Microalgae, a fast-growing photosynthetic microorganism with high lipid content, is a promising bio-resource of biofuel. Production steps of microalgae for biofuel mainly include cultivation, harvesting and oil extraction, in which harvesting is regarded as a bottleneck accounting for around 20-30 % of the costs due to the dilute culture of microalgae, small cell size and similar density with water (Danquah et al., 2009). Therefore, optimizing the harvesting efficiency is essential to the development of the production process into an industrial scale. Extensive research efforts have been dedicated to evaluate efficiencies of various harvesting methods such as centrifugation and sedimentation from an experimental approach for maximizing the recovery. Nevertheless, not many modeling works of the processes have been performed and very few concerns have been raised towards the interrelationship between cell recovery rates and cell characteristics, such as size and density (Shelef et al., 1984). Stokes Law has been suggested to apply to govern settling behaviors of microalgae in both sedimentation and centrifugation by relating settling velocities of the processes to cell diameters and densities (Al hattab et al., 2015), but more individual cell characteristics should be taken into considerations for improving accuracies of the predicted results.

This study applies Population Balance Equation (PBE) to simulate the microalgae harvesting process. PBE has been commonly employed to characterize evolutions of particle populations in chemical processes, such as polymerization reaction, mixing and

crystallization. Some studies used PBE for modelling of bacteria (Ramkrishna, 2000) or microalgae growth (Pahija et al., 2017). A few applied PBE to modeling separation processes (Grimes, 2012) such as microalgae pre-concentration or harvesting (Sirin 2013). Sirin's work in PBE was limited for flocculation process to estimate the sedimentation rate and floc size distribution. In the following sections, PBE is applied to modeling sedimentation and centrifugation processes for microalgae harvesting.

2. Methodology

A Population Balance Equation (PBE) model is developed to characterize centrifugation and sedimentation of microalgae. The aim of the model is to find out size dependent recovery and selectivity of these two methods at different operating conditions such as operating time, rotation speed, etc. Experimental data is used to verify the model.

2.1. Population Balance Equation model

A simplified form of PBE (Randolph and Larson, 1988) for describing evolutions of particle growth commonly includes two terms as follow:

$$\frac{\partial n(t, d)}{\partial t} + \frac{\partial [G \cdot n(t, d)]}{\partial d} = 0 \quad (1)$$

The two terms on the left side of the equation represent the change in particle number densities with time and size respectively, in which n is number density, t is time and G is growth rate of particles. For the centrifugation and sedimentation of microalgae, the growth of cells is neglected. Instead, the variation of number density was caused by the size and density differences of the cells. The modified PBE equation becomes the follow:

$$\frac{\partial n(t, h, d)}{\partial t} = \frac{\partial [v(t, h, d) \cdot n(t, h, d)]}{\partial h} \quad (2)$$

where $v(t, h, d)$ is the cell travelling velocity and h is the distance travelled.

It is assumed that the cells reach their terminal velocities within a negligible time, so the $v(t, h, d)$ becomes $v(d)$ that depends only on cell size. Using discretization method to solve equation (2) would give the following equation, in which N denotes the number of cells.

$$N(t + 1, h, d) = N(t, h, d) + v(d) \frac{\Delta t}{\Delta h} [n(t, h - 1, d) - n(t, h, d)] \quad (3)$$

Centrifugation and sedimentation of particles in fluid has been modelled commonly by Stokes Law (Lamb, 1945). It is applicable to systems with dilute suspensions, homogeneous fluid, spherical particles and low Reynolds number (<1), which are fulfilled by the microalgae culture. Equation (4) and (5) are employed for centrifugation and sedimentation respectively to calculate the corresponding cell terminal velocities.

$$v_{t,c} = \frac{(\rho_p - \rho_f)r\omega^2d^2}{18\eta} \quad (4)$$

$$v_{t,s} = \frac{(\rho_p - \rho_f)gd^2}{18\eta} \quad (5)$$

which $v_{t,c}$ and $v_{t,s}$ are terminal velocities of the cells in centrifugation and sedimentation respectively, ρ_p and ρ_f are cell density and fluid density respectively, d is cell diameter, η is fluid viscosity, r is centrifuge radius, ω is centrifuge rotational speed and g is gravity.

In addition, Langevin Equation (Langevin, 1908) describing Brownian motion is employed to govern thermal vibrations of the cells in the fluid. The motion is particularly significant in small cells since the velocity is inversely proportional to cell diameter as illustrated in equation (6).

$$v_B = \sqrt{\frac{4kT}{3\pi\eta d}} \quad (6)$$

which v_B is the velocity of cells induced by Brownian motion and k is Boltzmann constant with the value of $1.38 \times 10^{-23} \text{ m}^2 \text{ kg s}^{-2} \text{ K}^{-1}$, while T (temperature) is assumed to be 298 K. The cell travelling velocity $v(d)$ in equation (3) is denoted by summing up equation (4) and (6) for centrifugation and summing up equation (5) and (6) for sedimentation.

The impacts of concentration effect and wall effect have been investigated and are found to be negligible due to the dilute cell culture and the small cell size to tube diameter ratio.

2.2. Experiments

Experiments of centrifugation and sedimentation are performed in 15ml centrifuge tubes with a diameter of 17 mm and a height 120 mm. For centrifugation, a centrifuge (Hettich EBA 20) with a radius of 0.044m and the rotational speed of 500 rpm is used. Forces added to the vertically tilted tubes are dominantly in horizontal directions and cells travelling beyond half of the tube diameter (8.5 mm) are considered captured. Cells mainly stick on one side of the wall which is farther away from the center after centrifugation and samples are taken in the middle of the other half of the tube at 1, 2, 3 and 4 minutes. For sedimentation, forces are mainly in vertical directions and cells travelling beyond half of the tube height (60 mm) are considered captured. Samples are taken in the middle of the upper part of the tube at 3, 10, 35, 55, 75, 120, 180 and 270 minutes. In every sampling, electronic pipettes are used to take 1.5 mL solution for optical density (OD) measurement by a photospectrometer and 10 μL solution for size distribution analysis using a microscope and computer software. A calibration curve relating OD and cell concentrations are experimentally obtained prior to the harvesting experiments. The gravity, fluid density and viscosity are assumed to be 9.81 ms^{-2} , 1000 kg m^{-3} and 0.00089 Pas respectively for calculations.

3. Result and Discussion

Numerical simulations of the developed PBE model are performed to predict number densities of the microalgae harvested after centrifugation and sedimentation. Figure 1a and 1b show the experimental data and simulation results of centrifugation and sedimentation respectively.

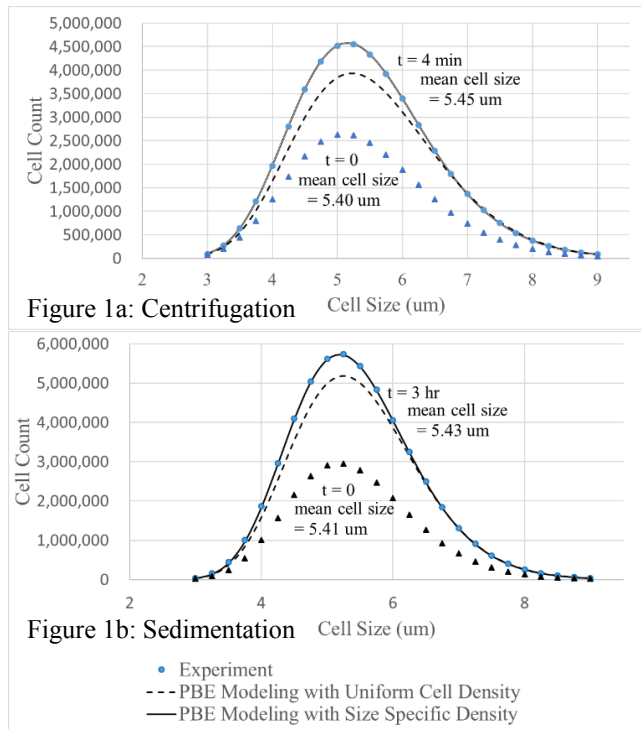

Figure 1. Experimental data and simulation results with uniform and size specific densities

The dash lines in the graph are the simulated results by assuming uniform cell densities ($1,070 \text{ kgm}^{-3}$) over different sizes, which the value is obtained from literature (Bonner, 1985). However, it is observed that the error with this assumption is significant as denoted in the figure. Therefore, the relationship between cell density and size is revised by analysing the data collected in the experiments. By evaluating the optical densities and size distributions of the centrifugation samples, the number of captured cells in each size is known. The sets of data are fitted into the PBE model and by allowing the travelling velocity $v(d)$ in equation (3) to vary, the velocity of each size of the cells is obtained. Finally, with equation (4) and (6), the size specific densities of cells can be calculated by plugging in the corresponding cell size and velocity.

The change in cell density with size is shown in Figure 2. The mean cell density is $1,110 \text{ kgm}^{-3}$ with a density range between $1,044$ to $1,137 \text{ kgm}^{-3}$, which is close to the literature value of $1,070 \text{ kgm}^{-3}$. The densities first increase with size and then decrease after the cells grow to a larger size of approximately 3.75 um . This observation perfectly aligns with the dark and light cycle of microalgae (Tamiya et al., 1953). First born cells,

also called nascent dark cells, consist of materials similar to those of their mother cells, which are composed of a higher portion of lipids with low densities. Along their growth to the next stage of active dark cells, fundamental cell materials are developed at the main priority so the cell densities rise. When the cells are mature and enter the stage of light cells, additional nutrients would be converted to lipids as an energy storage, resulting in the trend of varying cell densities throughout the life cycles.

Conventional methods to obtain algal densities mainly involve measurements of cell size and dry mass of the whole algal culture for calculating the average density value (Hu, 2014). However, it is too complicated to be possible to attain a full spectrum of cell densities varying with size accurately. This new approach to study the size specific behaviours of cells during harvesting can derive the relationship between cell density and size. Not only can it provide better understandings of cell characteristics as well as the growth kinetics, but also it can be performed without destroying the cells since drying is not required.

Figure 2. Size Specific Densities of Chlorella Cells

After substituting the derived size specific densities into the PBE model, as shown in Figure 1, the numerical solutions of both centrifugation and sedimentation converge on experimental results. This validates the accuracy and stability of the proposed model. After both harvesting methods, peaks of the cell size distributions shift to the right, representing that larger cells are generally more favorable as expected. This is because travelling velocities of cells in Stokes' Equation are proportional to the square of cell diameters, while in Langevin Equation, the velocities are inversely proportional to the square root of the diameters, which slightly hinders the shifts of the peaks to the right. On the other hand, the variations in size specific cell densities also affect the obtained size distributions since densities are directly proportional to terminal velocities of the cells.

4. Conclusion

Population Balance Equation is modified to model microalgae harvesting processes of centrifugation and sedimentation. Experimental data of the two methods is analysed by using a size specific approach and is combined with the mathematical model to predict harvesting efficiencies of the cells at different sizes. By studying optical densities and size distributions of the cells harvested after the experiments, a full spectrum of size specific densities is obtained with a range from 1,044 to 1,137 kgm^{-3} . It is found that the cell density first increase with cell size at the early stage until the size becomes around 3.75 μm and then decrease afterwards due to variations in cell compositions throughout

the life cycle. On the other hand, the numerical solutions obtained from the developed PBE model are validated by the experimental results, proving that it can efficiently generate stable and accurate solutions to characterise changes in number densities of microalgae at each size after harvesting. In this case, the harvesting efficiencies can be well predicted in relation to cell characteristics together with operation parameters of centrifugation and sedimentation.

Abstract

The aim of this study is to optimise the structural design of a central utility system for a Local Integrated Energy Sector, considering its environmental performance, such that Total Annual Cost is minimised. Environmental performance is captured by Greenhouse Gas emissions, Water, and Particulate Matter (PM) Footprints. To obtain the minimum cost solution, a Utility Systems Planner (USP) tool has been developed within the P-graph framework using a superstructure. The USP is applied to a case study with a chemical processing site and district energy demands. With the historically lower than average coal prices, the optimisation favours a utility system based on a coal boiler (68.4 MW) supplemented by geothermal clean energy plant (3 MW) to satisfy the 53 MW of process heat. Increasing the GHG emissions price from 5 €/t to 20 €/t shifts the optimisation in favour of natural gas as the primary fuel. Further increases in GHG prices to 95 €/t changes the optimal solution to biomass as the fuel with geothermal heat. Solitary focus on GHG emissions and its price, however, overlooks the immediate environmental impact of PM. Policy constraints on PM emissions to be at a safe level reverts the optimal solution to use natural gas as the fuel.

Keywords: Total Site; Process Integration; P-graph; Energy Planning.

1. Introduction

Growing global concern for pollution and irreversible environmental damage continues to drive governments and policymakers to implement incentives for clean and efficient energy supply. Reducing resource consumption through Locally Integrated Energy Sectors - LIES (Perry et al., 2008) and Total Site Heat Integration - TSHI (Klemeš et al., 1997) in addition to clean energy conversion technologies are meaningful ways to minimise harmful pollutants and conserve limited resources. Footprints metrics (Čuček et al., 2012) can help to capture the full environmental performance of an energy system. Quantifying the environmental footprints and intensities for a system represents a step forward (Ren et al., 2017), with the next step to influence industrial practice by identifying positive changes to typical technology selection, design, integration, and/or operation. For processing sites, the design and operation of the central utility system play a key role in achieving environmental performance goals.

There are three groups of studies that relate to the subject of the current paper. First, many recent studies have focused waste heat utilisation and utility systems optimisation without explicit consideration for environmental performance. For example, Oluleye et al. (2016) evaluated a range of waste heat utilisation technologies for industrial sites to increase overall energy efficiency. Second, studies have considered quantifying and comparing the environmental performance of a utility system to show the benefit of one technology over another. For example, Kelly et al. (2014) quantified the environmental performance of Combined Heat and Power (CHP) to demonstrate its important role in reducing electricity grid GHG emissions in the UK. Third, studies have focused on the design and optimisation of conventional central utility system, which consists of boilers and steam and gas turbine networks. For example, Luo et al. (2014) applied a multi-objective optimisation to determine a low-emissions utility system consisting of boilers, gas turbines, steam turbines, condensers, and let down valves, as well as emissions abatement technologies, with both coal and natural gas as the fuels. In general, these three areas of related research have lacked robust connections between the technology selection, optimisation, and integration of a site's central utility system and its environmental performance. The range of considered fuels and renewable energy sources, technologies, and environmental impacts have also been narrow. Addressing these gaps in literature is the focus of the study.

The aim of this study is to optimise the structural design of a Total Site (or LIES) central utility system, which cogenerates heating, cooling and power, considering its environmental performance such that Total Annual Cost is minimised. The study extends the work of Walmsley et al. (2018) that introduced a new Utility Systems Planner (USP) tool built as a P-graph superstructure (Friedler et al., 1996), to include estimations and pricing of three environmental footprints: Greenhouse Gas, Water, and Particulate Matter Footprints. The novelty of this work is derived from the comprehensive nature of the utility system superstructure in combination with accounting for environmental performance. Three scenarios are investigated using different environmental prices and constraints and, for each scenario, the USP superstructure is solved for minimum cost. A case study is presented to illustrate the new tool and its application.

2. Environmental Footprints

Utility systems are significant consumers of water and energy resources. In this study, environmental footprints related to these consumptions and emissions are incorporated into the optimisation of the utility system. Water Footprint (WF), initiated by Hoekstra and Huang (2002), has been well developed to quantify the amount of direct and indirect water use of a process, product or region. GHG Footprint (GHGF) is the total amount of GHG released from an operation (Čuček et al., 2012), expressed in the equivalent t of CO₂. A comprehensive estimation of WF and GHGF normally includes direct emissions from fuels and indirect emissions of fuel and material inputs. In studying a CHP system, Ren et al. (2018) found that >99.9 % of WF and GHGF was derived from emissions directly or indirectly relating to fuel consumption. As a result, this study approximates these footprints by only accounting for fuel-related emissions. Particulate Matter (PM) footprint measures the specific mass flow rate of particulates from direct and indirect fuel combustion (Yang et al., 2017). In this study, the PM Footprint (PMF) is defined by the PM10 criterion.

3. Utility System Planner

The USP superstructure, shown in Figure 1, contains a comprehensive range of fuels and resources as inputs to the central utility system, including Electricity, Biomass, Coal, Natural Gas (NG), Geothermal Heat, and Water. It also incorporates estimates for direct and indirect environmental footprints for GHG, PM10, and water. These are placed at the top of the superstructure. Below the fuels/resources are the energy conversion technologies, including Electric Boiler, Biomass Boiler, Coal Boiler, NG Boiler, NG Combined Cycle Gas Turbine (CCGT), NG Reciprocating Gas Engine (GE), Geothermal Clean Steam station, Thermal Vapour Recompression (TVR), Mechanical Vapour Recompression (MVR), Organic Rankine Cycle (ORC), Heat Pump (HP), Absorption Chiller (ACH), Electric Chiller (EC), Steam Turbine Stages (STS), and Let-down Valves (LV). These operations generate 9 intermediates utility levels. Varying shades of red through to orange for the lines and nodes indicate the hot utility levels from electricity through to hot water. Cold utility and water are indicated by lines with blue shades. These utilities then satisfy the energy demands of the industrial site and district heating and cooling.

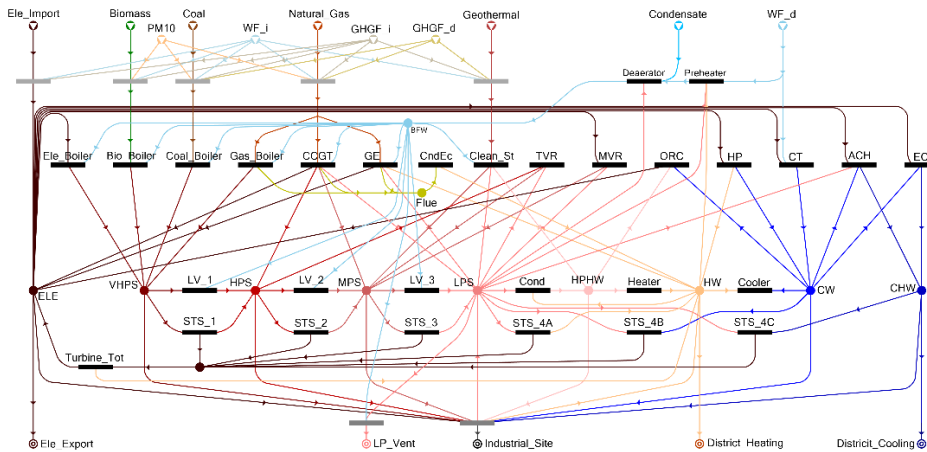

Figure 1: Utility Systems Planner tools – initial superstructure.

4. Method

The method to consider environmental performance in the USP involved three steps:

1) Estimate direct and indirect Emissions Factors (EF) for Greenhouse Gas, Water, and Particulate Matter (PM10). The estimation of each footprint is based on a coefficient approach, which can estimate the footprint of each fuel and resource input using Eq. (1).

$$F = F_d + F_i = \sum_{j=1}^n (\dot{m}_j \times EF_j)_d + \sum_{k=1}^n (\dot{m}_k \times EF_k)_i \quad (1)$$

Where F is the considered environmental footprint, EF is the emission factor for the considered impact, \dot{m} is the flow rate of the fuel, resource or material, subscripts d and i represent direct and indirect quantities.

2) Solve the USP superstructure to find the cost-optimal solution. The objective function of the USP is minimum Total Annual Cost (TAC), Eq. (2), i.e. the sum of utility cost (UC), annualized capital cost (CC), and operating and maintenance (OM).

$$TAC = UC + CC + OM \quad (2)$$

3) Project and input GHG emissions price increases to test various scenarios and constraints using the USP tool by finding the minimum cost solutions.

5. Locally Integrated Energy Sector case study

The considered LIES encompasses a representative industrial chemical processing site and the heating and cooling needs of the surrounding district. Figure 2 presents the Site Utility Grand Composite Curves for the industrial site and the entire LIES. The industrial site has a utility system Pinch between the MPS and LPS levels, which extends to between the MPS and CW levels once the district demands are included.

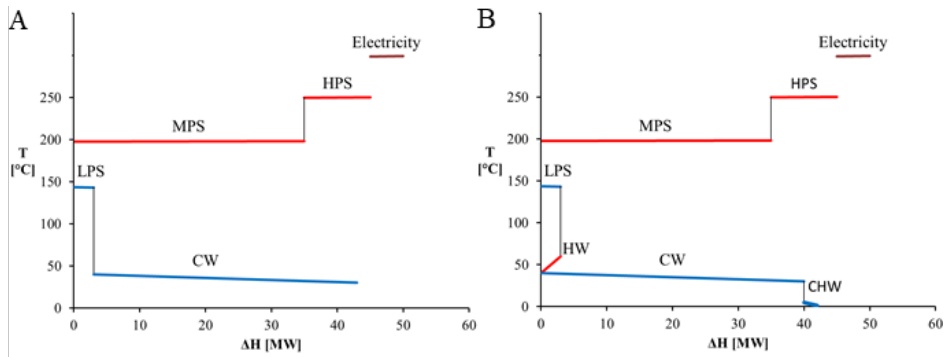

Figure 2: Site Utility Grand Composite Curves for the industrial site (A) and LIES (B).

Table 1 presents the energy prices and emissions factors for GHG and PM10 as well as water use rates (Gerbens-Leenes et al., 2008). For details on performance ratios of each energy conversion process, refer to the previous study by Walmsley et al. (2018).

Table 1: Initial industrial energy prices and GHG, PM10, and water emissions factors.

	Electricity	Biomass	Coal	NG	Geothermal
Price (€/GJ)	22.3	8.0	5.0	7.0	3.0
GHG Direct (kg/GJ)			91.4	55.2	1.3
GHG Indirect (kg/GJ)	77.6	0.8	0.4	5.5	0.2
Water Indirect (t/GJ)	6.8	70	0.2	0.1	0.5
PM10 Direct (g/GJ)		50	45	<0.1	

5.1. Scenario 1: Current energy and GHG emissions prices

The first scenario looked at the optimal solution based on present energy (Table 1) and GHG emissions prices (5 €/t). The energy prices are estimates based on Eurostat (2017). For these inputs, the USP consumes 68.4 MW_f of coal and 3 MW_f of geothermal heat. A two-stage steam turbine from VHPS to HPS and MPS (6.1 MW_{el}) means the self-sufficient in terms of electricity demand. This solution differs from Walmsley et al. (2018) due to the extension of the USP to include coal as a fuel option.

5.2. Scenario 2: Increasing GHG emissions price

The second scenario investigated the impact of varying the GHG emissions price from 5 €/t to 100 €/t (using 5 €/t increments) on the optimal USP solution with a focus on the fuel selection as shown in Figure 3. The GHG price increase was applied in the USP model to both direct (on-site) and indirect (off-site) GHG emissions. Conventionally, the emitter pays the cost of GHG emissions but then passes the cost on to the buyer, i.e. the utility operator. This means if the GHG price increases, the anticipated price of delivered fuels to a site will also increase to account for upstream GHG emissions cost.

Figure 3 shows that as the GHG emissions price increases from 5 €/t to 10 €/t, the amount of coal use slightly declined and replaced by geothermal. Once the price reached 15 €/t, the optimal solution comprised a coal boiler (60 MW_f), NG boiler (3 MW_f), and geothermal clean steam plant (10 MW_f) with the addition of an ORC unit (0.2 MW_{el}) to fully utilise the increased low-grade heat from geothermal. With the price between 20 €/t to 90 €/t, the solution changes to primarily use NG (56.9 MW_f) complemented by geothermal heat (10 MW_f) as well as electricity grid imports (0.3 MW_{el}). Once the price reaches 95 €/t the solutions changes to biomass (78.2 MW_f) with geothermal heat (10 MW_f) and grid electricity (0.3 MW_{el}).

Figure 3: Impact of GHG emissions price on the optimal fuel selection.

5.3. Scenario 3: PM10 constraint

Sole focus on the present is likely to mean an industrial site will use coal as the primary energy source since it's the lowest cost option. The GHG price must quadruple before NG becomes the economically favoured option and may happen in the long-term future. Coal, however, has an immediate environmental impact – PM emissions (11.1 kg/h in the original solution). PM is a significant cause of haze as well as respiratory health issues. Using local regulations, a PM emissions constraint may be placed on the system design. If the PM10 rate was limited to <0.01 kg/h, NG is the lowest cost solution.

6. Conclusions

Environmental performance during the cost-optimisation of a central utility system has been quantified using Greenhouse Gas (GHG), Water, and Particulate Matter (PM) Footprints with the recently developed Utility Systems Planner (USP) tool. For the case study, current energy and emissions prices led to the cost-optimal solution of using coal

as the primary energy source. Significant price changes are needed to shift the cost-optimal solution away from coal. For example, the GHG price must quadruple before Natural Gas (NG) becomes the cost-optimal solution. However, excessive particulate emissions from coal and other solid fuels have proven to cause serious health issues. Placing a constraint on PM emissions shifts the cost-optimal solution to choose NG. Future work will look at the impact of water price on the USP optimisation.

Abstract

The industrial sector will have to undergo major changes in order to reduce its emissions with the goal of climate change mitigation. In this context, the iron and steel subsector accounts for the highest CO₂ emissions share. This work uses a simulation model of the global energy system and quantifies the impacts of different measures for CO₂ reduction (such as fuel switching, electrification and Carbon Capture and Storage - CCS) on investment and operation decisions. The reported scenarios consider the implementation of a CO₂ price as a policy instrument to decarbonise the industrial sector. The selected case study covers steel production in the USA up to the year 2050. The results show that single measures such as fuel switching, electrification and CCS adoption alone have a limited impact on the decarbonisation of the iron and steel sector and should be rather implemented all together in an integrated approach towards climate change mitigation.

Keywords: energy, emissions, steel, CCS, integrated assessment model

1. Introduction

The global industrial sector is characterised by high Total Final Energy Consumption (TFEC) (36 % of the global TFEC in 2014) and high CO₂ emissions (24 % of the total global CO₂ emissions) (IEA, 2017). Consequently, decarbonisation of this sector plays a crucial role in order to meet ambitious climate targets. A broad set of measures, including electrification (assuming an increasingly decarbonised power supply), fuel switching and CCS, is required to decarbonise this sector (IPCC, 2014).

This work is motivated by investigating the potential of increased electrification in the iron and steel subsector. The reasons for this are twofold. Firstly, among the five most energy-intensive industrial subsectors, the biggest increase of electricity-proportion from TFEC in ambitious climate scenarios is assumed for iron and steel (from 12 % in 2014 to 25 % in 2060 in the 2 °C scenario) (IEA, 2017). Secondly, steel making is the industrial subsector with the highest overall CO₂ emissions (28 % of the global industrial CO₂ emissions) (IEA, 2017). While electrification is even more likely to happen in non-energy-intensive subsectors, these subsectors do not account for large shares of CO₂

emissions (IEA, 2017). Therefore, iron and steel has the highest potential for overall CO₂ emission mitigation by increased electrification. This paper goes beyond the investigation of electrification's potential. Further, it aims to examine the potentials for fuel switching and CCS penetration as suitable options for decarbonisation pathways in the iron and steel subsector. In order to explore these potentials, the Industrial Sector Module (ISM) of the MUSE model (ModUlar energy system Simulation Environment) was used.

The World Steel Association (Worldsteel, 2016) has reported that 98 % of the globally mined iron ore is used as primary input for steel making and that global crude steel production has reached 1,670 Mt in 2014. Primary production technologies for crude steel are Blast Furnace-Basic Oxygen Furnace (BF-BOF), Direct Reduced Iron-Electric Arc Furnace (DRI-EAF) and Smelt Reduction-BOF (SR-BOF). Recycled steel (scrap) allows to produce secondary steel by means of the scrap-EAF technology (IEA-ETSAP, 2010).

2. Methodology

2.1. Integrated Assessment Models (IAMs)

IAMs are global models of the energy system, which quantify production of material commodities, consumption of energy commodities and their corresponding impacts on climate change over time (IPCC, 2014). They mainly consider representations of climate, human systems (e.g. energy and economic system) and natural systems in order to produce pathways of energy and greenhouse gas emissions in return (IPCC, 2014).

2.2. The MUSE model

MUSE is a global IAM where demand, conversion and supply of energy interact according to the market equilibrium principles. The model has a modular structure where each specific energy sector is modelled using a bottom-up approach based on a detailed techno-economic characterisation of the technologies as well as of the key indicators, which determine the stakeholders' investments in that sector (Giarola et al., 2017).

In this paper, the focus will be on the ISM of MUSE. The ISM first simulates how the demand of industrial commodities might grow as well as how the existing stock might retire. A linear decommissioning profile is in place in order to represent the remaining lifetimes of existing plants in the base years (2010 and 2014).

The total capacity $C_{new\ plants, t}$ that must be installed in a period t includes the retired capacity ($C_{retired, t}$) and the increase of the demand (D_t) from the previous period divided over a facility utilization factor (UF)

$$C_{new\ plants, t} = C_{retired, t} + \frac{(D_t - D_{t-1})}{UF} \quad (1)$$

Then the ISM uses a merit-order approach to rank the available technologies and decide which technologies to bring online until the demand is met. In particular, in order to make investment decisions for new plants, investors' key metric is the Net Present Value (NPV):

$$NPV = \sum_{t=1}^T \frac{CF_t}{(1+r)^t} - CF_0 \quad (2)$$

where CF_t represents the net cash flow during time period t , CF_0 is the total initial investment cost and r is the interest rate (assumed to be 10 % in the model).

When a technology is available, the Discounted Cash Flow (DCF) is taken into account in order to decide which plants among the existing plants are operated for production:

$$DCF = \sum_{t=1}^T \frac{CF_t}{(1+r)^t} \quad (3)$$

The metrics are based on CAPEX (specific CAPital EXpenditures) and OPEX (specific fixed OPERational Expenditures, including CO₂ price), which are defined in the model for each technology. The major constraints for new capacity addition of each technology include annual maximum growth rate, annual maximum capacity addition and total maximum capacity in a region.

2.3. Relevant assumptions and data sources

The MUSE model has been calibrated for 2010 and 2014 in order to match the overall fuel and electricity consumption from the IEA (2016). Regional demand projections of single commodities are based on regressions of historical data for the past 25 years (UNSD, 2017). Emissions from electricity generation and international trade of material commodities were not included in the case study.

Specific Energy Consumption (SEC) for the iron and steel sector has been selected according to the recent literature (IEA, 2017; Morfeldt et al., 2015; van Ruijven et al., 2016). Prices for fuel and electricity have been selected according to IEA's (2014) 450 ppm scenario. CAPEX were averaged from the investment cost given by Morfeldt et al. (2015) and van Ruijven et al. (2016). OPEX were selected from Morfeldt et al. (2015). For plants with CCS, CAPEX and OPEX are in 2010 48 % (2030: 32 %) higher than for plants without CCS (IEA-ETSAP, 2010). CCS energy penalty was assumed to be 12 % (IEA-ETSAP, 2010). An utilization factor of 90 % was assumed for all plants.

3. Case Study

3.1. Steel making

In this paper, the selected case study covers the production of iron and steel in the USA up to the year 2050. Steel is mainly produced by the technologies BF-BOF, DRI-EAF and scrap-EAF. In ambitious climate scenarios, the SR-BOF technology is expected to penetrate the market in the future (IEA, 2017). While the primary steel technologies mainly use iron ore as raw material, the scrap-EAF technology is reliant on the availability of scrap to produce secondary steel. The energy consumption of the latter technology requires 6.7 GJ per ton of produced crude steel, which is about one third of the average energy intensity of the primary technologies (IEA, 2017). A wider adoption of the scrap-EAF technology has the potential to decrease the specific energy consumption of the sector and therefore its greenhouse gas emissions. However, the scrap-EAF technology is limited by scrap availability, which is expected to increase globally by 80 % until 2050 as steel is highly recyclable (Worldsteel, 2016). The BOF and EAF technologies have accounted for 73.7 % and 25.8 % of global steel production in 2014, respectively (Worldsteel, 2016).

According to Worldsteel (2016), 80 Mt of crude steel were produced in the USA in 2010. In comparison to the global average (29 % in 2010), in the USA a large share of steel is produced by EAF technologies (61 %) (Worldsteel, 2016). The TFEC in this sector in the USA was 706 PJ in 2010 (IEA, 2016). In the same year, the iron and steel sector in the USA was accounting for CO₂ emissions from fuel combustion of 49.1 Mt_{CO₂} (IEA, 2016).

3.2. Scenarios

Two scenarios were simulated to analyse the decarbonisation of the iron and steel sector in the USA. The first scenario (S1) does not include a CO₂ price, while the second scenario (S2) includes a moderate price on CO₂ emissions (averaged by Budinis et al. (2016) from '450 ppm full technology'-scenarios of selected IAMs in IPCC (2014)).

The maximum annual growth rate for the scrap-EAF technology was set to 1 %, based on expected development of scrap availability in the USA (Worldsteel, 2016). Growth rate for primary steel production technologies was set to 3 % in order to meet the projected steel demand while showing investments in a wider range of technology options.

4. Results and Discussion

Figure 1 shows the overall supply of steel by technology for S1 (left hand side) and S2 (right hand side). Both scenarios show an increasing share of the scrap-EAF technology (from 52 % to 58 % for S1 and to 61 % for S2). The remaining demand is met by BF-BOF and DRI-EAF technologies. In both scenarios, technologies with relatively high share of electricity consumption (i.e. both EAF technologies) increase their overall market share from 61 % up to 82 % (S1) and 79 % (S2). However, as the availability of scrap is a limiting factor, EAF technologies cannot penetrate the market even further.

Figure 2 is reporting fuel shares for the two scenarios. While coal, the cheapest but also the most CO₂ producing fuel, covers in 2050 62 % of the market in S1, it only covers 16 % of the market in S2, due to the implemented CO₂ price. In contrast, natural gas and electricity gain increasing market shares in S2. It should be considered that the TFEC in S1 increases between 2010 and 2050 by 69 %, while it increases in S2 only by 28 %.

Figure 1. Projections of steel supply by different process technologies in the USA between 2010 and 2050. (a) shows S1, (b) shows S2.

Figure 2. Fuel shares in USA's iron and steel sector in 2010 and in 2050 (S1 and S2). 'Others' include forest residues, heavy fuel oil, liquefied petroleum gas and naphtha.

Even though the share of EAF technologies increases in both scenarios, overall electrification is only found in S2. No overall electrification is found in S1, because more fuels (mainly coal) with a lower net calorific value than today will be used. This results in a higher demand of fuel per electricity and does therefore offset the increasing electrification from the growing share of EAF technologies.

Figure 3 reports the produced CO₂ emissions, disaggregated in CO₂ emitted to the atmosphere and CO₂ captured by CCS, for both scenarios. The results show that CO₂ emissions increase (+79% until 2050) when no CO₂ price is in place (S1). While total produced CO₂ emissions in S2 stay almost constant over time, an increasing share of these emissions will be captured and stored. The results show that the implementation of the CO₂ price results in 2050 in 30% of the steel produced by CCS technologies. As this happens to technologies with relatively high CO₂ emissions, up to 61% of the produced CO₂ is captured. This trend shows that the CO₂ price makes investors tend to invest into plants that provide CCS. However, the main barriers for CCS are political and societal issues, which were not taken into account within the model.

Emissions from electricity generation are not considered within this study (in 2010, specific CO₂ emissions were 0.52 kt_{CO2}/GWh, resulting in additional 23,500 kt_{CO2} for the iron and steel sector (EIA, 2012)). The electrification in S2 is consequently only an effective measure for decarbonisation when the power sector can generate sustainable and cost-effective electricity, by means of renewable sources and CCS. Overall, a CO₂ price is pushing the iron and steel sector towards less CO₂ producing technologies and fuels.

Figure 3. Produced CO₂ emissions (for S1 and S2) from the production of iron and steel in the USA, disaggregated in CO₂ emitted to the atmosphere and CO₂ captured by CCS.

5. Conclusion

This work has shown the penetration of different technologies into the market, with and without CO₂ price, in order to analyse potentials for fuel switching, electrification and CCS to decarbonise the industrial sector with focus on iron and steel in the USA.

The results have demonstrated that the assumed CO₂ price pushes investors towards less emitting fuels. Moreover, with and without CO₂ price, electrification takes place by means of EAF technologies' adoption. However, without CO₂ price this effect will be offset due to use of fuels with low net calorific value. Finally, the price for CO₂ emissions leads investors to invest in CCS plants, especially for CO₂ intensive technologies.

Each of the three measures has limited impact on the decarbonisation of the iron and steel sector, therefore they should be implemented all together in an integrated approach towards climate change mitigation. While CCS could be limited by political and societal factors that were not taken into account by the model, electrification by means of a shift to EAF technologies is limited by scrap availability. Therefore, the scrap recycling rate should be maximised. Other measures, such as energy and material efficiency, should also be implemented in order to reach ambitious climate goals.

Abstract

Polyphenol's extraction from grape marc (GM) represents an interesting alternative for valorisation of an industrial waste, with an important economic and environmental impact. Solid-liquid extraction is improved by using higher quantities of solvent, but this generates a much more energy intensive process for solvent evaporation in later stages. The objective of this study was to find the optimal operational conditions in a polyphenol's extraction process from GM, aiming to reach the maximum economical profit for the system. It is considered a multistage batch solid-liquid extraction system using fresh solvent (ethanol-water mixture) in each stage. A MINLP structure is proposed for the optimization with the following decision variables: the number of stages, the solvent/GM mass ratios and temperatures for each stage. The difference between the income from product sales (powder extract rich in polyphenols) and the operational costs (basically related with energy consumption) was maximized. The MINLP was solved using DICOPT solver in GAMS, and also employing a genetic algorithm in Matlab. In both cases identical results were obtained, with low computational costs, indicating that non-convexities would be negligible. The obtained results show that for optimum solvent use three contact stages must be realized, and the solvent/GM mass ratio and temperature for all stages must be the same adding 4 liters of solvent at 80 °C per GM kilogram. In these conditions the objective function reaches a value of 3.12 dollars per GM kilogram.

Keywords: Grape marc, Polyphenols, Solid-liquid extraction, Optimization.

1. Introduction

Grape marc (GM) represents an industrial waste from wine fermentation having high polyphenol content with antioxidant properties which is beneficial on human health. Extracts obtained from GM have a wide range of applications such as cosmetics, food and pharmaceutical industry (Fontana et. al; 2013). Conventional solid-liquid systems are the most applied technologies for antioxidant extraction from vegetal sources (Zhu et. al; 2015).

Proper selection of operational conditions is essential to achieve maximum global performance of the process in conventional solvent extraction (CSE). Operation

variables having high incidence on the CSE include: the type of solvent used, the time and the form of contact between solid and solvent, the solvent/solid mass ratio and the solvent temperature (Chan et al., 2014). Ethanol-water mixtures are an attractive option for use in industrial processes because of its low cost and its safety quality for use in food. Previous studies have confirmed that a 50 % (v/v) concentration of ethanol in the hydroalcoholic solution is the most effective for recovery of phenolic compounds from grape residues (Bucic'-Kojic et al. 2009). Other unit operations are required after extraction, such as distillation, evaporation and spray drying to obtain powder as final product. Polyphenol's extraction is improved by using higher quantities of solvent, but this generates a much more energy intensive process for solvent evaporation in later stages. There are many works published in which operating variables such as temperature and the amount of solvent used for polyphenols extraction from GM have been optimized. Most of them are based on response surface methodology maximizing the extraction yield (Shi et al., 2003). However, none of these optimization works consider economic aspects involved in the unit operations such as distillation, evaporation and drying required after the extraction to obtain the final product.

The aim of this study was to apply first-principles models and modern optimization methods to find the optimal operational conditions in a polyphenol's extraction process from GM, aiming to reach the maximum economical profit for the global system.

2. Materials and Methods

2.1. Process Description

The process to obtain a powder extract rich in polyphenols from GM is represented in Figure 1 (GM drying and milling stages previous of extraction process are not presented in the figure).

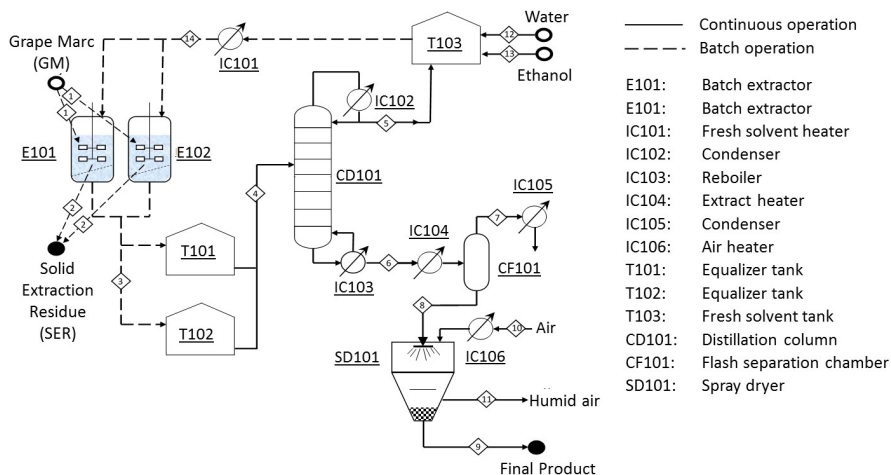

Figure 1: Proposed process for the obtention of a polyphenolic extract from GM.

A multistage sequential batch solid-liquid extraction system is considered (units E101 and E102). Cs_o is the total polyphenols compounds (TPC) in GM in grams of gallic acid equivalent (GAE) per kilogram [gGAE/kg]. The extraction solvent is a solution of 50 %

ethanol/water (v/v) and fresh solvent is used in each extraction stage. Extracts obtained are equalized (units T101 and T102) and then are fed to a distillation column (unit CD101). The residue from this column is fed into a one-stage flash evaporation system (units IC104, CF101 and IC105), without recovering the water stream going out of IC105. The concentrated extract is spray dried (unit SD101) obtaining a powder rich in polyphenols with a moisture content (X_p) of 11.1 % (dry basis) and a concentration of TPC ($C_{TPC,p}$) of 0.3 grams of GAE per gram of dry matter (Spigno et al.; 2007).

2.2. Polyphenols extraction modelling

Equilibrium at each extraction stage was assumed. This assumption is reasonable if the contact time in each stage is around 60 minutes, according to kinetic data from batch extraction published by Sant'Anna et al. (2012). Final TPC concentration in extracts after k stages is calculated from the TPC balance according to Eq. (1).

$$C_{f,k} = \frac{C_{S_{k-1}}}{L_k + \frac{K_k}{\rho_s}} \quad (1)$$

Where $C_{f,k}$ [gGAE/m³] is the final TPC concentration in the extract in k stage; $C_{S_{k-1}}$ [gGAE/kg], the final TPC concentration in the solid in $k-1$ stage; L_k [m³/kg], the solvent/GM mass ratio used in k stage; K_k [dimensionless], the TPC partition coefficient in k stage; and ρ_s [kg/m³], the solid density. The final TPC concentration in the solid at k stage is obtained by mass balance according to Eq. (2).

$$C_{S_k} = C_{S_{k-1}} - L_k C_{f,k} \quad (2)$$

The temperature incidence at k stage (T_k) is evaluated by the TPC partition coefficient function conforming to Eq. (3).

$$K_k = K_o \exp \left[\frac{\Delta H^\circ}{R} \left(\frac{1}{T_k + 273} - \frac{1}{T_o + 273} \right) \right] \quad (3)$$

Where K_o is the partition coefficient evaluated at T_o [°C] temperature; R , the ideal gas constant (1.987 cal/mol.K); and ΔH° [cal/mol], an enthalpy parameter of the model.

The following values were determined in a recent work (in progress by the authors): C_{S_o} =25.5 gGAE/kg, ρ_s =868.7 kg/m³, T_o =60 °C, K_o =5.20 and ΔH° =11.3 cal/mol. These values were determined with a more complete model (also including the dynamic behavior of the extraction processes) by fitting with experimental data published by Sant'Anna et al. (2012).

2.3. Product sale income and operation costs predictions

Product sale income (*PSI*) is calculated according to Eq. (4) in dollars per kilogram of dried and milled GM that is subjected to extraction. It is assumed that all TPC extracted with solvent is present in the final product obtained at the spray dryer.

$$PSI = PSP \left(\frac{1 + X_p}{1000 \cdot C_{TPC,p}} \right) \left[\left(\sum_{k=1}^m L_k C_{f,k} \right) - L_{ret} C_{f,m} \right] \quad (4)$$

Where PSP is the product sale price, assumed at 47 \$/kg (Casas et al; 2008); m the number of contact stages each of them with the addition of fresh solvent; and L_{ret} [m³/kg], the extract volume retained in solid extraction residue (SER) per kilogram of GM. Laboratory separation experiments allowed to estimate that SER obtained from one kilogram of GM, retains one liter of liquid extract ($L_{ret}=0.001$ m³/ kg).

The total operating cost in dollars per kilogram of dry and milled GM is calculated according to Eq. (5). Where $\alpha=66$ \$/m³ includes the costs due to: 1) solvent replacement not recovered from the extract, 2) energy dissipation in IC102 and IC105, and 3) energy consumption in IC103, IC104 and IC106; $\beta=0.08$ \$/m³°C represents the energy cost in IC101; T_{mean} [°C] is the arithmetic mean of all T_k values; T_{in} [°C], the solvent temperature in T103 (estimated to 32 °C); and $\gamma=0.24$ \$/kg represents the cost of solvent replacement not recovered from SER. α , β and γ values were calculated considering a price of 0.6 \$/kg for ethanol (Dimou et al., 2016) and 1.9 \$/t for process water required for solvent replacement. Energy dissipation cost was estimated for a price of 0.015 \$/t of cooling water (Dimou et al., 2016) and considering a range of 10 °C in the cooling tower. Energy consumption cost was estimated for a fuel oil price of 0.72 \$/L, and assuming a boiler that generate 13 kilograms of steam per liter of fuel oil. Solvent and energy dissipation/consumption requirements were calculated from the corresponding mass and energy balances. It is assumed that the ethanol retained in SER is not recovered. Mass and energy balances in distillation column were solved by a process simulation software (Aspen Plus, V8.4) resulting that 99.8 % of ethanol is recovered in distilled stream. Equilibrium conditions were assumed at 40 °C in CF101, and the outlet temperature in IC104 was set at 100 °C in order to prevent thermal degradation of phenolic compounds. Energy efficiency in SD101 was assumed to 57 %.

$$COST = \alpha \left[\left(\sum_{k=1}^m L_k \right) - L_{ret} \right] + \beta \left(\sum_{k=1}^m L_k \right) (T_{mean} - T_{in}) + \gamma \quad (5)$$

2.4. MINLP strategy for problem resolution

The structure of the optimization problem (MINLP) is given by Eq. (6). The difference between incomes from product sales and costs is assumed as the objective function to be maximized. Decision variables are: y_k , binary variables indicating whether stage k is performed ($y_k=1$) or not ($y_k=0$); and L_k and T_k , the solvent/GM mass ratio and temperature for each stage respectively. A maximum of seven contact stages with fresh extraction solvent is allowed (k : 1 to 7). The MINLP problem was solved in GAMS win664 24.8.5 software using DICOPT solver, and in Matlab R2015 using *ga* function for genetic algorithm implementation. It allows comparing performances between deterministic and non-deterministic tools and trying to deal with eventual non-convexities in the problem structure. The codes were executed in an Intel(R) Core(TM) i3-3240 CPU@3.4 GHz processor with 8 GB RAM memory.

$$\begin{aligned}
 & \max \quad z(x, y) = PSI(x, y) - COST(x, y) \\
 & x: L_k, T_k \\
 & y: y_k \\
 & \text{s.t:} \\
 & \text{Eq (2) to Eq.(5) and } C_{f,k} = (1 - y_k)C_{f,k-1} + y_k \left(\frac{Cs_{k-1}}{L_k + \frac{K_k}{\rho_s} + \varepsilon} \right) \\
 & y_{k+1} \leq y_k ; y_k L_{\min} \leq L_k \leq y_k L_{\max} ; T_{in} \leq T_k \leq T_{in} + y_k \Delta T_{\max} \\
 & L_k ; T_k \in \mathfrak{R}^n ; y_k \in \{0,1\}
 \end{aligned} \tag{6}$$

Where $\varepsilon=1\text{E-}7 \text{ m}^3/\text{kg}$ is a constant small value just introduced to avoid division by zero errors; $L_{\min}=0.004 \text{ m}^3/\text{kg}$ is the minimum solvent/GM mass ratio to ensure sufficient contact between solid-solvent and an adequate condition for mixing; $L_{\max}=0.05 \text{ m}^3/\text{kg}$ is a sufficiently large value; and $\Delta T_{\max}=48 \text{ }^\circ\text{C}$ is the maximum temperature increment allowed in IC104. This limits the maximum extraction temperature to $80 \text{ }^\circ\text{C}$ in order to prevent thermal degradation of phenolic compounds.

3. Results and Discussion

The solution found for the problem was the same with both methods and with low computational costs (resolution time of 4.22 s for ga function and 1.88 s for DICOPT). The optimal values for decision variables are shown in Table 1. The objective function reaches a value of 3.12 \$/kg and only three contact stages must be realized to maximize it. The cost associated to this optimal value is in the same order of magnitude respect to the one obtained in a similar process from Dimou et al. (2016). Respect to the optimal solvent/GM mass ratio, the results are the same for all stages and equal to the lower bound ($L_{\min}=0.004 \text{ m}^3/\text{kg}$). This result suggests that it is convenient to dose the extraction solvent in minimum quantities and in many contact stages. The optimal extraction temperature in all stages is $80 \text{ }^\circ\text{C}$, which is the maximum allowed in the problem to avoid possible polyphenols thermal degradation. This result is reasonable since as higher the temperature, higher the partition coefficient. As deterministic and non-deterministic approaches performed similar respect to the optimal solution, it could be stated that the current problem would present a convex nature. In this sense, the results can be interpreted as global optimization. Experimental data (Sant'Anna et al.; 2012) used for fitting the model, set a higher solvent/GM mass ratio ($0.05 \text{ m}^3/\text{kg}$) than the optimal, so new data should be obtained for further model validation in optimal conditions. In order to analyze the confidence of the results, a sensitivity analysis was carried out considering a variation of $\pm 30 \%$ for two relevant inputs (Cs_o and PSP), one at a time, resulting in the same values for the decision variables.

Table 1: Results for the optimization problem

k values	y_k	$L_k (\text{m}^3/\text{kg})$	$T_k (^\circ\text{C})$
For $k=1$ to 3	1	0.004	80
For $k=4$ to 7	0	0	32

4. Conclusions

A multistage sequential batch solid-liquid polyphenol's extraction process from GM was modeled and implemented in Matlab and GAMS. It assumed equilibrium conditions for each extraction stage in order to work with a simple but representative model. Optimal and confident operational conditions (number of stages, solvent/GM mass ratio, and temperatures) were found in order to achieve the maximum economical profit for the global system. Deterministic and non-deterministic optimization approaches were applied for solving the corresponding MINLP problem. Both methods revealed similar results, with a low computational burden, indicating that non-convexities would be negligible in this problem. A more completed work including model validation with new experiments, and the extraction process dynamics considering all solid-liquid contact times as additional decision variables, is in progress by the authors.

Abstract

In this study, two cryogenic nitrogen recovery processes integrated with natural gas liquefaction and NGL (Natural Gas Liquid) recovery are optimized using a commercial chemical process design simulator, gProms Processbuilder v.1.1 which is powerful at complex optimization problem. The difference of each process is the way the nitrogen is removed from product LNG: Stand-alone and integrated one for nitrogen removal unit. These two processes are compared with each other in terms of plant specific energy (kWH/kg_{LNG}) with respect to varying nitrogen content in the feed gas. In order for clear comparison, each process would meet the same product specification of flowrate and composition for NGL, LNG, and vent N₂ stream and nitrogen contents in the feed gas vary from 0 to 20mol%. Consequently, as the nitrogen content in the feed increases, the specific energy also increases for both processes while the integrated configuration becomes more efficient than the other after around 13 mol%. It should be noted that all of the optimization results for each process configuration are improved compared with those from other researches which have the similar configuration. From this study, we could be ready for a recent trend occurring in natural gas processing. This trend would last for more than decades and the way this study aimed could be reasonable guidelines for other chemical process designs.

Keywords: Process Integration, Optimization, Industrial Application

1. Introduction

In recent small to mid-size onshore LNG plants and some shale gas export projects, nitrogen recovery in natural gas processing has been of great importance as nitrogen content in the pipeline feed gas varies over time and location. When it comes to nitrogen recovery, possible nitrogen sinks in natural gas process are product LNG (N₂ less than 1 mol%), fuel gas, and/or vent gas (N₂ more than 99 mol%). Among these three sinks, the demand of fuel gas which is generated conventionally from an end-flash drum decreases as compressor drivers are gradually switched from steam turbines to aero-derivative gas turbines or electric motors which require less or no fuel gas for energy source in a plant. Then the rest of nitrogen should be vented to atmosphere while meeting the environmental regulations which limit the hydrocarbon content less than 1mol% in vent gas. These two major trends in recent LNG projects of varying feed composition and decreasing plant fuel

demand makes it necessary to completely recover nitrogen from methane in the product LNG, as traditional LNG process would generate large fuel gas and lose too much methane with the same conditions. In this study, two major nitrogen removal options are optimized and compared in terms of plant energy efficiency: one for standalone NRU, and the other for Integrated NRU. From this results, design favourability could be evaluated for each process for varying nitrogen content in the feed.

2. Conceptual Process Design

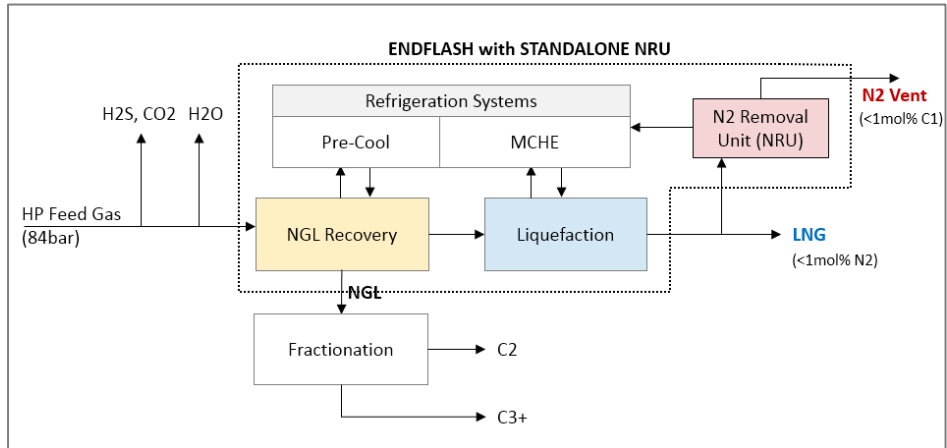

Figure 1. LNG Production Process with Standalone NRU

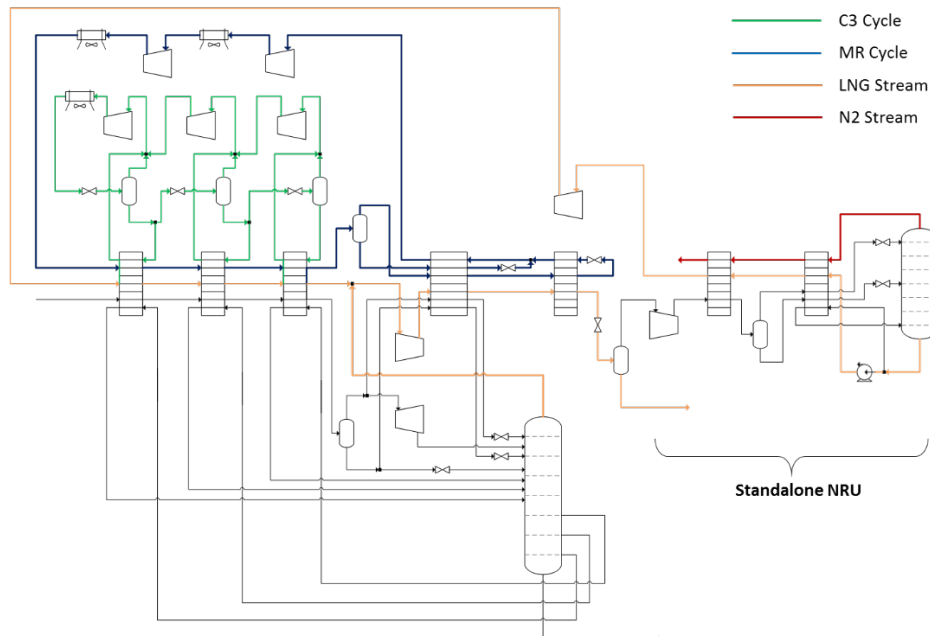

Figure 2. Process Flow Diagram for LNG Production Process with Standalone NRU

Integrated processes for LNG and NGL co-production with two nitrogen recovery schemes are illustrated in Figure 1 and 3, and each process flow diagrams are shown in Figure 2 and 4. For standalone NRU, NGL is firstly withdrawn from treated feed gas through GSP (Gas Subcooled Process) and C1 rich overhead stream is condensed and subcooled heading for end-flash drum to produce LNG. As nitrogen content in the feed increases, more flash gas from the drum is generated to meet the N₂ content specification in product LNG. In order to recover enough C1, N₂ is completely separated from C1 through standalone NRU and vented to atmosphere. For integrated one, N₂ separated between NGL recovery and liquefaction so that cryogenic heat source necessary in NRU is provided from refrigeration system in complete heat transfer network.

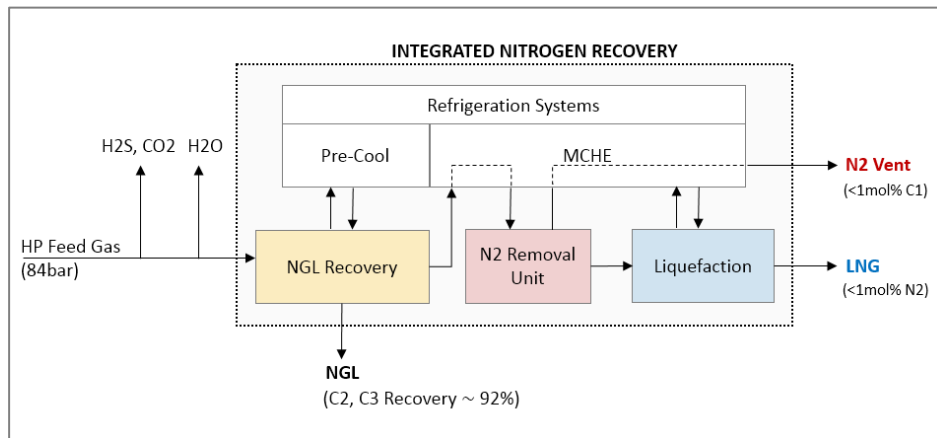

Figure 3. LNG Production Process with Integrated NRU

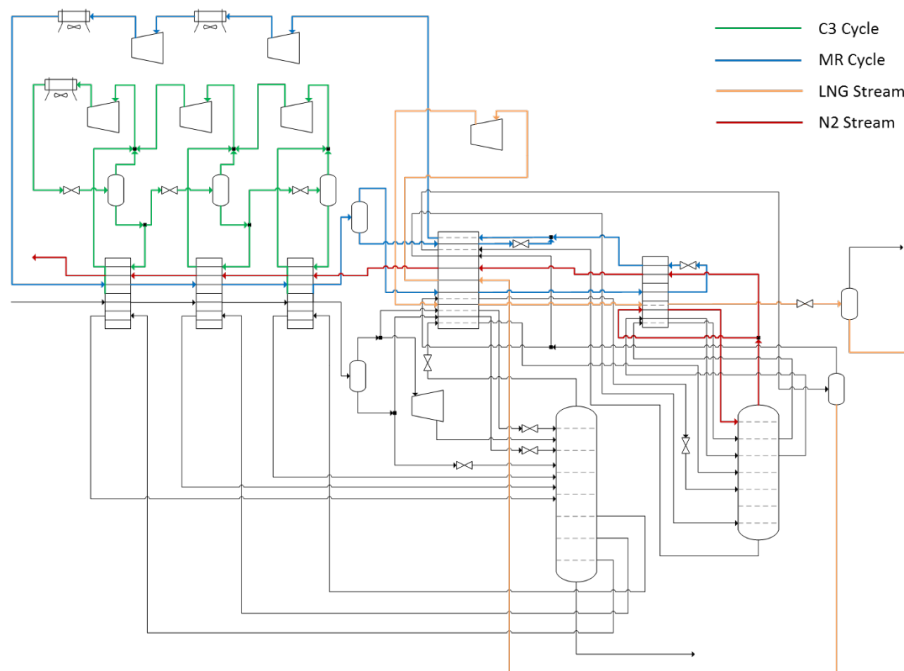

Figure 4. Process Flow Diagram for LNG Production Process with Integrated NRU

3. Optimization

Optimization structure is listed in Table 1. Objective function is specific power which is total power consumption for 1kg LNG production for 1 hour. In order to compare their energy efficiency clearly, product specification like C1, C2 recovery and impurity content and thermodynamic feasibility in heat transfer are constrained. As both standalone NRU and integrated one have same scheme for NGL recovery and refrigeration cycle (C3-MR) before nitrogen recovery section, they share similar control variables for optimization. Exceptionally for NRU, as standalone one should have additional compressor and two heat exchanger and integrated one draws two vapour side streams in rectifying section in the column for minimizing exergy loss in heat transfer, it makes few difference in the variable selection. In this chapter only 5 mol% N₂ Feed is evaluated for brevity.

Table 1. Optimization Structure for Standalone and Integrated NRU Process

	Standalone NRU	Integrated NRU
Objective Function	specific power [kWH/kg _{LNG}]	
Control Variables		
NGL Recovery	Cold reflux temperature Cold reflux flow ratio Side stream(1, 2, 3) flowrate	
MR Cycle	Pressure (High/Low) Heat exchanger outlet temperature (4th, 5th) Flowrate Composition(N ₂ , C1, C2, C3)	
C3 Cycle	Flowrate Split flow ratio	
NRU	NRU bottom pressure NRU reboling split ratio/ Flowrate NRU reflux split ratio/ Flowrate Compression ratio (Feed) Side stream Flowrate (1, 2)	
Inequality Constraints	C1 recovery > 0.99, C2 recovery > 0.92 N ₂ content in LNG < 0.01 C1 content in vent N ₂ < 0.01 MSHE MTA(Minimum Temperature Approach) > 3K	

Figure 5. Composite Curve of Multi-stream Heat Exchangers in Standalone NRU process

Figure 6. Composite Curve of Multi-stream Heat Exchangers in Integrated NRU process

After optimization, objective function value of each process is 0.39 for standalone and 0.48 kWh/kg_{LNG} for integrated one. Composite curves of heat transfer in all of the MSHE (Multi-Stream Heat Exchanger) are shown in Figure 5, 6. For standalone one, NRU plot is added as it has additional two heat exchangers independent on main heat transfer section for NRU feed precooling. It can be noticed from both plots that optimization of which the objective function is specific power minimize exergy loss in whole heat transfer section narrowing the space between hot and cold curves meeting 3K MTA constraints.

4. Varying Feed Composition

With respect to varying nitrogen content in the feed from 0 to 20 mol%, both processes can be optimized with similar optimization technique as shown in Table 2 and Figure 7. All three process also including base case (C3-MR LNG production process without NRU) lose their energy efficiency as nitrogen content in the feed increases, and it could be seen that any design with nitrogen content around 20 mol% is unfeasible for plant operation. Especially for base case, it should be noted that C1 recovery for LNG production drops significantly from 1.0 to 0.1 as nitrogen content increases because simple end-flash after liquefaction cannot afford to recover enough methane in order to meet the product specification of nitrogen content less than 1 mol% (C1 recovery for other cases is set to 1 for any nitrogen content). For two alternatives for nitrogen recovery, around 13mol% of nitrogen in the feed is the criteria for thermodynamically favourable design for LNG production. Integrated scheme also has less equipment like multi-stream heat exchanger and compressor so that it could have more favourability for highly leaner feed gas which contains larger nitrogen.

Table 2. Objective function values for varying nitrogen content in the feed

N ₂ Content		0	5	10	15	20
C1 Recovery for Base		1.00	0.79	0.56	0.28	0.08
Specific Power [kWh/kg _{LNG}]	Base	0.31	0.32	0.41	0.62	1.53
	Standalone	-	0.39	0.53	0.77	1.08
	Integrated	-	0.48	0.64	0.72	0.95

Figure 7. Comparison of Specific Power w.r.t. Varying N₂ Content in Feed

5. Conclusions

For varying feed composition in natural gas processing, two major nitrogen recovery scheme are optimized and evaluated for design favourability in terms of energy efficiency. In order to compare both processes clearly, product specification and thermodynamic feasibility like minimum temperature approach in heat transfer are fixed and optimization is performed for all discrete points (each process with nitrogen from 0 to 20 mol%) even for base case. Consequently two NRU options could completely recover nitrogen with reasonable energy efficiency for nitrogen content below 20 mol% in the feed. Especially integrated option becomes more favour after around 13mol% that standalone one, so that integrated design could be practically recommended for highly lean feed gas from unconventional natural gas sources like shale gas.

Abstract

Biogas is an important renewable energy source and potential raw material for the chemical industry. Its utilization frequently requires a treatment and/or upgrade step. The aim here is to maximize the exergy efficiency of a high-pressure water scrubbing process for upgrading biogas into biomethane by coupling a sequential modular simulation flowsheet with different optimization algorithms. By setting adequate operating pressures, and reducing cycle water and stripping air flowrates, an exergy efficiency of 92.4 % is reached.

Keywords: biogas, biomethane, high-pressure water scrubbing, sequential modular simulation, black-box optimization

1. Introduction and Motivation

Biogas is a mixture containing 50-75% CH₄, 30-50% CO₂, as well as H₂O, N₂, O₂, and minor amounts of contaminants such as H₂S, NH₃, aromatics, and siloxanes (Rasi et al., 2007). It is produced from the anaerobic digestion of different substrates by methanogenic bacteria. It plays an important role in a sustainable energy mix because, differently from other renewables, its production does not rely solely on climatic factors. The European Union has set a target of having 20% of its 2020 energy demand supplied by renewable systems, out of which at least 25% can originate from biogas (Holm-Nielsen et al., 2009). Biogas can be utilized for electricity and heat generation within a Combined Heat and Power (CHP) plant. The methane in biogas can alternatively be converted into syngas via reforming (Chen et al., 2017) or ethylene via oxidative coupling (Penteadó et al., 2017). A base treatment, consisting of cooling and drying followed by the removal or reduction of the H₂S content, is required prior to most biogas utilizations (Holm-Nielsen et al., 2009). The biogas upgrade consists in the removal of CO₂ to increase the gas' calorific value to that of pipeline-quality natural gas. The resulting gas is often called biomethane and can be employed as a vehicular fuel, in fuel cells, or injected into the natural gas grid.

Different processes are available to upgrade the biogas. Sun et al. (2015) published a major review on the available methods. The selection is done on a case-by-case basis, by considering the specific raw biogas composition, amount and nature of contaminants, production scale, application requirements, and available infrastructure and utilities. The most common ones are High Pressure Water Scrubbing (HPWS), Amine Scrubbing (AMS), Pressure Swing Adsorption (PSA), Gas Permeation (GP), and Cryogenic Distillation (CD) (Sun et al., 2015). Hybrid concepts can also be

employed to explore the main advantages of each technology (Scholz et al., 2013). The HPWS is one of the most used biogas upgrade technologies in Europe (Scheffelowitz et al., 2015). A quantitative comparison of the upgrade cost is presented in Figure 1. The calculation is done with the Biomethane Calculator (Miltner et al., 2013). Given inputs such as feed gas flow and composition; desired upgrading technology; and the required biomethane purity, the software yields methane recovery, production, investment and operating costs, and the specific biomethane production cost, thus enabling a preliminary assessment of upgrading plants. It can be seen from Figure 1, that for the gas composition and flow rate used in this study and specified in Table 1, the HPWS is very competitive. It tends to get even more competitive for larger scale plants.

A number of authors have assessed the HPWS process from an energy and economic standpoint. Rottunno et al. (2017) modeled this process in Aspen Plus using rigorous rate-based simulations to design the absorption and stripping columns. Budzianowski et al. (2017) also developed non-equilibrium Matlab models for a number of different configurations of HPWS and Near Atmospheric Pressure Water Scrubbing (NAPWS), using plant data for model validation, and finally estimating the energy requirement for the upgrade process in each configuration. The study concludes that using high pressure absorption, intermediary flash for methane recovery, and stripping for water regeneration provides an efficient solution. Wylock and Budzianowski (2017) later extend the previous contribution considering only the scrubber-flash-stripper configuration and focusing on the sizing of the column packing height, and further performance estimation for the system. While all of these studies perform the sizing and rating of the absorption and stripping columns using rigorous rate-based models, the operating conditions are determined by heuristics, experience, or by carrying out extensive simulations and sensitivity studies with one parameter being varied at the time, potentially leading to sub-optimal results. In contrast, the present study aims at determining the operating conditions for a HPWS process by means of mathematical optimization. The objective is to maximize the process' exergy efficiency given 8 continuous and bounded decision variables subject to product specification constraints. To this purpose, a framework for the optimization of sequential modular simulations is developed.

Figure 1: Comparison between different biogas upgrading technologies

2. Methods

A HPWS process using a scrubber-flash-stripper configuration is modeled in the software Chemcad7. The simulation flowsheet is presented in Figure 2. The raw biogas (stream 1) is pressurized in a three stage compression section (equipment 1, 20 and 4) with intermediate cooling (equipment 2, 21, 5) in the upstream of the absorption column or scrubber (equipment 6). In the scrubber, the biogas is contacted with pressurized water fed to the top of the column. The gases dissolve in water, allowing the removal of the CO_2 and H_2S , but also causing some CH_4 losses. The biomethane (stream 8), leaves the column at the top. The bottoms (stream 9) is then flashed (equipment 8) to an intermediate pressure in order to recover some CH_4 , which is recycled back to an intermediate compression stage. The flash's liquid (stream 12) enters the second column, where CO_2 and H_2S are stripped out with air (stream 13), which is fed via a blower (equipment 10). The stripper (equipment 9) is operated at a pressure of 1.1 bar. The regenerated water is partially purged

(stream 18), mixed with fresh water (stream 20), pumped to the absorption pressure (equipment 17), and passes through a heat exchanger (equipment 18) before being recirculated back to the absorption column. The gas stream leaving the stripper column passes a bio-filter (equipment 19) that removes the H_2S before leaving the process e.g. through a stack. The 8 continuous decision variables to be determined are the two intermediary pressures in the compression, the absorption pressure, the temperature of the gas and the liquid fed to the absorber, the cycle water and stripping air flowrates, and the cycle water purge ratio. Their initial values and bounds are listed in Table 2.

2.1. Modeling

The Volume-Translated Peng-Robinson Equation of State is used to model the system, allowing for consistent physical and chemical exergy calculations in both liquid and gas phases in all streams. The table of binary parameters is completed by using data from Schmid et al. (2014) and with Twu parameters from Dortmund Data Bank (2015). More modeling details and validations are described by Schöneberger and Fricke (2017).

A typical biogas composition, as given by Rasi et al. (2007), is assumed according to Table 1. The biomethane must contain at least 96 mol% of CH_4 and maximum 20 ppmv of H_2S . Compressors have an adiabatic efficiency of 50 % and inter-stage cooling to 5 K above dew point. Cooling water is available at 298 K.

Cycle water make-up is provided as saturated steam at 1.1 bar. This is done to reflect the exergy consumption for the water treatment and penalize fresh-water consumption, which would otherwise have zero physical exergy. The water pump (equipment 17) has an adiabatic efficiency of 70 %. Stripping air is fed at 298 K, 1.013 bar, and dry. Pressure drop in exchangers is neglected. The absorber and stripper are packed columns using Mellapak 250Y with 20 and 10 stages respectively. The use of non-equilibrium models largely increases computational effort and column flooding can cause non-convergence of the flowsheet, which are drawbacks for the application of such models within optimization. A rate-based model is, therefore used to estimate Murphree efficiencies that are then set constant in the equilibrium stage model used in the optimization.

2.2. Exergy Calculation

The exergy efficiency is taken as the main objective for the optimization, as it reflects thermodynamic inefficiencies that translate into operating cost (energy consumption) and environmental impact (methane slip). The exergy rate of a stream is given as the sum of its physical and chemical exergy rates, calculated as in Equations 1 and 2 respectively. The thermodynamic environment is defined at 298 K and 1.0 bar. Diederichsen reference environment and ideal mixing is assumed for chemical exergies. For the work streams in the compressors and pump, the exergy rate is equal to the calculated power. The exergy efficiency, given by Equation 3, is defined as the ratio between the recovered exergy rate in the form of the biomethane product stream and all exergy fed to the process in the form of electricity to run compressors and the pump, the biogas feed stream, the stripping air, and the steam make-up for the water cycle.

$$\dot{E}_s^{PH} = \dot{H}_s(T_s, p_s, z_s) - \dot{H}_s(T^{ref}, p^{ref}, z_s) - T^{ref} \cdot [\dot{S}_s(T_s, p_s, z_s) - \dot{S}_s(T^{ref}, p^{ref}, z_s)] \quad (1)$$

$$\dot{E}_s^{CH} = \dot{n}_s \cdot \sum_{c=1}^{NC} [z_{s,c} \cdot e_c^{CH} + R \cdot T^{ref} \cdot z_{s,c} \cdot \ln(z_{s,c})] \quad (2)$$

$$\eta_{exergy} = \frac{\dot{E}_8}{\dot{W}_1^{el} + \dot{W}_{20}^{el} + \dot{W}_4^{el} + \dot{W}_{10}^{el} + \dot{W}_{17}^{el} + \dot{E}_1 + \dot{E}_{19} + \dot{E}_{13}} \quad (3)$$

3. Optimization Framework

The aim is to maximize the value of the exergy efficiency. Constraints are set for a minimum CH₄ content of 96.0 mol% and a maximum H₂S content of 20 ppm_v in the biomethane product gas. To solve this NLP, a framework is developed in Matlab by using the OPC Toolbox to communicate with the Chemcad7 flowsheet as a black-box simulation server, as well as different optimizers. The implementation allows for an easy and flexible objective formulation in Matlab, by reading the enthalpy and entropy rates from the Chemcad7 flowsheet, and calculating the exergy rates and then returning the negative value of the exergy efficiency to the optimizer. In a similar fashion, the constraints are evaluated inside Matlab by reading the composition of the product stream. To avoid additional unnecessary time-consuming simulations, values are saved in variables accessible by both functions. With a single black-box simulation, it is possible to evaluate the objective and the constraints. The same is true for numerical evaluation of gradients and jacobians, if required by the optimizer.

Black-box optimization with sequential modular flowsheets is difficult because the problem structure typically causes the objective function to be discontinuous, non-differentiable, not defined in many points, noisy, and subject to relaxable and unrelaxable nonlinear constraints from the simulation environment (Martelli and Amaldi, 2014). The use of gradient-based algorithms, which are the preferred choice, can therefore become very challenging. The numerical gradients might be undefined, expensive to evaluate, or simply of no use because of poor quality. Hence, direct search methods became very popular among engineers and researchers to deal with this type of optimization (Martelli and Amaldi, 2014).

To allow for enough flexibility, both gradient-based and direct-search algorithms are implemented in the framework: Matlab's Genetic Algorithm (GA) and Particle-Swarm Optimization (PSO) solvers, and the Mesh Adaptive Direct Search (MADS) algorithm NOMAD (Le Digabel, 2011) provided in the OPTI-Toolbox (Currie and Wilson, 2012). In order to use the available Sequential Quadratic Programming (SQP) algorithm provided with Chemcad7, an additional VBA unit operation is added to the flowsheet and programmed to calculate the objective value. It is not the aim of this study to provide a rigorous solver benchmark, but rather demonstrate the flexibility and try to achieve better results by exploiting the advantages of each search method.

Table 2: Decision variables and results

Variables	Units	Lower Bound	Upper Bound	Initial Value	Results			
					GA	PSO	MADS	SQP
Exergy Efficiency	%	0	100	55.48	90.16	92.34	92.39	92.40
Function Evaluations	-	0	-	-	6,480	2,053	530	461
Intermediate Pressure	bar	1.1	15.0	2.6	6.91	6.48	8.30	7.72
Intermediate Pressure 2	bar	1.1	20.0	7.5	13.07	12.53	11.50	14.48
Absorber Pressure	bar	1.1	25.0	17.5	21.42	21.15	24.87	25.00
Liquid Feed Temperature	K	303	353	305	332	303	303	303
Gas Feed Temperature	K	303	353	323	328	351	353	303
Cycle Water Flowrate	Nm ³ /h	5	500	236	29.19	30.61	25.21	25.92
Stripping Air Flowrate	Nm ³ /h	10	1000	850	690.92	35.54	39.14	42.21
Purge Ratio	-	0.01	0.1	0.03	0.017	0.01	0.01	0.01

4. Results

The optimal value for the purge ratio is found to be at its lower bound. Even though a smaller purge requires a higher water recirculation rate and more pump duty, the effect of the reduced fresh water requirement and its associated exergy is much more pronounced. As expected, the liquid feed temperature is also at its lower bound. The gas feed temperature has little influence to the efficiency. The intermediate pressure 2 can be almost independently optimized. However, the intermediary/flash pressure, absorption pressure, cycle water flow rate, and stripping air flow rates are highly coupled and many points with high exergy efficiencies, i.e. $\geq 90\%$, have been found at fairly different conditions as intermediary results. A higher absorption pressure increases the compression duty, but reduces the required cycle water and stripping air flow rates to keep the product purity constraints fulfilled.

In this study, a rational exergy efficiency of 92.40 % has been reached. A large reduction in cycle water and stripping air flow rates could be achieved, while keeping the product within specification. Although not exactly an exergy efficiency, Rotunno et al. (2017) applied a conversion factor of 0.41 to transform primary energy into electricity and then calculated an efficiency of 87.3 % for a HPWS process using the same configuration. The results of this study are, thus in the same order of magnitude from previously published results. The optimal absorption pressure is found to be in its upper bound and above the initial point of 17.5 bar and above the range of 7-12 bar found as typical values in other literature cases such as (Budzianowski et al., 2017), (Wylock and Budzianowski, 2017), and (Rotunno et al., 2017). The reason is probably that considering the water make-up stream to be saturated steam over-penalizes the water usage and leads to an operating point at a higher pressure and with lower water recirculation and fresh water consumption. Nevertheless, if the water make-up stream would be liquid at ambient conditions, it would have zero physical exergy and lead to excessive use of water. To avoid this, a different objective function, e.g. operating cost, can be used in future studies.

The SQP algorithm is the most efficient and effective of the tested solvers, reaching a stationary point within 47 iterations and 461 function evaluations. The gradients are built by central finite differences with the default step size of 0.005. It is essential to keep the step size long enough compared to the simulation tolerance. Most numeric gradient methods used in optimization have a way lower step size by default, e.g. 10^{-6} , while tear-stream tolerances in sequential simulations is often 10^{-3} or 10^{-4} . The solver NOMAD with orthogonal polling directions provided great usability with significant objective improvement with its parameters left to default. For GA and PSO, a way larger number of function evaluations is required to reach similar objective values.

5. Conclusion

In this contribution, the operating conditions of a high-pressure water scrubbing process using a scrubber-flash-stripper configuration is determined by mathematical optimization. An operating point with 92.40 % exergy efficiency is achieved using a SQP algorithm. A flexible framework for the optimization of sequential modular simulations is developed and presented. Future works include extending its usability to handle larger and more complex flowsheets with integer and binary decisions. Parallelization must also be addressed given the speed-up potential.

Abstract

In this paper, extensions to the MINLP superstructure formulation for multi-period heat exchanger network synthesis (HENS) proposed by Zhang (2006) which is based on the work by Yee and Grossmann (1990) are introduced. These modifications allow for simultaneous HENS including storage-subsystems with different characteristics. Besides stratified tanks and two-tank systems models for latent heat thermal storages (LHTS) and sensible storages are presented. Also, a sequential targeting procedure for the integration of storages is presented which combines insights from pinch analysis methods and a MINLP-formulation to calculate an approximation for optimal storage size and melting temperature. The results of the proposed integration procedure for thermal energy storages is demonstrated using a case study adapted from literature.

Keywords: Mathematical Programming, Heat Integration, Thermal Energy Storage, Latent Heat Thermal Storage, Pinch Analysis

1. Introduction

The synthesis of cost-efficient heat exchanger networks (HENs) has been a topic of scientific interest for several decades now. However, only little research has been done towards the combination with cost-efficient storage integration for multi-period plant operation. Anastasovski (2017) used Pinch Technology for the introduction of two-tank systems in HENS. Storage costs are obtained by variation of storage parameters and temperature differences. Chen and Ciou (2008) proposed a MINLP superstructure formulation for cost-efficient indirect heat recovery using thermal energy storage. A sequential design procedure for HENS with selection of an optimal utility system and storage integration was proposed by Mian et al. (2016). They tried to overcome the drawbacks of the sequential approach by applying the derivative-free hybrid algorithm PGS-COM by Martelli and Amaldi (2014). To our best knowledge, no work has been published on cost-optimal HENS combined with the integration of LHTS or sensible storages with fixed mass. A rigorous optimization procedure for the integration of thermal energy storages such as multi-tank systems but also LHTS might be a door opener for industrial application of these heat recovery systems. In this paper an extension to the simultaneous MINLP superstructure formulation for multi-period HENS proposed by Zhang (2006) is presented that allows for storage integration with different characteristics. For the integration of LHTS and sensible storages with fixed mass such as fluidized bed regenerators (FBR) a targeting stage is proposed to identify (sub)-optimal storage mass.

2. Storage Integration Algorithm

Figure 1: Flow chart for the storage integration algorithm

The combination of simultaneous HENS for multi-period problems and the integration of thermal energy storages leads to a highly complex optimization problem. To reduce problem complexity a storage integration algorithm is proposed which splits the selection of the storage type, storage material and storage mass and thus storage capacity into individual problems. These are treated sequentially according to Fig. 1. A MILP targeting formulation described in section 2.1 is used to calculate the phase change temperature T_{melt} for LHTS which is then used to manually select a suitable phase change material. Also, storage materials for the FBR and two-tank system are selected by the user. For storages with fixed storage mass and variable storage temperature (LHTS, FBR) the target formulation is then used to find the optimal storage size. Finally, the extended MINLP superstructure formulation for multi-period HENS and storage integration (section 2.3) is set up with the predefined storage parameters to find the cost-optimal mixed heat recovery system.

2.1. Storage Target

The targeting procedure for the integration of sensible and latent thermal energy storage with fixed storage mass is formulated as a MILP model which is based on modified Grand Composite Curves (mGCC) which are similar to the shifted Grand Composite Curves (GCC) proposed by Bandyopadhyay et al. (2010) for total site integration. These curves are obtained by removing the "pockets" from the GCC, splitting it at the pinch point and shifting the two new curves back by $\Delta T_{min}/2$. The mGCCs, just like the GCC, provide information at which temperature heating or cooling can be supplied to the process. Within the MILP model the mGCCs for every operation period are then formulated as piecewise linear functions using binary variables. The optimal trade-off between storage size and external utility is then found by variation of the storage size and solving the MILP formulation until no improvement of the objective value can be obtained. No individual process streams and no individual heat exchangers are considered which makes the problem relatively easy to solve.

2.2. Storage Models

In this work generic models for LHTS, FBR and two-tank or stratified tank systems are presented which can be used in both the targeting formulation and the extended superstructure. All storages are modelled as a mass points (uniform temperature in the storage), process streams are connected to the storages by an intermediate storage cycle (ISC) via heat exchangers (HEXs), the storage state is equal at the beginning and the end of the process duration and the storage temperature during each time interval is considered to be equal to the storage temperature at the end of each individual time interval. The model equations for the cumulated storage energy and the ISC are equal for all storage types. The cumulated energy for each operation period $Q_{cum,p}$ in the storages is calculated as

$$Q_{cum,P} = Q_{shift} + \sum_{p=1,\dots,P} \dot{Q}_{charge,p} \Delta t_p - \sum_{p=1,\dots,P} \dot{Q}_{discharge,p} \Delta t_p, \quad Q_{shift} \geq 0, \quad P = 1, \dots, NOP \quad (1)$$

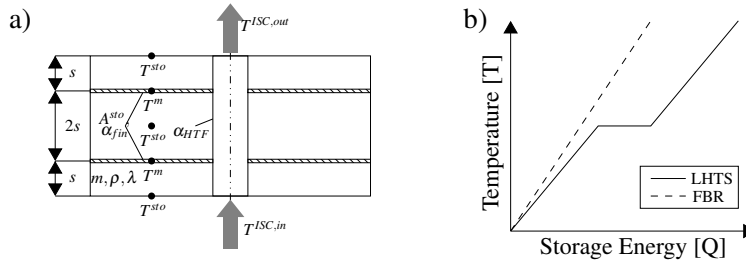

Figure 2: Schematic storage model and QT-characteristics for LHTS and FBR

where Q_{shift} is the storage load at the beginning of the storage cycle. $\dot{Q}_{charge,p}$ and $\dot{Q}_{discharge,p}$ are the charging and discharging loads of operation period p with the duration Δt_p . NOP is the number of operation periods. Simultaneous charging and discharging is not allowed and is prohibited by the constraints $z_{ikp}^{ISC} \leq 1 - y_p$ and $z_{jkp}^{ISC} \leq y_p$ where y_p are binaries that decide whether the storage is charged or discharged. The binary variables z_{ikp}^{ISC} and z_{jkp}^{ISC} determine whether the HEXs between the process streams (hot process stream i , cold process stream j) and the ISC are active in temperature stage k . For the two-tank model no HEX between the ISC and the storage vessels is needed as the heat transfer fluid (HTF) is stored directly. The lower and upper temperatures in the ISC correspond to the temperatures of the hot and cold storage tanks ($T_p^{ISC,hot} = T^{sto,hot}$, and $T_p^{ISC,cold} = T^{sto,cold}$). The minimum storage mass m is calculated by the nonlinear equation

$$Q_{cum}^{ub} - Q_{cum}^{lb} = (T^{sto,hot} - T^{sto,cold})cpm \quad (2)$$

where Q_{cum}^{ub} and Q_{cum}^{lb} are the maximum and minimum values of $Q_{cum,p}$. Opposed to two-tank systems in LHTS and FBR a HEX between the ISC and the storage is needed which is used for both charging and discharging. The necessary heat transfer area A^{sto} for this HEX is calculated by

$$A^{sto} \geq \frac{\sum_i \sum_k \dot{Q}_{ikp}^{ISC} + \sum_j \sum_k \dot{Q}_{jkp}^{ISC}}{U \Delta T_p^{sto}} \quad (3)$$

where \dot{Q}_{ikp}^{ISC} and \dot{Q}_{jkp}^{ISC} are the heat loads from the process streams to the ISC, ΔT_p^{sto} is the temperature difference between the storage fins T^m and the storage material T^{sto} . and U is the overall heat transfer coefficient in the storage HEX. ΔT_p^{sto} is calculated by

$$\Delta T_p^{sto} \leq T_p^{sto} - T_p^m + \Gamma y_p, \quad \Delta T_p^{sto} \leq T_p^m - T_p^{sto} + \Gamma (1 - y_p) \quad (4)$$

where Γ is a sufficiently large number used to activate and deactivate Eq. (4). The overall heat transfer coefficient U is derived from a simple model according to Fig. 2. The LHTS and FBR are modelled as shell and tube storages with radial fins that stretch out to the shell. It is assumed that the tube area is negligible compared to the fin area and thus all heat transfer is performed by the fins which are assumed to operate at the arithmetic mean of the HTF in- and outlet temperatures ($T^m = (T^{ISC,in} + T^{ISC,out})/2$). The characteristic length s for heat conduction is then calculated by $s = \frac{m}{A^{sto}\rho}$. The heat transfer coefficients from HTF to the fins α_{HTF} and from the fins to the storage medium α_{sto} are assumed to be infinite for the LHTS. This way the overall heat transfer coefficient is a function of the HEX area A^{sto} , the storage mass m , the thermal conductivity of the storage material λ and its density ρ . For the FBR model heat conduction is assumed to be negligible and a constant heat transfer coefficient between the fins and the storage material α_{sto} is assumed.

Table 1: Stream data and cost coefficients

	T _{in} (°C)	T _{out} (°C)	CP (kW/K)	Start (h)	End (h)
H1	170	50	3	0.3	0.8
H2	190	80	4	0.25	1
C1	100	160	8	0	0.5
C2	40	155	10	0.5	0.7
UT h	250	250	-	-	-
UT c	10	15	-	-	-

Exchanger cost = $1000+175[A(m^2)]^\beta \text{€y}^{-1}$, Storage cost (LHTS/FBR/2-tank) = $10,000/20,000/6,000[m(kg)/\rho(kg/m^3)]+50.7[A(m^2)]^\beta \text{€y}^{-1}$, $\beta = 0.6$, hot utility cost = $252 \text{€y}^{-1} \text{ kW}^{-1}$, cold utility cost = $22.68 \text{€y}^{-1} \text{ kW}^{-1}$, $dT_{min} = 5^\circ \text{C}$, years $y = 3$

Table 2: Storage material properties

	LHTS	FBR	2-tank
Material	Erythritol ^a	Quartz sand	Therm. oil
cp_s (kJ/kgK)	1.38	0.83	-
cp_l (kJ/kgK)	2.76	-	2
Δh (kJ/kg)	339.8	-	-
λ_s (W/mK)	0.733	-	-
λ_l (W/mK)	0.326	-	-
ρ (kg/m ³)	1390*	1300	1000
	(1480, 1300)		
T_{melt} (°C)	117.7	-	-

*average value, ^aF. Agyenim and I. Knight (2007)

$$U_{LHTS} = \frac{1}{\underbrace{\frac{1}{\alpha_{sto}} + \frac{s}{\lambda}}_0 + \underbrace{\frac{1}{\alpha_{HTF}}}_0} = \frac{\lambda}{s} = \frac{\lambda A^{sto} \rho}{m}, \quad U_{FBR} = \frac{1}{\underbrace{\frac{1}{\alpha_{sto}} + \frac{s}{\lambda}}_0 + \underbrace{\frac{1}{\alpha_{HTF}}}_0} = \alpha_{sto} = const. \quad (5)$$

For the LHTS different values for λ and thus U_{LHTS} are used for solid, liquid and transition phase, where for the transition the average of the solid and liquid values is used. Eq. (3) is adapted using the binary variables which are also used to model the piecewise linear QT-characteristics. This characteristic shown in Fig. 2 provides a relation between the storage temperature and the stored energy and depends on storage mass, specific heat cp , phase change enthalpy Δh and melting temperature T_{melt} . For FBR this characteristic is linear for fixed storage mass.

2.3. Extended Superstructure

In this paper a multi-period formulation based on the MINLP superstructure proposed by Zhang (2006) is used and extended for storage integration. The objective function in the extended version considers HEX between process streams and ISC, storage HEX in the case of LHTS or FBR and the mass of the storage material. The costs for storage construction and storage equipment are assumed to be proportional to the mass of the storage material and are considered in the cost coefficient for storage mass.

3. Example

To demonstrate the integration procedure a slightly adapted version of an example from Kemp (2007) was investigated. The example consists of two hot and two cold process streams with different start and end times leading to 6 operation periods. The process is assumed to be cyclic with a cycle duration of one hour. For higher accuracy for storage heat flows of LHTS and FBR all operation periods were split into two periods with equal durations. The stream data and cost coefficients, which are rough estimates based on material costs, are presented in Table 1.

In the targeting phase for the integration of a LHTS system an ideal phase change temperature for the PCM of 120°C was found. The sugar alcohol Erythritol with a phase change temperature of 117.7°C was then selected as storage material. For the FBR quartz sand and for the two-tank system thermal oil were selected as storage materials. The properties of the selected storage materials are shown in Table 2. The heat transfer coefficient between the fins and the storage material in the FBR was assumed to be $0.3 \text{ kW/m}^2 \text{K}$ based on the work by Molerus et al. (1995). The obtained targets for ideal storage masses for LHTS and FBR were 710.3 kg and 1725.5 kg respectively. After material selection and targeting for storage mass the extended multi-period MINLP superstructure was solved using the local MINLP solver DICOPT (Discrete and Continuous Optimizer)

Figure 3: a) Cumulated storage energy over process duration for two-tank system, LHTS and FBR, b) QT-diagram with storage states

Figure 4: Annual cost analysis for the obtained HEN with LHTS, FBR, two-tank system and without storage integration (PP= direct heat integration)

which is based on the outer approximation method with equality relaxation strategies presented by Viswanathan and Grossmann (1990). DICOPT was initialized using an approximate solution obtained by solving a linearized version of the formulation.

Fig. 3 a) shows the cumulated storage energy over time. Using the two-tank system the highest heat recovery was obtained followed by the LHTS system. The integration of the FBR yielded the lowest heat recovery which can also be seen from the utility costs in Fig. 4. In Fig. 3 b) a QT-diagram is presented which shows that the LHTS system operates in phase transition and in the liquid phase of the storage medium. The temperature range within the storage is small compared to the FBR where the storage temperature ranges from 62.5 to 166.8 °C. The two-tank system operates at 165 and 105 °C and the optimal storage mass is 3420 kg.

Comparison of the annual costs of the optimized heat recovery systems and the HEN without storage integration (Fig. 4) shows that the two-tank system is the most cost-efficient solution with total annual costs of 36,122 € compared to 60,116 € for the case without storage. Although, the costs for the storage vessels of the two-tank system exceed the cost for the LHTS, higher heat recovery can be obtained which makes the storage more cost-efficient. The least cost-efficient storage is the FBR with high costs for the storage vessel and low heat recovery. The HENs for all cases are presented in Fig. 5. The HENs with LHTS and two-tank system have one less utility exchanger than the HEN without storage integration. All four process streams are connected to the ISC. Using the FBR no reduction in the the number of utility HEXs was obtained.

4. Conclusion

The proposed procedure for storage integration allows for simultaneous optimization of HENs and storage subsystems. Storage models for two-tank systems, LHTS and FBR that will be validated in future work were presented that can be included in superstructure formulations for HENS. This allows for scenario analysis of different types of storages. The proposed targeting procedure helps to select a PCM with a suitable melting temperature for LHTS and to reduce problem complexity by providing estimates for optimal storage size. In the presented example a conventional two-tank storage system resulted in the lowest annual costs. Although, other storage systems might

Figure 5: Optimal HENs: a) LHTS, b) FBR, c) two-tank system d) no storage

be the better alternative if condensing and evaporating process streams are considered or for high temperature application. Whether storage integration is worthwhile highly depends on the costs for storage equipment and additional utilities. Also, low period durations for cyclic processes favour the integration of storage systems as higher heat recovery per storage volume can be obtained.

5. Acknowledgement

This integration method of thermal energy storages and the corresponding project were initiated and could be realized by means of the endowed professorship through the cooperation between AIT (Austrian Institute of Technology) and TU Wien (Vienna University of Technology) in the research-field of Industrial Energy Systems.

Abstract

To predict solvent degradation in an industrial CO₂ capture process and for a better understanding of the interactions between solvent degradation and performance of the capture process, an existing dynamic model of an amine based pilot plant for carbon capture has been improved and adapted at the University of Babeș-Bolyai on the basis of the kinetic model of solvent oxidative degradation proposed at the University of Liège. The developed dynamic model has been used to simulate the transient behavior of the CO₂ capture process with assessment of solvent degradation.

Keywords: CO₂ capture, dynamic model, solvent degradation

1. Introduction

Amine solvent based post-combustion capture is an efficient technique and it is based on an absorption-regeneration loop. However, there are many operational drawbacks for usage of amine solvents in industrial application. Among others, corrosion limits the amine concentration in the solution, thermal degradation may happen in the regeneration step and oxidative degradation is occurring in the presence of oxygen in the flue gas typical of absorber conditions. Moreover, the presence of impurities (SO_x, NO_x and fly ash) also leads to amine solvent degradation. These drawbacks lead to an increase in the process cost and environmental concerns, as the properties of the solution may be affected by the presence of degradation products that can also be emitted to the atmosphere. Previous results studying degradation in CO₂ capture pilot plants showed that oxidative degradation due to the presence of oxygen in the flue gas is the main degradation pathway (Lepaumier et al. 2011, Léonard et al. 2015a). In a first attempt to extrapolate these results, a steady-state model with assessment of solvent degradation has been developed (Léonard et al. 2014a; Léonard et al. 2015a) with assumptions allowing to consider degradation as a pseudo steady-state phenomenon. In a recent work, a dynamic prediction of solvent degradation has been proposed by Dhingra et al. (2017) as a function of the concentration of dissolved iron ions in the amine solution based on experimental results from 3 different pilot plants. However, this dynamic model does not consider the whole absorption-regeneration process, nor does it consider the influence of varying the operating parameters of the process.

On the other side, power plants are required to be operated in dynamic scenarios, due to the timely variation of the grid demand. The importance of dynamic models resides in the ability to study and to predict the dynamic behavior of a plant as function of time, which cannot be done with steady-state models. Therefore, these models allow the development of complex control strategies and the study of flexible operation of the plant. There are various dynamic models published in the literature, describing the absorption based CO₂ capture process. These models are used for process design improvement, dynamic behavior analysis, flexible operation studies etc. (Gaspar and Cormos, 2010). But these dynamic models neglect the degradation of the solvent, considering only the reaction between amine and CO₂. The aim of the present work was thus to update a dynamic model of amine-based CO₂ capture absorber validated with pilot plant data and to make it suitable for simulating the oxidative degradation of the solvent based on previous experimental results.

2. Mathematical model

The dynamic model of CO₂ absorption process in alkanolamine solution consists of partial differential equations that describe the total mass, component and energy balances of liquid and gas phases and constitutive relations (used to assess the physical and thermodynamic properties of the system). The developed model is based on the two-film theory and is using the following assumptions (Gaspar and Cormos, 2010): counter current plug flow regime of the two phases inside the column; the concentration of CO₂ and O₂ at gas-liquid interface are approximated using Henry's law; liquid and gas phases are assumed to be an ideal mixture; chemical reactions take place only in the liquid phase and the vapors condense at the gas-liquid interface; heat transfer by radiation as well as by conduction in the axial direction are neglected ; and finally, the fresh solvent is assumed to have been 100% regenerated. The partial differential equations of the model were discretized by spatial derivatives using first order approximations, and all mathematical equations have been implemented in MATLAB/Simulink.

2.1 CO₂ reaction kinetic model

The absorption chemical reaction is presented below:

The reaction mechanism implemented in the present model is based on data revised by Versteeg et al. (1996). The reaction between CO₂ and primary/secondary amines can be described with zwitterion mechanism. According to this mechanism the overall reaction order for MEA has a value of two. The reaction rate follows 2nd order kinetics and can be written as:

$$r = k_d \cdot C_{CO_2} \cdot C_{MEA} - k_r \cdot C_{MEACOO^-} \cdot C_{MEAH^+} \quad (2)$$

Where: $k_d = 4.4 \times 10^8 \cdot e^{-5400/T}$ [m³/mol.s] and k_r is computed from the reaction equilibrium constant (Versteeg et al. 1996).

2.2 Oxidative kinetic model

Amine solvent oxidative degradation is a very slow process. A pilot plant sample showed a degradation rate of 4% of MEA 30 wt.% after 45 days, when treating a flue gas containing about 5% O₂ in an absorption-regeneration loop (Lepaumier, 2008). In order to build a kinetic model of oxidative degradation of MEA, various accelerated experiments have been performed under conditions of pressure and temperature more severe than those of the pilot plant, using a Degradation Test Rig (DTR) developed at the University of Liège. The relevance of accelerated conditions is evidenced by reproducing in seven days lab experiments with similar degradation pathways as observed in CO₂ capture pilot plants (Léonard et al. 2015a).

Oxygen absorption into MEA aqueous solution can be described by two elementary processes: diffusion of gaseous O₂ through gas-liquid interface and chemical reaction with MEA taking place in the bulk of liquid phase. The oxygen mass transfer is described by the two-film theory considering a low reaction rate of oxidative degradation process. The exact reaction chemistry of oxidative degradation is not determined because of the complexity of the free-radical degradation kinetics. Based on the experimental results, Leonard et al. (2014b) proposed an apparent reaction mechanism consisting in an irreversible reaction implying the main identified degradation products. This apparent mechanism is reported in equation (3) and its kinetics is given in equation (4):

Where: R is the universal gas constant (8.314J/molK), T the temperature (K) and [O₂] the concentration of dissolved oxygen(mol/L). The value for the activation energy is given in J/mol and the pre-exponential unit is(mol/Ls)/(mol/L)^{1.46}.

3. Results

The developed dynamic model has been used to simulate the transient behavior of the CO₂ absorption process into an aqueous solution of MEA with assessment of solvent degradation. The capture rate equals about 97%. The solvent is recycled, in order to observe the solvent loss through degradation, while the gas flow is continuously fed to the absorber column. The experimental results published in literature by Aroonwilas et al. (2004) (pilot plant parameters: 30 wt.% MEA; Sultzer DX packing; absorber diameter 0.02 m, packed height 2 m) are used to validate the developed absorption model. A good correlation between experimental and simulation results with regards to CO₂ molar fraction was observed (R=0.98).

The simulation results showed 0.034 wt.% MEA degradation per day in case of 0.54 Nm³/h gas flow rate with 6 % of O₂ and 9.2 % of CO₂. The flue gas was considered to be under atmospheric pressure and at 298K. In the column, the concentration of O₂ in the gas flow and the O₂ dissolved into the liquid phase show slight variations around the values of 2.5 10⁻³ mol/L and 7.8 10⁻⁵ mol/L respectively. In Table 1, the oxidative degradation of the solvent is presented in weight % / day, for various operation conditions. As one can observe, the degradation effect is directly influenced by the increase of the oxygen concentration in the flue gas, but also by the flue gas flow rate.

Table 1. Solvent concentration variation for different operation conditions

Operation parameter	Degradation rate (wt.% /day)
Nominal values: $F_G = 1.64 \cdot 10^{-4} \text{ m}^3/\text{s}$; $C_{O_2} = 6 \text{ \%v}$; $C_{CO_2} = 9.2\text{ \%v}$.	0.034
+ 10% F_G	0.041
- 10% F_G	0.030
$C_{O_2 \text{ in}} = 8 \text{ \%v}$.	0.047
$C_{O_2 \text{ in}} = 4 \text{ \%v}$.	0.024

Figure 1. Absorber MEA concentration profile for 10% gas flow rate decrease

Figure 2. Absorber MEA output for 10% gas flow rate decrease

The increase by 10% of the gas flow rate causes a small increase in the oxygen concentration profile in the liquid, leading to an increase of MEA degradation to 0.041 wt.% per day. The O_2 concentration in the liquid and the system temperature were stabilized in 5000 s at the new steady-state, in case of 10% step change. The effect of the variation of the flue gas flow on the MEA concentration and temperature profiles in the column is showed in Figure 1 and Figure 3. For a more detailed view, the MEA output concentration is also presented in Figure 2. It is noticed that the decrease of the gas flow leads to an increase of the MEA concentration. This is not directly related to solvent degradation, but rather to the fact that when we decrease the flue gas flow, a lower absolute amount of CO_2 is absorbed in the column, leading to a larger relative concentration of MEA in the rich solvent. However, as the concentration of MEA is not considered in the kinetic model for solvent degradation, this variation of the amine concentration is not the reason for the change in the degradation rate. Instead, as can be seen in Figure 3, the modification of the gas flow leads to temperature variations in the column due to the exothermicity of the CO_2 absorption. In case of flue gas flow increase, the resulting temperature increase has two consequences. First, the oxygen equilibrium concentration in the liquid is decreased following Henry's law, and second the reaction rate of the oxidative degradation is increased. In total, following the two-film assumption with slow reaction rate in the liquid, this leads to an increase in the MEA degradation rate when the gas flow rate is increased.

Figure 3. Temperature profile in the absorber for 10% gas flow rate decrease

We also observed the effect of a change in the oxygen concentration in the flue gas, varying from 6 % to 4 and 8% respectively. A new steady-state has been achieved in 500 s after the disturbance. It appeared logically that the increase of oxygen concentration leads to more MEA degradation. The change with 2 % vol of O₂ input concentration causes a modification of ~0.010 wt% MEA degradation per day.

The predicted amount of MEA loss, in the presence of 6% of oxygen and 9.2 v% of CO₂ equals to 8.17 g MEA/t CO₂. Moser et al. (2011) report a degradation rate of 284 g MEA/t CO₂ in the pilot plant and in the absence of degradation inhibitors. Leonard et al. (2015b) report a degradation rate of 82 g MEA/t CO₂ when including the kinetic model for solvent oxidative degradation described by equation 4 in Aspen Plus steady-state model. This latter represents another pilot plant and other flue gas conditions (pilot plant described by Knudsen et al. (2011)). As a consequence, there is still a non-negligible difference between these simulation results, and also when compared with pilot plant results. The discrepancies observed between the present model and the steady-state model could be explained by the fact that in the case of our dynamic model, the inlet gas temperature of the absorber is lower than the typical gas temperature in the absorber (298 K instead of 313-323 K), limiting the degradation rate. Also some variables have been neglected in both degradation models that could explain the differences with the pilot plant results, such as the presence of impurities like SO_x, NO_x, dissolved metals and fly ash.

4. Conclusion

In this work, an existing dynamic model of amine based carbon capture has been improved and adapted by integration of the kinetic models for solvent degradation. In the model, the mass and energy balance equations of liquid and gas phases are used to describe the components concentrations and temperature profiles inside the packed column.

The developed dynamic model has been used to simulate the transient behavior of the CO₂ capture process with assessment of solvent degradation, in conjunction with integrated power plant. Typical disturbances have been investigated, such as the step increment in the flue gas flow rate with respect to its nominal operating point and the variation of oxygen concentration. The results show that the increases of flue gas flow

and oxygen concentration both lead to the increase of MEA degradation. However, discrepancies are observed between the present dynamic modeling approach and a previous steady-state model, probably due to the operating conditions of the modeled set-up so further work is required to confirm this assumption. Nevertheless, the present modeling approach may be successfully used to study the influence of varying operating conditions on the degradation of amine solvent. Further developments may include the influence of the amine concentration on the degradation kinetics. The entire absorption-regeneration loop may also be considered to study with more accuracy the process dynamics. Finally, further variations of the input conditions should be evaluated.

Abstract

Socio-economic aspects of technology implementation should be carefully examined in the design of regional energy systems. In this paper, we conducted a computer-aided socio-economic analysis on regional energy systems in isolated islands. Existing developed models were simultaneously utilized for characterizing the applicable technology options. At the same time, we analysed economic circulations induced by the utilization of locally available resources such as the residues of agriculture and forestry, which may twist the faucet of the cash effluent from the regions. A case study was conducted in an isolated island in Japan, Tanegashima, to demonstrate proposed computer-aided socio-economic analysis. The results clarified that the region-specific conditions on industrial structures can be revealed and visualized by preparing customized input-output table for the region. For the analysis of socio-economic aspects of newly installed technologies, computer-aided tools should be able to estimate the elements of input-output table based on the technological modelling with the locally customized input-output table.

Keywords: sugarcane bagasse, life cycle assessment, input-output table.

1. Introduction

The design of energy systems has become an issue all over the world. A single optimal system cannot be suggested, because the availability of infrastructure and resources should be considered locally with their social acceptability (Kikuchi et al., 2017). A computer-aided approach is necessitated for specifying possible solutions considering multiple requirements on energy such as low carbon resources, high stability, and high economic performance.

In this paper, we conducted a computer-aided socio-economic analysis on regional energy systems in isolated islands. Existing developed models on sugar mill (Ouchida et al., 2017) and wood-chip derived power generation (Kanematsu et al., 2017) were simultaneously utilized for characterizing the applicable technology options. At the same time, we analysed economic circulations induced by the utilization of locally available resources such as the residues of agriculture and forestry, which may twist the faucet of the cash effluent from the regions. A case study was conducted in an isolated island in Japan, Tanegashima, to demonstrate proposed computer-aided socio-economic analysis.

2. Materials and method

2.1. Requirements of socio-economic analysis in regional energy system design

As the elements in technology assessment, the relationships among sociosphere, econosphere, and technosphere are taken into account. Figure 1 schematically shows the elements of technology assessment represented as spheres related with technology implementation. Sociosphere includes the social systems and their thinking ways such as security, lifestyles, and health motivated or incentivized by general values and norms. Econosphere is composed of multiple-scale economy, e.g., industrial, regional, national, and global economy, which can be represented as their cash flows based on profitability of industrial activities. Technosphere means more technology-based systems which can be represented as mass or energy balance based on their conversion and efficiency originating from the mechanisms on natural sciences. Politisphere can be related with all other spheres by regulating the activities in technosphere based on the public benefits. These spheres have been recognized as the interfaces of interdisciplinary research to frame the actual situation for implementing novel factors such as marketing-natural environment (Neace, 1995), entrepreneurship ecosystems (Frederick, 2011), and interpretation of quantified environmental impact by life cycle assessment (LCA) (Hofstetter, 1998).

In micro-communities, the social aspects are important for renewable energy systems (Neves et al., 2014), the quantification of which can be conducted partly by contingent valuation methods, such as willingness to pay (Stigka et al., 2014). Sociotechnical research can provide wider feasibility checks on the outcome of technologies (Geels et al., 2017). The “feasibility” of technologies and systems has various aspects from technological, economic, and social viewpoints. The phases of technology development represented by technology readiness level (e.g., Australian Renewable Energy Agency, 2014) or technology implementation (Kaya and Okuwada, 2015) point out such feasibility. For example, the technological feasibility should be checked in multiple scales of production: laboratory, bench, and demonstration scales. The economic feasibility, including micro and macro level, should also be confirmed after demonstration experiments before commercialization. The social feasibility, generally represented as social acceptability and preference, is necessitated for letting the technologies and systems embedded in society, which is needed for radical innovation such as deep decarbonization (Geels et al., 2017). At that time, the general input-output tables (IO-tables) adopted in existing models for energy systems analysis such as the MARKAL (ESTAP, 2017) is not appropriate for the detail analysis in regional systems because the industrial structures are individually different from region to region.

Especially, the central industries in regions should be carefully considered in socio-economic analysis to visualize the effects of technology implementation. However, the construction of IO-table specified for a region requires a plenty of efforts to survey the sufficient quantity of data with adequate quality.

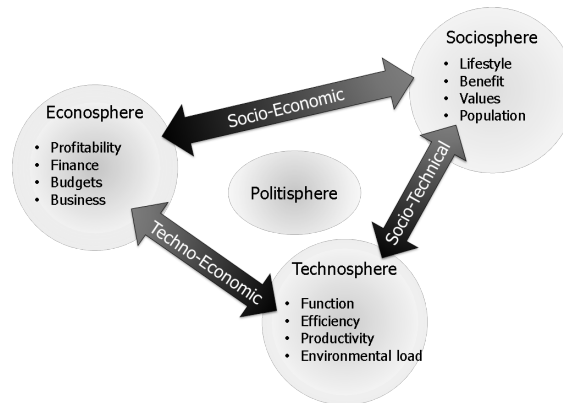

Figure 1 Spheres to be considered for energy system design

2.2. Case study in Tanegashima, Japan

Tanegashima is one of remote islands in Kyushu area of Japan that have independent electricity grids from four main islands of Japan. The power mix is mainly composed of diesel engines, the power generation costs of which are relatively higher than the other areas in four main islands in Japan due to the transport of fuels from oil refinery in main islands and technical staffs for maintenance, and so on. In such region, the social issues on energy security and depopulation have become critical rather than the most of other areas in Japan. A revitalization of the region has been strongly necessitated.

Several projects on energy systems in Tanegashima have been launched. The cane sugar mill at Tanegashima has a possibility to produce power and heat for the regional energy systems utilizing the excess bagasse (Ouchida et al., 2017) and unused woody biomass (Kikuchi et al., 2016). Woody biomass can also be utilized for the small- and medium-sized combined heating and power production (CHP) considering the available timber supply inside of Tanegashima (Kanematsu et al., 2017). The waste cooking oils had been converted into biodiesel by conventional wet-processing methods in Tanegashima and are applied into the demonstration experiments of solid catalyst method, a novel biodiesel production method (Chen et al., 2017). Regarding cane sugar mill, especially, the preferences of residents to the utilization of their unused sugarcane-derived resources are relatively high (Kikuchi et al., 2017). In addition to the previous studies on the techno-economic (Ouchida et al., 2017) and sociotechnical (Kikuchi et al., 2017) analyses on the advanced use of biomass-derived CHP installed at cane sugar mill at Tanegashima, a socio-economic analysis based on the Tanegashima-customized IO-table is conducted in this paper.

The customized IO-table for Tanegashima was constructed by the modification of IO-tables of Okinawa prefecture, Kagoshima prefecture, and whole Japan with the investigation of actual financial statements of industries. The changes of internal production and added values induced by the power generation based on the mixed bagasse and woody biomass, and biodiesel production were calculated by existing

developed models for material and energy flows in cane sugar mills (Ouchida et al., 2017) and their applicability as industrial symbiosis (Kikuchi et al., 2016), the temporal profile of locally available foresee resources considering sustainable foresee management toward leveled age class distribution in Tanegashima (Kanematsu et al., 2017), and biodiesel production with ion-exchange resin catalyst process (Chen et al., 2017). Note that the IO-table of Tanegashima has some uncertainties in the values due to the limitation of data availability. The calculation includes the effects of the cultivar shifting, ethanol production from molasses fermentation, biomass-derived power production, and biodiesel production from waste cooking oils.

3. Results

Figure 2 schematically show the results of analysis on the technologies in cane sugar mill. The power capacity at cane sugar mill can be higher than the half of maximum capacity by utilizing excess bagasse and currently available woody biomass (Kikuchi et al., 2016). This can be increased over 1,500 kW considering the shift of sugarcane cultivars (Ouchida et al., 2017) and the possible timber supply in sustainable forest management (Kanematsu et al., 2017). The shift of sugarcane cultivars can decrease the life cycle greenhouse gas (GHG) emissions by replacing the electricity from power grid (Ouchida et al., 2017) and enhance the profitability of sugarcane industries (Ouchida et al., 2017). The consumer preferences on renewable resources indicate the higher preferences to bagasse in Tanegashima (Kikuchi et al., 2017).

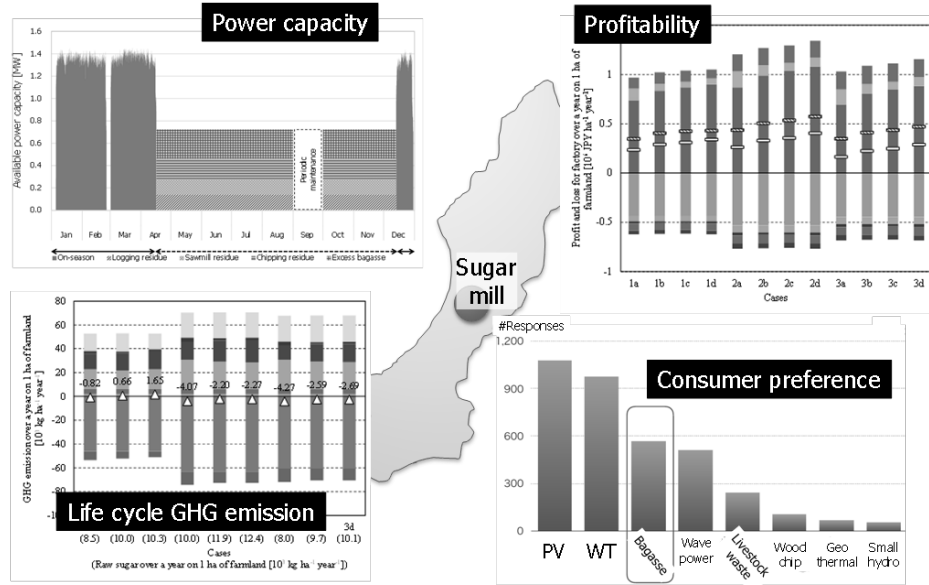

Figure 2 Previous analyses on the energy systems surroundings of cane sugar mill at Tanegashima; The combined heating and power production from cane sugar mill utilizing excess bagasse (Ouchida et al., 2017) and wood chip (Kikuchi et al., 2016).

Figure 3 shows the preliminary calculation results of the changes of the internal production and added values induced by the technology implementation in Tanegashima.

The biomass-derived power utilized excess bagasse and woody biomass. The cultivar of sugarcane was also shifted from NiF8 to NiF18 (Ouchida et al., 2017). The results indicate the increase in internal production and added values of sugarcane sector by this cultivar shift. Although it leads to the increase of internal production of raw sugar, the added value of raw sugar was decreased. This is because the current subsidies for raw sugar production in Japan was increased by the increase of sugarcane harvesting. The net of such positive and negative effects reached positive. This is nation-specific condition on production. Additionally, the power grid decreases the internal production, but increase the added value. This is a region-specific condition in Tanegashima and other remote islands. The electric power companies operate their power plants as deficit production, which needs the deficit covering from their other branches in other regions, i.e., the main island of Kyushu, Japan. The decrease of production lead to the increase of added value at Tanegashima.

Figure 3 Input-output analysis of the changes in internal production and added values induced by the technology implementation in cane sugar mill at Tanegashima.

4. Conclusion

The socio-economic analysis should be based on the region-specific conditions. General methods of socio-economic analysis cannot deal with such detail facts of energy systems. Our results clarified that the region-specific conditions on industrial structures can be revealed and visualized by preparing customized input-output table for the region. For the analysis of socio-economic aspects of newly installed technologies, computer-aided tools are needed to estimate the elements of IO-table based on the technological modelling, which can take into account the novel technology implementation. At the same time, the locally customized IO-table is also prepared for the detail analysis of socio-economic aspects of technology implementation by dividing or modifying generally available IO-tables normally including multiple local government and regions.

Abstract

The effective utilization of sewage sludge has attracted increasing attention, so various technologies are under vigorous research and developments. However, the discussion of general applicability and effectiveness of those technologies throughout diverse regions are not sufficient due to the limitation of regional data of existent sewage sludge treatment plants (STPs). A technological simulator was constructed which can characterize 149 technology scenarios and regional parameters of a thousand STPs located in Japan were prepared by utilizing statistics and the geological information system application. The analysis of sewage sludge treatment considering regional, social, and technological characteristics was performed with the index of life-cycle greenhouse gas emission by inputting prepared parameters of each STP into the constructed simulator. It was revealed that each technology has different performance according to the regional characteristics. The importance of considering actual regional characteristics was suggested.

Keywords: Sewage sludge utilization, Resource recovery Regional analysis, LCA, GIS

1. Introduction

The effective utilization of sewage sludge has attracted increasing attention as it is ubiquitous biomass and contains many useful ingredients like carbon and phosphorus, each of which can substitute exhaustible fossil fuels and phosphorus rocks, respectively. Other than simple incineration or landfill, there exists many emerging technologies and system options for utilizing the sludge. Between the alternative options, various kinds of trade-offs are often observed; some other options reduce the amount of greenhouse gas (GHG) emission at the sludge treatment plant (STP) but increase GHG at the landfill site. To discuss such trade-off quantitatively, life-cycle-based analyses have been often conducted (Pasqualino et al., 2009). Such analyses need inventory data for each scenario. In preparing many sets of inventory data for the analyses, simulation-based approaches are helpful because they can complement data of hypothetical scenarios and even save much time and money which are necessary for actual surveys.

As for utilization of biomass, analysis and discussion should be conducted according to the regional characteristics as the optimum option is dependent on each plant. (Kikuchi et al., 2015). However, most conventional researches assessing technologies for sewage sludge utilization were conducted by only considering specific regional conditions

(Mills et al., 2014), so quantitative discussion about the effect and importance of regional conditions was hardly performed. It seems that one of the biggest barriers is difficulty of collecting regional characteristics. Instead of collecting regional data manually or assuming regional parameters, accessing statistics and calculating by the geological information system (GIS) application leads to more granular information with less workload. Although the applicability and effectiveness of the GIS application in assessing alternatives options were mentioned (Goulart et al., 2017), few researches adopted GIS for data collection so far (Tampio et al., 2017).

In this study, 149 kinds of technology scenarios were generated by combining conventional, emerging technologies whose technological parameters were extracted from dozens of patents, papers, reports etc. Technological characteristics were synthesized into the technology simulator for assessing life-cycle GHG emission (LC-GHG) of each technology scenario. Parameters sets of each STPs which reflect regional and social characteristics in Japan were obtained from statistics, GIS calculations. Those parameters sets were input to the technology simulator to analyse the performance of technology scenarios at each STP.

2. Materials and method

2.1. Definition of requirements for the technological simulator and regional parameters

First principle of sludge treatment is detoxifying by treatments such as landfilling. Besides, incineration, anaerobic digestion and composting have been conducted to reduce the volume and odor of sludge conventionally. For further efficient utilization, various technologies are under research and development such as pyrolysis gasification, incineration power generation, etc. (Rulkens 2008) and phosphorus recovery from sludge, returning water, ash etc. (Cieslik and Konieczka, 2017). Simulation-based approach is effective to conduct iterative analyses in considering many kinds of scenarios and many sets of parameters of STPs.

It is well known that processes such as anaerobic digestion or dewatering change the condition of sludge and those changes affect the efficiency of subsequent processes. Therefore, each process should not be regarded as independent, but rather, subordinate to previous processes. Hence, the simulator for analyses should incorporate each technology option as unit process which calculate the conditions of processed materials based on the parameters of input materials to the process.

One of the most important parameters which affect the performance is the scale of STP as there are huge scale merits in power generation efficiency or construction. Besides scale, transportation distance to facilities which utilize sludge-derived products is regarded as an important parameter. In addition, temperature at each region affects the amount of heat needed for anaerobic digestion or other thermal processes and concentration of phosphorus and nitrogen in sludge also affect the collection rate of phosphorus recovery, the burden of returning water. These are regarded as distinctive parameters to each STP, so considered in the analyses below.

As for assessing GHG emission, LC-GHG emission from construction of equipment, consumption of chemicals, electricity, heavy oil, transportation, landfilling and deduction of sludge-derived products are considered in addition to actual emission of CH₄ and N₂O through each process. It is reported that dismantling comprises less than 2 percent of whole LC-GHG, so dismantling was excluded from consideration in this study.

2.2. Construction of the technological simulator and requirements for regional parameters

The adopted technologies are following: anaerobic fermentation, thermal hydrolysis of excess sludge, 2 dewatering methods (using organic with and without inorganic coagulants), 5 sludge stabilization methods (incineration, pyrolysis gasification with power generation, fuelization, composting, slagging), 4 phosphorus recovery methods (magnesium ammonium phosphate (MAP) recovery from digested sludge or returning water, hydroxyapatite (HAP) recovery from returning water or ash). Descriptions of some technologies are as follows. Dewatering by organic and inorganic coagulant leads to lower moisture content, but more phosphorous precipitates. Thermal hydrolysis improves the digestion rate of excess sludge but consumes much energy to increase the temperature of excess sludge to 170 °C. Dewatered sludge is dried by consuming heavy oil in fuelization, which produce coal-substituting fuel used in coal or biomass power plants. To analyse the result of each combination of technologies quantitatively, every technology was modelled to calculate the condition of sludge after treatment at the technology.

Process flow and the analysis boundary of sewage sludge treatment in the simulator is shown in Figure 1. 149 technology scenarios were generated by combining each technology. All utility input, output, transportation load and emission are counted from treating thickened sludges to the utilizing products or landfilling in each scenario. Technological characteristics were collected from various papers (Nakakubo et al., 2012), patents, literatures and reports (MLIT, 2015). To convert inventory data into LC-GHG, a variety of databases were referred (Nansai and Moriguchi, 2012, AIST and JEMAI, 2016, Swiss Centre for Life Cycle Inventories, 2010). Integrating the models of technologies, the simulator was constructed on the application soft of “Microsoft® Excel®”.

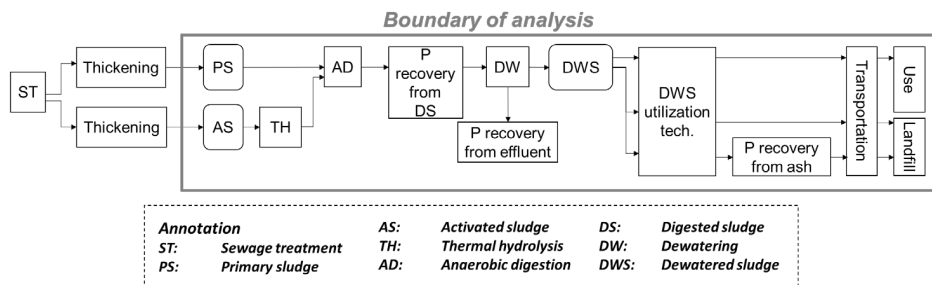

Figure 1: Process flow and the analysis boundary of sewage sludge treatment

Table 1: Parameter sets of two STPs.

STP	Distance to nearest facility		Annual average temperature of sewage	Primary sludge		Activated sludge		Total nitrogen amount
	Landfill site	Biomass/coal power plant		Total amount	Phosphorus amount	Total amount	Phosphorus amount	
[–]	[km]	[km]	[°C]	[t-DS/year]	[kg/year]	[t-DS/year]	[kg/year]	[kg/year]
A	27.92	5.24	14	2842	1407	745	5630	80225
B	4.76	4.68	15	183	1385	22	4399	32020

2.3. Preparation of parameters of each STP and synthesis into data sets

Data of the amount of and concentration of phosphorus, nitrogen in primary and activated sludge, water temperature was obtained from statistics (JSWA, 2016), some of which were calculated by considering the mass balance between input sewage and discharge water. Distances between each STP and facilities of using sludge-derived products were calculated by using “Esri® Arc GIS®” as follows. Firstly, positional information of STP, coal power plants and landfill sites was collected using the constructed database (MLIT, 2012). These parameters are thought to reflect regional and social characteristics around each STP. Prepared parameter sets of two STPs are shown in Table 1.

3. Results and discussions

3.1. Results of simulation

LC-GHG of 149 technology scenarios at a thousand STPs are calculated. Here, two STPs whose parameter sets are described in Table 1 are chosen as examples for brief explanation of the results (Figure 2). As shown in Figure 2, the GHG of each scenario and at each STP has different value. Generally, GHG values of scenarios are smaller in STP A than in STP B which is thought to be because of the scale merit. This is consistent with conventional knowledge about sludge treatment facilities. However, at the same time, some scenarios like scenario 75 and 128 have almost the same GHG values, which imply that scale merit of those scenarios are not significant as those two scenarios comprise technologies which need lower capital investment. Such differences of tendency can be observed throughout the simulations.

Figure 2: GHG emission of each technology scenario. (left: STP of A, right: STP of B)

Table 2: GHG emission of 4 technology scenarios at STP A and B.

Scenario	0	3	7	11
STP	[10 ³ kg-CO ₂ /t-DS]			
A	1.43	1.24	0.98	1.05
B	2.13	2.34	2.01	1.67

For further discussion, GHG values of some scenarios are listed in Table 2. Scenarios referred here are as follows; scenario 0 is the one of simple incineration after dewatering by only organic coagulant. In scenario 3, the process of anaerobic digestion and power generation by using methane is added to scenario 0. In scenario 7, the process of hydrothermal treatment before digestion to promote anaerobic digestion is still more

added to scenario 3. Scenario 11 replaces the dewatering process of scenario 0 with dewatering using organic and inorganic coagulants together.

Comparing the values of GHG emission at STP A and B, all scenarios give lower values to STP A with bigger sludge scale which is alike the tendency in Figure 2. Introducing anaerobic digestion can reduce GHG emission at STP A, but rather increase at STP B. At STP A, combining hydrothermal treatment with anaerobic digestion further decreases GHG emission. Even though only anaerobic digestion increases GHG emission at STP B, anaerobic digestion with hydrothermal treatment can reduce GHG emission. Dewatering using organic and inorganic coagulants together lead to less moisture content in dewatered sludge, which can reduce electricity and heavy oil consumption at incineration process. Thanks to these merits, both STPs can receive benefit from substituting the method of dewatering. Interestingly, the scenario which gives the lowest GHG emission among the 4 scenarios is different to each STP; scenario 7 is the lowest at STP A and scenario 11 is at STP B.

3.2. Discussions

From the results of simulations, it seems that regional and social characteristics affect the effectiveness of the technology, and optimum technology scenario varies at each STP. These results based on detailed regional characteristics are informative not only for actual decision-making of each STP to opt out technologies, but also for the companies, researchers to acknowledge what kind of technologies are appropriate, needed nation-widely. Extensive discussions of other technology scenarios, other indicators, and at other STPs are currently coped with and to be reported soon.

The approach adopted in this study makes it easy to extend the subjects of assessment by using simulation-based and statistical data, once the simulation structure is constructed. However, there needed many assumptions to perform analysis because of lack of statistical data of each STP and research time limitation; composition of sludge was calculated partly using the uniform value taken at the specific STP, the assumption that facilities around STP can accept whole sludge in each technology scenario was adopted etc. To improve the accuracy of simulations, these assumptions should be reviewed, discussed, and agreement should be built among the researchers. At the same time, maintaining databases for regional assessments should be promoted, especially in developing countries to induce development and installation of appropriate technologies in each place.

4. Conclusions

We analysed the LC-GHG of various technology scenarios at a thousand STPs in Japan by combining the technological simulator and prepared parameter sets of each STP. It was revealed that parameters which reflect social and regional characteristics certainly affected the LC-GHG of each technology scenario. Different optimum scenarios at each STP are different are partly discussed quantitatively in this report. These knowledges would be informative not only for actual decision-makers at each STP, but also for researchers and ministries who conduct research and subsidize various technologies. For refined research using regional data, it is implied that maintaining precise databases is needed.

Abstract

In pulp and paper production black liquor is burnt to recover base chemicals and to generate electricity and steam which is e.g. used in papermaking machines. In the event of paper tearing excess steam has to be condensed usually. We propose a latent thermal energy system to recover that energy and re-use it in the papermaking machines. A storage model was developed and experimentally verified by a lab-scale prototype. For the specific process, we designed a tube-bundle storage using thermally conductive HDPE as PCM and show that up to 30 MWh can be recovered per day. Finally, we describe the potential of storages to improve energy generation and efficiency in plants.

Keywords: pulp and paper, steam, latent heat storage, process integration, simulation

1. Introduction and Motivation

In pulp and paper production black liquor is a waste product resulting from the kraft process. To recover the base chemicals (NaOH, NaS) and the energy contained within the dissolved carbon compounds, the substance is burnt. The resulting steam is employed to produce electricity and in different processes (see section 4). Roughly half of the steam extracted from the turbine at 3 bars and 150 °C is used at the papermaking machines. Thus, in the event of paper tearing a large amount of excess steam cannot be utilized and has to be cooled in an auxiliary condenser.

In total 319 events per year with a maximum of 200 tons occurred at Smurfit Kappa Nettingsdorfer (SKN) (Figure 1). In 77 % the amount of excess steam was below 55 tons, which will be used as sizing input for the thermal storage system. The insert shows that excess steam events occur roughly once a day and last for up to a few hours with a maximum mass flow rate around 55 tons/hour and an average of 22 tons/hours.

The main idea to improve the efficiency of the plant is to store the energy contained in the excess steam instead of condensing it. We propose a latent heat storage system capable of storing that energy to generate steam at a later time. When the papermaking machines resume production after a paper tearing event, our systems adds additional steam to reduce the shutdown period, increase production capacity and save energy.

2. Latent Heat Storage

Making use of the high phase change enthalpy between melting and solidification, one can design energy storages with high thermal capacity. Since 2013 AIT investigates new phase change materials (PCMs), heat exchangers (HEX) and PCM storages based

on polymers. Especially high density polyethylene is a promising candidate because of several advantages (C. Zauner (2016), C. Zauner (2017), Marx (2017)). Recent work within the project StoreITup-IF shows promising results for the development of thermally conductive polymers suitable for PCM storages (H. Weingrill (2016)). For such materials, one can use a tube bundle heat exchanger and still achieve excellent storage power, which will be shown in more detail below.

Figure 1: Histogram of excess steam at SKN that had to be actively cooled in the auxiliary condenser. Insert: Annual distribution of events and steam mass flow rate to the aux. condenser.

To be able to design the storage, we developed a 3-dimensional node model consisting of the following physical relationships (Figure 2):

- A lumped capacitance model using a Gaussian distribution describes the HDPE phase change material at each node with appropriate constants c_i :

$$\frac{dQ_{pcm}}{dt} = m_{pcm} c_p \frac{dT_{pcm}}{dt}, \quad c_p(T) = c_0 + c_1 + c_2 \exp\left(-\frac{1}{2} \left(\frac{T - T_{phch}}{\sigma}\right)^2\right) \quad (1)$$

- Heat transfer between two adjacent radial PCM-nodes i and $i+1$ is modelled by conduction (convection can be neglected due to the high viscosity):

$$\frac{dQ_{i+1-i}}{dt} = 2\pi l \lambda_{PCM} \ln\left(\frac{r_{i+1}}{r_i}\right) (T_{i+1} - T_i) \quad (2)$$

- The heat transfer between the tube and the heat transfer fluid is modelled using well-known correlations from literature (VDI 2010).
- In addition, the tubes are longitudinally discretized and connected in series.

A lab-scale prototype filled with roughly 100 kg of HDPE was designed, built by a subcontractor and characterized at the thermal storage test lab at AIT (Figure 2). Thermal oil was used as heat transfer medium. The energy and power characteristics were calculated from measured inlet and outlet temperatures as well as mass flow. Figure 3 shows the characterization results for a step response as well as a comparison between measurements and simulation. Excellent agreement was achieved and proves that the model can be used for storage design as was intended.

Figure 2: Lab-scale prototype (left) and schematics of the storage model (right).

Figure 3: Power characteristics, stored energy of the lab-scale storage prototype for a discharging step response. Solid lines represent measurements and dashed lines simulation results.

3. Waste-to-Energy System using Latent Heat Storage

Based on the plant data presented above, we designed a latent heat storage system that is capable of storing the energy contained in 55 tons of steam (150 °C, 3 bar) which would otherwise have to be cooled by the auxiliary condenser (Figure 4, left).

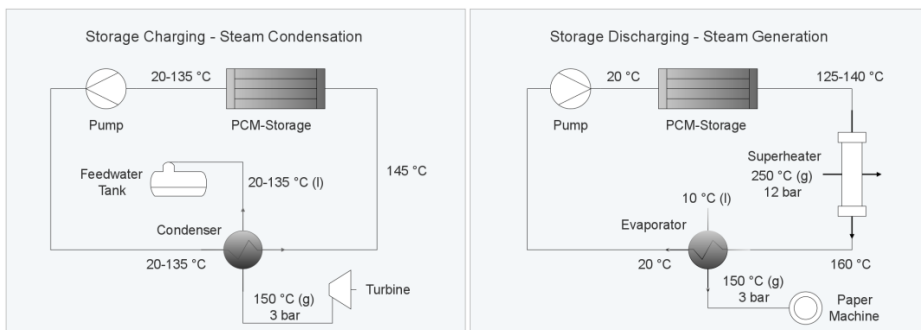

Figure 4: Left: Schematics of the system for charging the PCM storage with excess steam in the event of paper tearing. Right: Schematics of generating steam by discharging the storage.

The system was modelled and simulated in Modelica/Dymola. We use pressurized water in the storage loop to transfer a constant power of 15 MW from a condenser into the storage (charging: Figure 5). As PCM we use a thermally conductive HDPE (10

W/mK). The mass flow within the storage loop has to be controlled as shown to condense a constant excess steam flow of 22 tons/hour. The condensed water is transferred back into the feedwater tank to retrieve the remaining energy. Within this process of charging, the different layers of PCM are subsequently molten (observe the plateau around 130 °C) and heated from 20 °C to about 140 °C.

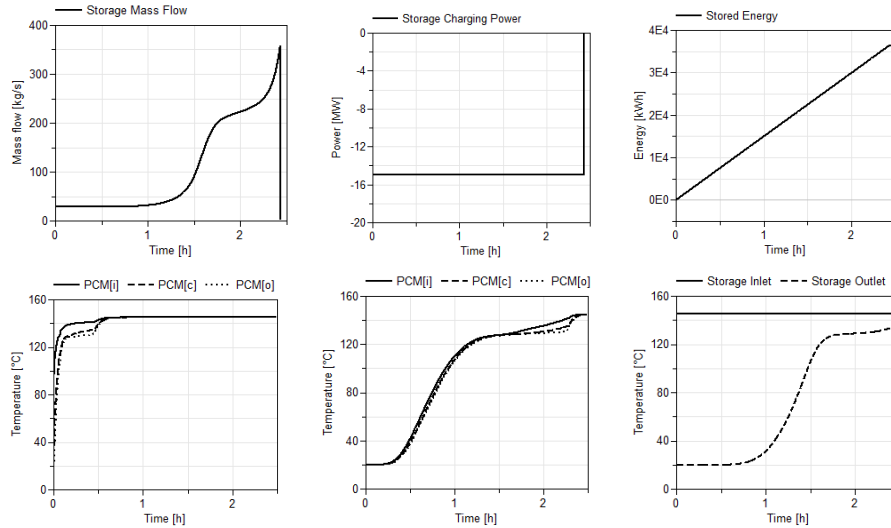

Figure 5: Bottom left: PCM temperatures close to the inlet of the storage (i...innermost node close to the tube, c...center node, o...outermost node). Bottom center: PCM temperature at the center of the storage.

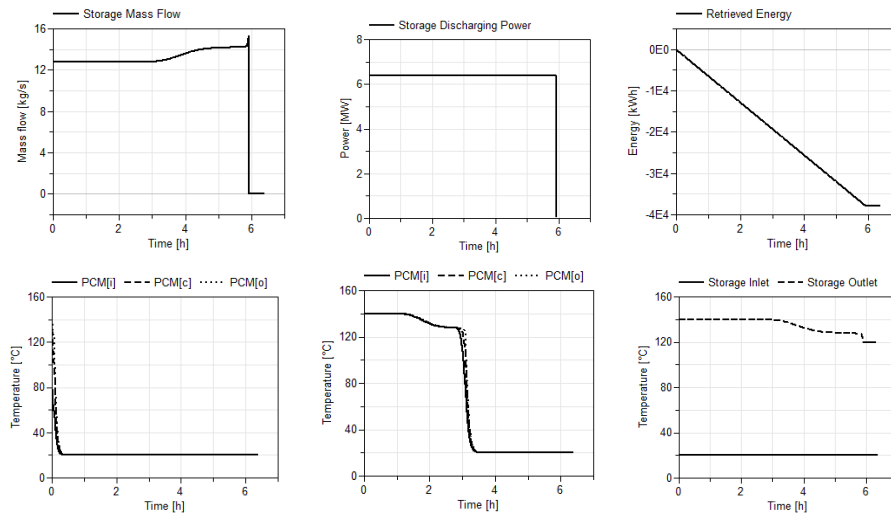

Figure 6: Bottom left: PCM temperatures close to the inlet of the storage (i...innermost node close to the tube, c...center node, o...outermost node). Bottom center: PCM temperature at the center of the storage.

In order to generate steam, the system on the right-hand-side of Figure 4 is used. The storage is discharged (Figure 6) using a constant inlet temperature of 20 °C which is heated up to 125 – 140 °C by crystallizing the PCM. A superheater fed by high pressure steam from the turbine is employed to heat the pressurized water further up to 160 °C. Adjusting the mass flow, a constant storage discharging power of 6.4 MW can be achieved, which is supplemented by 1.1 MW from the superheater. Thus, in this particular scenario, one can generate 10 tons/hour of steam (150 °C, 3 bars) over a period of roughly 6 hours, which can be used elsewhere (e.g. paper machines).

Table 1: Summary of PCM storage characteristics

	Energy [MWh]	Power [MW]	Amount of Steam [t]
Charging	36.4	15	55
Discharging	37.8	6.4	60 ¹
¹ The difference between charging and discharging is due to the energy supplied by the superheater.			

4. Steam Utilization

A typical integrated paper production process including waste-to-energy utilization starts with pulp production (screening, chip piles, digesters), proceeds to the pulp washing and storage (evaporation), the recovery paper treatment (pulper, screening) over the refining to the paper machine (wire-press-dryer section, pop roller, winder) different energy systems namely lime kiln, black liquor steam generator, and a 3-pass shell steam boiler are installed as energy supply system to fulfil the overall thermal and electricity energy demand. The black liquor steam generator is the base energy supply for the thermal and the electricity demand whereas the 3-pass shell steam boiler acts as peak load boiler.

According to Austropapier (2017) the end energy use in the industrial sector pulp and paper is 15700GWh per year with an electric portion of 33% and a sector share in industrial energy use of rd. 18%. The mechanical digestion (groundwood) 1100-1200 [kWhel/t] and thermo-mechanical digestion (mechanical pulp) 1800-3600 [kWhel/t] are one of the electrical major process-specific key figures in the papermaking process, ECJR (2015). One of the thermal major process-specific key figures are the paper machine (thermal energy input for drying processes in the paper machine and for the after-treatment steps) with 1200 [kWhth/t] and chemical digestion and black liquor recycling with total 1400-2100 [kWhth/t] (ECJR (2015)). Within the chemical digestion any flexibility measures by implementation of thermal energy storages (TES) is possible as a result of high thermal energy demand and batch process mode (ECJR (2015)). Some process integration options in the pulp and paper industry for energy system enhancing are discussed in Pettersson (2003) and Söderman (2003); any synthesis could be performed using pinch-analyses or optimization methods. On one hand side during paper production the required heating demand varies significantly and often abruptly. On the other hand side the overall paper process design specifies and restricts the flexibility and load change behaviour. As one major part the boiler construction design plays an important role. Any flexibility causes the change of pressure and therefore ideally the saturated steam temperature resulting in stresses to comply all permissible gradients in thick-walled components and limit values on the system (Hofmann (2014)).

TES can therefore contribute ideally to ride-through (bridging power failures), power quality (compensation of voltage fluctuations), energy management (decoupling of production fluctuations), and peak shaving. Thus the start-up process of the overall system (paper mill and steam boiler) may be speeded-up to decrease any production outages. Based on the examinations in Hofmann (2014), it is possible to provide parameters to optimally design the load change and start-up process of a peak load boiler. There are many parameters during a start-up/load change process to be fulfilled and it is often helpful to carry out a comprehensive FEM calculation (stress range, safety etc.) alongside an EN12952-15 calculation in combination with a temperature difference measurement device built-in into the e.g. drum shell to assign the permissible temperature differences to the current pressure to ensure compliance (Hofmann (2013)). To smoothening the steam extraction and reduce fatigue loads of components caused by cyclic loads (permissible stress ranges) TES can be ideally integrated into the process by additionally reducing the heat input of the peak load boiler significantly.

5. Conclusions

We developed a latent heat storage system that can be used to retrieve energy in the event of paper tearing in a pulp and paper plant. A storage model was experimentally validated and employed to recover up to 30 MWh per day. Finally, we showed how storages can be used to improve energy efficiency and generation.

Abstract

This paper studies technological pathways in the refinery sector, such as fuel switching, carbon capture and storage (CCS), energy efficiency as well as retrofit decisions (i.e. upgrading, scaling-up, and equipment modernisation) with the aim of decarbonisation. A global refinery outlook is presented for a 2.5 °C and 2 °C climate target scenario from 2010 through to 2050. The results highlight that a full portfolio of technologies (non-conventional processes, gas-/coal- based, with/without CCS, and biomass- based process) is necessary. Among the conventional refineries, only the most efficient ones or those investing in CCS to increase competitiveness and reducing emissions, can stay in the market.

Keywords: refinery, energy, emissions, carbon capture and storage.

1. Introduction

Refinery is responsible for 6 % of the total global CO₂ emissions (Brown, 2010) and represents one of the largest energy consumers. Although the carbon emission reduction targets in transport fuels (EC, 2009, EPA, 2007), have affected the operating strategies of many facilities as well as stimulated new investments in biorefineries (IEA Bioenergy Task 42, 2009, Mathews, 2008), the sector needs to undergo huge changes to address the challenges of decarbonisation. CCS is also deemed to play a fundamental role in this transition (IEA, 2016 (a)). In this regard, the investors's risk-aversion makes the diffusion of novel and expensive technologies more difficult.

Refineries have aimed at increasing their competitiveness in many ways, from the economies of scale to the equipment modernisation (Oil & Gas Journal, 2017). To capture the variety of industrial strategies for competitiveness in a carbon-constrained world, this paper examines the potential pathways for decarbonisation in terms of fuel switching, CCS, efficiency improvements, and typical retrofit decisions such as upgrading, scaling-up, and equipment modernisation. The analysis is carried out using a simulation approach where investors decide according to the profitability of the assets.

2. Methodology

Among the considered technologies, conventional refineries dominate the existing assets and are available in many configurations. They are classified according to the

number of processing units: distillation (atmospheric or vacuum), catalytic cracking, thermal cracking (delayed cooking or visbreaking), and hydrocracking leading to eight different refinery types (Table 1). For example, A only consists of a distillation unit; E adds a thermal cracking unit which enables the processing of different fuel types; C has the most complex configuration as it includes all the possible process units.

Table 1. The conventional refinery types

Type	Distillation	Thermal	Catalytic	Hydro	Refinery, Location	Crude Oil	Upgrade options

X: available; -: not available

As shown in Table 1, a prototype was selected to characterize the techno-economic parameters (i.e. product yield, carbon emission, capital costs, variable costs, fixed costs, and efficiency) of all refinery types (IEA 2016 (b), Gary, 2007, Maples, 2000). Every refinery type differs in terms of cost, output share, as well as fuel used (light, medium, and heavy oil) and can make specific investment decisions. While all the refineries can decide to modernize the equipment, scaling-up or investing in CCS, the upgrade to a more complex configuration is applicable to all refineries but type A and C. While scaling-up and modernization can increase the capacity or replace the aging processing units to extend lifetime, upgrading improves the performance of the refining process or reduces its emissions by adding CCS. The capital cost for retrofitting was derived by excluding some construction costs such as cost of establishing a company, the land and layout costs (for modernizing), the recruitment, training and start-up costs (for modernizing and scaling-up) (Favennec, 2001). The cost for upgrading was calculated by the difference between the cost of the more complex refinery and the cost of the current refinery.

3. Biorefinery and Refinery Sector Model within MUSE

MUSE, the ModULAR energy systems Simulation Environment, is an energy systems modelling framework designed to enable long-term analyses of the energy system transitions (S. Giarola, 2017). MUSE is a partial equilibrium model based on microeconomic foundations. It applies a modular approach to the modelling of the energy systems where the specific drivers of investments and operation are tailored to represent that observed in each specific energy sector. In its global version, MUSE models the global energy systems (i.e. including demand, transformation/conversion

and supply sectors) with a geographical disaggregation into 28 regions. Within the MUSE framework, the biorefinery and refinery sector model (BRMS) belongs to the conversion sectors which link supply and demand by transforming primary fuels to secondary fuels. The main focus lies on the production planning and capacity investments of the sector. Each technology is modelled using a bottom-up approach based upon the definition of the specific techno-economic and environmental characteristics for each of the 28 regions of MUSE. The initial stock in the base year and its decommissioning profiles are defined exogenously; forward demand of fuels, prices of primary energy commodities and carbon are dynamically exchanged with the core algorithm of MUSE. For an accurate determination of the production planning on long-term investment decisions, the BRMS uses a two-step simulation approach (Figure 1) to model investment decisions and operating strategies in the market. To capture the wide technology range in the refinery sector 39 plant types are considered and given in Table 2. This list is limited to existing fuel production routes where future productions paths, e.g. using solar energy, are not considered

Table 2 Refining technologies considered in BRSM MUSE

Conventional Refinery		Non-conventional Refinery	Bio-based Refinery		
1.	Refinery A	17.	GTL: Fischer-Tropsch	26.	BTL Direct

11.	Refinery C + CCS			36.	Landfill to biogas
12.	Refinery D + CCS			37.	Biomass to biogas + upgrade
13.	Refinery E + CCS			38.	Biomass to biosyngas
14.	Refinery F + CCS			39.	Biomass to biosyngas + upgrade
15.	Refinery G + CCS				
16.	Refinery H + CCS				

In the first step, the BRSM is designed to model the production of secondary energy commodities, including petroleum and non-petroleum products as well as biofuels.

A merit-order approach based on plant Gross Margin, representing the portion of each dollar of revenue that the company retains as gross profit, is used. The decision metric is calculated by

$$Gross\ Margin = \frac{\sum_i^N X_i P_i - \sum_j^M X_{con,j} P_j - X_c CP}{\sum_j^M X_{con,j} P_j} \quad Eq. 1$$

where $P_{i/j}$ is Price of product i/j ; X_i is amount of product i ; $X_{con,j}$ is the amount of input productions consumed; X_c is the CO2 emission; CP is the CO2 price. Based on the mix of technologies used, the required amount of primary energy commodities, the emissions and the market price of secondary fuels are determined.

In the second step, the BRMS estimates the capacity expansion required to meet the commodity demand and the potential profitability of a refinery upgrade, considering the decommissioning profile of the existing stock and simulates the operation of an asset as well as the consumption of primary energy. The investment decision is determined by looking at the future demand and available stock of refineries for a pre-defined number

of years ahead (typically 10). All potential new technologies and upgrading decisions are considered one by one in comparison to the existing technologies. An algorithm that determines the production of all refineries based on the current demand is carried out to determine the net present value (NPV), representing the profitability over the refinery lifetime, given for the possible set of new technologies. The NPV of each plants is calculated as

$$NPV = \sum_{t=1}^T \frac{C_t}{(1+r)^t} - C_0 \quad \text{Eq. 2}$$

where C_t is cash flow, C_0 is the capital cost, and r is the interest rate. All potential new technologies and upgrading decision are further ranked according to their NPV and one by one considered for commissioning. New plants are directly added to the system where retrofitting will be commissioned if it can increase the profitability of the corresponding existing assets.

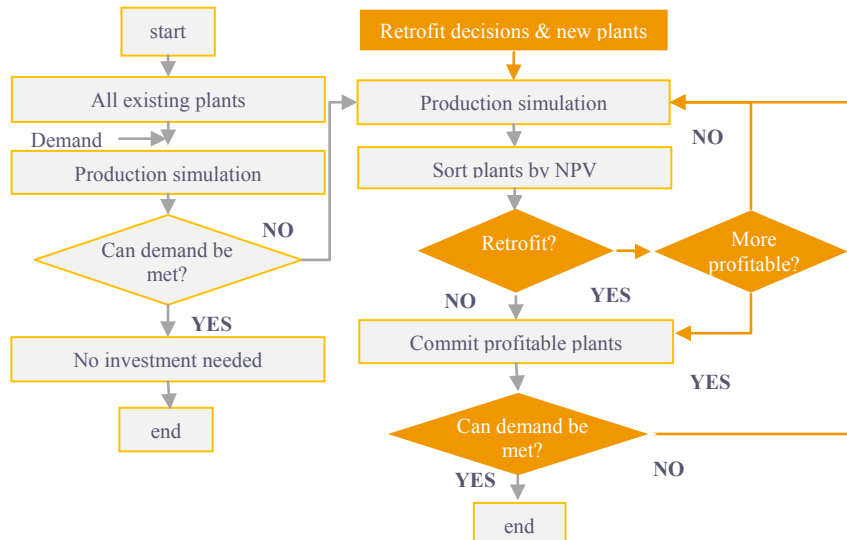

Figure 1 Flow chart of the functionality of the investment algorithm integrated in the BRMS

4. Case Study and Analysis

The transition of the refinery sector is analysed for three different carbon cost scenarios; zero carbon price scenario, 2.5 °C scenario and 2 °C scenario. The carbon prices for the refinery sector are determined using the carbon budget provided in (Rogelj, 2015). The analysis focuses on the uptake of bio-based refineries, non-conventional refineries (Table 2), and refineries with CCS with 90% capture rate as well as the difference in investments in retrofits and new plants. The results for the different scenarios are illustrated in Figure 2. In case of zero carbon price, the trend in the refinery sector is to shift towards more flexible large scale refineries, while the smallest ones are forced out of the market. This results from the upgrade of several unprofitable plants to more economic refinery types and the up-scaling and modernization of large scale plants with

a high NPV. The highest share of 72 % of refinery C tends to indicate that more complex and flexible technologies are favoured. In the 2.5 °C and 2 °C scenario, refineries in combination with CCS appear in the market.

Figure 2 Production by refinery type and year for zero carbon scenario (left), 2.5 °C scenario (middle) and 2 °C (right). The top graph shows the mix of different technologies, the bottom one illustrates the conventional refineries.

It is interesting to see that for carbon scenarios of 2.5 °C, there is a mix of all refinery types, with a predominance of type A (17 %) and G (10 %) without CCS, as they have the lowest emissions of the conventional refineries, where B and C have the highest share 34 % and 26 % respectively, among refineries with CCS; on the other side, there is uptake shift towards the integration of CCS to refinery type A (15 %), for a 2 °C scenario. The increase of bio-based refineries, in particular with CCS, increases with an escalating carbon price since these refinery types show zero net emissions and can yield negative emissions coupled with CCS. These present the most valuable technology options for a further limitation of the emissions in the refinery sector beyond the 2 °C scenario.

The most popular retrofit decision for the zero carbon price scenario presents the upgrading followed by scaling-up and modernization. This changes for the different carbon scenarios where the most popular retrofit option is given by the upgrade of CCS or the modernization and only a few refineries are upgraded to different refinery types

or scaled up. An interesting observation can be made in the investment in modernization measures for all scenarios. Modernizations of refineries are only conducted for larger scale refineries, since it is not economic to maintain small scale refineries due to their unprofitability.

5. Conclusion

This paper shows the impact of changes in the refinery sector due to retrofit and fuel switching on carbon emission profiles. The results of the different decarbonisation scenarios emphasize that a large portfolio of technologies is needed to achieve a decarbonisation of the global refinery sector. In particular, conventional refineries with CCS will still play an important role since the current refinery sector is dominated by conventional refineries and the integration of CCS units presents the most economical approach to face climate change. Biorefineries, with and without CCS, are essential on the other hand for a climate target beyond 2 °C.

Modelling and optimization of a geotextile dewatering tubes process

Franco Mangone*, Jimena Ferreira, Adrián Ferrari, Soledad Gutiérrez

Chemical and Process Systems Engineering Group – Chemical Engineering Institute - Engineering School – Universidad de la República, Julio Herrera y Reissig 565, PC 11300, Montevideo, Uruguay

Abstract

Sludge dewatering represents the general process of removing moisture from a sludge in order to reduce its total volume, and this is desirable in most cases for minimizing downstream sludge management and transportation costs. Many different technologies exist to accomplish this goal, such as decanter centrifuge and diverse press-like units. A simple alternative to these mechanical equipment are the geotextile dewatering tubes, which are disposable bags to which sludge is continually fed until a critical volume is reached, and then are allowed to drain naturally. Apart from having a simple operation, these bags allow for sludge accumulation over extended periods of time, until it is transported to the disposal site.

Although the process is apparently simpler than other alternatives, it involves a set of decisions such as feeding patterns, number of required bags and sequencing, etc., which could lead to sub-optimal utilization of the technology. The aim of this study is to detect these critical decisions, and then analyze strategies to optimize the process. The model used to represent the process will be the one proposed by Yee and Lawson (2012) will be used.

Optimization of the processing capacity of an individual tube is carried out, by finding a minimal operation time which in turn ensures that the optimization objective is achieved, as is described throughout this study.

Keywords: Dewatering tubes, Sludge, Optimization

1. Introduction

Among the several sludge dewatering systems available, geotextile tubes represent one of the simplest alternatives due to the lack of mechanical components in the equipment, and the simplicity of operation. They consist on tubes to which sludge is continually fed until a critical volume is reached, and then they are allowed to drain naturally. This pattern is repeated until enough solids are contained inside of the tube, and at that point they are cut open and their content is disposed of.

An optimal operation of this system involves decision making, such as when to stop dewatering for every cycle, the number of units needed for a tube network, etc. Also, the process might be affected by upstream conditions such as sludge purge frequency and flow, which could also be decision variables for a more plant-wide problem. The present work will focus on the optimization of a single tube operation, in terms of the

selection of the corresponding cycle times. No previous information regarding this matter was found in literature.

2. Modelling

A correct operative representation of a dewatering tube can be quite challenging because of how intricately the involved phenomena are related: a detailed model should incorporate a correct calculation of the tube's volume, which is related to tensile forces of its material and also to the forces applied by the contents of the bag, which vary during the operation. In this sense, Yee and Lawson (2012) described a simple model which gives a good approximation to the full operation discussed above. They tested it using gypsum slurry and contaminated sediments in order to conduct validation, yielding very good agreement with experimental data. A diagram summarizing the stages that are discussed next is available in Yee and Lawson (2012), see Figure 3 in their publication. Essentially, these stages are characterized by (i) a different size (i.e., volume and height; the length is fixed) of the tube, as well as (ii) different zones (i.e., a suspension, settling, and settled zone) that develop in the tube.

2.1. Filling

The operation is divided into filling and drawdown stages. Yee and Lawson (2012) propose that the modelling for both stages can be clearly differentiated. They assume that during filling, the output flow (the clarified liquid that drains through the tube wall) can be directly related to the feed flow, via a simple relationship given by Eq. (1):

$$\frac{Q_{out}}{Q_{in}} = A_P \cdot n_{in} = A_P \cdot (1 - \phi_{in}) \quad (1)$$

Where Q_{in} and Q_{out} represent the total feed and output flow rates (m^3/h) respectively; n_{in} is the porosity of the feed (dimensionless); ϕ_{in} is the volumetric solids fraction in the feed (dimensionless); and A_P is a parameter called "floc quality factor", dimensionless. This equation assumes that the turbulence inside the bag during filling is enough to resuspend any previously sedimented solids, and thus offering no additional resistance to permeate flow. It is possible to calculate the filling time using a simplified mass balance, given by Eq. (2):

$$\frac{\Delta V_T}{\Delta t} = Q_{in} - Q_{out} \quad (2)$$

Where V_T and t represent the bag volume (m^3) and time (h). The filling time can be calculated by knowing the set final volume (V_{max}), given by the manufacturer, as well as the initial volume for each cycle. Then, performing a mass balance in the tube, ϕ can be calculated for the final time, being the initial condition for the next drawdown phase.

2.2. Drawdown

During this stage, sedimentation occurs and the clarified liquid flow is hindered because of the additional resistance created by the sediment. To account for this phenomenon, Yee and Lawson (2012) utilize a variation of the equation proposed by Richardson and Zaki (1954) for hindered settling, represented by Eq. (3):

$$\frac{dh_T}{dt} = -(1 - \phi)^q \quad (3)$$

Where h_T is the total height of the tube (m); ϕ is the mean volumetric solids fraction of the contained sludge (dimensionless); and q is an empirical power factor, which relates to the resistance offered by the sediment. The height of the tube is related to the total volume through an empirical relationship proposed by Yee et al. (2012) and correlated with the more rigorous analysis of Leshchinsky et al. (1996) and Palmerton (2002), presented in Eq. (4):

$$V_T = L_T D_T^2 \left[\left(\frac{h_T}{D_T} \right)^{0.815} - \left(\frac{h_T}{D_T} \right)^{8.6} \right] \quad (4)$$

Where L_T is the total length of the tube (m) and D_T is the theoretical diameter (m), which corresponds to the diameter if the tube was completely filled, adopting a cylindrical shape. This equation gives good estimates for the volume in a range of h_T/D_T lower than 0.7. Additionally, it is possible to effectuate a solids mass balance between any two given times during drawdown. Assuming that no solids escape the tube, and taking the initial conditions for this phase ($\phi_0, V_{T,0}$), it is possible to state the following:

$$\phi = \frac{\phi_0 \cdot V_{T,0}}{V_T} \quad (5)$$

Then, by substituting Eq. (5) and Eq. (4) into Eq. (3), an ordinary differential equation is obtained, but because exponents are not integers, it cannot be solved by separating variables. Although an analytical solution is difficult to obtain, a numerical solution to the problem can be obtained. The original resolution proposed by Yee and Lawson (2012) involved a very simple discretization, but in this case, more accurate ODE solvers will be used.

3. Optimization

In the context of utilization of a single dewatering tube, the optimization in this work focuses on maximizing the capacity of the system, which translates into maximizing the amount of sludge that it admits over the full operating period. Depending on the particularities of the plant where the tube is installed, feed conditions might change and more degrees of freedom could be added to the problem. For simplicity, a first approach will be considered in which a constant feed flow is assumed during filling, and no flow is admitted into the system during drawdown.

The final moisture content and final tube volume for the entire operation (N cycles) are set as terminal constraints for the problem. In this sense, the objective will be to achieve these final conditions in the minimum time possible. This problem is analogous to studying the ratio between total drawdown time and total filling time, because the latter is fixed if a starting volume is given, due to the fact that the final volume is also fixed because of the maximum height condition. Therefore, the involved decision variables are the drawdown time spans, and also the number of cycles.

The problem to analyse represents a mixed integer non-linear programming (MINLP) problem. In order to reduce the complexity of the problem, a fixed number of cycles N will be assumed, and optimization will be carried out.

The resulting optimization problem is described by the following equations:

$$\min_{t_{cycle,n}} \sum_n t_{cycle,n} \quad n = 1, 2, \dots, N$$

$$\text{s.t.} \begin{cases} \text{Modelling: ODE system} \\ \phi(t = t_f) \geq 0.3 \\ V_T(t = t_f) \geq 0.85 \cdot V_{max} \\ t_{cycle,n} = t_{fill,n} + t_{draw,n} \end{cases}$$

Where t_{cycle} is the cycle time (h); t_{fill} and t_{draw} , represent the duration of filling and drawdown stages (h); t_f , is the final time for the whole process (h); and n , represent the cycle number.

Table 1 - Parameter values used for simulation

Parameter	Value	Dimensions
ϕ_{in}	0.05	-
Q_{in}	10	m ³ /h
L_T	20	m
D_T	2.9	m
$h_{T,max}$	2	m
A_P	0.7	-
q	18	-

Where $h_{T,max}$ is the maximum height of the bag, which is related to the V_{max} given by the manufacturer.

Optimization was carried out in Matlab R2015a using *fmincon* function and choosing solver *SQP*. The process parameters utilized during all calculations are shown in Table 1. Terminal conditions (final volume and moisture) would depend on local legislation and manufacturer recommendations, and the values utilized are taken just for the purpose of simulation. Additionally, the number of cycles N was set at 6 for the purposes of this simulation.

4. Results and discussion

The optimization results are shown in Figure 1.

Figure 1 - Simulation result at optimal operation.

The life time of the tube in optimal conditions is 393.6 hours. For comparison, a valid operative strategy would be to fix the drawdown cycle times at a value, for example 100 hours, and calculate the number of cycles needed. In this case, 5 cycles are needed to satisfy the final conditions, with a total operation time of around 670 hours, more than 50% above the optimal time calculated. The ratio of drawdown times to filling times was reduced to a minimum, thus ensuring maximum tube capacity.

Table 2 - Results for optimal cycle times

Cycle	Filling time (h)	Drawdown time (h)
1	35.0	0
2	0	0
3	0	32.2
4	11.5	57.5
5	7.51	90.5
6	5.76	154

A closer inspection of the solution to the problem reveals that the solver assigns a value of zero to some cycle times, which can be seen in Table 2. By doing this, the number of “effective” cycles in the solution (4) is lower than the one originally assumed (6), as is clear in Figure 1. Forcing any value of N lower than four will yield suboptimal solutions to the overall optimization problem as can be observed in Table 3.

Table 3 - Optimal total time for different values of N

Value of N	Total dewatering time (h)
2	1.29E4
3	419
4	394
5	394
6	394

This means that the simulation will yield the same result for any N equal or greater than four. For a more generic problem, carrying out optimization with increasing values of N until the solution presents times with a value of zero, will lead to the determination of the value of N that produces an optimal result. A simple iterative strategy is used in place of a MINLP solver.

5. Conclusion

Modelling of a geotextile dewatering tubes process was implemented in Matlab. Optimal operation for a single bag was studied under the assumption of a constant feed flow from the upstream wastewater treatment plant. The use of an MINLP structure was avoided by proposing an equivalent NLP problem, which is easier to solve. The results showed that the bag throughput was improved, and with a reduction in the required number of cycles respect to traditional strategies. An increase in drawdown times is observed as further cycles are started. Bag network analysis and optimization under feeding scheduling, including upstream conditions and constraints, represent an interesting challenge for the future.

Abstract

A multi-stage fluidized bed system for temperature swing adsorption (TSA), which uses solid amine sorbents for CO₂ capture and a heat pump for further optimization of the energy consumption, is studied in detail. The present work introduces detailed models for the most important aspects of the process, in order to study interactions in a simulation model. The overall efficiency depends on three different aspects: adsorption efficiency, heat transfer and heat recovery with a heat displacement system. These three modeling aspects have been combined to gain information about different limiting factors of the proposed TSA process for biogas upgrading. With the new TSA process model, a tool has been created which enables the design and dimensioning of a biogas upgrading plant, as well as the comparison to other biogas upgrading processes.

Keywords: modeling and simulation, fluidized bed, TSA, CO₂ capture, biogas upgrading

1. Introduction

Nowadays, it becomes more important to find alternatives to fossil fuels in order to reduce CO₂ emissions to the atmosphere. For example bio-methane from biogas upgrading can be used as a replacement for natural gas. Biogas contains about 15-40% CO₂ and 60-85% CH₄, depending on its feedstock (Ryckebosch et al., 2011). To supply bio-methane to the natural gas grid, a CO₂ capture process is required to fulfill the quality requirements. Several adsorption processes, such as pressure swing adsorption (PSA), membrane separation, amine scrubbing and physical adsorption, have been reported during the last few decades (Ryckebosch et al., 2011). None of them delivers an optimal solution when it comes to the costs of the upgrading step. More recently, an adsorption technology with solid amine sorbents in a temperature swing adsorption process (TSA) within a multi-stage fluidized bed system has been proposed for post-combustion CO₂ capture applications and may represent a cost efficient alternative to existing biogas upgrading processes. (Pröll et al., 2016; Schöny et al., 2017). The regeneration of the solid sorbent material is performed in the TSA system by lifting the temperature in contrast to the temperature for adsorption, which is performed at lower temperatures (temperature swing adsorption). Many adsorption separation processes, such as pressure swing adsorption (PSA), are based on fixed bed systems, which are operated in batch mode and have limited heat transfer rates (Nikolaidis et al., 2015). The introduced TSA fluidized bed system has an advantage over fixed bed systems, because of a continuous process

operation. In the proposed TSA process, the stages are operated in a counter current flow of the solid sorbents and the gas stream. In contrast to the application of TSA in post-combustion CO₂ capture, biogas upgrading with the proposed TSA process allows for the integration of a high temperature heat pump, due to smaller plants and therefore lower total heat requirement than in post-combustion CO₂ capture. Due to this advantage, the integration of a high temperature heat pump is proposed, in order to enable heat recovery from the exothermic adsorption and use this heat for the endothermic desorption. To enable an optimal heat displacement, every stage is equipped with immersed heat exchangers in the fluidized bed, which are designed in order to allow for preferably high heat transfer rates. As the efficiency of the heat pump is dependent on the necessary temperature swing between adsorber and desorber, the efficiency of heat transfer via the heat exchangers is essential. A simplified IPSEproTM model for the proposed TSA process for biogas upgrading, has been recently proposed by authors of this work (Vogtenhuber et al., 2017). Based on this work, in the following an introduction of the three main process aspects of the extended TSA simulation model will be presented.

2. Process Modeling Aspects

The process model is based on the IPSEproTM model that was previously introduced by (Vogtenhuber et al., 2017). The core of the simulation tool is represented by individual fluidized bed stage unit models that are connected to reassemble a 5x5-stage TSA process set up (see Figure 1).

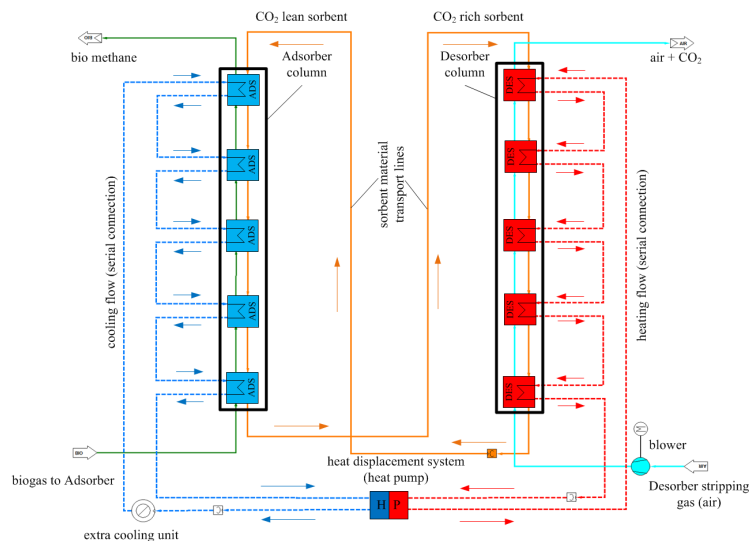

Figure 1: IPSEproTM simulation model

Each stage is based on mass and energy balances for all involved species in the gas and solid streams, according to Figure 1. Isothermal operating conditions as well as ideal gas-solids contact and ideal mixing of the fluidized sorbent material are assumed for each stage unit.

2.1. Adsorption Efficiency Modeling

The first aspect is based on the adsorption behavior of the gas species on the solid sorbent and deals with the deviation from equilibrium conditions. The assumption of having ideally mixed solids requires the CO₂ partial pressure in the outgoing gas stream to be determined by the equilibrium loading of the sorbent material within the stage. In order to determine the CO₂ equilibrium

loading, the adsorption model by Toth (Do, 1998) was used in this work. With the fitting of the Toth model parameters to experimentally determined CO₂ adsorption equilibria data, a suitable mathematical description of the CO₂ equilibrium adsorption capacities can be gained. The experimentally determined CO₂ equilibrium adsorption data on a solid amine sorbent (Lewatit® VP OC 1065), as well as the respective Toth parameter fitting was recently presented by authors of this work (Sonnleitner et al., 2017). With the fitted parameters, adsorption capacities at temperatures and CO₂ concentrations, which were not obtained experimentally, can be calculated. The calculated adsorption capacities reflect the capacity at equilibrium conditions, and presume ideal conditions, where the sorbent is exposed long enough to the adsorptive to reach equilibrium loading. The Toth model was embedded in the process simulation model, and allows for calculation of the CO₂ adsorption on any sorbent material, where a respective Toth parameter set is available.

Based on the findings in a previous study by authors of this work (Sonnleitner et al., 2017), the examined adsorbent material is considered to interact with CO₂, but not with CH₄ and therefore, no transport of CH₄ from the adsorber to the desorber needs to be considered. However, differences in the gas compositions are considered in the energy balances by accounting for the corresponding heat capacities of the individual gas streams. Furthermore, it is expected that H₂O, which is present in the biogas stream, plays an essential role for the overall heat management system. Veneman et al. (2015) determined a significant H₂O adsorption, which suggests a transport of H₂O from the adsorber to the desorber. Therefore, it was decided to incorporate a suitable model for H₂O adsorption in the simulation model.

The influence of other trace gases contained in the biogas, such as H₂S and NH₃, on adsorption properties, are currently not considered in the model, due to a lack of experimental data. Nevertheless, a potential co-adsorption of these species, on the solid amine sorbent material, as suggested by Belmabkhout et al. (2011), may be incorporated in the existing model, after further experimental evaluation. In case of a potential co-adsorption, the costs, for additional gas treatment to reach the specification for biomethane, may be reduced.

During experiments in an existing bench scale unit (Schöny et al., 2017), findings regarding the real behaviour of a 5x5-stage process have been gained. These experiments revealed that, operating conditions such as the gas-solid contact time and adsorption kinetics need to be considered. Therefore, an additional parameter, the stage efficiency, has been added. The stage efficiency reflects, based on experimental findings the proportionally reduced capacity of the sorbent under certain limiting operation conditions. The potentially limiting factors can be either a too high solids circulation rate, which may not ensure a long enough residence time to reach equilibrium loading, or low CO₂ concentrations, which potentially need more solids residence time in each stage. Another limiting factor could be the adsorber temperature, which may slow down the adsorption speed and equilibrium loading may not be reached at low temperatures, as reported for other solid amine sorbents. In order to assess and quantify the respective limitation on the stage efficiency, further experiments will be performed in the bench scale unit. Based on these results, process parameter dependent stage efficiencies will be incorporated in the simulation model, to indicate real operating performance.

As adsorption of CO₂ by the sorbent material is an exothermic process and desorption is an endothermic process, heat exchangers are included for the supply of the required cooling and heating demand in each stage. The total energy demand in the individual stages is the sum of the latent heat demand for adsorption/desorption of the CO₂ and the sensible heat demand for lowering/lifting the temperature of the incoming sorbent and gas stream. Whilst in the simplified adsorption IPSEpro™ model, no limitation on heat exchanging capacity is specified; in reality, the heat exchanger design is essential for the overall process in order to ensure a proper heat management. Therefore, the second modeling aspect deals with the proper design and construction for the heat exchangers to supply the required energy within the stages.

2.2. Heat Transfer Modeling

First of all, fluidized bed regimes are significantly better regarding the heat transfer, compared to other contacting regimes (i.e. fixed- and moving bed). As mentioned before, isothermal operation of each stage is considered, thermal fly-wheel and the mixing behaviour of the fluidized solids. To control and maintain the process temperature within the unit model, heat exchange with a heating or cooling medium is considered. The exchanged heat \dot{Q}_{cond} can be derived from the energy- and mass balance of the unit (see Figure 1) and is according to Eq. (1).

$$\pm \dot{Q}_{\text{thermal}} + \dot{Q}_{\text{cond}} = \dot{m}_{\text{sorb}} \cdot c_{p,\text{sorb}} \cdot (T_{\text{des}} - T_{\text{ads}}) + \dot{m}_{\text{gas}} \cdot c_{p,\text{gas}} \cdot (T_{\text{des}} - T_{\text{ads}}) \quad (1)$$

Depending on either adsorption or desorption, the term \dot{Q}_{thermal} has a positive or negative sign, due to the respective exothermal or endothermal reaction. The conducted heat \dot{Q}_{cond} between fluidized bed and stage heat exchanger is based on Fourier's law and can be defined as:

$$\dot{Q}_{\text{cond}} = \dot{m}_{\text{fl}} \cdot c_{p,\text{fl}} \cdot (T_{\text{fl},\text{in}} - T_{\text{fl},\text{out}}) \quad (2)$$

$$\dot{Q}_{\text{cond}} = k \cdot A_{\text{hex}} \cdot LMTD \quad (3)$$

where Eq. (2) comprises the fluid mass flow \dot{m}_{fl} through the heat exchanger tube and the temperature difference ΔT_{fl} between inflow and outflow of the cooling/heating medium. Another expression of the term \dot{Q}_{cond} is provided in the Eq. (3), where A_{hex} is the needed heat exchanger surface, $LMTD$ the logarithmic mean temperature difference and k the overall heat transfer coefficient between heating or cooling medium and the fluidized bed, through the tube-wall. The overall heat transfer coefficient equation is presented in the following general form:

$$k = \left(\frac{1}{\alpha_{\text{FB}}} + \frac{d_{\text{out}}}{2 \cdot \lambda} \cdot \ln \frac{d_{\text{out}}}{d_{\text{in}}} + \frac{d_{\text{out}}}{d_{\text{in}} \cdot \alpha_{\text{in}}} \right)^{-1} \quad (4)$$

where d_{in} and d_{out} are the tube diameters of the immersed heat exchanger. The heat transfer coefficient between tube and fluidized bed α_{FB} is the sum of the particle convective term $\alpha_{\text{par,conv}}$, the gas convective term $\alpha_{\text{gas,conv}}$ and the radiation term α_{rad} .

$$\alpha_{\text{FB}} = \alpha_{\text{par,conv}} + \alpha_{\text{gas,conv}} + \alpha_{\text{rad}} \quad (5)$$

The radiation term in Eq. (5) becomes more important at temperatures above 400°C and is therefore insignificant for this application (i.e. regeneration temperature $\approx 100^\circ\text{C}$). Literature offers a great spectrum of correlations of wall-to-bed heat transfer in fix or fluidized bed regimes. Many of them calculate the maximum heat transfer coefficients in a certain optimum fluidization range. Only few mathematical models, like Molerus et al. (1995) and Martin (2010), are able to describe the overall fluidized bed heat transfer coefficient as a function of superficial gas velocity and the tube diameter of the immersed heat exchanger. Another important influence factor on the mathematical model is the particle diameter of the used solid sorbent. Therefore, these two models will be incorporated into the simulation model, for calculation of the heat transfer coefficient α_{FB} . Further, the heat exchanger design within the adsorption/desorption stages plays an important role with regard to good heat transfer rates and performance of the heat pump. Different heat exchanger tube diameters and of course different layouts, especially tube bundles, in-line and staggered configuration particularly, influence the wall-to-bed heat transfer coefficient (Hofer et al., 2017). Currently, the implemented mathematical model in the simulation tool, is not able to represent suitable heat exchanger designs. Ongoing experiments investigate the aftermath of different heat exchanger arrangements with finned tubes in terms of heat transfer coefficient, compared to bare tube arrangements within a fluidized bed. Hence, bare tube and finned tube heat exchanger layouts will be implemented into a special circulating fluidized bed test rig with amine sorbent (i.e. to represent real process conditions) as bed material. Results from the empirical experiments will be used to evaluate possible new correlations or improve existing models to predict heat transfer coefficients regarding to parameters mentioned before. The potentially improved and adapted mathematical model will be incorporated to the IPSEproTM simulation model.

2.3. Modeling of the closed loop heat pump cycle

In order to ensure a proper heat recovery in the proposed TSA process, the third aspect deals with the integration of a heat pump model with standard components, such as heat exchangers, compressors, expansion valves, control systems, sensors, etc. The numerical models of the vapour compression heat pump for the heat displacement in the TSA process are written in the modeling language Modelica™. The models in Modelica™ are mathematically described by differential, algebraic and discrete equations. For the heat pump model, to be integrated in the TSA process, two configurations are considered, a single-stage heat pump cycle with optional internal suction gas heat exchanger, see Figure 2 (left) and a cascade configuration, see Figure 2 (right). The main components of the single-stage heat pump cycle are the compressor, the heat exchangers and the refrigerant. In principle, the cascade configuration consists of two single-stage heat pump cycles interconnected with an evaporator-condenser. For both configurations mass and energy balances equilibrium models have been used and following main model components are implemented to fulfill the requested temperature range.

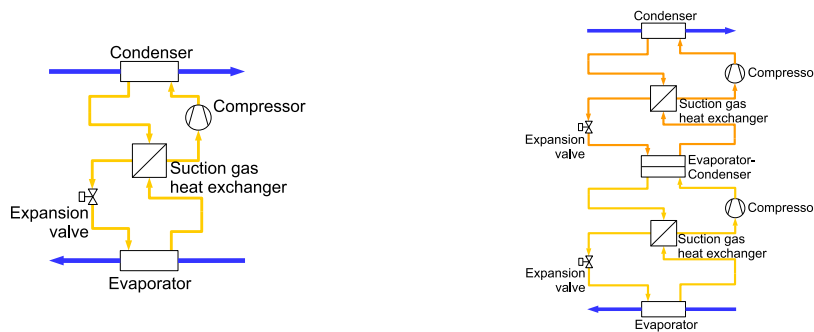

Figure 2: Single-stage heat pump cycle with optional internal suction gas heat exchanger (left) and Cascade configuration (right)

For the single-stage heat pump cycle, the fluid properties of R600 and R1234ZE(Z) are implemented. For the cascade configuration the combinations of R717/ R1234ZE(Z), R1234ZE(E)/ R1234ZE(Z), R717/ R600, R600a/ R600, R600a/ R1234ZE(Z) and R717/ R1336mzz-Z are implemented on the low temperature stage/high temperature stage. All the necessary fluid data is provided by existing Refprop (NIST, 2017) representations.

In order to describe the compression cycle, the isentropic and the volumetric efficiency are prescribed. They are usually given as a function of pressure ratio and condensing or evaporating temperature. An ideal isentropic compression is complemented by different physical effects, such as pressure drop on the suction and the discharge side, internal leakage, re-expansion of the compressed fluid and mechanical friction. The volumetric efficiency gives the relation between the geometrical mass flow and the actual mass flow in the compressor. The geometrical mass flow can be calculated with the known refrigerant properties on the suction side and the prescribed swept volume. The volumetric efficiency gives the relation between the geometrical mass flow and the actual mass flow over the compressor. The geometrical mass flow can be calculated with the known refrigerant properties on the suction side and the swept volume. In order to enable a quick comparison of different heat pump configurations, heat exchanger models based on the Number of Transfer Units method (NTU) are used. This method provides correlations between the heat flow rate and the required thermal conductance, depending on the heat exchanger geometry, which can be found in the literature (VDI, 2013). For the numerical comparison of the different heat pump configurations, the temperature input parameters of the heat exchangers (evaporator, condenser

and internal suction gas heat exchanger) are set equally.

3. Results and Conclusion

The introduced three aspects are implemented in an existing TSA system model in the IPSEpro™ environment. The process model for adsorption behavior (section 2.1) can be used to determine problematic operation conditions that are related to performance losses. High heat transfer rates between heat exchanger equipment and the fluidized bed can be ensured by optimal superficial gas velocity and optimized heat exchanger design and layout. A quick comparison of different heat pump configurations for the process heat supply, can be conducted by applying the introduced numerical models in the new simulation tool. Due to the interactions, of the three presented model aspects, several different operation modes of the TSA process are possible. For example, the optimum temperature for adsorption, which influences the performance of the heat pump, can be calculated with the TSA system model. Resulting from the empirical evaluation of the influence of different process parameters on the ideal model assumptions, a simulation tool has been created, which allows for more accurate process investigations for the future design of a TSA plant. The simulation model, will allow planning and dimensioning of a biogas upgrading plant, as well as for comparison to other biogas upgrading processes.

Reduced Model Describing Efficient Extraction of Hydrogen Transported as Co-Stream in the Natural Gas Grid

Werner Liemberger^{a,*}, Martin Miltner^a and Michael Harasek^a

^aTU Wien, Institute of Chemical, Environmental & Bioscience Engineering, A-1060 Vienna, Getreidemarkt 9/166, Austria
werner.liemberger@tuwien.ac.at

Abstract

The world's energy demand is increasing since years. Together with environmental issues (e.g. global warming) and energy security concerns, renewable energies are on the rise. As these are less predictable the importance of a cost effective and environmentally friendly energy storage and transportation system increases.

A solution might be hydrogen (H₂), as the gas has a high energy density and might be a future energy carrier. In a power-to-gas context electrical energy is used to produce H₂ via water electrolysis. The gas can be stored and transported, most cost- and energy-efficient via pipelines.

However, pipelines are capital intensive so the current natural gas-grid could be used to co-transport H₂. According to national pipeline regulations low H₂ concentrations are already possible (e.g. 4% (v/v) in Austria). While the injection is straightforward, the extraction is challenging. In previous work a process has been identified, experimentally validated and optimised via process simulation, that is able to extract H₂ at fuel cell quality (99.97% (v/v) according to ISO 14687-2:2012).

The previously gained knowledge is used in the current work to create a reduced model (combination of principal component analysis and trained artificial neural network). The model has a significantly increased performance compared to the whole process simulation. Therefore, it is computationally less expensive and can be easily implemented in further investigations like GIS based analysis and economic evaluations as done in ongoing work.

Keywords: hydrogen infrastructure, process simulation, future technology, fuel cell hydrogen, artificial neural network

1. Introduction

In the last decades, the awareness of climate change increased much. It is assumed that global warming can be reduced by reducing global greenhouse gas emissions. Therefore, renewable energies gain in importance. As these energy resources are less predictable than conventional, controlling electrical excess energy is more difficult.

The electrical excess energy is mostly stored and used when needed. Currently, the only large scale available storing technologies are pumped hydro-electric energy storage (PHES) and compressed air storage (CAS). For the future it is estimated, that 600 TWh have to be stored (Blanco and Faaij, 2018) which is higher than the potential of PHES. CAS could fulfil this, but the potential of chemical energy storage (like power-to-gas) is greater.

In a power-to-gas concept, hydrogen (H_2) is produced via water electrolysis from electrical excess energy. The gas can be stored, transported (most energy- and cost-efficient via pipeline) and re-electrified. As currently only 16×10^3 km of H_2 pipeline networks exist, the natural gas grid (already 2.2×10^6 km in Europe (Eurogas, 2015)) might be an option, especially when using it to co-transport H_2 , which is already allowed up to a certain limit (e.g. 4%(v/v) in Austria). In previous work (e.g. see Liemberger et al. (2017a)) a process has been presented, that is able to extract this H_2 , transported with the natural gas grid, at fuel cell quality (e.g. use for mobility).

The process, based on membrane technology and pressure swing adsorption, has been investigated experimentally and optimised with process simulation. Due to non-linear coupled equations its convergence is difficult and time-consuming. Further, when investigating internal recycles (required for a higher total H_2 recovery at lower energy demand), numerous recycle stream ratios are possible ($> 5 \times 10^5$ cases), increasing the simulative effort significantly. This makes it difficult to implement the full process simulation in detailed geographic information system (GIS) based and economic analyses. Therefore, a reduced model is required.

1.1. Process Simulation

In previous work (Liemberger et al., 2017b), several process designs have been studied via process simulation and optimisation to identify an energy efficient process design. Two designs are shown in Fig. 1, a simple (PR1; see Fig. 1(a)) one and a more complex (PR9; see Fig. 1(b)).

The simulations were done in MATLAB[®] (R2016b) with an in-house developed solution-diffusion based membrane model, a splitter model for the PSA and an isentropic compression model (adjusted by an efficiency coefficient of 72 %).

The membrane separation uses a solution-diffusion approach to determine the transmembrane flux for each component (function of difference in partial pressure and permeance). For multicomponent gases this leads to a system of coupled non-linear differential equations. The used in-house developed code uses a finite difference approach to solve this equation system in the modelled module. For more detailed information on the modelling approach see Liemberger et al., 2017b.

Figure 1: Investigated schemes with membrane pre-enrichment and a purification via PSA

The work has shown, that the process design with recovery membrane and sweep gas streams (PR9) requires the lowest specific amount of energy for the extraction of H_2 from mixtures with natural gas. Further, PR9 is able to achieve higher total H_2 recovery rates than PR1.

While the simulation of PR1 is straight forward (no recycle stream), the one of PR9 is more complex (higher degree of freedom). The configuration of both splitters as well as the

recovery membrane leads to two recycle streams. In case more gas is recycled, the total H_2 recovery can be increased. However, as the gas has to be re-compressed internally, more energy is required. This trade-off is an optimisation problem, computationally intense to solve. Therefore, the current work uses data from extensive simulation with rigorous model for a reduced model, easy to apply in further investigations like economic evaluations.

1.2. Model Reduction – Artificial Neural Network

Several modelling techniques are known in literature like partial least squares regression (PLS), principal component analysis (PCA) and artificial neural networks (ANNs) (Balabin et al., 2011).

In a PCA possible correlated variables are converted to a set of linearly uncorrelated values, called principal components.

ANNs are used to solve several problems, e.g., in process identification, classification, data analysis, control and fault detection (e.g. see Azlan Hussain, 1999). While they are used in several chemical engineering sectors like (i) oil and gas industry, (ii) environment, (iii) biotechnology, (iv) polymer industry, (v) nanotechnology (vi) mineral industry and others (Pirdashti et al., 2013) their public awareness has increased in the last decades due to big data and image recognition issue.

In an ANN simple mathematical operations (so called neurons) are combined with weighted connections (values adjusted during training). The final model is able to represent the data and might be suitable to predict new cases correctly (in this case the correct energy demand).

Depending on the way the neurons are connected different types can be encountered, mainly (i) feed-forward (single-layer perceptron, multilayer perceptron and radial based) and (ii) recurrent (Hopfield, Elman, Jordan and recurrent multilayer) neural networks are used (Pirdashti et al., 2013).

2. Methods

In the current work, a PCA is used in combination with an artificial neural network, trained with previously gained data from Liemberger et al. (2017b). The data was randomly split into a training (70% of data), test (15%) and validation (15%) set. Beside feed concentration (H_2 , CH_4 and CO_2), feed pressure, PSA recovery and membrane selectivity the total H_2 recovery is used as input parameter to the ANN.

A feed-forward network with 15 hidden layers was taken (see Fig. 2), as it had the best performance. The network contains seven layers with a hyperbolic tangent sigmoid transfer function, followed by three layers with a positive linear transfer function and five additional layers with hyperbolic tangent sigmoid transfer function. Finally, the output is scaled via a linear regression layer.

Before applied to the ANN the input data is pre-processed. The values are first cleaned (removal of constant rows) and normalised (scaled to a range from -1 to 1). Then principal components are gained via PCA and used as input variables to the ANN. The ANN is trained to produce values between -1 and 1 which are rescaled to the original output unit in a post-processing step. Finally, the specific energy demand is computed.

The network was trained supervised (model results are known from process simulation) where the model performance was evaluated by the mean square error (MSE). During the training the weight and bias values are updated in order to reduce the MSE. This was

Figure 2: Feed-forward ANN with 8 input variables, multiple hidden layers and one output variable, representing the specific energy demand

efficiently done with a Levenberg-Marquardt backpropagation algorithm implemented in the Neural Network Toolbox of MATLAB® R2016b.

To minimise overfitting a validation data set was used during the training. This dataset is taken to test if the model accuracy increases within the training, or if only the accuracy of model increases for the applied training data. In case the accuracy of the validation data set stays the same, the network has been overfitted and the training process is stopped.

After training the gained ANN is tested with unused data (test set).

Beside this standard procedure to create a neural network some example cases are investigated to check the plausibility of the gained results, especially for cases not included in the training, validation and test data.

3. Results and Discussion

3.1. Training, Validation and Testing

Fig. 3 shows the model quality for training, validation and test data. As it can be seen, all results are positive with determination coefficients (R^2) of 0.99879 (training data), 0.99863 (validation data) and 0.99872 (test data).

Figure 3: Regression plot of training, validation and test data of the ANN

3.2. Plausibility Checks

The plausibility checks are performed for various input parameters. If not changed during the variation the following variables have been chosen: (i) feed concentration H_2 4%(v/v), CO_2 1%(v/v), (ii) 51 bar feed pressure, (iii) selectivity of 75.68 for H_2/CH_4 , 3.37 for H_2/CO_2 and (iv) 80% PSA recovery. The current work uses a compression efficiency of 72% as this can be scaled directly and does not require a complex model.

3.2.1. Variation of H_2 Feed Concentration

In Fig. 4(a) the influence of the H_2 feed concentration is presented. A higher H_2 feed concentration requires less energy (at the same total H_2 recovery) for the extraction. The ANN slightly overestimates the compression energy at low concentrations, while the others are in good agreement. For the cases with 5%(v/v) H_2 (not part of the data set) it can be seen that the predicted energy demand looks reasonable.

3.2.2. Variation of Feed Pressure

Several feed pressures have been analysed and the results are presented in Fig. 4(b). Higher feed pressures reduce the required amount of energy. Anyhow, the off-gas has to be re-compressed to the feed pressure level. Subsequently, it is a trade-off between better membrane separation efficiency (greater pressure difference) and an increased re-compression effort. The ANN is in good agreement with the process simulation. However, the ANN curves are slightly wavy. Therefore, it is assumed that the model quality could be improved with more training data, varying the pressure.

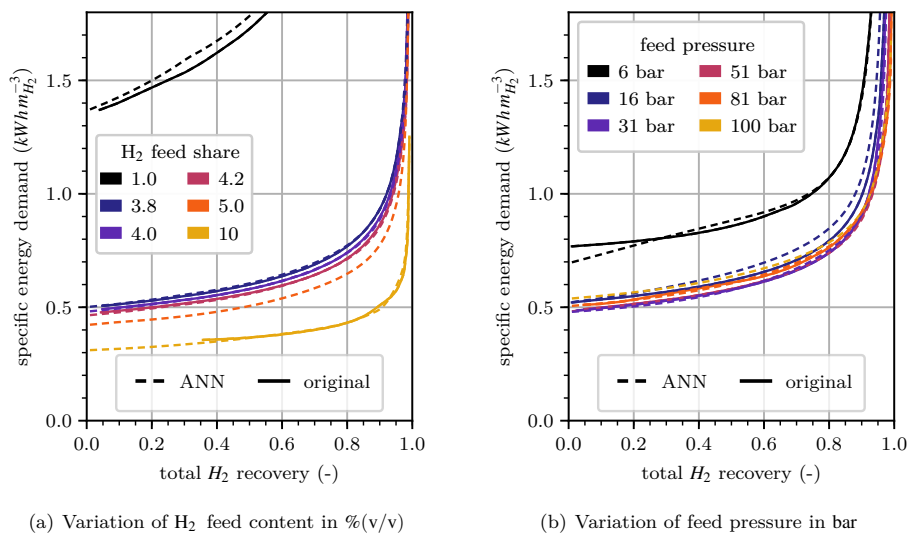

Figure 4: Variation of feed conditions (H₂ content and pressure)

3.2.3. Variation of Membrane Selectivity of H₂/CH₄

For the efficient separation a selective membrane is required. The influence of this material dependent parameter has been investigated and is shown in Fig. 5(a). The predicted values are in good agreement with the provided process simulation data. A higher selectivity reduces the energy demand, as the membrane separation is more efficient. The modelled energy demand for selectivity values that were not included in the data sets (see 150 and 250) look reasonable.

3.2.4. Variation of PSA Recovery

A higher PSA recovery reduces the required amount of energy as already presented in Liemberger et al. (2017b). The reduced model is able to properly predict the effect of changing the PSA recovery as shown in Fig. 5(b) of the dataset (70 %, 80 % and 90 %). Further, the prediction of an in-between value, 85 %, looks promising.

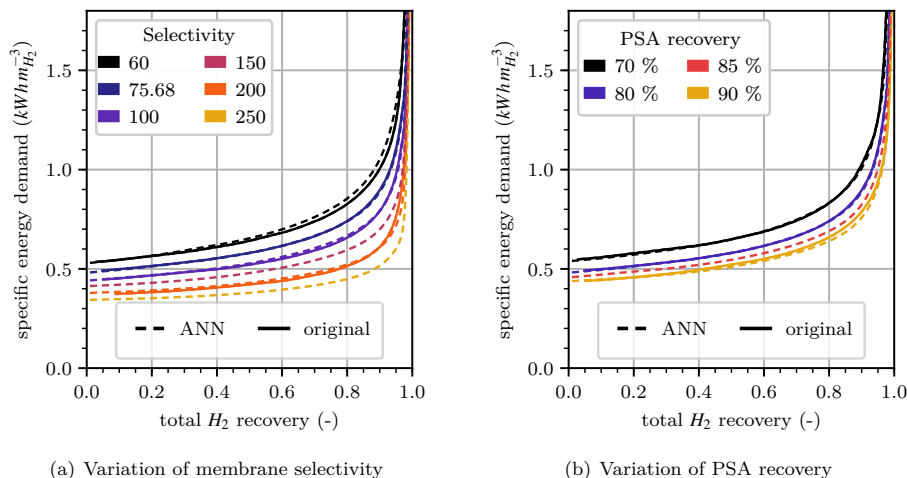

Figure 5: Variation of membrane H_2/CH_4 selectivity and PSA recovery

4. Conclusion and Outlook

This work presents a trained artificial neural network to predict the specific amount of energy required for the extraction of H_2 transported as co-stream with natural gas based on various input parameters like feed concentration, pressure, PSA recovery and more.

Beside results of the network creation step (network quality) further plausibility checks are shown. In conclusion the work presents a suitable method and model to identify the required energy demand used in ongoing work for detailed economic and siting evaluations.

Abstract

An autothermal sorption-enhanced steam methane reforming in a packed-bed reactor for production of high-purity hydrogen was studied by means of 1D numerical model. The reactor utilises a CaO/CuO/Al₂O₃(NiO) catalyst. This process is characterised by a number of challenges, such as the choice of the operating conditions to ensure both a production of high-purity H₂ stream and an autothermal sorbent regeneration stage. This paper addresses these challenges through numerical simulation. The results for the system cyclically operated in a packed-bed showed a methane conversion of 95%, and a hydrogen yield and selectivity around 3 mol_{H₂}·mol_{CH₄}⁻¹ and 90%, respectively.

Keywords: hydrogen, calcium oxide, copper oxygen carrier, nickel catalyst, fixed bed.

1. Introduction

Hydrogen is a secondary form of energy mainly produced by Steam Methane Reforming (SMR). However, SMR has two main drawbacks: the reforming reactions are strongly endothermic, hence an external heater is needed, and the effluent is a mixture of H₂ and CO, therefore a post-processing unit is required to obtain an enriched-H₂ gas stream (Marabàn and Valdés-Solis, 2007). Sorption-Enhanced Steam Methane Reforming (SE-SMR) is currently investigated as a feasible solution to address such drawbacks (Broda *et al.*, 2013). Reforming catalyst (Ni) and CO₂ solid sorbent, usually CaO, are mixed in order to carry out CH₄ reforming and CO₂ adsorption simultaneously, thus producing a high-purity H₂ stream. While the H₂ production and CO₂ adsorption stage is globally autothermal (Broda *et al.*, 2013), the heat required by endothermic sorbent regeneration reaction is the main drawback of SE-SMR. To overcome this engineering challenge, a novel CaO-based sorbent mechanically mixed with Cu-based oxygen carrier and Ni-based catalyst was recently developed. Such material enables providing the heat for calcination reaction by means of exothermic Cu reduction reaction (Manovic and Anthony, 2001). This study aims to prove the technical feasibility, and contribute to the scale-up and commercialisation, of this near-zero CO₂ hydrogen production technology.

2. Kinetic scheme and mathematical model

The adopted kinetic scheme is reported in Table 1. Three main stages can be distinguished in SE-SMR, namely reforming/CARBonation (CAR), OXidation (OX) and reduction/CALcination (CAL) stage. In CAR stage, methane and steam are fed to the reactor. Reforming reactions (R1-R3), methane decomposition (R4), carbon gasification by steam (R5) and by CO₂ (R6), as well as carbonation reaction (R7) occur simultaneously. As a result, a stream of high-purity H₂ leaves the reactor. In OX stage, a lean oxygen-nitrogen mixture is fed to the reactor and oxidation of Ni (R8), of Cu (R9), and of the carbon deposited onto the catalyst surface (R10) takes place. In CAL stage, CuO (R11-R13) and NiO (R14-R17) reduction reactions occur at the expenses of CH₄ oxidation, simultaneously with sorbent regeneration (calcination reaction, R18).

Table 1 – Kinetic scheme adopted.

Reaction	$\Delta H^0, \text{J}\cdot\text{mol}^{-1}$	
<i>Reforming/Carbonation stage</i>		
$\text{CH}_4 + \text{H}_2\text{O} \xrightarrow{\text{Ni}} \text{CO} + 3\text{H}_2$	206	R1
$\text{CO} + \text{H}_2\text{O} \xrightarrow{\text{Ni}} \text{CO}_2 + \text{H}_2$	-41	R2
$\text{CH}_4 + 2\text{H}_2\text{O} \xrightarrow{\text{Ni}} \text{CO}_2 + 4\text{H}_2$	165	R3
$\text{CH}_4 + \text{Ni} \xrightarrow{\text{Ni}} \text{Ni-C} + 2\text{H}_2$	74	R4
$\text{C} + \text{H}_2\text{O} \xrightarrow{\text{Ni}} \text{CO} + \text{H}_2$	131	R5
$\text{C} + \text{CO}_2 \xrightarrow{\text{Ni}} 2\text{CO}$	172	R6
$\text{CaO} + \text{CO}_2 \rightarrow \text{CaCO}_3$	-179	R7
<i>Oxidation Stage</i>		
$2\text{Ni} + \text{O}_2 \rightarrow 2\text{NiO}$	-479	R8
$2\text{Cu} + \text{O}_2 \rightarrow 2\text{CuO}$	-312	R9
$\text{C} + \left(\frac{I+\psi}{2}\right)\text{O}_2 \rightarrow \psi\text{CO}_2 + (I-\psi)\text{CO}$	[-787, -110]	R10
<i>Reduction/Calcination stage</i>		
$4\text{CuO} + \text{CH}_4 \rightarrow 4\text{Cu} + \text{CO}_2 + 2\text{H}_2\text{O}$	-178	R11
$\text{CuO} + \text{CO} \rightarrow \text{Cu} + \text{CO}_2$	-127	R12
$2\text{CuO} + 2\text{H}_2 \rightarrow 2\text{Cu} + 2\text{H}_2\text{O}$	-86	R13
$2\text{NiO} + \text{CH}_4 \rightarrow 2\text{Ni} + 2\text{H}_2 + \text{CO}_2$	161	R14
$\text{NiO} + \text{CO} \rightarrow \text{Ni} + \text{CO}_2$	-43	R15
$\text{NiO} + \text{H}_2 \rightarrow \text{Ni} + \text{H}_2\text{O}$	-2	R16
$\text{NiO} + \text{CH}_4 \rightarrow 2\text{Ni} + 2\text{H}_2 + \text{CO}$	203	R17
$\text{CaCO}_3 \rightarrow \text{CaO} + \text{CO}_2$	179	R18

The kinetic expressions of reaction rates are reported in Diglio *et al.* (2017a, 2017b, 2018). To describe axial concentration and temperature profiles in the reactor, a 1D pseudo-homogenous packed-bed model was used, as reported by Eqs. (1-4):

$$\varepsilon_g \frac{\partial C_i}{\partial t} + u_{sg} \frac{\partial C_i}{\partial z} = \varepsilon_g \frac{\partial}{\partial z} \left(D_{ax} \frac{\partial C_i}{\partial z} \right) - r_i \rho_{oc} \quad (1)$$

$$\frac{dX_k}{dt} = \sigma \frac{r_k}{C_k^0}, \quad \frac{dC_C}{dt} = r_C \quad (3)$$

$$\left[\varepsilon_g c p_g \rho_g + (1 - \varepsilon_g) c p_s \rho_{oc} \right] \frac{\partial T}{\partial t} + u_{sg} c p_g \rho_g \frac{\partial T}{\partial z} = \varepsilon_g \frac{\partial}{\partial z} \left(\lambda_{eff} \frac{\partial T}{\partial z} \right) + \rho_{oc} \sum_j (r_{R_j} \Delta H_{R_j}) \quad (2)$$

$$\frac{dP}{dz} = \frac{150 \mu_g (1 - \varepsilon_g)^2}{d_p^2 \varepsilon_g^3} u_{sg} + \frac{1.75 (1 - \varepsilon_g) \rho_g}{d_p \varepsilon_g^3} u_{sg}^2 \quad (4)$$

where C is the gas concentration in $\text{mol}\cdot\text{m}^{-3}$, C_C is the carbon concentration in $\text{kg}_C\cdot\text{kg}_{oc}^{-1}$, C_k^0 is the initial concentration of solid species in the carrier in $\text{mol}\cdot\text{kg}_{oc}^{-1}$, T is the temperature in K, X is the solid conversion, P is the pressure in Pa, ε_g is the bed void fraction, u_{sg} is the gas superficial velocity in $\text{m}\cdot\text{s}^{-1}$, z is the axial variable in m, D_{ax} is the axial dispersion, ρ_{oc} and ρ_g are the density of oxygen carrier and gas, respectively, in $\text{kg}\cdot\text{m}^{-3}$, $c p_g$ is the gas heat capacity in $\text{J}\cdot\text{kg}^{-1}\cdot\text{K}^{-1}$, μ_g is the gas viscosity in $\text{Pa}\cdot\text{s}$, λ_{eff} is the effective thermal conductivity in $\text{W}\cdot\text{m}^{-1}\cdot\text{K}^{-1}$, t is the time in s, d_p is the particle diameter in m, r is the reaction rate in $\text{mol}\cdot\text{kg}_{oc}^{-1}\cdot\text{s}^{-1}$, ΔH is the reaction enthalpy in $\text{J}\cdot\text{mol}^{-1}$, i is the gas species (CH_4 , H_2 , CO_2 , H_2 , CO , CO_2 , O_2 , N_2), k is the solid species (Ni, Cu, CaO).

The rates of consumption or formation of gas, r_i , and solid, r_k and r_C , species are determined by summing up the reaction rates of that species in all the reactions R_j ($j=1, \dots, 18$). To account for catalyst deactivation due to carbon deposition on its surface, with the exception of (R7), (R18), and (R10), all reaction rates were scaled by a deactivation function, ranging from 0 (fully poisoned catalyst) to 1 (carbon free catalyst), according to Diglio *et al.* (2016). The CO_2 adsorption capacity of the sorbent decreases in few carbonation/calcination cycles, after that assumes an almost constant value over around 50 cycles. To take into account the decay in CO_2 capture capacity, the approach suggested by Fernandez *et al.* (2012) was adopted, by assuming a maximum absorption capacity of 40% of its nominal value. The cyclic nature of SE-SMR was mathematically expressed by assuming that the initial conditions for each step (CAR, OX and CAL) are equal to the ones from the previous step. In addition, Danckwerts and Neumann boundary conditions were used. For evaluation of temperature, pressure and composition dependencies of reaction enthalpies, transport coefficients, and gas properties, the state-of-art correlations and assumptions were adopted. Further details can be found in Diglio *et al.* (2017a). The numerical model was solved using the commercial software Comsol Multiphysics®. Reactor length, L , was discretised with 1000 nodes and it was carefully checked whether further refinements of the spatial discretisation did not produce any significant variations in the computed concentration and temperature profiles. The validation of the model is reported in Diglio *et al.* (2017a, 2017b, 2018).

3. Results and discussion

Operating conditions, reactor and catalyst data used in the simulations are reported in Table 2. The period, and the consequent feed switch strategy, of each stage is not fixed *a priori*. Instead, a control that checks the conditions for switching between each stage based on the outlet gas stream composition was set up. Figure 1 reports gas molar fractions on dry basis at the reactor outlet as a function of time during the first CAR (A), OX (B) and CAL (C). During CAR, a high-purity H₂ gas stream is obtained (~95%). H₂ content of the outlet gas stream decreases as CaO sorbent approaches its saturation capacity, while CH₄ content increases. In order to ensure a high-purity H₂ production, the control orders the system to stop the CAR when outlet H₂ molar fraction decreases below 0.85 (Fig. 1A). With the aim to ensure thermal-neutral conditions during OX and to avoid high temperatures, which could lead to solid material deactivation, an inlet O₂ molar fraction around 0.03 is guaranteed by recirculating the nitrogen obtained at the outlet of the reactor. This stage should ensure that both Ni and Cu in the solid material are completely oxidized, thus the control ceases OX only when inlet O₂ molar fraction is detected at the reactor outlet (Fig. 1B). During the CAL, the heat released by exothermic Cu reduction should drive endothermic Ni reduction and sorbent regeneration. With this aim, a mixture of CH₄ and CO₂ is fed to the reactor with a CO₂-to-CH₄ feed ratio able to ensure autothermal conditions (Qin *et al.*, 2015; also see Table 2). Consequently, only steam and CO₂ are detected at the exit of the reactor. The control orders the system to stop the CAL when both CH₄ and CO₂ outlet molar fractions reach their feeding value. The former condition ensures that both Ni and Cu are fully reduced, while the latter ensures that the sorbent is fully regenerated (Fig. 1C). Starting from these results, cyclic operation consisting of a sequence of carbonation/reforming-purge-oxidation-purge-calcination-purge stages was considered. The purge stage between calcination and carbonation aims to pressurize the bed until $P_{CAR/OX}$ since the calcination stage is carried out at atmospheric pressure. The period of each purge stage was fixed to 100 s.

Table 2 – Parameters used in the simulations.

Parameter	Value
Feed temperature, T_f	1073 K
Initial temperature of the bed, T_0	1073 K
Carbonation and oxidation Pressure, $P_{CAR/OX}$	3.5 MPa
Calcination Pressure, P_{CAL}	101325 Pa
Reactor length, L	1 m
Reactor diameter, d_r	0.05 m
Particle diameter, d_p	0.01 m
Bed void fraction, ε_g	0.5
Mass of the solid in the reactor, m_s	1.6 kg
Mass fraction of sorbent, ω_{CaO}	0.45
Mass fraction of nickel, ω_{Ni}	0.10
Mass fraction of copper, ω_{Cu}	0.45
H ₂ O-to-CH ₄ feed ratio during CAR	5
CO ₂ -to-CH ₄ feed ratio during CAL	2.3
Mass flux of the gas phase in the CAR and CAL, $G_{CAR/CAL}$	1 kg·m ⁻² ·s ⁻¹
Mass flux of the gas phase in the OX, G_{OX}	10 kg·m ⁻² ·s ⁻¹

Figure 1 – Outlet gas molar fractions during the first CAR (A), OX (B) and CAL (C).

Figure 2 – Outlet gas molar fractions during multiple carbonation/reforming (in grey), purge (in white), oxidation (in yellow) and reduction/calcination (in blue) cycles as function of the time.

Figure 3 – Average CH₄ conversion in per cent (A), H₂ yield (B) and selectivity in per cent (C) during reforming/carbonation stage for all 4 SE-SMR cycles.

The results of cyclic operation of SE-SMR are reported in Fig. 2 in terms of outlet molar fractions as function of the time. It has been shown that 4 steps of cyclic operation are enough to attain regime conditions. Indeed, the period of each stage (*i.e.* the width of colourful strings in Fig. 3) reaches a constant value after just the first cycle. In Fig. 3, CH₄ conversion (A), H₂ yield (B) and selectivity (C) are reported as average values of reforming/carbonation stages for the 4 steps of cyclic operations: CH₄ conversion is around 95%, while H₂ yield and selectivity are about 3 mol_{H₂}·mol_{CH₄}⁻¹ and 90%, respectively. These last two parameters are higher than corresponding ones found in literature for alternative H₂ production process (Diglio et al., 2016).

4. Conclusions

A numerical investigation of autothermal SE-SMR process in packed-bed based on a CaO/CuO/Al₂O₃(NiO) catalyst is presented. The SE-SMR is intrinsically periodic, as reforming/carbonation, oxidation and reduction/calcination stages cyclically follow each other. A 1D pseudo-homogeneous model was used to find the operating conditions ensuring high-purity H₂ production over carbonation stage, thermal-neutrality over oxidation stage, and an autothermal reduction/calcination stage. The switch between each stage was dictated by monitoring outlet gas composition. At regime conditions, hydrogen yield and selectivity of 3 mol_{H₂}·mol_{CH₄}⁻¹ and 90% were reached, respectively.

A Heat Load Distribution Method for Retrofitting Heat Exchanger Networks

Hür Bütün^{a*}, Ivan Kantor^a, Alberto Mian^a and François Maréchal^a

^a*École Polytechnique Fédérale de Lausanne, IPESE, Sion, Switzerland*
hur.butun@epfl.ch

Abstract

Fluctuating energy prices, increasing environmental concerns, and regulations push industries toward more energy efficient plants. Process integration (PI) techniques, proven to be effective in providing solutions with improved energy and material efficiencies often neglect modifications to the heat exchanger network (HEN). HEN design methods have been studied extensively to overcome this drawback of process integration but often still focus on grassroots design to suggest retrofits. This work proposes a method to solve heat load distribution (HLD), a sub problem of HEN design, in the context of retrofit problems. The problem is solved using a mixed integer linear programming (MILP) model with integer cuts (IC) to obtain many retrofit options with high computational speed. The model is built on previously developed methods for PI (Maréchal and Kalitventzeff, 2003) and HEN design (Ciric and Floudas, 1989; Mian et al., 2016), such as mathematical programming (MP) and pinch analysis (PA). The objective function of the proposed method is minimisation of the estimated cost of the modifications required in an existing HEN, by considering the costs of repiping, additional heat exchanger area and additional heat exchangers. The estimated area of the potential stream matches is calculated using graphical techniques on the process integration results and taking into account correction factor. The additional heat exchanger area is constrained to practical limits available in the literature. The cost of heat exchanger area is calculated using piece-wise linearization of nonlinear cost functions. Solving the model yields information on stream matches and their heat loads as well as identifying which streams should be repiped and which heat exchangers should be modified or replaced. An industrial case study is solved to show the effectiveness of the proposed method resulting in annualized cost reductions of 9% considering the HEN design alone and 29% with modifications to the utility system to include heat pumping.

Keywords: process integration, heat exchanger network, retrofit, heat load distribution

1. Introduction

Industrial energy consumption represents 26% of the European total; industry is therefore incentivized by regulatory bodies to improve energy efficiency. Improving energy efficiency in industry has thus been a primary concern in research studies. PI techniques emerged after the oil crisis in 1970s and are still relevant and effective energy targeting methods to solve industrial energy efficiency problems (Klemeš and Kravanja, 2013). PI results typically propose solutions that require modifications to existing plants. Although investment in new technologies and equipment is considered with PI techniques, heat exchanger modifications are typically neglected. Several methods are available to include the cost of the modifications in the heat exchangers within PI (Bütün et al., 2017) or as post-processing (Ahmad et al., 1990). However, without knowing the

HEN superstructure or even the stream matches, estimation from these methods might deviate significantly from the real cost. HEN design has been deeply studied to improve calculation of the total cost of energy saving measures.

Yee and Grossmann (1990) proposed the SYNHEAT model using mixed integer non-linear programming (MINLP) to solve energy targeting, the matches between hot and cold streams and the optimal superstructure of the HEN simultaneously. One of the nonlinear constraints in HEN is calculation of logarithmic mean temperature difference (LMTD). Barbaro and Bagajewicz (2005) eliminated the nonlinear LMTD constraints by using fixed temperature intervals and formulated the HEN problem in the form of MILP by using linear cost functions.

Since heat exchanger network design is a difficult problem to solve, decomposition methods for dividing and solving it as several subproblems have been developed. The most common three subproblems of HEN are energy targeting (i.e. energy integration), minimum number of hot-cold stream matches (i.e. HLD) and minimum heat exchanger area cost (i.e. HEN superstructure). François and Irsia (1989) proposed the SYNEP model which solves the heat exchanger network subproblems by including heuristics. Mian et al. (2016) improved the heat exchanger network superstructure by allowing both parallel and series configurations and coupled MP methods with particle swarm optimization.

Retrofitting problems are currently the focus of many European industries since energy efficiency improvements are implemented on existing sites. Ciric and Floudas (1989) proposed a method to solve the HLD subproblem by including retrofit constraints. Afterward, a MINLP model formulation (Ciric and Floudas, 1990) was used to find the optimal retrofit superstructure applying an iterative procedure. Nguyen et al. (2010) proposed a MILP formulation using the fixed temperature interval model of Barbaro and Bagajewicz (2005).

A gap is identified for solving the HLD in retrofit situations since existing methods either do not clearly state how LMTD is calculated (Ciric and Floudas, 1989) or use predefined temperature intervals and linear cost functions (Barbaro and Bagajewicz, 2005) to fit within the MILP domain. This paper proposes a method to solve HLD retrofit problems based on the work of Ciric and Floudas (1989). The results of HLD can be used for heat exchanger network design in case of unsplit acyclic HENs or can be followed by superstructure synthesis.

2. Methodology

2.1. Energy integration

The energy integration (i.e. targeting) subproblem must be solved prior to considering HLD. The problem is defined with a set of units (**U**) consisting of the set of process units (**PU**) with fixed sizes and utility units (**UU**) which are scheduled using binary variables (y) and sized using continuous variables (f). The energy and material flows are modelled as thermal and mass streams with set of streams (**S**). Streams are assigned to units such that sizing and scheduling agree with their containing units. The details of the MILP formulation of energy integration can be found in Marechal and Kalitventzeff (2003).

2.2. LMTD calculation from graphical methods

LMTD evaluation is nonlinear and hence cannot be calculated within an MILP. One novelty this paper brings is the LMTD estimation at the level of HLD. The method to obtain vertical segments from the composite curves (Ahmad et al., 1990) is adapted. This way the LMTD for each vertical zone in the composite curve can be obtained. However, HLD is formulated with temperature intervals. The $LMTD_{ijk}$ of the hot ($i \in \mathbf{H}$) and cold ($j \in \mathbf{C}$) streams in each temperature interval ($k \in \mathbf{K}$) is calculated by taking the weighted average of the LMTD of the vertical segments in the

temperature interval. Afterwards, this parameter is used to calculate the area required for the heat transfer of the match i - j using Eqns. (1) and (2).

$$A_{ijk} = \frac{\dot{Q}_{ijk}}{U_{ijk} \cdot \text{LMTD}_{ijk} \cdot F_{corr}} \quad \forall i \in \mathbf{H}, j \in \mathbf{C}, k \in \mathbf{K} \quad (1)$$

$$A_{ij} = \sum_{z=1}^{\mathbf{K}} A_{ijk} \quad \forall i \in \mathbf{H}, j \in \mathbf{C} \quad (2)$$

2.3. Heat load distribution for retrofitting

The HLD problem is defined from the results of energy integration (EI). The units that are not used in EI are removed from the set of units for HLD. Since HLD focuses on heat, it only considers thermal streams from the overall set of streams. The unit sizes and hence the heat load of the streams are fixed as parameters. The existing heat exchangers in the system are defined as a set (\mathbf{X}). To model the stream segments, the set of stream groups (\mathbf{SG}) is used. As such, when a stream with phase change or varying heat capacity is defined, a stream for each segment is created but all are assigned to the same stream group. Stream groups are then separated into the set of hot stream groups (\mathbf{HG}) and the set of cold stream groups (\mathbf{CG}). The matches are created between $i \in \mathbf{HG}$ and $j \in \mathbf{CG}$ using binary variables (y_{ij}). The problem size is therefore greatly reduced in problems with segmented streams compared to existing methods available in literature. The heat load of the stream matches is determined using the heat flow model presented by (Floudas et al., 1986). Modifications in the existing heat exchanger network are classified into six categories as proposed by (Circic and Floudas, 1989). Each stream pair in the solution can be defined according to the required modifications, or lack thereof.

- **Category 1: No modification, no cost.** The existing stream match is housed in the current heat exchanger. Hence, no modification is required. The matches are assigned to this category using set **C1**
- **Category 2: Moving the heat exchanger.** The existing stream match is housed in an existing exchanger, though not the one currently employed for this purpose. Hence, this category requires moving the heat exchanger. The matches are assigned to this category using set **C2**
- **Category 3: Repiping one stream.** A new match is housed in a heat exchanger from the existing network which was housing either the cold or the hot stream of the match. The matches are assigned to this category using set **C3**
- **Category 4: Repiping two streams.** A new match is housed in a heat exchanger from the existing network which had no connection with either the cold or hot stream of current network. The matches are assigned to this category using set **C4**
- **Category 5: Purchasing a new heat exchanger.** An existing stream match is housed in a new heat exchanger. The matches are assigned to this category using set **C5**
- **Category 6: Purchasing a new heat exchanger and repiping.** A new stream match is housed in a new heat exchanger. The stream matches are assigned to this category using set **C6**

In contrast to the methods available in literature, only the matches that include at least one stream group from a process unit are considered for the listed retrofitting categories. This approach omits the cost of heat exchangers between utility units (e.g. boiler and steam network), thus only optimising interactions which affect the process units.

The cost of modifications according to the retrofitting categories can be summarised as moving a heat exchanger, repiping stream(s) and purchasing a new heat exchanger. In addition, when one of the heat exchangers from the existing networks is reused, its area can be increased (i.e. additional heat exchanger area). The cost of moving heat exchangers, repiping and additional heat exchanger area are calculated using linear formulas found in Rezaei and Shafiei (2009). Cost calculation for new heat exchangers is completed by applying piece-wise linearization to nonlinear

cost estimation formulae. The objective Eqn. (3) is minimization of the total modification cost required in the network.

$$\begin{aligned} \min_{y,n,A} & \sum_{y_{ijx}}^{C2} y_{ijx} \cdot c^{move} + \sum_{y_{ijx}}^{C3} y_{ijx} \cdot c^{rep1} + \sum_{y_{ijx}}^{C4} y_{ijx} \cdot c^{rep2} \\ & + \sum_{n_{ij}}^{C5} (n_{ij} \cdot c^{inst} + A_{ij}^{purc}) + \sum_{n_{ij}}^{C6} (n_{ij} \cdot c^{inst+rep2} + A_{ij}^{purc}) + \sum_{A_{ijx}}^X A_{ijx}^{add} \end{aligned} \quad (3)$$

The retrofit constraints are given in Eqns. (4) to (8). An existing heat exchanger is assigned to maximum one stream match by Eqn. (4). Each match is assigned to either an existing heat exchanger or a new one by Eqn. (5). Heat exchanger area required for each match must be equal to the heat exchanger area used from the existing exchangers and the new heat exchanger area using Eqn. (6). The new heat exchanger area assigned to a stream match is equal to either heat exchanger area added to an existing exchanger or the area of a purchased heat exchanger (i.e. a new heat exchanger) by Eqn. (7). The additional area to the existing heat exchangers is constrained to the practical limits by Eqn. (8). The heat flow model and the equations concerning stream matches can be found in Mian et al. (2016). Tbl. 1 depicts the description of the symbols used in the formulation.

$$\sum_{i=1}^{HG} \sum_{j=1}^{CG} y_{ijx} \leq 1 \quad \forall x \in \mathbf{X} \quad (4)$$

$$y_{ijx} + n_{ij} - y_{ij} = 0 \quad \forall i \in \mathbf{HG}, j \in \mathbf{CG}, x \in \mathbf{X} \quad (5)$$

$$A_{ij}^{new} + A_{ijx}^{exist} - A_{ij} = 0 \quad \forall i \in \mathbf{HG}, j \in \mathbf{CG}, x \in \mathbf{X} \quad (6)$$

$$A_{ij}^{new} = A_{ijx}^{add} + A_{ij}^{purc} \quad \forall i \in \mathbf{HG}, j \in \mathbf{CG}, x \in \mathbf{X} \quad (7)$$

$$A_{ijx}^{add} \leq A_{ijx}^{exist} \cdot add^{max} \quad \forall i \in \mathbf{HG}, j \in \mathbf{CG}, x \in \mathbf{X} \quad (8)$$

Table 1: Description of the symbols in the formulation

Symbol	Description	Symbol	Description
y	Binary to decide a stream match	$exist$	Existing
n	Binary to decide a new stream match	add	Additional
A	Area of the stream match	$purc$	Purchase
\dot{Q}	Heat load	$move$	Moving
\bar{U}	Overall heat transfer coefficient	$rep1$	Repiping 1 stream
F_{corr}	LMTD correction factor	$rep2$	Repiping 2 streams
c	Specific cost	$inst$	Installation

3. Case Study

An industrial production plant is studied to apply the proposed method. In the current state of the site, heat recovery between hot and cold processes is not applied. Therefore, all process heating requirements are supplied by the heating utilities and hot processes are cooled by cooling utilities. The existing plant uses a boiler to provide heating which is distributed to processes through the steam network. Air and water heat exchangers are both used to supply the process cooling requirements. The list of process streams, their current stream matches and heat exchanger area are given in Tbl. 2.

In addition to the existing utilities, integration of two heat pumps is considered. The evaporation and condensation temperature levels of the heat pumps are decided based on the grand composite curve (GCC) of the plant.

Table 2: Streams and initial heat exchanger areas of the case study

Stream	T _{in} [°C]	T _{out} [°C]	T _{sat} [°C]	ΔQ [kW]	Area [m ²]	Stream	T _{in} [°C]	T _{out} [°C]	T _{sat} [°C]	ΔQ [kW]	Area [m ²]

4. Results and discussion

The current energy bill of the plant is calculated to represent the base case scenario (BCS) and hence provide a basis of comparison for benefits of the energy saving solutions. EI is carried out in several scenarios. energy saving scenario 1 (ES1) presents a scenario where investment in new energy conversion technologies is not desired. Improvements in energy efficiency must therefore be through better use of the resources and systems available on the plant. In energy saving scenario 2 (ES2), integration of heat pumps is also considered.

Figure 1: Cost comparison of scenarios (left), distribution modifications in ES2 (right)

EI is followed by HLD retrofit optimization for each scenario (excluding the base case) which yields annualized cost estimation of the heat exchanger network modifications to achieve the improvements in energy efficiency assuming 20 years of life time and 8% interest rate. In Fig. 1 the comparison of the base case and energy saving scenarios can be seen. Operating cost is reduced by 33% with more efficient use of the steam network and another 28% with the integration of heat pumps. When the cost of the modifications estimated by HLD and the cost of the heat pumps are considered, the reduction in the total cost becomes 9% and 29% in ES1 and ES2, respectively. The details of heat exchanger network modifications for ES2 are given in Fig. 1. The distribution of the number of modifications of each type can be seen in the outer pie chart while the distribution of the cost of the modifications is plotted in the inner chart. The cost of the modifications is dominated by the cost of new heat exchangers added to the network. Since the remaining contributions are marginal, the distribution of cost amongst them is plotted separately. The cost of adding area to the existing heat exchangers has the largest cost contribution. One reason for this distribution is that repiping and moving heat exchangers have unit cost per modification while additional heat exchanger area also depends on the size of the modification.

In HLD, because of the nature of the problem, it is possible to obtain the same or similar objective function evaluations with different configurations. In industrial applications, these alternatives are important to provide several options for improvement since not all constraints are accounted for in the formulation of the optimization. IC is applied to the HLD retrofit of ES2. The comparison of IC scenarios is depicted in Fig. 2. With the integer cut solutions, ten different modification combinations are proposed, with objective values within 1% of the optimal.

Figure 2: Integer cuts results

5. Conclusion

In this work, a mathematical programming method is proposed to solve HLD in the context of retrofit problems. The categories of modifications are defined as moving heat exchangers, repiping stream(s) of an existing heat exchanger, adding heat exchanger area to the existing heat exchangers and adding new heat exchangers. The method is applied to a real industrial problem where the total cost of the system was reduced by 29% considering integration of new utilities, more efficient use of the existing ones and the estimated cost of the modifications in the heat exchanger network. Multiple options for retrofitting were obtained by applying integer cuts in HLD. The method can be used to make preliminary retrofit decisions as well as to determine the stream matches prior to HEN superstructure synthesis.

Abstract

In this study, a new Biomass-Gas-Nuclear heat-To-Liquid fuel (BGNTL) process is presented which uses high-temperature nuclear heat as the heat source for steam methane reforming (SMR). This process co-produces liquid fuels (Fischer-Tropsch liquids, methanol and DME) and power. The BGNTL process was simulated using a combination of different software packages including gPROMS, MATLAB, ProMax, and Aspen Plus. This included the use of a rigorous multi-scale model for the nuclear-heat-powered SMR reactor which was developed in a prior work in gPROMS. Energy efficiency and cradle-to-grave life cycle inventory and life-cycle impact analyses of greenhouse gas (GHG) emissions were accomplished to analyze the environmental impacts of the BGNTL system. Plant performance was compared with a base case Biomass-Gas-To-Liquid (BGTL) process at the same size. In both processes, a carbon capture and storage (CCS) option is considered. It has been found that both processes result in negative total life cycle GHG emissions due to the use of biomass as one of the feedstocks and CCS. Furthermore, the results of this study demonstrate that BGNTL process has 5% lower direct GHG emissions and 13% lower life cycle GHG emissions compared to the BGTL process due to the nuclear heat integration. Also, by using nuclear heat, fossil fuel consumption decreased by up to 10%.

Keywords: Biomass, Natural gas, Carbonless Heat, Polygeneration.

1. Introduction

When oil prices are high, there is significant incentive to use alternative methods of producing gasoline and diesel such as the gas-to-liquids process (GTL). Previous studies have shown that instead of using gas only, processes which integrate natural gas with other fuels can exploit certain synergies that yield both higher energy and carbon efficiencies (Khojasteh and Adams, 2013, Adams and Barton, 2011). In this process, natural gas and coal are used as the source of carbon, while heat and electricity are provided by an advanced type of nuclear energy source called a Modular Helium Reactor (MHR) (Adams and Barton, 2011). This forms the coal-gas-and-nuclear-to-liquids (CGNTL) process, which can be better both environmentally and economically than coal-to-liquids (CTL), coal-and-gas-to-liquids (CGTL), and other processes. However, even though the CO₂ can be eliminated during processing, one cannot prevent the CO₂ emissions from using the gasoline. Furthermore, coal is not of much interest to the Province of Ontario, Canada due to lack of local coal mines and the lack of political support. A recent study (Scott and Adams, 2016) presented a biomass-gas-and-nuclear-to-liquids (BGNTL) process to co-produce fuels and power which is meant to specifically take advantage of Ontario's interests and resources. In this process, nuclear

energy was used to power a copper-chloride cycle that produced hydrogen for syngas upgrading. However, it was found that it was not economical to use nuclear energy in this way (Scott and Adams, 2016). Instead, other approaches which take better advantage of the high-temperature ($>800^{\circ}\text{C}$) heat produced by some nuclear reactors may be preferable. This study presents the BGNTL process which uses high temperature nuclear heat as the heat source of steam methane reforming process and compares the efficiency and environmental impacts of this process with the BGTL process.

2. Methodology

Figure 1 shows the schematic of the BGTL and BGNTL processes. The process starts with biomass gasification using the high purity oxygen from the air separation unit (ASU), steam, and CO_2 . The produced hot syngas transfers its heat via a radiant syngas cooler (RSC) to either the integrated steam reforming process in the BGTL case or the steam generator in heat recovery steam generator (HRSG) section for BGNTL case. Then, the raw syngas is desulfurized in both cases and clean syngas is sent to the syngas mixing section. In the BGTL case, this CO-rich syngas is mixed with the hydrogen-rich syngas from the integrated RSC/SMR, syngas from the auto-thermal reforming (ATR) sections, and shifted syngas from the water gas shift (WGS) section to achieve a certain H_2/CO ratio for downstream processes. In the BGNTL case, CO-rich syngas is mixed with H_2 rich syngas from the integrated SMR/high temperature gas-cooled reactor (HTGR) to adjust the H_2/CO ratio. In this case, a WGS section is not necessary since nuclear-driven syngas has very high hydrogen content and all of the CO-rich syngas is required to obtain the desired H_2/CO ratio for Fischer-Tropsch (FT) synthesis and MeOH & DME processes.

The mixed syngas then is split into three streams and sent to either FT synthesis to produce gasoline and diesel, to the MeOH & DME section to produce DME and MeOH, or to the power generation section which includes gas turbine (GT) and solid oxide fuel cell (SOFC) sub-systems. The SOFC exhaust gas is mostly water and CO_2 which can be easily separated by CO_2 compression. The waste heat from the sections is recovered in the HRSG unit to produce steam for the plant needs and electricity via steam turbines if extra heat is available. Finally, 90% of the CO_2 in the FT feed syngas is removed using MDEA solvent, then this purified CO_2 and CO_2 from SOFC is compressed up to 150 bar for sequestration.

To simulate the BGTL and BGNTL processes, a combination of Aspen Plus V10, ProMax, gPROMS, and MATLAB software packages were used. Aspen Plus was used to model most of the process sections except CO_2 removal and integrated steam reforming sections. The PR-BM physical property package was used for most of the Aspen Plus simulations except the water-only streams in which NBS/NRC tables were applied, CO_2 /water mixture at high pressures for which PSRK was used, and MeOH/DME separation for which NRTL-RK was used. ProMax software was employed to model the CO_2 removal section due to more accurate physical property models (TSWEET) for this system. This model was developed by Adams et al. (2014). A reduced order model (ROM) of this process was developed based on the ProMax results and implemented in Aspen Plus. Also, gPROMS was used to model the integrated RSC/SMR system and integrated HTGR/SMR processes. The RSC/SMR process used in the BGTL case was modeled and validated using experimental data by Ghouse et al. (2015). Scott et al. (2016) developed a ROM of this process based on the

results of this model and implemented that in Aspen Plus. In addition, the integrated HTGR/SMR section of BGNTL process was modeled in gPROMS by Hoseinzade et al. (2017) and validated using two pilot scale facility design data.

Both BGTL and BGNTL cases were sized to have 1270 MW_{HHV} thermal input including woody biomass, natural gas, and nuclear energy (in the BGNTL case only). The amount of biomass fed is 100 tonne/hr in both cases; however, the amount of natural gas and nuclear heat are varied accordingly, noting that the ratio between natural gas and nuclear heat in the integrated HTGR/SMR is fixed based on design limits. Table 1 shows the raw material and energy input to the base case BGTL and BGNTL plants. Note that the nuclear heat input is nearly identical to the thermal output (115 MW_{th}) of the Peach Bottom I helium-cooled reactor constructed in 1967 (LaBar et al., 2010). Utility requirements in the plant such as steam and electricity are generated in the plant. As a result of using nuclear energy in the BGNTL process, fossil fuels consumption approximately decreased by 10%.

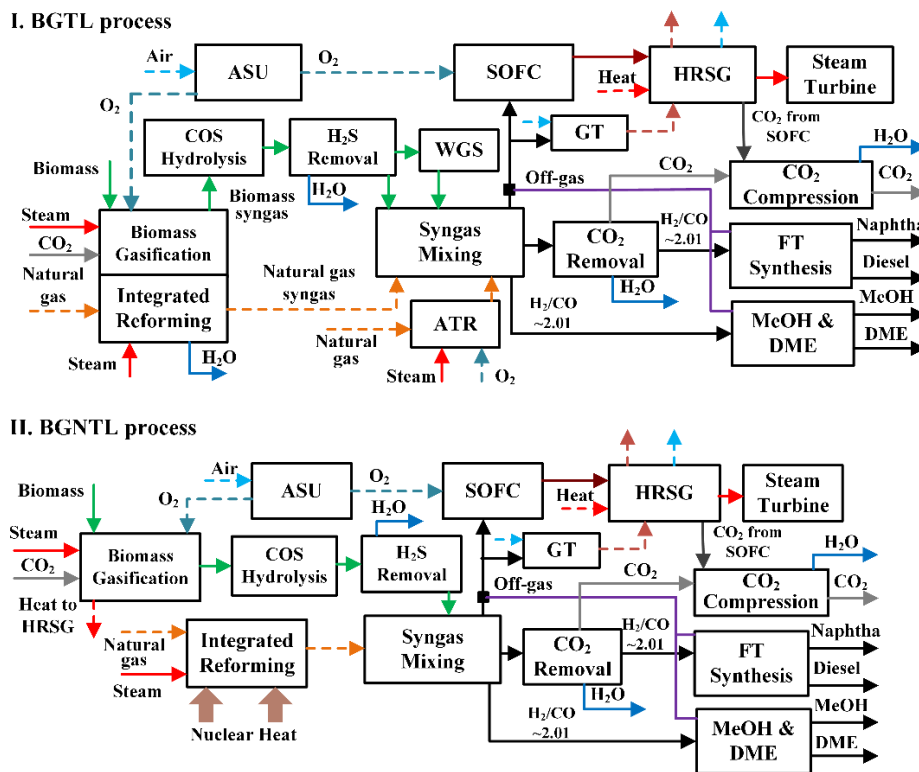

Figure 1. Schematic of BGTL and BGNTL processes.

Table 1. Thermal inputs to the plant (HHV basis where applicable).

Plant	Biomass (MW _{th})	NG feed to SMR (MW _{th})	NG feed to ATR (MW _{th})	Nuclear heat (MW)	Extra heat/power (MW)
BGTL	550.0	169.3	550.7	-	-
BGNTL	550.0	600.5	-	119.5	-

3. Results and discussions

To evaluate the performance of the BGNTL process, its energy efficiency, carbon efficiency, and environmental impacts are compared to the BGTL process. To have a consistent basis for the comparison, the total thermal input, operating conditions, and CO₂ capture percentages are set to be the same. In addition, the syngas molar split fraction to each of the FT, MeOH & DME, SOFC, and GT routes, and the molar percentage of MeOH product used for DME production is fixed and the same for both cases.

To develop the reduced order model of the integrated HTGR/SMR system, the rigorous model developed in gPROMS by Hoseinzade et al. (2017) was applied. The studied HTGR/SMR plant is a shell and tube heat exchanger which high temperature helium gas is flowing in the shell side, and methane is reformed to syngas in the tube side. This system contains 199 SMR tubes placed in a shell with 14 (m) length and 2.7 (m) inner diameter. To collect the data from the model, the natural gas flow rate and steam to carbon ratio in the feed were selected as the independent variables. 55 data points were randomly generated using Latin Hypercube (LH) sampling, and the key output variables including the methane and steam conversions, heat duty, reformer exit temperature and pressure drop were recorded for each data point. 40 data points were used to train the model for each of the outputs, and 15 data points were applied to test the accuracy of the model. The MVR method was employed to develop the ROM for each of the outputs. For many of the variables, a second-order polynomial was the best fit. In addition, for all of the cases, R² of both training and testing was over 0.99.

In addition, the CO₂ removal process used a MDEA / piperazine blend as the solvent with a 90% CO₂ capture rate. This model then was used to build a ROM to implement in Aspen Plus. 100 data points were generated using LH sampling to train and test the developed ROM. 75% of the data were applied to the training, and the rest was used for the testing. Independent variables of this model include the CO₂ flow rate in the feed and solvent to feed molar ratio. Key output variables were the CO₂, H₂S, and water flow rate in the outlet streams, makeup solvent amount, reboiler and condenser duties in the stripper, different cooler duties, pump power, and outlet stream pressure. The ROM was developed based on the MVR as the previous case, and the model accuracy for the train and test were demonstrated by an R² over 0.98 for all the cases.

For the given feed conditions in Table 1, simulation results for the BGTL and BGNTL cases are shown in Table 2. The results show that electricity percentage of the BGNTL process is higher than the BGTL plant; however, liquid fuels and chemicals rate is slightly lower than the BGTL process due to lower natural gas feed rate.

Table 2. Simulation results.

Plant	Naphtha (tonne/hr)	Diesel (tonne/hr)	MeOH (tonne/hr)	DME (tonne/hr)	Electricity (MW)
BGTL	2.7	5.8	4.1	47.9	45.9
BGNTL	2.4	5.2	3.7	42.7	67.1

To evaluate the performance of the plants, energy efficiency is used as one of the indicators. Energy efficiency for a plant is defined as the ratio of the sum of produced power and HHV of produced fuels to the sum of total HHV of the feedstocks and

nuclear heat thermal input (Khojashteh and Adams, 2013). The energy efficiencies of plants with the given conditions in Table 1 and results in Table 2 are calculated as 47.27% for the BGTL case and 44.21% for the BGNTL process. The lower efficiency of the BGNTL plant is due to the lower fuel production rate comparing to the BGTL. The carbon efficiency is defined as the percentage of the carbon atoms in the feed converted into the liquid fuels (Khojasteh and Adams, 2013). The carbon efficiency is 40.06% for the BGNTL process and 41.57% for BGTL. The carbon efficiencies of the plants are close, however, the BGTL carbon efficiency is slightly higher.

To evaluate the environmental impacts of both processes, a cradle to grave GHG emission analysis was conducted. In both cases, all of the CO₂ produced in the SOFC section and 90% of the CO₂ in the FT feed syngas is captured. The only direct GHG emissions from the plant are the GT emissions. To estimate the cradle-to-plant-gate GHG emissions, woody biomass cradle-to-plant-gate emission was considered as 0.133 tonne CO₂e/tonne (Zhang et al., 2010) and natural gas well-to-plant-gate emission was counted as 7.2 g CO₂e/MJ_{th,HHV} (Scott and Adams, 2016). Furthermore, a credit was considered for using biomass by estimating the equivalent CO₂ in biomass based on the carbon atom balance. The plant gate-exit-to-grave emissions include the GHG emissions from the produced fuels' dispensing, distribution and consumption stages. It is assumed that fuel dispensing and distribution GHG emissions are 138 g CO₂e/GJ and 575 g CO₂e/GJ, respectively; plant-to-grave emissions of gasoline and diesel are assumed to be 19.64 lbs CO₂e/gallon and 22.38 lbs CO₂e/gallon, respectively (Scott and Adams, 2016). The plant-to-grave emissions of methanol and DME were also estimated based on fully combusting those and calculated as 1.37 and 1.91 kg CO₂e/kg, respectively. Net sequestered CO₂ also represents the total CO₂ captured subtracted from any CO₂ input to the plant.

Table 3 shows the GHG emission results for the BGTL and BGNTL plants with and without CCS. The negative value for net CO₂e emissions represents the reduction in GHG emissions. Based on the results, both processes end up with a net reduction in GHG emissions, however, BGNTL process achieves 13.4% more life cycle GHG emission reduction and 5% less direct CO₂ emissions in the plant due to using nuclear energy. Based on the GREET (2017) model the cradle-to-plant gate-exit GHG emissions of coal-based DME is 92,700 gCO₂e/GJ_{DME} and its gate-exit-to-grave emissions are 60,280 gCO₂e/GJ_{DME} (Scott and Adams, 2016), so the cradle to grave GHG emissions of coal based DME is 152,990 gCO₂e/GJ_{DME}.

Table 3. Cradle to grave GHG emissions of the plants for 85% capacity.

GHG emission (tCO ₂ e/yr)	BGTL/CCS	BGNTL/CCS	BGTL/ woCCS	BGNTL/ woCCS
Direct GHG emissions	216,780	204,400	1,231,500	1,172,300
Cradle-to-plant-gate- entrance GHG emissions	-896,410	-916,940	-896,040	-916,940
Net sequestered	-941,210	-893,112	0	0
Plant-gate-exit-to-grave GHG emissions	914,990	814,310	911,450	813,390
Net Cradle-to-grave GHG emissions	-705,120	-791,340	1,327,700	1,149,500
Net Cradle-to-grave GHG emissions (gCO ₂ e/GJ _{HHV})	-48,372	-58,128	88,307	84,536

4. Conclusions

A base case design for the BGNTL process was presented and its performance was demonstrated by comparing the plant thermal and carbon efficiencies and life cycle GHG emissions to the base case BGTL process of the same size. It was found that both processes have significant negative net lifecycle GHG emissions owing to the sequestration of biogenic carbon. Even without sequestration, the lifecycle GHG emissions of the products are much lower than fossil fuels. However, BGNTL/CCS has 13% lower life cycle GHG emissions and 5% lower direct GHG emissions than BGTL/CCS owing to the use of nuclear energy. The BNGTL and BGTL have similar carbon efficiencies, but the BNGTL thermal efficiency is lower for this product mix.

In this work, the presented model used a mixture of products and technologies (such as both SOFCs and GT), but in practice, only a subset of these would be chosen. This was done because in future work, the model will be used in a superstructure optimization framework which will choose key process design parameters, outputs, and technologies based on a combination of economic and environmental objective functions. Based on the present results, the BGNTL process is expected to be more expensive but have less environmental impact than BGTL, and the optimization-based analysis will be used to better understand this trade-off. This will also determine if the integrated HTGR/SMR approach to integrating nuclear energy is preferable to the copper-chlorine cycle.

Abstract

A considerable amount of carbon-containing and nutrient-rich waste resources are generated globally each year, which could be converted via various routes to bioenergy and other value-added bio-products. In an industrial park setting in which multiple waste-streams of different compositions along with various treatment/recovery technologies may be present, significant opportunities for symbiotic interaction exist through appropriate coordination. To enable such a shift, this work introduces an optimisation framework suitable for handling such a problem, thus providing the potential for significant reductions in the environmental and financial costs associated with the wastewater treatment process. A superstructure is proposed whereby different waste streams of varying flow rates and compositions are input and acted on by a combination of different treatment/recovery technologies to produce a set of treated output streams. The process is captured within a Mixed-Integer Linear optimisation formulation (MILP), in which a combined set of (typically competing) objectives capturing the financial, energy and environmental considerations associated with the problem, is minimised. Variables representing design and operational decisions as well as time-varying flow rates and compositions are included, while the physical limitations of the system and the design requirements of the outputs are also captured.

Keywords: wastewater, optimisation, industrial process design

1. Introduction

Globally, expanding populations and rapid urbanisation, particularly in the Global South, are leading to grand challenges at the nexus of resources, water and waste. The projected 50% increase in global population in the 21st century (United Nations, Department of Economic and Social Affairs, Population Division (2017)), combined with non-OECD economic growth is expected to bring a increase in energy demand of over 30%, while intensifying the resource scarcity challenge e.g. for non-renewable phosphorus. Moreover, rising waste generation brings additional stress. Globally, out of a total of 0.12–4.3 kg per day per capita solid waste, 59%–68% is organic fraction and significant amount of (330km³, per year) municipal wastewater is generated (Hoorweg and Bhada (2012)). The global trajectory of solid waste growth is projected to rise to 6 million tonnes per year with a similar organic fraction level by 2025 and to exceed 11 million tonnes per day by 2100 under a *business as usual* scenario (Hoorweg et al. (2013)); such an increasing waste trend is particularly intense in less developed countries.

To achieve the responsive management of the environment and natural resources, a paradigm shift to resource-circular systems with waste recovery is underway. Industrial parks or complexes launched in many countries (Zhang et al. (2016)) offer potential solutions to integrate functional industry networks with eco-efficient design and value-added ecosystem services. For effective strategic planning (e.g. location selection) in such an industrial park context, water remediation strategies can play a critical role in the overall park sustainability. Despite the modelling advances in process design and rigorous life cycle sustainability evaluation, an integrated system modelling framework that can bridge process synthesis and resource recovery network planning in an industry park context remains a gap.

Defined in (Chertow (2000)) as *industrial symbiosis*, traditionally separate industries engaging in collective approaches to physical exchanges of materials, by-products, energy and water can lead to globally advantageous operation (Afshari et al. (2017)). Development methodologies for eco-industrial parks that can exploit these industrial symbioses are studied in (Farel et al. (2016)), with the particular relevance to developing countries of such methodologies emphasised in (Shi et al. (2010)). As is highlighted in (Rubio-Castro et al. (2010)), the integration of wastewater streams from different streams generated from industries of close proximity can lead to reductions in the quantity of wastewater discharged as well as the fresh water requirement.

Effective design of an eco-industrial park-wide treatment scheme requires an optimal mix of technologies to be chosen at an optimal set of locations in terms of the financial and economic performance indicators. In (Puchongkawarin et al. (2015)), a strategy for optimisation of the wastewater treatment process is defined, while in (Rubio-Castro et al. (2010)), a formulation is defined for determining an optimal wastestream network configuration in a park-wide context. In this paper, an MILP optimisation methodology is developed to bridge the gap between process and network optimisations. Given a known set of industrial wastewater producers, the formulation determines an optimal set of locations and types of waste treatment and resource recovery units to provide economically and environmentally desirable performance, while adhering to physical and regulation-based constraints. The formulation can incorporate transport considerations, circular bio-economy factors and policy-driven incentives such as taxes and subsidies.

2. Optimisation Framework and Objective Formulation

The wastewater treatment process can be comprised of many stages in which various technological pathways can be implemented to remove pollutants, recover resources and extract valuable by-products (e.g. energy) from wastewater streams. In an industrial park context, different classes of industry producing a wide range of waste streams of varying compositions can be present at a single location. If each waste producer is considered only in isolation, a decentralised set of treatment plants is required, which may not operate to maximise the economic and environmental targets of the park as a whole. Alternatively, a centralised treatment plant to which all waste streams are fed could be employed, benefiting from economies of scale; however, transportation of the waste streams is required and the treatment process must be designed to handle a wider range of waste flows and compositions.

Appropriate design of the treatment and resource recovery process for the complete industrial park, exploiting symbioses present between the different industries while combining decentralised and centralised strategies, requires an optimisation framework that can handle both spatial and temporal aspects with the flexibility needed to cater to a wide spectrum of stakeholders and technological pathways. By integrating local constraints and global objectives, the developed framework seeks to achieve this holistic design aim. The constraints and objectives associated with the proposed MILP formulation are given here.

2.1. Mapping waste production

To enable the wide range of waste producers that may exist in a given industrial park to be captured within the optimisation framework, each individual waste producer is characterised only by its location and by the flow-rate and composition of the waste produced. To efficiently define location, the specific industrial park is divided into a grid of arbitrarily sized cells. This allows distances between waste producers and treatment facilities to be approximated. Wastewater stream compositions are characterised in the model as a set of P parameters and constituent component concentrations. This set can include the chemical oxygen demand (COD), nitrogen concentration, phosphorus concentration and protein content. Depending on the context, these can be considered pollutants or useful resources. In a network of X cells with J waste streams, the parameters p of stream j generated in cell x at time t are then given as $gen_{j,x,p,t}$, while the flow rate of the stream is $fl_{j,t}m^3/h$.

2.2. Resource Removal and Recovery

As the global bio-economy becomes more advanced, the ability to recover resources to prevent depletion (e.g. Phosphorus) or for use as an energy source (e.g. as biogas) is likely to act as an ever-greater influence on the wastewater treatment facility design process (Venkata Mohan et al. (2016)). Here, the technologies used in the overall treatment process are categorised as treatment technologies and recovery technologies. The former category includes options such as aerobic membrane bioreactors, de-watering, de-nitrification and clarification units which reduce the pollutant concentration, while technologies classified here as recovery technologies include anaerobic digestion and ion exchange strategies in which useful resources are extracted from the stream.

The treatment technologies generically form the set Tr , with the presence of a particular treatment unit tr for waste stream j in cell x indicated by the binary term $\alpha_{j,x,tr}$. Each class of treatment technology introduces a change in each waste stream parameter p of $\Delta P_{tr,p}^t$. Similarly, Rec denotes the set of potential recovery units. The presence of a particular recovery unit re is indicated by the binary term $\beta_{j,x,re}$ and each class of recovery technology introduces a change in each waste stream parameter p of $\Delta P_{re,p}^r$. Additionally, a recovery unit can extract a certain proportion of the components of a wastestream on which it acts. The recovery efficiency is denoted for technology type re as $R_{re,p}$.

The composition of discharged waste from stream j is given as:

$$dis_{j,p,t} = \sum_{x \in X} \left(gen_{j,x,p,t} - \sum_{tr \in Tr} \alpha_{j,x,tr} \Delta P_{tr,p}^t - \sum_{re \in Rec} \beta_{j,x,re} \Delta P_{re,p}^r \right) \quad \forall p \in P; t \in T \quad (1)$$

The quantity of recovered resources from stream j is then given by:

$$rs_{j,p,t} = fl_{j,t} \sum_{x \in X} \sum_{re \in Rec} \beta_{j,x,re} R_{re,p} \Delta P_{re,p}^r \quad \forall p \in P; t \in T \quad (2)$$

To limit the discharge of excessive levels of pollutants, constraints can be enforced on the concentration of particular components in each wastestream. Where P_p^{max} and P_p^{min} are the upper and lower bounds associated with stream parameter p , the constraints can be defined for stream j as:

$$dis_{j,p,t} - P_p^{max} \leq 0 \quad \forall p \in P; t \in T \quad (3)$$

$$P_p^{min} - dis_{j,p,t} \leq 0 \quad \forall p \in P; t \in T \quad (4)$$

Maximum and minimum flow restrictions are included for each technology, with the assumption that each treatment and recovery plant can take in multiple wastestreams. For the treatment technologies these are defined as:

$$Fl_{tr}^{min} - \sum_{j \in J} fl_{j,t} \alpha_{j,x,tr} \leq 0 \quad \forall x \in X; tr \in Tr; t \in T \quad (5)$$

$$\sum_{j \in J} fl_{j,t} \alpha_{j,x,tr} - Fl_{tr}^{max} \leq 0 \quad \forall x \in X; tr \in Tr; t \in T \quad (6)$$

Where $u \ll 1$ is an arbitrarily small constant, the presence of at least one treatment or recovery unit in cell x visited by stream j can be represented by the binary term $v_{j,x}$.

$$v_{j,x} \geq u \left(\sum_{tr \in Tr} \alpha_{j,x,tr} + \sum_{re \in Rec} \beta_{j,x,re} \right) \quad \forall j \in J; x \in X \quad (7)$$

Similarly, the presence of a specific treatment unit in cell x applied to any stream is given by $\omega_{x,tr} \geq u \sum_{j \in J} \alpha_{j,x,tr}$ with the presence of a recovery technology given as $\phi_{x,re} \geq u \sum_{j \in J} \beta_{j,x,re}$.

2.3. Spatial aspects and transportation networks

To enable the costs associated with the transportation of the waste streams to be taken into account, the distance travelled by each stream must be included as an optimisation variable. The presence of a transport pathway between the waste generation at x and the waste treatment and recovery location at x' is given for stream j by the binary variable $\gamma_{j,x,x'}$ formed as:

$$\gamma_{j,x,x'} \geq G_{j,x} v_{j,x'} \quad \forall x \in X; x' \in X \quad (8)$$

where $G_{j,x} = 1$ if the waste stream j originates at x and is 0 otherwise.

Using $\ell_{x,x'}$ to represent the distance between cell x and x' (this distance matrix can be pre-defined to enable spatial and geographical restrictions associated with pipework installation to be considered), the transport distance for the j^{th} stream is then:

$$len_j^{ot} = \sum_{x \in X} \sum_{x' \in X} \gamma_{j,x,x'} \ell_{x,x'} \quad (9)$$

2.4. Defining the Objective

Effective wastewater treatment in an industrial park context is a subjective matter, with local and global priorities varying across different stakeholders. These priorities can conflict. While local government may have environmental targets, individual waste producers may have a more economically focussed preference. Furthermore, the specific environmental and economic indicators will be contextual, as different regions and countries seek to satisfy different demands and considerations. Once again, to maintain the flexibility of the optimisation framework, both environmental and economic objectives are incorporated in a manner that allows for the optimisation to be aligned with specific scenarios by choosing suitable weights.

To determine the associated capital costs, an approximate cost per unit distance of pipework is defined as Cap^l . The operational and maintenance costs of transporting waste per unit distance is then given as Op^l . The transport costs for the full network $Cost^l$ are defined for the time period T as:

$$Cost^l = \sum_{j \in J} \left(Cap^l len_j^{ot} + \sum_{t \in T} Op^l fl_{j,t} len_j^{ot} \right) \quad (10)$$

In addition to the transport costs highlighted in Eq.(10), capital costs exist for the construction of each treatment and recovery unit. These are denoted respectively as Cap^t and Cap^r . Similarly, operational costs for treating $1m^3$ of waste for one hour are defined for each treatment and recovery unit as Op^t and Op^r . The total costs for the treatment processes are then defined as:

$$Cost^t = \sum_{x \in X} \sum_{tr \in Tr} \left(Cap_{tr}^t \omega_{x,tr} + \sum_{t \in T} Op_{tr}^t \sum_{j \in J} fl_{j,t} \alpha_{j,x,tr} \right) \quad (11)$$

The costs for the recovery processes $Cost^r$ are similarly defined.

In a well functioning bio-economy, the ability to sell any valuable resources extracted from the waste streams can act as an incentive. Furthermore, costs associated with the disposal of undesired waste can be included (Op^{dis}). Subsidy and taxation policies can play a large role in the economic viability of the park's wastewater treatment strategy. In the proposed framework, a taxation cost can be applied to each specific disposed waste constituent, while subsidies for the recovery of bio-products can be included to incentivise environmentally beneficial operation. Aside from economic incentives and taxes, the recovery or disposal of specific resources can be targeted directly in the objective. The weights associated with this cost (w_p^a and w_p^b) can be arbitrarily chosen, depending on the needs of the user. These costs are given here as:

$$Cost^{fin} = \sum_{j \in J} \sum_{p \in P} \sum_{t \in T} \left((Op_p^{dis} + Tax_p + w_p^a) dis_{j,p,t} - (Price_p + Sub_p + w_p^b) rs_{j,p,t} \right) \quad (12)$$

The full objective J to be minimised is then given as:

$$J = Cost^t + Cost^r + Cost^r + Cost^{fin} \quad (13)$$

3. Framework Implementation

To demonstrate the operation of the optimisation framework, a simple case-study is presented here in which a hypothetical eco-industrial park consisting of 4 waste producing industries seeks to achieve the most cost effective approach for the treatment and recovery of the produced wastewater. The different wastestreams are characterised by the respective concentrations of each of three different components: COD, total nitrogen (TN), total phosphorus (TP). These compositions are taken from Henze and Comeau (2008). Two types of treatment unit and two types of recovery unit can be implemented at any location in a 4x4 grid, which represents the spatial layout of the park (as it is assumed that no physical barriers are present, euclidean distances are used to determine transport lengths). Capital and operational costs are estimated for the treatment and recovery plants as well as the transportation of waste to the plants. Policy-based costs and subsidies are neglected here. The optimisation is carried out using the CPLEX solver in GAMS v.24.9.1.

As notional cost values are used here, the exact cost impact of the optimisation-based approach is unlikely to be instructive; however, the importance of taking a holistic perspective when designing such facilities in an industrial park context can be illustrated. To do so, three different scenarios are shown here. In the first scenario, a high transport cost is assumed, while the sale of resources is assumed to not be possible. In the second scenario, the transport costs are reduced, while in the final scenario, the ability to profit from the recovery from the wastestreams of one of the components is introduced. As is shown in Fig. 1, the locations and technology types chosen for optimal performance are significantly different, with both decentralised and centralised approaches favoured, depending on the scenario. Beyond this simple illustrative case used here to emphasise the purpose of the methodology, the model has been applied to hypothetical design studies in which GPS-X and CapdetWorks were applied in simulation and techno-economic analyses; the modelling framework is also currently being expanded to incorporate the experimental work being carried out at the Chinese Academy of Sciences, where the reactor design and technology development are being developed for the case-specific industrial park in China.

Figure 1: Three design scenarios for wastewater treatment in eco-industrial park

4. Conclusion

The concept of Industrial Symbiosis, through which advantageous operation of the various actors in an eco-industrial park context is achieved by process integration has long been established. In this paper, the concept is applied to the design of park-wide wastewater treatment and resource recovery strategies. An MILP-based optimisation framework is formulated which enables the locations and types of treatment and recovery technologies to be optimised. The formulation takes into account financial aspects such as the capital and operational costs for the technologies themselves, the costs associated with the transport of waste around the park and other policy-based taxes and subsidies. Aside from the environmental constraints on pollutants in the waste streams, benefits associated with the recovery of valuable resources and by-products can be included. The framework is flexible enough to allow for an arbitrarily large range of technologies to be considered while also enabling individual user preferences to be incorporated. This flexibility is shown in a hypothetical case study in which changing contextual parameters are captured in the framework to produce the most suitable treatment design approach.

Abstract

In this work, the impact of Carbon Capture, Utilization, and Storage (CCUS) as a potential technology to reduce Germany's carbon dioxide (CO₂) emissions is studied. Carbon dioxide is used as a raw material for methanol production in the global market. Carbon dioxide is captured from power plants and can be reacted to methanol with renewable hydrogen. The study shows that the integration of hydrogen- and carbon dioxide supply chains is only feasible if the electricity needed for renewable hydrogen can be delivered for free.

Keywords: carbon dioxide capture and storage, MILP modeling, Hydrogen supply chain, methanol synthesis, carbon dioxide reduction.

1. Introduction

Oxfam (2017) reported for 2017 five major environmental and humanitarian disasters that can be attributed to climate change. Many scientists have linked global temperature rise (and climate change) to increasing levels of greenhouse gases in our atmosphere. One of the main greenhouse gases is carbon dioxide. In 2016 the global carbon dioxide emissions were approximately 36 Gtons and trends show that emissions will keep growing if nothing is done.

The main sources of carbon dioxide emissions stem from the energy production via fossil sources such as coal and oil. Future scenarios for energy production we will remain dependent on fossil fuel resources (the NPS, New Policies Scenario and the 450S scenario stay below an average temperature increase of 2 °C, see the report by the International Energy Agency. 2015).

This all indicates that there is an urgent need to reduce carbon dioxide emissions to our atmosphere. This might be viewed as an environmental alarm bell. However, as chemical engineers, we can view this as an opportunity to serve and supply many different sectors: carbon dioxide can be used to produce fuels, construction materials, food, polymers, etc. Germany can take a leading role here.

In the Climate Action Programme 2020 (Nature Conservation Federal Ministry for the Environment, 2014) Germany aims at dramatically reducing its carbon dioxide emissions. As a result of the energie-wende (energy transition), Germany has massively invested in renewable energy production. However, conventional coal and gas-fired

power plants still largely supply the German energy landscape. This is due to the discontinuous availability of renewable energy and its problematic storage.

The aim of this work is to setup and study an economically and technologically functioning supply chain for the utilization of carbon dioxide that is captured from major stationary point emission sources throughout northern Germany. A potential application of carbon dioxide is the reforming of it into methanol for which Germany has an annual demand of 940 ktons per year. The hydrogen that is needed for producing methanol can be generated via water electrolysis with renewable energy.

2. Model description

We will geographically restrict the area of interest to the federal states of Northwest Germany (Lower-Saxony, Bremen, Hamburg, and Schleswig-Holstein) and explore different scenarios of a potential future supply chain network. We will evaluate two cases: one in which we focus on meeting demand for methanol and in the other to maximize carbon dioxide reductions. For each case a spatially explicit mixed integer linear program (MILP) optimization model is developed in the Advanced Interactive Multidimensional Modeling (AIMMS) software, targeting the economically optimized supply chain structure.

The generated network (see Figure 1) consists of one carbon dioxide dominated- (upper part of Figure 1), one hydrogen dominated- (lower part of Figure 1), and one storage/utilization dominated section (shown on the right side of Figure 1). The power plants are the sources of carbon dioxide dominated section. With pressure swing adsorption, amine absorption or membranes the capture of carbon dioxide from these sources is possible. Afterwards, carbon dioxide is transported to a storage or methanol production site. The sources of the hydrogen section are at locations near excess renewable energy production. With this energy, hydrogen can be produced via electrolysis. To transport the hydrogen to the methanol sites pipelines are used. Currently, the model considers only one storage site. The potential locations where methanol can be produced are at all the locations of the power plants and excess energy production sites. In this network, the sources represent the suppliers (of carbon dioxide and hydrogen) and the carbon dioxide storage and methanol production locations can be seen as the demand sites.

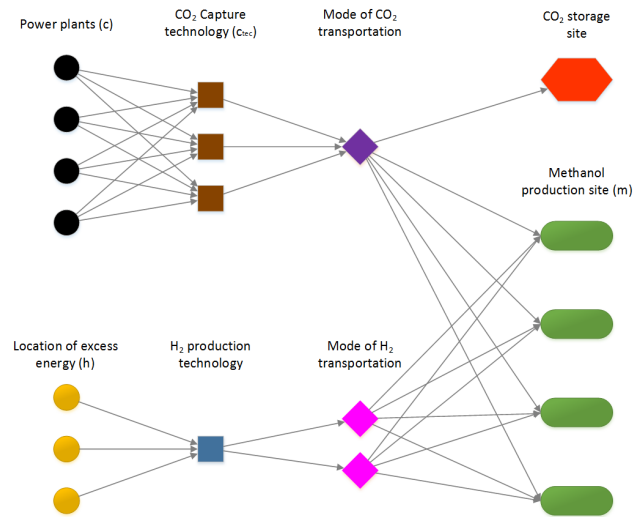

Figure 1: Network scheme of the CCS/CCUS Supply Chain

Form modeling the following assumptions are made:

- A capture plant is located at a carbon dioxide source to avoid the transportation of flue gas;
- a capture node can be connected by only one carbon dioxide source;
- the mode for transporting carbon dioxide is always pipeline;
- the H₂ production plants are located on the coast of the North Sea, near excess energy production;
- each location of excess energy can only provide one node of hydrogen production, and each hydrogen production node can only be provided by one location;
- hydrogen is produced through electrolysis;
- methanol is produced by direct, single step hydrogenation;
- all products can be sold at a stable price;
- there is only one carbon dioxide storage site, which has an infinite storage capacity;
- the network structure is fixed; time-dependent values are calculated to a yearly average through the specific lifetime of the component;

The type, location and yearly carbon dioxide emissions and flue gas compositions at the point sources are known. In addition, the cost and efficiencies of the capture and compression technologies that can be selected are given. Further, the carbon dioxide transportation via pipeline with its distances and costs are known. The location, price and amount of excess energy of the hydrogen sources are known and also the electrolysis as hydrogen production technology with its cost parameters are known. For the hydrogen transport technologies also distances and costs are given. For the methanol production plants, the hydrogenation of carbon dioxide is selected. For the methanol production plant also the locations and costs are given. Ultimately, the carbon dioxide storage site is going to be at Altmark while the storage costs, the methanol demand, and the carbon dioxide reduction target are fixed (the interested reader may contact the authors for the detailed dataset).

The objective is to minimize the costs of the supply chain which are composed of costs for carbon capture and compression, carbon dioxide transport, hydrogen production and transport, methanol production and carbon dioxide storage.

The following decisions must be made to minimize the costs: selection of the capture plant and the quantity that each plant captures, selection of the capture technology for each plant, used hydrogen production location and the quantity of produced hydrogen, transport mode for hydrogen, transport pathway for carbon dioxide and hydrogen, storage and methanol production site (inclusive the amount of stored CO_2 / produced methanol).

3. Data collection

For the hydrogen production facilities, a study from the Jülich Research Institute (D. Krieg, 2012) was used to identify the major offshore wind parks that can produce renewable electricity. These locations and capacities of these power sources provide power for the hydrogen production plants (HPP). We assume that the HPP should be located near the power sources.

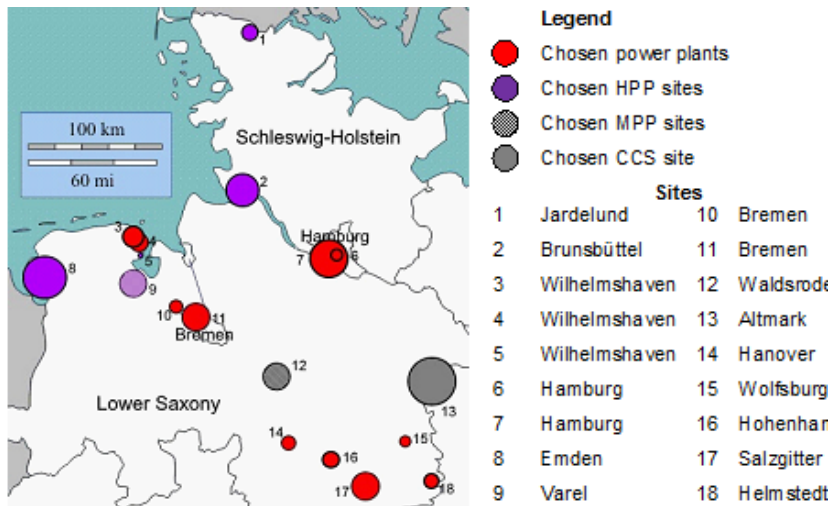

Figure 2 – Overview of all considered sinks and sources of the supply chain

A DEHSt report (Deutsche Emissionshandelsstelle, 2016) on power plant emissions was used to identify the major point sources of carbon dioxide. When considering only sources that emit 1 Mton or more, already more than half of the total carbon dioxide can be accounted for. All hydrogen production sites and carbon dioxide emission sites can be used as a methanol production plant (MPP). From the BMWi report (Federal Ministry for Economic Affairs and Energy, 2016) we identified one major carbon storage site (CCS). (See Figure 2).

4. Results and discussion

The model is formulated as a mixed integer linear programming model and has 4.950 constraints, 7.510 continuous variables, and 663 integer variables. AIMMS is used as optimization platform, and CPLEX 12.7 is selected as the preferred solver.

Two scenarios were evaluated. A methanol-driven scenario (to satisfy and/or to maximize methanol production) and a carbon dioxide-driven scenario (focusing on the reduction of carbon dioxide emissions to achieve the German emission targets for 2020). For both scenarios, the effect of electricity costs for hydrogen production and the possibility to store carbon dioxide were investigated; this leads per scenario to three alternative cases. The main outcomes are found in Figures 3 and 4.

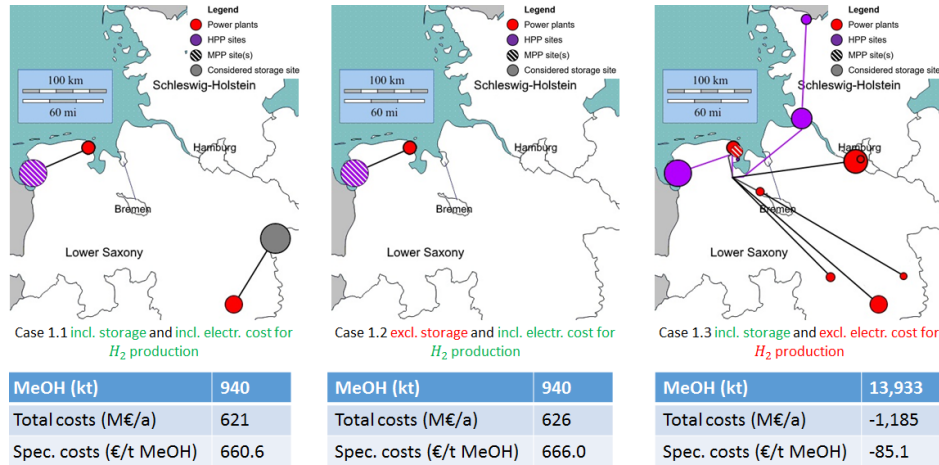

Figure 3 – Proposed structures for a methanol-driven supply chain

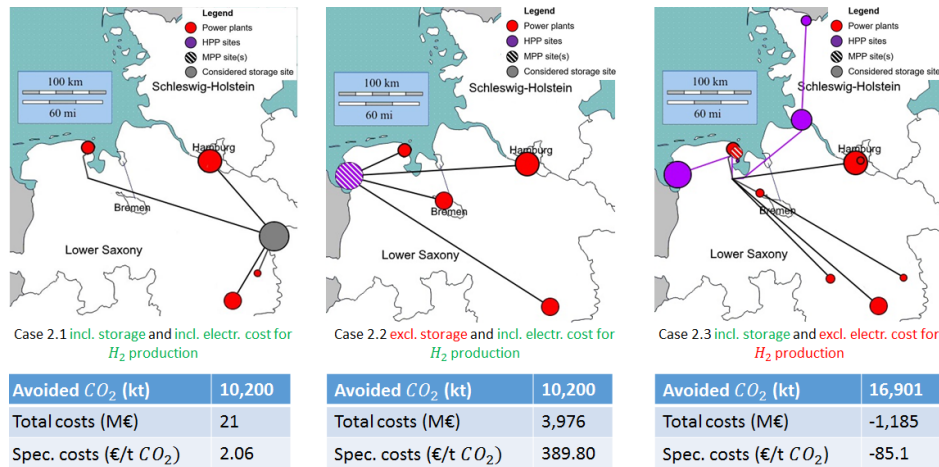

Figure 4 – Proposed structures carbon-dioxide-driven supply chain

The first scenario is the methanol-driven one. In this case including the option to store CO₂ and electricity costs for H₂ production (0.06 €/kWh; case 1.1), the specific MeOH production costs are 660.6 €/ton. Approximately the same costs were found in the case excluding the storage option and including electricity costs (case 1.2) with specific MeOH production costs of about 666.0 €/ton. The second scenario is carbon dioxide-driven one. Case 2.1 including storage option and electricity costs for H₂ production, leading to specific CO₂ avoidance costs of 2.06 €/ton. These marginal expenses are achieved by full storage of the captured amount of CO₂. Excluding storage option and

including electricity costs for H_2 production (case 2.2), leading to an economically intractive solution with nearly 390 €/ton avoided CO_2 . Based on public perception against storage option, the comparison of cases leads to the selection of case 1.2 as the most realistic scenario for a future supply chain.

5. Conclusions

A MILP model for the integration of carbon dioxide and hydrogen supply chain networks has been developed. This model has been used to investigate the techno-economic feasibility of such supply chain in northern Germany. Two scenarios were proposed, the first considered scenario is the methanol-driven one. The specific MeOH production costs are calculated to 660.6 €/ton. These costs are almost double the costs of the current methanol prices. The second scenario is based on carbon dioxide reduction. This scenario results in a price of nearly 390 €/ton avoided CO_2 . Moreover, when an including storage option, with free power for H_2 production the total costs reduce drastically for both scenarios and the network becomes economically feasible. However, it is noted that at this time the model does not limit the scale up of the MPP.

6. Acknowledgements

The authors gratefully thank Mr. Kevin Schmidtke, Mr. Sebastian Schulze and Mr. Sven Charmeteau who are students in the Process Systems Engineering Laboratory of Bremen University for their contributions to this project.

Abstract

Worldwide carbon dioxide emissions are constantly increasing. Carbon Capture and Storage emerged as a temporary solution to this problem, but even if these emissions were to be drastically decreased, the stored gas has to be given a purpose. The aim of this work is the study of the synthesis of carbon monoxide from CO₂ and its utilization as a raw material in acetic and formic acid synthesis. We propose a superstructure in which we include several consuming and non CO₂ consuming syngas synthesis technologies, an H₂/CO separation step and the CO utilization section. We solve the multi-objective optimization problem minimizing the Total Annualized Cost (TAC) and Global Warming Potential (GWP) as our economic and environmental indicators. Results show that the Tri-reforming process can be used to reduce emissions in the synthesis of CO and both acids, while Partial Oxidation results in a lower economic investment and a higher GWP.

Keywords: multi-objective optimization, CO₂ emission reduction, synthesis

1. Introduction

Synthesis gas (syngas) production is the cornerstone of many industries. This H₂/CO mixture is mainly produced from gasification (coal, heavy hydrocarbons) or reforming (light hydrocarbons). Steam, oxygen, carbon dioxide or mixtures of them act as reforming agents and react with the carbon source at high temperatures. Depending on the agent employed, the reaction conditions and composition of the synthesized syngas can greatly differ among technologies. The required composition of the mixture varies between applications, being the most common H₂/CO ratios of two (methanol and Fischer-Tropsch synthesis) or higher (hydrogen production). The synthesis of ethanol and higher alcohols, dimethyl ether and oxo-alcohols use lower H₂/CO ratios of about 1. However, if the ratio is reduced even further, the resulting gas is pure carbon monoxide. This gas is used without any hydrogen in the synthesis of small organic compounds, such as formic and acetic acid.

The synthesis of syngas is usually the most impactful step in both cost and emission in the synthesis of a syngas derived product. When the carbon source is natural gas (methane), the conversion to syngas is called reforming. Several technologies have been developed for the reforming of methane (Figure 1). The classic technologies offer syngas with high hydrogen content (Steam Methane Reforming, SMR) or with reduced operating investment (Partial Oxidation, POX; Auto-thermal Reforming, ATR;

Combined Reforming, CR). However, newer technologies, which are able to consume CO₂ (Dry Methane Reforming, DMR; Bi-reforming, BR; Tri-reforming, TR), even if they are more cost intensive or produce syngas with lower H₂/CO ratios, are still interesting options due to a reduced environmental impact under specific situations.

In a previous work, we studied the cost and emission associated with the synthesis of syngas for several compositions and pressures of the product (Medrano-García et al., 2017). The results showed that, when synthesizing syngas with an H₂/CO ratio of one at low pressure, an actual net consumption of CO₂ can be achieved with the proper syngas synthesis technology selection and separation unit configuration. This result led us to wonder the outcome of the synthesis at an even lower ratio, which is essentially carbon monoxide synthesis.

In this work, we propose a process superstructure in which several syngas synthesis technologies, a specific separation scheme to purify CO from syngas and two CO utilization processes (formic and acetic acid) are included. We apply the ϵ constraint method (Ehrgott & Wiecek, 2005) to solve the multi-objective optimization problem minimizing the Specific Total Annualized Cost (STAC) and Global Warming Potential (GWP), which result in clear trade-offs between both objectives.

2. Methodology

2.1. Superstructure overview

We propose a process superstructure (Figure 1) to tackle this optimization problem. The superstructure consists of a syngas synthesis, a CO separation, and a CO utilization section. The syngas synthesis section takes into account seven different alternatives (Figure 1) to produce the mixture. All of these alternatives use the methane reforming reaction for the synthesis but differ in the reforming agent employed, as well as the reaction conditions. The CO separation section consists of an initial flash unit, used to condense water, and two Pressure Swing Adsorption (PSA) units. The first one (PSA1) preferentially adsorbs H₂ (adsorption at 30 bar, desorption at 1 bar, 90 % H₂ recovery and 99.5 % purity (Chiang & Chang, 2014)), while the second one (PSA2) does the homologue for CO (3 bar adsorption, 90% recovery and 99 % purity (Kasuya & Tsuji, 1991)). The rejected flow of PSA2 passes through a diglycolamine (DGA) absorber which removes CO₂ (Nuchitprasittichai & Cremaschi, 2011), and the rest of the gases are burnt to fuel the reformer reactor. The H₂ flow separated in PSA1 can also be used to fuel the reformer reactor or in the production of electrical energy throughout a fuel cell. The use of a fuel cell is restricted by a maximum flow of H₂ that can enter this unit, but several fuel cells can be installed simultaneously to overcome the limit at the cost of a higher capital investment ((Chiang & Chang, 2014)). The maximum production of electricity allowed corresponds to the maximum electricity demand of the system. Finally, the CO utilization section consists of two different full processes: formic acid and acetic acid synthesis.

2.1.1. Formic acid synthesis

Formic acid (FAc) can be synthesized through methyl formate hydrolysis, oxidation of hydrocarbons or hydrolysis of formamide. In this work, we use the first method since not only uses CO as a raw material but it is also the most extended technology for formic acid synthesis worldwide (Hietala et al., 2000). The process flow diagram

proposed can be seen in Figure 2. First, CO and methanol in a proportion of 3.2:1 (MeOH/CO) are compressed to 45 bar and mixed. The mixture is heated up to 80 °C and enters the methyl formate (MeF) reactor R1 in which the following reaction takes place with a 95 % conversion of CO:

After the reaction, the mixture pressure is reduced to 9 bar and enters distillation column C1 where most of the methanol is recovered and sent back to the pressurization section along with the uncondensable CO. The distillate, which contains mainly methyl formate, is then mixed with water with a proportion of 5:1 (W/MeF). The mixture is heated up to 120 °C and enters the formic acid reactor R2:

The mixture enters distillation column C2 which separates the pairs MeF/MeOH and Water/Fac. The pair MeF/MeOH enters distillation column C4 where MeF exits as distillate and is recycled to the entrance of reactor R2, while MeOH exits as the bottom product and is recycled back to the MeOH and CO compression section. The pair Water/Fac enters distillation column C3 where the product formic acid is retrieved at an 85 wt% purity, and water is obtained as distillate which is recycled back at the entrance of reactor R2. Production of formic acid is set to close to 80 kt/y.

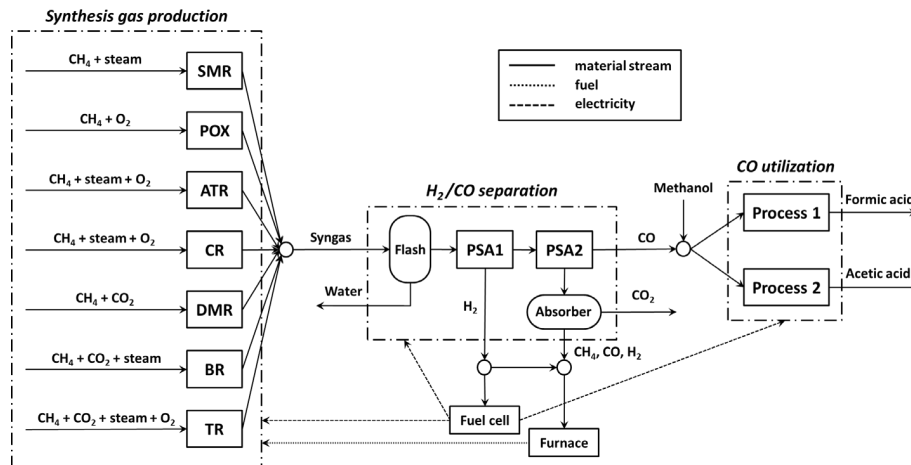

Figure 1. Process superstructure for the synthesis, purification and utilization of carbon monoxide.

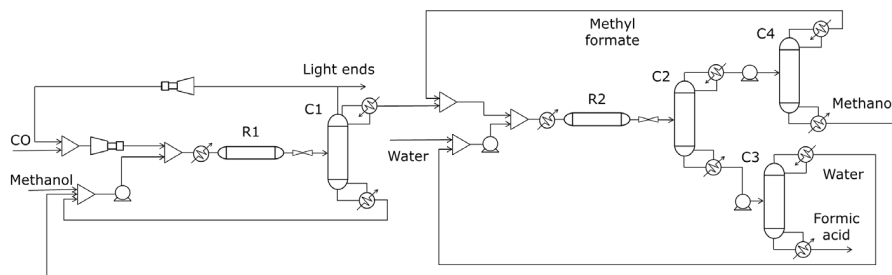

Figure 2. Proposed formic acid production flowsheet (Process 1).

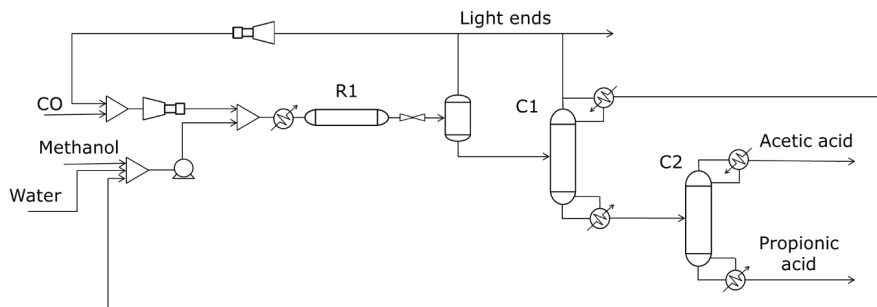

Figure 3. Proposed acetic acid production flowsheet (Process 2).

2.1.2. Acetic acid synthesis

The synthesis of acetic acid also has several procedures (fermentation, carbonylation of methanol, direct oxidation of saturated hydrocarbons, oxidation of acetaldehyde, synthesis from ethylene or ethane). We choose carbonylation of methanol for acetic acid synthesis due to it being the most important (Monsanto process, now improved by the Cativa process) (Le Berre et al., 2000). The proposed process diagram can be seen in Figure 3. A mixture of methanol and water (4.5 wt %) is compressed to 30 bar and mixed with CO. This water does not participate directly in the main reaction but it is necessary to activate the catalyst. The reactants are heated up to 175 °C and enter the acetic acid reactor R1, which main reaction is:

Methanol selectivity in the reactor reaches 99 %. The remaining methanol is transformed into propionic acid, which is the main byproduct of this process. Carbon monoxide selectivity only achieves 90 % due to the unavoidable reaction with water in the so called Water Gas Shift (WGS) reaction, which produces H_2 and CO_2 . After the reaction, the pressure is reduced to 1 bar and the mixture enters a flash unit in which most of the uncondensable gases (CO , CO_2 , and H_2) are separated. The liquid phase then enters distillation column C1. The rest of the gases are separated, mixed with the vapor phase of the flash unit and recycled after a 50 % purge. The purged gases are used as fuel. The distillate, formed mainly by methanol and water is recycled to the beginning of the process. Acetic and propionic acid exit the column as the bottom product, and enter distillation column C2. Here, propionic acid 99 wt% is obtained as a byproduct, and acetic acid 98 wt% is purified in the distillate. Production of acetic acid is set to approximately 100 kt/y.

2.2. Multi-objective optimization problem

The calculation of the composition of the synthesized syngas, utility consumption and capital cost is carried out using linear models obtained from simulations in Aspen HYSYS according to the optimal operating conditions specified in the literature. In addition, heat integration was applied before building the models (Medrano-García et al., 2017). Similarly, for the formic and acetic acid synthesis, we also built linear models which parameters depend on the total acid production.

We address the existence or inexistence of a unit or syngas technology using the Generalized Disjunctive Programming (Raman & Grossmann, 1994). The proposed disjunctions are then translated into algebraic equations using the Hull reformulation

(Lee & Grossmann, 2000). We apply the ϵ constraint method to solve the resulting MILP using an economic (Specific Total Annualized Cost, STAC) and environmental (Global Warming Potential, GWP) indicator to study the different scenarios (minimum cost and minimum emission) in the synthesis and utilization of CO proposed.

3. Results and discussion

We solved the MILP problem with GAMS and using the solver CPLEX. This problem consists of 336 equations and 345 variables, 18 of which are binary variables. Formic and acetic acid process flowsheets were simulated using Aspen HYSYS.

The trade-off between cost and emission of the synthesis of CO as well as the consumption of CO₂ can be seen in Figure 4. The lowest cost synthesis (0.149 \$/kg CO) is achieved using POX as the only reforming technology. However, this technology also provides the highest emission (0.904 kg CO₂-eq/kg CO). On the other hand, the use of TR achieves the lowest emission possible (0.602 kg CO₂-eq/kg CO) at the cost of increasing the STAC (0.258 \$/kg CO). The intermediate Pareto points consist of linear combinations of these extreme solutions. A direct CO₂ generation (up to 0.640 kg CO₂/kg CO) occurs at lower values of STAC (use of POX), however, at the maximum value of STAC (use of TR) a consumption of 4.162 kg CO₂/kg CO can be achieved.

The results of the synthesis of formic and acetic acid can be seen in Figure 5, and are obtained by varying the CO source (cost and emission) and maintaining constant the rest of process variables. It can be seen that the effect in STAC of the formic acid synthesis reaches almost a 20 % while the reduction in GWP barely surpasses a 5 %. However, when synthesizing acetic acid, an increase above 11 % of the cost results in a significant reduction of more than 15 % of the emissions, which sets carbonylation of methanol for the synthesis of acetic acid as an interesting process for further studies related to CO₂ reutilization.

Figure 4. STAC vs GWP (left) and net CO₂ consumption vs STAC (right) of the synthesis of CO.

4. Conclusions

We performed multi-objective optimizations to study the effect in the Specific Total Annualized Cost and Global Warming Potential of the synthesis of CO using CO₂. The use of CO₂ as a raw material through the Tri-reforming process decreases the emission a 33.4 % but increases the cost of the process up to a 73.1 % from its synthesis by Partial Oxidation. In the synthesis of formic acid, increasing the STAC a 19.9 % can result in a decrease of the GWP of a 5.2 %. On the other hand, when synthesizing acetic acid, a

reduction of a 15.5 % in GWP can be achieved by increasing an 11.3 % the cost of the synthesis.

Abstract

This research experimentally studied the concentration of high purity CO₂ from syngas after oxy-fuel combustion by pressure swing adsorption (PSA) process, so that the purified CO₂ can be captured and utilized/stored to reduce greenhouse gas emission. First, UOP 13X was used as adsorbent in this study due to its high adsorption amount and the selectivity of CO₂ to N₂ usually increasing with temperature. Then breakthrough curves and desorption curves were discussed by changing the feed flow rate and feed composition and were verified with a simulation program. Finally, carbon dioxide was purified by a single-bed four-step pressure swing adsorption process. The feed gas of PSA process was 95% CO₂ / 5% N₂, simulating syngas after oxy-fuel combustion. Variables such as vacuum pressure, adsorption time, cocurrent depressurization time and countercurrent depressurization time were discussed to find their effects on CO₂ recovery and purity in order to study the optimal operating conditions for obtaining high purity CO₂.

Keywords: Pressure swing adsorption, Carbon dioxide purification, UOP 13X zeolite

1. Introduction

Since Industrial Revolution in 19th century, the requirement of fossil fuels increases dramatically because of the rapid growth of economy. The large amount of greenhouse gases, especially CO₂, influences the climate change seriously. The United Nations signed the Paris Agreement in April 2016 in order to control the rate of temperature raising. The agreement includes restricting the increase of temperature within 1.5~2 °C and balancing CO₂ emission/nature consumption before 2050. Due to the legal validity of this agreement, the signatories show their determination to solve global warming.

There are several major technologies to capture carbon dioxide: absorption, cryogenic separation, membrane separation, high temperature solid looping systems and

adsorption (Abanades et al., 2015). Among these technologies, pressure swing adsorption (PSA) has advantages of low cost and being easy to operate. PSA can separate different gas mixtures by various adsorbents, which makes it very competitive.

In this study, carbon dioxide from the feed of syngas after oxy-fuel combustion was purified by PSA process. H_2 , CO , CO_2 , CH_4 , H_2O , and a small amount of N_2 and Ar are the typical syngas composition (Todd, 2000). After the syngas passes through the oxy-fuel combustion and water removal, the output gas concentration of CO_2 is about 95 % - 97.4 %. The feed of syngas composition is simplified as a mixture of 95 % CO_2 and 5 % N_2 , and UOP 13X zeolite is used as the adsorbent. Based on the breakthrough curve and desorption curve experiments, we carried out the single-column four-step pressure swing adsorption procedure to purify carbon dioxide and explored various variables to find the optimum operating conditions to obtain more valuable, high purity carbon dioxide.

2. Experimental Description

Adsorption amount and adsorption isotherm were obtained by using Micro-Balance Thermo Cahn D-200. Breakthrough curves, desorption curves and PSA process experiments were performed by adsorption bed. The concentration of outlet gas was detected by Thermo Fisher Scientific Trace-1300 GC. The single-bed four-step PSA process is shown as Figure 1 and the steps are pressurization, adsorption, cocurrent depressurization, and countercurrent depressurization respectively. The experiments started with a set of basic experiment, the operating conditions are shown in Table 1.

Table 1. Basic operating conditions of single-bed four-step PSA process.

Feed composition	95% CO_2 , 5% N_2
Pressurization time (s)	150
Adsorption time (s)	70
Cocurrent depressurization time (s)	170
Countercurrent depressurization time (s)	140
Feed pressure (atm)	3.47
Bed temperature (K)	358

Figure 1. Schematic diagram of single bed four-step PSA process.

3. Model Description

3.1. Mathematical modelling

The PSA dynamic model is made up of several partial differential equations, and the following assumptions are made:

1. Mass transfer resistance between gas phase and solid phase is considered; linear driving force model is used.
2. Extended Langmuir-Freundlich equation is used to calculate the adsorption amount.
3. Only axial concentration and temperature gradient are considered.
4. The ideal gas law is applied.
5. Non-isothermal system is assumed.
6. The pressure drop along the bed can be neglected due to large particle size.

The above assumptions are used in following equations (Huang et al., 2006):

Overall mass balance:

$$-\frac{\partial q}{\partial z} = \frac{\varepsilon A}{R} \frac{\partial (P/T)}{\partial t} + (1 - \varepsilon) A \sum_{i=1}^n \frac{\partial n_i}{\partial t} \quad (1)$$

Mass balance for component i:

$$\frac{\partial}{\partial z} \left(\frac{\varepsilon AD_{m,j} P}{RT} \frac{\partial y_i}{\partial z} \right) - \frac{\partial (y_i q)}{\partial z} = \frac{\varepsilon A}{R} \frac{\partial}{\partial t} \left(\frac{y_i P}{T} \right) + (1-\varepsilon) A \frac{\partial n_i}{\partial t} \quad (2)$$

Energy balance:

$$\begin{aligned} (A\bar{k}) \frac{\partial^2 T}{\partial z^2} - \frac{\partial}{\partial z} (\bar{C}_p q T) - \pi D h (T - T_w) \\ = \frac{\varepsilon A}{R} \frac{\partial}{\partial t} (\bar{C}_p P) + (1-\varepsilon) A \sum_{i=1}^n \frac{\partial}{\partial t} [n_i (\bar{C}_{p,i} T - H_i)] + (1-\varepsilon) \rho_s \hat{C}_p A \frac{\partial T}{\partial t} \end{aligned} \quad (3)$$

Linear driving force model:

$$\frac{\partial n_i}{\partial t} = k_{LDF,i} (n_i^* - n_i) \quad (4)$$

3.2. Adsorption isotherm on UOP 13X zeolite

The isotherm parameters of CO₂ and N₂ are regressed from measured adsorption data at different temperature. The model parameters of different gas adsorption on UOP 13X zeolite for Eq. (5) are listed in Table 2.

Langmuir-Freundlich isotherm for multiple components:

$$q_i^* = \frac{n_i^*}{\rho_s} = \frac{q_{m,i} b_i y_i^{m_i} P_j^{m_j}}{1 + \sum_{j=1}^n b_j y_j^{m_j} P_j^{m_j}} \quad (5)$$

Table 2. Values of model parameters in Eq. (5) for UOP 13X zeolite.

	Carbon dioxide	Nitrogen
a _{1,1} (mol/kg)	6.05	1.17×10 ²
a _{1,2} (mol/kgK)	-4.20×10 ⁻³	-1.28×10 ⁻¹
b _{1,0} (1/atm)	6.80×10 ³	1.65×10 ⁴
b _{1,1} (K)	1.90×10 ³	9.79×10 ²
m _{1,1} (-)	9.67×10 ⁻¹	1.12
m _{1,2} (K)	-2.33×10 ¹	-1.40×10 ²

$$\begin{aligned} q_{m,i} &= a_{i,1} + a_{i,2} T \\ b_i &= b_{i,0} \exp(b_{i,1}/T) \\ m_i &= m_{i,1} + m_{i,2}/T \end{aligned}$$

4. Results and Discussion

4.1. Adsorbent selection

The adsorbents from different companies such as COSMO 5A, UOP 5A, COSMO 13X, and UOP 13X were discussed respectively, and then the selectivities were calculated by Eq. (6) with feed concentration 95 % CO₂ and 5 % N₂ at different feed pressure: 1, 1.5, and 2 atm at various temperature.

$$\alpha_p = \left[\left(\frac{q_{\text{CO}_2, \text{pure}}^*}{q_{\text{N}_2, \text{pure}}^*} \right) \frac{y_{\text{N}_2}}{y_{\text{CO}_2}} \right]_{\text{feed}} \quad (6)$$

Table 3 shows that COSMO 13X and UOP 13X have higher adsorption amounts of CO₂ than 5A. Figure 2 is the comparison of selectivity of different adsorbents at different temperature. We can see that except the selectivity of COSMO 13X is higher than that of UOP 13X at 298 K, the selectivities of COSMO 13X are lower than those of UOP 13X at other temperatures. Most of all, the selectivity of UOP 13X usually increases with temperature. The range of operating temperature can be wider when the CO₂ is purified with 13X zeolite, so we choose UOP 13X zeolite as the adsorbent in this experiment.

Table 3. Adsorption amount of different adsorbents at different temperature with 1 atm. (unit: mol/kg)

Temperature (K)	COSMO 5A		UOP 5A		COSMO 13X		UOP 13X	
	CO ₂	N ₂	CO ₂	N ₂	CO ₂	N ₂	CO ₂	N ₂
298	3.427	0.445	3.407	0.555	3.926	0.338	3.808	0.347
328	2.965	0.237	3.035	0.306	3.277	0.224	3.318	0.237
338	2.834	0.225	2.975	0.266	3.015	0.215	3.047	0.228
348	2.779	0.199	2.747	0.231	2.586	0.184	2.824	0.207
358							2.761	0.148
368							2.621	0.144
378							2.336	0.122
398							1.857	0.112
418							1.681	0.098
458							1.047	0.094

Figure 2. Selectivity of different adsorbents at 1 atm.

4.2. Comparison of experiment and simulation for breakthrough curve and desorption curve

This comparison is used to verify the mass transfer coefficient ($k_{LDF,i}$) of linear driving force model predicted by theory (Ruthven and Farooq, 1990). The results are shown in Figure 3 and Figure 4. It shows that our simulation results are close to the experimental data. Therefore, the accuracy of simulation program can be trusted.

Figure 3. Breakthrough curve of CO₂ for gas mixture. (50 % CO₂, 50 % N₂)

Figure 4. Desorption curve of CO₂ by pure helium.

4.3. Comparison of different operating conditions for breakthrough curve and desorption curve

Effect of feed flow rate on breakthrough curve

Figure 5 is breakthrough curve of CO₂ at 1.72 atm and 298 K with different feed flow rate. The flow rates are 1.137 L/min, 0.788 L/min, and 0.511 L/min respectively. As observed from the figure, when the flow rate increases, the feed amount of CO₂ increases, resulting in a faster breakthrough in the adsorption bed.

Effect of feed composition on breakthrough curve

With the increasing concentration of CO₂, the feed amount of CO₂ increases. Therefore, the time for adsorption bed to achieve breakthrough reduces, resulting in a faster breakthrough in the adsorption bed.

Effect of feed flow rate on desorption curve

Figure 6 is breakthrough curve of CO₂ at 1.72 atm and 298 K with different feed flow rate. The flow rate are 1.737 L/min, 1.660 L/min, and 1.156 L/min respectively. When the H₂ flow rate increases, the feed amount of H₂ increases, resulting in decreasing the concentration of CO₂ in gas phase and increasing desorption rate of CO₂.

Effect of feed composition on desorption curve

Due to the different feed concentration of CO₂, which would change denominator C₀ of the dimensionless concentration during CO₂ desorption process, with higher feed

concentration of CO₂, its dimensionless concentration would decline more until the dimensionless concentration of CO₂ reaches 0.

Figure 5. CO₂ breakthrough curves at 298 K with different feed flow rate.

Figure 6. CO₂ desorption curves at 298 K with different He feed flow rate.

4.4. One-bed four-step PSA process

To separate high purity CO₂ from syngas after oxy-fuel combustion, one-bed four-step PSA process is used. There are many operating variables discussed, and the main experimental results are as following:

Effect of cocurrent depressurization time

As shown in Figure 7, with the increase of cocurrent depressurization time, the purity of CO₂ at the bottom product increases and the recovery decreases. N₂, as the weakly adsorbate in adsorbent, would be discharged as the cocurrent depressurization time increasing. When the bottom concentration of CO₂ increases, there will be more CO₂ discharged from the top of the bed at the same time. Therefore, the longer the cocurrent depressurization time, the more CO₂ that flows from the top stream, resulting in a decrease in the recovery of CO₂ at the bottom stream.

Effect of adsorption time

As shown in Figure 8, with the increase of adsorption time, the purity of CO₂ at the bottom is similar and the recovery decreases. As the adsorption time increases, the total amount of gas entering the bed increases, so that more CO₂ exits from the top of the bed. Therefore, the recovery at the bottom is relatively lower, but the concentration of CO₂ at the bottom is similar.

Effect of countercurrent depressurization pressure

As shown in Figure 9, with the increase of countercurrent depressurization pressure, the purity of CO₂ at the bottom increases and the recovery decreases. As the countercurrent depressurization pressure increases, the adsorption bed of bottom product discharge less, so that the bottom of the recovery decreases. The lower countercurrent depressurization pressure it is, the more amount of N₂ at the bottom it emits. Therefore, the bottom CO₂ purity decreases.

Effect of countercurrent depressurization time

As shown in Figure 10, increasing the vacuum time will cause the concentration of CO₂ at the bottom of the bed to go up first and then down, and the recovery will rise slightly. When the vacuum time increases from 140 s to 300 s, the adsorbent has a better desorption efficiency. This increases the amount of CO₂ released from the bottom of the bed, so it can improve the bottom concentration of CO₂. When the vacuum time increases from 300 s to 450 s, not only we can have more CO₂ from the bottom of the bed, but also get the N₂ amount relatively high. Hence, the bottom concentration of CO₂ decreases. If the bottom of the product flow slightly increases, the concentration keeps almost the same, so the recovery increases slightly.

Figure 7. Effect of cocurrent depressurization time on bottom product CO₂ purity and recovery.

Figure 9. Effect of countercurrent depressurization pressure on bottom product CO₂ purity and recovery.

Figure 8. Effect of adsorption time on bottom product CO₂ purity and recovery.

Figure 10. Effect of countercurrent depressurization time on bottom product CO₂ purity and recovery.

5. Conclusion

This research experimentally studied the concentration of high purity CO₂ from syngas after oxy-fuel combustion by PSA and also developed a simulation program. By the analysis of the adsorption amount and the selectivity of CO₂ to N₂ over different adsorbents, we chose UOP 13X zeolite as the adsorbent due to its high adsorption amount and the selectivity of CO₂ to N₂ usually increasing with temperature.

Breakthrough curves and desorption curves were discussed by changing the feed flow rate and feed composition. Increasing feed flow rate and enhancing the carbon dioxide portion in feed of CO₂/N₂ could help the adsorption bed to reach breakthrough faster in the breakthrough experiments. The adsorption isotherm parameters were regressed from experimental adsorption data, which were used in simulation. The simulation results of breakthrough curves and desorption curves agreed quite well with the experimental data, which shows the simulation program can be trusted.

Finally, CO₂ was purified by a single-bed four-step PSA process. The feed gas of PSA process was 95 % CO₂/5 % N₂. After a series of experiments, we found that the optimal operating conditions are feed pressure 3.47 atm, bed temperature 358 K, cocurrent depressurization pressure 1.33 atm, countercurrent depressurization pressure 0.38 atm, pressurization time 150 s, adsorption time 110 s, cocurrent depressurization time 250 s and countercurrent depressurization time 300 s. The experimental results of final conditions are 99.34 % purity and 30.69 % recovery of CO₂ at bottom product.

Abstract

Dealing with explosive wastes appropriately is a difficult problem recently. Many of them are just being buried and some of them are being treated. The main method to treat explosive wastes is to burn it with Rotary-kiln reactor. However this has a risk of explosion during the process because it is based on explosion mechanism. In addition, Rotary-kiln method can not deal with enough amount of explosive waste because Rotary-kiln method use batch reactor. Lastly, because of the limit of non-successive process, the efficiency of the purification process is low which results in an incomplete combustion. This incomplete combustion makes the exhaust gas more dirty which contains more harmful substances. To overcome the limits of Rotary-kiln method which are introduced above, development of combustion-based process is necessary. Therefore, a flow diagram which includes fluidized bed reactor was developed with Aspen Plus. A mixture of explosive waste slurry and water with the same ratio was fed in the fluidized bed reactor. Also, additional units were chosen and designed which clean exhaust gas to make the reactor more adaptable. The proposed process was thermodynamically analyzed and the efficiency evaluation was held. Also, the improvement possibility of the process was derived. The final exhaust gas from this process satisfied the environment regulation of Korea. This process can deal with 3000 ton/yr which is the total amount of waste propellant in Korea, while the exhaust gas fits the regulation of CO 25ppm/hr, NO₂ 0.10ppm/hr. This study is expected to contribute to the improvement of the efficiency of the explosive waste treatment process and the possession of domestic technology in Korea.

Keywords: fluidized bed reactor, flow diagram, double base propellant.

1. Introduction

The explosive waste treatment has been a major issue in chemical engineering field. The most common method to treat the explosive waste is burring in land. In this point of view explosive wastes in land occurs environment contamination in various aspects including groundwater contamination. Because of its toxicity, pancytopenia or cancer may occur(treatment methods for the remediation of nitroaromatic explosives). In this

point of view, an adequate method to make these wastes unarmful is required. Harmless wastes can be achieved by burning process. However, burning explosive materials have to be dealt carefully because it has explosive possibility. Rotary-kiln method is generally used in explosive waste treatment process. It was introduced at 1989 in Germany according to Poulin(2010). But Rotary-kiln method can not deal with massive amount of wastes. Moreover, it has a possibility of explosion during the process. To overcome this disadvantage of the Rotary-Kiln, this study proposed a new explosive waste treatment process with fluidized bed. With the benefit of fluidized bed reactor, the amount of allowance of propellant is larger comparing with Rotary-Kiln reactor. In this research, a treatment process of exhaust gas is introduced. The exhaust gas properties are calculated by the computer flow dynamic(CFD) by J.lee(2016) technology and the overall process flow scheme was configured and simulated.

2. Process descriptions

NO, NO₂, CO, CO₂ is target gases ingredients in this process. Table 1 shows the composition of exhaust gas from the fluidized bed reactor. Components which affect the environment are in Table 1 are NO, NO₂, CO, CO₂ according to the environment regulations at Republic of Korea. To satisfy the regulations, each components have to be handled appropriately before discharging it to the air. The schematic process flow diagram of the suggested process is illustrated in Figure 1.

Table 1. Composition of the exhaust gas from the incinerator

	Mole fraction	Mole flow (kmol/hr)
Water	0.023	6.69
NO ₂	0.005	1.49
NO	0.001	0.17
N ₂	0.767	220.37
O ₂	0.199	58.58
CO ₂	0.015	4.48
CO	0.008	2.30
total	1	294.09

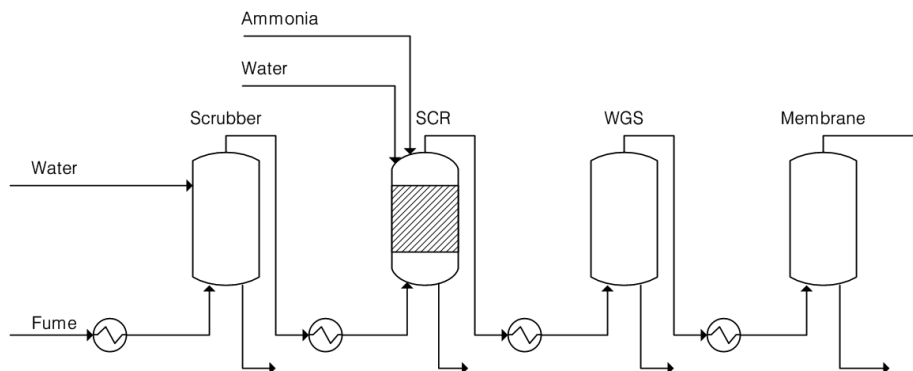

Figure 1. Overall flow diagram of the treatment process

2.1. NOx abatement process

Generally, there are two types of methods reducing NOx. One is wet method which uses the absorption principle and the other is dry process which use chemical interaction between NOx and other components. To define an appropriate unit to decrease NOx, both of the wet method and dry method were used to supplement the drawbacks of each other. At wet method, water was simulated as an absorbent. On the other hand, V₂O₅-TiO₂ catalyst was applied when simulating dry method. Equation (1) is the main reaction of wet method.

The main purpose of this reactor is to separate NO₂ from the exhausted gas. Because this is an equilibrium based unit, the conversion ratio was assumed as 0.9 according to the reference, Sweedney et al.(1999). On the other hand, a selective catalyst reduction reactor was used to simulate the process of abatement of NO. The inputted kinetics are equation (2) ~ (11).

$$-\frac{4dNO}{dt} = 1.5 \times 10^7 e^{-\left(\frac{E_1}{RT}\right)} (P_{NH_3})^{0.0005} (P_{NO})^1 (P_{O_2})^{0.5} \quad (3)$$

$$E_1=15\text{kcal/gmol} \quad (4)$$

$$-\frac{2dNO_2}{dt} = 1.5 \times 10^7 e^{-\left(\frac{E_2}{RT}\right)} (P_{NO_2})^1 (P_{NH_3})^{0.0005} (P_{O_2})^{0.5} \quad (6)$$

$$E_2=14.5\text{kcal/gmol} \quad (7)$$

$$+\frac{4dNO}{dt} = 1.5 \times 10^7 e^{-\left(\frac{E_3}{RT}\right)} (P_{H_2O})^{0.3} (P_{N_2})^0 \quad (10)$$

$$E_3=10\text{kcal/gmol} \quad (11)$$

The selective catalyst reduction(SCR) was simulated as a plug flow reactor. In the simulation which was handled in this research, scrubber mainly abated NO₂. To separate NO and NO₂ efficiently, scrubber and SCR was placed.

2.2. CO abatement process

To capture CO, water-gas shift reaction was used. According to the reference, the conversion ratio of CO was higher than 90% at 400°C. And when the H₂O/CO ratio was 7.5:1. To get reduce CO, water-gas shift reaction like equation (12) ~ (13) was used.

$$\Delta H = -41.2 \text{ kJ/mol}, \Delta G = -28.6 \text{ kJ/mol} \quad (13)$$

In according water-gas shift reactor in upon gas treatment system, Ni-Al₂O₃ catalyst was used. The conversion ratio at WGS reactor was 0.99.

2.3. CO₂ abatement process

To capture CO₂, a membrane reactor was used. The membrane is of asymmetric cellulose acetate hollow-fiber membrane. The separate ratio of CO₂ was 0.99. As a result, combined treatment process is shown at Figure 3. NO_x is captured at scrubber and catalyst reactor, CO is captured at water-gas shift (WGS) and CO is treated at membrane reactor.

Figure 3. Overall treatment process with simulation conditions

The overall process diagram is the exhaust gas treatment system. First, NO and NO₂ are separated with the scrubber and selective catalyst reduction (SCR). Six heat exchangers are placed to use the energy more efficiently. Because ammonia and water is the feed of NO abatement process, the SCR has three inputs. After separating NO_x, CO and CO₂ is treated gradually. The temperature and pressure conditions are shown in Table 2.

Table 2. Specifications of each units

	Temperature(°c)	Pressure (bar)
Scrubber	32.22	1
SCR	284.53 ~ 319.22	1
WGS	25	1
Membrane	25	1

3. Results

The final exhaust gas have reached the environmental regulation at Republic of Korea. Little amount of NO₂ was released and output of NO was 5ppm.

Table 3. Mole flow of inlet and outlet of each units

	Inlet (kmol/hr)	Outlet of NO _x abatement system (kmol/hr)	Outlet of WGS reactor (kmol/hr)	Outlet (kmol/hr)
Water	6.85	11.47	0.01	0.01
NO ₂	1.49	0	0	0
NO	0.17	5.19e-6	5.19e-6	5.13e-6
CO ₂	4.48	4.48	6.76	0.34
CO	2.30	2.30	0.02	0.02
N ₂	220.37	221.22	221.22	219.00
O ₂	58.58	58.35	58.35	57.77

After a proper amount of environmental harmful exhaust gas was achieved, building heat exchanger network was proceeded. During design, I.Lee(2017) was referred. With the heat curve of the process shown in Figure 4 and the temperature profile is summarized in Table 4, heat exchanger network was achieved as shown on Figure 6.

Table 4. Heat integration table

	Inlet T (°C)	Outlet T (°C)	MC _p (kJ/hr)	HTC (kJ/hr)	Flow rate (kg/hr)
WATER to HX3OUT	25.0	125.0	-	473,000	180.0
AMMONIA to HX2OUT	100.0	90.0	801.2	8012	360.0
EXTROTPT to HX4OUT	32.2	310.0	855.5	237,600	832.3
RECOU to HXOUT	206.3	-75.0	-	1,645,000	1372
SO ₂ to HX1OUT	356.9	17.8	-	302,800	843.7
INPUT To HXOUTSOX	426.9	356.9	9178	642,400	8437
SCR-RX heat	25.0	32.2	13210	95,420	-

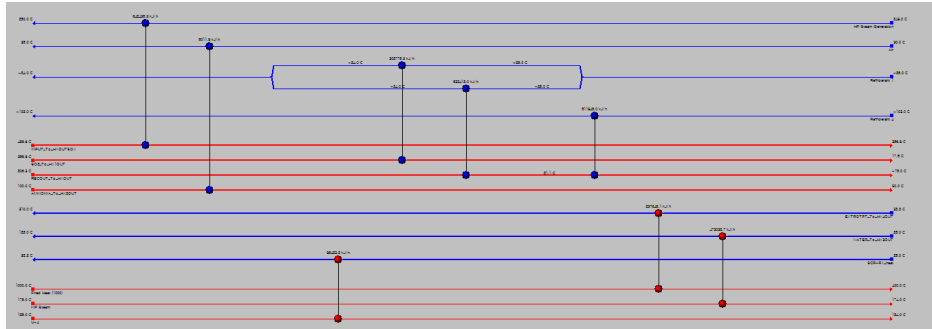

Figure 6. Heat exchanger network result

The most energy effective heat exchanger network point was heat exchange between HXOUT and RECOU. As a result, the proposed heat exchanger network (HEN) process can save energy by 833,412 kJ/hr. Including upon point, eight points are being exchanged to save energy.

4. Conclusions

To separate NO and NO₂ successfully and efficiently, both of SCR and scrubber have to be used. With upon four units, the final exhaust gas from the treatment process has satisfied the environmental regulation of Republic of Korea. Also, with the benefit of the heat exchanger network, almost 4 million kJ/hr of energy can be saved. With this simulated facility, large scale of waste ammunition can be treated. Because a lot of waste water occurs during the process, additional treatment system has to be handled to make a more comprehensive treatment system.

Integration of Renewable Resources into Petroleum Refining

Mohamed Al Jamri, Robin Smith*, Jie Li

Centre for Process Integration, School of Chemical Engineering and Analytical Science, The University of Manchester, Manchester M13 9PL, UK

Abstract

Integration of renewable resources into transportation fuel system requires investigation of resource compatibility with existing infrastructure and exploitation of potential integration points within transportation fuel system. This work focuses on co-processing fast pyrolysis oil (FPO) in refinery FCC units. In this work, a novel methodology is proposed for the modelling of catalytic cracking of a blend of vacuum gas oil (VGO) and fast pyrolysis oil in an advanced cracking evaluation (ACE-R) FCC unit. A new molecular-level characterisation method, based on MTHS matrix approach, is developed for the characterisation of blended feedstock. Molecular-level reaction models are then constructed based on large scale and complex reaction networks synthesised using MTHS matrix framework. The total number of reactions used to synthesise the reaction network in this work is 328. Kinetic parameters tuning problem is formulated as an optimisation problem in which the objective function is to minimise the difference between measured and predicted products yields at various conversion levels. An overall good agreement between measured and predicted yields is obtained using the developed kinetic model for VGO: FPO blending ratio, C/O ratio and reaction temperature of 95:5, 5 and 530°C, respectively. PONA composition in each layer of product stream (e.g. gasoline, diesel, gasoil, etc.), as well as oxygen compounds compositions and oxygen content is predicted. This creates potentials for rigorous optimisation of process parameters for refinery profit maximisation or better products' quality control. The methodology developed in this work can easily be extended to model other refinery processes.

Keywords: Catalytic cracking, Fast pyrolysis oil, biomass, refinery, MTHS matrix.

1. Introduction

Integration of renewable energy sources into transportation fuel system is increasingly becoming a priority for several developed countries, especially in Europe and North America. For example, EU members' aim to increase the share of renewable energy sources in their transportation fuel system from the current value of 6.5% to 10% by 2020 (The European Commission, 2015). In order to achieve this goal, infrastructure-compatible refinery bio-intermediates or completely fungible finished biofuels are considered to be the most, and perhaps, the only viable option which can help fulfilling this regulation requirement.

Second generation biofuels are produced from lignocellulosic biomass (mainly agriculture residues) and considered to be promising and sustainable option, especially since it does not create competition with food industry. Production of biofuels from second generation biomass can be achieved via two distinctive routes. The first route

starts with the gasification of solid biomass, which destroys the biomass building blocks to form carbon monoxide and hydrogen. Gasification products are then used as a feed for Fischer-Tropsch (FT) synthesis process or other liquid synthesis processes (MeOH or olefins synthesis), where synthetic liquid fuels are manufactured according to fuels' standards and refinery requirements. The second route involves the conversion of biomass polymers (cellulose, hemicellulose and lignin) into smaller molecules in the form of dense and viscous oil (bio oil) via pyrolysis processes. Obtained liquid asset is then upgraded via catalytic means in order to produce refinery intermediates and/or finished fuels. While the first option gives the refiner more control over yields and specifications of the various fuels cuts, the opportunities of integrating bio-intermediates using this route into existing refineries' infrastructure is limited. The second option, on the other hand, gives refiners more opportunities to exploit spare capacity available in their upgrading units, and allow them to use economy of scale to decrease the extra cost induced from introducing biomass into existing plants.

Co-processing biomass pyrolysis oil in refinery FCC process emerges as a promising option for the integration of renewable resources into transportation fuels system. This is mainly due to the ability of FCC units in handling different feedstocks and the tolerance of FCC catalyst to oxygenates, water, carbon monoxide and carbon dioxide. However, the effects of introducing bio oil to such a large and important refinery process must be carefully examined. In this work, the effects of co-processing bio oil with VGO in catalytic cracking unit (MAT) is investigated via process modelling techniques. The proposed method includes detailed, molecular-level characterisation of feed and product streams, as well as detailed reaction network and kinetic models which consider the complex interactions between the various molecules on the surface of cracking catalyst.

2. Integrated Modelling Methodology

Figure 1. Proposed MTHS Matrix Framework for Representation of Mixed Stream

Characterisation of process stream is a fundamental step in the development of process models. For complex reactive processes, such as upgrading processes found in petroleum refineries (e.g. FCC), characterisation of process stream has significant effects on model's quality and suitability for process integration and optimisation. For complex chemical streams, characterisation step involves measurements of bulk properties, as well as quantities of the various chemical families found in the stream.

2.1. Feed Characterisation Methodology

Stream characterisation for model development of refinery process is not trivial. Experimental approaches, although provide detailed molecular-level information, are time consuming and expensive. Non-experimental methods, such as pseudo-components and structural parameters approaches are fast and simple in application, however, does not provide molecular information, therefore, not compatible with reaction models.

Stream characterisation approach adopted in this work attempts to provide detailed molecular-level information compatible with reaction models, efficiently and at low cost. Molecular Type and Homologous Series (MTHS) matrix approach uses 2-D matrix to represent the size and type of a given molecule or lump in the characterised stream (Figure 1). The compositional matrix is obtained by solving an optimisation problem in which the objective function is to minimise the difference between measured and predicted bulk properties and structural information (Figure 2). The resultant matrix comprises petroleum-based hydrocarbon molecules, as well as bio-based oxygenated homologous series representing bio oil fraction in the blended stream.

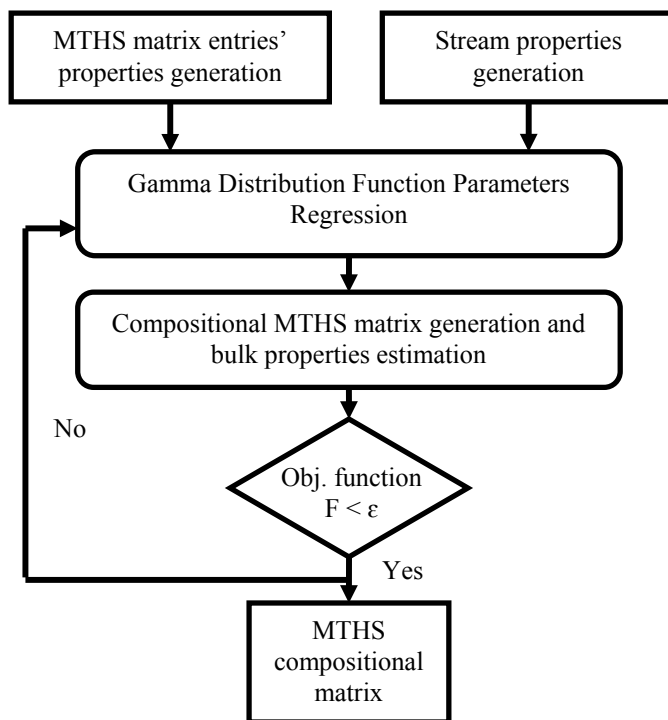

Figure 2. MTHS matrix Solution Algorithm

The proposed methodology has been tested against a blend of vacuum gas oil (VGO) and fast pyrolysis oil (FPO) at blending ratio of 95:5. The results exhibit maximum error of 8% in the prediction of stream density.

2.2. Reaction Network Modelling Methodology

Reaction network synthesis procedure starts by determining reaction pathways, kinetic expressions and kinetic parameters values. The literature is rich in hydrocarbons

reactions pathways and kinetic information (Jacob *et al.*, 1976; Araujo-Monroy and López-Isunza, 2006), however, the information available on bio molecules reaction pathways and kinetic data is scarce. In this work, hydrocarbons reaction network proposed by Gómez-Prado (2009) is adopted to represent catalytic cracking reactions of hydrocarbon molecules in feed stream. Reaction pathways for bio molecules are deduced from model compounds studies for catalytic conversion of bio oil (Adjaye and Bakhshi, 1995a), while kinetic expressions and initial values for kinetic parameters are taken from previous works in literature (Adjaye and Bakhshi, 1995b).

The developed reaction model includes 328 reactions used to describe the behaviour of 58 lumps and chemical species inside the reactor. The model exhibits ability in handling different feedstocks as well as different blending ratios (VGO and FPO) without the necessity of kinetic parameters re-fitting. In addition, industrial requirements for products quality control are fulfilled in this model. This is mainly due to the ability of this model in tracking structural groups (PONA) as well as oxygenated compounds at each boiling level of product stream.

The values of kinetic parameters are regressed using hybrid optimisation technique. In order to reduce the number of variables in the optimisation model, it was assumed that same types of reactions have similar activation energies. This resulted in a total of 14 optimisation variables, which are activation energies for 14 different types of reaction families included into the model. Because of non-linearity found in the optimisation/regression model, stochastic search method (Genetic Algorithm) has been used to increase the chance of obtaining a solution in the vicinity of global optimum. A deterministic search technique (SQP) has been used to improve the quality of the solution obtained by GA. The results obtained using this hybrid optimisation scheme show good agreement between predicted and measured products' yields.

3. Results and Discussion

Table 1. Predicted Composition of Blended Stream (VGO:FPO = 95:5)

	Light gas	L. gasoline	H. Gasoline	Diesel	Gasoil	Residues
P	7.67E-01	2.59E-02	7.01E-01	6.09E+00	2.99E+01	1.83E+01

Alcohols	0.00E+00	1.77E-02	3.13E-04	4.07E-06	0.00E+00	0.00E+00

The developed characterisation methodology has been used for the characterisation of a blend of 95 wt. % VGO and 5 wt. % FPO stream which is used as a feed for catalytic cracking unit. The compositional matrix obtained is condensed to show the total composition of each structural group in each fraction in the feed stream (Table 1). The

results obtained are compared with measured experimental data for the characterised stream. The results showed a maximum error of 8% in density predictions.

Compositional matrix obtained from characterisation step is fed to the reaction model and tested against a set of experimental data. Table 2 shows a comparison between measured and predicted yield values obtained from the model. Figure 3 is a parity plot used to measure the accuracy of the developed model. The figure exhibits R^2 (index of correlation) value of 0.985, indicating good accuracy of fitting parameters obtained.

Table 2. Comparison between Predicted and Measured Yields

WHSV	6		8		12		24	
	Pred.	Exp.	Pred.	Exp.	Pred.	Exp.	Pred.	Exp.
Dry Gas	1.47	2.54	1.46	2.21	1.43	2.06	1.40	1.87
LPG	38.40	39.91	37.60	39.47	35.34	34.50	33.27	30.05

Coke	6.02	6.08	5.92	5.56	5.65	5.29	5.39	4.99

Figure 3. Parity Plot of Model Predicted Yields and Experimentally Determined Yields

The novelty in this work is the ability of the proposed method in predicting the composition of the various oxygenated groups in each fraction of product stream. For example, Figure 4 shows the composition of phenolics and alcohols in diesel product fraction as a function of conversion. Validation of the values obtained is a matter of data availability.

Figure 4. Composition of Phenolics and Alcohols in Diesel Fraction

4. Conclusions

A methodology for molecular-level characterisation of mixed petroleum and bio oil streams is proposed. The methodology eliminates the need for detailed laboratory based characterisation by converting bulk properties of mixed streams, which are readily available and easily measured, into detailed molecular-level information via optimisation-based model. The proposed characterisation model is integrated into a novel catalytic cracking reaction model in which 328 reactions are used to describe the behaviour of 58 lumps inside a pilot plant scale MAT unit. The results obtained exhibits good accuracy when compared with experimental results and previous models with similar complexity.

Simulation of CO₂ Geological Storage Together with a Water Alternating Gas Process for Oil Production in Fang Oilfield (Thailand)

Kreangkrai Maneeintr,^{a,*} Hutthapong Yoosook^a

^a*Carbon Capture, Storage and Utilization Research Group, Department of Mining and Petroleum Engineering, Faculty of Engineering, Chulalongkorn University, Bangkok 10330 Thailand.*

Kreangkrai.M@chula.ac.th

Abstract

Due to the environmental concern, carbon dioxide (CO₂) emission into the atmosphere has been the main issue in petroleum industries. The sources of CO₂ come from natural gas processing and other processes. The current technology to mitigate CO₂ is carbon capture, storage and utilization (CCSU). However, oil is expected to produce more because of the higher consumption. Therefore, CO₂ geological storage in depleting oilfield together with an enhanced oil recovery can be a better technology to meet both targets. The excellent example of this technology is the Weyburn Project in Canada that can store CO₂ and produce more oil as well as prolong the reservoir life simultaneously. For this project, the technology is applied with the depleting oilfield for both oil production and CO₂ storage in Northern Thailand by using simulation model with the real data of the oilfield. Water alternating gas (WAG) process for enhanced oil recovery (EOR) is used to improve the mobility of the flooding system resulting in better sweep efficiency and an improvement in the oil recovery. Consequently, the objective of this research is to evaluate CO₂ injection together with WAG process as well as to investigate the effects the parameters such as chasing water rate and total HCPV injection on oil production, CO₂ consumption and sequestration. The total HCPV used in this study is ranged from 0.5 to 1.5 and the results are compared with that of CO₂ flooding. From the simulation, the results report that oil can be produced up to 57% recovery, CO₂ consumption is approximately 3 scf/bbl. Furthermore, CO₂ consumption increases with total HCPV injection. The results of this study can be applied as a fundamental data to develop the CO₂-EOR project in the depleting oilfield in the North of Thailand for both oil production and CO₂ storage in the future.

Keywords: Enhanced oil recovery, carbon dioxide, water alternating gas, CO₂ injection.

1. Introduction

The injection of CO₂ into oil reservoir is one method of enhanced oil recovery (EOR). The main recovery mechanisms are to reduce oil viscosity and to trap gas (Mohammed-Singh et al., 2006). In addition, CO₂-EOR can reduce Greenhouse Gas (GHG) emission to atmosphere (Le Gallo et al., 2002). Currently, there are three main operating strategies for CO₂ injection, including CO₂ Huff-n-Puff, CO₂ flooding, and water alternating gas (WAG). The operations of CO₂ Huff-n-Puff are injecting of CO₂ into oil reservoir until reaching of desired slug volume. Then, the well is shut-in for 2 to 4

weeks as a soaking period (Wang et al., 2013). Subsequently, the well is opened to produce back both oil and injected CO₂. These processes are repeated between 2 to 5 cycles or operated until insufficient oil production (Whittaker and Perkins, 2013). The cycle of CO₂ injection proved to be the most suitable for reservoirs with relatively small pool size (Song and Yang, 2013). Therefore, CO₂ Huff-n-Puff usually perform as pilot test in many field to confirm reservoir fluid response with injected CO₂ before beginning of full field implementation of CO₂ flooding or WAG (Simpson, 1988).

CO₂ flooding is a method by injected CO₂ into reservoir (Holm, 1982). However, the application of CO₂ flooding may potentially have problems of viscous fingering that caused of early breakthrough and poor sweep efficiency (Donaldson et al., 1989). To reduce the problem, the alternating slugs of injected water and CO₂ is applied to the field that known as water alternating gas (WAG) process. Moreover, the huge amount of CO₂ consumption in the conventional CO₂ flooding usually limits its widespread application and allows WAG to be taking place due to economic decision (Zekri et al., 2011). Finally, the integrated CO₂ Huff-n-Puff and WAG technique seem to be the effective process.

2. Reservoir model

The compositional reservoir simulator provided by CMG was used as a tools to construct the 3D reservoir model and to compare the results. The heterogeneous reservoir model was created based on a reservoir data in Fang oilfield, Thailand as shown in Figure 1. The pattern of producer and injector was quarter five-spot pattern that included one injector and producer at the opposite corner of this model. The reservoir properties of this models are summarized in Table 1. The API gravity of the reservoir fluid is about 31°API.

Figure 1. Reservoir model with location of injection and production wells

Table 1 Reservoir properties using for created reservoir model

Parameter	Values	Unit
Grid Dimension	25 x 25 x 6	Block
Reservoir Size	1250 x 1250 x 30	Ft.
Average Porosity	0.25	Fraction
Average Horizontal Permeability	150	mD
Average Vertical Permeability	15	mD
Rock Compressibility	0.000003	1/PSI
Initial Reservoir Pressure	680	PSI
Reservoir Temperature	144	°F
Reservoir Type	Sandstone	

3. Results and discussion

3.1. Sensitivity Analysis of CO₂ Huff-n-Puff

The sensitivity of these parameters on oil recovery factor is presented in Figure 2. In addition the most important parameter is production time, followed by production rate, HCPV injection, and injection time. And, the range for the incremental oil recovery factor at three cycle of CO₂ Huff-n-Puff process is 2.61% to 4.98% of original oil in place (OOIP).

Figure 2. Sensitivity analysis of oil recovery factor using CO₂ Huff-n-Puff process

3.2. Effect of Chasing Water Rate

The effect of chasing water rate of 300, 450, and 600 BWPD on oil recovery factor and CO₂ utilization was investigated as presented in Figure 3. The results showed that higher oil recovery can be obtained by additional injection rate. Moreover, the increasing of chasing water rate can reduce CO₂ utilization at all CO₂ HCPV injection. The lowest CO₂ utilization is achieved when injection of 600 BWPD at 0.5 HCPV that is about 13 scf/stb.

Figure 3. Effect of chasing water injection rate on oil recovery

3.3. Effect of CO₂ HCPV Injection

The HCPV injection has an effect on the performance of integrated CO₂ Huff-n-Puff and WAG technique as presented in Figure 4. The results showed that the highest oil recovery factor of each chasing water injection rate is obtained by injecting 2.0 HCPV of CO₂. When chasing water is injected at 300, 450, and 600 bwpd, oil recovery factor is achieved at the maximum values of 62.2, 64.3, and 65.7% of OOIP, respectively. The main reasons that can explain these circumstances are CO₂ solubility into crude oil and oil swelling factor. Sasaki et al., (2013) stated that the swelling factor increased by added reservoir pressure and CO₂ solubility also increased rapidly by increasing pressure below bubble point. Also, the results indicated that increasing of HCPV injection provides higher CO₂ utilization for every chasing water rate. The lowest CO₂ utilization is 13.2 scf/stb.

Figure 4. Effect of CO₂ HCPV injection on reservoir pressure and drainage area

3.4. Comparative study

From the simulation results, the highest oil recovery was achieved by using integrated CO₂ Huff-n-Puff and WAG method, followed by conventional CO₂ flooding method, as shown in Figure 5. With the natural flow, only 2% of OOIP can be recovered because the reservoir contained insufficient pressure. Once, the conventional CO₂ flooding process is applied into the field, it can improve oil recovery about 23% of OOIP beyond primary recovery. Moreover, the integrated CO₂ Huff-n-Puff and WAG process presents the highest oil recovery compared to others mentioned processes that it can recover oil up to 63% of OOIP. Comparing to other methods, the integrated CO₂ Huff-n-Puff and WAG method could produce oil 61% of OOIP more than primary recovery production. 38% of OOIP is recovered higher than the use of conventional CO₂ flooding. And, CO₂ utilization of the integrated CO₂ Huff-n-Puff and WAG method is 27.43 scf/stb that much lower than the use of conventional CO₂ flooding method which required up to 69.02 scf/stb. Finally, the main recovery mechanisms of the integrated CO₂ Huff-n-Puff and WAG method are reservoir pressure maintenance, oil displacement by CO₂ and water, sweep efficiency improvement, oil viscosity reduction due to oil swelling, and trapped gas effect.

Figure 5. Comparison of oil recovery factor for different recovery techniques

4. Conclusions

Based on the results of this study, it can be concluded that the key operational parameters of CO₂ Huff-n-Puff process in depleting reservoir are oil production rate and production time. Thus, these two parameters should be sufficient to produce the injected CO₂ and crude oil from reservoir until reservoir pressure nearly reaches inadequate pressure to recover oil. An integrated CO₂ Huff-n-Puff and WAG technique provides higher oil recovery than conventional CO₂ flooding technique due to the CO₂ EOR mechanisms and sweep efficiency improvement.

The main EOR mechanisms are reservoir pressure maintenance, oil viscosity reduction due to oil swelling, crude oil displacement by CO₂ and water, sweep efficiency improvement, trapped gas effect, and injected fluid's mobility reduction. Conventional CO₂ flooding provides the poor performance because very high mobility of CO₂ can cause the early breakthrough that allows low volumetric sweep efficiency. The chasing water rate has significant effect on the performance of integrated CO₂ Huff-n-Puff and WAG technique to enhanced oil recovery. Also, increasing CO₂ HCPV injection in integrated CO₂ Huff-n-Puff and WAG technique slightly offers additional oil recovery factor due to increased swelling factor and CO₂ solubility. However, the exceeding CO₂ HCPV injection requires considerable more amount of CO₂ that will extremely increase CO₂ utilization. Compared to other methods, the integrated CO₂ Huff-n-Puff and WAG method can provide higher oil recovery than other techniques.

Abstract

In this paper a novel multi-period MILP model is developed, and applied to show how: (1) integrating thermal energy storage with ASHP (i.e. power to heat storage) reduces the ASHP peak and total electricity demand by 78.2 % and 8.4 % respectively, and (2) proper sizing of the ASHP reduced its total electricity demand by 35%. The accuracy of the model is improved by using fewer time slices to capture technology and energy demand characteristics. Storage size and operation are determined based on the energy demand and economic price signals.

Keywords: heat electrification, ASHP, TES, MILP, domestic heating.

1. Introduction

Decarbonisation of domestic heating through electrification of heat, could go a long way in achieving the global energy-related CO₂ target of 50 % below current levels in 2050 (IEA, 2011). Air Source Heat Pumps (ASHP) are the preferred early option for heat decarbonisation especially where heat networks are not cost effective (Love et al., 2017). However, increased electricity demand is a challenge with heat electrification. In GB, for a 20 % heat pump uptake, the national grid evening peak demand increases by 14 % (Love et al., 2017), thus requiring new investments in both transmission and generation capacity to maintain security of supply. Integration of TES with ASHP, and proper sizing of the ASHP could reduce both the peak and total electricity demand. Therefore, tackling this challenge would go a long way in increasing deployment of ASHP. The system configuration and operating strategy of a dwelling energy supply system has been determined based on MILP models (Iturriaga et al., 2017). To simplify the representation of energy demand and technology characteristics, a 1 h time slice for reference days is applied in Iturriaga et al. (2017). Hourly time slices neglect the peak energy demand and are below the trading period of the national grid. Therefore making the existing model inadequate to design a system with ASHP and TES, and illustrate how both the peak and total electricity demand of the ASHP can be reduced. Even though 5 min time slice is applied in Zhang et al. (2012), the impact of TES was not investigated, and design was for reference days. Renaldi et al. (2017) designed for 365 days but an hourly time slice was applied. Therefore two challenges of integrating power to heat storage in dwelling identified from the literature survey are: (1) increased electricity demand, and (2) lack of

accurate systems integration method. The novel framework developed in this work addresses both challenges and proves the hypothesis that integrating TES with ASHP, and proper sizing of the ASHP could reduce both its peak and total electricity demand.

2. Methodology

The core of the developed methodology is the mathematical optimization model. The model presents a systematic framework for integrating power to heat storage in a dwelling energy system. The dwelling energy system refers to a generic plant with the layout in Figure 1. A graphical overview of the methodology is presented in Figure 2.

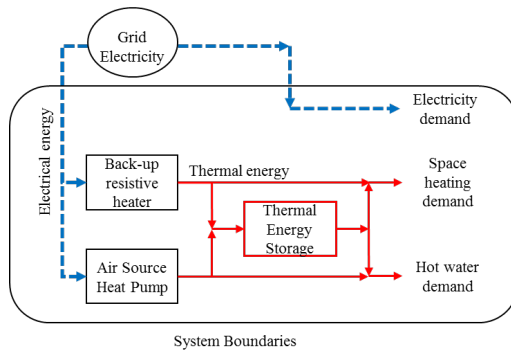

Figure 1. Dwelling energy system with air source heat pump and back-up resistive heater layout. The ASHP converts electricity imported from the grid to heat.

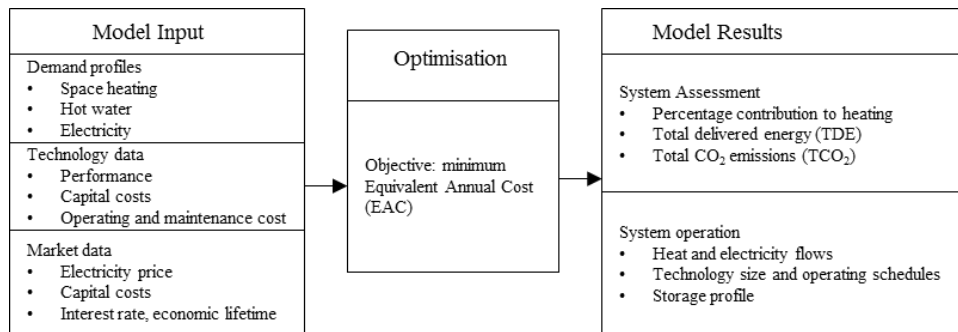

Figure 2. Methodology overview

The design objective in Eq. (1) is the sum of the annualised capital cost (ACC), the fuel cost (FC), maintenance cost (MC) and grid electricity import ($W_{GRID,IMP}$). Heat (Q) and electricity (W) balances were defined as part of the system constraint. The heat balance is the sum of the heat from the ASHP i , and heat delivered from storage, less the sum of heat fed into storage and the heat demand for every time slice r . The electricity balance is the sum of electricity imported to satisfy demand, electricity imported for the ASHP i less electricity demand for all time slice r . Another constraint was introduced such that the size of the ASHP is not exceeded in all time slice r . Other constraints for the existence and operation of the ASHP and TES are presented in Eq. (2) to Eq. (8). The TDE and TCO₂ were used to assess the system. The TDE is the fuel value of the total electricity imported, and the TCO₂ is CO₂ from total electricity import.

$$\text{Min} : [\text{ACC} + \text{FC} + \text{MC} + \text{W}_{\text{GRID,IMP}}] \quad (1)$$

$$Q_{i,r} - L \times Z_{i,r} \geq 0; \quad \forall i \in I, r \in R \quad (2)$$

$$Q_{i,r} - U \times Z_{i,r} \leq 0; \quad \forall i \in I, r \in R \quad (3)$$

$$Z_{i,r} - Y_i \leq 0; \quad \forall i \in I, r \in R \quad (4)$$

$$Q_{\text{out},r} - U_{\text{TES}} \times Y_{\text{TES},r} \leq 0 \quad \forall r \in R \quad (5)$$

$$Q_{\text{in},r} - U_{\text{TES}} \times (1 - Y_{\text{TES},r}) \leq 0 \quad \forall r \in R \quad (6)$$

$$0 \leq \left[\sum_{r=1}^r \left(\left(\frac{Q_{\text{TES,in},r} \times \eta_{\text{charge}}}{\eta_{\text{discharge}}} - \frac{Q_{\text{TES,out},r}}{\eta_{\text{discharge}}} \right) \times \text{ts}_r \right) + (Q_{\text{TES}} \times \text{ISH}) \right] \leq Q_{\text{TES}} \quad (7)$$

$$(Q_{\text{TES}} \times \text{ISH}) - 0.1 \leq \sum_{r=1}^r \left(\left(\frac{Q_{\text{TES,in},r} \times \eta_{\text{charge}}}{\eta_{\text{discharge}}} - \frac{Q_{\text{TES,out},r}}{\eta_{\text{discharge}}} - \frac{Q_{\text{TES}} \times \theta}{24} \right) \times \text{ts}_r \right) + (Q_{\text{TES}} \times \text{ISH}) \leq Q_{\text{TES}} \times \text{ISH} + 0.1 \quad (8)$$

Where Z and Y are binary variables for technology operation and existence, U and L define the upper and lower operational limits, θ is the daily TES loss, ISH is the initial store heat and η represents the efficiency. The above model was formulated in GAMS 24.7.3, and solved using Lindo Global solver on a 64 bit 3.40 GHz Intel ® Core™ i7-6700 CPU with 32 GB RAM.

3. Case study

In this case study, ASHP and TES are integrated into a detached house in the UK (121 m² floor area). The total electricity and heat (both space heating and hot water) demand are 8,387 kW_e and 11,620 kW_{th} respectively. The peak electricity and heat demand are 9.1 kW_e and 27.2 kW_{th}. The sizes of ASHP considered are 14, 8, 5 and 2 kW_{th}. The ASHP have electric resistance heaters as back-up and the size of the store is determined optimally. Further details of the house and assumed market data are in Oluleye et al. (2017). The electricity demand for the house and the ASHP electricity requirements (without TES) are presented in Figure 3 for all ASHP sizes. The ASHP peak electricity demand is more than twice that of the house demand. The peak electricity demand increases as the size of the ASHP decreases (Figure 3). As the ASHP size reduces, the contribution from the back-up resistive heater increases (Figure 4a). For a 2 kW_{th} ASHP, the back-up resistive heater contributes 45 % to the heat demand; therefore increasing the peak. When TES is integrated, the ASHP diverts heat to the store during off-peak hours and the contribution of heat from the resistive heater reduces (Figure 4b). The

combination of the two reduces the peak and total electricity demand (Figure 5). The 14 kW_{th} ASHP electricity demand is 50.6 % more than the building electricity demand, 8 kW is 51.4 % more, 5 kW is 56 % more and 2 kW is 87 % more (Table 1). For all sizes design with TES is more economic, the total delivered energy and CO₂ emissions are lower (Table 1). Reducing the peak electricity demand using power to heat storage reduces the investment in new transmission and generation capacity for the national grid.

When the model is run to consider discrete equipment sizing, the 5 kW_{th} ASHP was selected because it has the lowest EAC (Table 1). Compared to the worst case ASHP size (2 kW_{th}), the optimum size (5 kW_{th}) reduces the additional electricity demand by 35.38 %.

Figure 4. Contribution to heating for (a) design without TES, and (b) design with TES

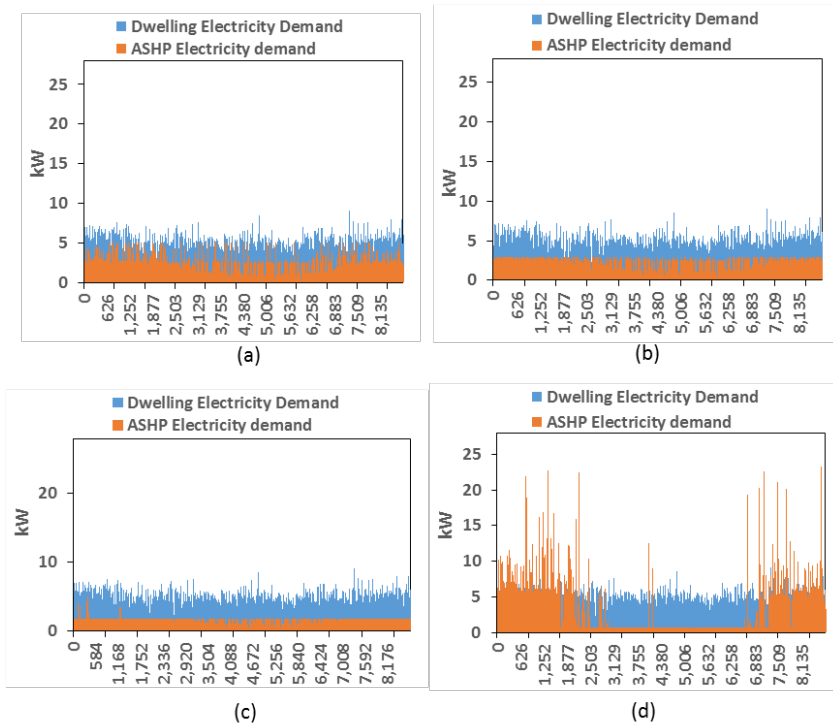

Figure 5. Electricity demand profile (design with TES) for (a) 14 kW_{th}, (b) 8 kW_{th}, (c) 5 kW_{th} and (d) 2 kW_{th}

Table 1. Model results summary

		EAC (£/y)	TDE (kWh/y)	TCO₂ (kg/y)	W_{ASHP,total} (kW)	W_{ASHP,Peak} (kW)
14 kW	No TES	2,183.5	31,580	5,642	4,245	18
	TES	2,183.8	31,535	5,634	4,227	5
8 kW	No TES	2,099	31,756	5,673	4,315	22
	TES	2,094	31,558	5,638	4,236	3
5 kW	No TES	2,075	32,710	5,844	4,697	24
	TES	2,029	31,709	5,665	4,297	5
2 kW	No TES	2,362	39,139	6,992	7,269	26
	TES	2,296	37,713	6,737	6,698	23

4. Conclusions

A novel multi-period MILP model is developed for integrating ASHP and TES (i.e. power to heat storage) in a dwelling. The model is used to determine whether power to

heat storage can reduce both the total and peak electricity demand required by the ASHP. The framework considers optimal sizing (in this case the ASHP and storage size are determined based on the energy demand and economic price signals) and operational planning. A case study was carried to demonstrate the validity and soundness of the approach. Results show that whilst proper sizing of ASHP reduces its total electricity demand, integrating TES reduces both the peak and total electricity demand. The results obtained and the framework are useful in determining the role of power to heat storage in decarbonising domestic energy systems. Even though we can achieve reduction in the ASHP total and peak electricity demand, connecting large number of heat pumps results in excessive voltage drop beyond allowed limits. Future work will to determine the maximum number of heat pumps to prevent excessive voltage drop.

Abstract

This paper introduces a new tool for HEN analysis and optimisation, tailored to retrofit for improving heat recovery. The HEN Matrix provides a scalable HEN representation, suitable for both mathematical treatment and interactive use by engineers, thus having the potential to further facilitate the work of energy managers and site engineers for improving the energy and emission performance of industrial sites. The types of industry expected to benefit from this decision-making tool include Oil and Gas, Chemicals, Food, Textiles, Pulp and Paper. The provided case study illustrates the usefulness and engineering potential of the new concept.

Keywords: Heat Exchanger Network, Retrofit, Matrix, Scalability

1. Introduction

Heat recovery in industry and residential applications plays an important part in reducing simultaneously costs, fuel consumption and environmental footprints. Process Integration (PI) and its core discipline – Heat Integration (Klemeš et al., 2014), have been assisting the improvement the process performance. Focusing on existing plants, there has been recently a resurgence in retrofit methods for heat recovery in industry – especially in the field of Heat Exchanger Networks (HENs) introducing the Energy Transfer Diagram (ETD, Bonhivers et al., 2014). That work has provided the thermodynamic reasoning and initial ETD, clearly showing the heat flows through energy systems, connecting the hot and cold utilities via the served processes. That has been followed by other developments – the “Network Table” (Bonhivers et al., 2017b) and Heat-Exchanger Load diagram (HELD) (Bonhivers et al., 2017a), giving rise to Bridge Analysis, which is itself a step-forward from a previous work on paths construction for HEN retrofit (Varbanov and Klemeš, 2000). Walmsley et al. (2017) have improved the concept, defining a Modified ETD (M-ETD), to show regions of net heat surplus/deficit within HENs, providing clearer insights to identify possible retrofit bridges for improving heat recovery.

These developments have marked a clear trend in binding together the topology and thermodynamic representations of a HEN using graphical means and matrix-style

representation. The current work takes this trend further by providing a combined HEN representation – a HEN Retrofit Dashboard (HENRD). This includes linking several modules: (a) the HEN topology, (b) the ETD Net Cascade Table (Walmsley et al., 2017), which is the numerical representation of the ETD and shows the net cascade of each individual heat exchanger within the HEN, and (c) the ETD plot.

The ETD plot allows to identify promising options visually, which is suitable for smaller HENs. Devising a numerical representation of the ETD, while respecting the HEN topology, provides the opportunity to automate the decision-making process and scale up its application to large retrofit problems (e.g. >40 streams). These tools are complemented by the Grid Diagram (Klemeš et al., 2014), including optionally its variations – the Shifted Retrofit Thermodynamic Diagram (Yong et al., 2015) and the Retrofit Tracing Grid Diagram (Nemet et al., 2015). The aim of this contribution is to develop a robust and scalable HEN retrofit tool, suitable for large retrofit problems (e.g. >40 streams), for improving the performance of industrial, commercial, administrative and residential facilities. The new tool is illustrated on a case study.

The next section overviews the evolution of the retrofit-related HEN representations, showing how the HENRD offers the means for devising improved methods for HEN retrofit with the right balance of automation and user interaction.

2. Analysis of HEN representations for retrofit

There have been several HEN representations, used for evaluation and improvement of the networks. The Grid Diagram (GD, Linnhoff and Flower, 1978) is a well-established, compact and intuitive HEN representation, clearly showing the network topology, stream temperatures and HE loads. In this capacity, it is an excellent tool for simulating, designing or retrofitting visually small-size HENs. The GD can also be used for displaying even larger-scale HENs within software tools (i-Heat, 2017).

The GD has been widely applied for HEN retrofit. One of the fundamental works on HEN retrofit (Tjoe and Linnhoff, 1986) introduced the of area efficiency as an indication the degree of the current network area utilisation. In that work, the GD was used for identifying heat exchangers (HEs) transferring heat across the Pinch (Linnhoff and Flower, 1978), performing the so called Cross-Pinch Analysis.

The Retrofit Thermodynamic Diagram (RTD, Lakshmanan and Bañares-Alcántara, 1996) was presented and extended later (Lakshmanan and Bañares-Alcántara, 1998). It is a variation of the GD, which represents HENs by showing both the temperature span and process stream CPs. This allows showing explicitly the heat exchanged between streams. A further development has been the Shifted Retrofit Thermodynamic Diagram (SRTD, Yong et al., 2015) which incorporates the minimum allowed temperature difference (ΔT_{\min}). Nemet et al., (2015) proposed the Retrofit Tracing Grid Diagram (RTGD), emphasising temperature feasibility and path tracing.

An interesting HEN visualisation by Gadalla (2015) plots the heat exchangers of a network as arrows of the temperatures of hot process streams versus those of the cold process streams. The indication of the Pinch point locations is performed by a pair of lines – a horizontal and a vertical one. This tool (T_H - T_C Plot) allows to easily spot the Cross-Pinch heat transfer, the Network Pinch (NP), and which are the Pinching Matches.

These HEN representations, as well as the Problem Table (PT, Linnhoff and Hindmarsh, 1983) and the M-ETD (Walmsley et al., 2017) form a pool of available tools for HEN analysis and improvement by parameter adjustment and retrofit.

However, when dealing with HEN retrofit, it is important to account for most system properties simultaneously. Moreover, the HEN size in terms of number of streams and/or HEs poses a challenge for visually inspecting the heat paths and system connections. With increasing the network size, the clutter on any of these visualisations grows exponentially and hinders the purely visual comprehension of the network interactions and the possible improvement options. This observation reveals also the need for scalability of the employed tools. Following the above reasoning, Table 1 compares the tools against the important criteria.

Table 1. Comparison of the HEN representations

	GD	(S)RTD	RTGD	T_H-T_C Plot	PT	(M-)ETD
Topology	Yes	Yes	Yes			
HE identification	Yes	Yes	Yes	Yes		Yes
Stream temperatures	Yes	Yes	Yes	Yes		
Stream CPs		Yes				
HE loads	Yes	Yes	Yes			Partly
Cross-Pinch heat transfer	Yes	Yes	Yes	Yes Explicit		Yes Implicit
NP identification	Yes	Yes	Yes	Yes Explicit		
Pinching Matches identification	Yes	Yes Explicit	Yes Explicit	Yes Explicit		
ΔT_{\min} embedded		Yes - SRTD			Yes	Yes – one of the variations
Heat Recovery Targets					Yes	Yes
Scalability	Limited				Yes	Limited

It can be seen from Table 1, that the considered HEN representations are suitable for different aspects of HEN analysis. All of them, except the PT, feature limited scalability, stemming from the goal of the diagrams to visualise each heat exchanger and each process stream in the HEN in specific ways. From these tools, only the PT features sufficient scalability, as it provides a collective numerical representation of the HEN streams and has a matrix form, suitable for mathematical treatment.

3. The HEN Matrix and the HEN Retrofit Dashboard

The M-ETD features a direct connection to the PT for a HEN problem. It is constructed using calculations of the HEs, sliced by temperature intervals, defined by the shifted start/end process stream temperatures - supplemented by temperature boundaries

stemming from the HEN topology. In this way, it bears the potential to be converted into a scalable tool. What is missing from the M-ETD, is the link to the HEN topology and to the process streams. The HEN Matrix, has to combine several key features:

- (i) Superimpose the HEs on the temperature intervals, so that each HE is sliced within the intervals it intersects with.
- (ii) Show visually and numerically the connections HEN topology.
- (iii) Minimise the clutter by providing a seamless representation.

While the GD variations can satisfy part of these requirements, they tend to clutter very quickly with the increase of the HEN complexity. The HEN Matrix represents all process streams and all heat exchangers within the columns of a table, while the rows are taken by temperature boundaries and temperature intervals. Combining the HEN Matrix with the M-ETD forms the HENRD (Figure 1). The tool is demonstrated in the next section.

4. Retrofit case study

A four-stream problem from Klemeš et al. (2014) is used to demonstrate the application of the new tools. The problem consists of two hot streams and two cold streams with two recovery exchangers, one heater and two coolers. The maximum energy recovery target for the retrofit problem is 1,950 kW. More details on this problem can be found in Walmsley et al. (2017). Figure 1 presents the proposed HENRD. Walmsley et al. (2017) demonstrated the M-ETD contains sufficient information to identify retrofit bridges between coolers and heaters as well as its maximum duty. A key limitation of the M-ETD is the lack of information regarding topology of the HEN. This study tackles the topology limitation through the HENRD where a vertical grid diagram is overlaid with the M-ETD Net Cascade Table and placed beside the M-ETD.

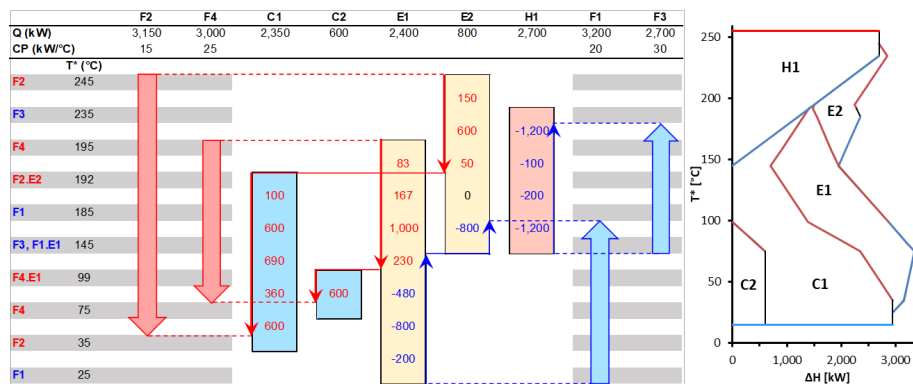

Figure 1. HEN Retrofit Dashboard for four-stream case study

Using the M-ETD, a retrofit bridge above the Pinch between C1 to E2 to H1 can be identified with a maximum duty of 700 kW (Figure 2). This bridge can then be translated to the rest of the HENRD. The topological details inform the designer that hot stream F2 is the same for both E2 and C1. If an additional exchanger between F2 and F3 (700 kW; T^* range = 195 – 245 °C), it will shift E2 to lower T^* intervals resulting in F2 leaving E2 at a lower temperature, which will reduce the C1 duty by 700 kW. So,

although the bridge displays as two steps, the only major physical change is one extra exchanger.

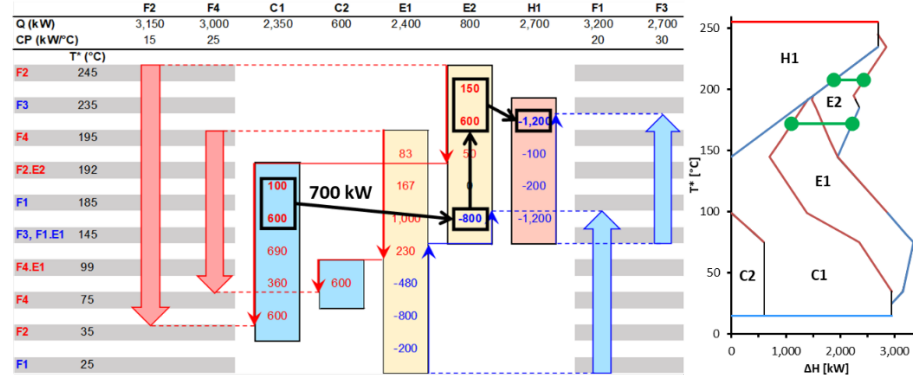

Figure 2. HEN Retrofit Dashboard for simple retrofit option

A second retrofit bridge can be identified on the HENRD (Figure 3). This bridge extends the total energy savings to reach its targeted maximum. A similar analysis of the topology leads to identifying the need for two new recovery exchangers for the second bridge.

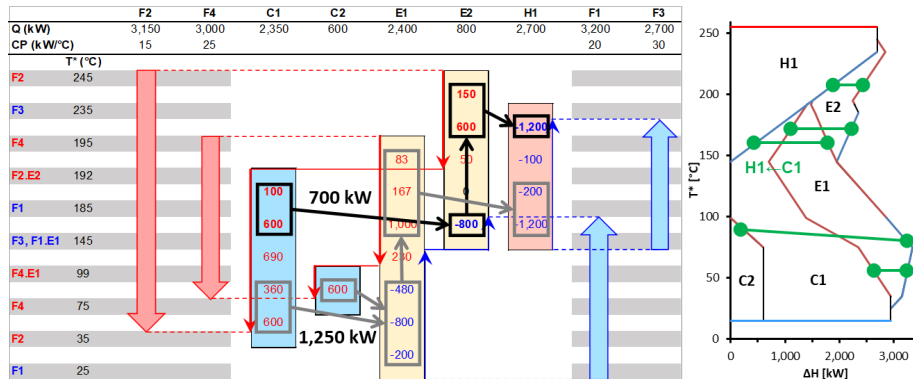

Figure 3. The HEN Retrofit Dashboard for maximum energy recovery retrofit option

5. Conclusions

The current paper proposes a new scalable tool for representing HENs for simulation, optimisation and retrofits, named the HEN Matrix. When combined with the well-known Grid Diagram and the Modified ETD, they have the potential to become the kernel of a powerful HEN Retrofit Dashboard - a tool for interactive HEN optimisation and evolution, which should be able to exploit both active engineer involvement and mathematical optimisation, in order to achieve heat recovery improvement at minimum cost, in a transparent manner. The provided case study clearly shows the usefulness of the proposed tools in representing a HEN, its analysis and targeting the retrofit steps. The future work will be directed towards tackling larger-scale HENs, binding the tools to underlying mathematical optimisation models and the full development of the HENRD.

Abstract

Climate change and energy security are complex challenges whose solutions depend on multi-faceted interactions between different actors and socio-economic contexts. Energy innovation through integration of renewable energies in existing systems offers a partial solution, with high potential identified for bioenergy and solar energy. In South Africa there is potential to further integrate renewable energies to meet local demands and conditions. Various concentrated solar power (CSP) projects are in place, but there is still land available to generate electricity from the sun. In combination with sustainable biomass resources these can offer synergetic benefits in improving the power generation's flexibility. While thermodynamic and thermo-economic modelling for hybrid CSP-Biomass technology have been proposed, energy modelling in the realm of supply chains and demand/supply dynamics has not been studied sufficiently.

We present a spatially and temporally Mixed Integer Linear Programming (MILP) model, to optimize the choice and location of technologies in terms of economic cost while being characterised by realistic supply/demand constraints as well as spatially-explicit environmental constraints. The model is driven by electricity demand, resource availability and technology costs as it aspires to emulate key energy and sustainability issues. A case study in the South African province of Gauteng was implemented over 2015-2050 to highlight the potential and challenges for hybrid CSP-Biomass and integrated systems assessment and the applicability of the modelling approach.

From the range of hybrid CSP-Biomass technologies considered, based on detailed techno-economic characteristics from the literature, the Biomass only EFGT plant is identified as the cost optimal. When distributed generation (DG) technologies, small-scale Solar PV and Wind Turbines were introduced to the model as a competing alternative, they were demonstrated to be more economically optimal (€65 mil against €85 mil with CSP-Biomass Industrial scale), driven by technology learning cost reductions, evidencing the case for DG technologies to gain momentum. Together these scenarios highlight the possible carbon savings from integrating multiple renewable energy technologies.

Keywords: Solar, Bioenergy, Renewables, South Africa.

1. Introduction

Driven by the growing global population and economic development, energy consumption is expected to increase by 48% by 2040 (EIA, 2016), which will exert unprecedented stress on environmental degradation and resource depletion. To combat climate change, the renewed commitments under the 2015 Paris agreement to maintain global average temperature are a testament to the decarbonisation acceleration (UNFCCC, 2015). Global and national policies have been addressing energy demand stress in conjunction with greenhouse gas (GHG) reduction, by actively promoting the low-carbon renewable energy sources (RES) technologies, which are projected to represent 50% the global energy generation by 2030 (Goldman Sachs, 2017). The integration of renewable energy in existing energy infrastructure offers one of the solutions to low-carbon economy transition, with high potential identified in the use of bioenergy and solar energy (IEA, 2015). Dispatchable renewable energy plants such as reservoir hydro, biomass and CSP with storage have been installed with more frequency, contributing to energy flexibility in the respective systems (REN21, 2016). Biomass and CSP in particular offer strong potential as they have the capability to store solar energy in addition to being well distributed globally and thus being a relatively accessible source of energy (Rosillo-Calle, et al., 2015). These technologies have contributed to grid flexibility and grown distributed generation, which has gained significant momentum in developing countries (REN21, 2016). Together they offer a technology solution with the potential of achieving environmental sustainability and economic viability. This paper focuses on the Hybrid CSP-Biomass integration in the context of South Africa.

South Africa has been swiftly implementing policies towards a low carbon economy that diversifies its energy mix by moving away from the current coal-dominant electricity generation (over 90%) (IEA, 2017). Despite the significantly increased electricity access (35% to 86% of population) in South Africa in the last two decades, over 60% of population in African continent still has no access to modern energy and infrastructure (projected to decrease to 35% by 2040) (AFDB, 2013), which constrains the regional economy and livelihood improvement; whereas two third of the Africa's electricity is supplied by South Africa (AFDB, 2013). The renewable energy is expected to play significant roles within the overall African energy portfolio to tackle the energy poverty and insecurity (IEA, 2017) as well as achieve the South African national targets on universal electricity access by 2025 (GNESD, 2017). Despite the modelling advances in thermodynamic and thermo-economic aspects, a gap emerged on the renewable energy system integration considering demand/supply dynamics in Africa. By applying MILP optimization approach, this study aims to advance the understanding of the hybrid CSP-Biomass system design at the spatial and temporal scales under the supply-demand as well as environmental constraints in South Africa.

2. Technology Description

CSP-Biomass Hybrid technology is still at early-development stage with significant data gaps emerged. In this study, the proposed technologies and the respective techno-economic characteristics were based on a combination of case studies (based on ENEA Archimede project, Griffith, Thermosolar Borges), and performances of operating plants (Thermosolar Borges). The range of technologies possesses different levels of biomass-

solar hybridisation and as such different techno-economic characteristics with varying outputs and resource requirements.

Specific CSP cost studies and analysis by IEA (for technology learning), NREL and IRENA were also used to gather more detailed costing data on the different components and resources required (i.e. water, land). These enabled to introduce variations to the representative technologies. An example of such variation is using dry cooling technology instead of the conventional wet cooling, which in turn has an impact on the capital input and operational cost, energy generation and efficiency.

In addition to these technologies, data for distributed renewable energy generation technologies in the form of small scale Solar PV and Wind turbines were collected to compare the industrial scale CSP-Biomass plants with DG technologies on a ‘per year’ basis. Table 1 shows the technologies included in the model.

Table 1 – Technologies modelled (NREL, 2013; Peterseim *et al.*, 2014; Pantaleo *et al.*, 2017)

Technology	DNI	Water (m ³ /yr)	Rated Output (MW)	MWh/Tonne Biomass
100% Biomass	NA	15,000	1.4	0.612
Pantaleo D (Wet Cooling) TES (1.3h)	2,256	32,283	1.4	0.769
Pantaleo E (Wet Cooling) (TES 5h)	2,256	41,997	1.4	1
B50 (Griffith) (Wet)	2,100	480,900	30	1.866
Borges Thermosolar (Wet) – peak	1,800	294,000	22.5	1.96
Borges Thermosolar (Wet) – night (no solar, biomass only)	2,130	159,000	12	1
Pantaleo D (Dry Cooling) TES (1.3h)	2,256	2,001	1.4	0.715
Pantaleo E (Dry Cooling) (TES 5h)	2,256	2,603	1.4	0.93
B50 (Griffith) (Dry)	2,100	29,815	30	1.735
Borges Thermosolar (Dry) – peak	1,800	18,228	22.5	1.823
Borges Thermosolar (Dry) – night (no solar, biomass only)	2,130	9,858	12	0.93

3. Methodology

The fundamental concept is to investigate the potential of the novel Hybrid CSP-Biomass renewable power generation in South Africa under a context with strong policy support for RES and abundance in biomass and solar resources. In addition to the insights into the economic feasibility of the technologies, the model aims to reflect the

underpinning sustainability challenges which are characterised by the supply chain, supply/demand constraints capturing the variability in electricity demands and resources. A spatial-temporal MILP model was formulated and solved in AIMMS using the CPLEX solver.

Table 2 Nomenclature for optimisation model

Sets	Description
g, k	Set of Cell locations $g \in G$
n	Set of biomass residue (source) locations
c	Set of candidate location cells for plant installation (demand location)
t	Time $\in \{Year\}$
b	Set of biomass residues= {maize residue, wheat residue, etc.}
m	Transport mode = {truck, rail}
kpi	Set of KPI = {cost, emissions}
p	Set of plant technology candidates
Binary Variables	
$A_{c,p}$	Existence of technology location cell.
$Flow_{n,c}$	presence of a link between a technology with a biomass field
Continuous Variables	
$EPro_{c,t,p}$	Energy production of a technology in a period (non-linear) (MWh)
$Tflow_{n,c,b,m}$	Transport flow of biomass between a biomass field and a technology location in a given period. (Tonne)
$TotalCost$	Total economics costs (Euro)

As presented in Eq.(1), the objective function is to minimise the total costs which account for the costs incurred by -1) the infrastructure ($CInf_{kpi,t}$, Eq. (2)) dependent on the annuity factor (Af_p) and related CAPEX cost ($Icon_{kpi,t,p}$); 2) cost of operation ($COp_{kpi,t}$, Eq. (3)) of plant technology determined by the energy production ($EPro_{c,t,p}$), the variable ($IOpVar_{kpi,t,p}$) and fixed ($IOpFix_{kpi,t,p}$) cost of operation; 3) and the supply chain costs of the biomass ($CBPro_{kpi,t}$, Eq. (4)) which are depend on direct (machinery, labour, fuel costs) and indirect costs (compensation in soil for loss of nutrients from removal of biomass residues) in the harvesting, collection, and treatment ($ICult_{kpi,b,t}$); 4) the cost related to the transport of the biomass ($CTn_{kpi,t}$, Eq. (5)), which depends on unit transport cost ($ITn_{kpi,m,t}$) and distance ($Dn_{n,c}$) is also included but is expected to represent a small share of the total costs.

$$TotalCost = \sum_{kpi,t}^{KPI,T} (CInf_{kpi,t} + COp_{kpi,t} + CBPro_{kpi,t} + CTn_{kpi,t}) \quad (1)$$

$$CInf_{kpi,t} = \sum_{c,p}^{C,P} Icon_{kpi,t,p} \times Af_p * A_{c,p} \quad (2)$$

$$COp_{kpi,t} = \sum_{c,p}^{C,P} IOpVar_{kpi,t,p} \times EPro_{c,t,p} + \sum_{c,p}^{C,P} IOpFix_{kpi,t,p} \times A_{c,p} \quad (3)$$

$$CBPro_{kpi,t} = \sum_{n,c,p,m}^{N,C,P,M} ICult_{kpi,b,t} \times Tflow_{n,c,b,m,t} \quad (4)$$

$$CTn_{kpi,t} = \sum_{n,c,p,m}^{N,C,P,M} ITn_{kpi,m,t} \times Dn_{n,c} \times Tflow_{n,c,b,m,t} \quad (5)$$

The model takes into account a range of constraints that ensure the method feasibility and applicability, which can be summarised as follows (formulation not included here):

- Total number of technology plants in operation per location is upper bounded by user-defined parameters;
- Logic constraints on the existence and number of links between biomass source n and technology plant location c ;
- Transport distance is constrained by user-defined upper bound;
- Equality and inequality constraints on the biomass supply-demand balances and flows;
- Inequality constraints on water and land resource availability and direct normal irradiance (DNI);
- Constraints on plant capacity and operational time.

4. Case Study: Gauteng Province (South Africa)

Table 3 - Data Inputs

Solar DNI	2,266 kWh/m ²
Biomass Availability	24,500Tonne
Unmet Electricity Demand to Satisfy	11.07 TWh/annum

Table 4 --Scenarios' key cost results in 2015

Scenario 1 (1 Technology Only)	223,428.00 kEuro
Scenario 2 (Multiple Technologies)	85,191.00 kEuro
Scenario 3 (Multiple Techs with DG)	65,162.00 kEuro

The modelled results indicated that among the technologies considered, the biomass externally-fired gas turbine remained the most cost optimal option, which can be explained by the CSP’s high CAPEX intensity and comparatively lower load factors. The cost optimisation scenario runs showed that DG technologies provide more economically competitive solutions. Throughout the time periods (2010s-2050s) modelled, the scenarios executed with DG technologies presented lower cost solutions in comparison with the scenarios without DG technologies (Figure 1). Technology learning effects represented as pivotal for DG technologies selected by the model.

Figure 1. Cost profiling for scenarios with/without DG technologies

While centralised generation of energy has demonstrated better economic performances due to the scaling-up effects, densification of generation and higher efficiencies, the advent of small scale generation technologies has been able to satisfy energy needs due to better geographical and operational flexibility compared with centralised generation. The input data used to characterise these DG technologies reflected their advantages, which were confirmed by the projected technology learning, in particular in attracting investments which in turn is expected to drive the economic profiles of the technology.

5. Conclusion

The optimisation model presented in this study generated insights into the economically feasible technology solutions under a given context. Such modelling approach could be widely applicable to inform decision-makers in terms of renewable energy integration system design. The model is capable of executing scenarios with a range of technologies considering their economic profiles incurred by capital inputs, technology operation, and transportation and sourcing of biomass feedstock. This model can be further expanded and adapted to a wider range of renewable energy systems. This study revealed that the small scale solar PV and wind turbines are more cost effective to satisfy the specified electricity demands than the large scale hybrid CSP-Biomass plants modelled. Such research findings are driven by a range of modelling factors including the low operation of technologies caused by the difference between demand and rated output of the technologies, the uneven use of resources (biomass residues), negligible resource footprint (water, land) assumed for the DG technologies. Thus it is worth implementing more small scale systems in the region to exploit the abundant solar and biomass residue resource potential. The South African region modelled in the case study showed great potential with abundant solar and biomass resources, and the urgent needs in African continent to increase the electricity access suggest the opportunity for RES generation systems in South Africa which is in line with the national/regional strategy.

Abstract

This study evaluated the use of artificial neural networks (ANN) as tools to predict and identify the experimental conditions used in the process of delignification of sugarcane bagasse using supercritical carbon dioxide (ScCO₂). The experimental conditions varied from 35 – 100°C to temperature, 75 – 300 bar to pressure and 0 – 100% to ethanol content, used as co-solvent in the extraction. HPLC and determination of insoluble lignin (Klason lignin) analysis were performed to evaluate the efficiency of the process. A database was constructed with the information of the experiments, dividing them into groups of training (70%) and test (30%). The models were obtained using toolbox of the MATLAB R2016b. In the developed neural network, the data obtained by the different techniques of analysis were used as neurons in the input layer and the percentage of insoluble lignin was used as neuron in the output layer. The performance of the neural network was evaluated by the correlation coefficient (R²) and the error indexes (MSE and SSE). The process of sugarcane bagasse delignification using ScCO₂ showed good yields. The model developed from the neural network was satisfactory, since the R² value was 99.58% and the error index values were 0.176 to SSE and 0.0147 to MSE.

Keywords: Sugarcane Bagasse, Lignin, Supercritical Carbon Dioxide, Artificial Neural Networks, Failure Prediction.

1. Introduction

Sugarcane bagasse is a vegetal biomass that has much potential for use because of its structural elements: cellulose, hemicellulose and lignin. In order to use it as a raw material to produce new compounds, sugarcane bagasse needs to undergo a pre-treatment process, leading to the removal of lignin from the vegetable fibers. Thus, cellulose and hemicellulose become more available for subsequent processes like chemical or enzymatic hydrolysis leading to improved fermentation procedure, for example, in the production of 2^o generation ethanol. The methodology of delignification

of biomass using ScCO₂ is a clean process that aims at the non-formation of intermediate residues.

The use of ANN modelling in chemical processes has increased because of its simplicity in solving complex problems. Alberton et al., 2016 uses ANN modelling to correlate compositions and properties as viscosity index of the extracted and raffinate phases in the liquid-liquid extraction process of API I group lubricants.

With the creation of recent technologies and the increase in the volume of instrumental data obtained every day, the use of ANN model in the identification of process conditions to avoid operational errors becomes relevant, since it is a technique that simulates the human reasoning, bringing greater security to the accomplishment of tasks. In the context of pretreatment of sugarcane bagasse, Valim et al., 2017 uses ANN for prediction and failures detection in the process.

2. Materials and Methods

2.1. Process of sugarcane bagasse delignification using supercritical carbon dioxide

Based on Rabelo et al., 2014 the sugarcane bagasse used in this work was washed under a stream of tapwater, dried in an oven at 45 °C for 48 h to reduce bagasse moisture content. The lignocellulosic biomass was homogenized in an electric crusher to reduce particle size, fragmented into small fine particles and stored in a dessicator with no moisture for later use in the delignification experiments with supercritical carbon dioxide pretreatment.

The use of co-solvents in supercritical fluid extraction has been used to improve efficiency, increasing productivity and modifying process selectivity (Dalmolin et al., 2010). In this work, the co-solvent used was commercial ethanol 92.8 °INPM.

According to Pasquini et al., 2005, temperature, pressure and co-solvent content are variables that influence the process of delignification of the biomass with ScCO₂. The experiments were carried out in a temperature range of 35 °C to 100 °C, in a pressure range of 75 bar to 300 bar and in a co-solvent content range of 0 % to 100 %. The reactions were processed in a Maqnagua supercritical extraction set. 46 g of the biomass was placed in the extractor, where 500 mL of the co-solvent solution was added. The reaction occurred for 1 h. After this time, the extract is collected and the sugarcane bagasse after pretreatment is washed with 550 mL of NaOH 1% (w/v) to remove the adsorbed lignin in the biomass fibers. The obtained pulp was filtered, washed with water and dried in an oven for further analysis. All tests were performed in duplicate.

2.2. Klason lignin determination

To determine the content of lignin insoluble was used the standard methodology NREL (60) (Sluiter et al., 2008). An aliquot of 300 mg was removed from the pulp obtained after delignification. This sample was hydrolysed with H₂SO₄ 72 % (v/v) for approximately 2 h. The acid was diluted to 4 % (v/v) and the sample was placed in an autoclave at 121 °C for 1 h. A vacuum filtration was performed in the autoclave solution using pre-weighed crucibles. The crucible with the filtered solid was placed in an oven at 105 °C for 12 h.

Eq. (1) shows the calculation of the lignin insoluble percentage in biomass, where m_1 corresponds to the mass of the empty crucible and m_2 corresponds to the mass of the crucible with the filtrate, after the autoclave stage.

$$\%Lignin = \left(\frac{m_2 - m_1}{0.3} \right) \cdot 100 \quad (1)$$

2.3. Glucose and Xylose determination

Aliquots of each hydrolysate, obtained after filtration of the acid hydrolysis, were neutralized with sodium bicarbonate to neutral pH. The neutralized hydrolysates were filtered directly into vials using 0.22 μm Milipore filters.

These samples were subjected to High Performance Liquid Chromatography (HPLC) analyses using a SUPELCOSIL LC NH₂ (250 x 4.6 mm) on a Shimadzu chromatograph. As a mobile phase, a aqueous solution of 75% acetonitrile with a flow rate of 1 mL/min at 25 °C was used. The compounds were monitored with a Shimadzu RID-10A refractive index detector.

The standard curve for the quantification of sugars in the samples consisted of seven points ranging from 0.1 g/L to 4 g/L. The solutions were prepared from standard solutions of 50 g/L glucose and xylose.

2.4. Artificial neural network architecture

An ANN topology was selected to predict the Klason lignin content in each sample of the experiment. In this study, MATLAB R2016b was used. The activation functions for the hidden layer neurons tested were *tansig* and *logsig* and the training algorithms were *trainbr* and *trainlm*.

To evaluate the performance of the ANN, the error indexes SSE (Sum of Squared Errors) and MSE (Mean Squared Error) were observed. In addition, other aspects such as value of Coefficient of Determination (R^2) and number of network parameters were evaluated.

3. Results and Discussion

3.1. Quantitative analysis of the sample fractions after pretreatment

Table 1 shows the insoluble lignin content in sugarcane bagasse, as well the glucose and xylose concentrations present in the biomass in each experiment. The BT sample refers to sugarcane bagasse before pretreatment using ScCO_2 and is used only as a reference.

The study presents preliminary quantitative results where it is possible to observe that in the biomass samples after pretreatment with ScCO_2 there was a reduction in the insoluble lignin content, suggesting that the difference, based on BT sample, was lignin removed in the extraction process.

It was expected that the samples with lower Klason lignin content presented higher concentrations of available sugars, since lignin acts as a protection for the cellulosic structure.

Regarding glucose concentration, the results were consistent, since the sugarcane bagasse samples after pretreatment, except sample 4, showed an increase when

compared to the BT sample. However, the sample 5, which presented a lower content of insoluble lignin, did not present the highest glucose concentration.

Table 1. Results of HPLC and Klason lignin analyzes on sugarcane bagasse samples before and after pretreatment using ScCO_2 .

Sample		Temperature (°C)	Pressure (bar)	Co-solvent (%)	Klason lignin (%)	Glucose (g/L)	Xylose (g/L)
BT	A	-	-	-	20.57%	0.73	0.64
	B				20.33%	0.70	0.65
1	A	74	190	50	19.03%	0.89	0.64
	B				18.23%	0.89	0.64
2	A	35	300	100	18.23%	0.89	0.61
	B				17.40%	0.88	0.60
3	A	91	75	100	16.20%	0.72	0.44
	B				14.93%	0.72	0.43
4	A	84	180	50	14.80%	0.62	0.47
	B				15.13%	0.60	0.47
5	A	47	75	0	15.40%	0.81	0.81
	B				14.53%	0.84	0.91

Regarding xylose concentration, the values obtained for the sugarcane bagasse samples after pretreatment remained similar when compared to the BT sample, except 3 and 4 that presented lower values. Sample 5, however, showed a significant increase in xylose concentration relative to the others.

3.2. ANN training and testing

The results of HPLC analysis and determination of insoluble lignin were used for ANN training (70% of the data set) and testing (30% of the data set). The mean results of each experiment were calculated to obtain more data for the neural modelling.

The variables used as neurons in the input layer were the Klason lignin content in biomass, glucose concentration and xylose concentration. The variable used as neuron in the output layer was the experimental condition identifier.

Table 2 shows some ANN topologies developed in this work. The selected ANN model presented 3 neurons in the hidden layer, being the simplest topology. The activation function used was logsig and the training algorithm was trainbr. This ANN, in addition to presenting a better correlation coefficient, presents SSE and MSE error indexes satisfactory.

Table 2. Some ANN topologies used in the model proposed in the delignification process of sugarcane bagasse with ScCO_2 , besides the activation function, training algorithm and the adjustment values obtained for each case.

Experimental condition identification in sugarcane bagasse after pretreatment						
Number of neurons in input layer	Number of neurons in hidden layer	Activation function	Training algorithm	R ²	SSE	MSE
3	4	tansig	trainlm	97.95%	0.080	0.0066
3	4	logsig	trainlm	96.82%	1.96E-04	1.63E-05
3	4	tansig	trainbr	99.38%	0.159	0.0133
3	4	logsig	trainbr	99.50%	0.133	0.0111
3	3	tansig	trainlm	97.21%	0.033	0.0027
3	3	logsig	trainlm	53.72%	7.52E-04	6.27E-05
3	3	tansig	trainbr	99.51%	0.133	0.0111
3	3	logsig	trainbr	99.58%	0.176	0.0147

Figure 1(a) shows the topology used, as well as the training algorithm and the SSE error index obtained. It is important to note that approximately 5 effective parameters were used in the ANN during the training, discarding the possibility of overfitting in the ANN model. Thus, it can be stated that the small number of experimental data obtained did not affect the model quality, since it was not necessary to use more than 5 arrays for ANN training. Figure 1(b) shows the R² values of 99.58% for the training stage obtained for the applied ANN topology. This ANN presented an SSE performance value of 0.176 and MSE of 0.0147.

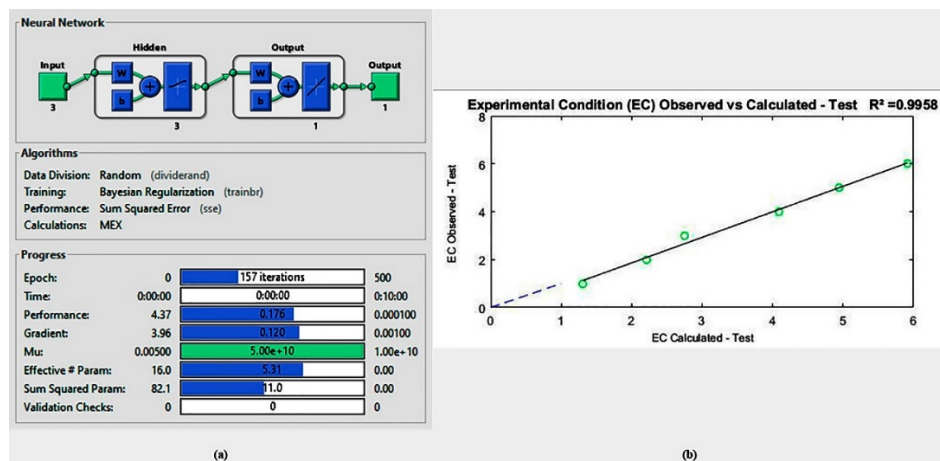

Figure 1. (a) Image obtained from MATLAB R2016b software that shows the ANN topology, as well as the training algorithm and the SSE error index obtained during the training stage. (b) Regression diagram for the ANN test stages used to predict the experimental condition used in the delignification process of sugarcane bagasse with ScCO_2 .

It is important to emphasize the importance of the construction of a model for the experimental conditions identification used during the delignification process of sugarcane bagasse with ScCO₂, due that the experimental results obtained have values very close to each other. This factor can cause confusion and insecurity in the operator who, when supported by an ANN model for identification, can prevent operational errors occurring.

4. Conclusions

The applied lignin extraction methodology was proven efficient, confirmed by the quantitative HPLC and determination of Klason lignin analyses. The most suitable condition for the process was the use of 0% ethanol as co-solvent at 47 °C and 75 bar resulting in lower insoluble lignin content and higher available sugars concentration. Data extracted from the analyses were essential for the ANN training, due to the low standard deviation of the analyses, increasing the quality of the selected ANN model. Regarding the predictions of the proposed model, the proposed ANN topology is considered adequate, since it presented satisfactory performance, confirmed by the observed SSE, MSE and R² values. Further experiments are needed to obtain more data and improve ANN training. However, the obtained ANN shows potential to be used, identifying with 99.58% safety the experimental conditions used during the process.

Abstract

The Food-Energy-Water-Waste Nexus (FEWWN) represents the interconnections between food, energy, water, and waste production systems and has become a key research area in recent years. Enormous quantities of agricultural and organic wastes are produced throughout the FEWWN, representing a hurdle to sustainability. Often, these wastes are not treated appropriately because their true costs are not only rarely quantified, but they are also usually externalised to the surrounding communities and environments. In this work, we address this shortcoming from a systems perspective fused with approaches from ecological economics and ecosystem service valuation. We construct a bioenergy production framework where the bioenergy may be produced from ethanol and/or agricultural and organic wastes. If waste is converted, we consider the regenerated ecosystem services as an economic benefit. We apply the framework to a multiobjective case study on the US state of Illinois where 160 PJ of bioenergy is to be produced considering objectives of net cost and Green GDP. Green GDP ranges from -\$125M/y to \$132M/y with corresponding net costs ranging from \$107M/y to \$260M/y.

Keywords: Biofuels, sustainability, Food-Energy-Water-Waste Nexus, ecosystem services

1. Introduction

Systems researchers have recently increased focus on the Food-Energy-Water (FEWN) Nexus (Garcia and You, 2016) and the broader Food-Energy-Water-Waste Nexus (FEWWN) (Garcia and You, 2017a). Sustainability of the Nexus is critical as global population increases, resource availability decreases, and the effects of climate change increase. A key hurdle towards sustainability of the FEWWN is waste production and management. Enormous quantities of agricultural and organic wastes are produced at nearly all scales and links along FEWN supply chains. Food supply chains are particularly wasteful; in the US, only about 70% (Garcia and You, 2017a) of the produced food is eaten – the rest is wasted along the way. Other unavoidable wastes are produced. For example, livestock produce copious amounts of manure. Waste throughout the FEWWN often occurs because the true cost of producing the waste is either not considered or is externalised to surrounding communities and the environment. However, these costs must be quantified and utilised in decision-making if the FEWWN is to become sustainable.

Ecosystems provide essential services – called Ecosystem Services (ES) – to humanity that make our lives possible, such as nutrient cycling within a forest or flood management from mangroves (World Resources Institute, 2005). Agricultural and organic wastes produced throughout the FEWWN can degrade local ecosystems in many ways, diminishing the level of ES they can provide. Swine manure often spills into nearby creeks, rivers, and streams, killing fish, impacting the local water supply, and dramatically reducing recreation in the area. It is not enough to focus on ecosystem impacts of only waste systems, however, as other FEWWN systems also impact ecosystems. Clearing forests for cropland to grow feedstocks for bioethanol destroys the services originally provided by the forest. Ecological economists aim to quantify the value of the services local ecosystems provide. There are many ways ES are valued. However, despite the importance of considering ecosystem health in sustainable decision-making, quantitative valuation of the negative or positive impact on ES by a proposed process or supply chain is rarely considered. In this work, we integrate ES valuation methods including the hedonic pricing method and an aggregated biome-services approach into a FEWWN decision-making modelling framework for bioenergy production. We consider “Green GDP” as an optimisation objective, which accounts for the value of ecosystems destroyed/regenerated. Total cost of the bioenergy production strategy is another objective in the multi-objective framework. We propose a framework that considers the value of ES destroyed by bioethanol production via conversion of land to managed cropland for feedstock production and the value of ES regenerated by conversion of agricultural and organic waste to renewable energy. We apply the framework to a case study on the US state of Illinois.

2. Problem Statement

The proposed framework can account for bioenergy production costs in tandem with changes in ES from conversion of livestock manure to bioenergy, restoring local ES, and conversion of forests/pastures to cropland to grow bioenergy feedstocks, destroying local ES. Thus, the framework is best applied at the local or regional scales. Taking the perspective of some local/regional government, the framework considers two objectives of minimum net production cost and maximum Green GDP. Bioenergy may be produced as either bioethanol or electricity from biogas produced from swine manure. Bioethanol may be produced from corn grain, corn stover, or switchgrass from any mix of 9 bioethanol production pathways, with different feedstock pretreatment options. Base operating and capital costs are known for a given capacity of each pathway. Instead of allowing each pathway to scale, we fix costs and capacities and allow multiple plants to be constructed. An example pathway is dilute acid pretreatment of switchgrass to fermentation and distillation (Humbird et al., 2011). We work with the US EPA’s level 4 ecoregions (Woods et al., 2006) to represent the different ecosystems and Monfreda’s Agro-Ecological Zones to estimate corn yields Monfreda et al. (2009). We utilise data from Kang et al. (2014) to estimate switchgrass yields. Population statistics, median household values, statistics on swine farms (number of farms and number of hogs on each farm), electricity prices, and existing cropland area are taken from the US DOE, USDA, and the US Census Bureau. Process data on biogas production systems from anaerobic digestion of swine manure is taken from Cowley et al. (2014) for two systems – complete mix/plug flow reactors and covered lagoons. Gains/losses in ES value are calculated in a few ways. For biomass feedstock production for ethanol, we assume the original ecosystem is cleared for managed

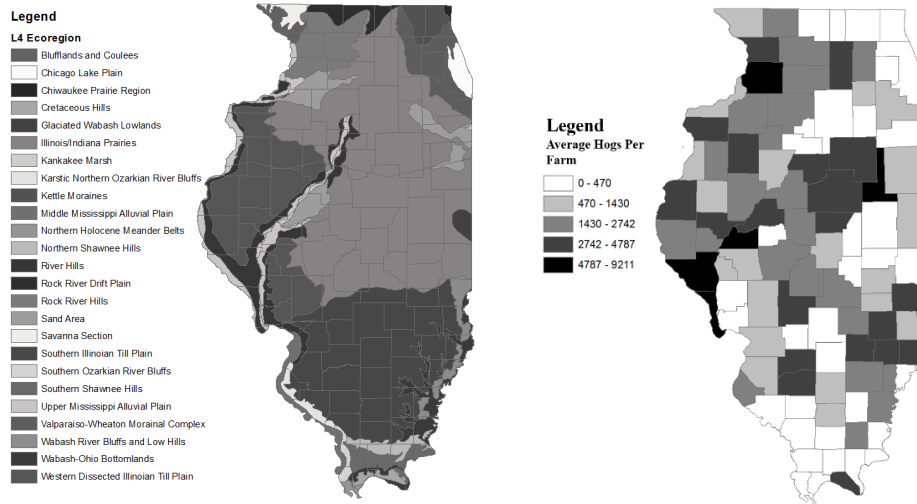

Figure 1. Selected data. Illinois ecoregions (left), and average hogs per farm (right).

feedstock cropland. Spatially explicit ES values are taken from The Economics of Ecosystems and Biodiversity (van der Ploeg and de Groot, 2010), database and applied in this framework via the benefit transfer approach. Values for each ecosystem (temperate grassland, temperate forest, floodplains) were aggregated with data from this database as per the method outlined in Garcia and You (2017b). We assume conversion of swine manure to biogas regenerates ES that were diminished before the manure was handled properly. Following an avoided cost/remediation approach, we assume creeks, rivers, and streams no longer become polluted by manure spills if a digester is constructed on nearby swine farms. These costs are estimated with historical records of relevant government fees and fines. Finally, we integrate the hedonic valuation approach for swine manure on nearby property values. If a farmer decides to convert the swine manure to bioenergy, we assume nearby property values no longer decrease due to odors, threats of spills, human health issues, etc. as quantified statistically by Herriges et al., (2005). We model an expected increase in nearby property values when manure is converted. The magnitude of the increase depends on distance from the hog farm and size of the hog farm. Next, the framework is applied to a case study on bioenergy demand in the US state of Illinois (Figure 1). Illinois produced approximately 160 PJ of corn ethanol in 2016, so we aim to identify from where the next 160 PJ of bioenergy should come to help Illinois reach its 20-25% renewable energy target by 2025.

3. Methodology

We processed, integrated, and analysed spatial data in ArcGIS 10.5 (ESRI, 2017). The data was imported into the mathematical programming model. Parameters are in lowercase with variables in uppercase (Table 1).

$$\min \sum_x \sum_c CC_{xc} \cdot \left(ic/1 - (1+ic)^t \right) + OC_{cx} - H_{cx} \cdot hfs_c \cdot ec_c \cdot ber - E_c \cdot epr \quad (1)$$

$$\min \sum_c E_c \cdot epr + EV + SP - \sum_b \sum_c EL_{bc} \cdot esval_b \quad (2)$$

$$\text{s.t. } ed \leq \sum_c \sum_x E_c + H_{cx} \cdot hfs_c \cdot ber \quad (3)$$

$$E_c = \sum_r \sum_c \sum_{x=eth} \sum_b CR_{rcxb} \cdot py_{rx}, \forall c \quad (4)$$

$$NT_{cx} \cdot bcap_x = \sum_r \sum_b CR_{rcxb}, \forall c, x \quad (5)$$

$$\sum_x \sum_{r=stover} \sum_b CR_{rcxb} \leq ssf \cdot \left(sa_c + \sum_x \sum_{r=corn} \sum_b CR_{rcxb} \right), \forall c \quad (6)$$

$$CC_{xc} = (NT_{cx} + H_{cx}) \cdot bcc_x, \forall c, x \quad (7)$$

$$OC_{cx} = (NT_{cx} + H_{cx}) \cdot boc_{cx}, \forall c, x \quad (8)$$

$$\sum_b EL_{b,c} \leq flm_c, \forall c \quad (9)$$

$$EV = \sum_c \sum_x H_{cx} \cdot mhv_c \cdot hi \cdot (sm_c \cdot hq_c (pcsqd + pcsqu) + sm_c \cdot hh_c \cdot pcsh + lg_c \cdot hoh_c \cdot pcloth) \quad (10)$$

$$SP = \sum_c \sum_x H_{cx} \cdot sab \quad (11)$$

$$EL_{bc} = \sum_b \sum_x CR_{rcxb} \cdot cy_{rb}, \forall b, c \quad (12)$$

$$\sum_x H_{cx} \leq hf_c, \forall c \quad (13)$$

where sets x, c, r, b represent bioenergy production options, c is counties, r is ethanol feedstocks, and b is BAMAs. The objective (1) accounts for annualised capital costs, annual operating costs, and revenue from electricity and ethanol. Objective (2) calculates the change in Green GDP, considering ethanol produced, changes in property values via the hedonic pricing method, avoided costs of cleanup/litigation for manure spills, and the value of lost ecosystems by clearing for ethanol feedstock production. Constraint (3) ensures bioenergy targets are met. Constraints (4)-(5) calculate ethanol produced. Constraint (6) controls stover utilisation. Constraints (7) and (8) calculate costs. Constraint (9) controls how much land may be converted to cropland. Constraints (10)-(12) calculates regenerated/lost ES values via the hedonic pricing method, avoided cost method, and aggregated valuation method, respectively. Constraint (13) ensures that no more hog farms install biogas-electricity generators than exist in each county.

4. Results and Discussion

All experiments were performed on a DELL OPTIPLEX 790 desktop PC with an Intel (R) Core (TM) i5-2,400 CPU @ 3.10 GHz and 8 GB RAM. We handle the multiobjective component of the problem with the ϵ -constraint method (Hwang and Masud, 2012). The mixed integer problems consisted of 4,596 equations, 32,338 continuous variables, and 1,326 discrete variables. All models and solution procedures were coded in GAMS 24.8.5 (Brooke et al., 1988). with the CPLEX 12 solver.

The Pareto-optimal frontier is shown in Figure 2. Green GDP ranges from -\$138M/y to \$144M/y, and the net cost ranges from \$107M/y to \$260M/y. Green GDP increases sharply from -\$125M/y to \$132M/y around a net cost of approximately \$200M/y. This sharp increase is likely primarily due to a shift from largely corn-based ethanol production in the lower cost solutions to utilising corn stover instead at the higher cost solutions. However, hog farms begin choosing to convert manure to biogas and electricity around this point as well. Small gains in Green GDP are made on either side of this sharp increase, reflecting hog farms who decide to convert manure to electricity. At the lowest cost solution, no farmers convert manure to electricity, while at Point A

Table 1. Parameters (lower case) and variables (upper case) in the model.

CC_{cx}	Capital costs	t	Annualisation timeframe (20 years)
H_{cx}	Number of hog farms in county c that integrate biogas technology x	epr	Ethanol selling price (avg 2012 spot price)
OC_{cx}	Operating costs	flm_b	Convertible land in county c
SV	Spill ES value loss avoided	cy_{rb}	Yield of crop r in BAMA b
E_c	Ethanol produced in county c	$esval_b$	Value of ES in BAMA b
EL_{bc}	Area of BAMA b lost in county c	hfs_c	Average hog farm size in county c
CR_{rcxb}	Mass of feedstock r grown in county c and BAMA b for conversion in x	hi	Annualised mortgage factor
NT_{cx}	Number of plants x in county c	ed	Bioenergy target
EV	Hedonic ES value recaptured	ec_c	Electricity cost in county c
sa_b	Original stover availability	ber	Biogas-electricity conversion rate
ic	Interest rate of capital	ssf	Sustainable stover harvest factor
bcc_x	Reference capital cost of x	$bcap_x$	Reference capacity of x
bop_{cx}	Reference operating cost of x in c	$bfop_x$	Reference fixed operating cost of x
mhv_c	Median property value in county c	py_{cx}	Conversion of r to ethanol in x
sm_c	1 if average hog farm in c is small	lg_c	1 if average hog farm in c is large
hq_c	Households within 0-0.4 km	hh_c	Households within 0.4-1.2 km in c
sab	ES value loss from manure spill avoided	$pcsqd$	Home value decrease 0.4 km downwind small hog farm
$pcsqu$	Home value decrease 0.4 km upwind small hog farm	$pcsh$	Home value decrease 1.2 km from small hog operation
$pcloh$	Home value decrease 2.4 km from large hog farm	hf_c	Number of hog farms in county c
hoh_c	Households within 2-2.8 km in c		

most do. Interestingly, fewer farmers convert manure to electricity at Point B than Point A. This may be due to the nature of the ϵ -constraint method combined with the increased cost of using corn stover over corn grain to produce ethanol. We chose the net cost as the constrained objective using the ϵ -constraint method. Thus, if corn stover is more costly to convert to ethanol, there is less “budget” in the net cost to convert manure to electricity. Using corn stover results in larger ES savings due to no longer clearing land; stover may be harvested from corn already produced. Thus, stover production is prioritised over manure conversion at Point B. Most of the Green GDP gain comes from growing corn in counties with lower BAMA values and by converting manure in counties with high median housing values. More farmers convert manure to

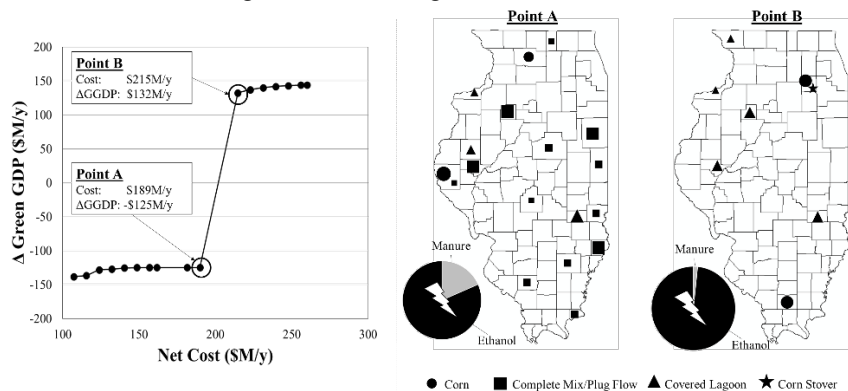

Figure 2. Pareto-optimal curve (left). Detailed results on Points A and B (right). Pie charts represent portion of bioenergy from ethanol and conversion of manure to biogas and electricity.

electricity from Point B to the highest Green GDP solution, where, as in Point A, all farmers convert manure to electricity. More farmers build covered lagoons over complete mix/plug flow reactors to convert manure to biogas and electricity in Point B.

5. Conclusion

A modelling framework for a bioenergy production strategy considering ethanol production and conversion of agricultural and organic wastes to biogas and electricity was presented. This work represents the first time several such impacts are valued and quantified via a range of ES valuation techniques. We applied the framework to a case study on bioenergy production in the US state of Illinois with two objectives of minimum net cost and maximum Green GDP. Considering ES values was shown to influence decision-making. Green GDP ranged from -\$125M/y to \$132M/y with associated net costs of \$107M/y to \$260M/y.

Abstract

The state of Qatar strives to diversify its energy portfolio whilst minimizing potential impacts on the environment from released wastes of multiple sectors. The current energy portfolio utilizes fossil fuels to drive the power sector which releases GHG's into the atmosphere. There has been significant progress in diversifying the global energy mix in order to limit GHG emissions. Biomass, which is a CO₂ neutral organic fuel, serves as a potential energy source for the generation of sustainable heat and power. The objective of this paper is to model a system that utilizes waste biomass from Qatar built environment to generate a high-energy product gas that contains hydrogen, carbon monoxide, and methane. There is a strong sustainable development component where there is a reduction in biomass waste and consumption of raw material as natural gas consumption is reduced. As such, the biomass can be utilized to generate a valuable product, whilst reducing GHG's and Qatar's dependency on reserves of natural gas. Gasification is considered as the preferred option for the processing of biomass where the product gas mixture (syngas) can be used to power generators/gas-turbines and produce clean energy since the process is carbon neutral. The syngas can be also used in the petrochemical industry to produce ammonia and methanol and reduce local dependency on natural gas. In this study, a computer simulation model of the biomass gasifier was developed using Aspen Plus considering Qatar's biomass characteristics. The results demonstrated the possibility to utilize domestic feedstock in Qatar such as date palm residues amongst others to generate syngas. Furthermore, the study determines the optimum blends of biomass feedstocks which are to be utilized in the existing gasification processes.

Keywords: biomass, gasification, date pits, optimization, nexus

1. Introduction

Like most countries, one of the main challenges facing the State of Qatar is the need to develop holistic waste management strategies which reduce environmental impacts from generated waste, estimated at 1.8 kg per capita per day (Ahmad, 2016). Coupled to this is the need to prolong the life time of natural resources, i.e. natural gas. Currently Qatar utilizes this commodity to meet its domestic needs for power, converted to LNG and other chemicals for export. Incidentally, Qatar strives to diversify its energy portfolio with the forthcoming integration of solar energy into the domestic electricity

grid. The management of biomass through a holistic utilization strategy can contribute towards national objectives of enhanced resource productivity, environmental protection and economic diversity. Biomass, which is a CO₂ neutral organic fuel, serves as potential energy source and renewable feedstock for the generation of sustainable heat and power (Gordillo et al., 2009). Gasification is considered as the preferred option for the processing of biomass where the product gas mixture (syngas) can be used to power generators/gas turbines and produce clean energy since the process is carbon neutral. The syngas can also be used to produce high value petrochemicals such as ammonia and methanol.

The objective of this paper is to model a gasification system that utilizes the waste biomass from Qatar built environment to generate a high-energy product gas that contains hydrogen, carbon monoxide, and methane. As such, the biomass can be utilized to generate a valuable product, whilst reducing GHG's and Qatar's dependency on the nation's reserves of natural gas. Furthermore, considering the various types of solid waste available in Qatar such as sewage sludge, date palm waste, and other organic waste, this study will determine the optimum blend of biomass feedstock which can be utilized in existing gasification processes to produce optimum product output. This study differs from other literature studies in terms of its optimization nature by including various biomass feedstocks that includes date pits. The potential of biomass gasification for the State of Qatar has been demonstrated through an energy, water and food (EWF) nexus case study for a hypothetical food security scenario for the State of Qatar (Al-Ansari et al., 2016). In this study, manure is gasified to produce syngas which is utilized for power generation purposes within the overall EWF nexus.

Since 2001, biomass gasification (BG) has received widespread importance in both academia and industry. This is primarily due to the need to mobilize effective strategies to combat climate change and the volatile oil prices. BG technology can reduce the generated carbon to hydrogen (C/H) ratio leading to a higher calorific value content and a favourable H₂ fraction. Furthermore, outputs from BG also yields many useful products, which include bio-fuels, bio-char, syngas, power, heat, and fertilizer. Syngas is a key product of BG and it mainly consists of Carbon monoxide (CO), Hydrogen (H₂), Methane (CH₄) and Carbon dioxide (CO₂). It is an important element in the production of environment-friendly fuels and chemicals and in the generation of power. However, various types of contaminants are associated with syngas production such as tars, sulphur inorganic compounds, particulates and nitrogenous compounds. The properties and quality of the gasification product and its associated contaminates depends on the gasifying agent, feedstock material and dimensions, reactor conditions and design, presence of sorbent and catalyst (Sikarwar et al., 2016).

Aspen plus, a process modelling software, has successfully been utilized to simulate gasification process systems. Incidentally, those related to biomass are less extensive than other sources of fuel used in gasification such as coal (Puig-Arnavat et al., 2010). Doherty et al. developed an Aspen plus model to simulate biomass gasification in a steam blown dual fluidized bed (DFB). The model is developed based on Gibb's free energy minimization and restricted equilibrium methods. The results demonstrated agreement with published data for syngas composition, heating value and cold gas efficiency (CGE) (Doherty et al., 2013). Trop et al. studied co-gasification of torrefied wood biomass and municipal sewage sludge for the production of methanol using Aspen Plus. A techno-economic study was performed in comparison with coal

gasification, where the results showed that the biomass combination can serve as a potential alternative (Trop et al., 2016). Han et al. developed a similar model for downdraft biomass gasification. The model was first validated with experimental data and then a sensitivity analysis was utilized to perform an investigation on the effect of gasification temperature, biomass moisture content and equivalence ration on the quality of synthesis gas (Han et al., 2017).

2. Model Development

The base model developed in this project is based on air-steam gasification of different feedstocks available in the State of Qatar to generate H₂-rich syngas. The Aspen Plus flowsheet of the biomass gasifier is modelled based on the assumptions of steady state, zero-dimensional, isothermal operation, atmospheric gasification pressure (P_g) (~1 bar) operation, neglected pressure drops, ideal gases, char is 100% carbon (C), tar formation is neglected, fuel bounds N₂, S, and Cl₂ are converted to NH₃, H₂S and HCl, respectively, instantaneous drying and pyrolysis, and heat loss from the gasifier is neglected.

Table 1: Proximate and ultimate analyses of biomass feedstocks

Mass Flow (tons/y)	Manure	Sludge	Date Pits
	5.27x10 ⁵	3.65 x10 ⁴	7.60x10 ³
Proximate analyses (wt %)			
Volatile matter	64.97	8.1	77.7
Fixed carbon	13.46	17.8	16.311
Ash	21.57	65.8	0.98
Moisture	27.4	8.3	5.01
Ultimate analyses (wt %)			
C	37.05	50.38	50.84
H	5.06	6.12	6.83
O	31.44	14.9	37.88
N	3.66	2.89	4.45
S	0.45	0.25	0
Cl	0.97	0	0
Ash	21.37	65.8	0.98
LHV (dry basis) (MJ/kg)	19.09	16.40	25.30

The equation of state selected for this model is Peng-Robinson with Boston-Mathias modifications. Biomass streams representing manure, dried sewage sludge and date pits feedstocks are specified as non-conventional streams with, ultimate and proximate analyses and assumed flow rates illustrated in Table 1. Stream thermodynamic conditions of 1 bar and 25 °C are assumed in accordance with the assumption of atmospheric conditions (Doherty et al., 2013). The mass yields of the non-conventional biomass streams into conventional components, have been determined and set using a calculator block according to the following formulation:

Table 2: Calculator block formulations of conventional components yield

WATER = PROXANAL(1)	[1]	CARBON = ULTANAL (2) / 100 * FACT	[6]
H2O = WATER / 100	[2]	H2 = ULTANAL (3) / 100 * FACT	[7]
FACT = (100 - WATER) / 100	[3]	N2 = ULTANAL (4) / 100 * FACT	[8]
ASH = ULTANAL(1) / 100 * FACT	[4]	CL2 = ULTANAL (5) / 100 * FACT	[9]
SULF = ULTANAL (6) / 100 * FACT	[5]	O2 = ULTANAL (7) / 100 * FACT	[10]

The outlet stream from the reactors is fed to a separator block to separate out the ash content. The rest of the components are directed to a stoichiometric reactor where 100%

of the fuel bound N_2 , S and Cl_2 are converted to NH_3 , H_2S and HCl , respectively through the following reactions:

The resulted components are removed from the main fuel stream via a separator. The main fuel stream is then fed to the gasifier simulated using a Gibbs reactor. The other two feed streams are the air and steam needed to gasify the biomass. The air stream is fed with specified mole fractions of 0.95 O_2 , 0.016 N_2 , and 0.034 Ar, which is the typical quality of air from an air separation unit. The temperature and pressure of the air and steam streams are set to 450 °C and 1 bar. The assumed gasification air-biomass ratio (GATBR) is 0.6. Whereas, the injected steam mass flowrate is calculated based on the mass flowrate of the biomass and its moisture content along with a 0.75 steam to biomass ratio (STBR). The gasification reactor is modelled utilizing the minimization of Gibb's free energy while restricting the chemical reaction equilibrium. The following reactions were specified with zero temperature approach:

Another Gibbs reactor block is utilized to perform the water shift and methanation reactions; Eq. (17) and (18), by means of restricting the reaction's equilibrium through specifying temperature approach values of (-265 °C and -90 °C respectively). This temperature approach values ensure that the model outputs a realistic syngas composition. The exit stream represents the final output syngas stream from the model.

3. Results

After the development of the air-steam gasification model, the biomass feedstock is optimized in order to find optimum blended feedstock. The optimization involves maximizing the syngas production whilst constraining the $H_2:CO$ ratio in accordance with the different syngas utilization processes, in particular the generation of power and liquid fuels (Iaquaniello et al., 2012). The results are summarized in Table 3.

The different $H_2:CO$ ratios have led to different blends of the biomass feedstocks. A Sensitivity analysis is then applied to understand the effect of changing the key gasification process parameters on the operating conditions and produced results as illustrated on Figures 1-4. The parameters considered include the: gasification temperature (T_g) and pressure (P_g), gasification air-biomass ratio (GATBR) and steam to biomass ratio (SATBR). The main observation results are, syngas composition in dry Vol%, lower heating value (LHV) in dry mass basis, cold gas efficiency (CGE) which is a measure of produced syngas heating value to biomass heating value. It can be seen that the LHV, CGE and syngas compositions demonstrate unrealistic results when the operating conditions.

Table 3: Results of biomass feedstock blends optimization

H ₂ :CO ratio	2:1	3:1	4:1
Syngas Composition, dry basis (mol%)			
N ₂	0.45	0.67	1.12
CO	20.20	12.57	6.02
CO ₂	35.90	48.65	68.79
H ₂	40.40	37.71	24.06
CH ₄	3.06	0.40	0.01
Feed Blend (wt%)			
Manure	0.16	39.15	46.69
Date Pits	99.68	39.15	6.62
Sludge	0.16	21.69	46.69
Syngas Yield (kg product/kg Feed)			
	2.27	2.13	1.96
LHV at 0 °C, dry basis (MJ/m ³)			
	8.20	6.21	4.07

Figure 1: Effect of changing gasification temperature (T_g) (STBR = 0.75, GATBR = 0.6, P_g = 1 bar)

Figure 2: Effect of changing gasification pressure (P_g) (STBR = 0.75, GATBR = 0.6, T_g = 850 °C)

Figure 3: Effect of changing gasification air-biomass ratio (GATBR) (STBR = 0.75, P_g = 1 bar, T_g = 850 °C)

Figure 4: Effect of changing steam to biomass ratio (STBR) (GATBR = 0.6, $P_g = 1$ bar, $T_g = 850$ °C)

4. Conclusions

This study demonstrated a methodology to maximise product output for a biomass gasification process through optimising a feedstock blend for a case study in the State of Qatar. From the results, it can be deduced that the LHV and CGE and syngas composition demonstrate unrealistic results when the biomass gasification process is operating under non-optimum conditions. Alternatively, optimal conditions in terms of gasification temperature (T_g) and pressure (P_g), gasification air-biomass ratio (GATBR), and steam to biomass ratio (STBR) demonstrate improvement in simulation output because of the higher presence of H₂ and CO in the produced syngas. This presence has been reflected in the increase of lower heating value and cold gas efficiency.

Abstract

As part of the drive for global food security, all nations will need to intensify food production, including those situated in hyper arid climates. The State of Qatar is one such example of a national system that whilst it is presented with environmental challenges, seeks to enhance food security. The energy, water and food (EWF) nexus approach is an effective means to accurately ascertain resource consumption, identify synergies and trade-offs, and quantify environmental burdens in the delivery of products and services. The EWF nexus theory has been uniquely applied to a hypothetical food system in Qatar where sub-system model's representative of EWF systems are developed. It has been suggested that the fertilization of agricultural systems with CO₂ can enhance their productivity. The study described in this paper considers the life cycle yield improvements which can be made possible at the farm level by utilizing the captured CO₂. This requires a modification of the EWF nexus model to consider the spatial characteristics of the modelled elements. The newly built model is used to investigate the CO₂ transport methods (pipeline and truck), and distance that CO₂ captured from combined cycle gas turbine (CCGT) and biomass integrated gasification combined cycle (BIGCC) sub-systems which may then be transported for CO₂ fertilization, and yield improvements to be justified from an energy utilization perspective. In this regard, an integrated analysis using GIS-based optimization is applied where the sub-systems are represented as geospatial elements together with their design constraints, such as the capacity-related parameters of the fertilization systems, and the energy requirements of the transport network connecting the CO₂ sources with the fertilization systems at multiple greenhouse locations in Qatar. These form part of the problem formulation for the determination of optimal locations of food production systems using Non-Linear Programming (NLP) to ensure the feasibility of CO₂ fertilization and realize environmental improvements within the overall EWF nexus framework. The results indicate the optimal locations and extents for new greenhouse developments that are constrained by the available farming infrastructures and CO₂ transportation options to balance for the net energy and water requirements for food production.

Keywords: EWF nexus, Food security, Meta-Heuristics, Life cycle, Agriculture

1. Introduction

Holistic approaches such as the energy, water and food (EWF) nexus are critical for addressing integrated challenges in uncertain environments. The State of Qatar is situated in a region characterised by a complex environment. Its climate is hyper arid, with high average temperatures and humidity, posing multiple challenges with respect to food production. Historically, Qatar has imported a vast majority of its food requirements from overseas markets. However, this is likely to change with the inception of food security projects, which are designed to increase Qatar's domestic food production capacity. Doing so will require a mobilisation of multiple resource sectors in order to transform the domestic food production operating within a challenging environment.

Agricultural intensification, as witnessed in the past, involved unsustainable practices, which has led to widespread environmental degradation. Going forward, the importance of understanding the relationship between the environment and food security outcomes will be critical, as agricultural productivity essentially depends on the condition of the environment. This introduces the notion of 'sustainable intensification', which is related to the need to meet the demands of nutritional demands of a growing environment without furthering degradation to the natural environment (Godfray and Garnett, 2014). There is much discussion on the effect of the elevated levels of CO₂ in the atmosphere on crops. The general consensus is that higher crop yields will be produced as a result. This is because CO₂ is an essential compound in the photosynthesis process where its carbon content is utilised to form carbohydrates. Furthermore, increasing concentrations of CO₂ inhibits the loss of water also known as transpiration due to increased resistance from the stomata. It has also been suggested that increased temperature and decreased soil moisture would have a negative impact on crop yields. This, however, would be offset by the natural fertilization of crops from the increasing concentration of CO₂ in the atmosphere (Lawlor and Mitchell, 1991). Moreover, the fertilization of plants using CO₂ not only results in increases in dry matter production, but is accompanied by improvements of water utilization efficiency (WUE) (Kimball and Idso, 1983).

The objective of this study is to utilize the EWF nexus model previously developed by the authors to explore the potential of enhancing agricultural productivity through CO₂ fertilization. The study utilizes a hypothetical food security scenario for the State of Qatar previously evaluated using a EWF Nexus approach (Al-Ansari et al., 2016; 2017). The case studied involves raising domestic production by 40 %. The configurations utilized in this research are adopted from Al-Ansari et al. (2016; 2017) as detailed in Table 1 utilising combined cycle gas turbine (CCGT), post carbon capture (PCC), biomass integrated gasification combined cycle (BIGCC) and bioenergy carbon capture and storage (BECCS) for power generation. The purpose of this work is, however, not to attempt to predict potential crop improvements from CO₂ fertilization, but to quantify the minimum yield improvement using an indirect, but related, measure of reduction in transpiration from crops that would be required in order to balance the amount of energy (or equivalent water requirement) used for CO₂ capture, compression and transportation to the agriculture zone, i.e. greenhouse. The objective in this case is to improve system wide WUE. It should be noted that calculations of expected crop productivity increase from CO₂ fertilization are not within the scope of this study. This research identifies the increase in energy required to enable CO₂ fertilization, which would need to be balanced out by increases in crop productivity, which in turn result in an overall reduction in the water requirement and, therefore, energy consumption.

Table 1. Scenario development

2. Available data and assumptions

The problem formulation developed in this study is based on multimodal datasets for the State of Qatar, each of which provides spatial information for: (a) distribution of land use for farming activities; (b) distribution of solar irradiance; (c) the locations of the major sources of CO₂ emissions; and (d) possible modes of CO₂ transport that are of interest in the current study, namely pipelines and road transport. Fig 1 illustrates the country wide distribution of resources, indicating the relevant spatial parameter inputs used in the formulation.

The extent of the feasible region for the determination of optimal greenhouse locations was based on the percentage of land use under the category of green areas, as shown in Fig 1(a), available from the public databases of the Ministry of Development Planning and Statistics (MDPS) in Qatar. The locations were assumed to be constrained to ensure the availability of infrastructure to provide resources, such as water for irrigation, fertilizer, and transportation, where necessary. Thus, a cut-off percentage of 20 % was assumed in this study to ensure that the proposed locations for greenhouses are within a radial distance of 5 km from existing farming areas.

An important part of the input data considered in this study is the spatial distribution of solar radiation component reported as Direct Normal Irradiance (DNI) and indicated as contours in Fig 1(b), modified after Martín-Pomares *et al.* (2017). The DNI was used to determine the depth of evapotranspiration, characterizing the loss of water (in mm/day) from agricultural lands, in general. It was assumed that the water loss is owing to transpiration in crops only, which constitutes up to 10 % of evapotranspiration (Doorenbos, 1977), and that it also applies to greenhouses with minimal control on the direct sunlight radiation, air temperature, air humidity and wind (Fazlil-Ilahil, 2009).

Additionally, the locations of CCGT and BIGCC power plants are indicated in Fig 1(c). A BIGCC plant, however, does not currently exist and was assumed to be located closer to the city of Doha, as it is expected that most of the biomass waste would be generated from this region which has the highest population density. With regards to the options for transportation of CO₂ captured from the power plants, underground pipelines and road transport were assumed (Fig 1(d)). The service pipeline corridors are already available in the State of Qatar, and thus any proposal for laying new pipelines for CO₂ transportation are expected to follow these routes as per the local regulations. It is also assumed that the

road network would be utilized only for the last mile delivery of CO₂ to the greenhouses to minimize any service delays or potential hazards caused by CO₂ transportation. In view of this, the distance of road transport was assumed to not exceed 10 km.

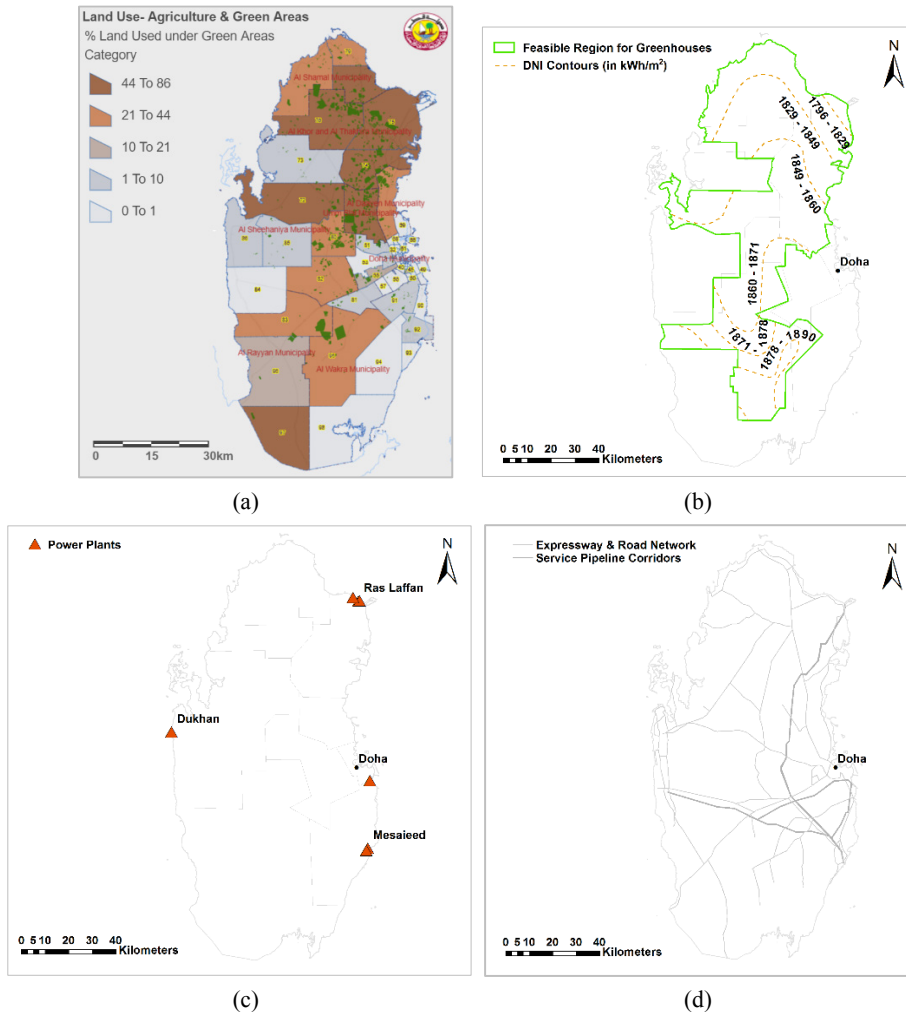

Fig 1. Maps of (a) agricultural land use and % coverage by the agricultural sector for municipalities, according to the 2015 census by MDPS, Qatar; (b) DNI contours (modified after Martín-Pomares *et al.* (2017)) for regions with the potential for new greenhouse development; (c) locations of CCGT and BIGCC power plants; and (d) transport network infrastructure available for the alignment with possible transportation of CO₂ from power plants to greenhouses.

3. Methodology

A non-linear programming (NLP) formulation was developed to determine the optimal location and minimum required area of greenhouses, based on the available data and assumptions posed as constraints in the problem. The nomenclature of variables used in the formulation is as follows:

Decision variables

- X_G, Y_G : easting and northing of the greenhouse (in metres).
- A_G : area of the greenhouse (in m^2).

Estimated variables

- X_F, Y_F : easting and northing of existing agricultural fields (in metres).
- X_D, Y_D : easting and northing of proposed CO_2 distribution centres (in metres).
- E_{CCT} : total energy consumption for CO_2 capture, compression and transport from the power plant to the greenhouse (in MWh/year), after Nie *et al.* (2011) and Al-Ansari *et al.* (2017).
- W_G : DNI equivalent for water loss (in MWh/ m^2), after Martín-Pomares *et al.* (2017).
- k_1 : conversion factor for equivalent water consumption (in m^3), after Al-Ansari *et al.* (2017).
- k_2 : conversion factor for equivalent depth of evapotranspiration (in m^3 /year), after Doorenbos (1977).

The optimization problem was posed with the objective of minimizing the net water consumption in the network subject to non-linear constraints, as follows:

$$\begin{aligned} & \text{Minimize } \{k_1 \times E_{CCT}(X_G, Y_G) - k_2 \times A_G \times W_G(X_G, Y_G)\} \\ & \text{subject to,} \\ & (X_G - X_D)^2 + (Y_G - Y_D)^2 \leq 10,000^2, \\ & (X_G - X_F)^2 + (Y_G - Y_F)^2 \leq 5,000^2, \text{ and} \\ & X_G, Y_G \in \text{DNI contour set.} \end{aligned} \tag{1}$$

4. Results

The NLP formulation in Eq. (1) was subsequently solved using a meta-heuristic algorithm called simulated annealing to determine the optimal solutions. Fig 2 illustrates the results obtained after solving the NLP problem described in the earlier section. It should be noted that multiple locations of CO_2 distribution centres were assumed at the intersections of pipelines and roadways for simplification purposes.

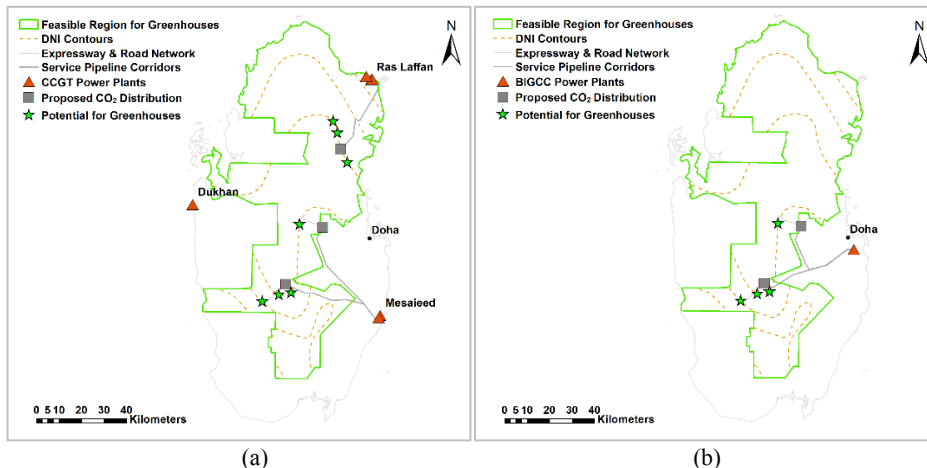

Fig 2. Optimized locations of greenhouses in the case of CO_2 captured from: (a) CCGT plants; and (b) BIGCC plants.

The optimal locations of the greenhouses are constrained on the DNI contour lines, which are used to estimate the water losses owing to crop transpiration. In addition, the ranges of the minimum area required for greenhouses were estimated under different scenarios of CO₂ captured from: (a) CCGT plants: 32,000 to 35,000 m²; and (b) BIGCC plants: 13,000 to 14,000 m², to minimize the net water consumption, or result in net water savings.

5. Conclusions

The authors present a decision framework based on the EWF nexus approach for the development of new greenhouses with the aim to enhance domestic food production in the State of Qatar. The results obtained thus far are promising from an environmental perspective, as the emission reduction that can be potentially achieved by the CO₂ fertilization network is around 0.5Mt/year considering the integration of capture technology for both CCGT and BIGCC, with the potential benefit of saving precious water resource. However, for such a solution to be viable, the question of economic feasibility needs to be addressed. This is a limitation of the analysis presented here, and is currently being studied under this framework.

Abstract

This paper presents a process design method using combined energy and water integration for a complete textile waste refinery process. The proposed method consists of a superstructure model taking into account balanced energy and water minimization targets and produces energy and water networks of maximum efficiency. It produces significant results both for independent and combined water and energy integration; Savings up to 71% for heating and 86% for cooling can be achieved by standalone energy integration and savings up to 38% for water consumption by applying independent water integration. On the other hand, combined energy and water integration can lead to 74.5% energy and 36% water savings, thus an increase of 3.5% in energy savings at the expense of just 2% reduction in water savings.

Keywords: water integration, energy integration, mathematical programming, superstructure model.

1. Introduction

The present work coordinates established and original Process Integration technologies to the solution of a new problem; the design of the sustainable Total Textile Waste Refinery (TTWR); a new waste recycling and refining process, that it is being currently developed in the course of the European Horizon2020 research project RESYNTEX. It uses the complete spectrum of waste textiles as feedstock, aiming to provide a holistic response to the largely overlooked waste textile management problem. TTWR is now just before the phase of pilot construction and process integration technologies are currently implemented to accelerate the design solution.

TTWR consists of gate links between textile materials with commodity and specialty products and chemicals. Feedstock includes the entire range of textile fibres and final products including bio-ethanol, adhesives used in the wood-based panel production, PET bottles and PA-derived value-added chemicals. Without any water integration attempts the water consumption is as high as 52 tonnes per tonne of feedstock, and it is shared among reaction and separation stages (mostly washing and filtration steps) at a 2:1 ratio. Contrary to the textile fabrication processes which uses an average of 30 MJ/kg of fabric (Kalliala and Nousianinen, 1999), TTWR is more energy intensive, requiring more than 53 MJ/kg of feedstock. The majority of the energy requirements (~40%) is used in reactions, which are mainly neutral thermochemical hydrolyses at high temperatures for PAs and PET, and biochemical hydrolyses at mild temperatures. Considering that water is

used at high ratios compared to the feedstock material in all reactions, it is also the main energy carrier in the reactors. This evidence indicates clear scope for a combined energy and water integration study, since water is used both as a cleaning agent for removing dyes and impurities as well as the main heating medium. Novel process integration tools have been developed for assessing alternative process integration scenarios and achieving maximum efficiencies in energy and water use in modern biorefineries (Koufolioulis et al., 2014; Nikolakopoulos and Kokossis, 2017a). Also, total waste management and recycle design technology has been produced to enable the development of designs for processes with minimum environmental impact (Nikolakopoulos and Kokossis, 2017b).

A new tool is proposed in this paper for targeting maximum energy and water efficiencies in the TTWR. It is developed by using a mathematical programming superstructure model which balances the preference towards energy and water saving goals. The application of the proposed tool in the design of the TTWR is able to produce significant energy and water saving targets, that may reach up to 71% for energy and 36% for water.

2. Methodology

The concept of combined heat and water integration is based on the idea of combining and reusing at water-using operations outlet water streams coming from other operations and also splitting and reusing outlet streams at other operations for reducing heating and cooling requirements and at the same time reduce fresh water requirements.

In order to calculate the reuse flowrates between operations that minimize the total fresh water use and the same time minimized energy requirements for heating water streams a superstructure of the processes is constructed to account for all possible connections between water using operations. The superstructure is represented by the superstructure model described next.

The objective function maximizes the weighted sum of normalized water and energy savings; W^S and E^S given by equations 32 and 33 respectively, where FW^{init} and TQ^{init} is the total fresh water and energy consumption prior to integration and FW , TQ^S are the consumptions after integration respectively. Depending on the value of the weighting factor a ; $0 \leq a \leq 1$, different balances between fresh water and energy use minimization are introduced, i.e. when $a = 1$, minimization of energy is neglected, while the opposite stands for $a = 0$, when water use minimization is not considered. In all cases though, the mass and energy balances are satisfied, resulting in feasible networks.

$$\max Z = a \cdot W^S + (1 - a) \cdot E^S \quad (1)$$

s.t.:

The total flow of fresh water required is:

$$FW = \sum_{i=1}^{No} Fwin_i \quad (2)$$

The wastewater flow is:

$$FWW = \sum_{j=1}^{S_j} FTPdis_j \quad (3)$$

The total flow of contaminants in the wastewater flow is:

$$FWW \cdot Cout, env = \sum_{j=1}^{S_j} FTPdis_j \cdot CoutTP_j \quad (4)$$

Equation (5) is the mass balance of water around operation i considering diluted streams, i.e. $Fin_i + Mc_i = Fout_i$, where Mc_i is the mass of contaminants removed by water in operation i .

$$Fin_i = Fout_i \quad (5)$$

Mass of contaminants removed by water in operation i , where Cin_i and $Cout_i$ are the inlet and outlet concentrations for operation i .

$$Mc_i = Fin_i (Cout_i - Cin_i) \quad (6)$$

Inlet flow for process i , summing up fresh water, reused water and treated water. The recycled flowrates are set to 0 for this study.

$$Fin_i = Fwin_i + \sum_{ii=1}^{No} Freuse_{ii,i} + \sum_{j=1}^{S_j} FTPtoP_{j,i}, \quad \forall i \quad (7)$$

Mass of contaminant entering operation i

$$Fin_i \cdot Cin_i = \sum_{ii=1}^{No} Freuse_{ii,i} \cdot Cout_{ii} + \sum_{j=1}^{S_j} FTPtoP_{j,i} \cdot CoutTP_j, \quad \forall i \quad (8)$$

Outlet from process i , including the waste water and water reused to other processes

$$Fout_i = Fwwout_i + Frest_i, \quad \forall i \quad (9)$$

The water reused from process i to the rest of the water using operations is:

$$Frest_i = \sum_{ii=1}^{S_j} Freuse_{i,ii}, \quad \forall i \quad (10)$$

The wastewater from operation i driven to the treatment process is:

$$Fwwout_i = \sum_{j=1}^{S_j} FPtoTP_{i,j}, \quad \forall i \quad (11)$$

The inlet flowrate for treatment process j is:

$$Ft_j = \sum_{i=1}^{No} FPtoTP_{i,j} + \sum_{jj=1}^{S_j} FTPtoTP_{jj,j}, \quad \forall j \quad (12)$$

The inlet mass flowrate of contaminant for treatment process j :

$$Ft_j \cdot CinTP_j = \sum_{i=1}^{No} FPtoTP_{i,j} \cdot Cout_i + \sum_{jj=1}^{S_j} FTPtoTP_{jj,j} \cdot CoutTP_{jj}, \quad (13)$$

The flowrate of treated water going to water using operations (= 0), other treatment processes (= 0) and to discharge is:

$$Ft_j = \sum_i^{No} FTPtoP_{j,i} + \sum_{jj}^{S_j} FTPtoTP_{jj,j} + FTPdis_j, \quad \forall j \quad (14)$$

$$FTPtoTP_{j,jj} = 0, \quad \forall j = jj \quad (15)$$

$$Freuse_{i,ii} = 0, \quad \forall i = ii \quad (16)$$

The mass of contaminant treated by wastewater treatment processes, is equal to the total mass of contaminant removed by water in water-using operations minus the

mass of contaminant discharged to the environment:

$$\sum_j^{S_j} Ft_j (CinTP_j - CoutTP_j) = \sum_i^{No} Mc_i - F_{ww} * Cout_{env}, \quad \forall i \quad (17)$$

Equation (18) is the inlet flowrate binary constraint for process j

$$Ft_j \leq z_j \cdot M \quad (18)$$

Equation (19) is the inlet concentration constraint for treatment process j

$$CinTP_j \leq Cin \max TP_j, \quad \forall j \quad (19)$$

The environmental limit concentration constraint is:

$$Cout_{env} \leq Ce \quad (20)$$

The maximum inlet concentration constraint for operation I is:

$$Cin_i \leq C_i^{in,max} \quad (21)$$

The maximum outlet concentration constraint for operation I is:

$$Cout_i \leq C_i^{out,max} \quad (22)$$

Equations (23-25) are the binary water using operation constraints

$$Freuse_{i,ii} \leq zp_{i,ii} \cdot M, \quad \forall i \neq ii \quad (23)$$

$$Freuse_{ii,i} \leq zp_{ii,i} \cdot M, \quad \forall i \neq ii \quad (24)$$

$$zp_{ii,i} + zp_{i,ii} \leq 1, \quad \forall i \neq ii \quad (25)$$

The heat coming in the heat exchanger before process I is:

$$Qin_i = \sum_{ii} (1000 * Freuse_{ii,i} \cdot Cp \cdot Tp_{ii}^{out} / 3600) \quad (26)$$

Equation (27) is the constraint for inlet energy in operation i .

$$Qin_i \leq Q_i^r \quad (27)$$

The additional heat required before entering operation i after integration is:

$$Q_i^{add} = Q_i^r - Qin_i \quad (28)$$

The total additional heat required for heating of streams before entering the unit operations is:

$$TQ^{add} = \sum Q_i^{add} \quad (29)$$

Inequality (30) represents the calculation of the overall energy savings.

$$Q_{ik}^s \geq Q_{ik}^{init} - (Q_{ik}^r - Qin_{ik}) \quad (30)$$

The total energy savings are:

$$TQ^s = \sum_{ik} Q_{ik}^s \quad (31)$$

The total water savings {0, 1} are:

$$W^s = \frac{FW^{init} - FW}{FW^{init}} \quad (32)$$

The total energy savings {0, 1} are:

$$E^s = \frac{TQ^{init} - TQ^s}{TQ^{init}} \quad (33)$$

3. Results

Water and energy consumption before any integration is 3.218 t/h and 192 kW respectively. By applying independent water and energy integration the respective consumptions are reduced to 1.998 t/h and 56 kW resulting in 38 % and 71 % savings for water and energy respectively. Using the model (1-33), and a range of different values for the parameter a , the superstructure is optimized, resulting in different water management networks for the of RESYNTEX process with increasing complexity as a increases. Table 1 reports the savings in fresh water and energy by first applying the superstructure optimization approach and then the conventional energy integration technology, accounting for the new, reduced energy requirements for the water streams entering the water-using operations. By varying the values of a , the region of attainable combined water and energy savings can be constructed. On the curve that fits the points lay all feasible combinations. Above and below the curve, no combinations are feasible in terms of network design.

Table 1 Water and energy savings vs values of a

a	Water consumption (t/h)	Water savings	Energy consumption (kW)	Energy savings (%)
0.2	2030	36 %	48.96	74.5
0.5	2025	37 %	50.16	73.95
0.8	2008	38 %	53.41	72.18

For values of $a = 0.8$ and 0.9 the Table 2 and Table 3 demonstrate - by presenting the resulting flows between water using operations - that by increasing water savings the resulting network becomes more complex and therefore difficult and costly to construct and operate. For $a = 0.8$ 14 operations connections are resulting, while for $a = 0.9$, 19 connections between water using operations are required at the benefit of insignificant increase in savings >38%. Small reduction in water savings results in significant reduction in energy requirements and network complexity.

Table 2 Water network flowrates for $a = 0.8$; water savings 38%

Process	1	2	5	6	7	9	10
2	0.179		0.004	0.004		0.003	
3	0.031	0.476			0.052		
7		0.003	0.1	0.073		0.011	0.044
8			0.101	0.13			

Thus, it is preferable to take advantage of larger energy requirements reduction versus trivially increased water savings, which at the same time are followed by increased and undesired network complexity. A realistic network (Figure 1) is produced by setting $a = 0.2$, which results into 9 connections with flowrates reasonable in terms of justifying a connection (piping and pumping) between operations.

Table 3 Water network flowrates for $a = 0.9$; water savings > 38%

Processes	1	2	3	4	5	6	7	9	10
2	0.153			0.008	0.039				
3	0.32	0.238							
7		0.024	0.002		0.064	0.087		0.015	0.04
8	0.013	0.013	0.019	0.025	0.016	0.02	0.094		0.031

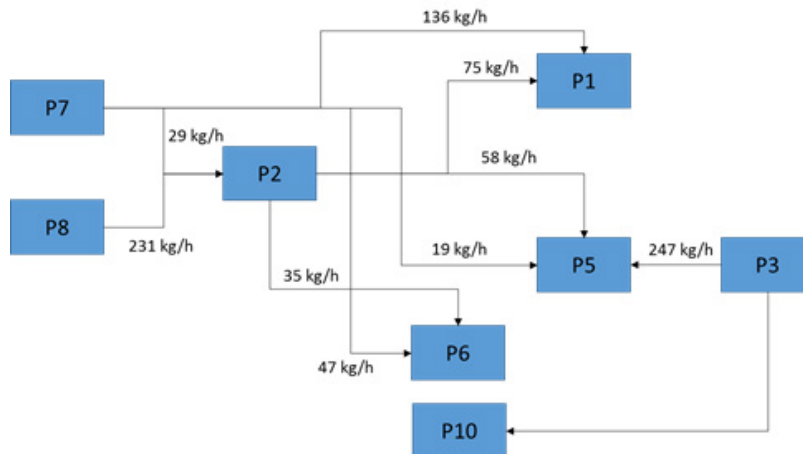

Figure 1 Proposed water network for $a = 0.2$

4. Conclusions

Energy and water integration produce significant results; up to 71% and 86% heating and cooling energy savings respectively, for independent energy integration, 38% savings for independent water integration, while combined energy and water integration can lead to 74.5% energy and 36% water savings, thus an increase of 3.5% in energy savings at the expense of 2% water savings reduction. For water integration, assumptions on concentration limits will have to be validated experimentally. In any case, the computational tools are developed in parametric form and can easily be applied to different process scenarios as well underline assumptions. The integrated process designs will be used for the techno-economic evaluation and for producing the final designs. Future work will also target the reduction of chemicals consumption and the optimization of sustainability metrics, as for example the minimization of CO₂ emissions.

Abstract

Global warming is directly related to the increasing GHG emissions from both natural and anthropogenic sources. The contribution of CO₂ emissions towards this phenomenon has propelled the international community to initiate research programs that aim to mitigate the emissions through process efficiency improvements, in addition to capturing CO₂ from flue gases at the power plant stacks. Such options have become especially attractive for implementation when they are economically viable. In this regard, one of the most promising technological approach is Carbon Capture and Utilization (CCU). It aims to reduce CO₂ emissions from electricity production and other chemical process industries by capturing CO₂ and subsequently utilizing it in several applications, such as for Enhanced Oil Recovery within the oil and gas industry. The optimum utilization of CO₂ as feedstock potentially enhances the efficiency of chemical conversion processes resulting in useful products of economic value. The objective of this study is to assess the integration of CO₂ utilization within existing processes and technologies to create economic opportunities within the State of Qatar. The methodology includes the development of a geospatial database - comprising information on the CO₂ sources and sinks, and the transport network linking them using GIS - followed by the techno-economic assessment and single-objective linear programming of the proposed CO₂ utilization network which includes the fertilizer and chemical additives industries in Qatar. It was shown that by linking the market prices of value-added products, namely urea and methanol, the optimal solution of the distribution and utilization of CO₂ within the industrial network changes, whilst considering the revenue and profit functions as the network objectives in separate case studies.

Key words: CO₂ Utilization, Linear Programming, Methanol, Urea

1. Introduction

The State of Qatar has recorded rapid economic growth as a result of the continuous development of its vast hydrocarbon resources. Industrial development of this kind will have corresponding environmental challenges in the form of GHG emissions. Qatar is a signatory to the Paris climate agreement which commits all participating nations to reduce their emissions. The development of alternative energy technologies, energy efficiency initiatives, and Carbon Capture and Storage (CCS) programs are critical to both satisfying energy demand and ensuring sustainable development (Ebinger *et al.*, 2011). Significant research and development has focused on CCS, as it is considered a possible strategy to maintain hydrocarbon-driven power generation whilst mitigating CO₂ emissions. In fact,

CCS has the potential to contribute to one-sixth of the emission reduction required by 2050 IEA (2013). The utilization of CO₂ in what is known as carbon capture and utilization (CCU) programs avoids the need to store CO₂ in underground storage sites. CCU enables the creation of an eco-system which encourages the recycling of CO₂ and conversion into value-added products, such as urea, methanol and cement, in addition to its possible utilization for enhanced oil recovery (EOR). An example of the latter is the world's largest EOR project called the 'Weyburn-Midale project' in Canada which has been injecting over 2 Mt CO₂/year for the past 15 years from a coal gasification plant into the Weyburn oil field (Brown, 2017). In the case of Qatar, however, utilization of CO₂ for EOR is yet to be practised commercially. This is primarily due to the lack of fully characterized CO₂ storage options and remains under study (Al-Menhali, 2016).

Multiple studies have considered CCU approaches for industrial zones within the State of Qatar. Using a systems approach, Al-Mohannadi *et al.* (2016) developed cost optimal allocations of natural gas with and without restriction of CO₂ emissions across multiple sources and multiple sinks. It was concluded that the use of renewable energy in power generation could save natural gas allocation and achieve CO₂ emission reduction and additional revenue. Alternatively, reducing the CO₂ emissions can be achieved by the integration of renewable energy systems, where it may compensate the energy lost due to carbon management strategies (Al-Mohannadi, *et al.* 2017). Furthermore, the integration of waste heat and carbon management system to achieve low cost net reductions in CO₂ emissions was also proposed to meet a specified emissions target for an industrial park (Hassiba, 2016). Hassiba and Linke (2017) aims to overcome the limitation of the sequential approach with an integrated optimization model to minimize the overall cost of the CO₂ emissions reduction, while simultaneously exploring the synergy amongst heat and carbon management integration in an industrial park for a pre-specified CO₂ reduction target. In addition, the model also considers renewable thermal energy options to be explored as additional possibilities to reduce CO₂ emissions. Multi-period carbon integration was proposed by Al-Mohannadi, *et al.* (2016) to optimize the transition planning over a time horizon which enables certain emission cuts in future dates.

The objective of this study is to develop an integrated methodology by considering the economic drivers of CO₂ utilization options. It considers a single CO₂ capture system located at the source with the highest CO₂ emissions, thereby reducing the cost of the required compression system and pipeline network. Based on this, a single-objective optimization framework using linear programming (LP) is proposed in order to find solution points that maximizes revenues/profits through increased production rate at the sinks, depending on the market prices of value-added products, whilst achieving CO₂ emissions reduction. This approach was applied for the fertilizer and methanol plants located in the Messaid industrial zone in Qatar as a special case study.

2. Available Data

The following subsections describe the data related to a specific CO₂ source, namely Qatar Aluminium (Qatalum), and two potential sinks that have been identified for the economic utilization of CO₂, namely Qatar Fertilizer Company (QAFCO) and Qatar Fuel Additives Company (QAFAC) in the Messaid industrial zone. The related costs for these include the capital cost of capture system, the cost of CO₂ compression and transportation, and other operating costs associated with the sinks.

2.1. CO₂ Source Data

The CO₂ emissions from Qatalum is around 4.7 Mt/year (DCLG, 2015), making it the highest emitter in the Messaid industrial zone. The capture of CO₂ is assumed to be achieved by chemical absorption using amine solvents, and thus the maximum achievable capture removal efficiency of 90% was assumed. Based on this the estimated cost of the capture system is around \$40/t of CO₂ (Hildebrand, 2009). This corresponds to an estimated capital cost of the capture system of approximately \$169 million.

2.2. CO₂ Compression and Transport Data

Compression is needed to overcome the pressure drop in pipelines and to meet sinks pressure requirements. The unit cost of compression and transportation per 100 km of the pipeline is approximately \$1.5/tCO₂ (Herzog et al., 2004). In this case study, the total cost of compression and transport to both QAFAC and QAFCO is approximately \$0.5 million.

2.3. CO₂ Sinks Data

2.3.1 Urea production

In this study, it is proposed that a reliable external source of CO₂ supply would be provided via CO₂ capture and utilization in order to produce additional urea with the excess ammonia available. Five ammonia plants are currently operating in the State of Qatar. In the event of an ammonia plant shutdown, there still exists an opportunity to sustain the production of urea by sourcing the excess ammonia and CO₂ from other operating plants. Qatar Fertilizer Company (QAFCO) exports around 15% of its ammonia produced which amounts to approximately which equals approximately 0.55 Mt/year in 2014. However, in this study it is suggested that it would be useful to monitor the price of ammonia in the Middle East spot market because in 2016 it had faced competition with the price of urea, thus leading to the essential question of whether it is more valuable to produce greater quantities of urea for export rather than exporting the surplus ammonia. On average, the 2016 prices of ammonia and urea were \$220/tonne and \$300/tonne respectively (Argus Media, 2017). Moreover, according to the relation between these products, one tonne of urea can be produced from 0.57 tonne of ammonia and 0.74 tonne of CO₂ (Park, 2001). Thus, if the exported amount of ammonia (0.55 Mt/year) is reacted with CO₂ (0.74 Mt/year), it would result in the production of 1.3 Mt of urea/year. When this quantity is exported, it would generate a revenue of \$390 million, which is greater than that generated by exporting the excess ammonia (approximately \$121 million), based on 2016 prices. In addition, the capital cost for the urea plant corresponding to this production capacity is approximately \$610 million (Kable, 2017).

2.3.2 Methanol production

Qatar Fuel Additives Company (QAFAC) operates a methanol plant based on natural gas feed (mainly methane C1) with a capacity around 3,000 tonne/day. The average market price was around \$220/t of methanol in 2016 (Argus Media, 2016). In this study, it is proposed that an external CO₂ source can be utilised to meet methanol production targets by integrating CO₂ source to the methanol synthesis unit with 500 t/day (Al-Hitmi, 2012). Additionally, an opportunity exists for QAFAC to increase the production of methanol by using hydrogen, which is available in Messaid, together with the captured CO₂ as raw materials with ratio H₂/CO₂ 3:1 (Pérez-Fortes, et al., 2016). This option can potentially contribute to a relatively higher net reduction in CO₂ emissions

for the same methanol production target. The capital cost of methanol plant corresponding to this target was estimated to be approximately \$1,200 million, with the average price of \$4,000/t of hydrogen (Pérez-Fortes, et al., 2016).

3. Methodology

The LP formulation for the proposed CO₂ utilization network, as illustrated in Fig 1, considers CO₂ resource allocation from Qatalum to QAFAC and QAFCO, constrained by their utilization capacities.

Fig.1 Proposed CO₂ utilization network in the Messaid industrial zone.

The nomenclature of variables used in the LP formulation is as follows:

Decision variables

- Q₁: fraction of CO₂ transported from Qatalum to QAFAC (using NG).
- Q₂: fraction of CO₂ transported from Qatalum to QAFACCO.
- Q₃: fraction of CO₂ transported from Qatalum to QAFAC (using hydrogen).

Parameters related to Qatalum

- η : efficiency of CO₂ capture system = 0.9.
- e : CO₂ emissions rate = 4.7 Mt/year.
- C_1 : cost factor incurred through CO₂ capture = $\eta \times e \times \$40/\text{t CO}_2$.

Parameters related to QAFAC (using natural gas)

- d_2 : pipeline distance from Qatalum = 3km.
- ρ : density of natural gas = 0.9 kg/m³
- C_{21} : CAPEX of methanol plant = \$1,200 million.
- C_{22} : cost factor incurred through CO₂ transportation = $\eta \times e \times (d_2/100) \times \$1.5/\text{t CO}_2$
- C_{23} : cost factor incurred from natural gas purchase = $\eta \times e \times 0.82 \times \$2.5/\text{ft}^3 \text{ NG} \times \rho$
- R_2 : revenue factor from methanol = $\eta \times e \times 1.82 \times \$220/\text{t methanol}$.

Parameters related to QAFACCO

- d_3 : pipeline distance from Qatalum = 5km.
- C_{31} : CAPEX of urea plant = \$610 million.
- C_{32} : cost factor incurred through CO₂ transportation = $\eta \times e \times (d_3/100) \times \$1.5/\text{t CO}_2$
- R_3 : revenue factor from urea = $\eta \times e \times 1.82 \times \$300/\text{t urea}$.

Parameters related to QAFAC (using hydrogen)

- d_4 : pipeline distance from Qatalum = 3km.
- C_{41} : cost factor incurred through CO₂ transportation = $\eta \times e \times (d_4/100) \times \$1.5/\text{t CO}_2$
- C_{42} : cost factor incurred from hydrogen purchase = $\eta \times e \times \$4000/\text{t H}_2$
- R_4 : revenue factor from methanol = $\eta \times e \times 1.82 \times \$220/\text{t methanol}$.

The goal is to find optimal solutions for allocation with the potential to maximize profit from the products manufactured at the sinks within the network. In effect, this also leads to the reduction in CO₂ emissions in an economical manner. Hence:

$$\begin{aligned} & \text{Maximize } \{Q_1 \times (R_2 - C_{11} - C_{21} - C_{22} - C_{23}) + Q_2 \times (R_3 - C_{11} - C_{31} - C_{32}) + Q_3 \times \\ & (R_2 - C_{11} - C_{41} - C_{42})\} \\ & \text{subject to,} \\ & Q_1 + Q_2 + Q_3 \leq 1, \\ & Q_1 \times \eta \times e \leq 0.60 \times 10^6, \\ & Q_2 \times \eta \times e \leq 1.01 \times 10^6, \\ & Q_3 \times \eta \times e \leq 1.83 \times 10^6, \\ & Q_1 \times (R_2 - C_{11} - C_{21} - C_{22} - C_{23}) \geq 0 \text{ (profit constraint for QAFAC using natural} \\ & \text{gas).} \\ & Q_2 \times (R_3 - C_{11} - C_{31} - C_{32}) \geq 0 \text{ (profit constraints for QAFAC), and} \\ & Q_3 \times (R_2 - C_{11} - C_{41} - C_{42}) \geq 0 \text{ (profit constraint for QAFAC using hydrogen).} \end{aligned} \quad (1)$$

3. Results

Tables 1 and 2 indicate the optimized CO₂ allocations when: (a) the profit constraint is non-negative as indicated in Eq. 1; and (b) the profit constraint is relaxed, i.e. the utilization network is only optimized for revenue, and thus can potentially make a loss.

Table 1. The profit constraints are non-negative.

Decision Variables (fractional amount of CO ₂ from QATALUM)	
Q ₁	0.0322
Q ₂	0.0453
Q ₃	0
Objective (Profit) \$	9.89x10⁷

Table 2. The profit constraints are relaxed.

Decision Variables (fractional amount of CO ₂ from QATALUM)	
Q ₁	0.142
Q ₂	0.241
Q ₃	0.431
Objective (Profit) \$	-6.06 x10⁹

The results illustrate that when the CCU network optimization is applied for the specified case study, a clear benefit is achieved in terms of generating revenues/profits at the sinks, whilst simultaneously reducing carbon emissions. The CCU network model is considered economically attractive when the price of methanol and urea increases, driven by the high demand, particularly in the Asian and European markets. The results of this study indicate the total CO₂ flow rate from the source to the sinks once the model optimized for profit and revenue are 0.3Mt/y and 3.4Mt/y respectively. In Table 1, the results correspond to the case where the model is optimized for profit such that the CO₂ will be consumed at a lower rate. On the other hand, the results in Table 2 correspond to the case where the model is optimized for revenue such that CO₂ is consumed more efficiently, whilst making a loss. These results suggest that the environmental and economic objectives are competing, as expected. Moreover, this is also a consequence of the high price of hydrogen as a raw material for the methanol plant. However, it is envisaged that the recovery of any network losses could be carried out within a time horizon of 5 to 10 years, subject to the demand, and consequently the selling price, of the value-added products.

4. Conclusion

The analysis presented considers CCU to increase methanol and urea production, whilst reducing CO₂. The approach demonstrates the potential economic benefit of a proposed CCU network in Qatar which is dependent on the market prices of value-added products. Considering that price fluctuations exist, future work will capture this effect by considering the economic life cycle of the network at the plant-level and modelling the economic objective in terms of the net present value (NPV) and internal rate of return (IRR), which will be implemented within a multi-period optimization formulation.

Optimization of Batch Heteroazeotropic Distillation Operational Strategies with Entrainer Recycle

Laszlo Hegely*, Peter Lang

Budapest University of Technology and Economics, Department of Building Service and Process Engineering, Muegyetem rkp. 3-9, H-1111 Budapest, Hungary

hegely@mail.bme.hu

Abstract

The batch heteroazeotropic distillation (BHAD) separation of a minimum boiling azeotropic mixture (isopropyl alcohol(A) – water(B)) with toluene as entrainer(E) is simulated and optimized with GA. The production cycle consists of processing three consecutive batches. Both BHAD operational modes (sequential (Mode I) and simultaneous (Mode II) distillation + decantation) are studied. The E-rich phase and (eventually) the off-cut can be recycled to the next batch to reduce the loss of both isopropyl alcohol and the entrainer. The optimization variables are the amount of E added to the charge and the reflux ratios of the steps. The effect of the recycling is discussed and the optimization results are compared with those of the non-optimized processes.

Keywords: batch heteroazeotropic distillation, optimization, entrainer recycle.

1. Introduction

For the separation of azeotropic mixtures a special distillation method, such as batch heteroazeotropic distillation (BHAD) must be applied. By BHAD an entrainer (E) is added to the binary mixture (A-B) before the start of the distillation which forms at least one heteroazeotrope with the original components. The liquid-liquid split (decantation) makes the separation feasible. BHAD can be performed by two operational modes. The whole amount of the E-lean phase is usually withdrawn; it is partially refluxed only if the E-rich phase does not provide sufficient reflux.

By Mode I, the distillation and decantation are performed sequentially (the whole amount of the E-rich phase is withdrawn with the E-lean one) while in Mode II simultaneously. By Strategy A of Mode II the whole amount of the E-rich phase is refluxed, by Strategy B, one part of it is also withdrawn.

The majority of E is present in the E-rich phase and a much smaller part of it in the E-lean one. For both economic and environmental reasons, E must be recycled and reused in the next batch. Luyben and Chien (2010) studied the dehydration of acetic acid with isobutyl acetate (E) by Mode II (Strategy A) without optimization where E was recycled.

In our previous work (Hegely and Lang, 2017), the dehydration of isopropanol(A)-water(B) mixture of azeotropic composition with toluene (E) was studied. Calculations were performed for Mode I and both strategies of Mode II. The values of the operational parameters were chosen to obtain a high specific product flow rate (SPF: amount of product/duration of the process). Strategy A of Mode II gave the highest recovery, but it was much slower than Mode I. Strategy B gave unsatisfactory results. In a cycle of 3

batches recycling made Mode I infeasible for Batch III because of the accumulation of B, while it had favourable effects (increased recovery, faster production) for Mode II. The goals of this work is to optimize the three-batch processes with a genetic algorithm (GA). The objective function to be maximized is the profit of the individual batches, which are optimized separately. The dynamic simulation is performed by ChemCAD. The description of the phase equilibria is made more accurate than it was in our previous work.

2. The separation process

The components form a ternary and three binary minimum boiling azeotropes (Table 1). The UNIQUAC binary interaction parameters were taken from Stankova et al. (1970) for the VLE and from Washburn and Beguin (1940) for the LLE at 25 °C (temperature of the decanter) which can be produced with inexpensive cooling water.

Table 1. Calculated boiling point (T_{bp}) and composition of the azeotropes (1.013 bar).

	T_{bp} (°C)	A (mol%)	B (mol%)	E (mol%)
ABE	76.6	36.4	37.7	25.9
ABE – E-rich phase (25 °C)		39.3	31.6	29.1
ABE – E-lean phase (25 °C)		14.3	84.5	1.2
AB	80.0	67.6	32.4	-
AE	81.3	81.3	-	18.7
A	82.3	100	-	-
BE	84.8	-	56.4	43.6
B	100.0	-	100	-
E	110.6	-	-	100

The composition of the ABE azeotrope is in acceptable agreement with the experimental one (33.6 % A, 38.5 % B and 27.9 % E). The azeotrope is close to the binodal solubility curve, thus it is important to calculate it accurately. (By repeating the calculations for Mode II, the production time was only the fifth of that of Hegely and Lang (2017)).

The aim is to produce A as the still residue in 98 mol% purity. For Mode I, processing of Batch I has the following steps:

- Step 0: Warming up of the charge (fresh feed+E) onto its boiling point and heating-up of the column under total reflux ($R = \infty$). This step is finished when the composition of the top vapour is close to that of the ternary heteroazeotrope.
- Step 1: Production of distillate with overall composition close to that of the ternary heteroazeotrope. The distillate has two liquid phases, and decantation is performed later in the distillate accumulator. A finite reflux ratio ($R_1 < \infty$, optimization variable) is applied. This step is finished when the aqueous phase disappears in the decanter. The E-rich phase of the accumulated distillate is recycled to the next batch.
- Step 2: Off-cut collection under $R_2 < \infty$ (optimization variable) to remove B and E from the still. This step is finished when the concentration of A in the still (product) reaches its specified value. The off-cut cannot be recycled (high B content).

For Mode II, only the differences are highlighted:

- Step 0: E is filled into the decanter instead of the still, as this was found to be more favorable (Hegely and Lang, 2017). This step includes the filling up of the decanter, and is finished when the prescribed levels of both liquid phases are reached.
- Step 1: Removal of B in the form of E-lean phase. Both liquid phases have a constant level in the decanter. The excess of E-lean phase is withdrawn as distillate, while that

of the E-rich phase is refluxed entirely to the column (Strategy A). R_1 is determined by the phase ratio (ca. 7.7 mol/mol) of the condensate. This step is finished when the E-lean phase disappears or the concentration of A in the still reaches the prescribed purity. The E-rich can be recycled to the next batch by mixing it to the fresh feed.

- Step 2: The off-cut can be recycled, as its B content is low.

For Batches II and III, Step 0 is slightly different from those of Batch I. The E-rich phase and the off-cut of the previous batch are mixed to the fresh feed before distillation. Fresh E can also be added to the charge (Mode I) or to the decanter (Mode II).

3. Optimization method

The three batches are optimised consecutively, that is, each batch is optimised separately for the charge composition (x_{Ch}) obtained by mixing fresh feed and the material recycled from the previous batch. The mass of fresh feed is calculated so as to always obtain the same charge volume (1.16 m³) before the addition of E.

The objective function (OF) to be maximized is the profit of the individual batches:

$$OF = p_A m_{pA} - p_E m_E - c_{inc} m_{inc} - c_{st} Q_{st} t \quad (1)$$

where m_{pA} is the mass of the product A, m_E is that of the fresh E, and m_{inc} is that of liquid to be incinerated (E-lean phase and for Mode I, the off-cut). p_A is the price of the product A (1 \$/kg), p_E is the price of E (0.672 \$/kg). c_{inc} is the cost of incineration (0.21 \$/kg), c_{st} is cost of heating steam (low pressure (4 bar) 8.308 \$/GJ), Q_{st} is the heat duty (0.4 GJ/h), and t is the duration of the whole process including warming-up of the charge.

For Mode I, the optimization variables are the amount of E added to the fresh feed (F_E) and the reflux ratios of the steps: R_1 , R_2 . The upper bound of F_E is 6.32 kmol, above which x_{Ch} is located in the distillation region, where E is the stable node instead of A. The lower bound for the reflux ratios is 0.2, the upper one is 10 and 15, respectively. The optimization of Mode I is performed by a real-coded elitist GA written in VBA under Excel. The parameters of the GA: mutation probability: 5 %, crossover probability: 70 %, population size: 30, number of generations: 100. OF is evaluated by dynamic simulation using different modules of the flow-sheet simulator ChemCAD. The failure to reach the specified purity of the product is penalized by changing the value of OF to -10,000 \$.

For Mode II, the possible optimization variables are F_E and R_2 , if taking off-cut is necessary. We found (Hegely and Lang, 2017) that an off-cut is only necessary above a certain F_E value. As we will show later, at the optimal F_E value, the prescribed purity is reached during Step 1, and no off-cut is taken. This reduces the optimization problem to a one-dimensional one, therefore the use of GA is not necessary.

The column has $N=28$ theoretical stages (excluding the reboiler and the condenser), with a liquid hold-up of 2 dm³/stage. Q_{st} is 400 MJ/h. The hold-up of the total condenser is 40 dm³. The hold-up of the decanter (83.1 dm³) is chosen to ensure a residence time of 5 min. The hold-up of the heavy (E-lean) phase is 6.4 dm³. For Mode I, Step 0 lasts 1 h. The column design is fix, but N could be included in the optimization when a new column is designed. This would change the optimal values of R , but not the main conclusions.

4. Optimization results

4.1. Mode I

For Batch I, the optimal F_E and reflux ratios are higher than in the non-optimized process (Table 2). The optimization made the process economical, mostly by increasing the amount of the product (income) and considerably decreasing the incineration cost (C_{inc}) by practically eliminating the off-cut (decreased from 7.05 to 0.01 kmol) due to the increased R_1 . The amount of the two-phase distillate increased, but only its E-lean phase has to be incinerated (1.83 instead of 1.05 kmol).

Table 2. Charge compositions, optimal values of the parameters, costs and profit of the optimized and non-optimized processes (Mode I).

Batch	$x_{Ch,A}$ mol%			F_E , kmol	R_1	R_2	Income, \$	Cost, \$			Profit, \$
	A	B	E					E	Incin.	Steam	
Optimized I	67.4	32.6	0.0	4.39	2.98	13.13	393	272	26	33	79
II	46.9	30.8	22.3	-	1.93	11.51	110	0	16	24	70
III	49.0	29.8	21.2	0.02	1.94	11.21	162	1	10	23	128
Non-optimized I	67.4	32.6	0.0	4.00	2.00	9.00	350	248	82	36	-16
II	55.8	31.0	13.2	1.56	2.00	9.00	237	96	10	20	110
III	47.5	30.4	22.2	0.09	2.00	9.00	78	6	28	20	25

The total amount of the E-rich phase from Batch I cannot be recycled to the next batch. The amount of recycled material is so high (15.96 kmol) that only 1.52 kmol fresh feed can be treated. The composition of the recycled material (Figure 1, point R) lies outside the distillation region where A is stable node, and by mixing this low amount fresh feed to it, the x_{Ch} of Batch II (point Ch) lies also outside the desired region. This means that E would be obtained as still residue instead of A, so the amount of recycled material must be reduced. The hold-up is recycled entirely, as its composition is favourable, but the amount of E-rich phase recycled is reduced so that x_{Ch} lie just inside the feasible region. However, this means that fresh E cannot be added to the charge, as it would move the composition outside of the region, thus F_E is not an optimization variable for Batch II.

Figure 1. The effect of recycling on charge composition by the different operational policies

The charge of Batch II has a low A/B ratio and high E content. This is the result of taking very low amount of off-cut, which is advantageous for Batch I, but significantly reduces the income of Batch II. The profit is lower than that of the non-optimized process. The reflux ratios of Batch II are lower than those of Batch I; R_1 is similar to that of the non-optimized process, while R_2 is higher. Unlike for Batch I, the total amount of the E-rich phase can be recycled to Batch III, so F_E is again an optimization variable.

By Batch III, x_{Ch} is more favourable than that of Batch II (Figure 1) with a higher A/B ratio. The small change in x_{Ch} results in a significant increase of the income and profit. Practically no fresh E is needed, and the reflux ratios are similar to those of Batch II.

The optimization more than doubled the profit of the cycle. The total income is identical, but the cost of E (C_E) and C_{inc} are greatly reduced. The recycling greatly affects the results (Table 3). The amount of fresh E is greatly reduced, but so is that of the fresh feed and the product, although the recovery of A (η_A) increases. The duration is shorter with recycling, but SPF decreases. However, without recycling the amount of material to be incinerated is ten times more, making the process uneconomical (total profit: -299 \$).

Table 3. Results of the optimized three batch processes (with and without recycle) for Mode I.

	F_E , kmol	Fresh feed, kmol	Product, kmol	Total non- recycled, kmol	Duration, h	SPF, kmol/h	η_A , %
Batch I	4.39	20.0	6.58	1.85	10.0	0.657	47.8
Batch II	0.00	3.07	1.80	2.26	7.1	0.254	21.3
Batch III	0.02	4.01	2.68	1.71	6.8	0.394	30.4
Total	4.41	27.1	11.1	5.81	23.9	0.463	59.4
No recycle	13.2	60.0	19.7	48.6	30.1	0.657	47.8

4.2. Mode II

For the optimal amount of E, no off-cut is necessary, thus F_E is the only optimization parameter (results in Tables 4 and 5). For Batch I, its effect was studied in the range 0.65-0.9 kmol. On the increase of F_E , m_{PA} increases. The increase of C_E is obvious. Both the cost of heating steam and C_{inc} have a minimum as a function of F_E . The minimum of C_{inc} is a result of two effects. By increasing F_E , it takes more time to remove E from the still. By decreasing it, however, the level of the aqueous phase in the decanter reaches its prescribed value slower. Nevertheless, the variation of C_{inc} is very slight. The profit has a minimum at $F_E=0.7$ kmol. Its total variation in the range studied is less than 9 \$.

Table 4. Charge compositions, optimal values of F_E , costs and profit of the optimized and non-optimized processes (Mode II).

	Batch	x_{Ch} , mol%			F_E , kmol	Income, \$	Cost, \$			Profit, \$
		A	B	E			E	Incin.	Steam	
Optimized	I	67.4	32.6	0.0	0.7	656	43	36	42	535
	II	65.6	31.4	3.1	0.09	617	6	33	41	536
	III	65.6	31.3	3.1	0.09	617	6	33	41	536
Non-optimized	I	67.4	32.6	0.0	0.843	670	52	37	45	533
	II	65.5	31.4	3.1	0.242	629	15	34	44	535
	III	65.6	31.3	3.1	0.240	629	15	34	44	536

As 0.60 kmol E is recycled to Batch II, only a small E make-up is necessary. Instead of the value necessary to reach 0.7 kmol ($F_E=0.104$ kmol), the optimal F_E value was lower

(0.09 kmol). The main differences between Batches I and II are that in Batch II, the A/B ratio of the charge is higher (Figure 1), and the greater part of E is initially in the still. The income of Batch II is lower, but so is C_E , thus the same profit is reached. By Batch III, x_{Ch} is almost identical to that of Batch II, thus optimization was deemed unnecessary.

Recycling reduces the amount of fresh E needed to less than half, but also the amount fresh feed processed by 12 % (Table 5). However, due to the increase in η_A , the amount of product is lower only by 4 %. The duration of the production is also lower with recycle. If no recycling is applied, C_{inc} is 50 \$ instead of 36 \$, thus recycling is preferable not only environmentally, but economically, as well.

Table 5. Results of the optimized three batch processes (with and without recycle) for Mode II.

	F_E , kmol	Fresh feed, kmol	Product, kmol	Total non- recycled, kmol	Duration, SPF, h	η_A , %
Batch I	0.7	20.0	11.1	6.7	12.7	0.872 80.4
Batch II	0.09	16.6	10.4	6.2	12.4	0.840 79.7
Batch III	0.09	16.5	10.4	7.5	12.4	0.838 79.6
Total	0.88	53.1	31.8	20.5	37.5	0.850 87.1
No recycle	2.1	60.0	33.2	24.0	38.1	0.872 80.4

In the non-optimized process, the decanter was completely filled with E in Batch I, and for Batches II-III, only the E lost in the previous batch was added to the decanter. The higher F_E increased both C_E and m_{pA} , however the profit was only very slightly lower for every batch. The charge compositions (without the E added) were almost identical to those of the optimized process. These results indicated, as well, that the profit is not very sensitive to the value of F_E , which could enable a robust technology in practice.

5. Conclusions

Dehydration of the isopropanol(A)-water(B) azeotrope with toluene as entrainer (E) by batch heteroazeotropic distillation was optimised by a GA. One production cycle consists of three batches. The E-rich phase is recycled to the next batch to reduce the loss of A and E. The profit of each batch was maximised separately. Optimization variables were the amount of E added (F_E) and the reflux ratio of the steps (R_1 , R_2). By Mode I, optimization greatly increased the profit by reducing the cost of E and incineration. The amount of recycled material was high, which significantly decreased the capacity, and changed the charge composition, but without E recycling, the process was uneconomical. By Batch II, the E-rich phase was only partially recycled to ensure the feasibility of A production and no fresh E was added. By Mode II, taking off-cut was not necessary at the optimal F_E . Since the profit was not very sensitive to F_E , the optimization only increased it slightly. Recycling reduced the E consumption to less than half, increased the recovery of A, but also reduced the amount of fresh feed treated. Mode II was superior to Mode I in every respect except the amount of non-recycled material. With E recycling, fresh E had to be added to Batch I by both modes, and Batches II-III required only a small E make-up. Future work could include simultaneous optimization of the batches that is computationally more intensive as the number of variables is three times higher.

Abstract

Gas separation processes are among the most important operations in the oil and gas related industries. The most common separation technology applied is distillation, which consumes large amounts of energy. Because of the good stability, non-volatility, tunable viscosity and designable properties, ionic liquids (ILs) are regarded as novel potential solvents and alternative media for gas absorption. Therefore, a strategy for hybrid gas separation process synthesis where distillation and IL-based absorption are employed for energy efficient gas processing has been developed. In this work, a three-stage methodology proposed for hybrid gas separation process design and evaluation is proposed: IL screening, where a systematic screening method together with a database tool is established to identify suitable ILs; process design, where the important design issues (amounts of solvent needed, operating temperatures and pressures, evaporation conditions, etc.) are determined; process simulation and evaluation, where the final separation process results are concluded.

Keywords: gas separation; ionic liquids; property model; process design

Introduction

Currently, traditional gas separation technologies are energy intensive distillation and solvent based absorption operations or flux limited adsorption and membrane-based operations. For most gas mixtures, the most common separation technology applied is distillation, which consumes large amounts of energy to give the high purity products. These distillation columns operate at low temperatures and high pressures and therefore require high energy consumption, leading to negative environmental impacts. Therefore, an alternative scheme, taking advantage of each individual technology, a hybrid gas separation scheme of combining distillation with absorption separation processes is proposed.

Due to designable properties as well as good stability and non-volatility, ionic liquids (ILs) are regarded as potential mass separating agents for gas absorption. In this work, a strategy for hybrid gas separation process synthesis where distillation and IL-based absorption are employed for energy efficient gas processing is presented. Most of the developments related to the use of ILs for gas absorption have concentrated on the CO₂ capture capacities of different ILs, which points to the potential of an IL-based gas decarbonization technology (Liu et al., 2016). Encouraged by good absorption of CO₂ with ILs, new studies have focused on the solubility of other gases in ILs. However, the

thousands of ILs that may be potentially applicable, makes it a challenging task to search for the best one for specific gas absorptions from different raw gas. In addition to the solubility of the selected gas in the solvent (ILs or other organic chemicals), the selectivity of the IL solubility for the gases to be separated is also very important, together with other pure component properties of ILs. Therefore, before a selection-screening method for ILs for use in absorption based gas separation tasks can be developed, the needed properties must be available in the form of data or property models from which they can be obtained. Several options, such as, group contribution (GC) based UNIFAC (Lei, Dai, Wang, & Chen, 2014) or the COSMO-RS method (Klamt & Eckert, 2000) can be applied for solubility and selectivity predictions, while a database or GC-based models for pure component properties may be used. In this paper, in order to lay a foundation for ILs screening and design, a database, containing experimental data for different gas solubility and Henry's law constants for gases in ILs, is established. Both the COSMO-RS method and the UNIFAC model are applied for the needed predictions of gas solubility in ILs. Further, a hybrid gas separation scheme to separate gases from a model shale gas mixture is developed and evaluated.

Methodology

In this work, a three-stage methodology for hybrid gas separation process design and evaluation is proposed. The first stage involves IL screening, where a systematic screening method together with a database tool is established to identify suitable ILs based on a collection of gas solubility data, Henry's law constant data as well as data estimated through reliable predictive models, for example, COSMO-RS (Klamt & Eckert, 2000), UNIFAC (Lei et al., 2014). Further, design of problem specific ILs for different gas-IL systems is developed. It should be noted that models and data operate at multi-scale. The second stage is process design, where the important design issues such as the amount of solvent needed, operating conditions (temperature and pressure), and solvent recovery are determined. This stage operates at macro scale. A hybrid gas separation scheme is designed to replace the conventional distillation process, where the only energy requiring step in the hybrid process is the flash-evaporation step (and the low energy consuming pre-distillation step, if employed). Potentially a large reduction of energy consumption is therefore possible by switching from distillation to the hybrid-absorption scheme for selective gas separation tasks. For example, replace distillation by absorption to remove only the gases present in smaller amounts in the gas mixture, thereby letting the larger amounts to go free as the exhaust gas product. This small amount of absorbed gas is easily separated from the IL solvent through evaporation or distillation, which only consumes a small fraction of the total energy of the conventional distillation based process. The third stage involves verification, sustainability and economic analysis based on rigorous process simulation of the generated hybrid gas separation process. Application of the methodology is highlighted for a gas separation problem involving a model shale gas mixture.

Database and model library

Database library

The database includes collected measured solubility data and Henry's law constant of gases in ILs at different temperatures. It covers 16 gases 260 ILs for the gas solubility data and 11 gases 110 ILs for the Henry's law constants. It also includes predicted data from COSMO-RS, covering 16 gases for 13585 ILs.

Property library

The solubility data generated through COSMO-RS have been reported (ref) to be useful for qualitative screening, where the activity coefficient calculated from the interaction of charge screening on molecular surface can be employed. However, a comparison between experimental activity coefficients of different gases in ILs and the COSMO-RS predicted values revealed that while for some light hydrocarbon gases, such as C_2H_4 and C_2H_6 , a fairly accurate model could be obtained (see Fig 1), for the CO_2 and CH_4 solubility, the errors were too large (see Fig 2). Equations 1-2 give the correlations obtained from the COSMO-RS and experimental data for gas solubility of C_2H_4 and C_2H_6 (see Table 1). For CO_2 solubility in IL, a new UNIFAC model is developed using the available experimental data only. Table 2 lists the 14 pairs of parameters (a_{ij}) that are fitted for 22 IL- CO_2 systems, containing 2 main cations with different alkyl chain as substituent and 11 anions. For CH_4 solubility in IL, only experimental data is used, until the extended UNIFAC-IL model parameters are available.

Case study

As a case study, the separation of gases from model shale gas with 5 gases (H₂, CO₂, CH₄, C₂H₄, C₂H₆) is considered as a conceptual example. The undesired absorbed gas is the one in the largest amount (CH₄, whose concentration is 80%) and H₂, which is lower boiling point than CH₄. Using the available data (measured and predicted), the Henry's law constants for CO₂ is plotted against selectivity of CO₂/CH₄ for different ILs and temperatures (see Fig 4).

Figure 4 Henry's law constant of CO₂ versus selectivity of CO₂/CH₄ (a); best IL structure (b)

The optimal IL should have low Henry's law constant of CO₂ and high selectivity of CO₂/CH₄, that is, lie in the area with colored background. With the temperature increase, the solubility of CO₂ and selectivity of CO₂/CH₄ all decrease. As IL= [thtdp][phos] shows the lowest Henry's law constant at relatively high temperature, it means that it may have a lower Henry's law constant and higher selectivity when the temperature is decreased. Therefore, it is selected as the potential solvent. The correlated models are used (Eqs. 1-2) for the other two gases (C₂H₄, C₂H₆). The selected IL turned out to have higher solubility for C₂H₄ than C₂H₆, and acceptable selectivity with respect to CH₄.

Based on the screening result, a preliminary scheme is generated, as shown in Figure 5. As a replacement for the distillation column, an absorber with the selected IL is considered. The objective of this design is to obtain 99% CO₂ removal and a 90% CH₄ recovery rate, and high utilization efficiency for the other two light hydrocarbon gases. The selected IL is first used to absorb CO₂, C₂H₄ and C₂H₆, which are then further separated by distillation or membrane (Tula et al., 2017). To obtain a high recovery rate of CH₄, it has one stream recycle to the absorber. Only 17% of the total gas needs to be absorbed, based on preliminary mass and energy balance, the amount of IL needed for 100 kmol/hr model shale gas separation is estimated to be 171 kmol/hr and the energy required for the evaporation of the gases is 13.5 kJ/mol gas. Although the price of the IL

is higher than the organic amine-based solvent for CO₂ capture (Huang et al., 2014), its advantage of no solvent loss and the low energy regeneration consumption indicates a long-term benefit. As one part of this case study, our group has evaluated an IL-based CO₂ capture process previously. Based on the economic analysis, it is turned out that the percentage of solvent cost in the total capture cost is very low (almost 1%) as solvent used is significantly lower. Up on request, the detailed simulation results from AspenPlus can be obtained from the authors.

Figure 5 Preliminary schemes for shale gas separation

Note, however, that for the purposes of simulation in AspenPlus, the NRTL model needed to be used. This means that the gas solubility data are used to regress the needed NRTL parameters. So, the screening and IL selection is made with data plus predictive GC based models, while the verification is made with the NRTL model for a fixed IL. A sensitivity analysis for the IL amount and pressure of absorber is performed to find the operation condition (amount of solvent and pressure). As shown in Figure 6, with the increase of IL flowing into the absorber, the capture rate of CO₂ increases suddenly and C₂H₄ and C₂H₆ increase slightly, the recovery of CH₄ firstly increases suddenly but slightly decreases because of being absorbed by IL. With the increase of pressure in absorber, the capture rate of C₂H₄, C₂H₆ and recovery of CH₄ all increase slightly, and the capture rate of CO₂ stays at the highest rate (99.9%) because of the highest solubility.

Conclusion and future work

This work laid a good foundation for novel IL-based hybrid gas separation process synthesis. The database contains sufficient experimental data on solubility and Henry's law constant of several gases in ILs. Hence, thermodynamic models, including correlated model regressed with data from the COSMO-RS model and a new UNIFAC model for gas-IL systems have been developed and validated. On the basis of the database and model library, a three-stage framework for the ILs screening, gas separation process design and evaluation has been implemented and validated with a case study involving the design of a hybrid gas separation scheme for model shale gas mixture. IL- based CO₂ capture, as the main part of this case, has been rigorously simulated and analyzed. The result indicates that because of the low solvent investment occupied percentage, the total separation cost of the IL-based processes is still reduced compared with traditional solvent absorption. Future work is continuing to make the economic analysis of the whole process and develop the UNIFAC model for more gas-ILs systems together with hybrid schemes for energy, cost efficient and environmentally benign gas separation systems.

Abstract

Environmental regulations for flue gas emitted from coal-fired power plants in past mainly focused on sulfur oxides (SO_x), nitrogen oxides (NO_x) and particulate matter (PM) generated during combustion. Actions and regulations for preventing global climate change have been actively addressed in these days and considerable attentions are being paid to the implementation of CO₂ capture and sequestration technologies. A wide range of CO₂ separation techniques based on amine solvents, CO₂ adsorbents, membranes and so on, are available and each technology has own technical advantages and disadvantages. Therefore, Techno-Economic Analysis (TEA) is required to compare CO₂ separation processes in a systematic and fair manner and, hence, to gain full understanding of techno-economic impacts associated with the introduction of CO₂ capture processes in process industries.

This presentation discusses costing basis and assumptions required for TEA, as well as explains costing methodology based on multi-parameters scaling concept. Major equipment cost, indirect cost (e.g. EPC cost, owner's cost, contingency, etc.) and operating & maintenance cost are considered for economic costing. In order to improve the accuracy of TEA results, reliable costing data and scale parameters are applied, based on industrial practices. Widely-practiced values for finance-related parameters, like interest rate and project life time for economic analysis, are adopted. The economics of several post-combustion CO₂ capture processes applied for coal-fired power plant is analyzed with the proposed TEA tool. A case study is carried out to demonstrate the applicability of TEA tool for evaluating CO₂ removal technologies and to provide economic impacts associated with capture processes. Process optimization is conducted for each CO₂ removal technology and TEA is made for the optimized process configurations with optimal operating conditions, as unrealistic results may be obtained with non-optimal process design. The process optimization is carried out with integrated framework in which process simulator and in-house models are linked with an optimization solver.

Techno-economics of CO₂ capture processes was evaluated on the basis of the Cost of Electricity (COE), the cost of CO₂ captured and the cost of CO₂ avoided. Breakdown of TEA results for each technology are made and compared to obtain comparative guidance for areas of further process development. Because the introduction of CO₂ capture process results in process changes/modifications of the power plant, increase in cost for power plant and CO₂ capture process is separately analyzed. Sensitivity analysis

is also done to understand impacts on costing when key design or costing parameters are varied.

Abstract

Global warming is now a global issue and about 42% of CO₂ emissions are associated with power plants in 2013 (IEA, 2015). Significant efforts have been made to the development of CO₂ capture technologies for power plants.

Technical progress being made in the area of CO₂ capture has mainly focused on single separation technology, namely, absorption, adsorption, cryogenic systems, membrane, etc (Freeman et al., 2012). In order to complement shortcomings of each technology and to maximize synergetic benefits, the attention of hybrid process using more than one CO₂ capture technology simultaneously has been recently drawn.

This study focuses on process design of CO₂ capture systems in coal-fired power plant by combining absorption and membrane separation methods together. Two absorption-membrane hybrid options for separating CO₂ from flue gas are investigated. Process modeling was carried out with Unisim® and Matlab® in an integrated manner. The hybrid process considered in this study is categorized to series and parallel schemes, according to the linking structure between absorption and membrane process.

For the hybrid series process, the flue gas emitted from the boiler is subjected to the absorption process to remove CO₂, while non-treated flue gas is fed into the membrane process in which a portion of the combustion air for the boiler is used as sweep gas to generate pressure gradient. CO₂ is then passed from the flue gas into the sweep air stream which is fed to the boiler. Accordingly, CO₂ concentration of the flue gas is increased, with which energy required for desorbing CO₂ in the stripper can be reduced.

In the hybrid parallel process, the flue gas discharged from the boiler is divided into two streams. One is fed to the absorption process, and the other is used as air sweep gas in membrane process. As CO₂ concentration of the flue gas increases and the feed flowrate to the absorption process decreases, there is a possibility to reduce capital cost of absorption process.

Case study was performed such that key design variables, including absorption CO₂ removal rate (only to parallel process), MEA solvent flowrate, the ratio of air entering the membrane, and membrane area were varied and their techno-economic impacts were evaluated in a holistic manner.

With the case study, it was found that hybrid process based on series arrangement can reduce reboiler duty for a stripper column, while hybridized parallel process can reduce the absorption column cost. In order to fully appreciate hybrid process between absorption and membrane, further detailed verification for potential negative impacts on power generation would be required if air sweeping were utilized in hybrid arrangement.

Abstract

The production of renewable fuels has been proposed as a feasible alternative, in the short- and medium-term, to mitigate the environmental impact due to the use of fossil fuels for the transport sector. Biodiesel and biojet fuel are promising fuels to partially replace their corresponding fossil fuels. To produce biodiesel, processes with supercritical alcohols shows some advantages over the traditional base-catalyzed processes, e.g., no undesired reactions occur when the raw material has high concentration of free fatty acids. It is worth to mention that this process operates at high pressure and temperature, so the energy demand is elevated. On the other hand, the biojet fuel production through the hydrotreatment process has been developed as a feasible alternative, due to its similarity with the conventional refining processes. Like the supercritical process for biodiesel production, bio-jet fuel production requires high pressure and temperature, thus having high energy requirement. In both processes, distillation, an energy-intensive separation process, is used to generate the desired hydrocarbons fractions. Thus, to determine potential reduction in the total energy requirements for both processes, the feasibility of energy integration between the supercritical biodiesel process and the hydrotreating process to produce bio-jet fuel is studied in this work. By this approach, reductions on the utilities costs are expected if compared with the individual processes. Also, due to energy integration, which reduces the external energy requirements, global environmental impact is expected to be reduced as well.

Keywords: process integration, hydrotreating, supercritical transesterification

1. Introduction

The current high energy demand, the instability on the fossil fuels price, and the increment of the concentration of greenhouse gases emissions make necessary the development of alternative energy sources; these sources allow to address those drawbacks, such as the production of renewable fuels. In the transport sector, among the main fuels used to satisfying the society requirements, diesel and jet fuel have high demand. Among the pathways to produce biodiesel, the use of supercritical alcohols has been proposed to perform the transesterification and esterification reactions, avoiding

the side reactions that occur in the traditional based-catalyzed process. Moreover, supercritical process can use low-quality or waste vegetable oils without a previous treatment, reducing the processing cost by 60-80% (Lee et al., 2011). It is important to mention that most of the supercritical processes require only few equipment compared to conventional processes (Gómez-Castro et al., 2017). Nevertheless, due to the high pressure and temperature conditions, under which the supercritical process operates, the energy demand is considerably high. On the other hand, bio-jet fuel is an emergent biofuel which has taken importance on the last years (Gutiérrez-Antonio et al., 2015a), due to the growth in the aviation sector. Bio-jet fuel can be produced using vegetable oils as raw material, converting it into a renewable fuel through two reaction steps. The first one is the hydrotreating step; the second one is formed by hydrocracking and hydroisomerization reactions (Gutiérrez-Antonio et al., 2015b). Like the supercritical process for biodiesel production, bio-jet fuel production requires high pressure and temperature, thus having high energy requirement. Moreover, the desired hydrocarbon fractions are obtained through distillation, which is known as an energy-intensive separation process. In 2017, Gómez-Castro et al. studied the energy and mass integration of a supercritical biodiesel process and a bioethanol production process from lignocellulosic biomass. The energy and mass integration were feasible, nevertheless, savings of 4.4% and 7.7% were obtained for heating and cooling, respectively; these energy savings are low, and they do not compensate the additional investment required. This tendency is due to high differences between temperature levels of both processes (Gómez-Castro et al., 2017). In this work, energy integration is proposed between the supercritical and the hydrotreating processes to produce biodiesel and bio-jet fuel, respectively; the aim is to reduce the use of external energy and improve the energetic savings. The design and simulation of both processes are performed, realizing a sensitivity analysis in the process equipment, aiming to reduce energy requirement for the individual processes as much as possible. Then, a pinch analysis takes place to identify the potential of process integration to reduce the total energy requirement for both processes. By this approach, reductions on the utilities costs are expected, if compared with the individual processes. In addition, global environmental impact are expected to be reduced, since the energetic requirements are almost fully satisfied by the energy delivered in the processes.

2. Process simulation

The design and simulation of both processes has been performed in Aspen Plus V. 8.0. For biodiesel production, according with Gómez-Castro et al. (2017), 1,284 kg/h of vegetable oil, represented as a mixture of triolein (70 mol %) and oleic acid (30 mol %) enter to the process; along with 3,358 kg/h of supercritical ethanol. The biodiesel production is roughly 12,000 t/y, being considered as a small-scale one (Skarlis et al, 2012). The reactants streams are conditioned at 330°C and 200 bar, before entering to the transesterification and esterification reactor. Kinetic parameters for a first-order model have been used to represent the reactions; which were obtained by adjusting the data reported by Varma et al. (2010). Due to high operational conditions, after reaction zone the pressure is reduced to 1 bar for entering the separation zone; where ethanol is recovered. The biodiesel and glycerol are separated by decanting. It is worth to mention that glycerol's purity is 99.5 mol %, which make it available as solvent. UNIFAC has been used to describe phase equilibrium. The flowsheet for the supercritical biodiesel process is shown in Figure 1.

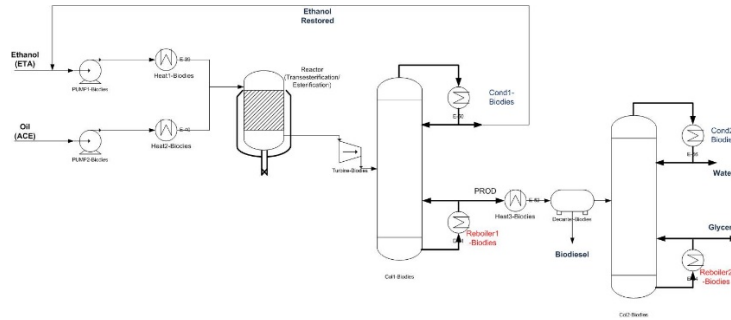

Figure 1. Supercritical biodiesel production flowsheet (Gómez-Castro et al., 2017).

On the other hand, the hydrotreating process to produce biojet fuel is integrated by two consecutive reactors and a separation zone, which is a direct distillation scheme. The vegetable oil used is *Jatropha Curcas* from Mexico; represented as a mixture of triolein (42 % wt), trilinolein (44% wt), tripalmitin (11 %wt) and tristearin (3 % wt), as major weight components. 1,710 kg/h of *Jatropha Curcas* oil enter to the process. Moreover, the hydrogen feeding enters in a ratio of 1500 mL of H₂/mL of oil to avoid coke formation (Gutiérrez-Antonio et al., 2017a). In the first reactor, hydrotreating reactions are carried out at 320°C and 80 bar; where the reactants must be conditioned before entering the reactor. A first-order lumped kinetic model, proposed by Sharma et al. (2012) has been used to represent this reaction zone. Carbon dioxide and carbon monoxide, water and lineal hydrocarbons are obtained as products. The first three compounds are separated before entering the hydrocracking – hydroisomerization reactor. The hydrocracking reaction is represented by the model of Shayegh et al. (2012); while hydroisomerization reaction is represented through the kinetic model proposed by Calemma et al. (2000). It is worth to mention that there is no additional feed of hydrogen, due to the excess introduced in the first reactor is enough for the whole reactive section (Gutiérrez-Antonio et al., 2016b). The operational conditions are 480°C and 80 bar. The stream leaving the second reactor is conditioned to 1 bar before entering the distillation train. Four products are obtained in this stage: light gases (C1-C4), naphthas (C5-C7), biojet fuel (C8-C16) and green diesel (C17-C21). The biojet fuel obtained by this process is roughly 3,671,000 L/y; quantity required by the Bajío International Airport to satisfy its renewable fuel demand, according with ASTM D7566 (Vásquez et al., 2017). Figure 2 shows the flowsheet for this process.

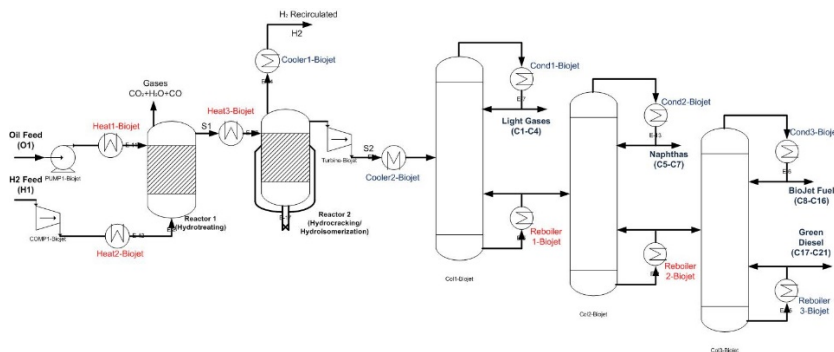

Figure 2. Bio-jet fuel production flowsheet (Gutiérrez-Antonio et al. 2016a).

In both processes, a sensitivity analysis has been performed for all process equipment with degrees of freedom, to minimize the energy requirements and keeping the quality required for the process streams.

3. Feasibility of energy integration

For both processes, the energetic analysis of all streams has been performed to obtain its enthalpy and temperature levels. Moreover, the equipment with energy inputs or outputs inside the process have been identified. At once, the heat cascade to predict the minimal heating and cooling services has been calculated, according with the pinch point analysis (Linnhoff et al., 1983). The minimal external services for both processes are then compared with the energy requirements of the individual processes; as well as the energetic savings obtained by the previous energetic integration for supercritical biodiesel and bioethanol processes (Gómez-Castro et al, 2017).

4. Results

The results of this work are presented and analysed in this section. The energetic characteristics of the streams entering and leaving the process equipment, the exothermal energy of reaction zone and the energy requirements for the distillation columns inside the supercritical biodiesel process are presented in Table 1. The same information for biojet fuel process is shown in Table 2. The total heating requirements for the streams in both processes is 2,143.40 kW, while total cooling requirements are 1,185.73 kW. It can be seen that, heating of ethanol previous to the transesterification/esterification reactor requires the highest quantity of steam for both processes. It can also be noticed that the condenser of the first distillation column for the biojet fuel process requires the use of a refrigerant. R-717 can be used for the temperature levels shown.

REBOILER 3	369.04	375.24	75.05
REACTOR 1	--	--	-787.45
REACTOR 2	--	--	-3.59 x 10 ⁻⁴

According with the pinch point analysis, the pinch point temperature for hot streams has been detected at 109.7°C, while for the cold streams 98.59°C, using a $\Delta T = 10^\circ\text{C}$. The minimal requirements of heating and cooling calculated by heat cascade are 1,129.07 kW and 63.078 kW, respectively. Savings around 47% may be achieving for heating utilities through energetic exchange between process streams, while, the savings in cooling requirements can be roughly 95%.

Feasibility of energy integration has been established for the streams in both processes. Moreover, the energy released by the reaction zone in the supercritical process and in the first reaction zone from hydrotreating process (around 819 kW) can be recovered, generating saturated steam with enough energy to satisfy the heating requirement in two distillations columns in the supercritical process. Likewise, the heating requirements for two distillation columns in the conventional train for bio-jet fuel process can be provided. Through this strategy, the whole savings for heating utilities are around 60%. On the other hand, in both process a turbine was installed to reduce the pressure before a distillation column. The electrical energy released for this equipment in both processes is 110.65 kW, covering roughly 67% the total electrical demand for the whole process. It is worth to mention that a flow of 3,131.7 kg/h is recovered and recirculated in the supercritical process to reduce the fresh ethanol stream. Likewise, the hydrogen stream recovered with a flow rate of 191.62 kg/h in the bio-jet fuel process is conditioned for return to the feed process.

5. Conclusions

Feasibility of energetic integration between supercritical biodiesel process and bio-jet fuel processes has been analysed. Savings of roughly 60% in heating requirements and 95% for cooling utilities have been obtained through the pinch point analysis; and by removing the released exothermal energy by transesterification – esterification reactions and by the hydrotreatment reactor. Obtained savings indicate that energy integration between the supercritical biodiesel process and the hydrotreating process for the production of bio-jet fuel has high potential for energy saving.

Abstract

Biodiesel is a promissory candidate to partially replace the use of fossil diesel in engines and other devices for energy production; it is composed by a combination of alkyl esters. It can be produced mainly from vegetable oils; which cost represents around 60-80% of the total production cost of biodiesel, affecting the selling price of the biofuel. Thus, the use of waste oils as raw material has been studied in the last years, because they are a cheaper alternative. However, they usually have a high content of free fatty acids, thus its conversion into alkyl esters require additional steps; since alkaline transesterification of oils with a high composition of free fatty acids is accompanied by saponification reactions. Usual pre-treatments involve the use of acid, homogeneous catalysts to transform the fatty acids into alkyl esters. On the other hand, the conversion of the oil into biodiesel is performed by reactions with alcohols, usually methanol which is produced commonly from petrochemical routes; this fact makes the production of biodiesel less sustainable. An alternative alcohol to produce biodiesel is ethanol, which can be obtained from other bioprocesses. In this work, the design of a low-cost biodiesel production process is reported, using waste cooking oil as raw material. Simulations of the process are performed in the process simulator Aspen Plus. Sensitivity analysis are performed to the equipment with degrees of freedom, to determine the design with the lowest energy requirement. Total annual costs and environmental impact are evaluated for the process.

Keywords: Waste oil, biodiesel production, process design, sustainable processes.

1. Introduction

The use of biofuels has been established as a strategy to reduce the mankind dependence on fossil fuels. Moreover, the partial substitution of fossil fuels with renewable fuels is expected to reduce the environmental impact due to the use of fuels in human activities. Biodiesel is one of the most known liquid biofuels, widely used in diesel engines, mixed with fossil diesel. This renewable fuel is obtained from raw materials rich in

triglycerides, as vegetable oils or animal fats. Nevertheless, one of the main contributions to the total annual cost in the biodiesel production is given by the raw material; thus, the use of waste oils has been proposed as an alternative raw material to reduce these costs (Lee et al., 2011). One of the main drawbacks of such approach is the high content of free fatty acids in the waste oils, which can cause saponification if basic catalysts are used (Gómez-Castro et al., 2015). To avoid such side reaction, an acid pre-treatment is commonly used, allowing the reduction of the concentration of free fatty acids in the stream entering to the basic transesterification reactor (Zanuttini et al., 2014).

One of the most important parameters to consider in the biodiesel production, together with the raw material, is the alcohol to be used as reactant. The alcohol most commonly used to perform the esterification and transesterification reactions is methanol, because the reaction with the triglycerides is fast, and it can easily dissolve sodium hydroxide. Nevertheless, methanol is toxic and relatively expensive. An alternative reactant is ethanol, which is less toxic; also, it can be produced from renewable raw materials, which may reduce the environmental impact due to the biodiesel production. One of its main disadvantages is its lower reaction rate, compared with methanol, and the azeotrope formed with water. These two issues cause the need of modified processing routes to transform the oils into biodiesel. According to the literature, the use of ethanol as reactant for the transesterification of waste oils has been performed through sonication (Martinez-Guerra and Gude, 2014), lipases (Ferrero et al., 2016), hydrotalcite catalysts (Ma et al., 2016), among others; in particular, the recovery of ethanol in these works is not addressed. Nevertheless, there have been several attempts to recover unreacted alcohol from the output mixture of the transesterification process through stripping or vacuum distillation or to remove it by flash evaporation or heating the mixture to 120 °C (Yaakob et al., 2013). To the authors' knowledge the use of glycerol, byproduct in biodiesel production, as solvent for the ethanol recuperation has not been reported. Therefore, in this work a proposal for a biodiesel production process from waste oil using ethanol as reactant is presented. The design of the process is constrained in terms of the raw material available in the municipality of Emiliano Zapata, Tabasco, México, where the plant is expected to be constructed. The flowsheet required to produce the biofuel is presented, and separation steps are proposed to reach the desired quality of biodiesel. Also, the recovery of ethanol is performed with glycerol, a byproduct in biodiesel production. The process is then assessed in terms of total annual costs, environmental impact and energetic efficiency, to determinate the economic potential of the proposed flowsheet to produce a competitive biofuel.

2. Case study

5,000 L per month of oil are treated, since it is the estimated availability of waste oil in the municipality of Emiliano Zapata, Tabasco, México. This amount of waste oil is equivalent to a daily feed of 163 kg. The waste oil is composed by fatty acids (6 wt%) and triglycerides (94 wt%). The distribution of components in the oil is shown in Table 1.

The oil composition shown in Table 1 is modelled for the production of biodiesel. Due to the high composition of free fatty acids, an acid pre-treatment is required. Moreover, since ethanol will be used as reactant, a purification step must be proposed to obtain a

high-purity biofuel. Finally, the design of the reactors is constrained because it must be adjusted to existent equipment.

Table 1. Composition for the raw material (Bulla Pereira, 2014).

Component	Mass composition
Palmitic	12.3 wt%
Oleic	24.0 wt%
Linoleic	56.6 wt%
Linolenic	7.1 wt%

3. Methodology

As aforementioned, 163 kg/h of waste oil are treated to obtain biodiesel. The process is simulated in the software Aspen Plus V8.4. In the simulator, thermodynamic data is not available for all the components, mainly for the ethyl esters; so, they are estimated using the group contribution methods available on the simulator, and the Constantinou-Gani method to determine the formation enthalpy and Gibbs energy. The phase equilibrium has been modelled using the UNIQUAC method, according to the diagram reported by Carlson (1996), considering the characteristics of the components involved.

Once the components are loaded and the thermodynamic model has been selected, the flowsheet is developed. The first step is the acid pre-treatment, where the RBatch module has been used, with a molar ratio ethanol/oil of 6:1 and 1 wt% of sulfuric acid as catalyst. The kinetic model used to represent the reaction is that reported by Neumann et al. (2016). Here, the main design variables are the reaction time and the temperature, which are modified in order to maximize the conversion of fatty acids. The size of the reactors cannot be modified, since they already exist. The stream leaving the first reactor enters to a neutralization equipment, which has been simulated using a RStoic module. The produced salt is removed by a filter. The stream leaving the neutralization step enters to a second reactor, where transesterification occurs with sodium hydroxide. Ethanol is fed in a 6:1 ratio with oil. The reaction takes place in a batch reactor (RBatch module). Once more, the effect of the reaction time and the temperature is analyzed. The kinetic model of da Silva et al. (2008) is used to represent the reaction. Finally, the purification train is established. In a first stage, a decanter is used to separate the glycerol phase from the biodiesel phase. The glycerol phase is neutralized using phosphoric acid. The solid by-product is removed by a filter. The resulting stream contains mainly glycerol and some water. On the other hand, the biodiesel is washed, representing the washing equipment as a liquid-liquid extraction column. The excess of water is removed from the biodiesel stream in a flash drum, to reach the biodiesel composition indicated by the international standards. The other stream leaving the washing tower contains ethanol and water, where the ethanol must be recovered. Nevertheless, the presence of water causes the formation of an azeotrope, which makes the separation difficult. An extractive distillation column is used to obtain ethanol with purity of 99.5 mol%. Glycerol is used as extraction agent, as recommended by Navarrete-Contreras et al. (2014). Such agent is obtained as by-product in the

reaction steps, so it can be used in the extractive distillation system. A sensitivity analysis is performed on this column, to obtain the design with the lowest heat duty. Then, the glycerol is purified in a conventional column. A simplified representation of the whole process is shown in Figure 1. Once the process has been simulated and the required yields and purities obtained, the capital costs of the process are computed using the Guthrie method (Turton et al., 2012), while the operation costs are estimated in terms of the utilities requirement. Environmental impact is computed in terms of the carbon dioxide emissions of the process, which are directly related with the total heat duty and the temperature levels required. The CO₂ emissions are estimated using the method proposed by Gadalla et al. (2005).

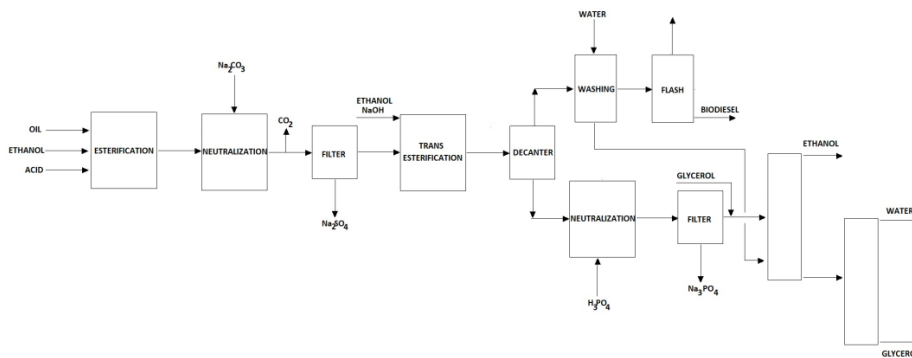

Figure 1. Block diagram of the biodiesel production process

4. Results

In this section, some of the major results of the analysis are presented. In the case of the esterification reactor, it has been determined that operating at 70°C with $t = 30$ min is enough to obtain conversion of fatty acids around 99 mol%. In the case of the transesterification reactor, the best temperature was determined as 70°C, with $t = 15$ min, obtaining conversion around 96 mol% of triglycerides to biodiesel. Other of the main equipment in the process is the extractive distillation column, which was designed with 12 stages, feeding the ethanol/water stream in stage 10, while the glycerol/water stream is fed in the stage 3. The whole process has energy requirement of 108 kW, where the flash drum contributes with around 62% of the total heating requirement of the process. The ethanol recovery train contributes with 36%.

Table 2 shows the equipment costs estimated with the Guthrie method, together with the operational costs and the total annual cost. It is important to notice that the total capital cost must be annualized to obtain the total annual cost (TAC). To do this, recovery time has been assumed to be 10 years. In the utilities cost, only the costs for steam and water are included. Here, the utilities cost represents around 46% of the total annual cost.

Table 3 shows the computed CO₂ emissions for the whole process. The use of two possible fuels to produce the steam is considered: gasoil and natural gas. As expected,

using natural gas reduces around 33% the carbon dioxide emissions in comparison with gasoil.

Table 2. Costs for the proposed biodiesel process.

Capital cost (USD)	Variable cost (USD/y)	TAC (USD/y)
221,009	18,693	40,794

Table 3. Emissions of carbon dioxide for the biodiesel process.

Carbon dioxide emissions (kg/h)	
Gasoil	Natural gas
38.12	25.61

The selling cost for biodiesel has been estimated, following the approach of Santana et al. (2010); where the annual equivalent cost, the annual operation cost and the annual production of biodiesel are involved. Also, the quantity of glycerol produced inside the process is considered. For the proposed process, the annual production of biodiesel is 57,115 kg/y, which is derived from the mean generation of residual oil in the municipality of Emiliano Zapata, Tabasco, México. Moreover, the process produces 2,621 kg/y of glycerol, which could be sold or used to partially fulfill the solvent requirements in the extractive distillation column. With this information, it has been determined that the unitary cost for the biodiesel obtained in the proposed process is 0.865 USD/l. The obtained cost is lower than the mean cost of fossil diesel in Mexico (around 0.965 USD/l), making the process competitive.

5. Conclusions

The design and simulation of a biodiesel production process from waste oil using ethanol as reactant has been proposed. The design of the process has been performed using CAPE tools, as the process simulator Aspen Plus. For this process, some of the equipment has been already acquired, particularly the reactors, which constrains the design step. The effect of the design variables in the main equipment of the process has been studied through sensitivity analysis, to generate a process with low energy requirement. One of the main differences with the traditional processes using methanol is the necessity of using special separation processes to recover the ethanol. In terms of the cost of the product, it has been estimated that the process has potential to produce a biofuel with lower selling cost than fossil diesel.

Abstract

The energetic requirements of several processes for high-purity lignin production from lignocellulosic waste streams has been studied in this work, based on simulation analysis performed with experimental data. The introduced variables were: two different raw materials (almond shell and olive tree pruning), the use of a pre-treatment stage and the application of two different sulphur-free delignification methods (organosolv and soda processes) with their subsequently lignin precipitation steps. In total, four scenarios were approached and assessed in terms of desirable product yields, water and chemical consumptions and energetic duties. Results showed a more efficient process when almond shell was used as raw material. In terms of the delignification process, organosolv method required a much lower quantity of chemicals due to the recycle and recirculation of the solvent (ethanol). The energy consumption associated to this recycle implied an increase of 18-12 % in the total energy consumption. On the other hand, lignin product yield was higher with soda process although its chemical consumption was found to be much higher, in terms of soda and sulfuric acid requirements.

Keywords: lignocellulosic biomass, biorefinery, lignin, energetic efficiency, simulation

1. Introduction

Technological routes and projects in which lignocellulosic biomass is used to produce energy and bio-based chemicals and materials have been increasing nonstop in the last years. Research and commercial efforts have been focused on improving the biorefinery processes making them susceptible of competing with the petrochemistry market (Montazeri and Eckelman, 2016). A variety of biomass pre-treatment strategies have been applied to separate the lignocellulosic biomass structure into cellulose, hemicelluloses and lignin, including the use of bases, such as sodium hydroxide, organic alcohols and acids (organosolv treatments) or ionic liquids. The lignin fraction has frequently been considered a by-product from the polysaccharides isolation process for biofuels production via hydrolysis and fermentation. Nevertheless, lignin has proved to have a big potential for the production of added-value chemicals and materials, due to the variety of functional groups in its chemical structure (Thakur et al., 2014). These lignin-based products must be competitive with their petroleum-derived counterparts. At this point, it is very important to design energy efficient process for the lignin

extraction and purification. Otherwise, it would be difficult to offer an actual alternative to consolidated products based on fossil resources (Mabrouk et al., 2016).

In this work, the lignin extraction and purification processes from two different lignocellulosic biomass sources (almond shell and olive pruning) by two different pre-treatments (organosolv and soda) are presented. The target has been the designing of an energy efficient process by simulating with using Aspen Plus[®] software the different sequences in order to minimize its energy consumptions.

2. Simulation procedure

2.1. Processes description

Experimental data was reported in a previous work (Fernández-Rodríguez et al., 2017), where almond shell and olive tree pruning were used as feedstock for lignin extraction. Compositions of these raw materials are described in Table 1.

Table 1. Chemical characterization of raw materials (Fernández-Rodríguez et al., 2017).

Macro-components	Composition (%)	
	Almond Shell	Olive Tree Pruning
Cellulose	39.93	50.01
Hemicellulose	8.29	12.74
Lignin	50.86	22.33
Extractives	0.07	11.46
Ashes	0.86	3.46

These materials were subjected to an autohydrolysis pre-treatment to increase lignin concentration prior the delignification stage. Reaction was carried out at 180 °C, using only water as reagent in a 1:8 solid/liquid ratio. After that stage, solid material was cleaned and driven to a pulping stage where lignin was extracted. Organosolv pulping was conducted using a mixture of ethanol/water (70/30 V/V) at 200 °C in a 1:6 solid/liquid ratio, whereas soda process was carried out at 121 °C using a NaOH 7.5 wt.% solution as reagent in the same solid/liquid ration of organosolv method. Regardless the used process, after the delignification stage, the undissolved solid was cleaned in two steps, first with the same solvent utilized in the reaction; and then with water to obtain a pulp enriched in cellulose. On the other hand, the black liquor obtained after the reaction was led to a precipitation stage. In the organosolv process, lignin was precipitated with the addition of acidified water (pH= 2) and then filtered to obtain lignin as the solid fraction. On the other hand, the soda black liquor was precipitated by lowering the pH down to 4 by sulfuric acid addition (96 wt.%). The filtered cake was then washed with water to remove the excess of salts that were generated by this precipitation method.

2.2. Simulation

Based on the experimental results of the above described processes, a simulation by Aspen Plus V8.8 was build up to stablish mass and energy balances that could allow to determine the influence of raw materials and delignification methods used in the energy requirements of the processes. The processes flowsheets are presented in Figures 1 and 2. The organosolv process includes a solvent recovering stage. Hence, a recirculation of

ethanol by distillation was proposed to reutilize this compound in the reactor and as washing stream.

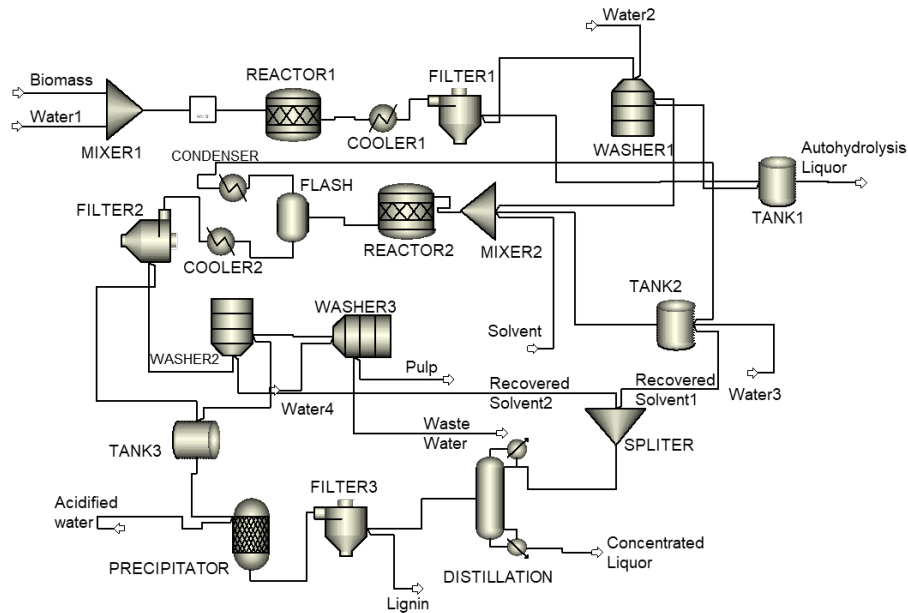

Figure 1. Flowsheet of the organosolv process.

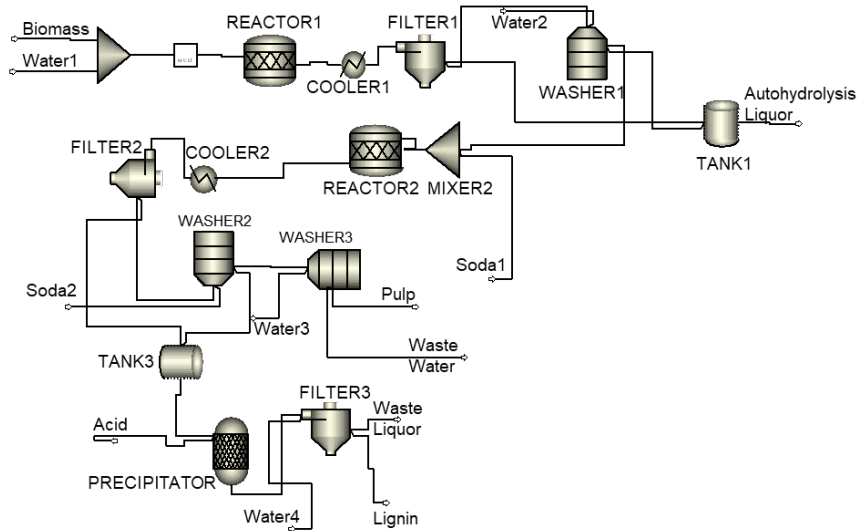

Figure 2. Flowsheet of the soda process.

NRTL-RK model was selected to simulate the thermodynamic properties of the streams involved in the process. The simulation basis was 100 kg/h of dry raw materials and 800 kg/h of water to the autohydrolysis reaction. A description of the equipment used in these processes is detailed in Table 2. The distillation column for ethanol recovery in the organosolv process was designed to obtain a recovered stream with the same ethanol

mass fraction as it was introduced to the system (74.7 wt.%). Reactions happening in autohydrolysis, delignification and precipitation stages were adjusted stoichiometrically following the experimental yields obtained (Fernández-Rodríguez et al., 2017). Lignin stream was obtained completely dry and with the same purity as it was experimentally reported (Fernández-Rodríguez et al., 2017).

Table 2. Blocks design for the simulation process.

Equipment	Aspen Module	Specification

3. Results

The comparison of the analysed scenarios is represented in Table 3. Process efficiency was evaluated in terms of water and chemicals (ethanol or soda) consumptions and total energy duties.

Table 3. Main results for the different processes approached. AO: almond shell, organosolv; OO: Olive tree pruning, organosolv; AS: Almond shell, soda; OS: Olive tree pruning, soda.

	Units	AO	OO	AS	OS
Lignin yield	%	4.63	2.81	10.1	6.91
Pulp yield	%	49.7	47.3	37.4	28.2
Solvent consumption	kg/h	20.11	18.40	427.8	387.6
Water consumption	kg/h	1626	1553	1072	1029
Acid	kg/h	-	-	39.01	35.40
Waste streams	kg/h	1693	1622	1594	1520
Energy requirement	kW	432.3	495.4	353.1	435.6

The generated waste streams were also considered as they should be treated before their disposal. The influence of the raw material used in the process can be noticed in all the

measured parameters. Almond shell presented in all cases, the highest lignin and pulp production yields for the same biomass feed to the system. When using this raw material, lignin yield was found to be 63.7 % higher than the obtained with olive pruning, for the organosolv process and 47 % higher in the case of soda process. The obtained pulp yields were found to be similar for both materials in the organosolv process but 33 % higher for almond than in the soda process. A higher chemicals consumption was needed when almond shell was used, particularly, a 10 % more of the reagents for the pulping stage (either ethanol or soda) was required and a 4% more of water. As a consequence, higher waste streams flow was produced (between 4-10 % of increase with regard to olive pruning scenarios). Regarding energy duties, lower energy consumption was experimented for almond processes. On the other hand, the influence of the used pulping process was particularly remarkable when comparing the lignin production yield, as the one obtained by the soda process was more than a 50% higher than the obtained by the organosolv method. However, lower pulp yields (24% in case of almond and 40 % for olive tree pruning) were obtained by the soda process. The comparison of both processes in terms of solvents consumption was favourable to the organosolv, since the ethanol recovery led to a very low consumption rate of this compound (0.25 times the quantity of used biomass), whereas in soda process the required soda solution quantity was around 4 times the quantity of the used biomass. Furthermore, soda process water requirement was 30 % higher than the quantity used in the organosolv scheme, due to the great quantity needed in the precipitation stage. In addition, the waste stream quantities were similar, (5-6 % lower for organosolv process). In terms of energy duties, the inclusion of the distillation stage for organosolv process led to an increase of 18-12 % in the total energy consumption. The evaluation of the energetic duties of both processes was carried out by the quantification of each stage with energy requirements. In Figure 3, the energy duties of the involved are presented.

Figure 3. Energy duties of the process stages. AO: almond shell, organosolv; OO: Olive tree pruning, organosolv; AS: Almond shell, soda; OS: Olive tree pruning, soda.

The stage with the highest energy duty was the heat exchanger “Cooler1”, after the autohydrolysis reaction. Concretely, this stage implied between 33 and 47 % of the total energy duties depending on the case of study. Autohydrolysis reaction was the operation with the second highest heat duty of the process. A considerable difference was found in this stage depending on the used raw material. Olive tree pruning required a higher heat contribution than almond shell in this operation. Distillation heat duty supposed only 13-10 % of the total energy duty for organosolv processes, indicating that, the inclusion of the distillation stage, did not led to a huge increase in total energy consumption. Furthermore, the organosolv process presented an advantage in the cooling of the stream produced in delignification stage by the inclusion of the flash unit and condenser to recirculate the ethanol. In the case of the soda process, the whole stream exiting the delignification reactor needed to be cooled. As summary, organosolv process presented higher energy duty considering the global process. However, its reduction in solvent consumption was found to be higher than the increase of energy duty. Therefore, a compromise should be set to determine what scenario would the most interesting.

4. Conclusions

Simulation by Aspen Plus V8.8 has been successfully applied to different scenarios based on experimental data. Almond shell was more suitable for lignin generation than olive tree pruning with lower energetic duty regardless the delignification method used. In terms of the delignification method used, soda process presented better values for lignin obtaining, whereas the pulp stream flow was lower. Much higher consumptions of solvent and acid were required in the soda scheme, while its was energetic duties were lower than the ones associated to the organosolv process. Regarding the energetic duties for each stage, the main energy consumption was located in the autohydrolysis stage. The identifying of the most critical points for energetic duties will lead to an energetic integration process in a further work.

Abstract

The chance of a successful industrial implementation of innovative or unconventional processes can be greatly enhanced if the analysis of economic feasibility and environmental impacts is performed from the beginning. In this study, Retro-Techno-Economic Analysis was expanded into Retro-Techno-Economic-Environmental Analysis (RTEEA), combining Life Cycle Analysis (LCA) metrics with economic ones, in order to define regions of feasible operation for the process. In addition, the selection of key process variables was done through global sensitivity analysis (GSA). RTEEA was applied to the case study, the production of succinic acid (SAc) from sugarcane sucrose. Greenhouse gases emissions (GHG, in kg CO₂ eq./kg SAc) and the process Net Present Value (NPV) were chosen as performance metrics. For mapping the GSA response surface, Latin hypercube sampling was used. Sensitivity analysis pointed out that GHG is only influenced by yeast selectivity while NPV was more sensitive to concentration, productivity and yeast selectivity (99.6% of explained variance). The feasible region is bounded by the limits in yeast selectivity and by the infinite productivity curve (obtained assuming instantaneous reaction). The methodology was able to identify the main process variables that influence the process economic and environmental performance, derive their threshold values, and make explicit their relations.

Keywords: global sensitivity analysis, life cycle assessment, feasible space, process simulation.

1. Introduction

To avoid potential losses of research and development (R&D) investments, it is necessary to screen possible economic bottlenecks, providing targets for the experimental teams ever since the beginning of the experiments (Furlan et al., 2016).

Indeed, Process Systems Engineering (PSE) tools, allied to techno-economic analysis (TEA) and life cycle assessment (LCA) can be useful for verifying and understanding the techno-economic feasibility and environmental impact of new processes. Usually, when the economic and environmental performance are considered, the best operational condition for an individual piece of equipment is not optimal for the whole process. Therefore, it is essential to include plantwide simulations, based on reliable experimental data, in order to verify the feasibility of the proposed solution according to techno-economic and environmental criteria.

TEA and LCA are usually used to assess the economic and environmental performance of predefined process conditions. RTEA (Furlan et al., 2016) is a novel approach that turns this problem upside down, providing targets of key process variables for R&D teams, in order to seek for feasible operational conditions, taking into account the overall process. In this work, RTEA was expanded to RTEEA (Retro-Techno-Economic-Environmental Analysis), incorporating life cycle assessment. This methodology is presented here, using NPV and GHG as metrics to define feasible regions. Rather than reporting an extensive techno-economic-environmental analysis of a process, a case study is reported, exemplifying a real application of the methodology. Therefore, techno-economic analysis and life cycle assessment were applied to the production of succinic acid from sucrose. Global sensitivity analysis (GSA) was carried out to search, with statistical criteria, the process variables that have the greatest influence on the process performance. This methodology can be used only in equation-oriented simulators (where no order is imposed to solve the system of equations), without relying on an external convergence loop.

2. Methodology

The production of succinic acid (SAC) from sugarcane sucrose by fermentation is described by Efe et al. (2013). RTEEA methodology is constituted by four parts: construction of a base case, incorporation of TEA and LCA analysis in the simulation, selection of key variables through global sensitivity analysis and delimitation of the feasible space. The Net Present Value (NPV) was chosen as economic metric while greenhouse gas (GHG) emissions was chosen as environmental metric. The techno-economic analysis was performed by Furlan et al. (2016) in a previous work. The cradle-to-gate GHG emissions of the production of succinic acid from sucrose was calculated using LCA methodology. The functional unit was defined as 1 kg of SAC. The system boundaries include the cultivation of sugarcane, conversion of sugarcane to sucrose and the microbial synthesis of succinic acid from sucrose. The 2007 Intergovernmental Panel on Climate Change (IPCC) Global Warming Potentials (GWPs) method was employed to convert GHG emissions to CO₂-equivalent emissions. The emission of CO₂ eq associated with the sugarcane cultivation and the process of sugarcane conversion to sucrose were obtained from Figueiredo et al. (2010) as 241 kg CO₂ eq (t sugarcane)⁻¹. GHG emissions for the process simulation were estimated by inserting equations and data from Weidema et al. (2013) into EMSO. Electricity and steam requirements obtained from the case study simulations were used to determine GHG emissions associated with energy consumption.

GSA indicated the process variables that have more influence on economic and environmental feasibility. Mapping of the response surface was carried out by Latin Hypercube Sampling (LHS), ensuring that the ensemble of random numbers generated was representative of the real variability of the parameters in the simulated process (Saltelli et al. 2008). Six process variables were initially selected: succinic acid concentration in the bioreactor, yeast specific productivity (SAC produced/yeast mass/reaction time), yeast selectivity (SAC produced/ethanol produced), selectivity of the adsorption column used to recover SAC, sucrose conversion, and crystals' drying temperature. To avoid a type II error when classifying an important factor as non-influential, the Latin hypercube was constructed with 10^4 points (Saltelli et al. 2008). Selection of the key variables was based on a cumulative explained variance. In order to provide a graphical representation of the responses, only the three most influential variables were selected.

For the RTEEA methodology it is essential that the variables chosen for analysis are inputs (i.e., process constraints). If not, other specified variable, correlated with the desired one, must be freed in order to keep the degrees of freedom null. The equation that equals the economic/environmental metrics with a threshold value was solved together with the model equations of the process (mass and energy balances, thermodynamics relations, etc). RTEEA swaps the specification of the chosen variables (which become output variables of RTEEA) for this equation. Zero net present value (NPV=0) and GHG emission by petrochemical route for SAC production were chosen as these threshold values. Detailed information can be found in Furlan et al. (2016).

The platform for the simulations was the software EMSO (Environment for Modelling, Simulation and Optimization, Soares and Secchi, 2003), an equation-oriented simulator.

3. Results and Discussion

To demonstrate the potential of this methodology, the production of SAC from sucrose was chosen as case study, based on a process described by Efe et al. (2013). The TEA was performed by Furlan et al. (2016) and compared to the original work.

The cradle-to-gate LCA was incorporated in the simulations, in order to determinate the GHG emissions of the whole production process. The major GHG contribution comes from agricultural management, which impacts directly on sucrose production.

The global sensitivity analysis was performed based on the previously described variables. Among more than 800 process variables, the selected ones were chosen in order to avoid type I errors, which indicates that a non-influential factor was defined as important (Saltelli et al., 2008). The analysis was performed in order to evaluate the total explained variance, based on the determination coefficient (R^2). Table 1 shows the R^2 calculated based on the data regression generated by LHS. The regression equations were composed by the mean of the all NPV and GHG values calculated in a simulation plus the linear and quadratic effects of the variable and the combinations of them, providing an equation with 28 terms.

Table 1: Coefficient of the determination (R^2) of the regressions: selected results with greater R^2 . When #1 is assigned to a variable, its linear and quadratic terms are taken into account. Variables i and j cross-terms are only considered when #1 is assigned for both variables i and j . The six elected variables were: succinic acid concentration (Csa), yeast productivity (Pr), sucrose conversion (Conv), succinic acid to ethanol selectivity (Select), selectivity of the adsorption column (Sel_ad) and the crystals' drying temperature (Temp). The number of variables analyzed at same time change, in order to determine the metric's most influential factor. Grey cells are the ones with the highest R^2 for each number of analyzed variables.

Simultaneously analyzed variables	Occurrence of the variable						R^2	
	Csa	Pr	Conv	Select	Sel_ad	Temp	NPV	GHG
5	1	1	1	1	1	0	0.9962	0.9944
4	1	1	1	1	0	0	0.9962	0.9943
3	1	1	0	1	0	0	0.9960	0.9941
2	1	1	0	0	0	0	0.9234	0.0864
	0	1	0	1	0	0	0.1089	0.9941
1	0	0	0	1	0	0	0.0014	0.9937
	1	0	0	0	0	0	0.6719	0.0395

GSA clearly shows the effect of the process variable on the performance metric. Succinic acid concentration has the greatest effect on process NPV, but its determination coefficient is low (0.6719). When two variables are considered simultaneously, the total explained variance increases. A maximum R^2 value of 0.9234 for the NPV occurs when Csa is combined with productivity. Adding yeast selectivity increases total variance explained to 0.9960. Using more than 3 process variables does not provide any relevant increment on correlation. GHG, on the other hand, is most influenced by yeast selectivity (0.9937 explained variability), while other variables have minor effects. Thus, as can be seen in Figure 1, the GHG performance is only limited by the yeast metabolism (Efe et al., 2013) and by the selectivity calculated based on GHG emissions for a petrochemical route for succinic acid production (Cok et al, 2013).

Based on Figure 1, that bounds the GHG feasible region, RTEEA was performed in order to determine economic feasibility. Figure 2 shows the isoeconomic surfaces (for $NPV = 0$) in terms of the process variables selected using GSA.

Productivity's effect on minimum feasible succinic acid concentration is greater at low selectivity. Nevertheless, this effect quickly decreases as selectivity increases. Selectivities above 12 have almost no effect on Csa, for productivities above 100

g/kg/h. Therefore, if selectivities above 12 are already achieved, there is no reason to invest on

Figure 1: GHG performance based on yeast selectivity. The petrochemical route emissions (1.94 kg CO₂ eq /kg SAc) provide the minimum value for selectivity, 7.02 (Cok et al, 2013) and the yeast metabolism the maximum value, 17.6 (Efe et al., 2013).

Figure 2: Succinic acid concentration (g/L) as function of the yeast selectivity (SAc produced/ethanol produced). The continuous lines are contour plots of isoeconomic surfaces (NPV=0) for various specific yeast productivities (SAc produced/yeast mass/reaction time). Feasible area (NPV>0) is above each line. Hatched areas are unfeasible regions.

increasing it. A better strategy is to increase succinic acid concentration, by increasing yeast resistance or by different process intensification techniques. Additionally, selectivities above 7 already lead to lower GHG emissions than petrochemical based succinic acid's. These comments exemplify how lab experiments can be quickly evaluated, and a new search direction for designing experiments can be derived, using RTEEA diagrams.

4. Conclusions

In this work, environmental analysis was coupled with techno-economic one to derive goals to R&D teams. The RTEEA methodology, an extension of RTEA, was able to identify the main process variables that influence the process economic and environmental performance, obtain their threshold values, and make explicit their relations. A case study was used to demonstrate the methodology capabilities. A set of six process variables were initially analyzed and their number reduced using global sensitivity analysis. With this methodology, a diagram was built which can be used to quickly derive new goals and directions for process development.

Dynamic Modeling of Butanol Production from Lignocellulosic Sugars

Cansu Birgen^{a,*} and Heinz A. Preisig^a

^a*Department of Chemical Engineering; NTNU; Trondheim, Norway*

Abstract

We proposed a dynamic model for butanol production from glucose and xylose as representative lignocellulosic sugars. The model consists of the extended Monod model for growth on mixed sugars with the effect of noncompetitive inhibition between them. The Luedeking-Piret model was used for butanol production. Sugar uptake equations were derived through a semi-empirical approach by employing yield coefficients. The proposed model has 10 parameters. We estimated the parameters by using data from a feed interval of a fed-batch fermentation experiment, which we performed with glucose and xylose by *Clostridium beijerinckii* NCIMB 8052. Parameter estimation imposed a constrained optimization problem where the objective was to minimize the sum of squared error (SSE) between the predicted and observed values of components. The constrained nonlinear optimization problem was solved using `fmincon` in MATLAB 2017b Optimization Toolbox based on the interior point algorithm. The problem was solved after 90 iterations and 1141 function evaluations resulting an SSE value of $8.9417e-14$. We validated the model with data sets of four other feed intervals, and the index of model accuracy, which was sum of squared relative error (SSRE) was 2.2245. We conducted the sensitivity analysis with end point deviations to identify the critical parameters. Substrate affinity constant for xylose, K_{sX} had the highest impact on cell mass, xylose and butanol concentrations, and had the second greatest effect on glucose concentration. This is the first study which addresses the dynamic modeling of simultaneous utilization of lignocellulosic sugars for butanol production. The proposed model is the first attempt to incorporate the interaction between sugars. The methodology we proposed provides an understanding in the dynamics of the butanol production from glucose and xylose, and it can further be used for guiding optimal process design and operation.

Keywords: dynamic modeling, butanol, lignocellulosic sugars, glucose, xylose

1. Introduction

Butanol has become a popular renewable energy carrier due to the depletion of fossil fuel resources and raising environmental concerns. However, its production has feedstock availability and low yield challenges. Ezeji et al. (2014) suggested that the exploitation of all the sugars bound in lignocellulosic biomass can contribute to solving these problems. Current studies mainly focus on single sugar systems, especially glucose, which does not reflect the true nature of the butanol production process from lignocellulosic sugars. Therefore, understanding the multiple sugar utilization in mixed form, the interactions between the sugars and resulting effect on cell mass growth and product formation is crucial. Our main objective is to develop a dynamic model for production of butanol from a mixture of glucose and xylose as representative lignocellulosic sugars. The developed systematic approach for dynamic modeling can also be applied for other types of microorganisms and sugars.

2. Theory

2.1. Kinetic model for butanol production from glucose and xylose

In this study, we established the kinetic model based on unstructured mathematical models which have typically been used to estimate the state of butanol production Srivastava and Volesky (1990). We developed a dynamic model for the process which describes cell mass growth, X , butanol production, B , and uptake of glucose, S_G and xylose, S_X .

In our previous study, we showed that the interaction between sugars was significant and in non-competitive inhibitory form Birgen et al. (2018b). Cell mass growth on glucose is shown in Equation 1 and, growth on xylose is shown in Equation 2.

$$\mu_G = \frac{\mu_{max_G} * S_G}{K_{S_G} * S_G * (1 + \frac{S_X}{K_{S_X}})} \quad (1)$$

$$\mu_X = \frac{\mu_{max_X} * S_X}{K_{S_X} * S_X * (1 + \frac{S_G}{K_{S_G}})} \quad (2)$$

where μ_{max_G} and μ_{max_X} are maximum specific growth rates on glucose and xylose, respectively. K_{S_G} and K_{S_X} are substrate affinity constants for glucose and xylose. Cell mass concentration change over time is shown in Equation 3.

$$\frac{dX}{dt} = (\mu_G + \mu_X) * X \quad (3)$$

Glucose uptake and xylose uptake are given in terms of the amounts utilized for cell mass growth and product formation, which can be seen in Equation 4 and Equation 5, respectively.

$$\frac{dS_G}{dt} = -\frac{1}{Y_{X/S_G}} * \mu_G * X - \frac{1}{Y_{B/S_G}} * \mu_G * X \quad (4)$$

where Y_{X/S_G} is the cell yield on glucose and Y_{B/S_G} is the butanol yield on glucose.

$$\frac{dS_X}{dt} = -\frac{1}{Y_{X/S_X}} * \mu_X * X - \frac{1}{Y_{B/S_X}} * \mu_X * X \quad (5)$$

where Y_{X/S_X} is the cell yield on xylose and Y_{B/S_X} is the butanol yield on xylose. The kinetic model for butanol formation is developed using the Luedeking-Piret model which only has a growth associated part as shown in Equation 6.

$$\frac{dB}{dt} = Y_{B/X_G} * \mu_G * X + Y_{B/X_X} * \mu_X * X \quad (6)$$

where Y_{B/X_G} is the butanol yield on cell mass utilizing glucose and Y_{B/X_X} is the yield on cell mass utilizing xylose.

2.2. Parameter estimation for kinetic model

Parameters of fermentation model that are listed in Section 2.1 are unknown a priori, therefore, we must estimate them from experimental data. In this work, the measured concentrations of cell mass, glucose, xylose, and butanol are used:

$$y = [[X] [S_G] [S_X] [B]]^T$$

for estimation of parameters

$$\Theta = [\mu_{max_G} \ K_{S_G} \ \mu_{max_X} \ K_{S_X} \ Y_{X/S_G} \ Y_{B/S_G} \ Y_{X/S_X} \ Y_{B/S_X} \ Y_{B/X_G} \ Y_{B/X_X}]^T$$

The parameter estimation poses a nonlinear least-squares optimization problem

$$\hat{\Theta} = \underset{\Theta}{\operatorname{argmin}} \sum_{i=1}^{N_m} \sum_{j=1}^{N_v} |\bar{y}_{ij} - y_{ij}|^2 \quad (7)$$

where $\hat{\Theta}$ denotes the estimated value of the kinetic parameters Θ ; and \bar{y} and y denote the measured and predicted concentration of the components; N_m is the number of measured components which is 4; N_v is the number of measurement points which is 14; and the subscript ij denotes the j^{th} value of the i^{th} measured component.

The objective of the parameter estimation problem in Equation 7 is to determine the parameters, Θ by minimizing the squared difference between the predicted and measured concentration of the components in y . The constrained nonlinear optimization problem is solved in using `fmincon` in MATLAB 2017b Optimization Toolbox based on the interior point algorithm together with `ode45` solver for the mass balance equations.

The parameter bounds considered in the optimization problem are given in Table 1. The parameter bounds for yield coefficients were determined using stoichiometric relations between the components Mayank et al. (2013). Rest of the parameter bounds were taken from literature Buehler and Mesbah (2016) and Eom et al. (2015).

2.3. Sensitivity analysis of kinetic model parameters

We conducted the sensitivity analysis 10% variations in each of 10 parameters presented in Section 2.1. The sensitivity can be measured by comparing the final concentrations with perturbed and unperturbed parameters. End point deviations (ED) of cell mass, glucose, xylose and butanol as a result of each parameter perturbation are assessed. ED is calculated as in Equation 8.

$$ED_i^P (\%) = \frac{y_i(\Theta + \Delta\Theta, t_{end}) - y_i^{ref}(\Theta, t_{end})}{y_i^{ref}(\Theta, t_{end})} \quad (8)$$

where $y_i(\Theta, t_{end})$ and $y_i(\Theta + \Delta\Theta, t_{end})$ represent the simulated concentration of i^{th} component in the fermenter at time t_{end} associated with unperturbed parameter Θ and perturbed parameter $\Theta + \Delta\Theta$, respectively. $y_i^{ref}(\Theta, t_{end})$ is the end concentration of the i^{th} component in the reference.

2.4. Model validation

We obtain the model after parameter estimation, and perform model simulations to check its validity for other feed intervals in the fed-batch fermentation experiment. We calculated sum of squared relative error (SSRE) between the predicted and observed values of the components as a quantitative measure of model accuracy, shown in Equation 9.

$$SSRE = \sum_{t=0}^{t_{end}} \left(\frac{\bar{y}_i(t) - y_i(t)}{\bar{y}_i(t)} \right)^2 \quad (9)$$

where $\bar{y}_i(t)$ and $y_i(t)$ denote the measured and predicted concentration of the components at time t , the subscript i denotes value of the i^{th} measured component.

3. Results and discussion

The optimization problem was solved after 90 iterations and 1141 function evaluations resulting an objective function, SSE value of $8.9417e-14$. First order optimality was $1.683e-07$. The optimization problem was solved when the size of the current step was less than the selected value of the step size tolerance, $1.0e-18$ and constraints were satisfied to within the selected value of the constraint tolerance which was set to $1.0e-12$. The estimated parameters are shown in Table 1.

Table 1: Estimates and bounds of model parameters.

Parameter	Lower bound	Upper bound	Initial point	Estimate
μ_{maxG}	0	1	0.5	0.3550
K_{SG}	0	2.5	1.25	0.8698
μ_{maxX}	0	1	0.5	0.3110
K_{SX}	0	2.5	1.25	0.8466
$Y_{X/SG}$	0	0.689	0.345	0.3982
$Y_{B/SG}$	0	0.412	0.206	0.2527
$Y_{X/SX}$	0	0.689	0.345	0.4294
$Y_{B/SX}$	0	0.494	0.247	0.3311
$Y_{B/XG}$	0	5	2.5	2.0367
$Y_{B/XX}$	0	5	2.5	1.5364

After the parameter estimation, we performed model simulations. Predicted and observed data are shown in Figure 1.

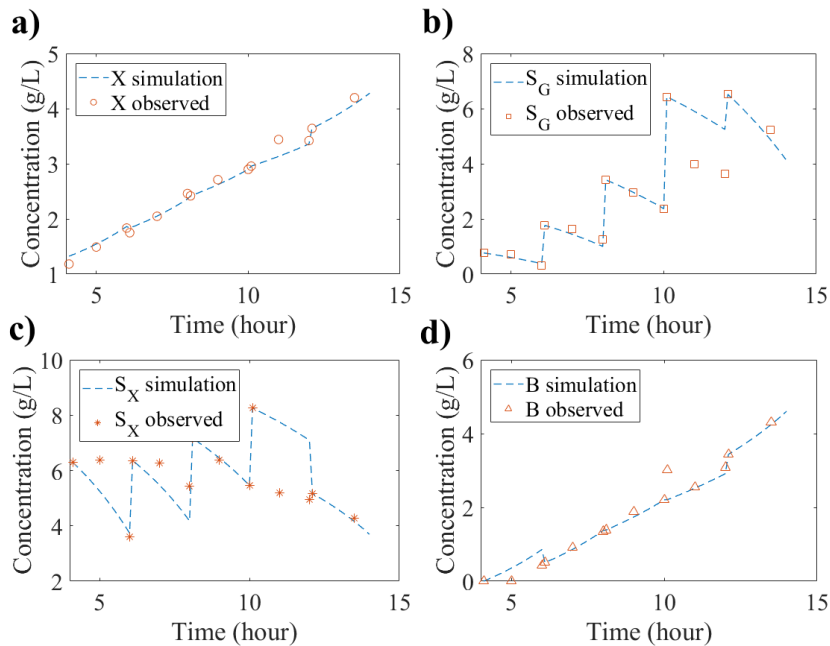

Figure 1: Predicted and observed values of a) cell mass concentration, b) glucose concentration, c) xylose concentration, d) butanol concentration.

The maximum specific growth rate on glucose was higher than on xylose, because its utilization yields more ATP and results in a higher cell mass growth rate. Furthermore, substrate affinity constant for glucose is larger indicating a lower affinity for glucose than xylose. This can be explained by our fermentation start up strategy that enables simultaneous utilization of sugars Birgen et al. (2018a), where the cells are first grown on a medium containing only xylose. Both the cell mass yield, Y_{X/S_X} and butanol yield, Y_{B/S_X} on xylose was higher than on glucose, which supports our motivation to investigate further on fermentation of xylose and other sugar mixtures.

Figure 2: Sensitivity analysis results for a) cell mass concentration, b) glucose concentration, c) xylose concentration, d) butanol concentration.

We performed model validation with other feed intervals in the fed-batch fermentation data. We calculated SSRE between the observed and predicted values of the concentrations for quantitative measurement of the model accuracy. SSRE was 2.2245, which is in the range of previous findings for similar modeling approaches Eom et al. (2015).

In the sensitivity analysis of the model parameters, the reference trajectory was the concentration at the end of the feed interval in the fed-batch fermentation resulting from successive simulation under given design and operation variables. Figure 2 shows the results of the sensitivity analysis for the concentrations of cell mass, glucose, xylose and butanol. Substrate affinity constant for xylose, K_{S_X} showed substantial effects on all components.

Since our target product is butanol, we focus on the parameters which has the greatest influence on its final concentration. The second greatest influence was from the butanol yield on xylose utilizing cells, Y_{B/X_X} . Next critical parameter was the μ_{max_G} . Yield coefficients related to glucose and cell yield coefficient on xylose, Y_{X/S_X} and butanol yield coefficient on xylose, Y_{B/S_X} had a minor influence on the final butanol concentration.

4. Conclusions

We proposed a dynamic model for butanol production from glucose and xylose as representative lignocellulosic sugars. The model consists of the extended Monod model for growth on mixed sugars with noncompetitive interaction between the sugars. The Luedeking-Piret model was used for butanol production. Sugar uptake equations derived through a semi-empirical approach by employing yield coefficients. The proposed model has 10 parameters. We estimated the parameters by using data from fed-batch fermentation experiments, which we performed with glucose and xylose by *Clostridium beijerinckii* NCIMB 8052. Parameter estimation imposed a constrained optimization problem where the objective was to minimize the sum of squared errors (SSE) between the predicted and observed values of components. The constrained nonlinear optimization problem was solved using `fmincon` in MATLAB 2017b Optimization Toolbox based on the interior point algorithm. Sensitivity analysis showed that Substrate affinity constant for xylose has the greatest impact on cell mass, butanol, glucose and xylose concentrations. In addition, yield coefficients were critical parameters for butanol concentration. The main contributions of this paper can be stated as below:

1. This is the first study which addresses the dynamic modeling of utilization of lignocellulosic sugars in mixed form for butanol production.
2. This paper provides insight into contributions of each sugar to cell mass growth and butanol formation by parameter estimation of yield coefficients.
3. The proposed model is the first attempt to incorporate the interaction between sugars.

The methodology we proposed provides an understanding in the dynamics of the butanol production from glucose and xylose, and it can further be used for guiding optimal process design and operation.

Abstract

Keratin rich waste material is an abundant by-product from the agroindustry, particularly the meat and poultry industries: skin remains, bristle, animal hair, horns and hooves, feathers, etc. This waste may not be incinerated due to environmental concerns, so producers seek waste valorization by upcycling this non-biodegradable by-product by depolymerization to extract soluble proteins, which can be used as animal feed supplements. This can be performed thermally, however high temperature processing destroys amino acids which are necessary in the product and are costly to later supplement. A novel two-stage enzymatic de-polymerization process for keratin is being investigated. The first stage involves growing the microbial keratinases on a substrate sample, and is optimized for maximal enzyme production. The second stage uses the keratinases in a bioreactor optimized for substrate hydrolysis. The enzymatic hydrolysis mechanism for keratin is not well documented rendering current the current industrial application limited. This paper presents lab scale experimental results from the second (hydrolysis) stage using a keratinolytic enzymatic cocktail with the filamentous bacterium *Amycolatopsis keratiniphila D2* (DSM 44409). Dynamic state data for the product (protein) and substrate (keratin) concentrations following varying substrate loading has been used to construct the first reduced order model for the enzymatic hydrolysis of waste keratin. Potential model applications include to dynamically optimize this second process stage by computing optimal dosage strategies (keratin deposit intervals and volume) to minimize processing time and cost to dispose or repurpose the biochemical waste.

Keywords: keratin, enzymatic hydrolysis, dynamic modelling, parameter estimation.

1. Introduction

1.1. Background

Keratin rich waste material is an abundant by-product from agroindustrial activities, particularly the meat and poultry industries (Daroit and Brandelli, 2014): skin remains, bristle, animal hair, horns and hooves, feathers, etc. It is estimated that five million tonnes per year of keratin waste is produced in these industries (Brebu and Spiridon, 2011), which is classified as a low-risk animal by-product. This constitutes the third most abundant renewable polymeric material present in nature after cellulose and chitin. This solid residue is not suitable for human consumption and must be treated for safe disposal, providing financial and environmental incentives for process development.

Recently, producers seek waste valorization by upcycling this non-biodegradable by-product by depolymerization to extract soluble proteins from the residual biomass to produce a saleable by-product, for example as an animal feed supplement. The aquaculture industry is one of the fastest growing sectors in food production, accounting for approximately half of the seafood consumed in the world. The availability of risk-free, easily accessible and economical feed ingredients for sustainable aquaculture production plays a key role in global food security; proteins obtained from the biodegradation of keratin could replace a significant fraction of the fish meal used in aquaculture feed formulation. Fish meal constitutes one of the main ingredients of fish feed and represents about 40% of its total weight (Fang et al., 2013), suggesting vast potential demand for such a product, under given purity and food safety specifications.

1.2. Enzymatic keratin bioprocessing

Traditionally keratin hydrolysis has been performed thermally (Jeske et al., 1976; Orzeszko and Sutarzewicz, 1979), however high temperature processing destroys amino acids necessary for the product to be used as animal feed and are costly to later supplement. Keratins are fibrous structural proteins containing many disulfide bonds in their primary structure. Based on their secondary structure, keratins, are divided into α - and β -keratin. The α -type (hard keratin) has a higher cysteine content which allows the formation of a larger number of disulfide bridges between cross-linking protein chains, rendering them water-insoluble and resistant to lysis by conventional proteolytic enzymes. Select bacteria, actinomycetes and keratinophilic fungi, have been found capable of synthesizing microbial keratinases (enzymes which hydrolyse keratins) when in an environment that the only source of carbon, nitrogen, sulphur and energy is from keratin biomass. Therefore, biodegradation using keratinolytic bacteria is an attractive way of converting keratinic waste into products of practical industrial value (Al-Musallam et al., 2003). This can include acting as a fish meal replacement in feeds for the aquaculture industry, where the product has an improved amino acid profile compared to thermal keratin processing (Korniłowicz-Kowalska and Bohacz, 2011).

Therein a novel two stage process can be performed for the conversion of keratin rich waste material into a useful protein rich product. Firstly, a keratin sample is used as a bacteria feed to promote the synthesis of microbial keratinases. Here, keratin consumption is not of interest and the process stage should be optimized solely for enzyme production and growth. Subsequently keratin hydrolysis may be performed using the enzyme produced in the previous stage. The two processes (enzyme synthesis and hydrolysis) are favoured in drastically different conditions, so staging is essential. The two stages can be physically separated via a cross-flow ultrafiltration membrane step, with each stage cyclically repeated in order to achieve semi-continuous operation.

It is desirable to perform the keratin degradation process stage at high solids loadings to maximize product titer and reduce process water, energy usage, and reactor size (Gong et al., 2015). As this is an industrial process in its infancy, the enzymatic hydrolysis mechanism is not well documented, rendering current industrial application limited. Therein lies a strong incentive for dynamic modelling of keratin hydrolysis, to facilitate high-fidelity process simulation and optimisation (Rodman and Gerogiorgis, 2017).

2. Materials and Methods

2.1. Enzyme preparation

Lab scale hydrolysis experiments have been performed using a keratinolytic enzymatic cocktail with the filamentous bacterium *Amycolatopsis keratiniphila* D2 (DSM 44409), first reported by Al-Musallam et al. (2003). The bacterium was cultivated on mineral keratin medium with the following composition: 0.75 g L⁻¹ NaCl, 1.75 g L⁻¹ K₂HPO₄, 0.25 g L⁻¹ MgSO₄·7H₂O, 0.055 g L⁻¹ CaCl₂, 0.010 g L⁻¹ FeSO₄·7H₂O, 0.005 g L⁻¹ ZnSO₄·7H₂O and 1% w/w poultry by-product meal (PBM) keratin powder. The medium is sterilized at 121 °C (20 min), and free keratinase extract is obtained for hydrolysis.

2.2. Keratinase activity screening

To screen for suitable reaction temperatures, enzymatic activity was monitored over time following isothermal incubation by assaying with azokeratin as a substrate. A range of temperatures were screened between 30 and 50°C, where an inherent trade off exists between increased initial activity and increasing activity decay rate. It was found that at 40 °C the activity was suitably high and did not decay prohibitively quickly, and has thus been implemented as the experimental and model reaction temperature.

2.3. Dynamic state data

Vials containing 2 mL keratinase preparation and varying solids loading (PBM meal) were placed in a thermoshaker at 40 °C and 600 rpm. At fixed time intervals, triplicate vials were removed for each solid loading considered. A sample from each vial was taken and the protein content determined by bicinchoninic acid (BCA) assay, and the remaining vial contents vacuum filtered, dried and weighed to determine residual substrate mass. Two campaigns were performed: firstly, initial reaction kinetics for four substrate concentrations (1.5, 3, 5 and 7% w/w) were considered with samples taken over time in the first hour, a period in which the consumption rate is approximately constant at the maximum (initial) value. Secondly, three substrate concentrations were considered (3, 5 and 7% w/w) with the hydrolysis performed for 72 h to construct state profiles for both substrate, $[K]$, and product, $[P]$, throughout the entire reaction duration.

3. Experimental Results and Dynamic Model Parameter Estimation

The keratinase activity profile at 40 °C can be seen in Fig. 1a, with Fig. 1b representing the initial substrate consumption rates at differing solid loadings. The gradients from Fig. 1b are used in the Lineweaver-Burk plot (Fig. 1c) to elucidate initial reaction kinetics. Fig. 2 presents the experimental state data over a 72-hr experimental campaign.

Figure 1. Enzyme activity, initial reaction rates and Lineweaver-Burk plot ($T = 40\text{ }^{\circ}\text{C}$).

Based on the experimental results, the following model is proposed for the enzymatic hydrolysis of keratin. The substrate is considered to consist both hydrolysable, $[K]_H$, and non-readily hydrolysable, $[K]_{NH}$, components (Eq. 1), where the later refers to keratins which *A. keratiniphila D2* is unable to digest. The hydrolysable fraction, H , is defined by Eq. (2). The consumption rate of the readily hydrolysable substrate is considered as the product of three factors (Eq. 4). Firstly, the Michaelis–Menten expression, φ_1 , describes the reaction kinetics (Eq. 5). Secondly, φ_2 relates to the keratinase activity: this term differs from a conventional two parameter first order activity decay expression by the addition of residual activity (R_A). This is a result of an enzyme cocktail being present in place of a single cell type, where components of the cocktail have drastically differing decay timescales at this reaction temperature. The residual activity represents the activity of the cells that do not notably decay within the hydrolysis timescale, which is visible from the activity in Fig. 1a plateauing well above 0. Lastly, an inhibition term, φ_3 , is considered as a function of the product concentration (Eq. 7), representing the proteins being produced impeding the keratin-enzyme interaction. A product ratio, f , relates protein production to substrate consumption, with the remainder of the consumed substrate mass consisting of released fats, lipids, peptides etc.

$$[K] = [K]_{NH} + [K]_H \quad (1)$$

$$[K]_H = H \cdot [K] \quad (2)$$

$$\frac{d[K]_H}{dt} = -r \quad (3)$$

$$r = \varphi_1 \cdot \varphi_2 \cdot \varphi_3 \quad (4)$$

$$\varphi_1 = \frac{V_{max} \cdot [K]_H}{K_M + [K]_H} \quad (5)$$

$$\varphi_2 = [E] = e_i \cdot \exp(-k_D \cdot t) + R_A \quad (6)$$

$$\varphi_3 = \frac{K_I}{K_I + [P]} \quad (7)$$

$$\frac{d[P]}{dt} = f \cdot r \quad (8)$$

Figure 2. Dynamic model trajectories vs. experimental data for substrate and product.

Table 1. Dynamic model parameter values computed for enzymatic keratin hydrolysis.

Parameter	Symbol	Value	Units	Data Source
Hydrolysable substrate fraction	H	0.63	(-)	Fig. 2
Maximum reaction velocity	V_{max}	3.20	$\text{g L}^{-1} \text{hr}^{-1}$	Fig. 1c
Michaelis–Menten constant	K_m	14.29	g L^{-1}	Fig. 1c
Initial enzymatic activity	e_i	39.96	kU L^{-1}	Fig. 1a
Enzyme decay constant	k_D	0.188	hr^{-1}	Fig. 1a
Residual enzyme cocktail activity	R_A	23.91	kU L^{-1}	Fig. 1a
Product inhibition constant	K_I	0.328	g L^{-1}	Fig. 2
Product ratio	f	0.548	(-)	Fig. 2

Of the eight model parameters, three (e_i , k_D and R_A) can be fit from the activity assay profile (Fig. 1a), whose solid line shows the fit using parameter values from Table 1. Two parameters (V_{max} and K_m) are determined directly using the initial kinetics via the Lineweaver-Burk plot method (Fig. 1c). Additionally, f can be directly inferred as the ratio between the protein and keratin state derivatives in Fig. 2, while H can be considered as the average of the total substrate fraction digested after the reaction is completed. Subsequently, the remaining model parameter, K_I , is estimated by minimizing the sum squared error between model and experimental data points, defined by Eq. 9 and solved using MATLAB (fminsearch); ode45 is used for model integration.

$$\min \sum (f(\mathbf{x}_j, \theta) - y_j)^2 \quad (9)$$

Here, $f(\mathbf{x}_j, \theta)$ is the model predicted keratin and protein state trajectory for experiment j , θ is the parameter vector and y_j is the experimental state trajectory. The data sets for 3% and 7% w/w initial substrate concentration were used in the fitting, leaving the 5% w/w profile as a supplementary dataset which is used for comparisons for model validation.

4. Discussion

It can be seen from Fig. 2 that the proposed model is able to effectively describe the key behaviour observed in the experimental data, both for keratin consumption and protein production. The dataset not used in the model parameter determination (5% w/w loading) shows good agreement between experimental data and the model prediction, suggesting the model can accurately describe keratin hydrolysis at 40 °C with *A. keratiniphila* D2. The model can be used to compute optimal substrate dosage strategies towards processing time and cost minimization in biochemical waste keratin hydrolysis.

The model assumption of a fixed fraction of the substrate being hydrolysable, H , is not able to fully capture the observed phenomena where yield decreases with solids loading. As a result, the model under-predicts keratin consumption at 3% w/w solids, and over predicts for 5% and 7% w/w (Fig. 2). If the value of H is defined individually for each solid loading campaign according to the observed experimental yield in that campaign and the model parameters re-determined, the fit is exceptional. This indicates that if the mechanism behind diminishing yield with increasing substrate concentration can be incorporated into an updated model it would be even more accurate in representing the dynamic system. It is known that as solids loading increases, factors that were insignificant in low-solid systems become more prominent (Modenbach and Nokes, 2013), which can restrict substrate conversion yield at higher loading and is found to be the case here. It is possible that mass transfer between the keratin and enzyme is becoming impeded at high substrate concentrations due to reduced free water content as the liquid absorbs into the biomass, as has been observed in high-solids enzymatic

cellulose hydrolysis (Hodge et al., 2009), a reactive system known to have many parallels to keratin hydrolysis; however further experimental work is necessary to confirm whether this is the precise mechanism responsible for the observed phenomena. Moreover, further experimental work to investigate parameter temperature dependence will have great value towards process development, facilitating model implementations towards simultaneous optimization of reactor temperature profile and keratin dosing.

5. Conclusions

The hydrolysis of keratin rich material with keratinolytic bacteria is an attractive way of transforming undesirable waste from agroindustrial activities into products of practical industrial value. A lab-scale experimental campaign has been performed, enabling the successful parameterization of a dynamic model for enzymatic hydrolysis of keratin. Michaelis–Menten kinetics with product inhibition allows the observed behaviour of the reactive system to be captured, with the model fit showing good agreement with experimental data. The development of such a model is an important contribution towards improving the competitiveness of this novel means of waste valorization via computational simulation, optimization and development of hydrolysis reactors. The model assumption of a fixed fraction of the substrate being hydrolysable cannot fully capture the observed phenomena, inasmuch as yield decreases with solids loading. Further experimental work is necessary to explore this advance, with the aim of better describing the apparent inhibition effect at higher substrate content, thus increasing model fidelity and enabling dynamic optimization of the keratin hydrolysis reactor.

Abstract

Lignocellulosic biomass, like oil fractions, is a source of hydrocarbons. The transformation from biomass to liquid hydrocarbons passes by several processes: pretreatment, conversion, followed by post-treatment. In one of the possible transformation schemes, the biomass undergoes fast pyrolysis, and the produced bio-oils are upgraded through hydroconversion and hydrotreating. Similar to the heavy oil fractions, bio-oils are complex mixtures and, consequently, they have a complex reaction behaviour. For this reason, in the present work, the reaction pathways of model molecules representative of bio-oil are studied under hydrotreating conditions over a NiMo/Al₂O₃ catalyst. To simulate the various transformations, a kinetic Monte Carlo method, called Stochastic Simulation Algorithm, is applied to guaiacol, furfural and D-glucose and compared to the experimental results.

Keywords: Bio-oil Model Compounds, Hydrotreating, Kinetics, Monte Carlo.

1. Introduction

To face the actual energetic dilemma, eco-friendly technologies are being studied. From the array of renewable energies, biomass takes a prime role, as it presents a higher energetic potential. This source, like the petroleum fractions, is a carbon-based reserve. It can therefore be transformed into chemical building blocks and fuels. In order to achieve this goal, biomass must undergo several transformations: biomass pretreatment, conversion, and upgrading. In one of the possible transformation schemes, the biomass undergoes fast pyrolysis to transform it into intermediate compounds such as bio-char, gases and bio-oil. These substances are subsequently upgraded and valorised. Through a dedicated upgrading process scheme that includes a series of hydrotreating and hydroconversion steps, the fast pyrolysis bio-oil is converted into valuable products.

Both the hydrotreating and hydroconversion steps have been studied by the scientific community (Elliot, 2007; Wang et al., 2013; Zacher et al., 2014). However, driven by the difficulty in understanding the bio-oil complexity, several authors turned to representative single model compounds and mixtures of these (Furimsky, 1999; Wang et al., 2013). Through these models, the reaction mechanisms, both of single molecules and mixtures, began to be documented. However, such type of experimental studies is not sufficient to uncover the global reaction network of actual bio-oils.

The present work proposes a new approach to investigate the reaction networks and the reactivity of bio-oils. A “on-the-fly” method, termed Stochastic Simulation Algorithm, allows the construction of a modelling and simulation tool for the conversion of bio-oil. This technique generates the reaction network while the simulation is unrolling thereby

avoiding the pre-definition of the bio-oil reaction pathways. Already applied to complex oil fractions (Oliveira, 2013; Oliveira et al., 2016; Lopez-Abelairas et al., 2016), this tool promises a potential solution for unravelling the global reaction network of bio-oils. Limited by the feed complexity, the present work will focus on the transformation of model compounds.

2. Model Development

The Stochastic Simulation Algorithm (SSA) (Gillespie, 1976; Gillespie, 1992) is based on the randomness of events, which can be represented by their occurrence probability. This algorithm is a kinetic Monte Carlo (kMC) method, which describes the evolution of a molecular system, molecule by molecule, and event by event. Unlike classic procedures, this method can describe the evolution of a molecular mixture over time without a pre-defined reaction network.

The stochastic approach is based on the identification of all possible reaction events at a given moment in time and on the calculation of the reactivities for each event, through the stochastic rate parameter (c_v) and the several combinations in which the reactants may collide and react (h_v). As described by Gillespie (1976; 1992), for monomolecular reactions, as in the case of hydrotreating reactions with hydrogen in excess, the combinatorial parameter equal 1, as there is only one possibility of collision. Furthermore, for the same type of reactions, Gillespie (1976; 1992) showed that the stochastic rate parameter can be determined by the deterministic rate parameter (k_v). Combining this information with the Arrhenius law, the stochastic rate parameter is given by Equation (1).

$$c_v = c_v(T_{ref}) \exp\left(-\frac{E_a}{R} \left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right) \quad (1)$$

where c_v is the stochastic rate constant of the reaction type v at the reaction temperature, $c_v(T_{ref})$ is the stochastic rate constant of the reaction type v at the reference temperature T_{ref} , E_a is the activation energy, R is the ideal gas constant, T is the temperature of the system, and T_{ref} is the reference temperature.

After calculating the apparent first order rate coefficients for the reactions, the reaction probability can be generated for each reaction event, as shown in Equation (2).

$$P_v = \frac{h_v c_v}{\sum_i^M (h_i c_i)} \quad (2)$$

By assembling all the probabilities of all molecules, the overall reactivity allows to determine, via Monte Carlo sampling, the time interval until the next reaction. A first random number (RN_1) is drawn to determine the reaction time step (Δt) between the current time t and the time at which the next, yet undefined, reaction will occur. This reaction time step is calculated by Equation (3), as proposed by Gillespie (1976; 1992).

$$\Delta t = -\frac{\ln(RN_1)}{\sum_i^M (h_i c_i)} \quad (3)$$

A second random number (RN_2) is drawn to select, from the normalized discrete probability density function (D_R), the next reaction (μ). More precisely, the reaction selection step is performed by drawing a number between zero and one. The value of this random number selects the next reaction from the cumulative probability distribution (D_R), as shown in Equation (4).

$$D_R(\mu-1) < RN_2 < D_R(\mu) \quad (4)$$

After calculating the time step and selecting the reaction, the reaction system is updated by executing the selected reaction, i.e. replacing the reactant(s) by the product(s), and incrementing the simulation time according to reaction time step (Δt). The simulation proceeds reaction by reaction, through the sampling of the mentioned variables. The procedure is repeated until the final simulation time is reached, leading to the set of product molecules.

The SSA requires as inputs a list of reactant molecules, the different types of reactions that can occur and the kinetic parameters associated to these transformations. Due to its stochastic nature, this method generates a different outcome for each simulation. Therefore, as with any stochastic approach, the method has to be based on several simulations, each of which calculates discrete time trajectories of molecular populations. Their average profile will converge to the same results as deterministic methods.

3. Results and Discussion

For the simulation of the hydrotreating of guaiacol, furfural and D-glucose (fructose), the reactions for demethylation, demethoxylation, transalkylation, dehydrogenation, hydrodeoxygenation, decarbonylation and hydrogenation of unsaturated bonds and rings were implemented. For the various model molecules, the SSA method is able to predict the expected trends, not only for the conversion of the reactants, but also for the generation of the various products and for the hydrogen consumption. Additionally, this approach also predicts the transformation of the intermediates into smaller molecules.

Due to the high reactivity of the model compounds, the heating and cooling periods contribute significantly to the overall conversion. Hence, the reactor simulations need to account for these dynamic periods.

3.1 Guaiacol simulation and kinetic model

The first application of our kinetic model has simulated the hydrotreating of guaiacol. The model results were compared to the experimental data obtained by Ozagac (2016) for the hydrotreating of guaiacol over a NiMo/Al₂O₃ catalyst in a batch reactor at 13 MPa and 300 °C and for reaction times of 3 h and of 5 h. For the experiments, a blank run was performed and showed an initial conversion of 10 % after the heating up the batch reactor to 300 °C and cooling it down to ambient temperature.

For the conversion of guaiacol into hydrocarbons, only the hydrogenation of rings, demethylation, demethoxylation, transalkylation, and hydrodeoxygenation reactions

were considered. The kinetic parameters of the reactions were estimated based on the guaiacol conversion for the three batches. For all these reactions, the same energy of activation was considered in order to reduce the number of kinetic parameters to be estimated. The reactions during the thermal history of the experiments (heating, reaction and cooling) were also taken into account.

A good agreement is observed with the experimental results, as shown in Figure 1 and Figure 2. The model predicts, within the error of the experimental data, the correct order of magnitude for the conversion of guaiacol and the selectivities towards methanol, phenol and dialcohols.

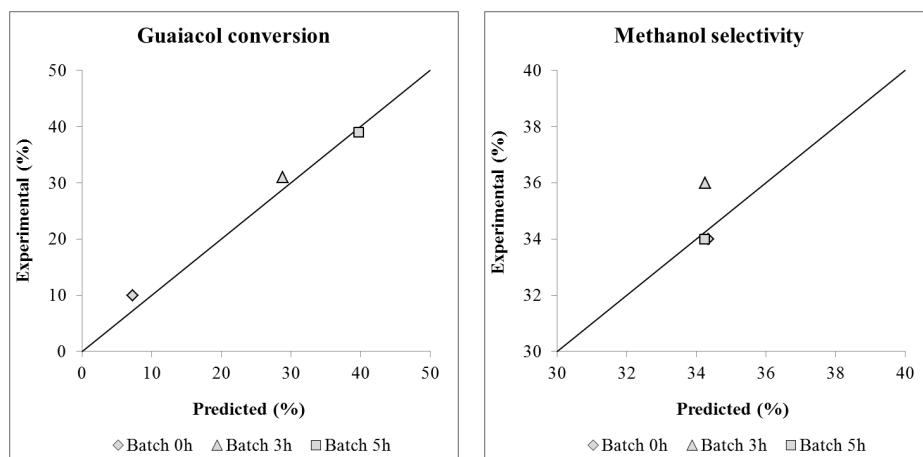

Figure 1 - Stochastic simulation of guaiacol hydrotreating based on the average of 50 simulations with 10000 molecules: a) Guaiacol conversion (%), b) Methanol selectivity (%).

Figure 2 - Stochastic simulation of guaiacol hydrotreating based on the average of 50 simulations with 10000 molecules: a) Dialcohols selectivity (%), b) Phenol selectivity (%).

3.2 Furfural and D-Glucose simulation

By extrapolating the kinetic parameters obtained for guaiacol according with Elliot (2007) reactivity scale, it is possible to simulate the hydrotreating for both furfural and D-glucose.

Similar to the guaiacol simulation, the reactions considered represent only the conversion of furfural and D-glucose into hydrocarbons. For the dehydrogenation, hydrodeoxygenation, decarbonylation and hydrogenation of unsaturated bonds and rings, the same energy of activation was once again considered. The thermal behaviour of the reactor during heating, reaction and cooling was again taken into account.

The simulations for both compounds were performed at 13 MPa and 300 °C during 1 h. As shown in Figure 3, the disappearance of furfural (monoaldehyde) is leads to the generation of monoalcohols, by hydrodeoxygenation, and hydrocarbons, by decarbonylation, as seen in the experimental results of Ozagac (2016).

Figure 3 - Stochastic simulation of furfural hydrotreating based on the average of 50 simulations with 10000 molecules: Major compounds fraction (%).

Figure 4 - Stochastic simulation of D-glucose hydrotreating based on the average of 50 simulations with 10000 molecules: Major compounds fraction (%).

The gradual loss of the hydroxyl group, as shown in Figure 4, reflects a transformation of D-glucose via dehydration and hydrodeoxygenation. As seen in the experimental results of Ozagac (2016), both pathways are the main conversion routes of D-glucose into hydrocarbons, thus illustrating the consistency between the simulations and the experimental results.

4. Conclusions

The SSA methodology was applied to bio-oil model molecules. The kinetic model generated is able to simulate the reactions of guaiacol under hydrotreating conditions. The simulations showed the correct trends when compared to available experimental data. The model was also used to simulate the hydrotreating for both furfural and D-glucose. Access to further experimental data will allow to compare these simulations to experimental data, and to improve and extend the proposed kinetic model.

The results presented here also show that the SSA method is an excellent simulation tool for complex reaction networks without the need for a pre-defined reaction network. Additionally, these simulations enable a better understanding of these systems, making the SSA method suitable to be applied to a full range bio-oil.

Ontology Modelling for Lignocellulosic Biomass: Composition and Conversion

Madeleine Bussemaker*, Nikolaos Trokanas, Linsey Koo, Franjo Cecelja

Univeristy of Surrey, Guildford GU2 7XH, UK

m.bussemaker@surrey.ac.uk

Abstract

This paper presents an expansion of an already developed ontology BiOnto (Trokanas, Bussemaker, Velliou, Tokos, & Cecelja, 2015) and processing technology eSymbiosis ontology (Raafat, Trokanas, Cecelja, & Bimi, 2013) towards valorisation of lignocellulosic biomass. The ontology provides a reference model interpretable by humans and computers by further classifying and characterizing lignocellulosic biomass (LCB) in several ways, such as: lignin, hemicellulose and cellulose content, C5 and C6 composition, elemental composition, and heat value. Similarly, LCB processing technologies are classified and characterised based on the input of LCB components, with related conversion rates of specific components. The combination of these classifications can elucidate additional information to assist in decision making for the ontology user. For example, the theoretical conversion rates of C5 and C6 polymeric sugars to ethanol are 0.5987 and 0.5679, then by employing the inference capabilities of the knowledge model, the user can gain insights into theoretical ethanol yields for various biomass types based on their C5 and C6 polymeric composition. This can also be applied to theoretical and actual yields of technologies modelled within the ontology, providing a useful reference tool for biorefinery development.

Keywords: lignocellulose, ontology, biomass, biorefining.

1. Introduction

In the process engineering ontologies are commonly used for knowledge representation. Historically, their potential has been recognised in many different domains such as the biomedical (Musen et al., 2012), legal (Casellas et al. 2011), financial (Montes et al. 2005), agricultural (Soergel et al. 2006), as well as chemical and process engineering.

Lignocellulosic biomass (LCB) is an attractive feedstock for numerous biorefining processing technologies due to its low cost, abundance and widespread availability. The technology configuration for LCB biorefining varies according to the desired end products and LCB composition. In addition, the characteristics of the conversion of the LCB depends on the characteristics and composition of the feedstock LCB. For example, pyrolysis to bio-oil, hydrolysis and fermentation to ethanol, anaerobic digestion for bio-gas and pelletisation for heat fuel are all processes that convert LCB based on alternate characteristics of the feedstock such as heating value, carbohydrate content, sugar composition, and lignin components. Therefore and as proposed in this paper, it is of interest to model the knowledge available around lignocellulosic biomass, to capture its development to enable facile analysis of biomass conversion potential for various applications. To the best of the authors' knowledge this is the first presentation

of the knowledge modelling of LCB to this level of detail for conversion using a range of technologies. This in turn can assist in decision making for the development and operation of LCB biorefineries.

2. Biomass Classification and Characterisation

The BioOnto ontology structure has been described previously (Trokanas, Bussemaker et al. 2015). In brief, this includes the classification of biomass as a material and using the following material properties: *PlatformMaterial*, *MaterialbyPhysicalForm*, *FeedstockMaterial*, *WasteBiomass* and *Other*. Here the names of the properties are self-explanatory.

The volatile nature of biomass makes it essential to characterise different types of biomass in detail. Characterisation addresses many aspects of the biomass, mainly focusing on the characteristics that affect its processing. In BiOnto, all types of biomass are characterised to primarily reflect composition of interest, which are further enhanced by introducing the restrictions on properties with user defined ranges (Figure 1).

Figure 1 Restrictions for Paper

In cases where more complex information is required, characterisation is extended to include other composite elements of biomass. Looking for example at certain types of lignocellulosic biomass, information vital to decision making goes beyond the content of cellulose, hemicellulose and lignin to the specific composition of these three building blocks. The example of Aspen, a type of hardwood, is presented in Figure 2. Again here the names of ontology classes and properties are self-explanatory.

Figure 2 Characterising Aspen

To achieve this level of detail it is also important to take advantage of the advanced expressivity of ontology language OWL2 (Welly et al. 2004) and more specifically the keyword 'that', which enables one level of reification statements.

An excerpt of a detailed characterisation of the composition for lignocellulosic biomass types is presented in Table 1.

Table 1 LCB Characterisation

	Cellulose (C6)	Hemicellulose (C5 and C6)	Lignin
Aspen	53.02	27.04	19.09
Poplar	43.67	19.55	27.23
Switchgrass	33.75	26.02	16.82
CornStover	37.4	27.3	18
Mixed hardwood	42.6	18.7	28.3
Loblolly Pine	43.6	21.2	26.8
Eucalyptus	46.7	13.8	29.4

Then, additional detail such as the sugar components of the hemicellulose within the biomass are also modelled (Table 2).

Table 2. Composition of Hemicellulosic components of LCB

	Xylan (C5)	Arabinan (C5)	Mannan (C6)	Galactan (C6)
Aspen	19.09	4.24	2.12	1.59
Poplar	15.63	0.71	2.27	0.94
Switchgrass	22.13	2.81	0.19	0.89
CornStover	21.1	2.6	1.6	2
Mixed hardwood	15.1	0.5	2.1	1
Loblolly Pine	6.6	1.6	10.8	2.2
Eucalyptus	12.3	0.2	0.6	0.7

One of the complexities of biomass is the reporting of composition and the non-uniformity of compositions of various feedstocks. For instance, hemicellulosic sugars are often reported as their polymeric form (xylan, mannan, galactan, arabinan), of the corresponding monomers (xylose, mannose, galactose, arabinose). However, within the plant the hemicellulose actually occur as combinations of these components, such as arabinoxylans, glucomannans, xyloglucan and glucuronoxylans which are composed of the monomeric sugars, including glucose. Current technologies are mostly aimed at conversion of the sugars in biomass which relies on knowledge of the C6 and C5 sugar composition which can be inferred from the hemicellulosic and cellulosic composition. As biorefining technologies are developed, alternative targeted approaches to other biomass components are likely such as recent interest in arabinoxylans. Hence the ontology provides a method/framework to catalogue biomass types for varieties of uses.

3. Biorefining Processing Technologies Classification and Characterisation

The ontology part representing biorefining technologies consist of 3 sub-ontologies: i) ByProcessType, ii) ByProcessStage and iii) ByProductHeatingValue, as described previously (Trokanas, Bussemaker et al. 2015).

Biorefining technologies have been modelled in detail to widen the scope of potential applications. Each biorefining technology in BiOnto, has been modelled in terms of

feedstock materials, output products and by-products. Operational characteristics have also been modelled for each technology. These include conversion rate, required/permissible moisture content, operating temperature and product heating value. This information has been modelled using restrictions on properties. The example of a fixed bed gasifier is presented in Figure 3. The restrictions in Figure 3, describe FixedBedGasifier technologies, which is defined having a conversion rate between 60-80%. The same technology has a defined range of product heating value (≤ 5) that leads to the reclassification of this technology as a low heating value technology.

Figure 3 Fixed-bed Gasifier Restrictions

In addition to the cataloguing of technologies, theoretical yields have been modelled based on known stoichiometry, assisting the user in decision making at a more granular level. Often technologies give an overall conversion rate, however in reality, if considering an alternate biomass, the conversion rate will be more dependent on the composition of the biomass. For example, the reactions and theoretical conversion rates of hydrolysis and fermentation, which are dependent on the C5 and C6 sugar composition within the biomass type. Here we show the example of the C5 hydrolysis and fermentation below:

Hydrolysis:

Every process is explicitly defined in the ontology, as demonstrated in Figure 4 and Figure 5.

Figure 4 Hydrolysis model

Fermentation

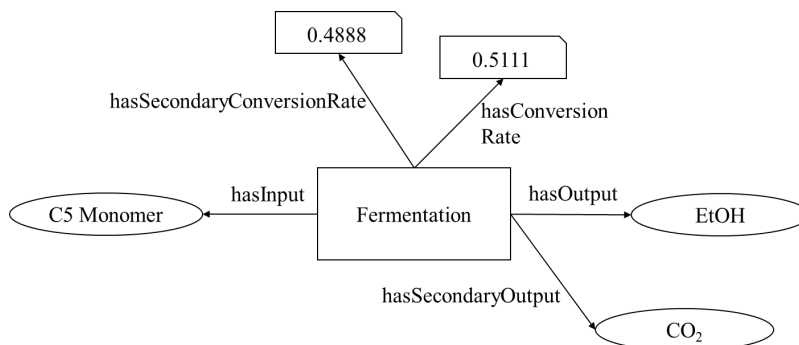

Figure 5 Fermentation model

The explicit modelling of each process, in combination with the graph nature of the ontology, allow the extraction of new knowledge, in the form of valorisation paths for inputs as well as processing paths for targeted outputs. This is achieved with the use of semantic rules. The following rule, modelled in SPARQL, identifies potential paths for a specific input (?targetInput) and constructs a new process in the ontology model. The new process is characterised by a new theoretical conversion rate, derived from the individual conversion rates from the processes involved. The new process is also linked to each step, to provide a level of provenance for the user.

```

CONSTRUCT {
    ?newProcess a Process .
    ?newProcess hasOutput ?output2 .
    ?newProcess hasInput ?targetInput .
    ?newProcess hasConversionRate ?overallConversion .
    ?newProcess hasStep1 ?process1 .
    ?newProcess hasStep2 ?process2 .
}
WHERE {
    ?process1 hasInput ?targetInput .
    ?process1 hasOutput ?output1 .
    ?process1 hasConversionRate ?rate1 .
    ?process2 hasInput/^hasOutput ?process1 .
    ?process2 hasConversionRate ?rate2 .
    ?process2 hasOutput ?output2 .
    BIND(?rate1 * ?rate2 AS ?overallConversion)
    BIND(UUID() AS ?newProcess)
}
    
```

In the case of the processes presented in Figures 4 and 5, the new conversion rates are calculated as:

$$1 \text{ ton C5 polymer} = \frac{69}{117} \text{ ton EtOH}$$

$$1 \text{ ton C6 polymer} = \frac{46}{81} \text{ ton EtOH}$$

4. Using BiOnto

BiOnto has been developed in order to expand the previously developed ontology for industrial symbiosis, called eSymbiosis ontology (Cecelja, Raafat et al. 2015). However, it has the potential to support other applications, serving as a common vocabulary and classification of biomass and bio-processing technologies. Current implementation supports selection of Biomass Type, Output and Platform material. The characterization allows for investigations into biomass types and theoretical yields using the information provided by the ontology. For example, if the user is interested in theoretical ethanol yields from various biomass types. It also has a potential to support various aspects of biorefining decision making, the aspects which is currently being tested in practice.

5. Conclusions

The presented ontology models biomass and biorefining technologies in detail, allowing the ontology to be used in a range of applications. Validation was performed through case study in Industrial Symbiosis domain where the ontology was used to collect information from the users and identify symbiotic matches between available feedstocks and technologies. Further testing was performed with data and model integration approach in the domain of biorefining. However, BiOnto is open to other applications as well. Future plans include the use of BiOnto to enable model and data integration in biorefining domain and incorporation of the ontology in the decision making process of value chain modelling for biorefineries.

Abstract

Non-ideal mixing is an important challenge in industrial scale enzymatic hydrolysis reactors. This work, therefore, optimizes a hydrolysis reactor after considering non-ideal mixing. The flow rate of heating fluid was used as the decision variable for maximization of glucose problem, and flow rate of the heating fluid and enzyme loading was used as decision variables for maximization of profit problem. The non-ideal mixing was represented by dividing the reactor into three levels and each level comprising 12 compartments connected to each other by circulation and exchange flows. Multiple cases with the substrate either uniformly or non-uniformly distributed in the reactor were studied. It was observed that the optimal decision variables for maximization of glucose problem were dependent on the substrate distribution for the initial hours of hydrolysis and the optimal decisions do not differ much in the later stages of hydrolysis. For maximization of profit problem, the enzyme requirement changed significantly, but the flow rate of heating fluid did not change much for the ideally mixed reactor. However, for the non-ideally mixed reactor, both the flow rate of the heating fluid as well as the enzyme requirement changed significantly. The use of optimal decisions from a non-ideally mixed reactor instead of an ideally mixed one lead to 3.19 % and 6.63 % reduction in deviation of glucose and profit from ideally mixed reactor.

Keywords: Mixing, Optimization, Cellulose, Hydrolysis

1. Introduction

Optimization of enzymatic hydrolysis of cellulose is important to improve economic efficiency by increasing yields, reducing enzyme requirements or both. However, most of the optimization studies in the literature are carried out assuming a well-mixed reaction system. This assumption is not suitable for large-scale industrial reactors and insoluble substrates like cellulose, especially at high solid loadings. Under these conditions, the problems related to heat and mass transfer are more prominent. Moreover, local hot spots for temperature and enzyme concentration may be created. This reduces the overall conversion of cellulose to glucose. Therefore, considering the non-ideality in mixing is essential. Selecting the appropriate reactor design, and impeller type are design decisions to address this problem. Impeller speed can also be manipulated to achieve better mixing. Additionally, conversion in non-ideally mixed reactors can be increased by regulating operating variables such as the rate of heating, amount and feeding rate of substrate and enzyme. Optimizing the operating variables is also desirable as it gives an additional degree of freedom to address issues of uncertainties in feedstock composition and reaction kinetics. This work, therefore, explores this option to optimize an industrial scale non-ideally mixed reactor. The

benefit of this approach is quantified by simultaneously studying the well-mixed reactor system.

The article is arranged as follows. The non-ideal mixing and cellulose hydrolysis models are explained in Section 2. Sections 3 and 4 discuss the glucose maximization and profit maximization problems, respectively, and the important conclusions are summarized in Section 5.

2. Model Description

Computational fluid dynamics (CFD) is a good method to understand the mixing behaviour. However, using a CFD model for optimization studies will lead to computational complexity. Compartment modelling approach, on the other hand, is less complicated than CFD and represents non-ideal mixing reasonably well. Cui et al. (1996) represented a reactor mixed with multiple impellers using compartment modelling approach. In this approach, the reactor is divided into smaller compartments of equal volume connected by circulation flow and exchange flow due to mixing. The flow rate generated by the circulation flow and exchange flow are functions of impeller type and dimensions (Cui et al., 1996). This model has been widely adapted in literature to study non-ideal mixing (Vrábel et al., 1999; Caccavale et al., 2011).

In this work, the approach proposed by Cui et al. (1996) was adapted for a reactor with a single impeller. The reactor was divided into three levels along the vertical direction, and each of these levels was further divided into 12 compartments of equal volume which are assumed to be well mixed. These compartments are connected to each other by circulation flow (F_C) along the radial direction and exchange flow along the axial direction (F_E). The circulation and exchange flow rates are functions of impeller geometry and mixing speed. Level 1 (top level) and Level 3 (bottom level) are mixed by circulation flow $F_C/2$ whereas level 2 (middle level) is mixed by circulation flow F_C due to proximity to the impeller. The previous studies using this approach had considered the non-ideal mixing of single phase reaction mixture. However, the enzymatic hydrolysis involves a multi-phase solid-liquid mixture. Therefore, an additional parameter representing the efficiency of multi-phase mixing was added, based on a similar approach used in literature for liquid-gas systems.

The reaction kinetics for conversion of cellulose to cellobiose and glucose in each of the reactor compartments were modelled based on Kadam et al. (2004). The thermal deactivation kinetics of cellulase (E_1) and β -glucosidase (E_2) were based on Caminal et al. (1985), where the model parameters were re-estimated using experimental data from the literature. The changes in the concentration of cellulose, cellobiose, cellulase, and β -glucosidase in every compartment due to reaction and mixing were tracked using Eq. 1. The reactor was assumed to be at an initial temperature of 298 K, and a heating fluid of 328 K was passed through the jacket enclosing the reactor. The temperature changes in the jacket and reactor compartments were modelled based on energy balance equations (Eq. 2, 3). The following equations are written for component 'i' in compartment 'h'

$$\frac{dC_{i,h}}{dt} = R_{exn_i} + \frac{F_C}{V} (C_{i,s} - C_{i,h}) + \frac{F_E}{V} (C_{i,l} + C_{i,u} - 2C_{i,h}) \quad (1)$$

$$\frac{dT_j}{dt} = \sum_{h=1}^{n_c} \beta_h \frac{US(T_{Rh} - T_j)}{V_j \rho_j C_{pj}} + \frac{(T_{in} - T_j)}{V_j} \quad (2)$$

$$\frac{dT_{Rh}}{dt} = -\beta_h \frac{US(T_{Rh} - T_j)}{V_c \rho C_{pr}} + \frac{F_c(T_{Rs} - T_{Rh})}{V_c} + \frac{F_E(T_{Rl} - T_{Ru} - 2T_{Rh})}{V_c} \quad (3)$$

$i=1,2,\dots,5$ and $h=1,2,\dots,36$.

In Eq. 1, $C_{i,h}$ is concentration of i^{th} component in h^{th} compartment. $R_{\text{ex}n_i}$ refers to the formation or conversion of i^{th} component. F_C is the circulation flow rate (m^3/s), F_E is the exchange flow rate (m^3/s), and V is the volume (m^3). $C_{i,s}$, $C_{i,l}$, and $C_{i,u}$ (g/L) are the concentration of i^{th} component in side, lower and upper compartments, respectively. In Eq. 2, T_j , β , U , S , T_{Rh} , V_j , T_{in} are the jacket temperature (K), fraction of heat transfer area available, heat transfer coefficient ($\text{kJ/h.m}^2.\text{K}$), temperature in compartment 'h' (K), jacket volume (m^3), and temperature of heating fluid at jacket inlet, respectively. β_h , T_{Rs} , T_{Rl} , T_{Ru} , and V_C are the fraction of heat transfer area available for compartment 'h', temperature of side compartment (K), temperature of lower compartment (K), temperature of upper compartment (K), and compartment volume (m^3).

This model was used to study a 3 m^3 enzymatic hydrolysis reactor. The reactor and impeller dimensions from Corre a et al. (2016) were adapted, and solid loading was 10 %. The initial cellulose and background glucose and xylose loadings were chosen based on the typical composition of acid pretreated lignocellulosic substrate. The composition used was 49 g/L of cellulose, 14.85 g/L of glucose, and 11.35 g/L of xylose. The enzyme concentration and background glucose and xylose were considered same in all reactor compartments. The mixing efficiency parameter was estimated based on mixing speed of 470 rpm and assuming that a completely mixed system is obtained in 35 h. Two different problems, namely maximization of glucose at the final time and maximization of batch profit, were solved. The economic parameters were taken from literature. The flow rate of jacket fluid was used as decision variable for glucose maximization, while flow rate of jacket fluid and enzyme loading were used as decision variables for profit maximization problem. Optimization studies were solved with the initial substrate along the the top (level 1) or bottom (level 2) or side compartments.

3. Maximization of glucose

Maximization of glucose problem was solved for batch times 12 hr to 72 hr (Fig. 1). The results showed that the optimal flow rate for non-ideal mixing was higher than that of ideal mixing for all batch times. This was because the heat supplied by the heating fluid in the reactor jacket does not reach the inner compartments effectively with non-ideal mixing and hence more heat has to be supplied to the reactor. The optimal flow rate for non-ideal mixing was 86.8 times higher than that for ideal mixing for 12 hr batch time. Non-ideal mixing in addition to small batch time was the reason for this observation. However, the difference in non-ideal and ideal mixing case reduced drastically for batch times of 24 hr and higher (Fig. 1). Availability of larger mixing time, in addition to degradation of enzyme upon exposure to higher temperature for a longer time, was the reason. It was also observed that the optimal flow rate was dependent on the initial substrate distribution in the reactor. However, this difference again diminished as the batch time increased beyond 24 hr.

The final glucose concentration was highest when ideal mixing was assumed, and the corresponding optimal heating fluid flow was used. The benefit of the proposed approach was quantified by applying the solution for an ideal reactor to a non-ideally mixed reactor ("Ideal optima" in Fig. 2), which is the conventional approach. The deviation in glucose concentration from the ideal case for this option was then compared with the deviation for optimal solution considering non-ideal mixing (proposed approach, "Non-ideal optima" in Fig. 2). The results showed that the proposed approach provided noticeable benefit as compared to the conventional approach, especially for smaller batch times. When the substrate was present in level 1,

the reduction in deviation from ideal was very less because, except the side compartment, the compartments in level 1 were not in direct contact with the walls of the reactor. However, when the substrate was present in level 3 or sides or uniformly distributed, there was a noticeable reduction in the deviation in glucose concentration from ideal.

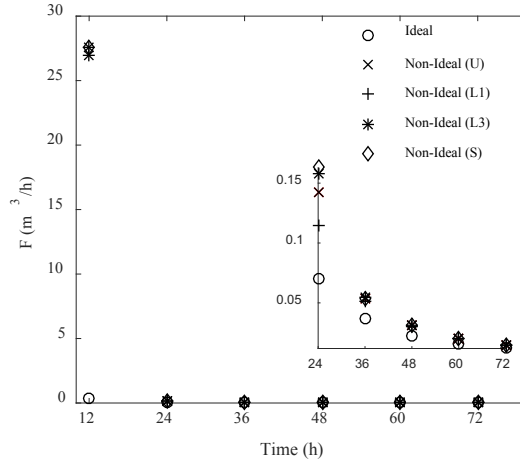

Figure 1: Flow rate of heating fluid required for maximization of glucose for the ideally mixed reactor and non-ideally mixed reactor with the different initial distribution of substrate. (U-uniformly mixed substrate, L1 - substrate in top compartments only, L3 - substrate in bottom compartments only, S- substrate along sides only)

4. Maximization of profit

The significant increase in the optimal flow rate of jacket fluid for the non-ideal case has not resulted in substantial increase in the glucose concentration. This makes the economic feasibility of the optimal solutions questionable. Therefore, the maximization of profit problem was solved with flow rate of heating fluid, enzyme loading as decision variables. The cost of enzymes E_1 and E_2 were assumed to be 368 Rs./kg and the cost of heating was assumed as 7.12 Rs./kW. The revenue from glucose was 52 Rs./kg. For ideal mixing, even though the optimal enzyme loading of both cellulase (E_{1T}) and β -glucosidase (E_{2T}) reduced, the heating fluid flow rate was similar to that for glucose maximization problem. However, for non-ideal mixing, a significant reduction in the flow rate of heating fluid as well as E_1 was observed (Fig. 3). The reduction in E_1 could be due to the high cost associated. However, E_2 , which costs the same as E_1 , was found to increase which could be because E_2 used was already low. Subjecting the reduced amount of enzymes to higher temperature will lead to loss of enzyme due to deactivation and hence reduced profit. In case of different initial distribution of substrate, all the non-ideal scenarios were less profitable than ideal one. Similar to maximization of glucose problem, significant reduction in the deviation of profit from ideally mixed reactor was observed when optimal decisions corresponding to non-ideal mixing pattern and substrate distribution was used instead of optimal decisions from ideally mixed reactor (Fig. 4).

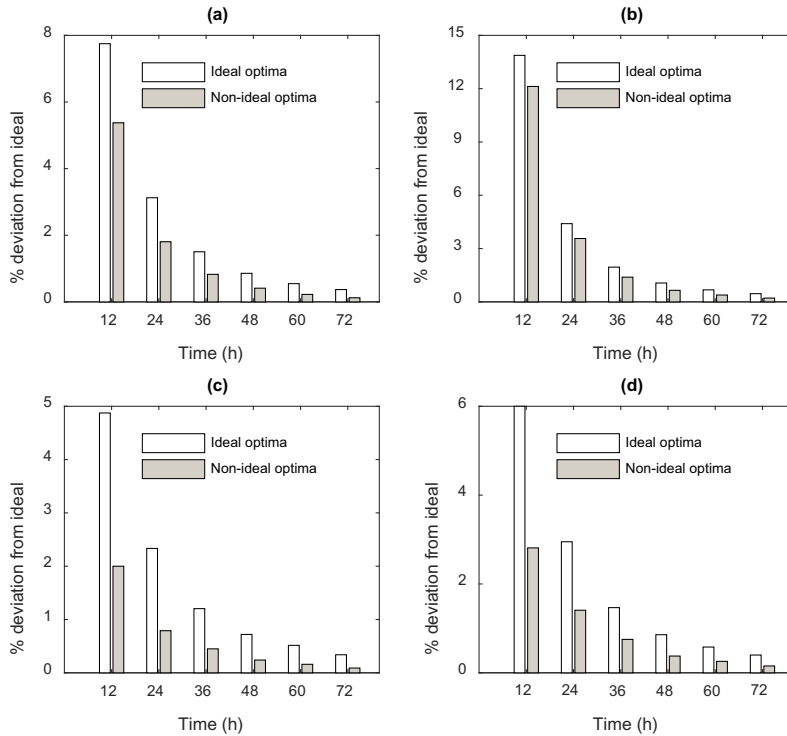

Figure 2: Glucose concentration for different initial substrate distributions with optimal flow rate of jacket fluid from ideally and non-ideally mixed reactors. (a) Uniform substrate (b) Substrate in level 1 only (c) Substrate in level 3 only (d) Substrate along sides only.

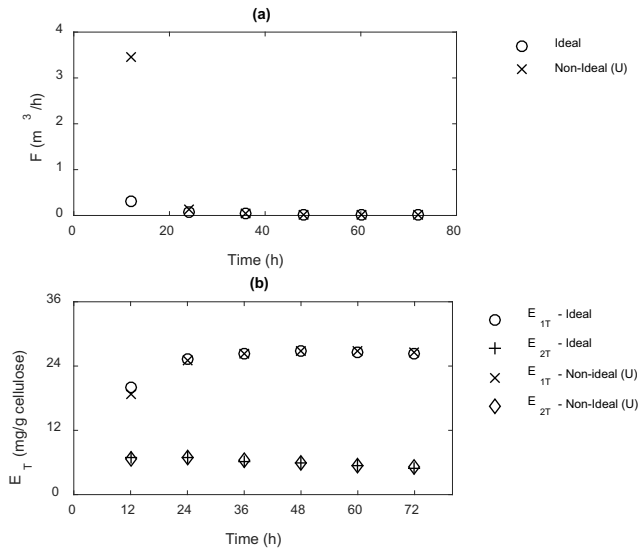

Figure 3: Flow rate and enzyme loading comparisons for ideally mixed and non-ideally (uniform substrate) mixed reactors for maximization of profit

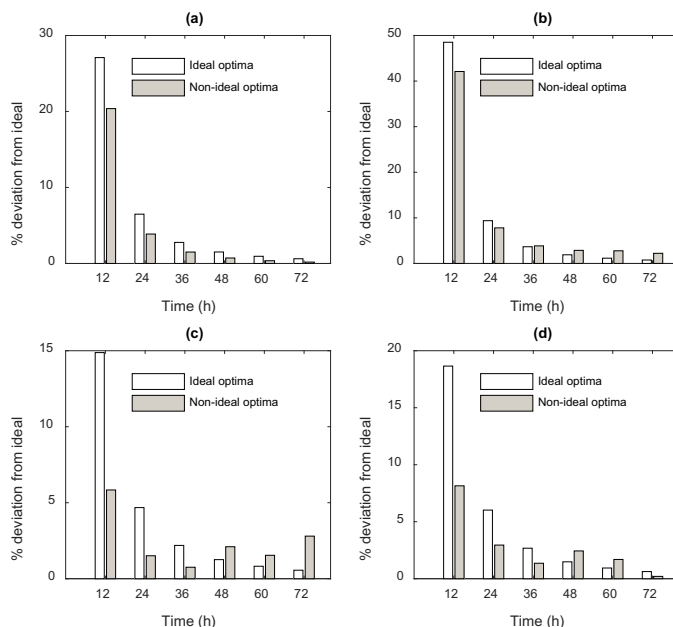

Figure 4: Profit for different initial substrate distributions with optimal flow rate of jacket fluid from ideally and non-ideally mixed reactors. (a) Uniform substrate (b) Substrate in level 1 only (c) Substrate in level 3 only (d) Substrate along sides only

5. Conclusions

This work optimized the enzymatic hydrolysis batch reactor considering non-ideal mixing. The results showed that the use of optimal decisions from non-ideally mixed reactor over an ideally mixed reactor was beneficial in terms of glucose concentration as well as profit for shorter batch times. Significant change in enzyme loading between maximization of glucose and maximization of profit problems for ideally mixed reactor was observed. For non-ideally mixed reactor, in addition to significant changes in the enzyme loading, the optimal flow rate also changed significantly between maximization of glucose and maximization of profit problems. The use of optimal decisions from a non-ideally mixed reactor instead of an ideally mixed one lead to 3.19 % and 6.63 % reduction in deviation of glucose and profit from ideally mixed reactor. These results provide guidelines for optimally operating industrial reactors.

Abstract

Biorefineries offer promising alternatives to the use of fossil fuels to produce energy and chemicals. This work describes the development of a biorefinery concept to produce adipic acid from Swedish forest residues and lutein from micro-algae. A description is provided for each process line available, its technology readiness level (TRL) and the tools available to model it. Scenarios of the integrated concept are built with associated material flow analysis. Key results of the material inventory of the base case scenario are presented as well as insights into the development of further scenarios. Material flow inventories can then be further used for economic and environmental assessment. Major challenges of integration are discussed in terms of uncertainties and data gaps for processes with low TRL such as scaling up lab experiments, understanding the restrictions of material recycling and its impact on process performance. The feedback given through these scenarios can help guide further experimental efforts.

Keywords: Process design, Process modelling, Biomass, Integrated system

1. Introduction

Problems such as climate change and resource depletion pose significant challenges in the 21st century. There is increasing pressure to find more sustainable solutions to produce energy and materials. While the use of renewable sources of energy, such as wind and solar power, can reduce the world's dependence on fossil fuels, 85 % of the chemicals used today are produced via non-renewable sources (Morales et al., 2017). Second and third generation biorefineries provide promising alternatives to the use of fossil fuels to produce energy and chemicals. In a biorefinery concept, where an array of value added chemicals are produced, mass and energy integration of the different chemical production lines is crucial to maintain the feasibility of the design concept in terms of reduced costs and environmental impacts.

The biorefinery concept described in this work combines the production of a bulk product, adipic acid (AA), from forest residues (GROT abbreviation in Swedish) in Sweden and a fine chemical, lutein, from micro-algae. AA is an important high-volume chemical that is produced from petroleum derivatives such as benzene, cyclohexane and phenol. It is mainly used in the production of nylon which has wide ranging and fast-growing applications such as in the automotive industry and footwear sectors. Lutein is a carotenoid that has several uses in the food and pharmaceutical industries. It is a high-value chemical with growing market demand. It is currently produced from marigold flowers.

The continuous development of new processes is a key factor in increasing the efficiency of biorefineries and their competitiveness. The incorporation of new concepts and process alternatives in the design phases of biorefineries can help identify more optimum process operation alternatives, as well as better integration and symbiosis potential. Technology readiness level (TRL) is a measure of the maturity of a process alternative. TRL 1 is the lowest and denotes a technology where only basic principles are reported, while TRL 9 is the highest where the technology is proven in an actual operational environment. Despite the advantages of incorporating promising new technologies in early design stages, the integration of several process lines at different TRLs is a major design challenge. The variation in the quality and sources of data could pose an obstacle to integration efforts.

This work describes the development of scenarios for the integrated biorefinery concept, the different production lines with their uncertainties at their respective TRL and the consequent challenges and restrictions of formulating and analysing integrated scenarios.

2. Biorefinery processes

Figure 1 shows the schematic of the proposed biorefinery concept and proposed production lines and their current TRLs. The different process lines can be connected through the recycling of water, CO₂, nutrients, and heat streams across the process. Optimizing key connection points is the basis for process integration efforts. In this section a description of the biorefinery, its products and investigated technologies is given as well as the data sources and modelling tools available. An accounting of integration restrictions as well as process uncertainties is also provided.

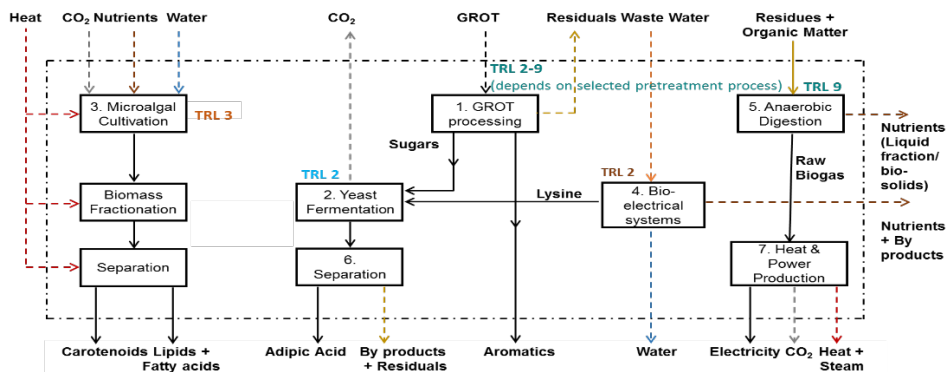

Figure 1. Biorefinery concept starting from GROT and micro-algae

Forest residues are processed to produce sugars, which are fermented to produce AA as the main bulk product. The choice of the GROT pre-treatment method can influence the range of by-products available as well as define the TRL of this process section. An effective pre-treatment method would allow for the efficient separation of lignin, cellulose and hemicellulose fractions. Steam explosion at 7 bar and 140 °C is used as a first step in the pre-treatment process to open up the biomass fibers followed by a refining step and an acidic or alkaline pre-treatment step. Pre-treatment using acids (e.g. sulfuric acid) is the conventional industrially established method. However, it suffers from several disadvantages including lower quality lignin fractions and increased impurities that may inhibit the subsequent fermentation, and thus require further processing steps (Kumar and Sharma, 2017). The use of alkaline pre-treatment maximizes the potential use of lignin as a starting material for chemical production rather than its use only as an energy source. The Kraft cooking method using sodium sulphide, hydroxide and carbonate has been extensively used in the pulp and paper industry. Another method under investigation is the soda cooking method as a sulphur free alternative to the Kraft method (Bose et al., 2009). Lignin produced from the Kraft method can be separated from the cooking liquor using the LignoBoost process, and then converted into aromatics and bio-oil by mixing the lignin with K_2CO_3 and phenol and brought to the reaction conditions at 350 °C and 25 MPa (Nguyen et al., 2014). Lignin through this process yields 27 % aromatics mainly anisoles and alkyphenols among others and 55 % bio-oil product of a higher heating value than lignin and the rest is char. Experimental data are used to carry out a material flow analysis of the steam explosion, Kraft and soda cooking methods, while literature data is used for the LignoBoost and lignin depolymerization processes. Figure 2 shows a schematic of the alkaline pre-treatment with Kraft cooking with subsequent lignin valorization processes.

Cellulose and hemicelluloses produced then go through hydrolysis which yields a mixture of pentoses and hexoses. These sugars are then fermented to produce AA via lysine in a two-step process (Burgard et al., 2013). Data regarding the conversion of glucose to lysine are obtained from experimental procedures reported in literature (Kiefer et al., 2004). There is still an ongoing exploration to find a suitable microorganism to increase yields of AA, with the major obstacle to achieving high enough rates for commercialization being the tolerance to the AA product (Karlsson et al., 2017). As such, this section of the process has one of the lowest TRLs in the biorefinery concept with many uncertainties that can severely affect the overall process. Examples of such uncertainties include the possibility of carrying out the process to produce lysine at more concentrated sugar levels than 40 mM glucose as reported in literature, which would be too dilute for commercial applications, and whether similar conversion rates and products can be expected for sugars other than glucose. Theoretically a 90 % conversion of lysine to AA is possible; however, without large scale experiments, this value remains uncertain. The effect of possible impurities from the pre-treatment section is also uncertain. The recovery of AA from the fermentation broth is rigorously modelled using the process simulation software Aspen Plus V8.8. The process features the concentration of AA through a multiple effect evaporator, followed by crystallization and filtration as shown in Figure 2.

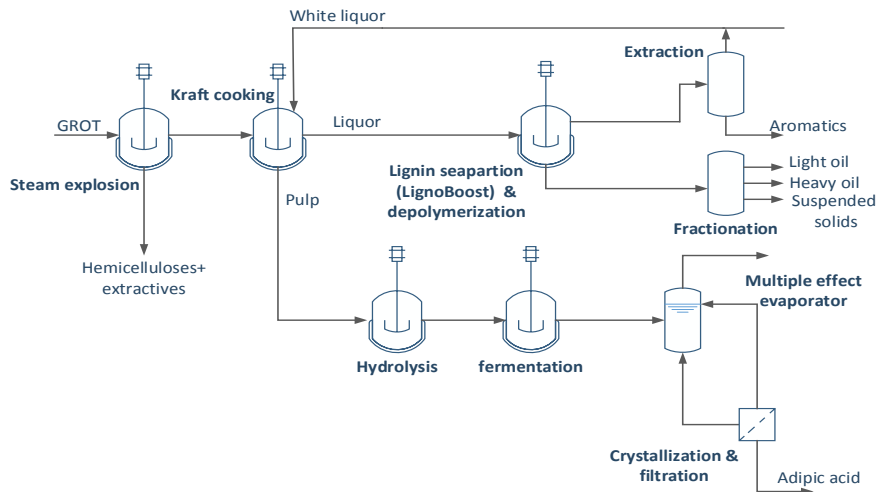

Figure 2. Major units of the alkaline pre-treatment of GROT with lignin valorization and the AA production line

The lutein production line starts with the cultivation of the micro-algae followed by flocculation, sedimentation and centrifugation. The supernatant fraction is recycled while the solid fraction is dried and methanol is used to extract lutein. The solvent is then recycled while the remaining biomass can be utilized as protein rich animal feed. Data are obtained from experimental procedures and the process is described by Mayers et al. (2016). The solvent recovery process is modelled in Aspen Plus V8.8.

Waste water streams from the process are sent to an anaerobic digestion unit to produce biogas, which is an industrially established process. Two reactor configurations are investigated for anaerobic digestion, one using a continuous stirred tank reactor (CSTR) and the other using an internal circulation (IC) reactor.

Another investigated technology with a low TRL where data are also only available at lab scale is the use of bioelectrical fermentation systems to produce chemicals such as lactic acid and lysine (Xafenias et al., 2017). This presents an opportunity for waste streams and nutrients to be utilized, while increasing the biorefinery product portfolio and enhancing the yield of AA by recycling lysine. However, a major challenge to integration efforts is the lack of data considering scale-up as well as the application to sugars other than glucose that might be present in waste streams, in addition to the inhibiting effects that impurities from waste streams or the upstream pre-treatment of GROT may incur.

3. Results and discussion

To tackle the difficulties posed by uncertainties described in the previous section, scenarios are created where all processes are simplified and represented through material and energy flow inventories. These inventories are then used to carry out capital and operating cost evaluations and life cycle assessment. All scenarios must have a pre-treatment option, an AA production line and an anaerobic digestion unit. The microalgae and the bioelectrical fermentation units are optional. Figure 3 shows the range of possible scenarios. Table 1 shows an excerpt from the material flow inventory

of the base case scenario, denoted by the dotted lines in Figure 3, where key process units are combined to produce 10,000 t/y AA: 1) the alkaline pre-treatment unit with the Kraft cooking, 2) AA production assuming conversion of only glucose at 40 mM to lysine and 90 % conversion of lysine to AA, 3) Anaerobic digestion unit and 4) the micro-algae unit with a maximum productivity 19 t biomass/ha/y and a maximum available area of 10 ha with CO₂ recycled from the AA fermentation unit.

AA currently has a market size of about 3,800,000 t/y. Extrapolating from the base case scenario presented in Table 1 shows that the production of 100,000 t/y of AA would require 1.9 Mt/y of GROT which is comparable to the entire Swedish yearly production. Physical availability of GROT is then the limit for production, where the only way to increase AA yield beyond these values is by converting other sugars that were considered inert in this scenario, given that already a 90 % conversion of lysine to AA was assumed.

Table 1 also shows that the microalgae production line and its requirements are very small compared to the size of the AA line. Lutein has a price that is 3 orders of magnitude higher than AA, but material requirements for this line can be very small in comparison to the main bulk line. For example, the microalgae line represents less than 0.07 % of the NaOH requirements in the combined process, despite being a major cost and environmental factor for the non-integrated micro-algae line. Moreover, water, nutrients, CO₂ and energy for drying can all be recycled from the main line. However, caution should be taken regarding impurities, while NH₃ present in the water streams as a by-product of AA production could be beneficial for the microalgae, other impurities such as traces of sugars could be detrimental. The CO₂ recycled should be from the fermentation unit rather than from the combustion of lignin for example, to avoid affecting the ability to market the micro-algae line products as of food grade quality.

Different scenarios would yield varying product portfolios. It is important to note that the scenarios discussed here are only those which would highly impact the process yield, but not those that would affect the performance. For example, in the microalgae line the use of chemicals for sedimentation and flocculation (e.g. NaOH) can be replaced by more intensive energy use for centrifugation, but the yield of lutein is unaffected. Another example would be the number and configuration of the evaporators in the AA line.

An understanding of the impact of impurities is crucial to continue building scenarios, e.g. the use of IC reactors in anaerobic digestion units may reduce the equipment size drastically, but such reactors are more sensitive to solid particles.

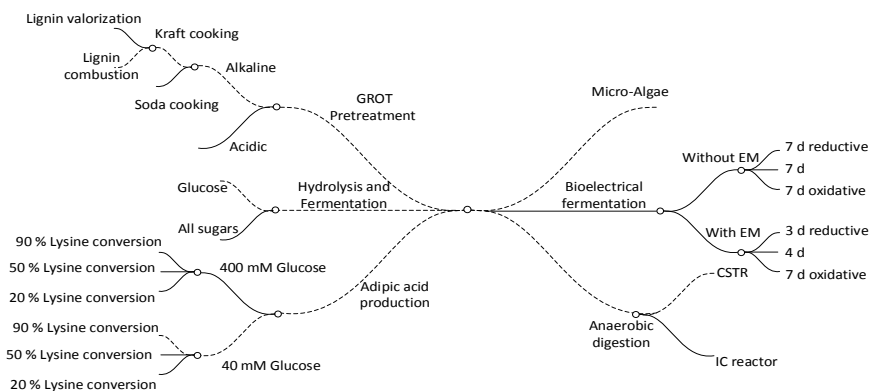

Figure 3. Depiction of the range of process scenarios. Dotted lines show chosen base case scenario.

Table 1. Excerpt from inventory analysis of base case scenario

Input	t/y	Output	t/y
GROT	190,000	Adipic acid	10,000
Methanol	750	Lignin	34,000
NaOH	2,300	Biomethane	3,000
		Lutein	0.95

4. Conclusions

This work describes the development of a biorefinery concept to produce bulk and fine chemicals. It has been shown that evaluating technologies at different TRLs can be difficult due to the uncertainties incurred at the preliminary stages of process development and varying levels of available data sources and quality. However, the questions generated at this stage may be valuable to guide further experimental efforts, e.g. by repeating experiments at expected impurity levels. Scenarios can be created to determine the cut-off levels for the feasibility of a process, e.g. minimum conversion of lysine to AA for the process to be commercially valid, or the required size of bioelectrical fermentation unit to be economically feasible within this concept. Results generated from the material and energy flow inventories of these scenarios would be used for further economic and environmental assessments. With material integration, recycling of process material including impurities is inevitable. Developing an understanding of the impacts and restrictions of material integration is crucial for further design development. It is important in the case of integrated scenarios, to identify and fully characterize the bottleneck technologies and thus determine the size of a biorefinery concept like this one.

Abstract

Integrated biorefinery concepts have become important sustainable alternatives for the production of fuels and chemicals to replace fossil feedstocks. The utilization of lignocellulosic biomass frequently requires the extractive separation of lignin from cellulose and hemi-cellulose. Minimizing solvent usage and maximizing lignin extraction help to make this process more efficient. The extraction process is often carried out in packed beds, where a uniform distribution of the solvent in the packed bed helps to maximize the contact time between solvent and particles and increase the efficiency. Computational fluid dynamics simulations can give a very detailed view about the flow behaviour and distribution in these packed bed systems.

In this study, a packed bed of particles was created using an in house discrete element method code. A packing geometry was extracted and meshed, and the flow field was solved using the open-source package OpenFOAM[®]. Radial and axial distribution of the porosity and also the velocity distribution and high velocity points along the bed were extracted and analyzed. Pressure drop and residence time distribution at different flow rates were extracted and compared.

It was observed that the pressure drop along the bed height increases non-linearly with the flow rate and the RTD narrows representing a more uniform flow through the packed bed but shorter contact time between solvent and particles.

Keywords: Computational Fluid Dynamics (CFD), Lignin, Organosolv, Extraction, Discrete Element Method (DEM).

1. Introduction

Integrated bio-refinery concepts have become important sustainable alternatives for the production of fuels and chemicals to replace fossil feed stocks (Cherubini, 2010). The utilization of lignocellulosic biomass frequently requires the separation of lignin from cellulose and hemi-cellulose. Solvent extraction of lignin using alcohol/water mixtures at elevated temperatures and pressures - the organosolv process - has recently gained more attention due to high quality sulfur-free lignin which can be produced from a variety of different biomass feedstock. A key parameter for the success of the technology is to minimize the use of solvent and maximize the lignin extraction efficiency (Sluiter et al., 2008).

Usually, the extraction process is performed in fixed bed extractors where the solvent mixture is passed over the biomass packed bed. A uniform distribution of the solvent

through the packed bed helps to maximize the extraction by increasing the contact time and surface area of the solvent. In addition, multiple solvents may be used, in the case of exchange of solvent "A" by solvent "B" minimizing the mixing of the solvents is of interest, too. Thus, the extractor design with a proper solvent distribution is essential (Delgado, 2006).

In this study, the flow pattern, wall effects, pressure drop and residence time distribution of the water/ethanol mixture through a biomass lignin extraction process using computational fluid dynamics (CFD) were investigated and the effect of flow rate on these parameters was studied.

2. Methodology

The analysis of random packings of particles poses a great challenge on CFD as the creation of the complex, unstructured geometry cannot be created with usual CAD tools. A code based on discrete element modelling (DEM) from TU Wien using particle clumps to consider non-spherical or fibrous biomass particles was used in combination with the open-source CFD tool OpenFOAM® (version 4.1, 2016) for the simulation of the flow (Haddadi et al., 2016). An automated procedure was generated to prepare the filling of the extractor geometry with arbitrary non-spherical finite geometries representing the biomass pieces, including the STL file creation and meshing through SnappyHexMesh. The developed workflow also contains the computational extraction of general packing properties, e. g. the void fraction distribution over radius or bed length. This information reveals non-ideal structures in vicinity of the walls or macrovoids inside the packing which may cause short-cuts or channelling.

3. Packing creation

Packing was created using an in-house discrete element method (DEM) code. DEM is a numerical approach for modelling large number of particles interacting with each other. There are various methods for simulating non-spherical particles. A very well established model is the multi-sphere approach. In this approach the non-spherical particles are represented by overlapping sub-spherical particles which interact just with sub-spheres from other particle clumps. However, these sub-sphere particles are smaller and have higher overlaps compared to the main particle characteristic length, resulting in a more accurate representation of the non-spherical particle. An optimum sub-sphere size is important for reasonable particle representation and computational time. The contact between sub-spheres with each other and the walls were modelled using the soft-sphere approach (Norouzi et al., 2016).

In this study, a packed bed of cylindrical rods with two different sizes was created. The particle size and DEM clumps properties are listed in Table 1.

Table 1: Particles size and DEM clump properties

	Length [mm]	Diameter [mm]	Sub-sphere diameter [mm]	Sub-sphere overlap [%]
Particle 1	30	5	5	70
Particle 2	40	4	4	70

Around 1400 particles (50 % particle 1 + 50 % particle 2) were randomly packed into a cylindrical bed with a radius of 75 mm. the particles were released from a flat plane

300 mm above the bottom of the bed. Particles had an initial velocity of 0.15 m/s along the gravitational direction. The gravity was 9.8 m/s^2 along the bed axis, the created packing consisting of the clumps can be seen in Figure 1 – a. After packing the particles into the bed the representing particles' surface stereolithography (stl) was extracted to be meshed in the next step (Figure 1 - b).

Figure 1: Created packing, a – clumps, b – stl

4. Meshing and solution

The created stl geometry was meshed using the open-source meshing tool snappyHexMesh. The packing stl file was inserted into a cubic background mesh with mesh size of 5 mm (Figure 2 – a). The base mesh was refined up to three levels on the particles edges and two levels on the particles body. In each refinement level the background mesh is divided into two cells in each direction (overall eight new cells per each refinement level). In the next step the mesh points are moved to be placed on the stl surface (snapping). The final mesh had around 2.4 million cells (Figure 2 – b, c, d).

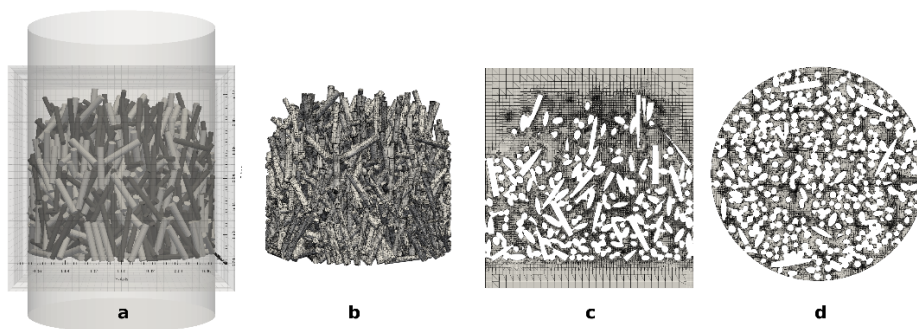

Figure 2: Mesh, a – Inserted background mesh, b – Particles mesh, c – Vertical symmetry mesh cross section, d – Horizontal symmetry mesh cross section

Fluid flow through the meshed packed bed was simulated using the open-source CFD package OpenFOAM[®]. A steady state incompressible solver was selected (simpleFoam) which was based on the semi-implicit method for pressure linked equations (SIMPLE) pressure-velocity coupling algorithm and the residence time distributions were calculated using scalarTransportFoam which solves a scalar transport equation based on

the velocity field derived from simpleFoam. The liquid used in the simulations was a 60 % volume mixture of ethanol/water entering the bed from bottom (z direction) at 0.01 m/s and exiting from top at ambient conditions (298 K and 10^5 Pa). The initial and boundary conditions are listed in Table 2.

Table 2: Boundary conditions and initial conditions

	Velocity [m/s]	Pressure [Pa]	RTD scalar [-]
Inlet	0.01	Zero gradient	1.0
Outlet	Zero gradient	10^5	Zero gradient
Walls	No slip	Zero gradient	Zero gradient
Particle 1	No slip	Zero gradient	Zero gradient
Particle 2	No slip	Zero gradient	Zero gradient
Internal field	0.0	10^5	0.0

Gravity was 9.8 m/s^2 along the bed axis. The density of the mixture was 891 kg/m^3 and the dynamic viscosity was $0.0023 \text{ Pa}\cdot\text{s}$. The Reynolds number was below 600 based on the maximum local velocity and Sauter mean particle diameter; therefore all the simulations were performed laminar.

5. Results and discussion

5.1. Radial and axial porosity

The overall porosity of the bed was around 0.61. As shown in Figure 3 axial and radial porosities are also extracted and plotted. The axial porosity shows the bed porosity along the main bed axis from bottom of the packing to the top of the packing. At the bottom of the packing because of the wall effect between particles and walls the porosity is higher, then it sharply decreases and - toward the top of the bed - it increases again representing a looser packing at the top of the packing.

Figure 3: Bed porosity along the bed height and radius (wall at a radial distance of 75 mm, top of the bed at axial distance of 100 mm)

On the other hand the radial porosity is the lowest in the centre of the bed which shows a denser packing of the particles in that region. By moving along the radius from centre of the bed toward the wall the porosity remains almost constant and then it rises close to the walls because of the particle wall effect.

5.2. Pressure drop

Pressure drops along bed height at 10 equally distanced positions were extracted and plotted. Figure 4 shows the relative pressure to the outlet (10^5 Pa) excluding the hydrostatic pressure, by moving from bottom of the bed to the top of the bed the pressure decreases, and this decrease is not linear because of the non-linearity in the bed porosity. The overall pressure drop along the bed is around 12 Pa.

Figure 4: Relative pressure along bed height

Also the inlet flow rate was varied to study the effect of the flow rate on the pressure drop along the bed height (excluding hydrostatic pressure). For this purpose the inlet velocity of the packed bed was increased from 0.01 m/s up to 0.05 m/s. As expected, by increasing the inlet velocity the pressure drop along the bed also increases (Figure 5).

Figure 5: Pressure drop along bed height versus inlet velocity

5.3. Velocity

In detailed CFD studies also the velocity distribution in the bed can be extracted and analyzed. Based on the performed simulations the highest velocity in the bed is around 0.12 m/s and occurs close to the walls. In Figure 6 velocity contour plots at different heights from bottom of the packed bed are extracted. Some high velocity spots can be observed close to the walls which show the channeling in the bed and smaller contact time between particles and liquid and consequently lower extraction performance. Also high velocity points are shown in Figure 6, all the regions with velocity higher than $8 \times$ inlet velocity are extracted and plotted. Most of these regions are close to the walls which also confirm the non-ideal distribution of the flow in the packed bed.

Figure 6: Velocity magnitude contour plots at different heights from bottom of the packed bed and high velocity points with velocity $8 \times$ bigger than the inlet velocity

5.4. Residence time distribution

Figure 7 shows the residence time distribution for the investigated packed bed at different Re numbers (particle based). By increasing Re (inlet velocity) the relative breakthrough time is slightly reduced, but the slope of the sigmoidal breakthrough curve is higher. The RTDs clearly show strong non-ideality in the flow structure in the packing.

Figure 7: RTD curve at different Reynolds numbers

6. Conclusion and outlook

In this study organosolv solvent flow over a packed bed was investigated. A packed bed geometry of two different types of cylindrical particles representing straw-like biomass was created using an in-house DEM code. The required stl file of the packing geometry was also generated by the in-house DEM code, and a mesh was prepared in OpenFOAM[®]. A generic workflow is now available to generate packings from multiple arbitrary non-spherical particle geometries.

Porosity distribution along the bed height and bed radius were extracted and analyzed. In addition, pressure profiles and pressure drops in the bed were investigated at different flow rates, and high velocity points in the bed were extracted. Most of the high velocity points were close to the walls due to higher porosities in the near-wall regions. Significant non-idealities in the fluid flow occur in these type of beds. As a consequence, liquid redistribution plates or other design measures may be required to improve the extraction process. As a next step, the lignin extraction process – dissolving lignin from the biomass particles resulting in a species source term in the extraction fluid – will be implemented based on previous CFD studies of adsorption processes (Haddadi et al., 2016).

jkim21@khu.ac.kr

Abstract

In this study, hybrid poplars were genetically engineered to increase their biomass volume and change their biochemical composition to improve the pyrolytic production of bio-oil. Wild-type hybrid poplars (WT) and genetically engineered hybrid poplars (TP) were comparatively investigated with regard to their pyrolysis characteristics and kinetics via thermogravimetric analysis (TGA) and isothermal pyrolysis within a micro-tubing reactor. Model-free methods were used to determine the activation energy for the thermal decomposition of the WT and TP samples. The results showed that the activation energy of the WT sample was always greater than that of the TP sample at the same level of conversion. Isothermal pyrolysis experiments of the two biomass samples were performed at various temperatures (360–400°C) and durations (1–5 min) using a micro-tubing reactor. A reaction network and quantitative kinetic model were proposed for pyrolysis of the WT and TP samples. Kinetic parameters were obtained through an optimization function and used to explore the parameter space in order to predict product yields as a function of reaction time and temperature for both WT and TP feedstocks.

Keywords: pyrolysis, hybrid poplar, model-free method, reaction network, kinetic model.

1. Introduction

Pyrolysis of hybrid poplar trees has attracted considerable attention in recent years. Özyurtkan et al. (2008) investigated the effects of carbonization conditions of hybrid poplars such as the heating rate, particle size, and sweep gas flow using TGA method. The experimental results indicated that biochar yields decreased with an increased heating rate and sweep gas flow rate, but increased with an increase in particle size. Additionally, the kinetic parameters were also determined separately for the carbonization of cellulosic and lignin components of hybrid poplars. Xiang et al. (2016) studied the kinetic mechanism with regard to the thermal decomposition of hybrid poplar sawdust through thermogravimetric experiments at different heating rates and a model-free method was used to determine the kinetic parameters. In general, these studies focused on the pyrolysis characteristics and compositions of pyrolytic vapor products for hybrid poplar trees utilizing TGA and Py-GC/MS methods. However, there have been few studies regarding pyrolysis kinetics and quantitative kinetic models of

genetically engineered hybrid poplars, which is necessary for the design and operation of biomass pyrolysis systems.

In this study, WT were genetically engineered to TP to increase their biomass content and change their biochemical composition to improve the pyrolytic production of bio-oil for the first time. Afterwards, the pyrolysis characteristics and kinetics of both WT and TP samples were investigated via TGA and isothermal pyrolysis reactions in a micro-tubing reactor, respectively. For an improved understanding of the pyrolysis mechanism, a quantitative kinetic model was applied based on a reaction network for the pyrolysis of the WT and TP samples. Finally, kinetic parameters calculated from the kinetic model were used to predict the pyrolysis product distributions (biochar, bio-oil and gas products) as a function of reaction temperature and duration.

2. Pyrolysis kinetics of hybrid poplars

The kinetic parameters for pyrolysis of the WT and TP samples were determined through analyses of differential thermogravimetry (DTG) data obtained at different heating rates. For the global reaction scheme of solid biomass \rightarrow char + volatiles, the kinetic equation for the pyrolysis of biomass can be described as follows (Vo et al., 2017; Ma et al., 2015):

$$\frac{dX}{dt} = A \exp\left(-\frac{E}{RT}\right) f(X) \quad (1)$$

where A is the pre-exponential factor, E is the activation energy of the reaction, R is the universal gas constant, T is the absolute temperature, and X is the conversion value..

Integrating both sides of Eq. (1) after introducing the heating rate $\beta = dT/dt$ yields Eq. (2) (Vo et al., 2017):

$$g(X) = \frac{AE}{\beta R} \int_0^x \frac{dX}{f(X)} = \int_{T_0}^T \frac{A}{\beta} \exp\left(-\frac{E}{RT}\right) dt \quad (2)$$

In this study, the Kissinger-Akahira-Sunose (KAS) method and Flynn-Wall-Ozawa (FWO) method were used (Ceylan et al., 2014). These model-free methods have been widely used for the estimation of activation energy since they can be used without knowledge of the reaction model (Ceylan et al., 2014).

Based on Eq. (2), the KAS method can be derived as follows (Vo et al., 2017):

$$\ln\left(\frac{\beta}{T^2}\right) = \ln\left[\frac{AR}{Eg(X)}\right] - \frac{E}{RT} \quad (3)$$

and the FWO method can be expressed as follows (Takeo, 1965):

$$\ln(\beta) = \ln\left(\frac{AE}{Rg(X)}\right) - 5.331 - 1.052 \frac{E}{RT} \quad (4)$$

Using Eqs. (3) and (4), the apparent activation energy could be obtained from the plot of $\ln(\beta)$ versus $1000/T$ for the FWO method and $\ln(\beta/T^2)$ versus $1000/T$ for the KAS method at a given conversion X .

Fig. 1 (a-b) and Fig. 1(c-d) show the plots used for the KAS and FWO methods, respectively. Between the conversion range of 10–80%, the apparent activation energy values for the WT sample were 231.24–282.89 kJ/mol for KAS and 233.67–284.48 kJ/mol for FWO, respectively, while those for the TP sample were 169.16–234.58 kJ/mol for KAS and 167.66–231.26 kJ/mol for the FWO method.

Although the activation energy values calculated from the KAS and FWO methods showed very similar results, it was obvious that both the WT and TP samples exhibited different activation energy values due to different biochemical compositions (Slopiecka, et al., 2012). Between the conversion range of 10 to 35% for the WT sample and 10 to 40% for the TP sample, the activation energy increased with conversion, which could be attributed to the degradation of hemicellulose. Afterwards, the activation energy decreased with an increase in conversion up to 60% for both biomass samples, which could be due to the decomposition of cellulose crystals, of which the activation energy decreased with an increase in conversion (Hu et al., 2016). For conversion values above 60% for the WT and TP samples, the activation energy slowly increased due to the slow decomposition of lignin. The fluctuation in activation energy with conversion indicated that different pyrolysis mechanisms existed depending on the decomposition of different biochemical compositions (Hu et al., 2016). Also, the apparent activation energy of the WT sample was always higher than that of the TP sample at the same conversion value, which could be due to a higher lignin content in the WT sample (Burhenne, et al., 2013).

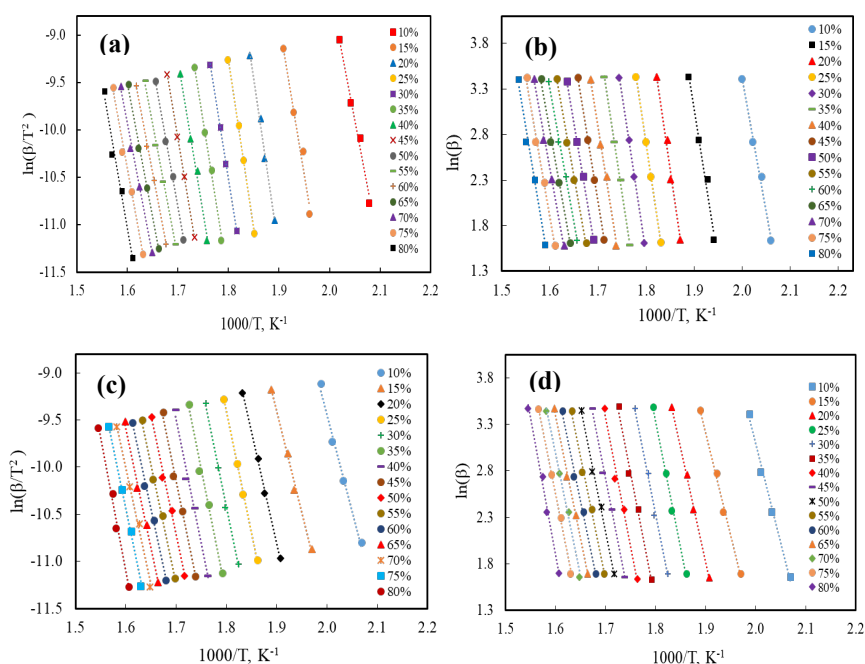

Fig. 1. KAS (a, c) and FWO (b, d) plots of the WT sample (a, b) and TP sample (c, d) at different conversion values. (Vo et al. (2017))

3. Kinetic model for pyrolysis of hybrid poplar trees

A previous study on pyrolysis of individual biomass component (hemicellulose, cellulose, and lignin) showed that the pyrolytic product included liquid oil and gas products. Among the products, the gas product could be produced directly from the degradation of biomass component or from the secondary cracking of volatiles (Yang et al., 2007). In this study, pyrolysis mechanisms were described as the independent primary thermal decomposition of hemicellulose, cellulose and lignin into a liquid phase (bio-oil) with gas products, followed by secondary cracking of the bio-oil to yield gas products. Based on this reaction network, a quantitative kinetic model was proposed for the isothermal decomposition of WT and TP samples in a micro-tubing reactor. For simplicity, it was assumed that all reactions were first-order and irreversible. By applying the apparent rate equation, the reaction rate for each pathway can be written as follows:

$$\text{Hemicellulose: } \frac{dx_{1,h}}{dt} = -(k_{1,h} + k_{2,h})x_{1,h} \quad (5)$$

$$\text{Cellulose: } \frac{dx_{1,c}}{dt} = -(k_{1,c} + k_{2,c})x_{1,c} \quad (6)$$

$$\text{Lignin: } \frac{dx_{1,l}}{dt} = -(k_{1,l} + k_{2,l})x_{1,l} \quad (7)$$

$$\text{Bio-oil product: } \frac{dx_2}{dt} = -k_3x_2 + k_{1,h}x_{1,h} + k_{1,c}x_{2,c} + k_{1,l}x_{1,l} \quad (8)$$

$$\text{Gaseous product: } \frac{dx_3}{dt} = k_{2,h}x_{1,h} + k_{2,c}x_{1,c} + k_{2,l}x_{1,l} + k_3x_2 \quad (9)$$

Here, $x_{1,h}$, $x_{1,c}$, $x_{1,l}$, x_2 , and x_3 correspond to the mass fractions of hemicellulose, cellulose, lignin, bio-oil, and gaseous products, respectively. The mass fractions of hemicellulose ($x_{1,h}$), cellulose ($x_{1,c}$), and lignin ($x_{1,l}$) in the original biomass are the product of the total solid fraction (x_1) and their fraction in dry ash-free biomass. This relationship can be illustrated by Eq. (10):

$$x_1 = x_{1,h} + x_{1,c} + x_{1,l} \quad (10)$$

The system of ordinary differential equations (5)-(9) was solved, and the rate constants (k_j) were estimated using a least-squares objective function (Q), which was defined as the summation of the squared differences between the experimental yield for each product fraction (x_i^{exp}) and the model value (x_i^{model}) at a given reaction temperature.

$$Q = \sum_i \sum_t [x_i^{\text{exp}}(t) - x_i^{\text{model}}(t)]^2 \quad (11)$$

A MATLAB optimization function was used to minimize the value of the objective function (Q) at each reaction temperature (Valdez and Savage, 2013). Initially, the boundary conditions of the rate constants were fixed within $0.00\text{--}0.48\text{ min}^{-1}$, and the fixed-step size for the solver was 0.05 seconds. These constrained conditions were short enough to avoid very long computational times but long enough to supply the fastest paths observed experimentally.

Fig. 2 shows correlations of the model (solid line) to the experimental product yield data (discrete points) obtained from pyrolysis of the WT and TP samples at various temperatures. In general, pyrolysis of the WT and TP samples revealed similar trends with regard to the evolution of solid, bio-oil and gas product yields according to the pyrolysis temperature and duration. Herein, it should be noted that the initial solid yields of 100% excluded the ash content of the woody biomass because most of the ash content was not involved in the conversion to pyrolytic products. As can be seen in Fig. 2, the bio-oil yield for both the WT and TP samples increased with an increase in reaction time at pyrolysis temperatures of 360 and 380 °C. However, at a pyrolysis temperature of 400 °C, the bio-oil yield increased dramatically only during the initial 3 minutes, afterwards the bio-oil yield began to decrease slightly with further reaction time. At a high pyrolysis temperature of 400 °C, the conversion of biomass into bio-oil was complete within a short reaction time; further reaction time facilitated the conversion of bio-oil to gas. The gas yield always increased with increases in reaction time and temperature for both the WT and TP samples.

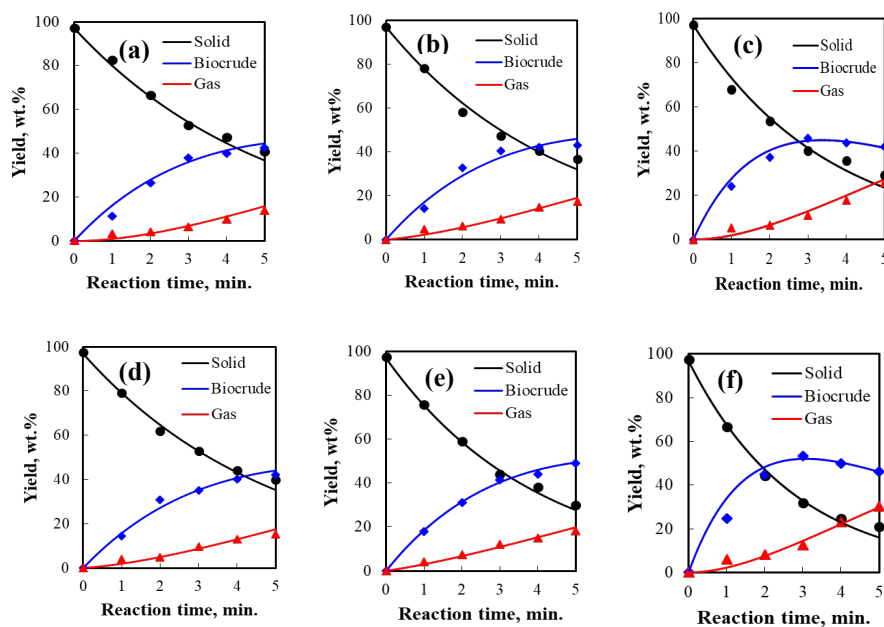

Fig. 2. Experimental (discrete points) and calculated (solid lines) yields of solid, bio-oil, and gas products as a function of reaction duration at various reaction temperatures for the WT (a, b, c) and TP (d, e, f) samples at 360 °C (a, d), 380 °C (b, e), and 400 °C (c, f). (Vo et al. (2017))

4. Conclusion

A comparative study on the pyrolysis characteristics and kinetics of WT and TP samples was performed via TGA and isothermal pyrolysis experiments. Between the conversion range of 10–80%, the apparent activation energy values for the WT samples were 231.24–284.48 kJ/mol while those for the TP samples were 167.66–234.58 kJ/mol. A quantitative kinetic model was applied to the isothermal experiment data. The results showed that the model accurately represented the experimental data for both the WT and TP samples. An estimation of the rate constants suggested that the dominant reaction pathway was the formation of bio-oil from cellulose and hemicellulose. Additionally, the TP samples always exhibited a higher rate constant for every reaction compared to the WT samples. This suggested the potential for genetic engineering to improve biomass feedstocks for the pyrolytic production of bio-oil.

Abstract

Promoting and ensuring widespread usage of biofuels throughout the European Union are two crucial targets of the existing strategic measures tackling global warming (Eurostat, 2017). Selection of adequate biofuel feedstocks, however, remains a major challenge obstructing large-scale production of biofuels. Microalgal biomass has been recently recognized as a promising biofuel feedstock due to its ability to accumulate significant amounts of starch (a raw precursor of sugar-based fuels) and lipids, when grown under nutrient-limited conditions (Markou et al., 2012; Suganya et al., 2016). However, such strategies need to be carefully implemented since they are typically characterised by a trade-off between biomass growth and starch/lipid accumulation. We previously identified and validated a starch-enhanced batch-mode cultivation scenario by means of a kinetic model capable of predicting the nitrogen limited dynamics of mixotrophic algal growth and simultaneous starch and lipid formation (Figueroa-Torres et al., 2017). This work focuses on starch accumulation, and the validated model is exploited by establishing an optimal fed-batch cultivation strategy capable of enhancing starch formation whilst sustaining algal growth. Optimal fed-batch operating conditions were identified by means of a model-based optimisation study maximising starch concentration. The computed fed-batch starch-enhanced scenario was subsequently verified against experimental data obtained from lab-scale cultures of *Chlamydomonas reinhardtii* CCAP 11/32, which yielded a 37 % increase in starch concentration with respect to that obtained by standard batch operation. Results highlight the potential use of predictive kinetic model as optimisation tools for the establishment of large-scale algae-to-fuel cultivation strategies.

Keywords: microalgae, *Chlamydomonas reinhardtii*, modelling, fed-batch, biofuels.

1. Introduction

Transportation industries are responsible for more than two thirds of the total crude oil and petroleum products consumed throughout the European Union. In an effort to mitigate overconsumption of fossil-based fuels and their associated contribution to climate change, the European Council established a strategic framework mandating all Member States to use by 2020 a minimum 10 % of renewables sources, such as biofuels, to satisfy their transport fuel consumption (Eurostat, 2017). The race towards meeting such a renewable energy target requires the successful implementation of large-scale biofuel technologies. However, widespread production of biofuels from biomass has thus far been severely restricted by the use of traditional, but highly controversial,

food-based feedstocks and/or complex lignocellulosic materials (Chundawat et al., 2011; Suganya et al., 2016).

A promising alternative to traditional biofuel feedstocks is microalgal biomass because it naturally accumulates starch, a carbon-based compound from which sugar-based fuels (e.g. bioethanol, biobutanol) could be obtained. Nevertheless, optimal large-scale cultivation systems need to be developed before microalgal starch becomes a low-cost and renewable feedstock suitable for biofuel production. A popular algal cultivation strategy which significantly increases typical starch contents involves nitrogen limitation (Markou et al., 2012). However, such cultivation strategies should be carefully implemented to: i) prevent a decrease in overall biomass growth, and ii) additionally portray the dual distribution of the intracellular carbon pool towards not only starch, but also lipid formation (Bekirogullari et al., 2017). In our previous work, we identified optimal starch-enhancing batch-mode cultivation strategies by means of a robust modelling framework predicting nitrogen-limited mixotrophic algal cultivation dynamics (Figueroa-Torres et al., 2017). Thus, the focus of this study was to develop a model-based strategy for enhanced starch formation during fed-batch algal cultivation.

2. Modelling and optimisation of algal fed-batch cultivation

2.1 Kinetic modelling

The predictive kinetic model developed in Figueroa-Torres et al. (2017) is capable of portraying the nitrogen-limited mixotrophic growth dynamics of the following 8 cultivation variables: total biomass, X (gC L^{-1}); nitrogen N (gN L^{-1}); nitrogen quota q_N (gN gC^{-1}); acetic acid A (gC L^{-1}); starch S (gC L^{-1}); lipids L (gC L^{-1}); active biomass x^* (gC L^{-1}); and pH, H . The corresponding accumulation rate of each variable is described by the following set of ordinary differential equations:

$$\frac{dX}{dt} = \mu \cdot X \quad (1)$$

$$\frac{dN}{dt} = -\rho_N \cdot X \quad (2)$$

$$\frac{dq_N}{dt} = \rho_N - q_N \cdot X \quad (3)$$

$$\frac{dA}{dt} = -\frac{1}{Y_{X/A}} \cdot \frac{\mu_H(A)}{\mu_H(A) + \mu_P(I)} \cdot X \quad (4)$$

$$\frac{dS}{dt} = r_1 \cdot \frac{N_{\text{int}}^{n_S}}{N_{\text{int}}^{n_S} + (N_{\text{int}}^2/k_{i,S})^{n_S}} \cdot \left(1 + \frac{e^{\phi_S \cdot A_{\text{int}}}}{\mu}\right) \cdot \frac{k_1}{k_1 + N/N_0} \cdot \mu \cdot x^* - \frac{r_2}{q_N} \cdot X \quad (5)$$

$$\frac{dL}{dt} = r_3 \cdot \frac{N_{int}^{n_L}}{N_{int}^{n_L} + k_{s,L}^{n_L} + \left(N_{int}^2/k_{i,L}\right)^{n_L}} \cdot (\mu + 1) \cdot \frac{k_2}{k_2 + N/N_0} \cdot \mu \cdot x^* - \frac{r_4}{q_N} \cdot X \quad (6)$$

$$\frac{dx^*}{dt} = \frac{dX}{dt} - \left(\frac{dS}{dt} + \frac{dL}{dt} \right) \quad (7)$$

$$\frac{dH}{dt} = \left(\frac{x^* - x_0^*}{x^*} \right) \cdot K_H \cdot \frac{dx^*}{dt} \quad (8)$$

The specific growth rate, μ , is a function of: the heterotrophic growth (driven by the acetic acid concentration); the phototrophic growth (driven by the light distribution across the culture vessel); and the nitrogen-dependent growth (driven by the nitrogen quota):

$$\mu = \mu_{max} \cdot [w_H \cdot \mu_H(A) + w_P \cdot \mu_P(I)] \cdot \mu_N(q_N) \quad (9)$$

$$\mu = \mu_{max} \cdot \left(w_H \cdot \frac{A}{A + K_{s,A} + A^2/k_{i,A}} + w_I \cdot \frac{I}{I + K_{s,I} + I^2/k_{i,I}} \right) \cdot \left(1 - \frac{q_{N,0}}{q_N} \right) \quad (10)$$

As shown in Eq. (5) and Eq. (6), the formation of starch and lipid molecules is primarily regulated by the intracellular nitrogen ($N_{int} = q_N X$), and acetate ($A_{int} = A - A_o$) concentrations. On the other hand, the nitrogen uptake rate (ρ_N) shown in Eq. (2) and Eq. (3) is expressed as:

$$\rho = \bar{\rho}_{N,max}(X, N_0) \cdot \frac{N}{N + K_{s,N} + N^2/k_{i,N}} \cdot \frac{A}{A + K_{s,A,N} + A^2/k_{i,A,N}} \quad (11)$$

$$\bar{\rho}_{N,max}(X, N_0) = \rho_{N,max} \cdot \frac{N_o^n}{N_o^n + K_{N_o}^n} \cdot e^{-\phi_N \cdot X} \quad (12)$$

Kinetic parameter values throughout Eq's. (1) – (12), along with their corresponding definition and respective units, are summarised in Table 1.

2.2 Optimisation of fed-batch cultivation

The above modelling framework was shown to be a robust optimisation tool for the establishment of batch-mode cultivation strategies enhancing starch formation (Figueroa-Torres et al., 2017). However, a common setback of batch-mode systems is nutrient exhaustion, which causes cellular death towards the end of the cultivation and consequently halts starch production. Therefore, a model-based fed-batch strategy was envisaged whereby growing cultures undergoing nitrogen limitation were supplied with a pulse of acetic acid (major carbon source in standard TAP medium). Preliminary experiments, however, indicated that the above model was unable to capture the ability of growing cells to regain their nitrogen uptake capacity when supplied with a pulse of acetic acid. Therefore, the model was adjusted by: i) expressing the pulse-associated

nitrogen uptake rate as a function of the increase in biomass concentration from any starting cell density (i.e. $X-X_0$), rather than by just the residual biomass, and ii) by expressing the saturation constant, K_* , as a function of both the initial cell density and nitrogen concentration, as shown in Eq. (13).

$$\bar{\rho}_{N,\max}(X, N_0, X_0) = \rho_{N,\max} \cdot \frac{N_0^n}{N_0^n + [K_*/(1 + X_0/N_0)]^n} \cdot e^{-\phi_N \cdot (X - X_0)} \quad (13)$$

In order to establish an optimal starch-enhancing fed-batch cultivation strategy, the adjusted model was then employed to identify two operating parameters: i) the optimal injection time of the acetic acid pulse, t_{pulse} , and ii) the required concentration of acetic acid in the pulse, A_{pulse} . These operating parameters were identified by maximising the following objective function:

$$\text{Objective} = \max S(t_{pulse}, A_{pulse}) \quad (14)$$

where S is the predicted starch medium concentration, subject to the governing model equations (i.e. Eq.(1)-Eq.(13)), and t_{pulse} and A_{pulse} are the degrees of freedom. The maximisation problem was solved by means of a stochastic optimisation algorithm (simulated annealing), coupled with a deterministic method (SQP) as in Vlysidis et al. (2011). Both routines were implemented in Matlab R2015a.

3. Materials and methods

3.1 Strain and cultivation.

Experimentation was carried out with the strain *Chlamydomonas reinhardtii* CCAP 11/32c, maintained mixotrophically in standard TAP medium at 25 °C, 150 rpm, and a light/dark cycle of 16/8 h (Figueroa-Torres et al., 2017). Cultivation experiments were performed in multiple identical vessels containing 500 mL of TAP medium which allowed duplicate samples to be fully harvested throughout cultivation (before/after pulse injection). Growth was initiated by inoculating culture vessels simultaneously with a 1 mL aliquot of an active algal inoculum. Vessels were kept at the same environmental conditions described before. During the course of cultivation, a sterile nutrient pulse was aseptically injected into growing cultures as per the optimal fed-batch operating conditions (i.e. A_{pulse} and t_{pulse}) identified by the optimization study.

3.2 Analytical methods.

Biomass concentration (cell dry weight) was measured gravimetrically by drying harvested cultures overnight at 70 °C. Starch was quantified as per a Total Starch kit supplied by *Megazyme International, Ireland*. Lipids were quantified in a SOXTEC Unit 1043 using hexane as extracting agent as in Bekirogullari et al. (2017). Extracted lipids were then determined gravimetrically. Residual nitrogen concentration was measured in a TOC-VCSH/TNM-1, Shimadzu (Total Organic Carbon/ Total Nitrogen). Acetic acid was measured by HPLC (High Pressure Liquid Chromatography) using an Aminex HPX-87H column (8 m, 300x7.7mm) with sulfuric acid 5mM as mobile phase (50 °C and 0.6 mL min⁻¹) and a UV detector set at a wavelength of $\lambda=210$ nm.

4. Results and discussion

As described in the preceding section, the original maximum nitrogen uptake rate expression was modified to accurately portray algal growth dynamics subject to a single acetic acid pulse. Consequently, the values of the kinetic parameters in Eq. (13) (i.e. $\rho_{N,max}$, K^* , n , and ϕ_N) were re-identified as per the methodology of Vlysidis et al. (2011) to ensure that predicted dynamics were still consistent with those original datasets presented in Figueroa-Torres et al. (2017). Final parameter values are shown in Table 1.

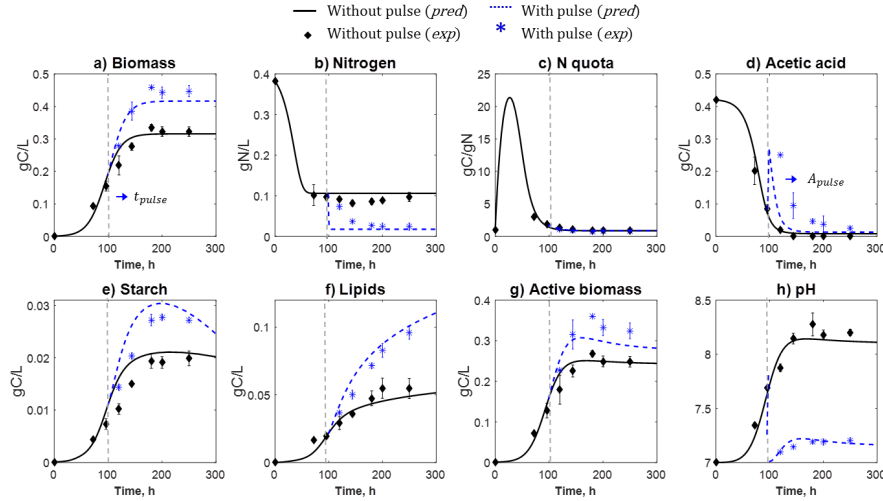

Figure 1. Predicted and experimental dynamics obtained by *Chlamydomonas reinhardtii* cultures grown under batch and fed-batch (pulse injection) cultivation.

The optimisation study was subsequently carried out with the adjusted model, which indicated that the optimal fed-batch operating conditions maximising starch concentration (i.e. Eq. (14)) required a nutrient pulse with concentration equivalent to $A_{pulse} = 0.21 \text{ gC L}^{-1}$, to be supplied at a time equivalent to $t_{pulse} = 97.5 \text{ h} \sim 100 \text{ h}$ (4th day). The pulse injection (10 mL) accounted for a 2% volume increase in the overall culture medium, and was considered negligible in calculations.

Table 1. List of parameter employed in the kinetic model (Figueroa-Torres et al., 2017).

Symbol	Definition	Value	Units	Symbol	Definition	Value	Units
μ_{max}	Maximum specific growth rate	0.106	h^{-1}	$K_{i,A,N}$	Uptake saturation constant, A	1.004	gC L^{-1}
$q_{N,0}$	Minimum nitrogen quota	0.876	gN gC^{-1}	$k_{i,A,N}$	Uptake inhibition constant, A	1.098	gC L^{-1}
$K_{i,A}$	Acetate saturation constant	1.789	gC L^{-1}	r_1	Rate of reaction	0.049	gC gC^{-1}
$k_{i,A}$	Acetate inhibition constant	0.109	gC L^{-1}	r_2	Rate of reaction	0.003	$\text{gN gC}^{-1}\text{h}^{-1}$
$K_{i,L}$	Light saturation constant	1.4	$\mu\text{mol m}^{-2}\text{s}^{-1}$	r_3	Rate of reaction	0.162	gC gC^{-1}
$k_{i,L}$	Light inhibition constant	186.52	$\mu\text{mol m}^{-2}\text{s}^{-1}$	r_4	Rate of reaction	0.005	$\text{gN gC}^{-1}\text{h}^{-1}$
$Y_{X/A}$	Yield coefficient	0.059	gC gC^{-1}	$k_{i,S}$	Inhibition constant	0.214	gN L^{-1}
σ	Light attenuation coefficient	1	$\text{L gC}^{-1} \text{m}^{-1}$	n_S	Shape parameter	4.145	-
$\rho_{N,max}$	Maximum nitrogen uptake rate	34.56	$\text{gN gC}^{-1}\text{h}^{-1}$	k_I	Regulation constant	0.110	-
K^*	* Saturation constant, N_0	0.310	gN L^{-1}	Φ_S	Regulation coefficient	0.675	L gC^{-1}
n	* Shape-controlling parameter	19.10	-	$K_{s,L}$	Saturation constant	0.023	gN L^{-1}
Φ_N	* Uptake regulation coefficient	138.74	L gC^{-1}	$k_{i,L}$	Inhibition constant	0.086	gN L^{-1}
$K_{s,N}$	Uptake saturation constant, N	0.163	gN L^{-1}	n_L	Shape parameter	1.812	-
$k_{i,N}$	Uptake inhibition constant, N	0.113	gN L^{-1}	k_2	Regulation constant	0.213	-

* Parameters re-identified in this work accounting for pulse-associated nitrogen uptake.

The computed optimal fed-batch strategy was validated experimentally and further compared against a simple batch control case. Both predicted and experimental dynamics are shown in Figure 1, where it is observed that the adjusted kinetic model was capable of accurately describing the dynamics of biomass growth, nutrient uptake, and starch and lipid formation both before and after the pulse addition. Compared to standard batch-mode, fed-batch conditions yielded 37% increase in starch concentration with a corresponding 76% increase in lipids. The effect of acetic acid, an organic carbon source, has been shown to enhance microalgal growth in *C. reinhardtii* when compared to standard phototrophic conditions which rely solely on inorganic CO₂ (Bekirogullari et al., 2017). Results from this work further show the advantage of fed-batch cultivation, where the exhaustion of carbon (e.g. acetate) leading to cell death is avoided.

5. Conclusions

A model-based optimisation study was carried out to identify optimal operating parameters suitable for the enhancement of starch formation by fed-batch algal cultivation. The optimisation problem (i.e. maximising starch formation) was solved by means of a global optimisation algorithm, subject to a validated predictive kinetic model for nitrogen-limited mixotrophic algal growth. The computed fed-batch optimal cultivation strategy yielded a 37% increase in starch against standard batch cultivation and was validated against experimentally generated data.

Abstract

A mechanistic process model describing a lactic acid bacteria (LAB) fermentation was applied to develop a continuous fermentation process. Producing LAB for the dairy industry in a continuous cultivation, which would allow harvesting the cells during the cultivation, would reduce production costs compared to traditional batch processes. To this end, a validated mechanistic model of a *Streptococcus thermophilus* fermentation was used for a model-based continuous process evaluation. The fermentation model consists of biological and chemical mechanisms including a description of the growth rate as a function of pH and inhibition effects of metabolites. The optimal dilution rate and substrate concentration in the feed were estimated in order to maximize the cell yield (biomass concentration) and to minimize the waste of substrate during the continuous fermentation in a 50 m³ bioreactor for two scenarios: downstream capabilities are i) flexible, and ii) fixed. The biomass concentration is restricted by the growth-inhibiting lactic acid concentration, which is produced by the growing bacteria. Furthermore, the substrate, which is supplied by the feed, should be consumed completely in the fermentation and not wasted in the bioreactor effluent owing to raw material costs. The resulting non-linear optimization problem was formulated and solved in MATLAB[®]. A Monte Carlo simulation showed the robustness of the results, where a biomass concentration of 5 g L⁻¹ could be achieved in the continuous fermentation with a substrate wastage of less than 3 % in the bioreactor effluent. The productivity of the continuous process was similar to a traditional batch process, but frequent cleaning and sterilization are no longer necessary in a continuous process resulting in a shorter unproductive downtime of the bioreactors. This promising potential of a continuous process for LAB cultivations encourages pilot-scale studies for a comprehensive techno-economic evaluation.

Keywords: continuous lactic acid bacteria fermentation, modelling, process development, Monte Carlo simulation

1. Introduction

Mechanistic models are increasingly applied in the biotechnological industry in order to develop, understand, optimize, monitor, and control fermentation processes. They can support the development of fermentation processes and give insight into the process during operation. There are several applications for mechanistic models: E.g. they may be applied offline to determine appro-

appropriate process operation conditions and control strategies, or online as soft sensor for model-based monitoring and control (Mears et al., 2017).

In this study, a mechanistic model describing a *Streptococcus thermophilus* fermentation was applied to design a continuous fermentation process. The food industry strives for continuous fermentations to reduce production costs compared to traditional batch fermentations, which are still the standard operation. The model predicted biological state variables, such as the biomass, substrate (lactose), and lactic acid concentrations. In addition, the model predicted the pH of the fermentation broth by solving the dissociation reactions of the charged components, as lactate, ammonia, carbonate and phosphate. The aim of this study was to propose the optimal process conditions for a continuous lactic acid fermentation to design a beneficial process compared to a batch process. To this end, the model was utilized to optimize the dilution rate and substrate concentration in the feed stream by maximizing the biomass concentration and reducing the substrate waste in the bioreactor effluent.

2. Nomenclature

Symbol	Description		
C_i	concentration (g L ⁻¹)	μ_{max}	max. specific growth rate (h ⁻¹)
F	medium flow rate (L h ⁻¹)	α	growth related production coefficient of lactic acid (g g ⁻¹)
K_I	substrate inhibition constant (g L ⁻¹)	σ_{pH}	std. deviation in the pH function
K_S	limiting substrate constant (g L ⁻¹)		
K_{La}	lactate inhibition parameter (L g ⁻¹)		
$K_{P,La}$	2. lactate inhibition param. (L g ⁻¹)		
$K_{P,pH1}$	lactate inhibition pH parameter	Subscripts i	
$K_{P,pH2}$	2. lactate inhibition pH parameter	La	dissociated lactic acid
pH_{opt}	optimal pH in the pH function	P	by-product: lactic acid
t_{lag}	lag-time coefficient (h)	S	substrate: lactose
V	volume of the bioreactor (L)	S_i	lactose in the feed inlet
Y_{gal}	galactose yield (g g ⁻¹)	X	biomass

3. Materials and Methods

3.1. Fermentation Model

A first principles model describing the homolactic *S. thermophilus* fermentation was applied for a continuous fermentation. The model was validated previously with 2 L batch fermentations at different pH set points (pH 5.5 - 7.0) and initial lactose (substrate) concentrations (20 and 70 g L⁻¹). Furthermore, the model was validated with a continuous accelerostat fermentation at lab-scale to ensure that the model predicts limiting substrate conditions as they occur in continuous cultivations, as well (manuscript in preparation). The studied strain consumes lactose, yielding biomass, lactic acid, and galactose because galactose is not metabolized but secreted. In the present study, the bacterial cells (biomass) are the product of interest. The growth rate expression (Eq. (1)) depends on the lag time, lactose inhibition and limitation (Åkerberg et al., 1998), pH dependent lactate inhibition, and the pH of the cultivation broth (Schepers et al., 2002).

$$\frac{dC_X}{dt} = \mu_{max} \cdot (1 - e^{-t/t_{lag}}) \cdot \frac{C_S}{C_S + K_S + \frac{C_S^2}{K_I}} \cdot \frac{1}{1 + e^{\frac{K_{P,La} \cdot (C_{La} - K_{La})}{1 + e^{\frac{1}{K_{P,pH1} \cdot (pH - K_{P,pH2})}}}}} \cdot e^{-\frac{(pH_{opt} - pH)^2}{\sigma_{pH}^2}} \cdot C_X - \frac{F}{V} \cdot C_X \quad (1)$$

Table 1: Kinetic parameters for the dynamic model of the *S. thermophilus* fermentation.

Parameter	Unit	Value	95 % confidence interval (CI)		Reference

The expression for the lactic acid secretion rate as by-product (Eq. (2)) is considered to be growth dependent (Peng et al., 1997).

$$\frac{dC_P}{dt} = \alpha \cdot \frac{dC_X}{dt} - \frac{F}{V} \cdot C_P \quad (2)$$

The lactose uptake rate expression (Eq. (3)) is the sum of the growth and lactic acid secretion rate expressions taking the secretion of galactose (Y_{gal}) into account.

$$\frac{dC_S}{dt} = \frac{F}{V} \cdot (C_{Si} - C_S) - (1 + Y_{\text{gal}}) \cdot \left(\frac{dC_X}{dt} + \frac{dC_P}{dt} \right) \quad (3)$$

The chemical model (for the pH calculation) comprises the dissociation reactions of the charged components in the fermentation broth, such as lactate, ammonia, carbonate, phosphate, and water (Musvoto et al., 2000). The kinetic model has been implemented in MATLAB® (The MathWorks®, Natick, MA) and the ODEs were solved with the ode15s solver. The kinetic parameters (Table 1) were derived from a consistent parameter estimation as described in Spann et al. (2017).

3.2. Design of the continuous fermentation conditions

The continuous process was a single stage chemostat cultivation without recirculation, hence the process is continuously fed with the growth medium and the culture broth is withdrawn at the same rate in order to maintain the bioreactor volume constant. The target product of the fermentation

Table 2: Description of the design problem (LB: lower bound, UB: upper bound).

Scenario	Description	Flow rate [$\text{m}^3 \text{h}^{-1}$]		C_{Si} [g L^{-1}]	
		LB	UB	LB	UB
Scenario 1	50 m^3 bioreactor downstream flexible	1	20	50	150
Scenario 2	50 m^3 bioreactor downstream restricted		fixed to 10	50	150

Figure 1: Scheme of the continuous lactic acid bacteria fermentation and downstream units.

process are the cells, as they are used in the dairy industry for yoghurt and cheese production, subsequently. Optimal process conditions for a continuous *S. thermophilus* fermentation process were predicted for two scenarios (Table 2): Scenario 1) A 50 m³ bioreactor is available and the downstream units will be built based on the calculated bioreactor effluent flow rate (Fig. 1). Scenario 2) A 50 m³ bioreactor and the downstream units for centrifugation and pelletizing are already available with given capacities. The flow rate is fixed to 10 m³ h⁻¹ here. For scenario 1, the feed flow rate and lactose concentration in the feed solution were optimized. For scenario 2, only the lactose concentration in the feed solution was optimized. The carbon source lactose will be growth limiting. The challenge of the design problem for an optimal feed flow rate and inlet substrate concentration was that the lactic acid concentration in the broth is determined by the biomass concentration but lactic acid inhibits biomass growth at the same time. The objective was: i) to maximize the biomass concentration in the bioreactor effluent; and, ii) to minimize the waste of substrate in the bioreactor effluent for both scenarios. The objective function was solved in MATLAB using the built in solver, fmincon. The mean values of the biological model parameters were used in the optimization step.

3.3. Monte Carlo simulation

100 independent input samples were created in the probability range [0 1] with the Latin Hypercube Sampling (LHS) technique (McKay et al., 1979; Sin et al., 2009). Then, the Iman Conover method (Iman and Conover, 1982) was applied to induce the correlation between the model parameters, which was derived from a parameter estimation. The samples were finally converted into the real parameter space using the Matlab function icdf, in which all uncertainties were assumed to be normally distributed. A Monte Carlo simulation of the continuous fermentation process was performed considering both the biological model parameter uncertainties (Table 1) and variations of the lactose concentration in the feed (which was obtained in the previous optimization step) with $3\sigma = 10\%$.

4. Results and Discussion

Two scenarios were investigated considering both the new construction of the production facilities (scenario 1), and the limitations of an already available plant (scenario 2). For scenario 1, the capacities of the downstream units were considered to be flexible. A flow rate of 5 m³ h⁻¹ was estimated with a lactose concentration of 54 g L⁻¹ in the feed solution (Fig 2). For scenario 2, an already existing production plant was assumed given limitations in the flow rates. Here, the estimated lactose concentration in the feed solution was 50 g L⁻¹. More lactose would be wasted in the bioreactor effluent in scenario 2 since the dilution rate is almost twice as high as in scenario 1, and the lactic acid bacteria cannot consume all the supplied lactose at this high rate.

The continuous fermentation starts with a batch phase with 65 g L^{-1} lactose initially (Fig. 3). During the exponential growth in the batch phase, the biomass concentration increased before the continuous fermentation started. The optimal time to switch from the batch to continuous mode will not be easily detectable since there is no dissolved oxygen (DO) tension signal in this non-aerated cultivation, where DO is usually used in aerated cultivations to monitor biomass activity. However, the base addition rate will in this case indicate when growth slows down as lactic acid secretion is diminished at the same time (data not shown). The Monto Carlo simulations considering model parameter uncertainties and variations of the lactose concentration in the feed inlet show that the considered uncertainties had a minor effect on the target biomass concentration with acceptable $3\sigma < 0.5 \text{ g L}^{-1}$.

A continuous cultivation could be a profitable alternative to a batch process for the industrial production of lactic acid bacteria as the cells are the desired product that can be produced in a continuous manner, similar to primary metabolites. In addition, naturally derived lactic acid bacteria might be less prone to genetic instability, which might for example be an issue in a continuous cultivation with genetically modified organisms that are often used in the pharmaceutical industry. However, the application of a continuous cultivation is quite limited in the biotechnological industry so far. This might be mostly because of the risk for process contaminations, which could cause more harm in a continuously operated reactor than a batch culture. Nevertheless, especially in the presented lactic acid bacteria cultivation, the lactic acid concentration is already inhibiting the growth of many contaminants as the lactic acid concentration will be higher than 25 g L^{-1} . In a traditional batch process with an initial lactose concentration of 65 g L^{-1} a biomass concentration of 6 g L^{-1} was reached (see the initial batch phase in Fig. 3). The batch process will be, however, more expensive than the continuous culture due to more frequent cleaning, sterilization, pre-culture preparation tasks, etc., provided that the continuous process could be maintained stable with a low risk of failure.

Figure 2: Contour plot of the normalized objective function value with respect to the lactose concentration in the feed and the feed flow rate. The minimum for scenario 1 is at $F = 5 \text{ m}^3 \text{ h}^{-1}$ and $C_{Si} = 54 \text{ g L}^{-1}$. The minimum for scenario 2 is at the lower limit $C_{Si} = 50 \text{ g L}^{-1}$ with the given $F = 10 \text{ m}^3 \text{ h}^{-1}$.

Figure 3: A continuous *S. thermophilus* fermentation with a batch phase in the beginning. 95 % confidence bounds for the limiting substrate lactose, dry cell weight, lactic acid concentration, and the pH (from left to right). A Monte Carlo simulation of 100 input samples was performed considering model parameter uncertainties, and variations of the lactose concentration in the feed solution.

Mechanistic models, as applied in the present study, are preferably used for off-line cultivation process development because of their many advantages (Mears et al., 2017): Mechanistic models are often able to extrapolate to process conditions outside the conditions that were used to develop the model. In addition, mechanistic models provide a flexible model structure that could be adjusted to several processes by adjusting the model parameters. Furthermore, some companies prefer to apply mechanistic models, e.g. for control purposes, because they want to understand where the predictions derive from, instead of following a black-box prediction. Due to these advantages, one should accept a longer model development and validation time of a mechanistic model compared to black-box models.

Further research is necessary to validate the presented model predictions in lab- or pilot-scale experiments. Biotechnological companies and further studies could use the presented case study by also including an economical objective function, e.g. considering sales revenue and expenses, such as operation and raw material costs, in order to design the most profitable continuous cultivation.

5. Conclusion

This study used a mechanistic model describing the production of *S. thermophilus* in a fermentation process to propose the optimal conditions for a continuous cultivation. The fermentation conditions were estimated for two scenarios: downstream capabilities are i) flexible, and ii) fixed. A continuous process is regarded as more cost effective than a traditional batch process, and especially mechanistic models are valuable for process design purposes because they might be capable to predict also conditions which were not experimentally investigated beforehand. In conjunction with uncertainty considerations, a probability distribution of the model prediction was obtained and the uncertainty in the biomass prediction was low, which shows the robustness of the model for analysis. Further studies are needed to validate the model predictions experimentally at pilot-scale and economic issues could be included in the optimization problem.

Abstract

Continuous manufacturing of pharmaceuticals requires effective control strategies to meet the tightly regulated critical product quality attributes, which has triggered a wide interest in model predictive control (MPC) techniques. This study applies a linear form of MPC to a nonlinear seeded continuous MSMMPR crystallization process of acetaminophen in water, by using a global linearization technique; input-output state-feedback linearization (SFL). The two novelties are the application of MPC with SFL to continuous crystallization for SISO and MIMO systems; and the handling of the constraints as part of the SFL framework. For a single-input single-output system (SISO), MPC with SFL is applied to achieve a supersaturation reference trajectory by manipulating the coolant temperature subject to bounds and constraints. Additionally a multiple-input multiple-output (MIMO) case is presented using MPC with SFL and decoupling (SFLD). The supersaturation control from SISO was implemented in conjunction with crystal mean size control by manipulating the seed loading rate within bounds. The SISO configuration managed to control the crystallization process to within 1% of a prescribed set-point value within 2 residence times. In contrast, the MIMO controller was only able to stay within 4% of the set-point after 10 residence times, likely due to the highly coupled effects of the inputs on the outputs, which are lost in part due to the SFLD.

1. Introduction

The pharmaceutical industry is currently facing the challenges of transforming traditional batch production methods to robust continuous manufacturing processes, which can reduce manufacturing costs and time, whilst producing more consistent product (Mascia et al., 2013, Benyahia, 2018). Alongside this paradigm shift, the pharmaceutical industry is increasingly seeking advanced optimization and control strategies to meet tight regulatory requirements (Lakerveld et al., 2015). One tool that can effectively achieve these objectives is model predictive control (MPC): a powerful model-based optimization and control technique that has been used across many industrial sectors. Many pharmaceutical processes are complex with nonlinear dynamics and exhibit a highly coupled multiple-input multiple-output (MIMO) structure, one notable example being crystallization, making it a good candidate to demonstrate MPC capabilities (Lakerveld et al., 2013, Benyahia et al., 2012).

Nonlinear control techniques, such as nonlinear MPC (NMPC), have emerged to control nonlinear processes, such as polymerisation. Examples of the implementation of the NMPC on crystallization were also reported more recently. Nagy (2009) implemented

NMPC onto a batch crystallizer to control the crystal size distribution and Damour et al (2010) presented the implementation of NMPC on an industrial crystallizer using an artificial neural network model. Despite this relative success, NMPC is not as computationally efficient as linear MPC. The developed of robust control of nonlinear systems with MPC is one area still in need of further exploration and one particular technique of interest is input-output state-feedback linearization (SFL), a subset of global linearization.

The pairing of MPC with SFL can be used for single-input single-output (SISO) systems and has been applied to batch crystallization for supersaturation control (Jansen, 2011), but without implementation of realistic bounds or constraints on the manipulated input (coolant temperature). One potential constraints application for SFL is introduced by Schnelle and Eberhard (2015) for trajectory tracking of a multibody system, and should be suitable for crystallization control. Additionally, MIMO MPC is a desirable control configuration and can be achieved using SFL with decoupling (SFLD). Few applications of MPC with SFLD have been reported in the open literature; Chang and Chen (2015) applied the approach to a proton exchange membrane fuel cells. In crystallization control, Hernandez et al (2012) implemented nonlinear MIMO control onto continuous cooling crystallization using SFLD but with a proportional-integral-derivative (PID) controller. The most notable contribution on constraint handling for SFLD is by Deng et al (2009) using a dynamic neural network to handle constraints, but this would be too computationally expensive for controlling a crystallization process in real-time. Therefore a combination of approaches is needed to demonstrate the effectiveness of constrained MPC with SFL/SFLD for crystallization.

This paper discusses the application of bounded and constrained MPC with SFL to a continuous MSMPR crystallization simulation for SISO control of: supersaturation by manipulating the cooling jacket temperature; and number averaged mean crystal size by manipulating the seed loading. Moreover, the MIMO control of the above system is also demonstrated with bounds and constraints using MPC with SFLD, to establish if this control technique is adequate for MIMO control of a continuous crystallization process.

2. Model and Control Method

2.1. Crystallization Model

Cooling crystallization processes operate by cooling a solution with a dissolved solute into an unstable region where there is a driving force for the solute to crystallize out of solution by nucleation, or growth on existing crystals suspended in the mixture. Crystals may also be fed into the crystallizer as a seed to promote growth and suppress nucleation. To capture these kinetics and associated properties, the crystallizer model equations include the population (Eqs. 1 & 2), mass (Eq. 3) and energy balances (Eq. 4), the system-specific crystallization kinetics (Eqs. 5 & 6) and thermodynamic solubility. The population balance equation is simplified to only include nucleation and size independent growth kinetics, and subsequently can be solved using the method of moments. The mass balance is in terms of the concentration of solute dissolved in solvent, the kinetic equations for nucleation and growth are power laws, and solubility is a second order polynomial with respect to solution temperature.

$$\frac{d\mu_0}{dt} = B + \frac{F_{in}}{V} \mu_{0,in} M - \frac{F_{out}}{V} \mu_0 \quad (1)$$

$$\frac{d\mu_i}{dt} = iG\mu_{(i-1)} + \frac{F_{in}}{V} \mu_{i,in} M - \frac{F_{out}}{V} \mu_i \quad i = 1, \dots, 3 \quad (2)$$

$$\frac{dC}{dt} = -k_v \rho_c 3G\mu_2 + \frac{F_{in}}{V} C_{in} - \frac{F_{out}}{V} C \quad (3)$$

$$\frac{dT}{dt} = -\frac{UA_c(T - T_c)}{\rho V c_p} + \frac{F_{in}}{V} T_{in} - \frac{F_{out}}{V} T \quad (4)$$

$$B = k_b (C - C^*)^b \mu_2 \quad (5)$$

$$G = k_g (C - C^*)^g \quad (6)$$

Here, k_b and b are empirically derived nucleation kinetic parameters, and similarly k_g and g are growth parameters. F_{in} and F_{out} are the volumetric flow in and out respectively, V is the volume, μ_i is the i^{th} moment and $\mu_{i,in}$ are the i^{th} moments of the seed distribution. The shape factor of crystals and crystal density are k_v and ρ_c respectively, the overall heat transfer coefficient is U , the area of heat transfer is A_c and the density and specific heat capacity of the coolant fluid are ρ and c_p respectively. The two inputs (i.e. manipulated variables) are the temperature of the coolant T_c and the seed loading multiplier M .

2.2. Model Predictive Control with State Feedback Linearization

The model predictive control framework for a SISO MPC with SFL is shown in figure 1. There is an input u into the crystallizer and a measured output y . The output is passed to a predictor model in the MPC; this also receives a set of transformed inputs from the optimizer in the MPC \hat{v} to determine the future output trajectory \hat{y} . The trajectory is compared to a set-point or reference trajectory y_{ref} and the vector of errors e is passed into a constrained optimization problem for minimization. Once the optimal transformed inputs are found, the input and output horizons are calculated and the first transformed input v from the vector \hat{v} is passed into the control law, with the current process states from the crystallizer, to find the next input u to the process. The MIMO case is an extension of the SISO framework where there are 2 inputs and 2 outputs for the simulated crystallizer and 2 reference trajectories whose tracking problems are described by a single optimizer, and the control law replaced with a decoupling matrix.

The control law for the SISO system is shown in equation 7 (Jansen, 2011). The decoupling matrix for the MIMO case is shown in equation 8 and the SFLD control law in equation 9 (Deng et al, 2009). The decoupling matrix must be square and non-singular (invertible) to determine feasible control laws (equation 9).

The SISO supersaturation control case has a set-point of 0.006 g/g where a bounded coolant temperature (between 273 K and 340 K) and constrained to change no more than 2 K min^{-1} , is used a manipulated variable. The seed moments are calculated for a seed loading of 0.5 g L^{-1} and $10 \text{ }\mu\text{m}$ seed size along with a seed loading multiplier of $M = 1$. With a residence time of 15 minutes, the ideal case for SISO is to start-up the MSMPR and reach steady state, at which point the supersaturation will be within 1% of the set-point, in a short time. The MIMO case is an extension of SISO where there is

also a targeted set-point that consists in achieving a crystal size of 20 μm at steady state using the seed loading multiplier as a manipulated variable, bounded between 0.25 and 2. Similar performance criteria to the SISO case were used in the MIMO case.

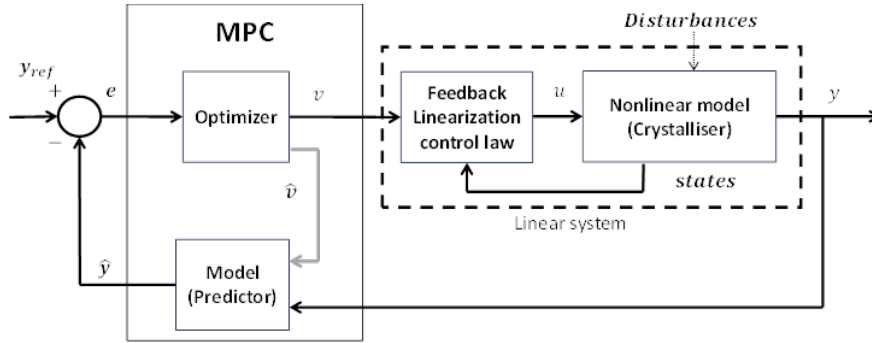

Figure 1 – Model Predictive Control with State Feedback Linearization

$$u = \frac{v - \sum_{k=0}^{r-1} \beta_k L_f^k y}{\beta_r L_g L_f^{r-1} y} \quad \begin{cases} L_g L_f^k y = 0 & k = 0, \dots, r-2 \\ L_g L_f^{r-1} y \neq 0 \end{cases} \quad (7)$$

$$E = \begin{bmatrix} \beta_{1,r_1} L_{g_1} L_f^{r_1-1} y_1 & \dots & \beta_{1,r_1} L_{g_n} L_f^{r_1-1} y_1 \\ \vdots & \ddots & \vdots \\ \beta_{n,r_n} L_{g_1} L_f^{r_n-1} y_n & \dots & \beta_{n,r_n} L_{g_n} L_f^{r_n-1} y_n \end{bmatrix} \quad \text{where } L_g \text{ and } L_f \text{ are Lie derivatives} \quad (8)$$

$$u = -E^{-1} \begin{pmatrix} \sum_{k=0}^{r_1} \beta_{1,k} L_f^k x_1 \\ \vdots \\ \sum_{k=0}^{r_n} \beta_{n,k} L_f^k x_n \end{pmatrix} + E^{-1} v \quad (9)$$

3. Results and Discussion

3.1. SISO MPC with SFL

The SISO MPC with SFL results for supersaturation control by manipulating the coolant temperature of the crystallizer is shown in figure 2. The top graph is the output and at the bottom is the input. The supersaturation was within 1% of the target of 0.006 g/g within 2 residence times during start-up and maintained throughout, meanwhile all the input changes are feasible. The coolant and solution temperatures are changing over 10 residence times though, indicating a slow progress to steady state. Despite that, it is clear from these results that the input is capable of controlling this crystallizer to steady state without violating the bounds or constraints. This demonstrates a working MPC controller with SFL for this SISO configuration; another set of results has also been obtained for a second SISO configuration to control the crystal mean size to a target

size, by allowing the seed loading multiplier to change within bounds, with a fixed coolant temperature, and the results will be published in detail in an extended version of this article.

Figure 2 – SISO MPC with SFL for supersaturation control

3.2. MIMO MPC with SFLD

The two SISO results are used independently to validate that this method of constraint handling does indeed work for MPC with SFL and further to inform some set points or trajectories for the MIMO case. The latter is important because of the coupled dynamics; the seed loading will be used to control the crystal mean size but will also affect the supersaturation consumption; similarly, the temperature of the coolant is used to control the supersaturation, but also affects the mean crystal size.

Figure 3 – MIMO MPC with SFLD for supersaturation and mean-size control

The results of the MIMO MPC with SFLD are shown in figure 3 where the top two graphs are the outputs (supersaturation and crystal mean size), with their respective inputs being the bottom two graphs. Both output set-points are met while the inputs are feasible. However, the outputs are only within 15% of the set-points at 5 residence times, and within 4% after 10. The settling time is larger than the one observed with the SISO approach too, which is likely due to the simultaneous coupled effects of seed

loading and coolant temperature. Although these are drawbacks, the results sufficiently demonstrate that the crystallization process can be controlled using this constrained MIMO MPC with SFLD, but not as effectively as SISO.

4. Conclusions

A SISO MPC with SFL and constraints has been applied to supersaturation control of a continuous crystallizer and the coolant temperature input changes did not violated their bounds and constraints. A MIMO MPC with SFLD was also developed and applied to the crystallizer but was not as effective as SISO, with longer time to steady state and 3% further away from the set-point, likely due to the decoupling procedure. However, the MIMO system did not violate constraints and did demonstrate a steady convergence towards the set-points, so is suitable as a controller for crystallization.

Abstract

We developed models for designing rapid and effective H₂O₂ decontamination processes in the manufacturing of sterile drug products such as injectables. Decontamination is a critical change over process to establish proper environment, e.g., isolator, for sterile filling, with a trade-off between the level of sterility assurance and the hours of time required. Our model defines these performances as the objective functions, and H₂O₂ injection profile and initial humidity in the isolator as the design variables. Using statistical methods, a set of models was developed and validated, where experiments with an industrial-scale isolator provided necessary data. The models were applied in a case study where Pareto-optimal conditions could be indicated given the target concentration of H₂O₂ in the isolator. The study revealed that around 10% of the process time could be reduced at most, without compromising the sterility assurance, which is significantly relevant to the productivity of drug manufacturing.

Keywords: multiobjective design, statistical modeling, drug product manufacturing, biopharmaceuticals, change-over

1. Introduction

Sterile drug products such as injectables of biopharmaceuticals are filled into vials in isolators or in clean rooms, where the environment must be sterile. Decontamination is a critical change over process to irreversibly deactivate, namely kill, microorganisms in the isolator, before a batch operation of filling can start. As a disinfection agent, hydrogen peroxide (H₂O₂) is used typically in the industry. The process consists of two steps: (a) sterilization by injecting H₂O₂ into the air of the isolator, and (b) aeration by ventilating the inside air for decreasing H₂O₂ concentration to a target, e.g., 0.5 ppm. One of the key issues is the time intensity; for example the entire process takes up to ten hours while the filling of injectables takes a couple of hours. This time-intensive process is, and will be more critical for the productivity due to the trend of small scale production along with the introduction of personalized medicine. However, realization

Figure 1. Injection profile and measured profile of decontamination process

of rapid decontamination processes is not simple because sterility assurance and speedy completion of the process are competing objectives.

In the literature, some authors tackled this relevant but complex process. Unger-Bimczok et al. (2008) identified H₂O₂ concentration and humidity as important parameters; Radl et al. (2009, 2011) developed models for analyzing physical behavior of H₂O₂. Wang et al. (2014) showed that the residual H₂O₂ after aeration may oxidize products during storage; Hubbard and Eppler (2015) investigated the uptake of H₂O₂ into a product for understanding the oxidation effect. Our group proposed the decision-support model for shortening the time required by the decontamination process (Sugiyama et al., 2017). However, design of decontamination processes requires incorporation of various aspects such as quality, productivity, or safety, which need to be incorporated into decision-making. In this study, we present a set of process models which can be applied to the multiobjective design of decontamination processes considering rapidity and sterility.

2. Model development

2.1. Overview

The design variables were defined as injection rate x [g/min] and injection time t [min] of H₂O₂(aq), and initial relative humidity H_0 [%] in the isolator. Figure 1 shows typical profiles of H₂O₂(aq) injection, and measured H₂O₂ concentration and humidity. In sterilization, H₂O₂(aq) is injected into the isolator at rates of x_1 and x_2 during the time t_{s1} and t_{s2} , respectively. In aeration, H₂O₂ concentration, which is around 500 ppm at the beginning, is decreased until the target concentration such as 0.5 ppm by ventilating the air inside the isolator.

As the objective functions, sterility assurance level (SAL; PIC/S, 2011) and process time were considered. SAL is an industrially known indicator that represents the probability of a microorganism to be present in the product, and thus the degree of sterility assurance of an operation. SAL is defined as Eq.(1):

$$SAL = 10^{-n} \quad (1)$$

where n is an index number. A larger value of n means that the operation ensures a higher level of sterility. Process time t_{total}^c is defined as Eq.(2):

$$t_{total}^c = t_{s1} + t_{s2} + t_a^c \quad (2)$$

where t_a^c is aeration time for decreasing H₂O₂ concentration to target value c .

For mathematically connecting the design variables to the objective functions, intermediate indicators D-value [min] (ISO, 2006) and the amount of H₂O₂aq loaded per unit volume of an isolator, Q [g/m³], were considered. D-value is the time duration required for killing 90 % of the surviving microorganisms, i.e., small D-value means high disinfection efficacy. Generally, D-value is calculated according to an industrially established procedure using biological indicator (BI), a microbiological sampler that contains a predetermined number of microorganisms. Using D-value Eq. (1) can be transcribed as Eq.(3):

$$SAL = 10^{6 - \frac{t_{s1} + t_{s2}}{D}} \tag{3}$$

where the constant six is the standard value in the evaluation of SAL. The parameter Q can be calculated using Eq.(4):

$$Q = \frac{x_1 t_{s1} + x_2 t_{s2}}{V_{iso}} \tag{4}$$

where V_{iso} [m³] is volume of the isolator, and Q was reported as the important parameter for the process (Sigwarth and Moirandat, 2000). Among these parameters, there are two relationships that need to be quantified: (i) between design variables and D-value, and (ii) between design variables and aeration time. In order to describe these relationships as model equations, experiments were conducted using a typical industrial-scale isolator.

2.2. Experiment

Figure 2 shows the isolator used in experiments (Airex Co., Ltd.) which has the volume of 2.4 m³ as V_{iso} , and four gloves for intervention and tank and evaporator of H₂O₂aq (omitted in the figure). Inside of this isolator was almost empty: only a metallic mesh and measurement instruments were present, and the isolator did not have any manufacturing equipment such as filling machine. For the sake of simplicity, H₂O₂ concentration, relative humidity, and temperature were considered homogeneous inside the isolator. The injection technology of H₂O₂ is an Airex system, which generates

Figure 2. Isolator used in experiments

condensate of H₂O₂ and H₂O during sterilization. The measurement instruments used in the experiments were three H₂O₂ concentration meters (Dräger and Picarro), and instrumentation for humidity and temperature (Testo). The air inside the isolator was circulated from the start of the process until the middle of aeration, and was ventilated afterwards for aeration. Several sets of BIs (Mesa Labs), which were placed on the metallic mesh, were periodically taken out from the isolator through a vent port set-by-set. Each set of the BIs was then separately cultivated to determine the D-value. In the experiments, H₂O₂aq of 35 wt% (Wako Pure Chemical Industries), and liquid cultivation media (Atect) were used.

Among the design variables, x_1 , x_2 , t_{s2} , and H_0 were varied in the experiment. The parameter t_{s1} was kept constant in order to describe the dependence of D-value on x_1 , which was considered the most critical for disinfection. The entire decontamination process was performed 31 times. D-value was calculated from the seven-day-cultivation result of the BIs according to the minimized Limited Spearman Karber Method (LSKM) (Sigwarth and Moirandat, 2000). The parameter t_a^c was determined as the time point when the H₂O₂ concentration went below the fixed target concentration c .

2.3. Model development and validation

The models for evaluating SAL and process time were developed based on the regression analysis from the experiment result. Among 31 data points, 26 data points were used for developing the models, and residual five data points were used for validating the models. If all of five data points were included inside the 95% prediction interval of the model equation, the model was judged as validated.

The D-value estimation model was developed as follows:

$$D = 3.7 - 0.72x_1 \quad (5)$$

which was then validated according to the criteria, and this equation can be used in the same range as the experimental condition. The units of the first and second coefficients on the right side are min and min²/g, respectively. R-squared was 0.885. As for the result of t_a^c , where c was set as 0.5 ppm, the developed model was as follows:

$$t_a^{0.5 \text{ ppm}} = 0.90 + 1.6Q + 0.37H_0 \quad (6)$$

This model equation was validated as well, and the valid range of this equation is same as Eq.(5). The units of the first, second, and third coefficients on the right side are min, m³min/g, and min, respectively. Figure 3 presents the result and model validation where all of the five data points for validation were included in the 95 % of prediction interval. R-squared was 0.742. Based on these models, the process time and SAL can be evaluated using Eq.(2) and Eq.(3), respectively.

3. Application of the model

As an application of the developed models, this paper presents the design of decontamination process for the isolator shown in Figure 2, with specifying c as 0.5

Figure 3. Result and model validation of aeration time

ppm. All parameters in the evaluation were same as the values and the ranges used in the experiments except for t_{s2} , which was considered modifiable in this investigation.

Figure 4 shows the evaluation result, and this contour plot is valid for the fixed t_{s1} and t_{s2} , which are constant values in this case. SAL was independent on the initial relative humidity H_0 because only injection rate x_1 was statistically relevant in estimating D-value. The condition which gave better SAL was larger x_1 , while the condition which gave shorter process time was smaller x_1 and smaller H_0 ; Pareto optimal conditions were described as the chain line. Figure 5 shows the multiobjective evaluation of the entire alternative conditions for decontamination covered in Figure 4. Evidently, the trade-off relationship between sterility assurance and process time was observed. From Figure 5, the alternatives on the left side line are Pareto optimal, the selection of which depends on the priority in the drug manufacturer. One extreme option was SAL of 10^{-7} and process time of 77 min (point A), and the other extreme option was 10^{-18} and 101 min (point B). At one SAL, process time has a range around 10 %, i.e., there is a possibility that maximum 10 % of process time can be shortened without sacrificing SAL.

For the actual development of the isolator, the results in Figure 5 can be used to determine initial but promising conditions before introducing various equipment inside. Further experiments are needed to decide the final conditions after installing equipment such as filling machine, however, the availability of good initial conditions would reduce try-and-errors, and thus accelerate the development. The results in Figure 5 can also be used for similar isolators like the one shown in Figure 2, which is industrially typical regarding volume and H_2O_2 evaporation system.

Figure 4. Evaluation result of Process time and SAL

Figure 5. Multiobjective evaluation result

4. Conclusions and outlook

We presented a set of validated statistical models for designing rapid and effective H₂O₂ decontamination processes in sterile drug product manufacturing. The models can estimate SAL and process time, with the input information on injection rate and time of H₂O₂, and initial relative humidity inside the isolator. Experiments were performed using an industrial-scale isolator to obtain necessary data for model development as well as validation. The multiobjective evaluation result also indicated that around 10 % of process time can be reduced at most without sacrificing the SAL. For the actual isolator development, the obtained results can be used to determine initial but promising conditions, which can accelerate the development by reducing try-and-errors.

The future plan is to develop physical models for elucidating the relationship between physical phenomena such as condensation of H₂O₂ and the experiment results obtained in this study. The integration of physical and statistical models will enhance the application capability for various types of isolators and also clean rooms.

Acknowledgements

Abstract

This contribution consists of a multi-flow rate optimization method to maximize the key performance indicators, yield, degree of resin utilization and productivity for a chromatographic loading step. The protein adsorption to the resin is modeled using a mechanistic column model with a steric mass action adsorption isotherm. The model was used to optimize the flow rate trajectories and the loading duration by using a simultaneous method where the controls and state variables were discretized using a direct and local collocation method on finite elements in the temporal dimension and a finite volume weighted essentially non-oscillatory scheme in the spatial dimension. The discretized nonlinear program was solved using an interior point method. The two and three dimensional pareto fronts for the multi-objective optimization are presented and the multi-flow rate strategy showed considerable improvement in all objectives at different points on the pareto front.

Keywords: Modelling, Optimization, Collocation, Protein, Chromatography

1. Introduction

Purification of proteins typically consists of a clarification step, a chromatographic capture step and one or several additional orthogonal chromatography steps. This contribution is concerned with the loading of the chromatography columns and mainly the loading of the capture step. Since the capacity of chromatographic resins are low, resin utilization is of great importance. Resin utilization is especially important in the capture step since the capture step receives the highest amount of product protein and makes use of expensive resin, e.g. protein A or mixed-mode resins. In addition to resin utilization, product yield and production rate needs to be taken into account when optimizing the loading phase. To increase the resin utilization and product yield several design and control approaches have been suggested. Capture-SMB (Angarita et al., 2015) and periodic counter current chromatography, which uses two and three columns in sequence to fully load one of the columns while collecting the product breakthrough on the following column. Both of these approaches have the drawback of needing extra columns and equipment as well as a flow rate limitations due to the increased pressure drop over the interconnected columns. Another approach has been to use dual-flowrate loading strategies on a single column to maximize the dynamic binding capacity and productivity. This approach does not need any extra equipment or columns and still outperforms single loading strategies (Ghose et al., 2004).

The aim of this study is to expand the dual-flowrate strategy to include any number of flowrates during the loading. This is achieved by mechanistic modeling of the process and discretization of the temporal domain while keeping a constant flowrate in each time horizon, i.e. piecewise constant controls. Yield, production rate and degree of resin utilization are identified as key process indicators (KPIs) which are weighed together to form a scalar objective. This approach results in

a large-scale dynamic optimization problem constrained by partial differential algebraic equations which is solved for both single and multiple flowrates and variable loading time. A case study where a 4 g/L lysozyme solution is loaded on a 1 ml prepacked Sepharose SP Fast Flow column is presented to show the advantages of the multi-flow rate strategy compared to the single flow rate strategy.

2. Chromatography Model

The Transport-Dispersive Model (Schmidt-Traub et al., 2006) was used to model the breakthrough curves of protein during column loading. The model equations, Eq. 1 and 2, are defined over the spatial, $z \in [z_0, z_f]$ and temporal, $t \in [t_0, t_f]$ domain. The mass-balance over the mobile and stationary phase is governed by:

$$\frac{\partial c_\alpha}{\partial t} = \frac{\partial}{\partial z} \left(D_{\text{ax}} \frac{\partial c_\alpha}{\partial z} - \frac{\dot{Q}}{\varepsilon_t A_c} c_\alpha \right) - \frac{1 - \varepsilon_c}{\varepsilon_t} \frac{\partial q_\alpha}{\partial t}, \quad \alpha \in \{\text{lys}, s\} \quad (1)$$

$$\frac{\partial q_\alpha}{\partial t} = \begin{cases} -k_{\text{film}}(q_\alpha - q_\alpha^*) & \text{for } \alpha = \text{lys} \\ -\nu \frac{\partial q_{\text{lys}}}{\partial t} & \text{for } \alpha = s \end{cases} \quad (2)$$

where c_α is the concentration of component α in the mobile phase, t is time, z is the spatial coordinate, D_{ax} is the axial dispersion, \dot{Q} is the volumetric flow rate, ε_t is the total void, ε_c is the column void, A_c is the column cross section area, k_{film} is the film mass transfer parameter, q_α is the concentration of component α in the stationary phase, ν is the characteristic charge of lysozyme and q_α^* is the adsorbed concentration of component α at equilibrium with the mobile phase, which is governed by the steric mass action isotherm (Brooks and Cramer, 1992):

$$0 = c_\alpha - \frac{1}{K_M} \frac{q_\alpha^* c_s^\nu}{\left(\Lambda - (\sigma + \nu) q_\alpha^* \right)^\nu} \quad (3)$$

where K_M is the equilibrium constant, Λ is the total ion exchange capacity and σ is the steric shielding parameter. The SMA isotherm was then reparametrized according to:

$$K_{\text{eq}} = K_M \Lambda^\nu, \quad q_{\text{max}} = \Lambda (\sigma + \nu)^{-1} \quad (4)$$

where K_{eq} is the new equilibrium constant for adsorption and desorption of lysozyme and q_{max} is the maximum concentration for adsorbed lysozyme. The total film mass transfer resistance is the sum of the inner and outer film resistance. The total film mass transfer parameter, the inner film transfer parameter (k_s) and the outer film transfer parameter (k_o) depends on the stationary phase saturation and flow rate according to (Steinebach et al., 2016):

$$k_{\text{film}} = \left(\frac{1}{k_s} + \frac{1}{k_o} \right)^{-1}, \quad k_s = k'_s \frac{(1 - \Gamma)^{1/3}}{1 - (1 - \Gamma)^{1/3}}, \quad k_o = k'_o \left(\frac{\dot{Q}}{A_c \varepsilon_c} \right)^{1/3} \quad (5)$$

where k'_s is the inner film mass transfer resistance parameter, Γ is the saturation level of the stationary phase, i.e. $\Gamma = q_\alpha / q_{\text{max}}$ for rectangular isotherms and k'_o is the outer film mass transfer resistance parameter. Danckwert boundary conditions are used for the column inlet and homoge-

neous von Neumann conditions are used at the column outlet:

$$D_{\text{ax}} \frac{\partial c_{\alpha}(t, z_0)}{\partial z} - \frac{\dot{Q}}{A_c \varepsilon_t} c_{\alpha}(t, z_0) = \frac{\dot{Q}}{A_c \varepsilon_t} c_{\text{load}, \alpha} \Pi(t, t_0, \Delta t_{\text{load}}) \quad (6)$$

$$D_{\text{ax}} \frac{\partial c_s(t, z_0)}{\partial z} - \frac{\dot{Q}}{A_c \varepsilon_t} c_s(t, z_0) = \frac{\dot{Q}}{A_c \varepsilon_t} c_{A, s} \quad (7)$$

$$\frac{\partial c_{\alpha}(t, z_f)}{\partial z} = 0 \quad (8)$$

$$\frac{\partial c_s(t, z_f)}{\partial z} = 0 \quad (9)$$

where $c_{\text{load}, \alpha}$ is the load concentration of component α , $\Pi(t, t_0, \Delta t_{\text{load}}) \in [0, 1]$ is a smooth rectangular function in the temporal horizon $[t_0, t_0 + \Delta t_{\text{load}}]$, Δt_{load} is the load time and $c_{A, s}$ is the salt concentration in the low salt buffer. At the start of each run the column only contains low salt buffer. The column void, ε_c , was 0.3 and the total void, ε_t , was 0.9. The isotherm and mass transfer coefficients are summarized in Table 1.

Table 1: Model parameters used to model the adsorption of lysozyme to the resin.

q_{max} [mol m ⁻³]	ν [-]	K_{eq} [(mol m ⁻³) ^{ν}]	k'_s [s ⁻¹]	k'_0 [m ^{-1/3} s ^{-2/3}]	Pe [-]
17.6	5.97	$3.40 \cdot 10^{14}$	$1.11 \cdot 10^{-13}$	$2.42 \cdot 10^{-2}$	0.50

3. Multi-Objective Dynamic Optimization Problem

To formulate the optimization problem, a well-defined objective function is needed. The basis of the objective functions is the three different key performance indicators (KPIs) for the process. The KPIs are weighed together to form the objective function. In this case yield, $Y(t)$, productivity, $P(t)$ and degree of stationary phase utilization, $U(t)$ are the KPIs of the process. The KPIs are defined as:

$$Y(t) = m_c(t) m_{\text{in}}(t)^{-1}, \quad (10)$$

$$P(t) = m_c(t) \left[\Delta t_{\text{load}} + \Delta t_w \right]^{-1}, \quad (11)$$

$$U(t) = m_c(t) \left((1 - \varepsilon_t) V_c q_{\text{max}} \right)^{-1} \quad (12)$$

where m_c is the amount of lysozyme adsorbed to the stationary phase, m_{in} is the amount of lysozyme loaded to the column, Δt_w is the time it takes to wash, clean and regenerate the column and V_c is the column volume. The amount of lysozyme adsorbed to the stationary phase and loaded is defined as:

$$\frac{dm_{\text{in}}(t)}{dt} = \Pi(t, t_0, \Delta t_{\text{load}}) \dot{Q}(t) c_{\text{feed}}, \quad (13)$$

$$\frac{dm_c(t)}{dt} = \Pi(t, t_0, \Delta t_{\text{load}}) \frac{1 - \varepsilon_c}{\varepsilon_t} A_c \int_{z_0}^{z_f} \frac{dq_{\text{lys}}}{dt} dz \quad (14)$$

The cost function for the optimization can then be expressed as:

$$- \left[\omega_Y \bar{Y}(t_f) + \omega_P \bar{P}(t_f) + \omega_U \bar{U}(t_f) \right] + R_Q \sum_{i=1}^{N_Q-1} \Delta \hat{Q}_i^2, \quad (15)$$

$$\sum_{i \in \{Y, P, U\}} \omega_i = 1 \quad (16)$$

where the bracketed term is the weighted normalized KPIs, the second term is penalizing the squared difference between two flow rates and R_Q is the penalizing weight. The penalizing term is added to make the resulting flow rate trajectory smoother and to avoid pressure spikes caused by a large step-wise change in flow rate. The complete multi-objective dynamic optimization problem can finally be formulated as:

$$\min. \quad - \left[\omega_Y \bar{Y}(t_f) + \omega_P \bar{P}(t_f) + \omega_U \bar{U}(t_f) \right] + R_Q \sum_{i=1}^{N_Q-1} \Delta \dot{Q}_i^2, \quad (17a)$$

$$\text{w.r.t. } \mathbf{x} : [t_0, t_f] \rightarrow \mathbb{R}^{N_x}, \quad \mathbf{y} : [t_0, t_f] \rightarrow \mathbb{R}^{N_y},$$

$$\mathbf{Q} \in \mathbb{R}^{N_Q}, \quad \Delta t_{\text{load}} \in \mathbb{R},$$

$$\text{s.t. } \mathbf{0} = \mathbf{F}(t, \dot{\mathbf{x}}(t), \mathbf{x}(t), \mathbf{y}(t), \dot{\mathbf{Q}}(t), \Delta t_{\text{load}}), \quad \mathbf{x}(t_0) = \mathbf{x}_0, \quad (17b)$$

$$\mathbf{g}_e(t, \dot{\mathbf{Q}}(t)) = 0, \quad (17c)$$

$$Q_L \leq \dot{Q}(t) \leq Q_U, \quad \Delta t_L \leq \Delta t_{\text{load}} \leq \Delta t_U, \quad (17d)$$

$$\forall t \in [t_0, t_f]$$

The optimization variables consist of the piecewise constant flow rates, \mathbf{Q} , the free manipulated variable, Δt_{load} , the state variables, $\mathbf{x} = (c_{\text{lys}}, q_{\text{lys}}, c_s, m_c, m_{\text{in}})$ and the algebraic variable $\mathbf{y} = q_{\text{lys}}^*$. The trajectories \mathbf{x} are determined by the PDAE in Eq. (17b), the equality constraint on \mathbf{Q} in each time horizon in Eq. (17c) and the bounds on \mathbf{Q} and Δt_{load} in Eq. (17d).

4. Modeling and Optimization Environment

The model presented in section 2 and the dynamic optimization problem presented in section 3 were implemented in the Modelica and Optimica languages. The open-source platform JModelica.org (Åkesson et al., 2010) was used for both simulation and optimization purposes. The spatial domain was discretized using 25 finite volumes and a weighted essentially non-oscillating (Shu, 1998) scheme with 3 sub-stencil was used to approximate the convective and diffusive flux.

For simulation purposes the model was compiled to a functional mock-up unit before being interfaced with CVode from the SUNDIALS solver suite (Hindmarsh et al., 2005). The backward differentiation formula and a relative and absolute tolerance of 10^{-10} was used to simulate the model. The multi-objective dynamic optimization problem presented in section 3 was solved using a direct and local collocation method with 150 finite elements. Each element contained two Radau points and the solution was estimated using Lagrange polynomials (Magnusson and Åkesson, 2015). The nonlinear program resulting from the collocation was solved using the the primal-dual interior point method IPOPT (Wächter and Biegler, 2006) and the linear solver MA57 from HSL (HSL, 2013). The automatic differentiation package, CasADi (Andersson, 2013), was used to compute the first- and second-order derivatives. The starting point of the optimization was obtained by simulating the flow rate trajectory with a constant control signal of 2 ml min^{-1} . The optimization was solved with a tolerance of 10^{-8} .

5. Results and Discussion

Two different cases were optimized to assess the performance of the suggested multflow rate loading strategy. The conventional single flow rate i.e. $N_Q = 1$ was used as a base case and a multflow rate strategy with $N_Q = 50$ was used to demonstrate the advantages with multflow rate loading. The resulting breakthrough curves and optimal flow rates for two different objective weight combinations can be seen in Figure 1. Subplot a) and c) has the objective weights, $\omega_P = 0.440$,

Figure 1: Optimal breakthrough trajectories for the column. The solid black step-function is the flow rates used to load the column, the solid gray line is the protein breakthrough at the column outlet and the gray area indicates the reduction in cycle time, i.e. $t_f - \Delta t_{load}$. The solution to the optimization problem using $N_Q = 50$ is shown in subplot a) and b). The solution to the optimization problem using $N_Q = 1$ is shown in subplot c) and d).

$\omega_U = 0.160$ and $\omega_Y = 0.400$, which results in comparable results with respect to utilization and productivity but the multi-flow rate strategy has a 15% increase in yield. Comparing the results in subplot b) and d), 1.5 – 3.4% lower results in all objectives can be observed for the single flow rate strategy while loading 777s (63.7%) longer than the multi-flow rate strategy. Thus if only a shorter loading time can be allowed, the results of the single flow rate strategy will decrease more than the results of the multi-flow rate strategy. Furthermore any time-saving improvements to the elution, cleaning and regeneration strategy i.e. lowering of Δt_w in Equation 11, will result in a higher relative improvement in production rate for the multi-flow rate strategy.

For each of the cases, a three-dimensional and three two-dimensional pareto fronts were sampled, presented in Figure 2. The complex trade-off between the three objective functions can be seen in the three-dimensional pareto plot. For combinations containing a high weight in yield the multi-flow rate strategy shows better performance in all objectives compared to the single flow rate strategy. This is due to the fact that for single flow rate loading having a large weight on yield means running the process at a low flow rate to avoid protein breakthrough. A constant low flow rate also means that only a small amount of protein will be loaded onto the column i.e. resin utilization and production rate will be low. For the multi-flow rate strategy the process can be run at high flow rates until breakthrough occurs and then gradually decrease the flow rate to maximize the amount of protein loaded while minimizing the breakthrough.

Figure 2: The multi-flow rate strategy is the o markers while the single flow rate strategy is x in all subplots. The result from the tri-objective optimization is presented in the leftmost sub-plot. The three two dimensional sub-plot show the pareto front with one objective fixed to zero.

6. Conclusions

The presented multi-flow rate approach outperforms the single flow-rate for most points on the three dimensional pareto front. The advantage is most pronounced for pareto solutions where no objective function has a weight of zero. However the multi-flow strategy still outperforms the single flow strategy for most weight combinations if $\omega_P = 0$ or $\omega_U = 0$. For $\omega_Y = 0$, the single and multi-flow rate strategies collapse to the same Pareto front because breakthrough of protein has no impact on the production rate and resin utilization, instead all the solutions uses the highest flow rate and only Δt_{load} varies between solutions.

Abstract

Moisture migration occurring during storage in multicomponent food systems is one of the most common problems facing the food manufacturing industry. An example for such a food system is a mass of ice cream in contact with a wafer. In this work, a dynamic moisture migration model for a confectionery food system consisting of a wafer separated by a moisture barrier from a high water activity component (e.g. ice cream) is developed. The 1D diffusion equation was solved for the barrier and wafer each having different transport properties. The developed model predicts the moisture content of the wafer in different locations throughout the product's shelf life.

Keywords: mathematical modelling, moisture migration, multicomponent food.

1. Introduction

Moisture migration in manufactured foods can significantly affect their quality, nutrition, sensory attributes and shelf life. It can occur between foods and the surrounding atmosphere or between different compartments of manufactured foods when they have different water activities. Changes in food attributed to moisture migration include softening, toughening, breakdown, swelling or shrinkage of the material (Roudaut and Debeaufort, 2011). Such changes can have a detrimental effect on the organoleptic properties of the food leading to consumer rejection.

Several studies can be found in published literature on moisture migration in food materials. However, in most moisture migration is usually coupled with a heat transfer process (e.g. baking, freezing). A smaller number of studies is focused on moisture migration in multicomponent food systems during storage at constant temperature. Hao et al. (2016) investigated moisture migration in a biscuit – hawthorn and a biscuit – agar gel system at 25°C. Guillard et al., (2003a) studied a two component food system of a sponge cake in contact with a fresh wet filling at 20°C. Gulati et al. (2015) studied moisture migration in a bread with a chicken filling sandwich during storage at 25°C.

In several food systems, an edible moisture barrier can be employed between two different water activity materials to minimise moisture transfer. An example for such a material is chocolate flavoured films which have been extensively used in the confectionery industry. Biquet and Labuza, (1988) conducted a study to experimentally

evaluate a semisweet dark chocolate film as a moisture barrier at 20°C. Guillard et al. (2003b) evaluated the barrier properties of various edible films at 20°C while Bourlieu et al., (2006) characterised nine lipid-based edible barrier films at the same temperature.

In this work a phenomenological model to predict dynamic moisture migration for a multicomponent food system has been developed using food material transport properties as inputs. Experimental data obtained at room temperature conditions are used to predict the moisture content in the different components in contact. Room temperature conditions are significantly higher than the temperature of interest for this application. However, this study aims to present the predictive capabilities of the model and serves as a starting point for further investigation.

2. Models and methods

The system used as a case study consists of a wafer cone internally coated with moisture barrier and it is filled with ice cream as seen in Figure 1. The product is usually packaged in a material considered mostly impermeable to moisture.

Figure 1: Different components of the investigated system

2.1. Moisture transfer

To simulate the moisture migration a 1D mass transfer equation is used (Guillard et al., 2003a). As the driving force for moisture migration is the water activity (α_w) gradient between the materials in contact, the mass transfer equation needs to be expressed in terms of α_w :

$$\frac{\partial X}{\partial t} + D_{eff} \frac{\partial^2 X}{\partial x^2} = \frac{\partial X}{\partial \alpha_w} \frac{\partial \alpha_w}{\partial t} + D_{eff} \frac{\partial}{\partial x} \left(\frac{\partial X}{\partial \alpha_w} \frac{\partial \alpha_w}{\partial x} \right) = 0 \quad (1)$$

where X (wt/wt) is the moisture content calculated on a wet base, D_{eff} (m^2/s) is the effective diffusivity, x (m) is the location and t (s) the time. Solving the above equation requires information specific to each material at the temperature of interest. These are the materials' D_{eff} and moisture sorption isotherms both usually obtained experimentally.

Equation (1) is a 2nd order partial differential equation and it is usually solved numerically. Different methods can be used as the finite element method (Hao et al. 2016) or finite differences (Guillard et al., 2003a).

2.2. Moisture sorption isotherms

Moisture sorption isotherms relate α_w to the corresponding material X . They are unique for each material and temperature and they are usually obtained gravimetrically. To obtain moisture absorption isotherms an initially dry sample is placed in environments of increasing α_w . For each α_w level, the weight of the sample is measured continuously until equilibrium is observed. In theory equilibrium is established when the weight of the sample remains constant over time. However, in practice the sample is considered at equilibrium when the change of weight over a predefined period of time is sufficiently small (Bourlieu et al., 2006).

2.3. Effective diffusivity

The sorption kinetics data obtained from the sorption experiments can be used to obtain the D_{eff} values assuming they are constant for each α_w step. The data can be fitted to an analytical solution of the mass transfer equation to obtain the D_{eff} . Fick's 2nd law can be solved analytically for a variety of common geometries such as infinite plane, cylinder and sphere. For a flat sample whose geometry can be simulated as an infinite plane, the analytical solution is (Guillard et al., 2003a):

$$m(t) = m_0 + (m_\infty - m_0) \left[1 - \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(1+2n)^2} \exp \left[-(1+2n)^2 \pi^2 \frac{D_{eff} t}{h^2} \right] \right] \quad (2)$$

where m (kg) is the mass of the sample, m_0 (kg) is the mass at $t=0$, m_∞ (kg) the mass at equilibrium and h (m) the thickness of the sample.

3. Implementation

3.1. Material moisture sorption isotherms

The wafer's moisture sorption isotherm was experimentally obtained at 25°C. This temperature was selected to allow for comparisons against published data. The Direct Vapour Sorption (DVS) equipment manufactured by Surface Measurement Systems was used. The sample is initially desiccated and then humidity is increased in a stepwise manner. The thickness of the wafer is ca. 2.4mm.

Water activity was increased from 0 to 0.9 with a 0.1 increment and the maximum investigated α_w was 0.95. Equilibrium was assumed to have been achieved when the change of sample mass over 5 minutes became smaller than 0.002%/min. The obtained wafer moisture sorption isotherm is shown in Figure 2a.

For the mathematical representation of the isotherms a variety of models can be found in published literature but not all of them give a good fit for all food materials throughout the entire α_w range. The best fit for the wafer isotherm was found to be given using the Freundlich model (Chen and Chen, 2014) described by equation (3):

$$X = 0.5176(a_w)^{4.050} \quad (3)$$

Currently, no isotherm has been obtained for the moisture barrier. However, to be able to use the developed model the use of an isotherm is imperative. The isotherm presented in Guillard et al., 2003b was used where authors used the Ferro – Fontan model to fit

the data which is described by equation (4). The isotherm was obtained at 20°C and is shown in Figure 2b.

$$X = \left[\ln \left(\frac{1.895}{a_w} \right) \left(\frac{1}{0.634} \right) \right]^{-9.312} \quad (4)$$

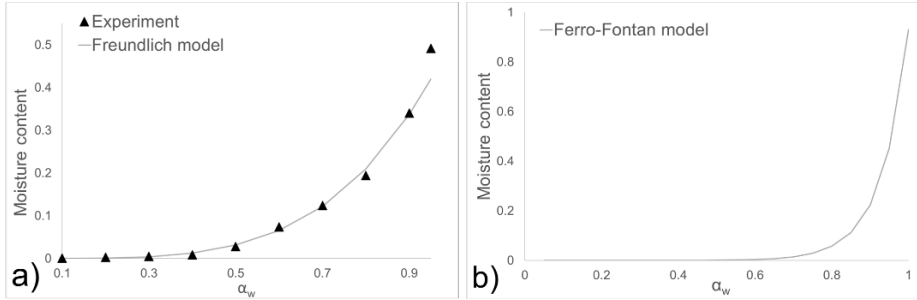

Figure 2: a) Wafer moisture sorption isotherm, b) Dark chocolate flavoured coating moisture sorption isotherm in Guillard et al., (2003b).

From Figure 2 it can be observed that for the same value of α_w the wafer absorbs more moisture compared to the moisture barrier suggesting it's more hygroscopic.

3.2. Material effective diffusivities

For the wafer the data obtained from the moisture sorption isotherm experiments were used. As the geometry of the wafer can be simulated as an infinite plane equation (2) was used to fit the D_{eff} value for each α_w step. An average value for the entire investigated α_w range was used equal to $5.41 \cdot 10^{-11} \text{ m}^2/\text{s}$.

No sorption kinetics data were available for the moisture barrier. However, permeability data obtained at 4°C using the water method ("ASTM Standard test methods for water vapor transmission of materials," 1995) were available. Combining the definition of the flux with and Fick's first law an average D_{eff} value of $5.94 \cdot 10^{-13} \text{ m}^2/\text{s}$ was calculated.

3.3. Phenomenological model for moisture migration in an ice cream cone

Equation (1) was solved numerically using the method of lines (Cutlip and Shacham, 1998). To use this method the materials are separated in grids and their X is calculated at each location using equation (1) for different time intervals.

The boundary conditions are obtained from the description of the system as shown in Figure 1. On the left hand side, the moisture barrier is in direct contact with a mass of ice cream calculated to be at $\alpha_w=0.84$. On the right hand side, the wafer is assumed to be in contact with a moisture impermeable barrier. The number of grids required to discretise the moisture barrier was selected to be 200. As the thickness of the moisture barrier is ca. 0.6mm and the wafer's 2.4mm, to maintain constant grid thickness in both materials, the number of grids required to discretise the wafer was found to be 800.

The initial condition for the system is that $\alpha_w=0.45$ in both materials. This value is calculated using the wafer's isotherm as at the start of the manufacturing process for the wafer $X=2\%$. Uniform initial conditions are used to ensure the only α_w gradient is between the ice cream and the first grid of the moisture barrier.

4. Results and discussion

The time allowed for the simulation is 48 hours as the moisture barrier appears to equilibrate with the ice cream fast. This can be attributed to the isotherm which was obtained at 20°C, a temperature significantly higher than the temperatures of interest for this application. Therefore, this study serves to showcase the predictive capabilities of the model and serve as an initial starting point for future investigation at lower temperatures.

4.1. Space domain

Figure 3 depicts the a_w and corresponding X of the materials in contact as a function of space after 6, 24 and 48 hours.

Water activity in all test locations increases over time. Closer to the ice cream the increase is more prominent as the flux is higher due to the higher a_w gradient. The same effect can be observed in Figure 3b. The discontinuity in this Figure occurs at the interface between the two materials and is a result of the materials having different isotherms leading to different X for the same a_w .

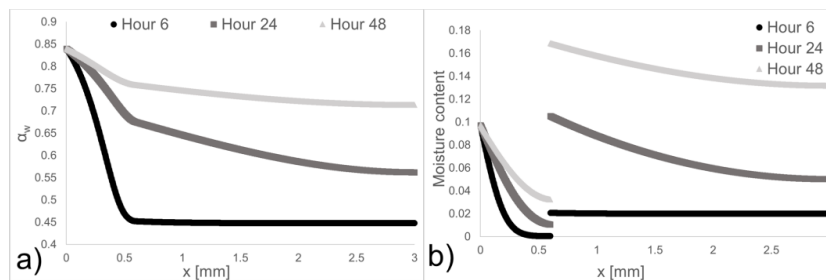

Figure 3: a) Water activity as a function of space after 6, 24 and 48 hours, b) Moisture content as a function of space after 6, 24 and 48 hours.

4.2. Time domain

Figure 4 depicts the a_w and corresponding X of the employed materials as a function of time at specific locations. Two locations in each material were selected to represent the areas closest to the boundaries and areas close to the interface. It is observed that for the location closest to the ice cream, a_w increases rapidly and reaches approximately equilibrium with the ice cream in about 48 hours. For the other investigated locations, a plateau is initially observed before a_w starts to increase. This is because moisture must progress through all previous locations and the D_{eff} of both the chocolate layer and the wafer present significant resistance.

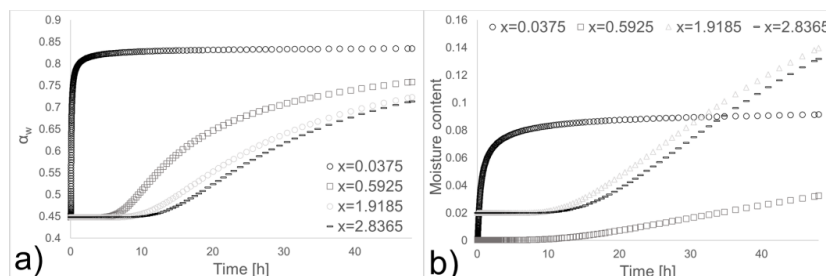

Figure 4: a) Water activity as a function of time at specific locations, b) Moisture content as a function of time at specific locations.

In Figure 4b the significance of the moisture sorption isotherms is showcased. Location $x=0.5925\text{mm}$ in the moisture barrier has a significantly higher α_w , compared to the wafer location at $x=1.9185\text{mm}$. However, the corresponding X of the moisture barrier's location is lower than the wafer's. This is due to the wafer being more hygroscopic and thus absorbing more moisture for the same α_w value.

5. Conclusions

A mathematical model for the prediction of moisture migration in a multicomponent system was presented. Experimental and published data at room temperature conditions were used as inputs to calculate the X of the different materials in contact in different locations over time. The moisture barrier at room temperature conditions cannot protect the wrapping wafer effectively as it appears to be reaching equilibrium with the high α_w material in 48 h.

Further work is required to obtain input data for different temperatures including below zero conditions. As the model considers a uniform moisture barrier layer using data at different temperatures will allow the designers to understand whether moisture migration occurs through the materials (diffusion limited). Otherwise this suggests the presence of imperfections in the moisture barrier whose influence should be investigated.

Abstract

The main challenge of anesthesia is the maintenance of the desired sedation level before, during, and after the induction. We developed an in-silico model-based control loop for the administration of an analgesic opioid, remifentanyl, and of an anesthetic, propofol. The patients' response (i.e. the real process) is predicted in-silico by a physiologically-based pharmacokinetic model, conjugated with suitable pharmacodynamic models that simulate the dynamic response of heart rate, arterial pressure, and bispectral index. We simulated the induction phase of anesthesia and obtained a fast and safe patient's response by setting the arterial pressure and bispectral index as controlled variables, and implementing proper bounds on both the plasma concentration and the controlled variables.

Keywords: model-based control, anesthesia, analgesia, pharmacokinetics, pharmacodynamics.

1. Introduction

Different drugs are responsible for the anesthesia cocktail, i.e. (i) a hypnotic for unconsciousness, (ii) an analgesic for pain relief, (iii) a neuro-muscular blocker to avoid undesired reflex activity. Most of these drugs feature a narrow therapeutic range that makes their titration critical. The anesthesiologist usually selects an initial dose according to standard protocols. This dose is then subject to variations based on measurable (e.g., hemodynamics, muscle and cerebral activity) and subjective (e.g., eyes movement, response to calling) physiological indicators of the patient's status. Indeed, the induction allows reaching a certain “depth of anesthesia” (DOA) that has to be kept throughout the operation (i.e. maintenance) until the end of the surgery. In engineering terms, the anesthesiologist acts as a “human” feedback controller and implements actions based on the patient's response. The actuator of this control-loop is usually a target control infusion (TCI) pump, which implements a three-compartment pharmacokinetic (PK) model to determine the infusion rate that allows achieving the desired target concentration. However, these models do not have any correspondence with the real physiology of human body, and the adaptive parameters are often identified by fitting the measured drug concentration in healthy volunteers (Minto et al., 1997; Schnider et al., 1998). Therefore, these models may not be suitable to determine the adequate anesthesia dose for special population (e.g., ill, elderly). Recent years have seen a rising interest in the application of medical devices for Physiological Closed-Loop Control (PCLC) (FDA, 2015). Anesthesia practice may benefit from the introduction of automated controllers. In fact, the anesthesiologist's control action is intrinsically subjective and intermittent, and often irregular, with possible adverse effects on the patient's health and longer times for recovery. Researchers are

investigating different control strategies, e.g., PID, fuzzy controllers, neural networks, model-based control (FDA, 2015). Anesthesia challenges call for (i) robustness towards disturbances (i.e. nociceptive stimuli) and measured variables noise, (ii) control effort minimization to avoid overdosing, (iii) management of drugs dynamics and interactions that may alter pharmacokinetics and pharmacodynamics. Model predictive control (MPC) can tackle these tasks. We developed an in-silico loop for anesthesia induction and maintenance with co-administration of the hypnotic propofol and the analgesic remifentanyl.

2. Methods

Figure 1 shows the structure of an in-silico loop for induction and maintenance of anesthesia. For the sake of correctness, we introduced a “mismatch” between (i) the model that represents the real patient and (ii) the model implemented in the controller. We chose to use a physiologically-based (PB) PK model (Abbiati et al. (2016)) to represent in-silico the PK response of the real human body. This model is more complex than classical PK models, as it features compartments that correspond to real tissues and organs and includes realistic metabolism/elimination paths. Indeed, PBPK models are nearer to the anatomy and physiology of patients and this makes the individualization of both prediction and treatment easier.

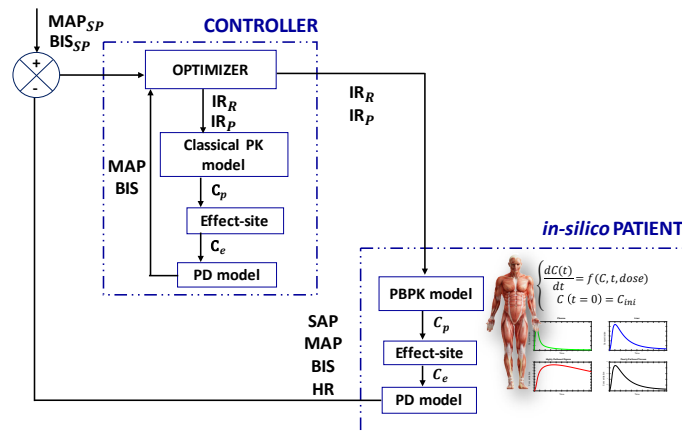

Figure 1 - In-silico loop scheme for control of anesthesia with propofol and remifentanyl. The main elements are: (i) the controller PK three-compartment model combined with Hill equation (PD), (ii) the real patient model, i.e. PBPK model combined with Hill equation (PD), (iii) the optimizer, (iv) the control specifications on MAP and BIS, (v) the manipulated variables IR_R and IR_P (remifentanyl and propofol infusion rates, respectively).

Our PBPK model is conjugated to suitable pharmacodynamic (PD) models (i.e. modified Hill equation) as discussed in Savoca et al. (2017), to predict mean arterial pressure (MAP), systolic arterial pressure (SAP), heart rate (HR), and bispectral index (BIS). In particular, AP and HR depend on remifentanyl concentration while BIS depends on propofol concentration, as it is an unconsciousness measure that depends on the hypnotic. The MPC controller implements a classical three-compartment PK model, which is simpler and faster than the PBPK counterpart. Once again, the adopted PD models remain the same. We use PK model parameters for remifentanyl from Minto et

al. (1997) and for propofol from Schnider et al. (1998). The manipulated variables are remifentanyl and propofol infusion rates. The corresponding controlled variables are MAP and BIS. We chose MAP as the analgesia controlled variable over HR and SAP, because (i) it is more reliable than SAP and DAP, and (ii) the PD model provided better results in the validation phase with experimental data from the scientific literature. However, the objective function includes a penalty when the plasma concentration overflows the therapeutic range. We chose BIS as the hypnosis controlled variable because several authors consider it a reliable measure of the sedation level. We remain aware of some controversies arising in case of neuromuscular-blocking agents use (Schuller et al., 2015). Eq. (1) is the objective function that is minimized at each discrete control time k of the prediction horizon. The result of the optimization is a set of optimal control actions evaluated over a specific control horizon. The first control action is assessed in-silico using the PBPK/PD model whose output is passed at the following time instant to the controller as an input value.

$$\min_{\mathbf{u}(k), \mathbf{u}(k+1), \dots, \mathbf{u}(k+h_c-1)} \left\{ \sum_{j=k+1}^{k+h_p} \left[w_y e_y^2(j) + PF_x(j) \right] + \sum_{i=k}^{k+h_p-1} \left[w_u \Delta \mathbf{u}^2(i) \right] \right\} \quad (1)$$

The first term in Eq. (1) accounts for the minimization of the distance of the model prediction from the assigned set-point trajectory. The second term minimizes the control effort to avoid steep changes of the manipulated variables (i.e. the infusion rates). In addition, we implemented suitable penalty functions for the plasma concentration and the controlled variables MAP and BIS (summarized in PF_x). The MPC code is written in Fortran 90.

3. Results

3.1. Induction and maintenance simulation

The goal of induction is to rapidly reach a desired DOA level (i.e. setpoint in control terminology). It is worth underlining that the scientific literature does not provide any unique definition of DOA. We define DOA as BIS=45 [-] and MAP=70 [mm Hg], since the sedation range is BIS=40-60 [-], and MAP is around 70 [mmHg] in conditions of adequate analgesia. These are the setpoints assumed for induction and maintenance in our simulations. The control action starts 5 min after the simulation begins (to simulate the pre-induction phase when a null drug concentration corresponds to baseline values of awake patients, i.e. MAP=100 [mmHg] and BIS=90 [-]). The desired DOA level is achieved with a balanced control action (Figure 2, medium panel) that is steep at $t=5$ min (i.e. bolus) to ensure fast reaching of the set point (see top panel) but decreases gradually once it is reached. The rise-time of MAP is 2.69 min. The time required for unconsciousness (i.e. the time for BIS to reach 70 [-]) is 1.593 min, while the time to start incision (i.e. BIS=50 [-]) is 2.814 min. It is worth observing that in both cases (i.e. remifentanyl and propofol) the concentration remains within the therapeutic range (remifentanyl 3-8 ng/mL ensures adequate analgesia while 1.3-6.8 $\mu\text{g/mL}$ is the therapeutic blood range for propofol). Particularly, the controller prioritizes the error of set point term rather than the plasma concentration PF, as the MAP set point is maintained even though the controller model analgesic concentration is below the adequate range. The physiological time delay between the drug concentration in plasma and the corresponding clinical effect is represented by the lag between plasma and effect-site compartments (bottom panel).

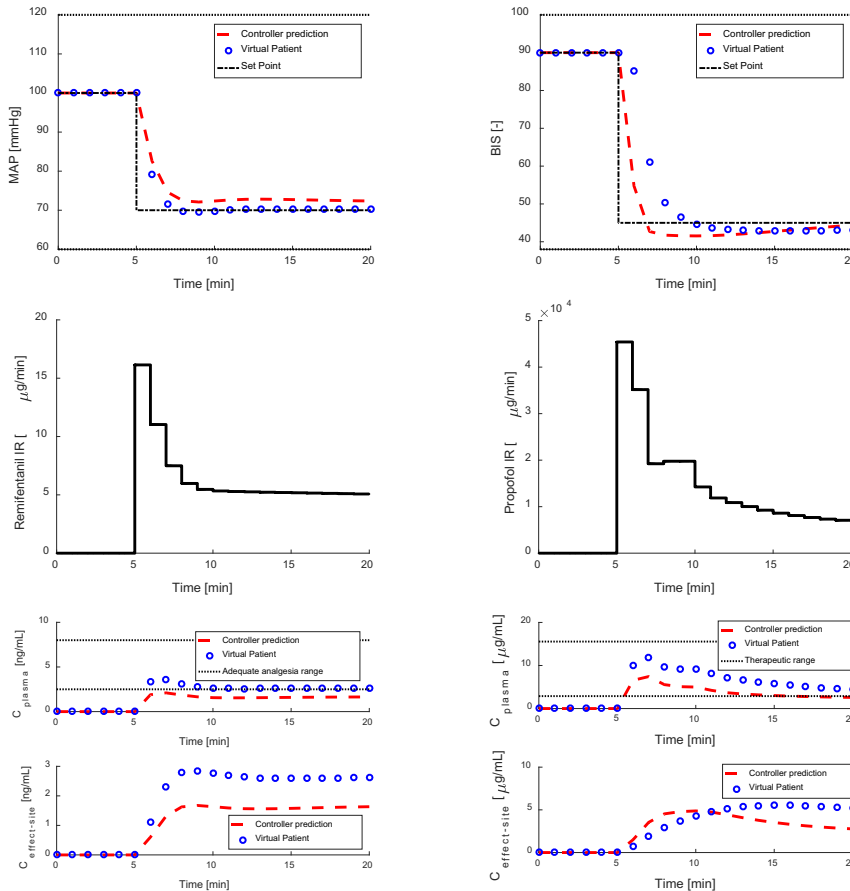

Figure 2 - Simulation of the induction phase. Left diagrams refer to analgesia while right diagrams refer to hypnosis. (Top) Dynamics of controlled variables. (Medium) Manipulated variables. (Bottom) Time profiles of monitored plasma (top) and effect-site (bottom) pharmacokinetics predicted by the controller model (red dashed line) and the virtual patient model (blue circles).

This delay depends on distribution/diffusion processes, age, presence of impairments, and PK input. Therefore, different PK models for the same drug display different lags.

The CPU time for the simulation of 20 control actions (discrete control time=1 min), as shown in Figure 2, is 10.05 s (Intel® Core™ i7-3770 CPU @ 3.40 GHz, 8 GB RAM), proving that the in-vivo and online application of MPC to surgical anesthesia is today feasible. Figure 3 shows that in absence of disturbances, after the induction, the controller can maintain both MAP and BIS target values for a prolonged time (i.e. the duration of the surgical procedure, hereby assumed 50 min) without showing any stability problems.

3.2. End of surgery simulation

Unlike the simulation of Section 3.1 based on a 50 min surgical maintenance, we now want to reproduce the end of surgery at $t=30$ min (by modifying the MAP and BIS

setpoints to 100 and 90, respectively), which corresponds to the completion of drugs infusion.

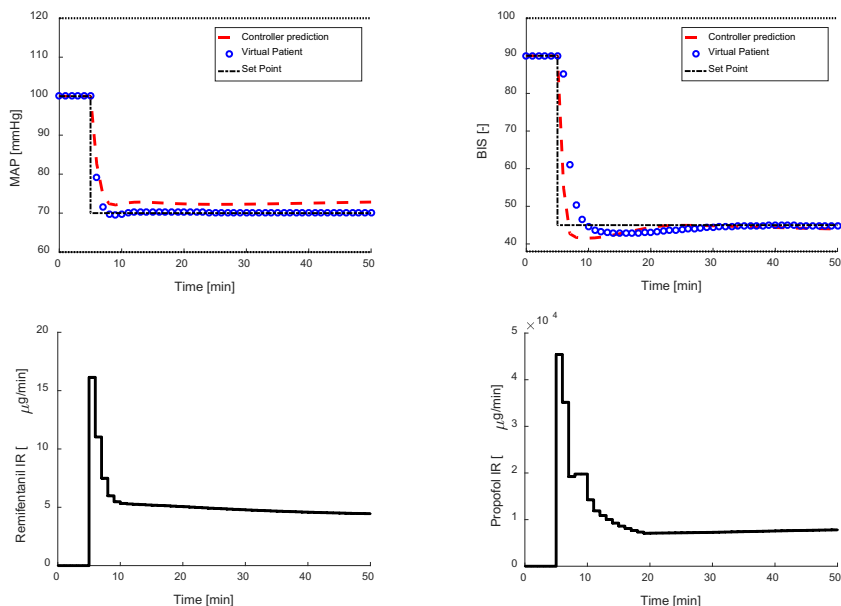

Figure 3 - Controlled (top panel) and manipulated (bottom panel) variables during maintenance phase (on the left, MAP dynamics; on the right, BIS dynamics). The duration of the surgical procedure is 50 min. The controller can maintain the targeted set points with no instabilities.

As expected, the manipulated variables go to zero and, since the drugs are progressively cleared from the virtual patient body, the pharmacological effects (i.e. MAP and BIS) increase towards the baseline values, i.e. awake patient (Figure 4). The estimated time for recovery from anesthesia is around 46.22 min, which is consistent with real surgeries. In fact, although the recovery time from opioids and hypnotics is subject to inter-individual differences, Misal et al. (2016) report that “complete physiologic recovery takes place by 40 min in 40% of the patients”. For the sake of clarity, it is important to underline that the controller is not responsible in influencing the velocity of the curve after the infusion ends, as there are not any antidotes to remifentanyl and propofol. Consequently, the profile depends on the metabolic and elimination characteristics of the patient, i.e. the PBPk/PD model. The recovery from anesthesia is very critical and we are aware that in the practice BIS and MAP observations are not sufficient. Other measurable and non-measurable (i.e. movement, response to calling) variables must be considered to assess the level of awareness. For this reason, the expertise of the anesthesiologist remains essential.

4. Conclusions

According to our findings, the designed MPC controller allows achieving a safe induction with plausible results concerning the end of surgery. The use of a PBPk/PD model leaves space for treatment personalization and analysis via in-silico simulation. In fact, “special” individuals can be simulated, such as ill patients. Future work will investigate the controller response to intraoperative disturbances, e.g., nociceptive

stimuli. The final goal of our research line is clinical validation. In this case, the controller would feature the PBPK/PD model and the patient would be in-vivo rather than in-silico. This is a key point as, in the literature, to our knowledge, no one has combined anesthesia control with the physiological approach to PK/PD modeling.

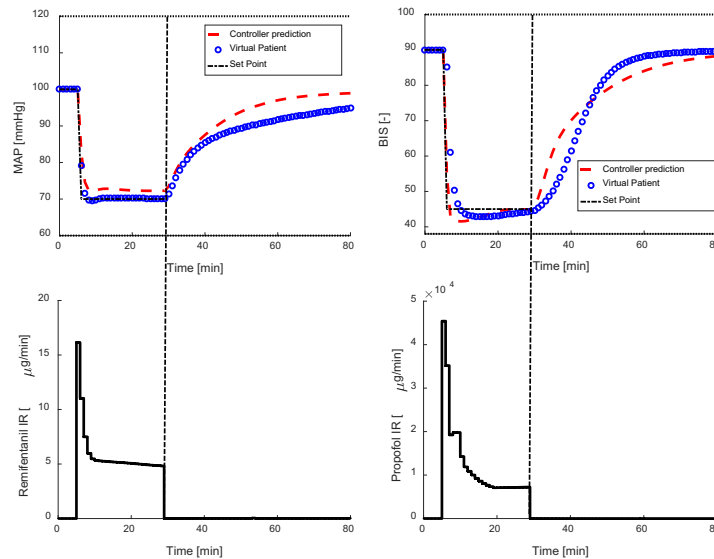

Figure 4 - Controlled (top panel) and manipulated (bottom panel) variables after the end of anesthesia. Control action stops at $t=30$ min, as shown by the vertical dotted line.

Process modelling, design and technoeconomic evaluation for continuous paracetamol crystallisation

Hikaru G. Jolliffe, Dimitrios I. Gerogiorgis*

School of Engineering (IMP), University of Edinburgh, Edinburgh, EH9 3FB, UK

D.Gerogiorgis@ed.ac.uk

Abstract

Continuous Pharmaceutical Manufacturing (CPM) has received significant research interest as a way to achieve a step-change in the performance of pharmaceutical production, where innovations are incremental at best due to the current paradigm – batch production – being a relatively mature technology. In this work, a Continuous Oscillatory Baffled Crystalliser (COBC) for paracetamol crystallisation has been modelled and optimal design and operation has been determined via nonlinear optimization (NLP). Clear trends emerge, with rate of antisolvent use having a marked impact of COBC volumes; crystal seed mass loading also has a strong effect. However, there are tradeoffs between mass efficiency, cost and volume, and product crystal size. The trends and optima illustrate how process modelling, simulation and optimisation provide clear insights into process performance and decisions on acceptable tradeoffs.

Keywords: Continuous Oscillatory Baffled Crystalliser (OBC), paracetamol.

1. Introduction

Pharmaceutical production has long relied solely on batch processing, and while it has many benefits including equipment flexibility and the know-how of a mature technology, in an environment of growing R&D expenditure and a greater awareness of and a drive to be more sustainable, research interest has turned towards Continuous Pharmaceutical Manufacturing (CPM); continuous production can achieve higher yields purities, better heat and mass transfer, decreased processing times, and better efficiency and reliability. The need for cost-effective R&D methodologies brings process modelling and simulation to the forefront of initial stages of process option evaluation. Furthermore, they are also of great utility in evaluating alternative design parameters for existing or newly developed processes (Benyahia et al., 2012). Continuous crystallisation has received significant research attention toward developing separation technologies for CPM, with both stirred tanks and tubular crystallisers types studied in great detail (Ferguson et al., 2014; McGlone et al., 2015; Diab and Gerogiorgis, 2017).

In previous work, we have used modelling and simulation to economically evaluate two CPM processes, and we have also used nonlinear optimisation of these process models to determine optimal design and operating parameters for key product separation operations (Jolliffe and Gerogiorgis, 2017a, 2017b). In the present work, we systematically incorporate models for continuous crystallisation, published crystallisation kinetic data, and economic analysis into a nonlinear optimisation model

to determine optimal crystallisation operation and design for the recovery of an analgaesic Active Pharmaceutical Ingredient (API), paracetamol. This key API has been widely used as a model API for CPM studies, with published data on crystallisation kinetics available (Brown et al., 2015; Cruz et al., 2016). The impact of temperature, crystalliser size and configuration, antisolvent type and quantity, and flowrate are considered. The optimisation cases are formulated into a nonlinear optimisation model to determine optimal Continuous Oscillatory Baffled Crystalliser design variables and process conditions. Technical (API recovery), environmental (E-factor) and economic metrics (Capital Expenditure, CapEx) are used for comprehensive process evaluation.

2. Continuous Oscillatory Baffled Crystallisers (COBC)

Continuous Oscillatory Baffled Crystallisers (COBC) are a development of Oscillatory Baffled Reactors, and in essence are a series of baffles in long (i.e. high length-to-diameter ratio) tubes, and in appearance are similar to Plug Flow crystallisers with baffles. COBC units tend to offer improved performance over the latter, as well as over batch crystallisers. They offer improved scaling, heat and mass transfer and decreased processing times (Lawton et al., 2009). COBC units operate by inducing an oscillatory flow in the fluid contents, and there is also a net flow through the unit (as this is a continuous process) which is independent of the oscillatory flow. The use of a reciprocating pump is a common way to generate the oscillatory flow: as the fluid moves back and forth across the baffles, the eddies generated enhance mixing and thus improve local crystallisation performance considerably. Baffle design primarily varies in terms of the orifice-to-internal diameter ratio, the gap between the baffles and the number of orifices in the baffles; in some cases constrictions are used instead of baffles.

3. Nonlinear optimisation and process model

The objective function to be minimized is a Capital Expenditure (*CapEx*) function (Eq. 1), from a capacity-power law using crystalliser volume. The coefficient a and exponent n were generated by fitting publicly available data for cost and capacity of commercial COBC units. Crystalliser volume is computed in a relatively straightforward manner (Eq. 2), from total volumetric throughput and the residence time required to achieve the desired objectives (such as yield). The population balance (Eq. 3) and mass balance (Eq. 4) are solved via a moment transformation (Eq. 5) (Brown et al., 2014). Key variables in (Eq. 5) include characteristic crystal length L (m), growth rate G (m s^{-1}). The volume shape factor k_v is taken to be 0.866, typical for the monoclinic Form I of paracetamol which is often encountered (Brown and Ni, 2011), and the crystal density ρ_{API} is 1.3 g.cm^{-3} . Nucleation is considered to be negligible, so the Br_o^j terms are ignored. Growth rate G is computed via the an empirical correlation (Eq. 6) (Brown and Ni, 2011), where ΔC_{API} is the degree of supersaturation (Eq. 7), \dot{Q}_{AS} is the rate of antisolvent addition in mL min^{-1} , and the oscillatory flow Reynold Number Re_o (Eq. 9). In the latter term angular velocity $\omega = 2\pi f_{osc} a_{osc}$ (ms^{-1}) replaces the superficial fluid velocity found in the normal (Net Flow) Reynolds Number (Re_n , Eq. 9). Here, f_{osc} and a_{osc} are the frequency and amplitude of the fluid oscillation, respectively (normally taken to be 2 Hz and 10 mm in this model). In the literature, values for both Re_o and Re_n are suggested to achieve the best mixing, often above 300 for the former and above 50 for the latter. In this model we have imposed similar requirements, although with a higher Re_o ; values over 4,000 are reported (Brown and Ni, 2011). The Re_o to Re_n ratio (ψ) has an optimal mixing interval; operation may vary outside reported ranges (Eq. 9) by as much as 10%.

The solubility of paracetamol in different solvent systems has been commonly studied in the literature. Here, the use acetone as process solvent is modelled, with either water or toluene as antisolvent. Empirical values for paracetamol were taken fitted high order polynomial surrogate equations to calculate solubilities (Eq. 8) (Fig. 1). With water use there is a solubility peak, and within a certain range adding water will in fact increase API solubility. To avoid this, the rate of antisolvent use was limited to a range of 50:50 to 20:80 by weight (process solvent acetone : antisolvent). It transpires that the use of toluene results in highly impractical residence times and volumes (very long/large), and so the results presented in this work refer to the use of water as an antisolvent.

Seed crystal loading can vary from 0.5% to 2.0% by weight (seed w.r.t. solvent and antisolvent). The following assumptions are made: a) seed crystals are monodisperse (i.e. of same size) and of monoclinic Form I; b) no nucleation, agglomeration or

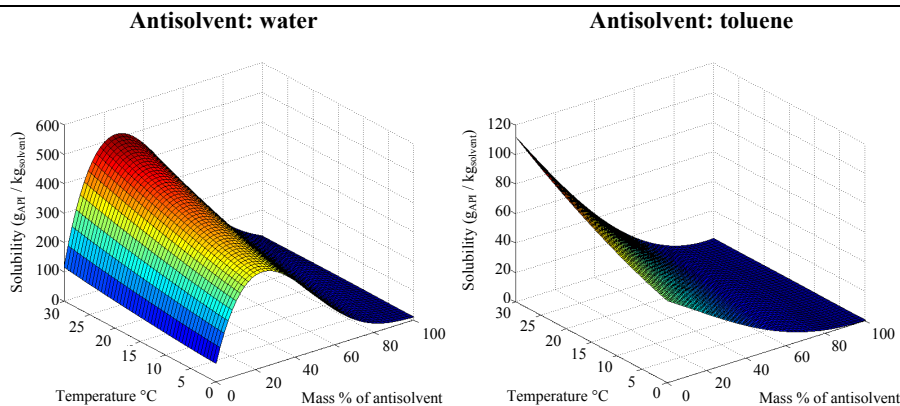

Figure 1. Paracetamol solubility in acetone-antisolvent mixtures (Granberg and Rasmuson, 2000).

breakage of crystals; c) crystal growth rates are size-independent; d) no impurities; e) sufficient heat transfer available to maintain a linear cooling profile. In terms of temperature, the inlet temperature can vary between 30 to 70 °C, and cooled to 5 °C; an inlet temperature of 50 °C is the default studied, and the other values investigated to see how optimality varies. Likewise, seed crystal size has been set at 40 microns by default, and larger sizes are investigated to study the optimal solution variation. Separate optimisation cases are formulated for varying inlet temperature and seed crystal size.

The MATLAB solver employed here is a constrained minimization routine (trust region reflective algorithm) with tolerances (stopping criteria) set to 10^{-6} . Gradients have been computed by the solver itself, and the solution time is reasonably fast, ranging between 30–100 seconds (the latter is the time required to generate capital expenditure response surfaces, while the time to run a single optimisation case is between 5–10 seconds). As stated, separate cases were formulated for initial temperatures. Separate cases were also performed for seed crystal sizes. A quick global search has been performed by checking convergence from multiple initial starting points; the runs always converged to the same point, and the absence of other local minima can be concluded with high confidence.

4. Results and discussion

Given a desired yield of 50%, the total cost response surface for an inlet temperature of 50 °C and a seed crystal size of 40 microns is given in Fig. 2A. The optimal solution (cost = 101,370 GBP) is pushed to bounds. It is evident that the rate of antisolvent use affects the total cost more significantly than the seed mass loading. Greater rates of antisolvent use result in lower costs via lower required residence times, due to faster growth rates. The tabulated values (Table 1) illustrate how the optimum changes with varying inlet temperatures, with a constant seed crystal size of 40 microns. Increasing the inlet temperature can drastically lower the cost via small required volumes and residence times. We can also see how the product crystal size varies, increasing with inlet temperature (and lowering with lower inlet temperature). This makes sense, as we assume the same initial supersaturation ratio ($S = 1.5$, Eq.7) in all cases: the higher the inlet temperature the higher the inlet solubility, thus higher supersaturation, thus greater API content, thus greater API precipitation for the same yield, thus larger product crystal sizes (as seed count is the same). Table 1 presents how capital cost, volume, residence time and product crystal size vary as a function of the seed crystal size used.

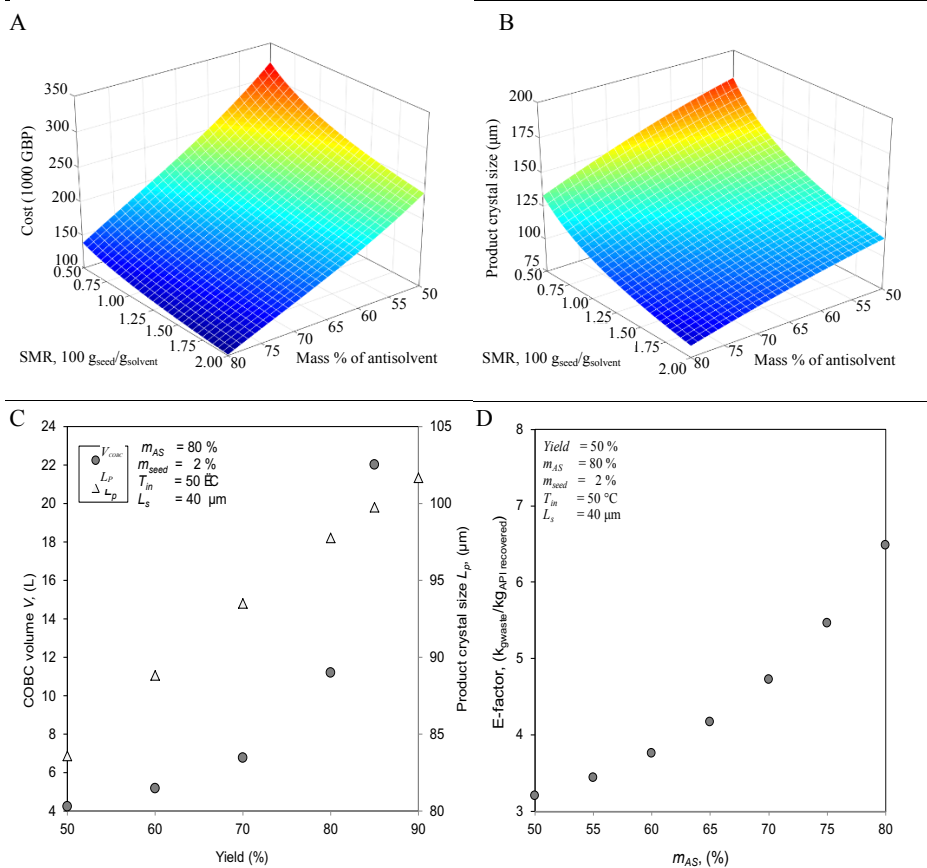

Figure 2. Total cost (A) and product crystal (B) response surfaces, volume and product size variation with required yield (C), and E-factor variation with antisolvent use (D).

For the same inlet temperature of $50^\circ C$; optima variation is less pronounced as with different inlet temperatures. Of course, for a given seed mass loading, larger seed crystal sizes mean lower seed counts. The response surface for product crystal size is given in Fig. 2B. Lower antisolvent amount results in larger product crystals; again, this is an effect of seed count. With lower antisolvent amount, the mass of seed crystals added in absolute terms is less. Therefore, the seed count will lower, meaning crystals must grow more in order to achieve the same yield. The reason lower seed mass loading increases product size is similar. The change in required COBC volumes as a result of oscillation in the COBC unit is straightforward (values not shown): Higher angular velocities (ω , a combination of the oscillation frequency and amplitude) produce a clear trend of lower volumes; this is to be expected, as higher ω increases Re_o , which increases growth rates. Fig. 2C illustrates the variation of volumes and product crystal sizes for different required target yields (other results here are for a 50% yield). The inlet temperature is $50^\circ C$, with a seed crystal size of 40 microns. Product crystal size increases linearly, while crystalliser volumes increase exponentially; achieving 90% yield is impractical.

Table 1. Optima variation for differing inlet temperatures (left) and seed crystal size (right).

T_{in} (°C)	Seed crystal size $L_s = 40\mu\text{m}$				Inlet temperature $T_{in} = 50^\circ\text{C}$				
	CapEx (10^3 £)	V_{COBC} (L)	τ_{req} (s)	L_p (μm)	L_s (μm)	CapEx (10^3 £)	V_{COBC} (L)	τ_{req} (s)	L_p (μm)
70	37.032	0.941	91	118.0	80	161.060	8.499	822	167.2
60	60.337	1.954	189	99.2	70	147.280	7.435	719	146.3
50	101.370	4.250	411	83.6	60	132.970	6.380	617	125.4
40	170.600	9.265	896	71.5	50	117.700	5.315	514	104.5
30	283.530	19.822	1917	62.4	40	101.370	4.250	411	83.6

Finally, evaluating E-factors (mass of waste per unit mass of product; a measure of mass efficiency – lower is better) in Fig. 2D, we can see that for a given yield they worsen with increasing antisolvent quantity; E-factor is invariant with seed mass loading. However, with worsening E-factor, costs improve, highlighting the conflicting requirements in process design and evaluation, and the need for tradeoff decisions.

5. Conclusions

The solved optimisation cases illustrate the benefits and drawbacks of different combinations of solvent and antisolvent, in both technical and sustainability terms, and the varying impacts of inlet temperature, seed mass loading, seed crystal size, mechanical operation of the crystalliser, and rate of antisolvent use. For a desired yield of 50 %, the latter has the most significant effect on crystalliser cost (Capital Expenditure), while seed mass loading also has a strong effect. Higher required yields require exponentially larger and more costly crystallisers. The tradeoff between material efficiency (which has been calculated by means of the E-factor metric), and volumes and cost, underscores competing objectives that frequently arise during process design.

Process modelling, simulation and technoeconomic optimisation for continuous pharmaceutical manufacturing of (*S*)-warfarin

Samir Diab, Dimitrios I. Gerogiorgis*

School of Engineering (IMP), University of Edinburgh, Edinburgh, EH9 3FB, UK

D.Gerogiorgis@ed.ac.uk

Abstract

Continuous pharmaceutical manufacturing (CPM) has the potential to attain several technical and operational economic benefits compared to the currently prevalent batch production paradigm. Despite the variety of demonstrated continuous flow syntheses of active pharmaceutical ingredients (APIs), the limited number of cost-effective continuous separations is a bottleneck to end-to-end CPM. Establishing promising APIs for integrated CPM is paramount. (*S*)-Warfarin is an anticoagulant API whose continuous flow synthesis features a single reaction with high enantiomeric selectivity followed by liquid-liquid extraction (LLE). This work describes the steady-state process modelling and technoeconomic optimisation for the upstream CPM of (*S*)-warfarin, implementing reactor design and LLE solvent comparison for purification. Ethyl acetate, isopropyl acetate, isobutyl acetate, 1-heptanol, 1-octanol and heptane are candidate LLE solvents. Reported reaction conversions and computed LLE efficiencies allow mass balance calculation and total cost estimation to establish promising LLE solvents. The nonlinear optimisation problem is formulated for total cost minimisation. Liquid-liquid phase equilibria, API phase compositions and solubilities for LLE design are implemented via surrogate polynomials based on extensive UNIFAC modelling; API recovery rates are calculated via detailed mass transfer correlations. The methodology used here screens optimum process configurations to achieve a technoeconomically optimal design for a continuous (*S*)-warfarin manufacturing plant.

Keywords: Continuous Pharmaceutical Manufacturing (CPM), (*S*)-warfarin.

1. Introduction

Continuous pharmaceutical manufacturing (CPM) is a key area of green chemistry research with the potential for significant technical, operational and economic benefits over currently prevalent batch manufacturing methods (Koenig and Dillon, 2017). Despite the numerous demonstrations of continuous flow syntheses (Britton and Raston, 2017) towards active pharmaceutical ingredients (APIs), including end-to-end production campaigns (Adamo et al., 2016), only certain synthetic routes benefit from continuous operation (Hartman et al., 2011) and the lack of demonstrated continuous purification and separation methods integrated in CPM plants is an important obstacle (Bana et al., 2017). Establishing promising APIs for CPM application and screening for those with the highest likelihood of success is imperative for the elucidation of potential process configurations and successful implementation of continuous manufacturing routes (Teoh et al., 2015), and process modelling is critical in performance evaluation.

(*S*)-Warfarin is an anticoagulant API, commonly known as Coumadin[®], commonly used for the treatment of deep vein thrombosis and pulmonary embolism (Porter, 2015). The continuous flow synthesis of (*S*)-warfarin features a single reaction and subsequent liquid-liquid extraction (LLE) process (Porta et al., 2015). Comparison of different conceptual separation process alternatives is essential for establishing cost-effective, materially efficient designs for upstream CPM configurations. Screening of candidate continuous LLE configurations for CPM of this API has yet to be conducted; process modelling, simulation and optimisation of continuous separation processes are valid alternatives to laborious experimental efforts for rapid design space investigation to elucidate technically feasible and economically viable processes (Jolliffe et al., 2018).

Here, we implement steady-state process modelling and nonlinear optimisation for the upstream CPM of (*S*)-warfarin, including continuous flow synthesis and LLE. Flowsheet development based upon the published continuous synthetic route and a conceptual continuous LLE process are presented, comparing various separation solvents. Thermodynamic models for liquid-liquid phase composition and API solubility prediction in non-ideal, multicomponent mixtures for LLE design are described. Nonlinear optimisation problem formulation for total cost minimisation are presented. Minimum total costs, optimal API recoveries and material efficiencies for different process configurations are compared to establish promising LLE solvents.

2. Process Modelling and Nonlinear Optimisation

2.1 Continuous Flow Synthesis and Process Flowsheet

The flowsheet for the CPM of (*S*)-warfarin (API) is shown in Fig. 1 (Porta et al., 2015). The continuous flow synthesis of the API features the nucleophilic addition of 4-hydroxy-coumarin with benzalacetone in the presence of trifluoroacetic acid (TFA) and a chiral amine catalyst at 75 °C in 1,4-dioxane, with a reported conversion of 61%. Aqueous HCl (10% w/w) is added to the reactor effluent before entering the LLE unit. Upon addition of the candidate LLE solvent, the process forms an organic (product) phase containing recovered API and an aqueous (waste) phase, between which API partitions. Several candidate separation solvents are compared for continuous LLE: ethyl acetate (EtOAc), isopropyl acetate (iPrOAc), isobutyl acetate (iBuOAc), 1-heptanol (HepOH), 1-octanol (OcOH) and *n*-heptane (nHep), as per (Alder et al. (2016).

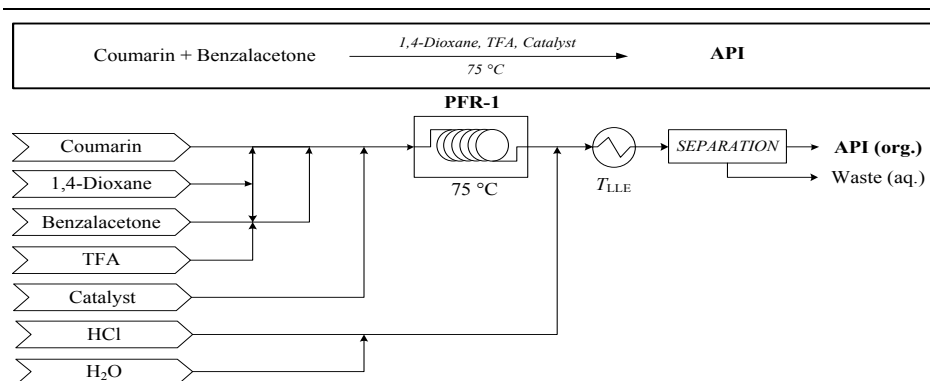

Figure 1: Process flowsheet for continuous (*S*)-warfarin production (Porta et al., 2015).

2.2 Separation Design and Thermodynamic Modelling

Continuous separation (LLE) processes are modelled as single-stage mixer-settlers at $T_{LLE} = 20, 40, 60$ °C and solvent feed rates $r = 1-4$ (mass basis). The rate of API recovery, \dot{f} , is described by Eq. 1. K is the overall mass transfer coefficient, a is the volume-specific interfacial area, V_{LLE} is the tank volume, and C^* and C are the theoretical and equilibrium API concentrations in the product phase, respectively. k_i and Sh_i are phase mass transfer coefficients and Sherwood numbers, respectively, D_{API} is the API diffusivity, d_{32} is the dispersed phase Sauter mean droplet diameter, Sc is the Schmidt number, Fr is the Froude number, EO is the Eotvos number, ϕ is the dispersed phase volume fraction, Re_i is the impeller Reynolds' number, d_i and d_t are the impeller and tank diameters, respectively, We is the Weber number, N_i is the impeller rotation speed, ρ_c is the continuous phase density and σ is the interfacial surface tension (Skelland and Moetti, 1990).

$$\dot{f} = KaV_{LLE}(C^* - C) \quad (1)$$

$$K = (k_c^{-1} + k_d^{-1})^{-1} \quad (2)$$

$$Sh_d = \frac{k_d d_{32}}{D_{API,d}} = 6.6 \quad (3)$$

$$Sh_c = \frac{k_c d_{32}}{D_{API,c}} = 1.25 \cdot 10^{-5} Sc_c^{1/3} Fr_c^{5/12} EO^{5/4} \phi^{-1/2} Re^{2/3} \left(\frac{d_i}{d_{32}}\right)^2 \left(\frac{d_{32}}{d_t}\right)^{1/2} \quad (4)$$

$$d_{32} = \begin{cases} 0.052 d_i We^{-0.6} \exp 4\phi & , We < 10^3 \\ 0.390 d_i We^{-0.6} & , We > 10^3 \end{cases} \quad (5)$$

$$We = \frac{d_i^3 N_i^2 \rho_c}{\sigma} \quad (6)$$

$$a = \frac{6\phi}{d_{32}} \quad (7)$$

Phase compositions and mixture API solubilities are predicted via the UNIFAC model. LLE stage efficiencies (E_{LLE}) allow calculation of actual product API concentrations from theoretical API concentrations in the product phase.

$$E_{LLE} = ((Ka\tau_{LLE})^{-1} + 1)^{-1} \quad (8)$$

2.3 Nonlinear Optimisation Formulation

The aim of the optimisation is to minimise the total cost objective function (*Cost*).

$$\min Cost = CapEx + \sum_{t=1}^{\tau} \frac{OpEx}{(1+y)^t} \quad (9)$$

$$\tau_{LLE} > 0 \quad (10)$$

$$1 < r < 4 \quad (11)$$

The discount rate ($y = 5\%$) accounts for inflation and τ is the plant lifetime (20 years). Annual operation of 8,040 hours is considered. Optimisation decision variables are the LLE residence time (τ_{LLE}) and relative solvent feed rate (r). Capital (*CapEx*) expenditure includes battery limits installed costs, construction and working capital; operating expenditure (*OpEx*) is the sum of material costs, utilities and waste handling requirements (Schaber et al., 2011). Solvent recovery after LLE is assumed to be 70%; all material requirements are scaled to account for reaction and separation inefficiencies.

3. Results and Discussion

Minimum total costs for each LLE solvent and operating temperature are shown in Fig. 2. The LLE solvent with the lowest minimum total costs is iBuOAc ($293.87 \cdot 10^6$ GBP, 60°C), followed by EtOAc ($299.91 \cdot 10^6$ GBP, 20°C) and iPrOAc ($299.93 \cdot 10^6$ GBP, 60°C). These solvents perform comparably due to their similar molecular structures and polarities, inducing similar phase compositions and thus comparable API recoveries. This effect is also observed for HepOH and OcOH, which attain the next lowest total costs ($339.43 \cdot 10^6$ GBP and $324.54 \cdot 10^6$ GBP, respectively) both operating at $T_{\text{LLE}} = 60^\circ\text{C}$. The poorest performance is attained via nHep (min cost = $350.52 \cdot 10^6$ GBP, 60°C).

For most cases, increasing operating temperature leads to lower total costs due to the enhanced mass transfer (recovery) rates of API into the product phase, which requires shorter LLE tank residence times (lower *CapEx*) and material requirements (lower *OpEx*) to meet the plant capacity of 100 kg per annum. When nHep is implemented as a separation solvent, *OpEx* is significantly higher for all LLE operating temperatures (20 , 40 , 60°C) considered, due to the low API recoveries attainable in comparison to other separation solvents considered in this work (Fig. 3). In all process configurations, the solvent feed rate (r) is pushed to its lower bound ($= 1$). The solvent feed rate and its assumed recovery following LLE directly affects materials and waste treatment costs (key *OpEx* components). The sensitivity of total cost minima to varying solvent recovery can be readily compared using the methodological framework described here.

Figure 2: Minimum total costs attainable for different continuous LLE configurations.

Attainable E -factors for all processes vary between 57–127; whilst these values are high in comparison to other manufacturing sectors ($E < 0.1$ for oil and gas processing), they are reasonable for pharmaceutical manufacturing processes (Roschangar et al., 2015). The E -factor variations are directly related to corresponding API recoveries; as API recovery increases, material requirements and waste (and thus the E -factor) decrease. Implementing the process configuration with the lowest total costs (iBuOAc, 60 °C) attains $E = 58.4$, which is very low in comparison to other configurations in this work.

The described framework can be used to perform sensitivity analyses with respect to economic data (e.g. varying material prices, rates of interest for inflation) and other operational assumptions (e.g. achieved solvent recovery). It also allows the investigation of the effect of scaling plant capacity on total cost components and E -factors, an essential consideration during process development. Candidate separation solvents investigated for application here have been selected based upon their suitability for LLE (i.e. exhibit rapid phase splitting with the process mixture and are considered suitable with respect to detailed EHS criteria). (*S*)-Warfarin is available in both liquid (dispersion) and solid (tablet) formulations, and thus consideration of crystallisation and downstream processing following the upstream CPM considered in this work. Consideration of the effects of LLE solvent choices and resulting API recoveries and purities in the organic product phase on the requirement for additional purification prior to further processing will aid LLE solvent selection. The methodology described in this work can be implemented for other APIs requiring continuous LLE, provided that kinetic and thermodynamic data are available for modelling and total cost minimisation.

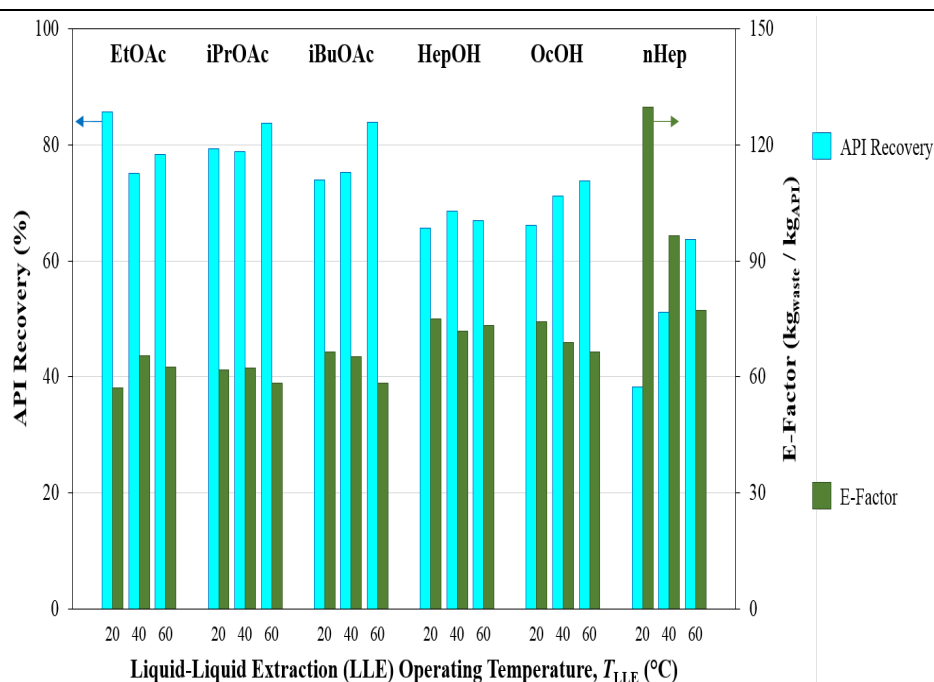

Figure 3: API recoveries and E-factors corresponding to total cost minima.

4. Conclusions

This paper presents the systematic evaluation of six candidate separation solvents for the continuous liquid-liquid extraction (LLE) of (*S*)-warfarin following the experimentally demonstrated continuous flow synthesis (Porta et al., 2015). Comparison of minimum total costs via nonlinear optimisation with LLE solvent feed rate and tank residence time as decision variables establish promising candidate LLE solvents for the CPM of (*S*)-warfarin. Isobutyl acetate (iBuOAc) emerges as a promising candidate LLE solvent, attaining the lowest minimum total costs of $293.87 \cdot 10^6$ GBP and a reasonable E-factor of 58.4, followed by ethyl acetate and isobutyl acetate. The considered alcohols (1-heptanol and 1-octanol) and *n*-heptane attain inferior performance (higher total costs) due to lower maximum (theoretical) API recoveries estimated by the UNIFAC method.

The technoeconomic and environmental impact analyses presented in this work can inform the future design of CPM processes for this societally important API. Consideration of wider operating parameter sets and additional LLE solvents can be performed by adapting the existing framework, given the availability of required thermodynamic data and physical properties. Sensitivity analyses with respect to varying performance assumptions (e.g. varied attainable reaction and separation efficiencies upon scale up) and economic considerations (available solvent recovery, interest rates etc.) can be implemented within the framework and will add robustness to the presented results. Consideration of carrier and separation solvent combinations on subsequent upstream (e.g. crystallisation) and downstream (product formulation) unit operations is essential for successful implementation of a fully continuous process.

Dynamic modelling and simulation of reactive transport phenomena in an amperometric blood glucose biosensor

Fergus McIlwaine, Dimitrios I. Gerogiorgis

School of Engineering (IMP), University of Edinburgh, Edinburgh, EH9 3FB, UK

Abstract

The treatment of diabetes as well as several other diseases which affect millions of patients worldwide strongly depend on deploying affordable technologies for frequent and accurate monitoring of blood glucose concentrations. Both theoretical and experimental investigations of novel blood glucose biosensor concepts pave the way for fast efficiency analysis of candidate biosensor designs. Recent studies have addressed the operation of amperometric biosensors, within which a combination of an enzymatic reaction and an enzyme deposited on an electrode allows for conclusive blood glucose detection. This paper models a single droplet of blood on an amperometric glucose biosensor to investigate the sensitivity of sensor performance to varying transport phenomena parameter values. The work presents a comprehensive sensitivity analysis, based on a new two-dimensional spatiotemporal model (constructed in MATLAB) which studies the combined reactive transport phenomena within a blood droplet deposited on an enzyme-coated surface. The sensitivity analysis explores the variation of electrode response (current density) and concentration profiles throughout the droplet and the enzyme layer subject to varying initial conditions and component diffusivities. Results clearly indicate a strong dependence of output profiles on the said sensitivity parameters: ensuring high current density (especially for small droplet volumes) is a prerequisite for developing reliable glucose biosensors of high accuracy and precision.

Keywords: Modelling; simulation; diabetes; glucose; biosensors; reaction-diffusion.

1. Introduction

Approximately 5% of the UK population have some form of diabetes: many patients require home glucose biosensors (Peng et al., 2016). Diabetes treatment is dependent upon the availability of reliable and affordable technologies to monitor blood glucose levels. The development of low-cost but high-fidelity biosensors for blood monitoring is pivotal, especially for underprivileged communities and countries with growing populations but modest healthcare expenditure. Both theoretical and experimental investigations of novel blood glucose biosensor concepts are essential, particularly because the latter is essential to determine prior to industrial-scale production ventures (Cambiaso et al., 1996). Recent studies consider amperometric biosensors, in which an enzymatic reaction on an enzyme-coated electrode allows the measurement of blood glucose concentrations (Baronas and Kulys, 2008). Modelling and simulation allows the effects of many parameters to be studied with relative ease and speed compared to experimental methods. This paper models a single droplet of blood on an enzyme coated electrode, modelling a glucose biosensor. Sensitivity analyses of blood glucose concentration variation for different transport properties allows insight into essential design considerations for the development of high-fidelity glucose biosensors.

2. Sensor Model

The blood droplet contacts an enzyme coated electrode. It is assumed that blood droplet geometry remains fixed. The 2D model domain is split into two subdomains: the droplet and the enzyme, which are created in MATLAB using finite difference analysis.

2.1 System Geometry

The system is modelled as a half ellipse (the blood droplet) on a rectangle (the enzyme coating). Dimensions of the droplet and enzyme considered are shown in Fig. 1.

Figure 1: Geometry of a blood droplet on the enzyme-coated electrode of a glucose biosensor.

2.2 Enzymatic Reaction

The enzyme (Glucose Oxidase, GOx) is immobilised in the coating and catalyses the reaction of glucose to gluconic acid ($C_6H_{12}O_7$) and hydrogen peroxide (H_2O_2).

where E is the enzyme, C is the substrate-enzyme complex, S is the substrate (glucose) and P is product. Rate constants of the forward and backward reactions (Eq. 2) are k_{1+} and k_{2+} , respectively. Current is produced by the oxidation of H_2O_2 (Eq. 3).

2.3 Transport Phenomena: Partial Differential Equations (PDEs)

Reactant and product diffusion occurs in the blood droplet; chemical reaction only occurs at the enzyme layer. Mass transfer is modelled via Fick's second law of diffusion

$$\frac{\partial C_S}{\partial t} = D_{S,1} \nabla^2 C_S \quad (4)$$

$$\frac{\partial C_P}{\partial t} = D_{P,1} \nabla^2 C_P \quad (5)$$

where $D_{S,1}$ and $D_{P,1}$ are the diffusivities of S and P in the droplet, respectively, and C_S and C_P are the concentrations of S and P in the droplet respectively. Reaction occurs in the immobilized enzyme layer; concentrations obey the reaction-diffusion PDEs (eqs. 6-7).

$$\frac{\partial C_S}{\partial t} = D_{S,2} (\nabla^2 C_S) - \frac{V_{\max} C_S}{K_M + C_S} \quad (6)$$

$$\frac{\partial C_P}{\partial t} = D_{P,2} (\nabla^2 C_P) + \frac{V_{\max} C_S}{K_M + C_S} \quad (7)$$

where V_{\max} is the maximum enzymatic rate ($= k_{2+} C_S$), K_M is the Michaelis-Menten constant, $D_{S,2}$ and $D_{P,2}$ are the diffusivities of S and P in the enzyme, respectively.

2.4 Dimensionless model

We introduce the dimensionless parameters X , Y , T , \bar{S} and \bar{P} as the dimensionless 2D spatial coordinates (x and y), time coordinate (t), C_S and C_P , respectively. Dimensionless parameters are calculated as the ratio of the dimensional coordinate to a characteristic value. The reaction-diffusion PDE for glucose become dimensionless when substituted (eqs. 8-9). $L^* = 1$ mm, $T^* = 10$ s and $U^* = 4$ mmol L⁻¹ are the characteristic values for spatial coordinates, the time coordinate and concentrations, respectively.

$$\frac{\partial \bar{S}}{\partial T} = \frac{D_s}{L^{*2}} (\nabla^2 \bar{S}) - \frac{V_{\max} \bar{S}}{K_M + S^* \bar{S}} \quad (8)$$

$$\frac{\partial \bar{P}}{\partial T} = \frac{D_s}{L^{*2}} (\nabla^2 \bar{P}) + \frac{V_{\max} \bar{S}}{K_M + S^* \bar{S}} \quad (9)$$

2.5 Boundary Conditions

No flux conditions exist on the curved surface of the droplet, i.e. $\nabla \bar{S} = 0$, $\nabla \bar{P} = 0$. On the electrode, it is assumed that P is readily consumed (i.e. $\bar{P} = 0$) and there is a no flux condition for S. On the edges of the electrode, we assume $\bar{S} = 0$, $\bar{P} = 0$. Furthermore, we assume no flux conditions in the area of enzyme which is not contacting the droplet.

Table 1: Base-case kinetic and transport parameters and initial conditions for the model.

Parameter	Units	Value
k_{+1}	m ³ mol ⁻¹ s ⁻¹	1.20·10 ⁻²
k_{-1}	s ⁻¹	0.68·10 ⁻³
k_2	s ⁻¹	5.00·10 ⁻²
k_M	mol m ⁻³	4.22
E_0	mol m ⁻³	1.25·10 ⁻¹
V_{\max}	mol m ⁻³ s ⁻¹	6.30·10 ⁻³
$D_{S,\text{droplet}}$	m ² s ⁻¹	6.00·10 ⁻¹⁰
$D_{S,\text{enzyme}}$	m ² s ⁻¹	3.00·10 ⁻¹⁰
$D_{P,\text{droplet}}$	m ² s ⁻¹	6.00·10 ⁻¹⁰
$D_{P,\text{enzyme}}$	m ² s ⁻¹	3.00·10 ⁻¹⁰
C_{S0}	mmol L ⁻¹	4.00

3. Results and Discussion

Reaction kinetic and transport phenomena parameters and initial conditions (including the initial enzyme concentration, E_0) used as a base case in the model are shown in Table 1. The choice of initial glucose (substrate) concentration, C_S , is based on the minimum fasting blood glucose concentration for a healthy individual (Sarwar et al., 2010). Sensitivity analyses investigate the effect of varying reactant and product diffusivities in the droplet and enzyme layer and initial blood glucose concentration on the glucose biosensor electrode current density, as well as output reactant and product concentration profiles. Other parameters are kept constant for all sensitivity analyses.

Fig. 2 shows sensitivity analyses for the transient current density of the biosensor electrode. At low substrate diffusivities in the droplet ($D_{S,\text{droplet}}$), longer timescales are required for substrate to reach the enzyme layer and produce current (Eq. 3); consequently, a plateau in current density is gradually attained. For high $D_{S,\text{droplet}}$, substrate reaches the enzyme layer faster than it is reacted, leading to an initial peak in

current density followed by a gradual decrease. For low substrate diffusivities in the enzyme layer ($D_{S,enzyme}$), lesser enzyme layer surface areas are available for substrate reaction, and hence current density peaks are observed followed by gradual decline. As $D_{S,enzyme}$ increases, a greater surface area is available for reaction, and thus plateaus are gradually attained. As product diffusivities in the droplet ($D_{P,droplet}$) increase, less product produced in the enzyme layer occupies enzyme surface area for reaction, hence induced current densities increase. When product diffusivity in the enzyme layer ($D_{P,enzyme}$) is lower, less area is available for reaction, due to the lower propensity for product transport from enzyme, and longer times are required for maximum currents.

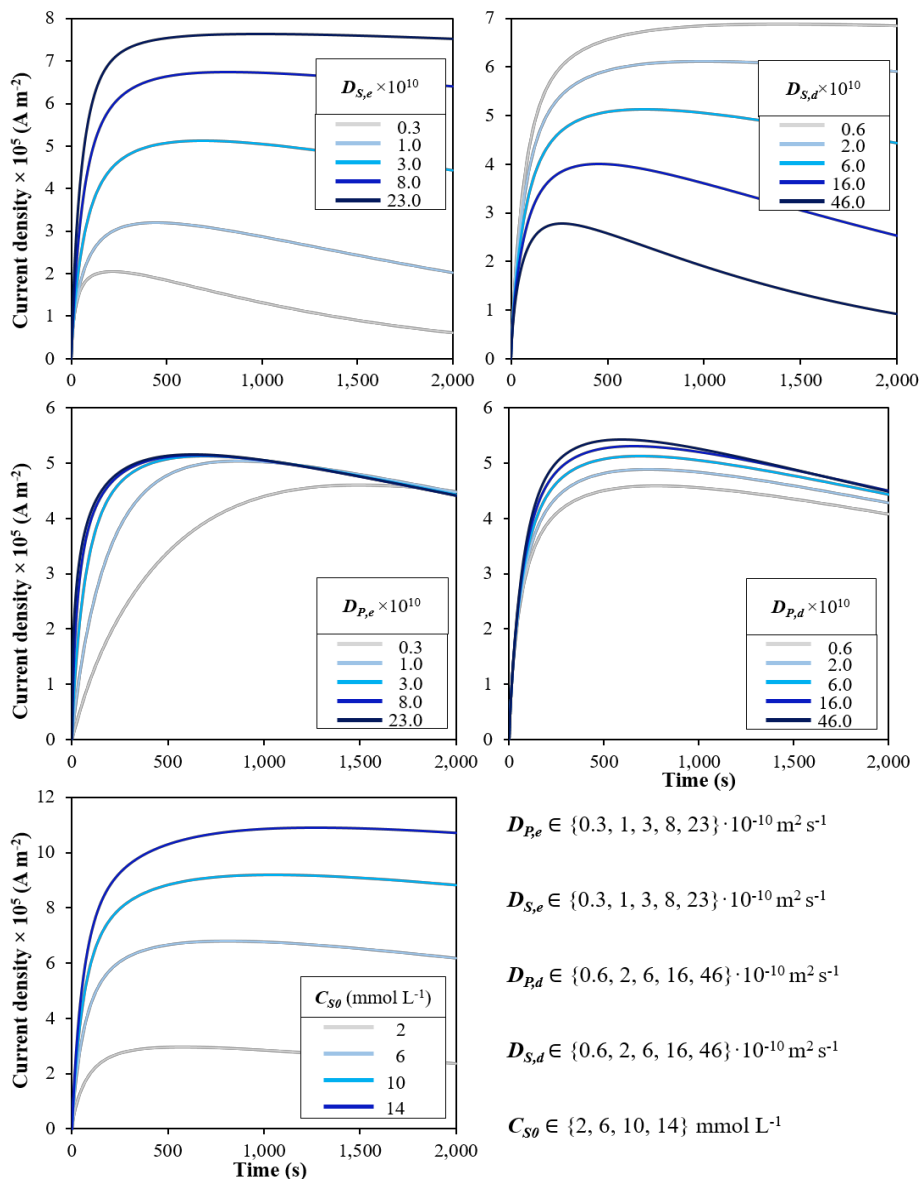

Figure 2: Effect of model parameters on transient biosensor electrode current densities.

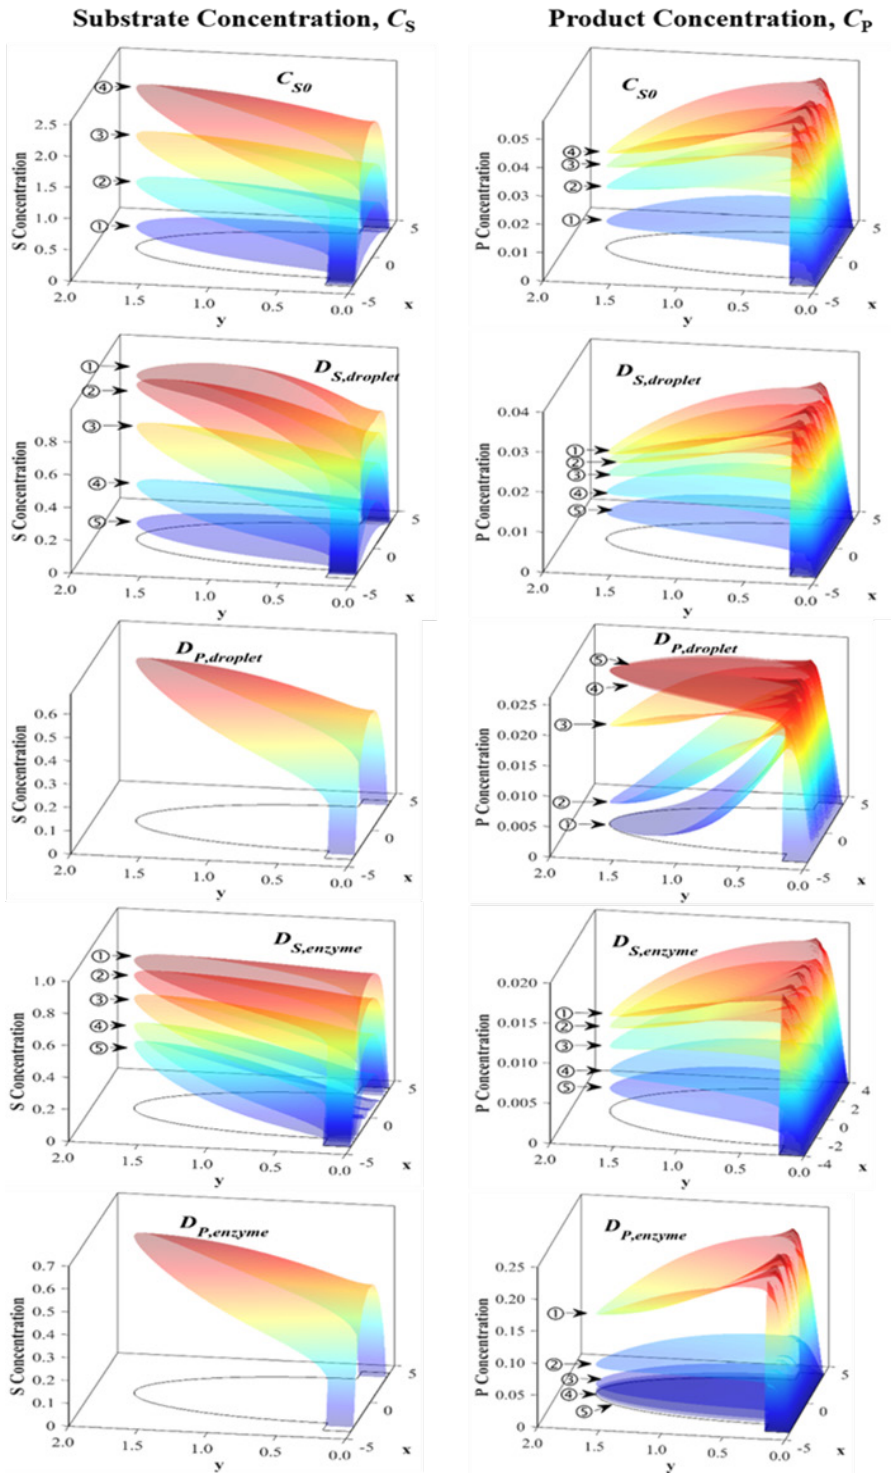

Figure 3: Sensitivity of output concentration profiles vs. model parameters (Table 2).

Table 2: Parameter variation for the model-based sensitivity analysis shown in Fig. 3.

Fig. 3 notation	C_{S0} (mmol L ⁻¹)	$D_{enzyme} \cdot 10^{10}$ (m ² s ⁻¹)	$D_{droplet} \cdot 10^{10}$ (m ² s ⁻¹)
①	2.0	0.3	0.6
②	6.0	1.0	2.0
③	10.0	3.0	6.0
④	14.0	8.0	16.0
⑤	–	23.0	46.0

Transient current densities illustrated in Fig. 3 clearly increase with initial blood glucose concentrations; greater initial substrate (glucose) concentrations incur greater amounts of H₂O₂, which thus induces greater current (eqs. 1-3). Current densities plateau beyond 500 s for all initial concentrations considered. Biosensor performance is strongly dependent on patient-to-patient physiological variability, as well as on the temperature dependence and sensitivity of hence varying enzymatic reaction kinetic parameters.

Fig. 3 shows the variation of substrate and product concentration profiles in the droplet with varying transport properties; parameter values associated with individual analyses are provided in Table 2. Increasing initial blood glucose concentrations lead to higher concentration profiles throughout the droplet. As substrate diffusivity in the droplet ($D_{S,droplet}$) increases, concentrations decrease throughout the droplet; expectedly, product concentrations decrease with increasing distance (y) from the enzyme layer. Increasing product diffusivity in the droplet ($D_{P,droplet}$) significantly affects profiles due to the effect of product diffusion on enzyme layer surface availability discussed previously. Increasing substrate diffusivities in the enzyme layer ($D_{S,enzyme}$) result in decreasing concentrations in the analysed blood droplet. Increasing product diffusivities in the enzyme layer ($D_{P,enzyme}$) incur rapidly decreasing product concentrations in the droplet due to the preferential diffusion of product in the enzyme layer to the blood droplet.

4. Conclusion

Numerical modelling of a blood droplet on a glucose biosensor with parametric sensitivity analysis has been conducted to investigate the sensitivity of glucose biosensor performance to essential operating parameters. Transient electrode responses (current densities) vary significantly with initial blood glucose concentration. Sensitivity analyses show larger electrode responses are gained for higher enzyme layer diffusivities. This work illustrates the importance of ensuring high current densities for effective biosensor performance and the potential for tuning enzyme layer properties for the design of high-fidelity glucose biosensors for their application in modern medicine.

Abstract

Large-scale experimental results are presented, which compared batch and continuous pharmaceutical tablet manufacturing towards the development of process evaluation models. In the experiment, fluidized bed, high shear, and continuous granulators were used with the same raw materials, and the similarities and differences in the process and the products were analyzed. The maximum scale was 100 kg/lot. The experimental results were compared regarding quality of granules as well as tablets, and also regarding economic performance of the process. The analysis revealed significant differences in the product such as size/shape of granules; yield of the process was found to be an improvement opportunity for the continuous technology. Based on these findings, a strategy was created to develop models that can support process design of tablet manufacturing with considering product quality and process performance.

Keywords: Continuous manufacturing, granulation, product quality, economy, process design

1. Introduction

Continuous manufacturing is attracting attention in the pharmaceutical industry as an alternative to conventional batch manufacturing (Lee et al., 2015). Different authors contributed to the computer-aided design/operation of continuous manufacturing processes, such as Jolliffe and Gerogiorgis (2016) for active pharmaceutical ingredients (APIs), or Singh et al (2015) and Kruisz et al (2017) for tablets. Currently, the industry is highly interested in the capability of this novel manufacturing technology, especially regarding product quality and process economy. With a focus on tablet manufacturing, Järvinen et al (2015) compared product quality, and Sugiyama et al (2017) compared the economic performance of batch and continuous technologies.

For process designers, models would be of high relevance that could estimate the resulting performance depending on the technology choice given the product components. Meng et al (2017) presented the effects of the process- and design-parameters on granule size distribution in the continuous technology, with comparing physical properties of granules. However, the previous experiments remained on a small

scale, which leaves the opportunity for a larger scale investigation to develop realistic models. In this work, we

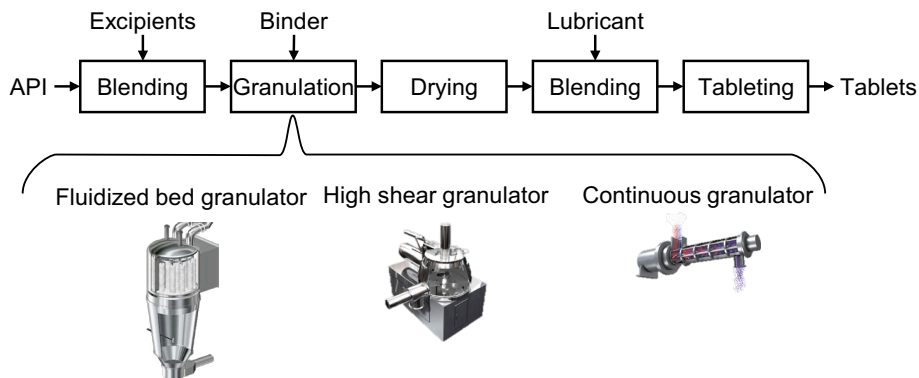

Figure 1 Manufacturing processes and granulators used in the experiments

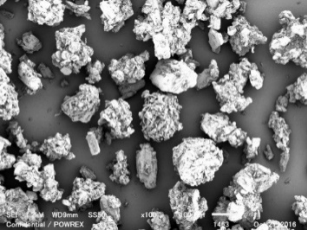

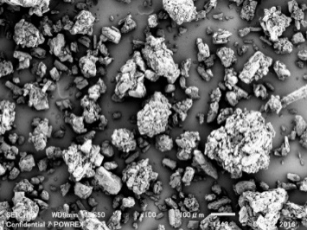

performed large-scale experiments at maximum 100 kg/lot, for comparing batch and continuous tablet manufacturing technologies, towards the development of design-support models for the industry.

2. Materials and methods

Tablets were produced in the experiment, which contained 30 % ethenzamide and 70 % consisting of mannitol and crystalline cellulose as excipients, hydroxypropyl cellulose as a binder, and magnesium stearate as a lubricant. Figure 1 shows the manufacturing process consisting of the units of mixing, granulation, drying, blending, and compression. Wet granulation method was applied in the experiments; Figure 1 also shows the granulators used. The initial experiment was conducted at the scales from 5 to 10 kg/lot, and the full-scale experiment was done at the scale of 100 kg/lot. As shown in Figure 1, two types of batch technology and one type of continuous technology were adopted in the experiment. The speed of the continuous granulation was set as 25 kg/h. Although the mechanics of granulator were different between batch and continuous technologies, same materials were used with the same condition through the experiments.

During and after the experiments, quality of granules and tablets, and the characteristics of the process were assessed for analyzing the differences between batch and continuous technologies. Particle shape, particle size, and bulk density were measured for the granules, and hardness, API content, and dissolution were measured for the tablets. For assessing the tablets, the following was set as the target: (i) tablet hardness is higher than 40 N, (ii) API content is between 95 % and 105 % of an absolute target, and (iii) dissolution rate is higher than 80 % within 30 minutes. The processes were characterized by the yield of the entire process, the causes of losses, and the amount of each loss cause. Here, yield was defined as the mass ratio of the total amount of the final tablet to that of the input raw materials. For the sake of space, this paper reports the results of the full-scale experiment mainly, with focusing on fluidized bed granulation and continuous granulation.

Table 1 Characterization results of granules and tablets

	Batch technology (fluidized bed)	Continuous technology
Granules		
SEM pictures		
Mean diameter	1.627×10^{-4} m	2.031×10^{-4} m
Loose bulk density	348 kg/m^3	510 kg/m^3
Tablets		
Tablet hardness	65 N	65 N
API content	97.5 %	99.3 %

3. Results

3.1. Characterization results of granules

The upper three rows of Table 1 shows the characterization results of granules: scanning electron microscopy (SEM) pictures, mean diameter, and loose bulk density. The SEM pictures suggest that the granules produced by fluidized bed granulation were porous, and those by continuous granulation were spherical. From the results of mean diameter and loose bulk density, the granules produced by the fluidized bed were smaller and had a lower density than those by continuous granulation.

3.2. Characterization results of tablets

The lower two rows of Table 1 shows the characterization results of tablets: tablet hardness and API content, which satisfied the target values specified.

Figure 2 (a) shows the comparative results of dissolution test between batch and continuous technologies, where all tablets achieved the target value, i.e., higher than 80 % within 30 minutes. In the pharmaceutical industry, so-called similarity factor f_2 is widely used to evaluate the similarity of one dissolution profile with the other. The

$$f_2 = 50 \cdot \log \left\{ \left[1 + \frac{1}{n} \sum_{t=1}^n (R_t - T_t)^2 \right]^{-0.5} \times 100 \right\} \quad (1)$$

factor f_2 is defined as Eq. (1):

where the parameters n and R_t/T_t represent the number of time points, and the dissolution values at time t . If value of f_2 is higher than 50, dissolution of produced tablets is regarded as equivalent to the reference in the industry. The calculated value of f_2 between

Figure 2 Results of dissolution test: (a) comparison between batch and continuous and (b) comparison between large and small scale in continuous technology

batch (fluidized bed) and continuous was 76.0, which conformed the capability of the continuous technology at an industrial scale. Further new findings were obtained by comparing the results of dissolution tests between small- and large-scale experiments.

Figure 2 (b) shows the comparative results of dissolution test between the initial (5 kg/lot) and the full-scale (100 kg/lot) experiments in continuous technology. Although same equipment was used in both two experiments, the value of f_2 was calculated as 38.2, i.e.,

the profiles were judged as different. When the full-scale experiment was conducted for the first time, all the conditions were specified the same as in the initial experiment, except for the running time (changed from 12 minutes to 4 hours). However, the completion of the four-hour-operation needed adjustment of machine equipment and also the inlet water content, which caused the difference of the dissolution profile. This experiment was an actual case where the scale-up, which is believed to be easy in continuous technology, was not straightforward.

3.3. Characterization results of process

Regarding the performance of the process, yield was analyzed by measuring and calculating the amount of the final products and losses, which is summarized in Figure 3. In batch technology, yield was more than 93 % where the major causes of losses were sticking to the granulator and condition setting of compression. However in continuous technology, yield was 89 %, and a major cause of losses was stabilization at the beginning of the process.

Regarding this improvement opportunity of the continuous technology, a further investigation was performed on the dynamic variation of mean granule diameter monitored by a process analytical technology (PAT) tool. This PAT tool was only for monitoring, and not for controlling the process. In the experiment, nine minutes were needed until the mean diameter of granules became stable, until which the products were discarded. The total rejected amount was 3.75 kg, i.e., 3.53 % lowering of yield, indicated as “stabilization of the process” Figure 3 (b). However, after this nine minutes, mean granule diameter and also dissolution profiles of the sampled tablets were not changing significantly, i.e., the process was stable for the remaining running time. These findings indicate that stabilizing the start-up operation is a great improvement opportunity for continuous technology to be economically competitive against batch technology.

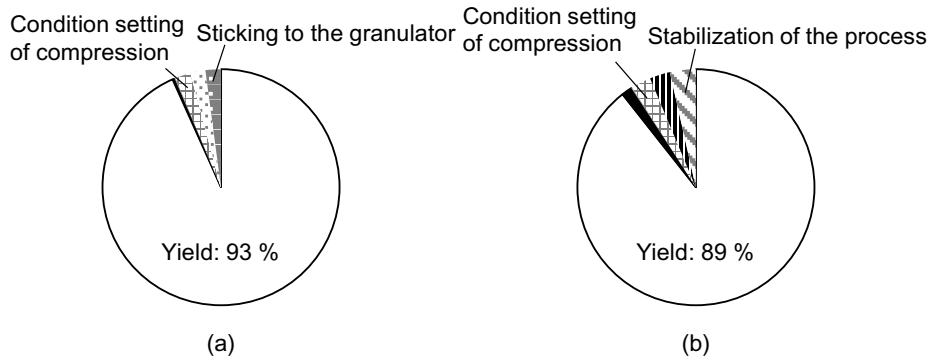

Figure 3 Results of yield and losses: (a) batch technology (high shear granulation), and (b) continuous technology

4. Strategy for model development

This chapter presents the way to utilize the results of large-scale experiments towards the development of process evaluation models. Figure 4 shows an overview of the models to be developed. The input parameters are defined, which could affect the quality of granules and tablets, such as physical properties of raw materials, machine types, and process conditions. The final objectives are the set of information that the process designer would require for decision making, such as dissolution profile of tablets. Also, the intermediate objectives are defined that are affected by the input parameters and affect the final objectives, such as bulk density of granules. The strategy is to describe each relationship in the entire system (indicated by arrows in Figure 4) as a mathematical model (indicated by the equation in Figure 4).

The experimental results shown in the previous chapter serve as the initial step of such model development. For example, a relationship was observed between the machine types, i.e., fluidized bed or continuous granulator, and the physical properties of granules/tablets, e.g., size/shape, or tablet hardness. Process conditions such as the water content amount during granulation process were also found to influence on the dissolution profile of the tablets in the continuous manufacturing. Quantifying such tendency on continuous technology is already novel by itself, because the knowledge of the process/technology is still to mature, as compared to long-established batch technology.

Our strategy for the model development is to conduct further experiments with varying the values of the input parameters and to investigate the impact on the outcome. Design of Experiments (DoE) based approach is currently undertaken to find the critical input parameters, considering both physical properties of raw materials and process conditions.

5. Conclusions and outlook

We presented 100 kg-scale experimental results on batch and continuous manufacturing technologies towards the development of design-oriented process evaluation models. To our knowledge, this is the first time report of the industrial scale experiments of continuous technology, being compared with the conventional batch technology. In the experiment, differences were observed in the granule properties between two technologies, however, looking into the obtained tablets, the dissolution profile was

Figure 4 Overview of process evaluation models

similar, and the quality was all above the target values. Regarding continuous technology, stabilization of the start-up operation was identified as the opportunity to reduce the product loss and to improve economic performance. As to the future work, further DoE-based experiments will provide the information for developing process evaluation models that can be comprehensively used for process design of pharmaceutical tablet manufacturing.

Abstract

A process systems approach towards the development and integration of computational models to describe the application, adhesion, spreading, and stability of a reacting hyaluronic acid gel onto the Olfactory mucous layer as well as the release of drug from particles dispersed in the hydrogel matrix, diffusion, and transfer through the mucous layer is described. The initial results from this systems approach reveal the connection between the physico-chemical processes which can lead to design limitations, e.g., gel extrusion time influences the extent of spreading on the mucous layer.

Keywords: adhesion, spreading, gelation, hydrogel, olfactory.

1. Introduction

Central nervous system (CNS) disorders (e.g., multiple sclerosis, Alzheimer's, Parkinson's, etc.) represent a growing public health issue, primarily due to the increased life expectancy and the aging population. The treatment of such disorders requires the delivery of therapeutic compounds to the brain in sufficient amounts to elicit a pharmacological response. The role of the nose as an entry point for the brain-targeted delivery of various medications has long been identified, revealing an unprecedented opportunity to deliver drugs to the brain, thus posing a promising alternative to intravenous delivery. Although highly advantageous due to its non-invasive nature, rapid onset of action, highly localized delivery, and low systemic exposure, the delivery of medications to the brain via the nasal cavity exhibits particular challenges associated with poor permeability across biological barriers (e.g., nasal and olfactory mucosae) and poor stability attributed to enzymatic activity observed in the nasal cavity.

The development of an innovative nanotechnology-based formulation is described that can be applied to the nasal olfactory region for the chronic treatment of CNS disorders. The novel formulation consists of biodegradable polymer nanoparticles loaded with drugs (e.g., long-acting cognition enhancing insulin analogues). The drug loaded particles are embedded into a biodegradable hydrogel that is deposited, via a nasal endoscopic applicator as a thin liquid-gelling film, onto the olfactory region (Figure 1). By controlling the molecular and morphological properties of the biodegradable hydrogel and the embedded polymeric nanocarriers, a controlled and sustained release of the therapeutics can be achieved thus resulting in improved drug delivery.

Figure 1. Hydrogel application, spreading, adhesion and drug release

In this work, a process systems computational approach, comprising models at different time and length scales, is applied to elucidate the fundamental physical, transport and biological processes related with nose-to-brain delivery of biopharmaceutics. In particular, it includes a CFD-based computational model to describe the flow of a reactive polymer solution through an applicator in terms of flow rate and tube characteristics (e.g., tip geometry, diameter). The extrusion of the reactive polymer solution and its conversion to a solid hydrogel film is examined for different tip placements, tip shapes, and total extruded matrix volume. The muco-adhesive forces, which control the hydrogel film spreading, are considered via the development of a hydrogel/mucus model. The long-term stability of the deposited hydrogel matrix is examined in terms of the hydrogel swelling and degradation kinetics. A dynamic drug release model is developed to describe the drug release rate from the drug-loaded microcarriers embedded in the hydrogel matrix in terms of molecular and morphological properties of polymeric carriers-hydrogel system. From the numerical solution of the above computational models, the dynamic drug mass transfer rate from the hydrogel matrix to the mucosa interface will be calculated. Finally, the drug flux from the hydrogel-mucosa interface to the olfactory bulb (i.e., drug transfer through the mucous layer in series with the epithelium) will be calculated.

The various mathematical models will be integrated following a PSE approach to obtain a general computational framework that will identify the key characteristic system's design parameters that will optimize the complex formulation-deposition process to achieve a desired therapeutic effect.

2. Computational Model

The overall model integration is shown in Figure 2. There are two groups of sub-models which differ mostly in their time scale. Group A describes the extrusion of the gelling hyaluronic acid solution as well as the hydrogel adhesion, spreading, and stability on the olfactory mucous layer. Group B describes the long terms changes in hydrogel (i.e., due to gelation, swelling, and degradation), the drug diffusion, and the transfer rate through the olfactory mucous layer. The underlying models are tightly interconnected in each group. Group A and B are connected only by the hydrogel shape after the end of the application process (gel shape, $G(x,y,z,t_{ext})$).

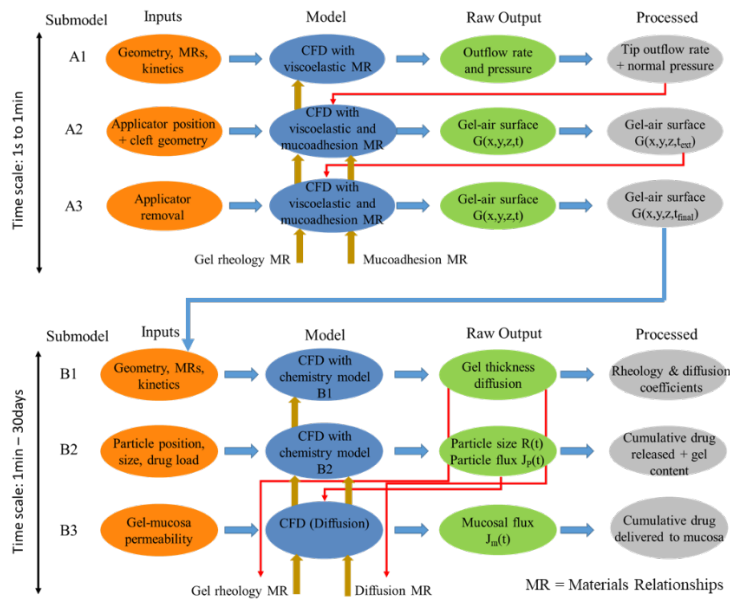

Figure 2. Modelling approach in N2B-patch programme. (de Baas, 2017).

In order to design an optimal in-situ gelling system the relationship between gelation, delivery (i.e., extrusion from the applicator tube), attachment (i.e., mucoadhesion), spreading, and stability must be described (i.e., Group A models in Figure 2). These factors are shown in Figure 3. The hydrogel is formed in situ according to a characteristic gelation time, t_{gel} . The hydrogel is delivered to the olfactory mucosa via extrusion from an applicator tube with an application time of t_{ext} . The hydrogel adheres to the mucous layer and spreads, with a characteristic time of t_{spr} , under the influence of surface forces and viscoelasticity which vary with continuing gelation.

It is clear that if the application time is larger than the gel time $t_{ext} \gg t_{gel}$ then the extrusion process becomes problematic. Moreover, if $t_{gel} \ll t_{spr}$ there is insufficient spreading over the mucous layer, while if $t_{gel} \gg t_{spr}$ the gel will deform under the influence of gravity and detach due to capillary instability.

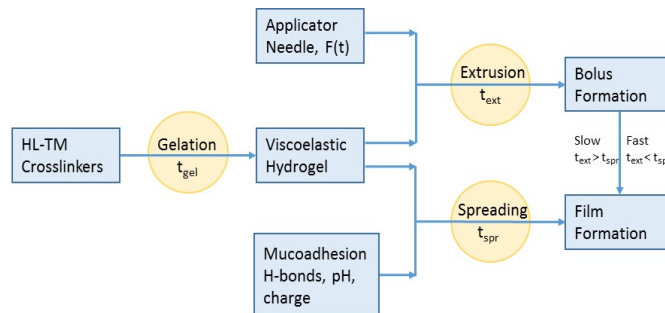

Figure 3. Key mechanisms involved in hydrogel extrusion, gelation, and spreading.

2.1. Applicator Flow.

In the applicator device hyaluronic acid (HA) and cross-linking fluids are mixed in situ and then directed to the applicator tip in the Olfactory cleft while undergoing gelation. For this system it can be shown that both the Reynolds and the Dean numbers are small, i.e., $\ll 1$. Consequently there are no inertial or secondary-flow effects and the problem can be treated as steady-state creeping flow through a straight tube.

The pressure drop through the applicator tube is determined by (Bird et al., 1987):

$$\Delta P = \frac{8Q}{\pi R^4} \int_0^L \eta(z) dz \quad (1)$$

where Q is the flow rate and $\eta(z)$ is the shear viscosity which varies with position due to the gelling reaction. For HA solutions the shear-viscosity over a range of shear rates from 10^{-3} to 10^3 s^{-1} were reported by Malecki et al. (2007) and have been found to follow a power law model, e.g., with coefficients: $m=14$ and $n = 0.2951 \text{ wt. \%}$.

Assuming a simple first order scheme for the gelling kinetics and extending the shear-rate behavior of the HA solution to the early phase of gelation by increasing the low shear-rate power-law viscosity value Eq.1 can be solved. The computed pressure drop, increases with the Damköhler-I number, $Da = t_{\text{ext}}/t_{\text{gel}}$, which is equal to the ratio of the extrusion to the gelation times. The key design criteria is to maintain $Da < 1$ because for larger values, i.e., $Da > 1$ the pressure drop in the applicator tube increases significantly. A similar approach can be employed with more detailed kinetic schemes for gelation. CFD simulations can also be performed to include the static mixer and examine the extent of mixing and also possible dispersion effects within the applicator tube.

2.2. Droplet Spreading.

To examine the spreading of large hydrogel droplets on solid surfaces the approach described by Härth and Schubert (2012) is employed where the droplet shapes are approximated with spherical caps. This is a good approximation if the droplet radius is significantly larger than the capillary length.

Figure 4. HA droplet spreading over the olfactory mucous surface

The net driving force, F_{tot} , for deformation and spreading of the hydrogel droplet is a sum of capillary, gravitational, viscous, and elastic terms.

$$F_{\text{tot}} = F_C + F_G + F_V + F_E \quad (2)$$

If it is further assumed that the net acceleration is zero, then the rate of change in the radius, dr/dt , can be obtained according to:

$$0 \approx 2\pi r \left(S + \gamma_L \frac{2r^2}{r^2 + h^2} \right) + \frac{4\rho g V^2}{3\pi r^3} + \frac{r^6 \eta \frac{dr}{dt}}{\xi V^2} + 2\pi r h \frac{\eta}{\lambda} f\left(r, \frac{t}{\lambda}\right) \quad (3)$$

Figure 5. Initial (dashed line) and final (full line) droplet aspect ratios, i.e., $Z = r/h$, for different extrusion times and initial droplet radii, R_0 . ($V = 2 \text{ cm}^3$, $\gamma = 45 \text{ mN/m}$, rheology data from Lee et al., 2008).

where γ_L is the surface tension, S is the spreading coefficient, V is the droplet volume, ρ is the hydrogel density, $\xi = 37.1 \text{ m}^{-1}$, and f is an elastic spreading function.

In Figure 5 the spreading of hydrogel droplets on the olfactory mucous layer is shown. It is clear that the final aspect ratio depends strongly the initial contact radius of the droplet as well as the applicator extrusion time due to the gelling reaction and changing rheological properties. Capillary instability occurs below values of $R_0 = 1.237$, which corresponds to a critical Bond number of:

$$Bo = \rho g R_0^2 / \gamma = 12 \tag{4}$$

It should be noted that small unstable droplets (i.e., $z < 1.665$ and $R_0 < 1.237$) can be kinetically stable due to the increasing elasticity and viscosity of the hydrogel.

Figure 6. HA droplet spreading over the olfactory mucous surface

2.3. Drug Release and Diffusion.

The drug release and diffusion is also a highly complicated process operating over longer times (days and weeks instead of seconds) Figure 6. The drug is released from the dispersed particles and then transfers through the hydrogel to the olfactory mucous layer. At the same time there is continuing gelation combined with swelling and degradation of the hydrogel. Consequently the particles experience continuously changing local environments and therefore drug release rates. The flux from the hydrogel to the mucous layer controls the net flux to the brain and is connected to the particle release flux according to Eq. (5).

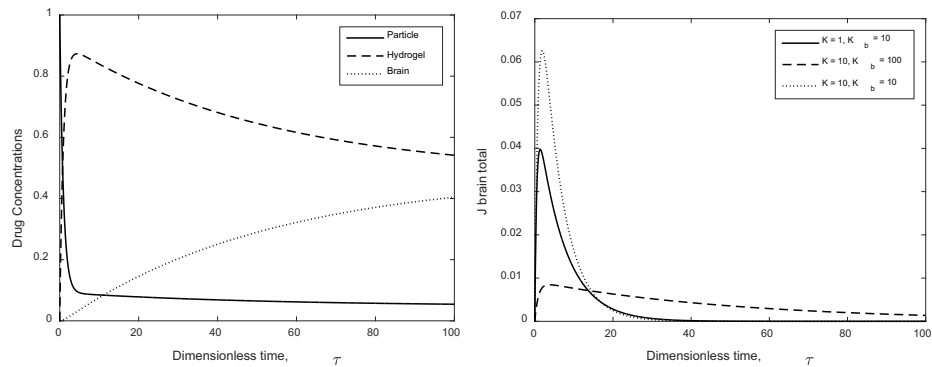

Figure 7. Hydrogel drug transfer. (a) Dimensionless drug concentration in the particle, hydrogel, and brain, (b) Total flux to the brain. K is a dimensionless drug release rate and K_b is a dimensionless ratio of release to mucous layer transfer rates.

$$J_m(t) = NJ_p(t) + \frac{d}{dt} \int_0^H C_H(z, t) dz \quad (5)$$

where N is the particle and C_H the drug concentrations in the hydrogel.

In the case of surface loaded drug release by adsorption/desorption dynamics the drug concentration and hydrogel to mucous layer flux are shown in Figure 7.

3. Conclusions

A process systems approach taking into account the key processes and their relevant time and length scales is necessary to describe nose to brain drug delivery using hydrogel films. The applicator function depends critically on the extrusion and gelation times while the hydrogel gel spreading depends on the applied volume and the extrusion time. Different flux behaviour can be found depending on the state of the hydrogel, the drug diffusion coefficient, and the particle loading profile.

Abstract

In this work, a methodology is presented to develop an artificial vision system to characterize the particle size distribution of granular products in motion on a conveyor belt. This methodology exploits the wealth of information stored in videos of the bulk material and, in particular, the information on the particle size distribution is extracted by multivariate and multiresolution image texture analysis.

The method is applied to the case of a granulated microcrystalline cellulose directly discharged from a hopper on a conveyor belt. The effectiveness of the presented methodology to estimate the particle size distributions is demonstrated in terms of estimation accuracy, velocity, reliability, and non-invasiveness of the system.

Keywords: granular materials, conveyor belt, particle size distribution, multivariate image analysis, multiresolution texture analysis.

1. Introduction

The characterization of the particle size distribution (PSD) of a granular material is of paramount importance in a wide series of industrial sectors (e.g.: pharmaceutical industry, food manufacturing, mineral or metals treatment). Typically, the PSD of a granular product can be characterized by means of hand-made measurements, which require trained and dedicated personnel who sieve and weigh samples of the granular materials. Unfortunately, this off-line procedure entails the loss of time, money and part of the material.

Among the innovative analytical technologies, artificial vision systems (AVS) gained great interest (Gosselin et al., 2008), because of their versatility, rapidity and the relatively low cost. However, the available AVS are limited to at-line systems that carry out the measurement of single particles, but do not measure the PSD from the bulk granular material.

Few examples of AVS were developed to characterize a granulate material from the granulate bulk. These methods exploit multivariate image texture analysis to describe the texture of the product surface that is included in an image scene. The textural information on the spatial variability of the light intensity are extracted, in such a way as

to relate image texture to the granulate PSD. These methodologies were proposed in different sectors, such as batch crystallization monitoring (Calderon De Anda et al., 2005), pharmaceutical powders classification (Garcia-Muñoz and Carmody, 2010) and particle growth monitoring in granulation (Nalesso et al., 2015). However, these applications are limited to the description of unimodal PSDs in terms of average particle diameter and particle diameter standard deviation.

Recently, Facco et al. (2017) proposed a systematic methodology for the development of an AVS for the estimation of multi-modal granulate materials PSDs from multivariate and multiresolution texture analysis of images of the product bulk. This comprehensive methodology was developed in the case of a static application within a laboratory environment, when the granulate material is settled in a static sample holder.

In this work, the methodology proposed by Facco et al. (2017) is extended to a dynamic case study in which the granular materials are moved by means of a conveyor belt and the collected images are the frames of a video. The proposed methodology is tested in the case of a granulated microcrystalline cellulose (MCC), which is a common excipient frequently utilized in the pharmaceutical manufacturing.

2. Experimental apparatus and video collection system

The experimental campaign was carried out in the apparatus that is represented in the scheme of Figure 1. The experimental system was composed by:

- a wedge shaped hopper with an outlet size of $0.075 \text{ m} \times 0.045 \text{ m}$ located at a distance of 0.005 m from the conveyor belt. The granulate material layer left on the conveyor belt was about 0.005 m thick and 0.110 m wide;
- a conveyor belt 0.750 m long and 0.250 m wide. The conveyor belt was moved by means of a three-phase electric motor (C.A.T.I. S.p.A., Padova, Italy) with a frequency of 50 Hz and a power of 0.37 kW , whose velocity was controlled by a Micromaster 420 inverter (SIEMENS, GmbH, Manchester, U.K.);
- an artificial vision system for the collection of the granulate mixtures videos (approximately of the duration of 20 s , each).

Figure 1. Scheme of the experimental apparatus for the collection of videos of granulate materials moved by means of a conveyor belt.

The image acquisition system was made of a digital mvBlueFox videocamera (Matrix Vision GmbH, Oppenweiler, Germany) with USB interface with proprietary

wxPropView software, which collected the videos at a rate of 10 frames per second. The camera was equipped with a F 3.5 diaphragm (utilized at its maximum aperture) and a Fujinon lens whose focal length is 25 mm. A lighting system was adopted to light up the mixtures. This was composed of a 180 LEDs ring with a power of 4.8 W for each LED. This was also used to shade the inspected granular material from the external environmental light.

3. Data collection and artificial vision system

In this work, the methodology adopted to build the AVS is the one proposed by Facco et al. (2017) and represented in Figure 2. This methodology is divided in two parts:

- design of experiments for mixture preparation and data collection;
- artificial vision system development and validation.

The data collection was organized preparing several batches of granulate MCC according to the procedure described in Nalesso et al. (2015). The granular material was sieved (Retsch AS 200, Germany) in 4 different classes (namely, 4 different ranges of particle size): range A of 600-800 μm particles, range B of 800-1000 μm particles, range C of 1000-1400 μm particles, and range D of 1400-2000 μm particles. These granular classes were then mixed in different proportions to prepare the granulate mixtures to be analyzed by the AVS.

Design-of-experiments (DoE; Montgomery, 2008) was then utilized to design the granulate mixtures. In particular, a space filling design was used, based on the algorithm of Kennard and Stone (1969) to suggest the mixtures to be prepared. A total of $N=100$ mixtures were prepared varying the factors of the DoE. The cumulative weight fractions of the granulate classes were varied on 11 levels: $y_i = 0.00, 0.10, 0.20, \dots, 0.90, 1.00$. Videos were collected for each mixture (appropriately charged and mixed in the hopper) that was moved by the conveyor belt. Three typical images [768 pixel \times 1024 pixel] collected in a video are shown in Figure 3. Only the images where granular material was present without including any portion of the conveyor (Figure 3b) were considered. A number of $R = 5$ frames of each mixture were extracted from the respective video (the image scene of each frame did not overlap with that of the following).

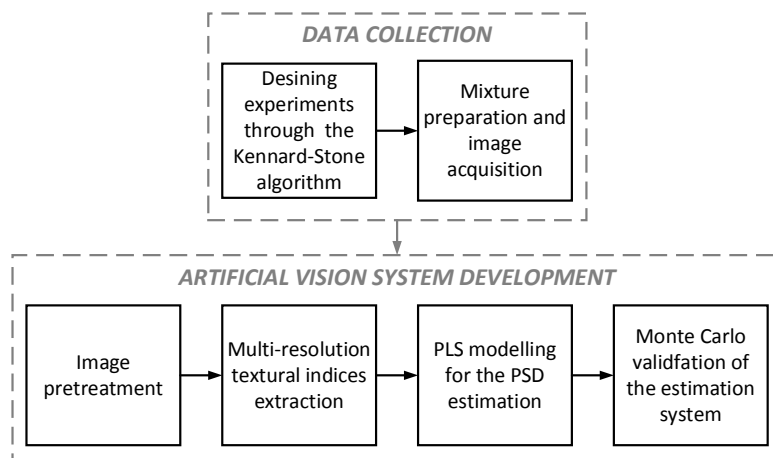

Figure 2. Scheme of the methodology proposed by Facco et al. (2017) to develop artificial vision systems for the PSD estimation in granulate mixtures.

Figure 3. Typical images of a collected video for a granulate mixture: (a) initial image; (b) image scene during the video; (c) final image. Images containing portions of conveyor belt such as (a) and (c) were discarded before the analysis.

The artificial vision system was calibrated according to the methodology proposed by Facco et al. (2017):

- images were pretreated through image adjustment and wavelet detrending (Addison, 2002) to remove the effect of both the light shades and granulate surface curvature;
- multiresolution textural indices were extracted from the pretreated images following the procedure suggested by Facco et al. (2010). Wavelet decomposition was adopted to extract multiple resolution scales ($M=6$) of the pretreated images and $S=6$ statistical indices (e.g.: mean, standard deviation, skewness, kurtosis, entropy, energy) were then calculated from the histogram of pixel light intensities for every scale;
- multiway Partial Least Squares (PLS; Geladi and Kowalski, 1986; Nomikos and MacGregor, 1995) was used to estimate the cumulative weight fractions of the granulate classes in a mixture from the multiresolution textural indices, used as predictors. In particular, a global PLS model was used to identify the 30 calibration mixtures that were more similar to the validation one; than a local PLS model (Shank et al., 1998) was built on the selected mixtures for the estimation of the granulate mixture PSD in validation. Local models are tailored on each specific validation sample and guarantees a higher specificity of the model, accordingly ensuring better estimation performance than a global estimation model. Note that, the predictors, originally organized in a three dimensional matrix $\underline{\mathbf{X}} [N \text{ mixture} \times (M \cdot S) \text{ textural indices} \times R \text{ video frames}]$ were treated with a hybrid unfolding of the data, as suggested by Facco et al. (2017). This allows dealing with both the correlation among multiresolution textural indices within single frames of a video and, at the same time, correlation between the textural indices of different frames of the video. As a consequence, the hybrid unfolding helps to consider all the effects of the local differences among the frames, the local inhomogeneity of the mixture in the image scene, and also the effect of partial segregation;
- the estimation model was finally validated through a Monte Carlo procedure in $N_{IT} = 100$ iterations. In each iteration $N_C = 80$ (over the total 100) randomly selected mixtures were used for local PLS model calibration, and other $N_V = 10$ were randomly selected for validation.

4. Results

Two typical examples of estimated PSD are presented in Figure 4. Figure 4a shows the estimated PSD for the validation mixture #1, in which the PSD is uni-modal. The estimation performance is satisfactory, because the estimated value (i.e., the grey dashed

line) is very close to the real measured PSD (i.e., black line). The maximum error in this case is ~4.1% in correspondence of the cumulative weight fraction of the classes A+B.

Figure 4. Examples of estimated PSD compared to real measured ones: a) validation sample #1; b) validation sample #2.

Figure 5. Mean absolute PSD estimation error for the cumulative weight fractions of the granulometric classes A, B and C.

Figure 4b shows the case of validation mixture #2, which clearly displays a bi-modal PSD. In this case, the estimation performance is absolutely accurate, as well. In fact, the estimation errors are below 4%, and the multi-modal trend is fully identified.

Finally, the mean absolute estimation error for the estimation of the PSD is considered to evaluate the estimation performance of the model with the Monte Carlo validation procedure which include $N_{IT} = 100$ iterations of the random partition of the available mixtures in $N_C = 80$ randomly selected mixtures considered for calibration and $N_V = 10$ randomly selected mixtures for validation. The mean absolute error of estimation MAE is used as an estimation performance index:

$$MAE = \frac{1}{N_{IT}N_V} \sum_{h=1}^{N_{IT}} \sum_{v=1}^{N_V} |y_{h,v} - \hat{y}_{h,v}| \quad (1)$$

where the error is the difference between the measured value of the cumulative weight fraction $y_{h,v}$ at iteration h and for validation mixture v , and its estimated value $\hat{y}_{h,v}$. The error is averaged on all the N_{IT} iterations and on all the N_V validation samples.

It can be observed that the estimation performance of the AVS are very good, because the *MAE* is well below 10% for all the granulometric classes, where 10% is the width among the different levels of the factors utilized in the DoE.

5. Conclusions

This work extended the use of a methodology to develop an artificial vision system to estimate the particle size distribution of granular materials in bulk mixtures to the case in which the material is moved in conveyor belts. The proposed methodology utilized digital videos of a granular bulk. The outcomes demonstrated that the particle size distribution of a granulated product can be estimated very satisfactorily from videos of a bulk mixture in movement on conveyor belts, also in case of multi-modal particle size distributions.

Future works will be oriented to two main aspects: the development of a method to identify the most appropriate number of videos to calibrate an accurate and reliable system and the test of robustness of the proposed system to disturbances that are related to the different conveyor belt velocity and to particle segregation.

Abstract

Advanced model based control strategies are necessary for efficient bioprocess control. In order to ensure continued control it is essential to detect controller failures in time. Redundant controllers allow for detailed diagnostics and maintenance during the process. Within this contribution a hierarchical combination of three different controllers was developed for setpoint control of biomass specific uptake rates of glucose and lactose of a green fluorescent protein producing *E. coli* strain. To achieve this, a model predictive controller (MPC) based on a dynamic mechanistic model for biomass growth and substrate uptake, a controller based on biomass estimates derived from elemental balancing of inflows and outflows (EBC) as well as an open-loop controller with predefined feed profiles were combined. A strategy was developed to trigger reversible switches between the different controllers in case of failures. To achieve this, measures for failure detection were identified. This permanent controller diagnostic and automatic controller switches are essential tools allowing continued control even in case of malfunctions.

Keywords: bioprocess control, controller diagnostics, failure detection, model based control, model predictive control, state observer

1. Introduction

E. coli processes are frequently used for the production of biopharmaceuticals (Sanchez-Garcia et al. (2016)). In order to guarantee the quality of their products, producers have to control and continuously improve their production processes which is further motivated by PAT (FDA (2004)) and QbD (FDA (2008)) guidelines. Model based methods are powerful tools to achieve efficient processes with constant quality. They allow the control of only indirectly measurable physiological entities such as growth, uptake and production rates (Schaepe et al. (2014)). Various model types can be applied, e.g. purely data-driven models (Kadlec et al. (2009)), models based on first principles (Wechselberger et al. (2013)) or mechanistic models (Jenzsch et al. (2006)).

Open loop control systems following a predefined feed trajectory are widespread due to their simplicity (Stanke and Hitzmann (2012)). Simple models can be used to define the feed trajectory: exponential feeding based on a constant substrate to biomass conversion rate was successfully used to maintain high growth in non-recombinant *E. coli* strains (Lee (1996)). However, without feedback for biomass growth this strategy might fail in case of deviations (e.g. because of a changed yield coefficient due to increased by-product formation). More elaborate controllers are

based on elemental balances (Wechselberger et al. (2013)). Biomass formation rates are estimated by consumed oxygen and emitted carbon. Feed addition is based on the current biomass estimation. However, the underlying model is only valid in case of strict sugar limitation and predictions are not possible. Dynamic models allow the usage of nonlinear MPC's, where optimized inputs (e.g. feed rates) are applied. Additionally, technical and physiological constraints can be defined. Typically, the real-time optimization is performed based on the most probable state of the system. This is determined by state observers based on measurements and model predictions. Examples are Kalman or particle filters (Goffaux and Wouwer (2005); Simon (2006)). Successful MPC implementations can be found in oil refineries and chemical plants (Qin and Badgwell (2003)), whereas applications in biopharmaceuticals industry are still rare (Sommeregger et al. (2017)). Uncertainty about the model, severe non-linearities or limited measurements are the main reasons why those powerful controllers can fail in practice. Typical measures to repair a failed controller include laborious and time-consuming steps like parameter re-estimation or elaborate analysis of offline samples. Therefore it is important to have a back-up controller running in parallel in case of failures. Within this contribution, a methodology is suggested, which bases on the combination of different controllers to achieve efficient and continued control. For this, we combine a MPC based on a mechanistic process model, a controller based on elemental balances (EBC) and an open-loop controller based on a predefined feed trajectory. The control goal was simultaneous control of two interdependent substrates (glucose and lactose) in a green fluorescent protein (GFP) producing *E. coli* fed-batch process (Wurm et al. (2017)). Controller reliability was automatically evaluated by statistical and biological measures. By diagnosis of failures, automatic switches between super-ordinate and subordinate controllers are triggered to ensure reliable and continued control. The outline of this contribution is a description of the process and the three different controllers. Failure diagnostics for the different controllers were then presented, followed by a description of our combined control strategy.

2. Materials and Methods

2.1. Cultivations

Fermentations were conducted in a parallel bioreactor system (DASGIP, Eppendorf AG, Germany). GFP producing *E. Coli* cells were cultivated in chemically defined media with a limited amount of glucose (5 g/L). After C-source depletion, a fed-batch on glucose was conducted for around 12 hours with feed (450 g/L glucose) addition via peristaltic pumps (DASGIP MP8, Eppendorf AG, Germany). Afterwards the induction phase started by additionally feeding lactose (180 g/L). The pH, measured by potentiometric pH sensors (Hamilton, Switzerland), was maintained at pH 7 by adding NH_4OH (12.5 %), which was used additionally as N-source. Oxygen saturation measured by optical DO probes (Hamilton, Switzerland) was kept over 30 % by increasing the oxygen content in the inflow air, which was supplied with 2 vvm via a L-sparger. Four dip tubes were used for feed, base addition and offline sampling. The exhausted gas composition was analysed by a ZrO_2 sensor for O_2 and an infrared sensor for CO_2 analysis (DASGIP GA4, Eppendorf AG, Germany). Dry cell weight (DCW) was determined by centrifugation (4500g, 4 °C, 10 min) of 1 mL cultivation broth and subsequent drying of the cell pellet at 105 °C for 48 h. Cell-free samples of the cultivation broth were analysed for concentrations of substrates and metabolites by HPLC (Agilent Technologies, USA) with a Supelco gel C-610 H ion exchange column (Sigma-Aldrich, USA) and a refractive index detector (Agilent Technologies, USA). The mobile phase was 0.1 % H_2PO_4 with a constant flow rate of 0.5 mL/min.

2.2. Controllers

In order to maintain the predefined biomass specific uptake rates of glucose and lactose three different controllers were implemented.

MPC: The controller was based on a mechanistic model for cell growth on two substrates. Specific uptake rates of glucose and lactose were modelled Monod-like. Maximal specific lactose uptake rate was assumed to depend on specific glucose uptake rate as described in Wurm et al. (2017). The model described biomass with an error below 5 %. An extended Kalman filter (EKF), as described in Simon (2006), was taken for filtering, which was based on oxygen uptake rate (OUR) and carbon emission rate (CER) measurements. They were predicted with an error below 5-10 %. The objective function for the optimization was to minimize the deviation between the defined setpoints for specific glucose and lactose uptake rates and the model predictions, constrained by maximal feed-rates and reactor volume. Additionally, highly varying feed rates were penalized. The optimization algorithm, an adaptation of the Nelder-Mead method, was implemented in Python. Data transfer from and to the DASGIP process control software was performed via Open Platform Communications (OPC).

EBC: A controller relying on elemental balances was used. It is assumed that substrate, ammonia and oxygen are converted to biomass and carbon dioxide. The unknown biomass formation rate can be determined by applying elemental balances such as the C-balance or the degree of reduction balance. Based on measured reactor inflows (feeds and air supply) and outflows (offgas composition and sample volume) the formed biomass was estimated as described in Wechselberger et al. (2013). Based on this estimation the feed rates needed to maintain the predefined set points were directly calculated. The algorithm was implemented in the process control software (DASGIP Control v4.5, Eppendorf AG, Germany) and works only in sugar limited fed-batch processes with negligible product and by-product formation. Update frequency was a time interval of 60 s.

Open-loop: As the simplest feed controller constant or exponentially increasing feeds as described in Lee (1996) were included and implemented directly in the process control software.

3. Results and Discussion

The MPC and the EBC were tested in simulations on historical datasets and were also applied in the described microbial process. Generally, all three controllers showed the ability to maintain the desired specific uptake rates of glucose and lactose. Results can be found in Kager et al. (2017) and Wurm et al. (2018). Nevertheless, several controller malfunctions occurred and could be described.

3.1. MPC failure detection

Besides system breakdowns, failures of the MPC were observed mainly because of wrong estimations due to the model (inappropriate parameters or structure) or the Kalman filtering process. The most promising indicators to recognize these failures automatically were identified as follows: (1) Time-out errors were used to detect system breakdowns. (2) The covariance matrix P computed during the EKF procedure is a classical criterion to assess the reliability of the estimates of the EKF. However, the EKF is known to (possibly) fail due to inappropriate configuration (Dochain (2003); Agarwal and Bonvin (1989)). In a few cases numerical instabilities were observed leading to overestimated or underestimated covariances (Huang et al. (2008)). Therefore, additionally (3) directly the distance between the model and the measurements was considered. In Figure 1 an example for measurements and filtered estimates of CER (A), OUR (B) and biomass (C) in the induction phase is shown. The offline samples for biomass show an overestimation after 23 hours. The entries of P indicating variances of biomass did not behave conspicuously. However, the percentual deviation of OUR was bigger than 5 % after 23.6 hours; for CER this was observed after 25.4 hours. The reason for the deviation was an underestimation of glucose consumption and an overestimation of the biomass yield. Parameter recalibration of the related parameters would lead to better predictions. This example shows, that deviations higher than 5% for one of the measurements are indicators for deviations between model and process.

Figure 1: Real-time diagnostic of MPC: A) measured and estimated CER, B) measured and estimated OUR, C) offline reference measurements and estimation of biomass.

3.2. EBC failure detection

The carbon and the degree of reduction balance can be used to determine the unknown biomass formation rate. This over-determined equation system allows to improve estimation accuracy by data reconciliation and to check data consistency (Wechselberger et al. (2013); Jobe et al. (2003)). For the latter the h -value can be used: the hypothesis is tested whether deviations are only due to expected measurement errors or additionally due to gross errors, such as neglected metabolites, changing metabolism or others (Van der Heijden et al. (1994)). In our application values above 3.68 (95 % confidence level) indicate the existence of such gross errors. The threshold for the h -value depends on the degree of redundancy as well as on the desired confidence level (Jobe et al. (2003)).

In addition to the statistical h -value, the biomass to substrate yield can be used for estimator diagnostics. Although not stringently constant over the whole process (Wechselberger et al. (2013)) substrate to biomass yields are by nature within certain ranges. A yield around 0.5 g biomass/g glucose is often reported for *E. coli* (Shiloach and Fass (2005)). Ranges between 0.3 and 0.6 were selected to be physiologically meaningful.

In Figure 2 the h -value (A), the yield (B) as well as offline data for glucose and lactose concentrations (C) are shown for a real fermentation process. From 20 hours onwards, the h -value is several times above the threshold of 3.68. Additionally, from 24 hours onwards the online calculated yield drifted. Both measures indicate potential malfunction of the controller. This is confirmed by offline analysis of sugar concentrations, which revealed accumulation of glucose and lactose. In this case the assumptions of the EBC are no longer valid. Violations at the beginning of the fed-batch phase after 5 hours were due to inaccurate measurements in the offgas composition.

3.3. Overall control scheme

As described above, the MPC as well as the EBC might fail. Diagnostics to recognize them were defined. Typically elaborate and time-consuming measures to overcome the controller failure like parameter re-estimation or analysis of the sugar concentrations have to be performed. However, due to the swift growth of the bacteria, rapid responses will be needed. This can be ensured by automatic switches to another, in this situation possibly more reliable controller.

In Figure 2 D a possible switch is shown. To prevent glucose accumulation, caused by the faulty EBC, alternative outputs from MPC or open loop could be used. Applying a constant feed could effectively prevent further accumulation of substrates, but desired uptake rates are no longer maintained and will decrease over time. The MPC is favourable as it optimizes the current and future process inputs to reach the desired objectives. In our case, the feed pumps would be turned off until the accumulated substrate is consumed, followed by an optimized feeding profile in order to maintain a constant uptake rate. The underlying model is extendable and works also in case of substrate accumulation. However, the MPC might fail due to too simplified model assumptions,

Figure 2: Real-time diagnostic of EBC: A) h-value trajectory, B) online biomass to substrate yield estimation, C) offline reference measurements of sugars, D) glucose feeds of implemented controllers.

wrong parameters or errors during the filtering process. In those cases a switch back to EBC can give more reliable results and lead to more stable behaviour. However, as noted above, the EBC is not operational in case of substrate accumulation or noisy or imprecise measurements. The overall control scheme is shown in Figure 3. If the MPC is expected to fail (indicated by timeout errors, the covariance matrix or deviations from the measurements), a switch to the EBC is performed. In case the EBC possibly fails, which is analysed by the h-value and the yield ($Y_{X,S}$), a constant feed is performed to avoid substrate accumulation. However, as soon as the superordinate controller is expected to work again, a switch back to it is performed. Thresholds as well as update rates should be defined by evaluating historical datasets.

Figure 3: Implemented controller scheme ensuring the safe usage of advanced controllers in highly dynamic microbial processes. Automatic switches are performed according to online diagnostics.

4. Conclusions

Summing up, for the model predictive controller (MPC) as well as the elemental balance controller (EBC) measures were defined to identify controller failures. For the MPC these were timeout errors, the covariance matrix P of the EKF and deviations between estimates and measurements. For the EBC, the h-value as well as the biomass to substrate yield were taken to detect gross errors. To ensure continued process control even in case of failures, a strategy was developed that triggered automatic switches between the different controllers. Especially in processes with relatively fast dynamics, like *E. coli* fed-batches the implemented control scheme enabled the usage of MPC while ensuring continued control in case of malfunctions. Within this system MPC's can be further developed and tested in biopharmaceutical processes, triggering the usage of these promising controllers. In the current application an extended model as well as additional measurement devices could further improve the quality of the MPC and allow complex control of unmeasurable variables considering physiological and technical constraints.

A Novel Dynamic Model of Plate Heat Exchangers Subject to Fouling

Shunfeng Guan^a, Sandro Macchietto^{a*}

^a*Department of Chemical Engineering, Imperial College London, South Kensington Campus, London SW7 2AZ, UK*

s.macchietto@imperial.ac.uk

Abstract

The modelling of plate heat exchangers (PHEs) for dairy applications is revisited utilising recent concepts that have proved very effective in different but related areas, in particular dealing with fouling in tubular exchangers and crude oil refinery applications.

The approach initially proposed by Georgiadis and Macchietto (2000) is followed, but coupled with a more detailed 2D distributed model capable of describing and characterising deposit layer growth. The proposed model, illustrated for a single channel in a PHE, includes an improved milk and protein aggregation/deposition model, independent deposition on the plates at each side of the channel, the interaction of local operating conditions and deposit formation (via a moving boundary at the fluid-deposit interface), and the asymmetric deposition due to different boundary conditions at the two sides of a plate. It is shown that the model adequately predicts the distribution of deposit along the plates and provides useful insights into problematic plate regions.

Keywords: dairy processes, energy recovery, plate heat exchanger, fouling, dynamic model.

1. Introduction and background

Plate heat exchangers (PHEs) are widely used, particularly in the food industries, as they are compact, configurable in different arrangements (Figure 1) and easily cleaned. The deposition of materials on hot surfaces (fouling) reduces thermal and hydrodynamic performance, requires periodic cleaning (often after just few hours of operation) with heavy economic and productivity losses. Simulation models help predict these effects and enable smarter operation and design decisions. In spite of a rich literature there is still significant interest in improving models accuracy and useability in practical applications. Current mechanistic models of PHEs dynamic behaviour with fouling typically rely on simplifying assumptions, limiting their predictive ability. Deposit changes inside the PHE plates are either ignored or captured indirectly as an overall thermal fouling resistance. Computational Fluid Dynamics (CFD) models (e.g. Choi et al., 2013) start to include relevant detailed hydrodynamics, e.g. plates corrugations, with good results. However the CFD environment and solution times (often days) prevent incorporating other aspects (e.g. control) and their use for optimising PHEs design and operation within overall heat exchanger networks, for example, to optimise cleaning schedules. Here, the modelling of PHEs fouling for dairy applications is revisited utilising recent concepts that proved very effective in related areas, in particular for fouling in tubular exchangers and crude oil refinery applications. The basic mechanistic,

1D distributed, dynamic model approach initially proposed by Georgiadis and Macchietto (2000) is followed, however coupled with a more detailed 2D distributed model capable of describing and characterising deposit layer growth, of the type used by Coletti and Macchietto (2011) and refined by Diaz Bejarano et al. (2016). The goal is to develop a more predictive, yet far simpler model than CFD ones, enabling its use in optimisation of single PHEs and whole heat exchanger networks that include PHEs. In the following, the proposed model is illustrated for a single channel in a PHE subject to milk fouling, with validation against experimental results. Results for full PHEs will be presented elsewhere.

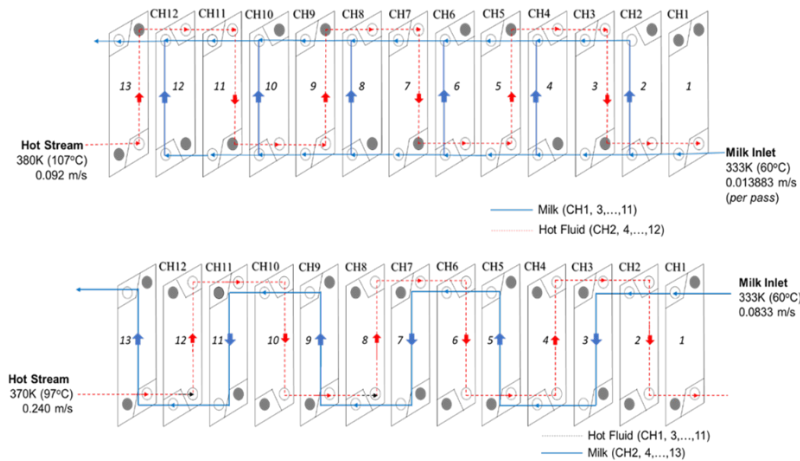

Figure 1. Two different Plate Heat Exchanger arrangements: 1 (top) and 2 (bottom).

2. Model of PHE plate with fouling deposition

The well-established β -lactoglobulin reaction scheme (Georgiadis & Macchietto, 2000) was used to model milk deposition, with some parameter changes to better characterise the protein polymerisation process above 90 °C. The PHE channel model considers the independent growth of a fouling layer on each of the two hot walls j and $j+1$ of a channel j where a fouling fluid flows, being heated. The model (Figure 2) is distributed in 2D, longitudinally (coordinate x) and across (coordinate y) the plate. Uniform distribution is assumed along the plate width, W . Five domains (left to right) are defined along the plate length, $x = [0, L]$:

- 1) Ω_W^L : Left plate wall domain, between outer and inner plate walls, $y = [-P_o, -P_i]$;
- 2) Ω_L^L : Left plate deposit layer domain, $y = [-P_i, -P_{flow,L}]$;
- 3) Ω_F : Channel fluid flow domain, $y = [-P_{flow,L}, P_{flow,R}]$;
- 4) Ω_L^R : Right plate deposit layer domain, $y = [P_{flow,R}, P_i]$;
- 5) Ω_W^R : Right plate wall domain, $y = [P_i, P_o]$;

Figure 2. Channel j delimited by plates j (on left) and $j+1$ (on right), 5 domains modelled, reference coordinates and Lagrangian transformation a). Boundary conditions applied b).

The temperature profiles in each domain are given by a thermal balance over a differential element Δx (Figure 2). Assuming uniform plate geometry and constant material properties (wall thermal conductivity, λ_w , density, ρ_w , specific heat capacity, Cp_w), the standard heat conduction equation and Fourier's law give the local temperature T_w^i (K) in the plate wall vs time and location (x, y) and the heat flux q_w^i (W/m²) across the wall:

$$\frac{\rho_w Cp_w}{\lambda_w} \frac{\partial T_w^i(x, y)}{\partial t} = \frac{\partial^2 T_w^i(x, y)}{\partial y^2}; \quad \forall i = L, R \quad (1)$$

$$q_w^i(x, y) = -\lambda_w \frac{\partial T_w^i(x, y)}{\partial y}; \quad \forall i = L, R \quad (2)$$

The two deposit domains, Ω_L^L on the left and Ω_L^R on the right plates of the channel are modelled as a conductive fouling layer, assuming constant deposit density, ρ_L , specific heat capacity, Cp_L and thermal conductivity, λ_L , no deposit ageing, and no heat source and variations in the x -direction:

$$\frac{\rho_L Cp_L}{\lambda_L} \frac{\partial T_L^i(x, y)}{\partial t} = \frac{\partial^2 T_L^i(x, y)}{\partial y^2}; \quad \forall i = L, R \quad (3)$$

T_L^i is the local temperature of the deposit layer (K), and λ_L is the thermal conductivity (W/m.K), both of which are functions of spatial coordinates (x, y) as well as time. The heat flux at any point along the thickness of the deposit is:

$$q_L(x, y) = -\lambda_L(x, y) \frac{\partial T_L^i(x, y)}{\partial y}; \quad \forall i = L, R \quad (4)$$

To more easily solve the system of PDEs, the moving boundary between each deposit layer and the fluid is dealt with using a Lagrangian transformation, as in Diaz-Bejarano et al. (2016). The transformed dimensionless deposit domain, $\tilde{\Omega}_L^R$, now with a constant boundary, is shown in Fig. 2a. For the new right domain, $\tilde{\Omega}_L^R$, \tilde{y}^R , Eq. 3 and 4 become:

$$\frac{\rho_L Cp_L}{\lambda_L} \left(\frac{\partial T_L^R(x, \tilde{y}^R)}{\partial t} - \frac{\tilde{y}^R}{\delta^R(x)} \delta^R(x) \frac{\partial T_L^R(x, \tilde{y}^R)}{\partial \tilde{y}^R} \right) = \frac{1}{\delta^R(x)^2} \frac{\partial}{\partial \tilde{y}^R} \left(\frac{\partial T_L^R(x, \tilde{y}^R)}{\partial \tilde{y}^R} \right) \quad (5)$$

$$q_L(x, \tilde{y}^R) = \frac{\lambda_L}{\delta^R(x)} \frac{\partial T_L^R(x, \tilde{y}^R)}{\partial \tilde{y}^R} \quad (6)$$

For the new left domain, $\tilde{\Omega}_L^L$, \tilde{y}^L , Eq. 3 and 4 become:

$$\frac{\rho_L C p_L}{\lambda_L} \left(\frac{\partial T_L^L(x, \tilde{y}^L)}{\partial t} - \frac{\tilde{y}^L}{\delta^L(x)} \dot{\delta}^L(x) \frac{\partial T_L^L(x, \tilde{y}^L)}{\partial \tilde{y}^L} \right) = \frac{1}{\delta^L(x)^2} \frac{\partial}{\partial \tilde{y}^L} \left(\frac{\partial T_L^L(x, \tilde{y}^L)}{\partial \tilde{y}^L} \right) \quad (7)$$

$$q_L(x, \tilde{y}^L) = -\frac{\lambda_L}{\delta^L(x)} \frac{\partial T_L^L(x, \tilde{y}^L)}{\partial \tilde{y}^L} \quad (8)$$

where $\dot{\delta}^i$ (m/s), the rate of change in fouling layer thickness, δ^i , over time represents the volumetric flux of deposit material, in $\text{m}^3/\text{m}^2 \cdot \text{s}$.

$$\dot{\delta}^i = \frac{d}{dt} (\delta^i); \quad \forall i = L, R \quad (9)$$

A standard enthalpy balance applies to the fluid domain:

$$\begin{aligned} \frac{\partial}{\partial t} (\rho_f C p_f T_f A_{flow}) &= -\frac{\partial}{\partial x} (\rho_f C p_f T_f u_f A_{flow}) + \frac{\partial}{\partial x} \left(\lambda_f A_{flow} \frac{\partial T_f}{\partial x} \right) \\ &+ Wh(T_L^R|_{\tilde{y}=1} - T_f) + Wh(T_L^L|_{\tilde{y}=1} - T_f) \end{aligned} \quad (10)$$

where $T_f(x)$ is the fluid bulk temperature (K), $u_f(x)$ (m/s) is the mean fluid velocity derived from the flow area, A_{flow} , h is the local film heat transfer coefficient and W is the plate width (wetted perimeter). The fluid physical properties, $\rho_f(x)$, $C p_f(x)$, and $\lambda_f(x)$ are functions of the mean fluid temperature at each local point. The variation in $A_{flow}(x)$ is due to the moving deposit boundaries on both sides of the plate.

$$A_{flow}(x) = W(P_{flow,L} + P_{flow,R}) \quad (11)$$

The Biot number is broken down into a local thermal resistance variable, providing insights into the fouling thickness along the plate length. This neglects possible fouling removal (due to shear forces), but nonetheless provides useful distributed information on the deposit. Using the Biot number definition of Fryer and Slater (1985):

$$Bi = \frac{h_f^o \delta_d}{\lambda_d} \quad (12)$$

into the rate of deposition yields the following expression:

$$\frac{d \delta_d(x)}{dt} = \lambda_d \left(\frac{\beta k_w C_{AP}^*}{h_f^o} \right) \quad (13)$$

where h_f^o (W/m²·K) is the local heat transfer coefficient for the fluid in clean conditions and other variables as in Fryer and Slater (1985). The layer thickness, δ_d , is determined by integrating eq. 13, given the thermal conductivity, λ_d , of the newly deposited layer.

Uniform Wall Temperature (UWT) boundary conditions were used here, i.e. a constant wall temperature was fixed on the outside of each plate. Various single channels of a PHE undergoing heating were simulated, starting from clean conditions. A first-order backwards discretisation method was used with 50 points in the axial flow direction and 10 points along the y axis for the plate domains. Similar temperature profiles were generated with 10 to 500 discretisation points across the layer thickness (y axis) without impacting accuracy, so 10 points were used. Temperature dependent milk physical

properties were used (De Jong, 1997). The single channel model contains 1445 variables and simulation of 6 h of heating takes about 11.45 s of CPU time using gPROMS.

3. Results, discussion and conclusions

The model described was used to simulate the dynamic fouling behaviour of 5 individual channels (no. 3, 5, 7, 9 and 11 in Arrangement 1, Figure 1). Channel 1 was omitted as negligible fouling was recorded (Delplace et al., 1997). Average plate temperatures calculated from a previous model were taken as the UWT boundary values for the *right* and *left* plates of each channel (Table 1). Except for channel 3, these outside temperatures on the two walls are asymmetric. Table 1 also details for each channel the results obtained after 6 h of simulation: outlet milk temperatures, mass of deposit (overall and on each of the two side walls) and max deposit thickness on each side. The total deposit mass on channels 3, 5 and 7 match exceptionally well the available experimental data for similar conditions (Delplace et al., 1997). For channels 9 and 11 the deposited masses are substantially over-predicted. A plausible cause is that the heating loads in the latter channels are higher, involving temperatures beyond 363 K (90°C) where the kinetic parameters used in the fouling reaction schemes are known to diverge from those at a lower temperature range (Jun & Puri, 2006). An identical deposit mass profile was generated on the plates on either side of channel 3, as its boundary conditions were symmetrical. For all other plates, deposition is different on the left and right plates, which have different UWT boundary temperatures. The deposit thickness distribution along channels 3, 5, 7 (Figure 3), shows that (for the imposed conditions), except for channel 3, fouling is not uniform along the flow axis, with most deposit near the end of the plates and asymmetrical on the two side plates.

Table 1. Boundary conditions and summary of results after 6h of operation for each channel, using the 2D distributed model

Channel No.		3	5	7	9	11
UWT (K) <i>Boundary Condition</i>	<i>R</i>	355.00	359.30	362.10	366.89	369.97

R: Right plate of channel, *L*: Left Plate of channel; ^aDelplace et al. (1997)

Figure 3. Deposit thickness distribution along channel length after 6 h of operation.

The new model accounts for interaction of local operating conditions and deposit and asymmetric deposition due to different boundary conditions at the two sides of a channel. It predicts the distribution of deposit along the plates and gives useful insights into problematic plate regions. It is a suitable component for industrial PHEs configurations, for simulation, to determine optimal operation and cleaning policies, and to study optimal sensor locations as required for online monitoring.

Abstract

Release of manufactured lots is a major decision point in reaching the goal of a customer – the product quality is reasonably good – and of manufacture – no rework/scrap/lost revenue. In this study we will focus on pharmaceutical industry (solid dosage form).

Adaptive Bayesian sample size determination. In this study we used adaptive Bayesian approach to determine the number of lots needed to estimate inter/intra lot variability. This was dictated by limited number of lots available in the study. Specifically, a linear random effects model was built and fitted to tablet data from multiple lots. The estimate was considered accurate enough when change in signal (or variability estimates) disappeared within noise. In our case we considered 1% of label claim as noise level. However, if signal to noise ratio was high, additional lot was sampled. Sampling included traditional content uniformity and dissolution testing. In order to be consistent with pharmacopeia 10 tablets from a lot were used for content uniformity testing while 12 tablets from the same lot were used for dissolution testing. Manufacturer, however, may not need this step since historical production information may be used to estimate the inter/intra lot variability by employing Bayesian methodology. It is important to note that analytical variability component was factored out which is not easily done with traditional frequentist methodology.

Estimation of probability that product is within specifications at given confidence level. The next step was to estimate the probability of product being within specifications at a given confidence level which is metrics used for lot release by ASTM E2709–12 standard. However, the approach delineated in the standard was extended by Bayesian treatment. Specifically, inter/intra lot variability estimates were used to determine the probability while confidence level was replaced by the Bayesian credible interval concept. As delineated in ASTM E2709–12 standard this non-trivial task using frequentist methodology was very straightforward when using Bayesian methodology.

We propose that lot can be released (consistently with ASTM E2709–12 standard) when the probability of product being within specifications at a given confidence level is high enough not to cause any harm to the patient. In order to determine the probability threshold, we propose to perform virtual clinical study with Simcyp or PK-Sim to determine if there is no harm to the patient and drug product is efficacious, i.e. drug plasma levels are within therapeutic window for prescribed dosing regimen.

We verified the proposed methodology on seven immediate release products from different manufactures. We found that there are large differences in inter/intra lot variability between different manufacturers. Based on our experience more than six lots are typically required to establish accurate variability estimate.

The current pharmacopeia doesn't incorporate inter lot variability and therefore our proposed approach is more restrictive in the sense that it allows releasing lots that contain safer and more efficacious product than using existing lot release criteria. It is based on FDA's risk based approach. From manufacturers perspective it supports the FDA's quality metrics initiative to assure that only safe and quality medicine is being produced. While this study considered solid dosage form the proposed methodology could be easily generalized for different dosage forms and any batch processing industries.

Abstract

The Eddy Dissipation Concept (EDC) is a well working concept for turbulent reacting flows, which depicts the influence of chemical reactions as well as turbulence. The problem when using detailed chemical mechanisms - necessary for more information about radical species and pollutants - is the vastly increased computational demand. Operator splitting and in situ adaptive tabulation (ISAT) can be a way to reduce the computational effort and improve the application of detailed chemical mechanisms with the EDC. Two operator splitting mechanisms are presented and used for the simulation of Sandia Flame D. The computational time can be decreased and the results fit well to the experimental results.

Keywords: turbulent combustion, OpenFOAM, Eddy Dissipation Concept (EDC), operator splitting, in situ adaptive tabulation (ISAT)

1. Introduction

Simulation can be a great tool to improve the understanding of complex processes and consequently enhance efficiency and reduce emissions. In many systems, such as biomass combustion, pulverized coal combustion or blast furnaces, gas phase combustion occurs and needs to be modeled.

The Eddy Dissipation Concept (EDC) (Magnussen, 1981) is a widely used combustion model, which couples the effect of chemical reactions and the effect of turbulence. It has been widely used for many applications, e.g. by Zahirović et al. (2010), Stefanidis et al. (2006) and Rehm (2010). When using detailed chemical mechanisms the computational demand increases significantly compared to global or skeletal mechanisms. Therefore, computational improvements for the EDC are necessary to make use of detailed chemical mechanisms possible to enable additional insight on radical species or NO_x formation.

In situ adaptive tabulation (ISAT) has been proposed by Pope (1997) to decrease the computational time for reactive flow calculations. Originally, it has been used in combination with PDF methods, but it can also be used in conjunction with the EDC. In the EDC the species concentration in the reacting structures can be described by an ordinary differential equation (ODE)-system. Mixing and chemical reactions are taken into account there. ISAT can only be used for the chemical part of the equations, since taking both into account would distort the table and make a look-up inefficient, (Pope, 1997) and (Rehm, 2010). Therefore, operator splitting has to be used to split the ODE and enable ISAT.

Rehm (2010) presented two operator splitting methods for the EDC. The computational

time could not be reduced there, but also no results with regard to the accuracy were presented.

In the following the EDC and operator splitting methods are explained. These methods are then used to simulate Sandia Flame D in OpenFOAM, a turbulent methane-air jet flame. Experimental flame data from Barlow and Frank (1998) and Schneider et al. (2003) is used to validate the simulation results. Moreover, operator splitting and direct integration results are compared.

2. Model Description

2.1. Eddy Dissipation Concept

The EDC models the interaction between turbulence and chemical reactions. It assumes that the fluid consists of surroundings and fine structures, whose size is in the order of the Kolmogorov length scale (Magnussen, 1981). Since educts need to be mixed on a molecular scale to react, reactions only occur in the fine structures.

Magnussen (1981) derived the description of the fine structures based on an energy cascade model. The fine structure fraction γ^* is expressed by the turbulent kinetic energy k , the dissipation rate ε , the kinematic viscosity ν and a constant $C_\gamma = 2.13$, Eq.(1). The mass transfer between the fine structures and the surroundings per unit of mass of the fine structures and time can also be expressed by ν , ε and $C_\tau = 0.41$, Eq.(2). The residence time in the fine structures τ^* is the reciprocal of \dot{m}^* . The mass transfer per unit of fluid \dot{m} can be calculated by the mass transfer per unit of mass of the fine structures and the fine structure fraction, Eq.(2).

$$\gamma^* = C_\gamma^3 \left(\frac{\nu \varepsilon}{k^2} \right)^{\frac{3}{4}} \quad (1)$$

$$\dot{m}^* = \frac{1}{C_\tau} \left(\frac{\varepsilon}{\nu} \right)^{\frac{1}{2}} = \frac{1}{\tau^*} = \gamma^* \frac{1}{\dot{m}} \quad (2)$$

To obtain the mass transfer rate for one species R_i^* per unit volume of the reacting fine structure fraction χ , the species concentration in the fine structures and the surroundings is required, Eq. (3). The concentration and the density in the fine structures and the surroundings are also taken into account. When using the detailed chemistry approach, the fraction of the reacting fine structures χ is usually set to one, as suggested by Gran and Magnussen (1996). The relation between some property Ψ in the surroundings (\circ), the fine structures ($*$) and the fluid average ($\bar{}$) is given in Eq.(4).

$$R_i^* = \frac{\dot{m}^* \rho^*}{1 - \gamma^* \chi} \left(\frac{\bar{c}_i}{\bar{\rho}} - \frac{c_i^*}{\rho^*} \right) \quad (3)$$

$$\bar{\Psi} = \gamma^* \chi \Psi^* + (1 - \gamma^* \chi) \Psi^\circ \quad (4)$$

Different concepts exist to model the chemical reactions in the fine structures: the fast chemistry approach (Magnussen, 1981), the local extinction approach (Byggstoyl and Magnussen, 1983) or the detailed chemistry approach (Gran and Magnussen, 1996). To use a detailed chemical mechanism, the latter has to be used. There, the fine structures are treated as adiabatic and isobaric perfectly stirred reactors (PSRs). This leads to the following set of ODEs, Eq.(5). Where h^* is the enthalpy, p^* the pressure and Y_i^* the

mass fraction of species i in the fine structures. $\dot{\omega}_i$ denotes the reaction rate and Y° the concentration of species i in the surroundings.

$$\frac{dh^*}{dt} = 0 \quad \frac{dp^*}{dt} = 0 \quad \frac{dY_i^*}{dt} = \dot{\omega}_i + \frac{1}{\tau^*} (Y_i^\circ - Y_i^*) \quad (5)$$

2.2. Operator Splitting

Operator splitting splits the species conservation equation in Eq.(5) into a chemical and a mixing part, solves them separately and combines the solutions to get a solution of the original ODE. Two second order operator splitting methods, Strang splitting and Staggered splitting, which are used for the simulation in OpenFOAM are presented here.

2.2.1. Strang Splitting

The chemical subproblem is denoted by A and the mixing one by B. Strang splitting (Strang, 1963), shown in Figure 1, provides a solution of the original ODE by first solving subproblem A on a time interval $\Delta t/2$, Eq.(6). Then subproblem B is solved on a time interval Δt with the solution from A as its initial condition, Eq.(7). The final solution, marked by a circle, Eq.(9) is obtained by solving subproblem A again on the remaining time interval $\Delta t/2$, Eq.(8).

Figure 1: Strang splitting scheme

$$\frac{d(Y_i^*)_A}{dt} = \dot{\omega}_i \quad \text{with } (Y_i^*)_A(t=0) = Y_i^*(t=0) \quad (6)$$

$$\frac{d(Y_i^*)_B}{dt} = \frac{1}{\tau^*} (Y_i^\circ - Y_i^*) \quad \text{with } (Y_i^*)_B(t=0) = (Y_i^*)_A(t = \Delta t/2) \quad (7)$$

$$\frac{d(Y_i^*)_A}{dt} = \dot{\omega}_i \quad \text{with } (Y_i^*)_A(t = \Delta t/2) = (Y_i^*)_B(t = \Delta t) \quad (8)$$

$$Y_i^*(t = \Delta t) = (Y_i^*)_A(\Delta t) \quad (9)$$

2.2.2. Staggered Splitting

Figure 2 shows the solution procedure of the Staggered splitting scheme. Subproblem A is solved for a time step Δt from n to $n+1$ and subproblem B is solved from $n+\frac{1}{2}$ to $n+\frac{3}{2}$, taking the solution from subproblem A as initial condition. The solution is approximated by the mean of the solutions of subproblem A and B marked by circles in Figure 2, Eq.(10). The initial time step, needs special treatment: the mixing subproblem is solved on a time interval $\Delta t/2$ to obtain the initial conditions for subproblem A.

Figure 2: Staggered splitting, adapted from Ren and Pope (2008)

$$Y_i^*(t=n) = \frac{1}{2} \left((Y_i^*)_A(t=n+1) + (Y_i^*)_B \left(t = n + \frac{3}{2} \right) \right) \quad (10)$$

3. Simulation Details

Sandia Flame D was simulated in OpenFOAM using the in-house solver rhoEdcFoam. A 2D-wedge was simulated with a grid of 4329 cells (4218 hexahedras and 111 prisms). A transient simulation was conducted for 0.5 seconds to achieve a description of the steady-state of the flame. Radiation was neglected due to studies showing, that radiation has a minor impact on the results (Li et al., 2017).

For the chemical reactions the detailed chemical mechanism GRI-3.0 from Smith et al. (2017), including 53 species and 325 reactions, was used. The simulations have been conducted with direct integration and the presented operator splitting methods in conjunction with ISAT. The retrieval tolerance for ISAT was set to 10^{-4} . The results from a simulation using a global mechanism are also added for comparison.

The presented operator splitting methods are second order methods, i.e. the error is proportional to $\mathcal{O}(\Delta t^2)$. To improve the predictions and limit the error done by operator splitting, a maximum operator splitting time step size of $\Delta t = 10^{-3}$ s and $\Delta t = 10^{-4}$ s was tested.

4. Results and Discussion

Figure 3(a) to Figure 3(c) show the centerline profiles of temperature, CO₂ and NO mass concentration for the different simulations (x/d represents the axial position normalized by the jet diameter $d=7.2$ mm). The results from direct integration fit best to the experimental results for temperature and CO₂ mass concentration. The profiles show, that operator splitting approximates the solution well, but is a bit less accurate. For the NO mass concentration the solution from Staggered splitting fits even better to the experimental results than the direct integration.

To quantify the accuracy of the predictions, the sum of squared errors (SSE) was calculated for all available data points and for different quantities (temperature T, velocity u, and different species concentrations). The SSE was normalized to the SSE of direct integration to compare the different simulation settings (Figure 3(d)). Staggered splitting seems to be even more accurate than direct integration. The improved predictions could result from increased stability or be due to error compensation resulting from taking the mean in Eq. (10). Strang splitting gives in general better predictions than the global mechanism but gives less accurate predictions than the other simulations.

Figure 3(e) to Figure 3(h) show results from Staggered splitting and Strang splitting with and without limited time step size. The time step size was limited to 10^{-3} s and 10^{-4} s for Staggered splitting. The profiles of the temperature at the centerline (Figure 3(e) and Figure 3(g)), show that the limited splitting schemes give a bit improved, especially smoother, predictions. The SSE was calculated and normalized to the simulations without time step limitation. For Staggered splitting, the limited case gives improved predictions for all quantities, except methane. The smaller limit for the time step, i.e. 10^{-4} s, did not lead to a significant improvement. Therefore, the time step limit was only set to 10^{-3} s for Strang splitting.

For Strang splitting the improvement is not as big and also for methane no improvement is achieved through the limited time step size. In general the limited time step size gives a bit more accurate predictions, with only minimally increased computational demand.

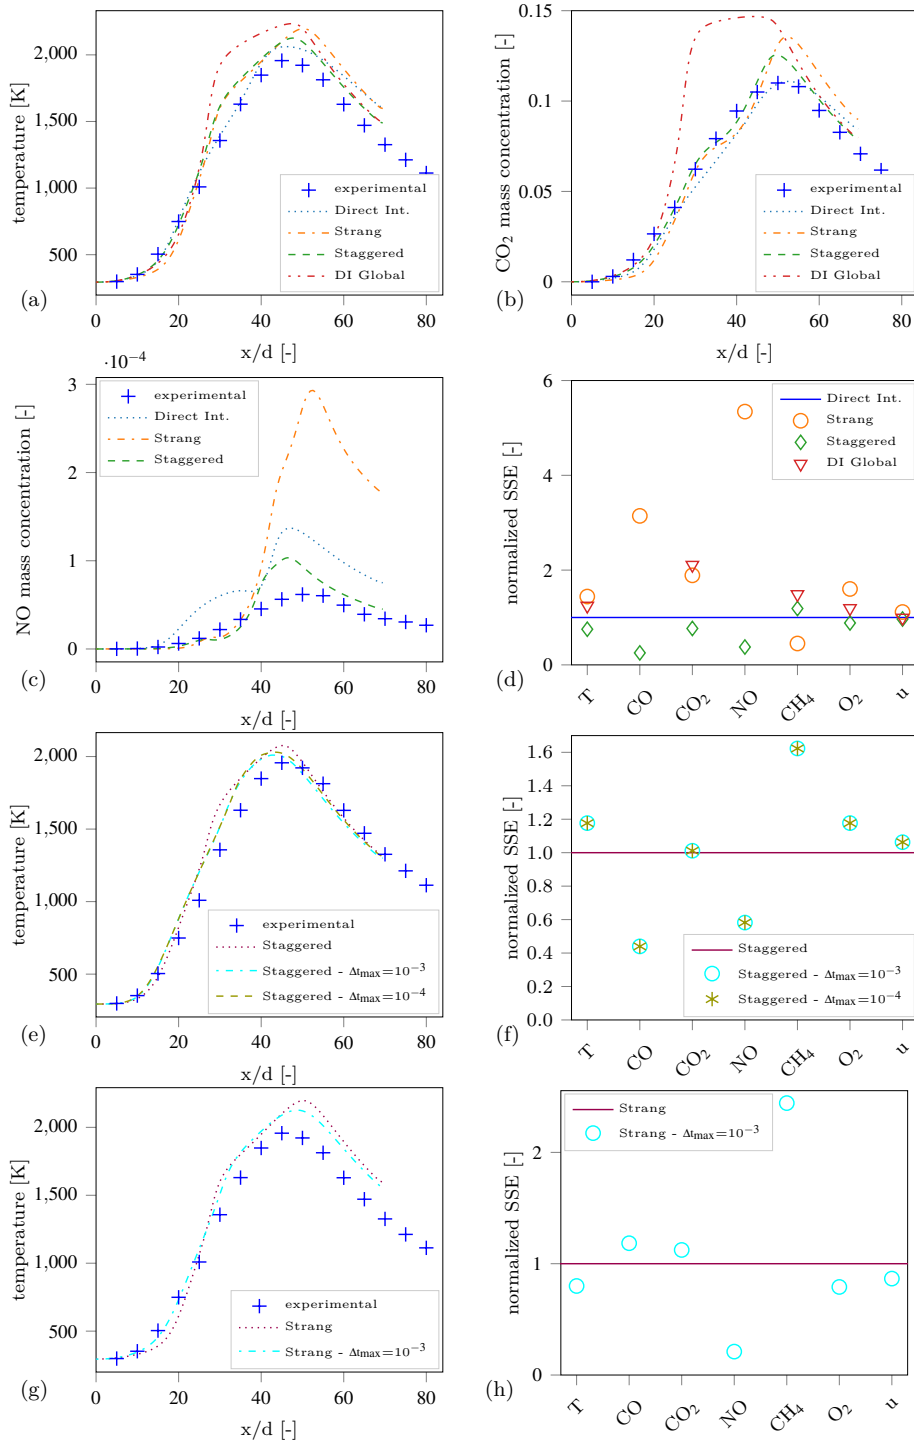

Figure 3: Comparison of simulation results and experimental data for (a) temperature (b) CO_2 and (c) NO mass concentration and (d) comparison of the normalized SSE for all data points; Results using limited time steps in (e) to (h)

Since the simulations were not carried out on the same computers, the computational time can only be roughly compared. Using Strang splitting with an ISAT-tolerance of 10^{-4} , the computational time could be reduced by approximately 23 % compared to direct integration. Further comparisons on the computational time with different ISAT settings and without ISAT are presented by Wartha (2017).

Staggered splitting is even faster than Strang splitting, since it needs less function calls for one operator splitting step. The reduction of computational time for Staggered splitting compared to Strang splitting is around 20 %.

5. Conclusion and Outlook

The use of a detailed chemical mechanism is important to predict species like radicals or pollutants, which are not present in global mechanisms. The presented operator splitting methods, Strang and Staggered splitting, work and can reduce the computational demand when detailed chemical mechanisms are used in conjunction with the EDC. Good predictions for temperature and concentrations have been achieved for Sandia Flame D. For some cases Staggered splitting gives even better results than direct integration. Furthermore, the computational demand is smallest for Staggered splitting. Therefore, Staggered splitting seems to be the best choice.

To substantiate those findings, further test cases with other flames should be conducted to ensure, that the presented findings are also valid for other combustion regimes.

Active Learning of Process Control

Manuel Rodríguez^{a*}, Alberto Prada^a, Ismael Díaz^a, Emilio Gonzalez^a, María González-Miquel^a

^a*Universidad Politecnica de Madrid, José Gutierrez Abascal 2, Madrid 28006, Spain*
manuel.rodriguez@upm.es

Abstract

Process Control is a course that needs a thorough understanding of how the different unit operations work and what are the implications of changing operation variables in a process. This paper presents how education innovation can help students to improve their learning and understanding of the different concepts and thus to get better results in the subject and to achieve the desired outcomes. The Process Control Course is taught in the Bachelor Degree in Chemical Engineering at the Technical University of Madrid. Different methodologies have been integrated and used in the course as: flipped classroom, peer instruction, and gamification. In order to implement the mentioned methods, the following material has been developed: screencasts, concept tests, trivia contest and simulations besides the traditional material (slides and text). First year results show high student motivation, higher participation in class and better results (marks) in the subject.

Keywords: Active learning, adaptive learning, flipped classroom, gamification, just in time teaching.

1. Introduction

Lecturing has been the usual way of instruction since universities were founded more than 900 years ago. There are theories emphasizing the need of changing this approach to allow the students develop their understanding. Active learning, understood as an instructional method that engages students in the learning process, seems fundamental in the new teaching/learning paradigm which is student-centered. Freeman et al (2014), did a meta-analysis study where they demonstrate that active learning increases performance in STEM (Science, Technology, Engineering and Mathematics) disciplines. New education methodologies exist to tackle this new way of teaching.

One of the most used learning approaches related with active learning, Lucke and Dunn (2017), is flipped (or inverted) classroom, which can be defined, as stated by Lage et al. (2000): “Inverting the classroom means that events that have traditionally taken place inside the classroom now take place outside the classroom and vice versa”. This definition is somehow limited and we prefer the definition given by Bishop and Verleger (2013): “[...] is a new pedagogical method, which employs asynchronous video lectures and practice problems as homework, and active, group-based problem solving activities in the classroom. It represents a unique combination of learning theories [...]”. Another important learning methodology is game-based learning or gamification. In Bodnar (2014), they explore the impact of gamification in students in an engineering discipline getting very positive results. This paper is focused on active learning of the subject Process Control. Some previous experiences can be found in

literature related to applying the flipped classroom to this subject, like in Marlin (2016) but it is basically based on the flipped classroom methodology. Our approach, although relying in flipping the classroom, extends this method with the use of other learning experiences as gamification, peer instruction, group problem solving or simulations.

1.1. The motivation

How to select the best control structure for a unit operation or a reactor? How many degrees of freedom does a process have for control? How to develop a P&I starting with a process flowsheet from scratch? These questions are addressed and explained in the course Process Control. This course needs a thorough understanding of the operations to be controlled and the implications of all the units in a process. These concepts are difficult to grasp for many students and they stay in a quite passive attitude, so a different innovative approach has been implemented in order to increase students understanding and participation.

1.2. The objective

The main objective is to foster a student-centred learning methodology. A motivating active learning that allows a personalized evolution of the student. This objective is decomposed in the following sub-objectives:

- Implement a new student centred learning methodology
- Increase student motivation and participation in class
- Increase the understanding of the more complex concepts by the students
- Improve student results and the outcomes acquired
- Make the students aware of the importance of self-learning

2. The active learning approach

In this approach, different education innovation experiences have been integrated. Although the core methodology is flipped classroom, it is complemented with gamification activities, adaptive learning and peer instruction. In order to implement the methodology, the following elements have been developed: screencasts, concept tests, dynamic simulations and gamification (trivia like).

2.1. Educational material

•Concept tests: These correspond to the contents of the course and are focused on checking the students comprehension. They are multiple choice questions, like the one shown in Fig. 1.

Next figure shows a control scheme where the valves:

- Must have the same pressure drop
- One must have greater pressure drop than the other
- Both must be fail open or fail close
- One must be fail open and the other fail close
- a) and c) are correct
- b) and d) are correct

Figure 1. Concept test example

- Gamification: Trivia like competition, single elimination tournaments or spotting errors (in given P&Is) competition have been developed.
- Screencasts: Educational videos have been recorded for every topic. These are the main material for flipping the classroom. The videos have a teacher narrative to explain the main concepts of the lessons and they have a lecture-like format. This is a very valuable material as it allows the student to assimilate the concepts prior to the classroom and they are available for reviewing as needed depending on the learning evolution of the student. Videos solving problems (basically developing the control structure of a process) have also been recorded. Fig. 2. shows a snapshot of the explanation of Valve Position Control.

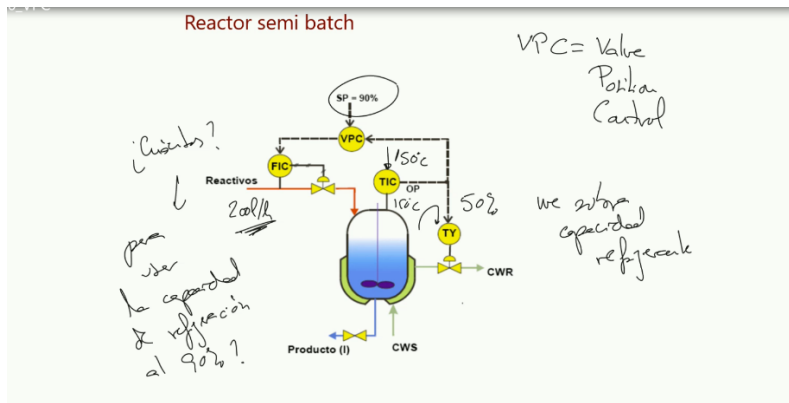

Figure 2. Snapshot of a screencast explaining Valve Position Control in a semi batch reactor

- Simulations

An operator training simulator has also been developed. It has a HMI (Human Machine Interface) as shown in Fig 3. It allows to act as an operator and perform tasks such as: change operation modes (manual, automated), tune controllers, see variables evolution, etc.

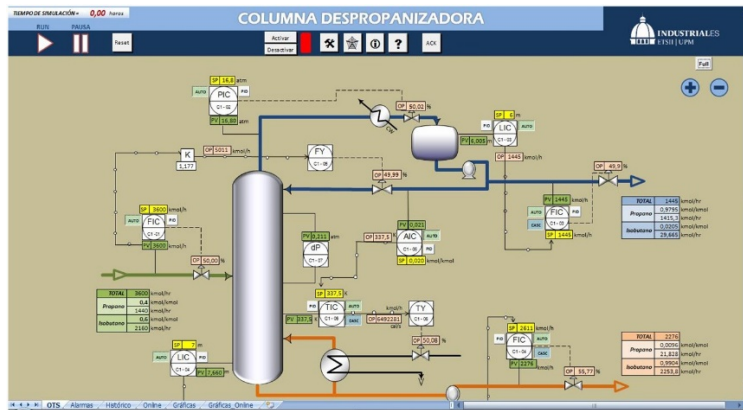

Figure 3. Snapshot of the OTS showing a distillation column with its control

2.2. Methodology

The methodology applied is not based on a single one but on the application and integration of several ones, like the ones that are described below.

- Flipped classroom

This methodology has been applied using educational videos/screencasts and complemented with traditional material as slides or texts. The student learns by himself in advance the contents of the topic to be discussed in the following class.

- Peer instruction: This is achieved using concept tests. Individual student understanding is evaluated through the use of concept tests. Then small groups of students get together and think about the more difficult topics (tests with more wrong questions) and the test is run again. Finally, the instructor explains the topic in detail.

- Gamification: The main purpose of gamification is to improve the classroom experience and to have more active and participative classes. Gamification is a powerful methodology since it can motivate the students and help to fix concepts however it has to be used with caution and keeping in mind its final objective: learn and understand (in a funnier way).

The above methodologies (along with some others) are used in an integrated and varied way allowing to have motivated students and helping to fix concepts.

3. Implementation

Screencasts along with slides are provided beforehand to flip the classroom. Concept tests (implemented using the *Gopollock* platform – gopollock.com–) are made at the beginning of the class to check the understanding of the students and to work on the more difficult concepts. The students comment on the question and it is answered again (peer instruction), finally, the instructor gives the explanation. Dynamic simulations are provided so they can check how different control loops work. Besides from time to time a gamification activity is done covering several lessons.

All these activities are complemented with the use of a virtual environment (Operator Training System - OTS) of a process plant previously developed. The OTS allows the student to operate a plant, changing its conditions, operating parameters, activate alarms, see the evolution of variables, change the tuning of controllers, etc.

It is important to change what is done from class to class. If the same procedure is regularly done then the students will, finally, lose the motivation and the effort that has been put into the development of these educational methodologies will be partially lost. In the subject of Process Control, the use of concept tests are not used in every class (they are used in about 30-40% of the classes). Not all the course topics are explained flipping the classroom, some of them are explained in a traditional way but always keeping in mind to have an active and participative audience. Interaction while presenting the lesson has been achieved in this case using *Mentimeter* (mentimeter.com), a platform that allows to create different type of questions that the students answer and see the results in real time as they are answering. Fig 4. shows a summary of the implementation done. Students get the screencasts and additional educational material before class. Then concept tests are done in class along with peer instruction. Team work for case based problems and for theory topic discussion are created. Some gamification activities (in the figure a tournament recreating Game of Thrones is shown, where the teams were families and the winner got the Iron Throne – besides some extra points).

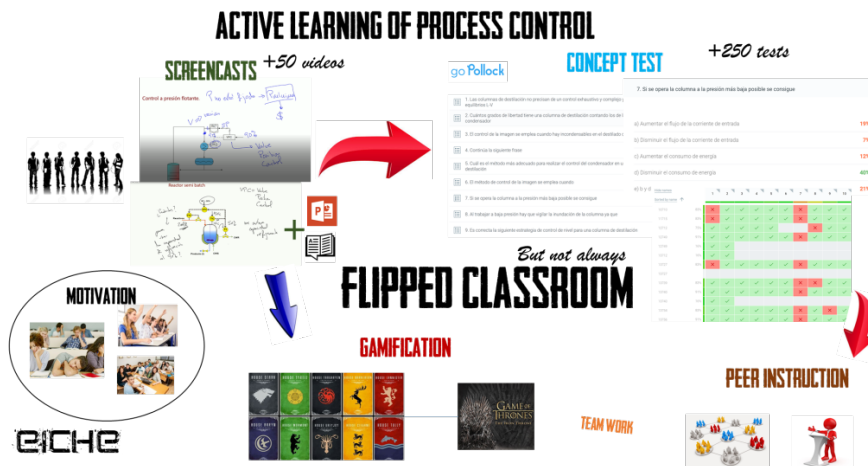

Fig 4. Implementation of active learning for process control

3.1. Results

The results obtained come from a one year experience. Most of the students prefer this approach to the classic one of traditional teaching with slides. Some motivation has to be included in order to get most of the class having the previous work, needed to have the flipped classroom, done. The incentive used is getting marks after completing the activity (it is not necessary that all the activities provide marks). As a result the class is more dynamic and active and the student participation is much higher. The core of the contents are more progressively learned along the course and the use of the tests shows

that the concepts are better understood. At this moment partial results are available. A process control theory exam has been done. Results compared with the two preceding years are presented in Table 1:

Table 1. Results obtained in the last four years

Year	Average grade (out of 10)	% Passed	% Failed	Students
2017	7.4	91	9	54
2016	6.8	67	34	39
2015	5.6	72	23	43
2014	6.7	75	25	32

Although these results have to be taken with caution it seems that a significant improvement has been achieved. Not only in the students that have passed the theory exam but in the average grade obtained.

4. Conclusions

New innovative education methodologies are not just a hype but a true improvement over traditional ones. Implementing a flipped classroom allows to focus on the difficult parts of the lessons, instead of giving time to all the concepts as in the traditional approach. Students are more active, motivated and get a better understanding. Flipped learning is a useful methodology but it is not the only one and abusing of it or of any other will make it quite less efficient. An important conclusion of this project is that what best fits for a new way of teaching or better a new way of learning is using several approaches (flipped classroom, gamification, peer instruction, team work, case based learning, etc). This will make the students alert, motivated and highly participative.

Combining Open Source and Easy Access in the field of DEM and coupled CFD-DEM: LIGGGHTS®, CFDEM®coupling and CFDEM®workbench

Dr. Alice Hager^{a*}, Dr. Christoph Kloss^a and Dr. Christoph Goniva^a

^a*DCS Computing GmbH, Industriezeile 35, 4020 Linz, Austria*

alice.hager@dcs-computing.com

Abstract

Discrete Element Method (DEM) and DEM coupled to Computational Fluid Dynamics (CFD-DEM) are powerful techniques for optimization and design of particle processes. Macroscopic granular particles or flow involving fluids and granular particles are everywhere - in industry, environment and everyday lives: sugar, sand, ores, tablets, chemicals, biomass, detergents, plastics, crops, fruits need to be harvested, produced, processed, transported and stored.

We highlight our vision of providing cutting edge simulation technology to an open public via the open source CFD-DEM software CFDEM®coupling (cf., Goniva et al. (2012)) and the open source DEM software LIGGGHTS® (cf., Kloss et al. (2012)).

While open source guarantees transparency and security of investment it does not automatically enable everyone to easily apply the software. Often the installation of the required operating system or third-party software are hindering potential users from using open source software. By developing the commercial GUI CFDEM®workbench we provide an easy access route to the complex field of DEM and CFD-DEM modelling, which is fully compatible to its open source advantages. It combines the strength of the open source simulation software with the comfort of a guidance through the installation and setup process. We give an introduction to the software tool and highlight possible applications in fields such as steel industry, chemical industry, pharmaceutical industry, consumer goods industry, agricultural machinery production, food production, powder metallurgy and plastics production.

Keywords: CFD-DEM, DEM, Open Source, GUI

1. Introduction

The multidisciplinary of modern computer aided process engineering leads to a variety of challenges, some of which are listed here:

- process / operating conditions
- determination of main influence factors
- development of models for depicting the different physical effects
- transferring the models to efficient computational tools
- choosing appropriate material parameters
- model setup and simulations with interpretation of results

Each of the mentioned points comes with very specific requirements that differ strongly: In some areas detailed knowledge about the process itself is necessary while in others programming skills or a fundamental theoretical background is required. There are many experts that work on one or a couple of the mentioned points, but it rarely happens that a single person covers the complete list of tasks. Besides developments in the dedicated areas it is particularly important to create strong links between them to guarantee a possibly complete information transfer and optimal usage of the different tools. Thus, either a strong team of experts or an efficient and easy-to-use workflow is needed to tackle modern CAD engineering tasks.

With the combination of LIGGGHTS®, CFDEM®coupling and CFDEM®workbench we provide a combination of versatile tools that on the one hand allow for the implementation of new models by scientists, developers and students and on the other hand support a straight forward application by engineering experts. The modular structure of the open source DEM code LIGGGHTS® and the open source CFD-DEM code CFDEM®coupling makes it possible to apply newly developed models universally. This paves the way to de-couple scientific model development and its industrial application. Fig. 1 for example shows a selection of particle types, which can be used in combination with different physical models.

In this paper we first introduce the theoretical background of DEM and coupled CFD-DEM. Then we propose two entirely different approaches for applying LIGGGHTS® and CFDEM®workbench: the objective of the first example is the application of a complex, already implemented model and the specialisation on the variation of material parameters. The second example shows the implementation of a new model and its application in a simulation. Both examples demonstrate ways for teaching simulation tools for computer aided process engineering.

Figure 1. Different particle types in LIGGGHTS®: superquadrics (top left), flexible fibers (top right), a buoy on a chain modeled by complex multispheres (bottom left) and convex particles (bottom right).

2. Theoretical background – The governing equations

The discrete element method (cf., Cundall and Strack (1979)) is a Lagrangian method, in which the trajectory of each particle is calculated explicitly under simultaneous consideration of the different forces in the system. In pure DEM calculations these are

particle-particle as well as particle-wall interaction forces, in coupled calculations also the impact of the surrounding fluid is considered. The governing equations for the translational and rotational motion are based on Newton's second law (cf., Kloss et al. (2012)):

$$m_p \frac{du_p}{dt} = F_{p,p} + F_{p,w} + m_p g + F_{p,f} \quad (1)$$

$$I_p \frac{d\omega_p}{dt} = T_p \quad (2)$$

Here m_p is the mass of particle p , v_p is its velocity, $F_{p,p}$ stands for the particle-particle and $F_{p,w}$ for the particle-wall forces. The term $F_{p,f}$ stands for the forces that are exerted by the surrounding fluid. For calculating the contacts between the particles and particles and walls, the so-called soft-sphere approach (cf., Cundall and Hart (1992)) is used. In this method the particles in contact have a slight overlap and elastic, plastic and frictional forces are calculated with the aid of the spatial overlap. LIGGGHTS® provides a large number of different models for handling normal and tangential contacts as well as the effect of friction, rolling resistance, cohesion, liquid films etc. Models for computing the contribution of $F_{p,f}$ are available in CFDEM®coupling.

Coupled CFD-DEM comes in two flavours, namely as resolved and unresolved CFD-DEM. The first method is a direct numerical simulation method where each particle is resolved within the fluid mesh, in the second method the particles are smaller than the cells of the fluid mesh. The latter method was first introduced by Tsuji et al. (1993) and is suitable for running simulations with large numbers of particles. The governing equations are the volume averaged Navier Stokes equations:

$$\frac{\partial \alpha \rho}{\partial t} + \nabla \cdot (\alpha \rho U) = 0 \quad (3)$$

$$\frac{\partial \alpha \rho U}{\partial t} + \nabla \cdot (\alpha \rho U U) - \nabla \cdot (\alpha \tau) = -\alpha \nabla p + R_{s,l} + \alpha \rho g, \quad (4)$$

where α denotes the voidfraction of the fluid, ρ its density, U the fluid velocity, p the pressure, τ the stress tensor and $R_{s,l}$ the solid-liquid interaction force, which is computed as following:

$$R_{s,l} = K_{s,l} (U - U_s), \quad (5)$$

where $K_{s,l}$ is the interaction force coefficient and U_s the average particle velocity calculated on the cells of the fluid mesh (cf., Goniva et al. (2012)).

3. Example A: Studying the behavior of a load responsive wall in the presence of cohesive granular matter

The use scenario in this case is a process engineer without deep knowledge on the DEM and the underlying equations can set up a case study that relies on highly complex models.

The basic setup of the case consists of a cylinder which is closed by a plate. The plate is defined in a load responsive manner, i.e. it starts to tilt in y-direction as soon as a load is applied. Particles are inserted into the cylinder and under the influence of gravity they start to settle. As soon as they hit the plate, the latter tilts enough for displaying a gap, though which particles could fall out of the cylinder. The load reduces, since the kinetic energy of the particles is absorbed by the plate and the gap is closed again. Fig. 2 gives an overview of the case setup.

Figure 2. A pack of particles is inserted in a cylinder. As soon as they exert force on the plate, it starts to tilt.

It is assumed that the granular material is cohesive, and that the user wants to determine the cohesiveness for which a certain fraction of the material exits the cylinder. One of the provided cohesion models for particle-particle and particle-wall contacts (e.g. sjkr, c.f., DCS Computing GmbH. (2016)) is chosen and the parameter for the cohesion energy density is varied. Fig. 3 shows results and the comparison of the particle number for two different cases. While for the lower cohesion there is still a significant number of particles that falls out, the higher cohesion leads to the formation of a clump and only few particles exit.

Figure 3. Comparison of the results of calculations for low and high cohesive energy density. For the lower value more particles leave the domain while for the higher value most of the mass remains.

The workbench automatically saves all particle data such as position, radius, velocity, angular velocity, force, etc., all global data such as number of particles, kinetic energy of the system, etc. and all forces and torques on the plate. For visualization one can either use paraview (for the particle data, see the two images in Fig. 3), the live-graph-view that comes with the workbench (esp. suitable for monitoring the results during the simulation) or other tools as for example octave for comparing the global data of several simulations (see plot in Fig. 3).

4. Example B: Implementation of a lubrication force model and its application

In this example we show how one can use the advantages of the open source framework of LIGGGHTS® to implement a new model in combination with the flexibility of CFDEM®workbench for using it in simulations. The use scenario here is a scientist developing a new model which is then applied by an engineer.

The motivation for the new model is the following: when colliding particles are surrounded with a fluid or even a gas, the displacement of the fluid in the gap between two particles causes a force – the lubrication force. In many cases this force is relatively small and thus neglected, but when considering highly viscous fluids or light and small particles it might be worth considering. The formulation of the lubrication force F_{lub} (cf., e.g., Davis et al. (1986)) is given as

$$F_{\text{lub}} = -6\pi\mu r_{ij}^2 \left(\frac{1}{h} \right) v_n, \quad (6)$$

where r_{ij} is the effective radius defined as

$$\frac{1}{r_{ij}} = \frac{1}{r_i} + \frac{1}{r_j}, \quad (7)$$

with i and j denoting two arbitrary particles. h is the minimal distance between the surfaces, μ the dynamic fluid viscosity and v_n the relative velocity of the two particles.

4.1. Implementation

The lubrication force acts when two particles approach each other or move away from each other after a collision, i.e. when two particles are close but not in contact. This makes the lubrication force similar to a cohesion. For implementing the model one can now use an arbitrary cohesion model as template and start to replace the equations. When implementing the model one has to limit the radius of action of the lubrication force – for very small values of h the force would become too big and if h becomes too large, the contact search would become too expensive. This approach was also used by Sun and Xiao (2016) in their implementation. Fig. 4 shows two small parts of the implementation.

```

if(h<minDist || h>deltaC)
{
    if(scddata.contact_flags)
        *scddata.contact_flags &= ~CONTACT_COHESION_MODEL;
    return;
}

// force component
const double mult = 6.*M_PI*mu*r_ij*r_ij/h;
const double fx = mult*vn2;
const double fy = mult*vn2;
const double fz = mult*vn3;

```

Figure 4. Two small code snippets of the implementation: radius of action of the lubrication force model is limited (left), computation of the force components (right).

4.2. Application

While the implementation of the new model requires deeper knowledge of the code and the equations, its application is relatively simple within CFDEM®workbench. The user has to select the option “custom” for all cohesion models (for the particles this setting is made in the pair_style tab, for the walls the cohesion model has to be selected in the wall/gran tabs), and define the custom cohesion model “lubrication” in the Custom Settings tab. As the lubrication force requires information about the fluid viscosity, an additional custom global property must be added (cf., Fig. 5). The remaining settings are identical to the ones of the original case.

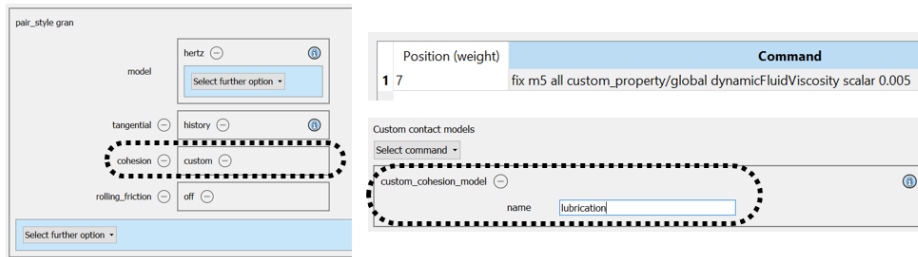

Figure 5. Necessary settings for using the lubrication force model in CFDEM®workbench.

Conclusion

With the presented software tools we bridge the gap between research, development, application and education. With CFDEM®workbench we lower the entry barrier for users to access the capabilities to the complex simulation engine LIGGGHTS® while the advantages of open source are fully maintained. This approach is not only advantageous to industry, where development and application often happen in different divisions, but also for education, where time limitations often make it difficult to teach complex methods that can easily be applied and modified at the same time. Currently it is already possible to run one-way coupled fluid-particle simulations, which consider the impact of a fluid field on the particles or the prepare the DEM side for a fully coupled simulation. The future goal is to bring CFDEM®coupling to the workbench as well.

Abstract

As part of the freeware, open-use and community-based movement on education in the process system engineering discipline, we present the *OpenIMPL* initiative that is a forum to exchange ideas, learnings, know-how, experiences and data using the free training license of IMPL (Industrial Modeling and Programming Language) for open-use. IMPL is both a structural and semantic language with its concepts, constructs and configurations of the Unit-Operation-Port-State Superstructure (UOPSS) and the terms and details of its Quantity-Logic-Quality Phenomena (QLQP). This forum is primarily intended to discuss problems found in the Batch and Continuous Process Industries when solving design, planning, scheduling, optimization, control, parameter estimation, data reconciliation and simulation examples although interesting and suitable instances found in other industries are also welcome and encouraged. By extensively performing industrial applications around research and development types of initiative, we provide industrial modeling frameworks (IMF) as a jump-start to an industrial project implementation since it can be easily enhanced, extended, customized, modified, etc. to meet the diverse needs of your project and as it evolves over time and use. IMF's also provide graphical user interface prototypes for drawing the flowsheet and typical Gantt charts and trend plots to view the solution of quantity, logic and quality time-profiles. Current developments use Python integrated with open-source Gnome Dia and Matplotlib modules respectively, but other prototypes embedded within Microsoft Excel/VBA for example can be created in a straightforward manner. The primary purpose of the IMF's is to provide a timely, cost-effective, manageable and maintainable deployment of applications to formulate and optimize complex industrial manufacturing systems in either off-line or on-line environments. Using IMPL alone would be somewhat similar (but not as bad) to learning the syntax and semantics of an AML (Algebraic Modeling Language), although in IMPL there is no needs of coding all of the necessary mathematical representations of the problem including the details of digitizing your data into time-points and periods, demarcating past, present and future time-horizons, defining sets, index-sets, compound-sets to traverse the network or topology, calculating independent and dependent parameters to be used as coefficients and bounds and finally creating all of the necessary variables and constraints to model the complex details of logistics (discrete) and quality (nonlinear) industrial optimization

problems. Therefore, IMF's and IMPL give to the end-user, in our opinion, a more elegant and structured approach to industrial modeling and solving so that you can capture the benefits of advanced decision-making faster, better and cheaper. Upon agreement to join in the community of the industrial optimization and estimation applications, all model and/or problem data used with the free training license of IMPL must be made available to the *OpenIMPL* initiative. As such, it is the sole responsibility of the academic, non-commercial and/or home user to ensure that the model and/or problem data can be released and shared publicly.

Abstract

At present, technological innovation can be used as a tool in the teaching-learning process through the implementation and use of an interactive virtual laboratory. Large-scale resources could be simulated, overcoming the drawbacks associated with the physical space, infrastructure and instrumentation required to carry out process engineering practices at different levels (laboratory, pilot and industrial). In this type of laboratory, students can enter a virtual environment where they must apply the acquired knowledge to select solution options and make decisions in situations similar to a real environment, allowing them to experience the resulting consequences.

The LaVIP (for its acronym in Spanish for Virtual Laboratory of Process Engineering) is being developed at the Universidad Autónoma Metropolitana (Cuajimalpa Campus), where practices are being implemented that support undergraduate degrees such as chemical engineering, biological engineering and related. In particular, this work shows the methodology used for the development and implementation of the LaVIP, as well as the results of an interactive virtual practice for an isothermal batch reactor where an enzymatic hydrolysis reaction occurs.

The LaVIP is accessed through a website, which includes the information architecture of an educational platform that guides the user, providing tools to: (i) motivate and involve the student in the development of a practice in a quasi-real environment, and (ii) improve teaching and evaluate learning. The educational platform is developed using usability techniques, maintaining indispensable characteristics such as access security, an intuitive environment, access to information (offering resources such as glossary, help, descriptions, etc.), student progress monitoring, and a simple administration portal.

The functions and executable programs of process engineering practices are developed using the Matlab Production Server application. This tool provides web clients, which through a process and administration server allow users to run programs developed in Matlab without having an own license. The main server is able to generate scripts, which are used in the website developed in the standard HTML5 language.

As case study, the calculations and analysis of an isothermal batch reactor where the enzymatic hydrolysis of cellulose to produce glucose is carried out. The kinetics is Michaelis-Menten type and the main objective is to determine the values of the kinet

- (1) trial and error, where the kinetic parameters are estimated from a plot of experimental data;
- (2) linear regression, where the parameters are calculated from the linearization of the Michaelis-Menten equation; and
- (3) optimization, where an objective function is minimized to determine the optimal parameter values.

So far, LaVIP has its own systematic development process for lab practice implementation. Currently its use is internal and being in evaluation. In the future, more practices will be added and LaVIP use will open for other institutions.
